VetBooks.ir

This book is dedicated to our parents,
Alan and Christine Divers and Dale and Brenda Stahl.
Your unconditional love and support gave us
the opportunity to make this important contribution
to the health and welfare of these unique animals we love.
Thank you, mom and dad, for everything.

With love,
Steve and Scott

FOREWORD

VetBooks.ir

The art of reptile and amphibian medicine has progressed from knee-jerk reactions to basic signs and symptoms to advanced, pragmatic, evidenced-based medical care. Although there are still those that think a paramedian incision is the only way to enter a coelom or that Baytril is all you need to be a successful herp doctor, for the majority, the approach to diagnosis and treatment has finally started to catch up with real veterinary medicine. Of course, I am referring to the level practiced on dogs and cats.

As far as I can tell, the first published work on "Diseases of Reptiles" was authored by Dr. H. Spencer Glidden, an MD, *not* a DVM. The work was penned in 1936 and published by the Florida Reptile Institute, Silver Springs, Florida. The entire manuscript was a whopping *four* pages long. Dr. Glidden was an instructor in Pathology and Bacteriology at the Tufts College Medical School.

"Respiratory," "Mouth Rot," and "Bad Sheds" (which included retained eye-caps) were about the extent of the spectrum of reptilian diseases. For years, that was it.

Sick reptile treatments started with gentamicin and progressed to enrofloxacin. Now, dozens of pharmacodynamic studies exist to validate drugs and dosages. It is no longer "one dose fits all."

As a young herp doc, I was taught that anesthesia involved placing the lizard in the refrigerator for a few hours. Pain control? Not necessary—reptiles don't feel pain.

Fortunately, those antediluvian beliefs have gone the way of the dinosaurs.

Compared to Dr. Glidden's 4-page tome, the first edition of this series, *Reptile Medicine and Surgery,* had over 500 pages. This current edition has over 1500 pages of advanced medical knowledge.

Drs. Divers and Stahl have done an amazing job gathering and incorporating specialists in several disciplines into the production of this book. In addition, they have integrated experts from across the oceans, erasing the myopic tenet that only the United States' viewpoints were relevant. So much research has been done overseas that it is refreshing to see the valuable information being disseminated here.

Whether you are just a novice herp veterinarian, an ectoderm enthusiast, or someone studying for one of the specialty examinations, you need to have this book on your shelf—and you also need to read it!

I am so proud to pass the torch on to the next generation of brilliant herp medicine enthusiasts. It has been such a ride watching the evolution of herp care from simple antibiotics to advanced health care.

If you are going to talk the talk, you have to walk the walk.

Douglas R. Mader, MS, DVM

Diplomate, American Board of Veterinary Practitioners (Reptile/Amphibian)
Diplomate, European College of Zoological Medicine (Herpetology)
Fellow, Royal Society of Medicine

PREFACE

VetBooks.ir

Welcome to the third edition of the quintessential veterinary reference on reptile and amphibian medicine and surgery. When Douglas Mader passed over the editorial reins of his book to us, we knew we had large shoes to fill. Doug remains a major contributor and pioneer in the field of herpetological medicine and surgery, and his contributions to the literature culminated in the first and subsequently greatly expanded second edition. The second edition represented the most comprehensive veterinary text on reptile medicine and surgery and quickly became established as *the* reference worldwide by private practitioners, specialists, and veterinary students. The second edition became standard reading for the veterinary specialty examinations of the American, European, and Australian specialty colleges and boards. Indeed, such was our reliance on this book that it quickly became a trusted resource or colleague, and basically everyone referred to the tome as *Mader.* It seemed only right and proper therefore that this sentiment be continued, and in honor of his numerous and ongoing contributions, this new edition bears the title of *Mader's Reptile and Amphibian Medicine and Surgery*.

The goal of the current editors was to continue the evolution of this specialty reference that Doug had started, and we have approached this challenging task in several ways. First, this third edition is 25% larger to accommodate our continued growth in knowledge of these animals, with each chapter undergoing a major review and rewrite. Some areas have expanded greatly, requiring the division of some topics into multiple chapters, while many chapters appear for the first time. A perusal of the table of contents will readily convey this expansion, including greater inclusion of amphibians with dedicated biology, husbandry, anesthesia, and surgery chapters. In addition, we have made great efforts to include many recognized specialists from around the world. This created obvious language challenges in some cases, and we are extremely grateful for the extra effort taken by authors, whether they were writing in a second language or providing additional editorial assistance to their international co-authors. However, the inclusion of such a varied assortment of international specialists has resulted in a truly global perspective that benefits us all. Second, we have tried to continue the evolution of our specialty away from anecdote and opinion and toward more evidence-based medicine through greater reliance on peer-reviewed science. To this end, the authors and editors have toiled to include only peer-reviewed journal and published book materials in their references. Non–peer reviewed and unavailable proceedings papers have not been utilized in the chapter bibliographies, so the reader is assured that any reference number refers to a peer-reviewed journal or published book chapter. This is particularly important in this edition because all references have been removed from the printed book and placed online. This proved necessary because of space constraints and is in keeping with other major texts like Ettinger's *Textbook of Veterinary Internal Medicine.*

Section 1 details practice management and development and has been expanded from 3 to 6 chapters, including specialization, the value of herpetological publication by clinicians and academics, and statistics for the clinician. Our specialty depends on continued informational growth, and we encourage everyone to be part of that development by submitting to the *Journal of Herpetological Medicine and Surgery*.

The previous biology and husbandry section has been separated into two separate sections and expanded. Section 2 covers anatomy, physiology, and taxonomy of all the major taxa and now includes tuatara and amphibians, as well as behavior, training, welfare, and stress. The husbandry Section 3 is updated for all reptile taxa and also includes tuatara and amphibians. There are also updated chapters on environmental lighting, disinfection, quarantine, and nutrition.

A new Section 4 details infectious diseases and laboratory sciences, while Section 5 focuses on clinical techniques and procedures. Our knowledge of anesthesia and analgesia has grown considerably in the last decade, and Section 6 includes dedicated chapters on sedation, general and regional anesthesia, analgesia, and amphibian anesthesia. Diagnostic imaging Section 7 has been expanded to include taxa-based radiography (for snakes, lizards, chelonians, and crocodilians), ultrasonography, CT, MRI, and scintigraphy. Section 8 details endoscopic equipment and diagnostic and surgical procedures. However, probably the greatest reorganization has occurred in the medicine and surgery sections, where we have tried to emulate domestic animal and human medical texts by organizing the material by major organ systems. Medicine Section 9 now includes dedicated chapters on urology, hepatology, cardiology, dermatology, ophthalmology, otorhinolaryngology, gastroenterology, pulmonology, neurology, oncology, endocrinology, theriogenology, musculoskeletal, vascular/hematopoietic/immunology, behavioral medicine, nutritional diseases, perinatology, geriatrics, emergency and critical care, toxicology, and amphibian medicine. The previous single surgery chapter has been expanded into a dedicated Section 9 and includes chapters focused on specific organs or systems, including eye, ear, rhinarium, oral cavity, integument, coeliotomy, respiratory tract, gastrointestinal tract, urinary tract, reproductive tract, cloaca, external coaptation, internal fracture fixation, spine, amputation, shell, and amphibian soft tissue surgery. Similarly, the previous single therapeutics chapter has been expanded into a 19-chapter Section 11, and in addition to updates of the usual drug classes also includes new chapters on mental health treatment, photobiomodulation, rehabilitation and physical therapy, and wound management. The clinically useful differential diagnosis Section 12 has been retained and updated to include a new amphibian chapter.

Another major area of change occurred with Section 13 on specific diseases and conditions. Much of the detailed information has been moved and incorporated into the aforementioned medicine and surgery sections. However, we recognized the value of retaining this section as a quick reference guide for busy practitioners needing a brief summary during a consultation. Therefore these clinical diseases and conditions have been condensed into a more abbreviated format to facilitate rapid review during a busy practice day, with cross-references to the major chapters for more in-depth information.

Section 14 is new and focused on population and public health, including zoonoses, free-ranging reptiles, management and rehabilitation of sea turtles, commercial reptile farming, large collection management, breeders/wholesale/retail, laboratory management, conservation, and ecosystem health. Section 15 on legal topics includes updated chapters on international, European, and American legislation, and there are new chapters on forensics and jurisprudence.

Our wives tell us that childbirth is one of the most painful but ultimately rewarding experiences. Pregnancy seems like an appropriate metaphor for this book, because after a 3-year gestation, months of labor, and a painful delivery, we can now, at last, lay back and bask in the glow of this wondrous creation. We invite you, our colleagues and friends, to peruse its contents. We hope it will become a valuable asset to your work, and we look forward to your feedback—just in case we are ever crazy enough to attempt a fourth edition. Welcome to the third edition of *Mader's*!

Stephen J. Divers
Scott J. Stahl

ACKNOWLEDGMENTS

First things first—thank you, Doug Mader. Thank you for being the driving force behind the first, second, and current therapy editions. Your dedication to the specialty has and continues to be an inspiration for all of us. It was the fall of 2015 when Penny Rudolph of Elsevier first approached Doug and myself about a third edition. Doug took a big gulp, staggered slightly, regained composure, and said he wanted to step down as editor. That's when I knew the editorial umbilicus had been cut and I was on my own! While quick to accept the challenge, I did so without any real thought to the monumental task that lay before me. Doug tried to convey this, but I was an enthusiastic and naive fool. However, in addition to maintaining the impeccable standards previously set by Doug, I knew that I wanted to see further progression away from anecdote and opinion, toward more evidence-based medicine and clinical science. I sent out an initial draft chapter outline to a series of close colleagues and trusted friends: Charles Innis, Steve Barten, Paul Gibbons, Mark Mitchell, Tom Boyer, Doug Mader, and Scott Stahl. Their positive feedback not only gave the vision structure but also highlighted the enormity of the task ahead and the need for additional help. Fortunately, I did not have to look far to locate an equally gullible and unwitting optimist, and Scott Stahl joined as co-editor.

Everyone has always referred to the first edition as *Mader*, then the second edition as *The New Mader*, so one thing was abundantly clear from the start—this book was going to be called *Mader*! Therefore, as homage to Doug, we elected to officially change the name of the text to *Mader's Reptile and Amphibian Medicine and Surgery*. In addition to Mader, it might also say Divers and Stahl on the front cover, but this was very much a community effort. They say it takes a village to raise a child; well, this big baby took 130 authors from around the world to produce what we believe is THE definitive text on reptile and amphibian medicine and surgery. The authors worked tirelessly, many in their second language, to ensure a truly international perspective.

None of us get rich writing textbooks. We do it out of passion for our colleagues and our specialty. Therefore, it was critically important to us as editors that the authors felt proud of their contributions and the final product. We hope you agree that the publishers have not disappointed. We are indebted to our *family* of contributors, not least because most, if not all, are close colleagues and personal friends. This is their book as much as ours. Our only sadness, and the one thing from the second edition that is sorely missing in the third, is Kevin Wright; however, Kevin is still in these pages in spirit and content, and his name remains as a co-author on the amphibian medicine and surgery chapters.

Penny Rudolph retired in 2017, and we thank her for her tireless support and wisdom over the years—we miss you. There was a dedicated group at Elsevier that stuck with us to the very end. Jennifer Flynn-Briggs (Senior Content Strategist) and Ellen Wurm-Cutter (Senior Content Development Manager) kept everyone's eyes on the goal, while Becky Leenhouts (Senior Content Development Specialist) endured a lot by being at the sharp interface between authors and editors. Clay Broeker (Book Production Specialist) also showed great professionalism in the face of numerous about-turns and changes during the proof stages, while Renee Duenow was responsible for book design and Madelene Hyde for Global Content.

There is no doubt that I am where I am today not because of any genetic talent but because of the environment and training I have been fortunate to experience. Professionally, I stand on the shoulders of those that gave me their time and shared their knowledge. Calvert Appleby, Oliphant Jackson, John Cooper, Martin Lawton, Neil Forbes, Peter Scott, Fred Frye, Phillip Lhermette, and Dermod Malley were mentors from my student and early post-graduate days in England. I remember fondly my friends and colleagues within the British Veterinary Zoological Society, and then, after I moved to the United States, within the Association of Reptilian and Amphibian Veterinarians (ARAV). The ARAV continues to play a critical role in my career, and I owe this group so much—not least for being the catalyst for the development of many close personal friendships, including Charles "Chuckles" Innis, Kevin "Lick" Wright, Mitchell "Elvis" Mitchell, and of course my co-editor, Scott "Baby Face" Stahl. Since I first met Scott in 1996, we have always been close friends, and I think of him as a brother. Although, over the years, he has been gracious enough to share his knowledge about reptiles and their medicine with me, my efforts at trying to educate him on the rules of cricket have been universally unsuccessful. I have enjoyed countless hours laughing with him (or at him) at conferences and working together on research projects and co-teaching wet-labs. I am especially grateful for his friendship, support, and the life lessons he has taught me. He is a gentleman and a scholar, and I am so thankful to be able to call him my friend.

I am particularly pleased that there are many contributions from my colleagues at the University of Georgia's (UGA) College of Veterinary Medicine (Departments of Small Animal Medicine and Surgery, Pathology, Veterinary Biosciences, and Diagnostic Imaging), Odum School of Ecology, and Warnell School of Forestry and Natural Resources. One area of nationally renowned expertise is Educational Resources at the College of Veterinary Medicine, with their award-winning medical illustrators. A look through these pages will reveal some incredible illustrations designed and drawn by a group of talented artists. Thanks to Kip Carter, Amanda Slade, Danielle VanBrabant, and Katelyn Snell for making the pages come alive. I am fortunate to work in an incredible state-of-the-art hospital with an amazing team of dedicated faculty, notably Joerg Mayer, and technicians, including Ashley McGaha, Nia Chau, and Danielle Stewart, within the zoological medicine service. Zoological medicine has become an integral part of the curriculum and clinical service at UGA, and many of the developments that can be found within these pages are due to the institutional support I have received from current (Spencer Johnston) and past department heads and the administration of the Veterinary Teaching Hospital. During the development of this text, zoological medicine interns/residents Emi Knafo, Rodney Schnellbacher, Lara Cusack, Izidora Sladakovic, Dan Cutler, Spencer Kehoe, and Jessica Comolli played crucial roles as authors and/or acquirers of clinical material. I am proud of their accomplishments to date and look forward to seeing their continued contributions to the field. Also deserving of special mention are Paul Gibbons, Eric Klaphake, Kurt Sladky, James Carpenter, Brent Whitaker, and Colin McDermott for enabling us to use their recently updated formularies and clinicopathology tables from the recently revised *Exotic Animal Formulary*.

There have been thousands of e-mails, telephone calls, text messages, meetings, and conference calls, not to mention the occasional sleepless night and sporadic (but essential) alcoholic drink. This undertaking consumed a lot of time, and my closest friends and family have endured much during this process. My parents, Alan and Christine, have always been completely dedicated and supportive of my education and career. They were visibly relieved when I elected veterinary medicine over human medicine, and I owe them everything. My wife, Leticia, whose lessons in compassion and forgiveness have helped me cope with missed deadlines and many other frustrations along the way, is my foundation and my rock, and her love and patience have given me the strength to

VetBooks.ir

finish what has at times seemed like a never-ending process. I was especially pleased to see her participate as an author. My 6-year-old son, John-Eduardo, on the other hand, was less patient than his mother, but his interruptions and insistence on regular breaks to build Lego rocket ships or duel with Star Wars lightsabers were equally essential to maintain my sanity and productivity. I look forward to spoiling them both now that this is finished.

Stephen J. Divers

As I began writing these acknowledgments, I assumed it would be a short and relatively easy endeavor. However, I quickly realized that this required just as much careful thought and attention as the rest of the book. There are so many people to thank for the opportunity to co-edit this contribution to the medical care of the beloved animals for which I have dedicated my career.

I am deeply grateful for Stephen J. Divers, my co-editor and dear friend of the last 20 years. My involvement in this project is the result of his belief in me and our mutual lifelong love for reptiles and amphibians (or maybe I was the only one who would agree to work with him). Since we met in 1996 at an Association of Reptilian and Amphibian Veterinary (ARAV) Conference in Tampa, Florida, we have been close.

I thank Steve for always encouraging me to grow and challenge myself professionally. We have traveled the world together, educating practitioners about exotic animal endoscopy. (Thank you for the support, Christopher Chamness and everyone at Karl Storz Veterinary Endoscopy). This opportunity has enriched my life with knowledge, adventure, and much laughter. Steve is an amazingly talented clinician, orator, and teacher. His willingness to share research ideas, techniques, studies, and publications with his students and colleagues is selfless. He truly is committed to the goal of improving our clinical knowledge and understanding of zoo and exotic animals. I am thankful he has allowed me to join him on numerous research endeavors, and although he left me out of his research trip to the Galapagos (he called me from the island to rub it in), I have since forgiven him. In hindsight, would I have wanted to be stuck on a small island with him for any great length of time anyway? I digress. However, because the completion of this book has sometimes felt never ending, I couldn't imagine collaborating with anyone else. Yes, I had to be the "voice of reason" at times and drag him off a few soapboxes, and there were a few spirited phone conversations, but we still like each other. Mate, thank you for this opportunity, and cheers to many more adventures together. I love you brother.

As Steve has mentioned in his acknowledgments, this book would not be possible without the monumental efforts of our veterinary colleagues and fellow herpetologists who have advanced this discipline. I would personally like to thank Frederick L. Frye for being the first of our clinical colleagues to put together a comprehensive surgical and medical book on reptiles *(Biomedical and Surgical Aspects of Captive Reptile Husbandry),* which was the catalyst for all subsequent books, including his even more comprehensive two-volume set years later. Fred had the foresight to recognize the need for clinical knowledge about these unique animals. I used to sleep with his books under my pillow as a pre-veterinary student (what a reptile geek). As a young veterinary student on a trip to California for a conference, Fred agreed to meet with me for a chat. He was gracious with his time and encouragement, and that meeting reinforced my commitment to herpetological medicine. Thanks, Fred, for your confidence in me and your friendship. Another personal hero and mentor of mine is Elliott R. Jacobson, who I fortuitously heard lecture on herpetological medicine in the early 1980s at a Virginia Herpetological Society meeting. At that time, I was an undergraduate studying biology at the University of Richmond. His dynamic presentation was an "a-ha" moment for me and skewed my original plan for a career in zoology (herpetology) to that of veterinary medicine. Elliott went on to become a legend in our field, recognizing the need for sound research and validation, especially regarding infectious diseases. I am grateful for his vast contribution to our field, his encouragement, and his friendship. And, of course, I thank Douglas R. Mader and echo Steve's sentiments that without Doug's tremendous effort, foresight, and dedication to the field of clinical herpetological medicine and surgery, we would not have this opportunity. I first met Doug when I attended a North American Veterinary Conference as a young veterinary graduate. Anyone who has attended one of Doug's lectures will confirm that his passion, charisma, and enthusiasm are contagious. Doug, thank you for your support, mentorship, and friendship over the years. I am delighted that we can honor you with this edition, appropriately entitled *Mader's Reptile and Amphibian Medicine and Surgery.*

I send love to all my colleagues in my ARAV family (many of whom made important contributions to this book) and thank them for their support and dedication to our field. I have enjoyed coming together annually to share ideas (okay, and drink beer and laugh till we cry), with the common goal of elevating our medical knowledge of these beloved animals. I don't have room to name everyone, but Charlie "Chuckles" Innis, Mark "Teddy Bear" Mitchell, Tom "Tommy-Boy" Boyer, and Steve "Shutterfly" Barten must be called out! It feels like we have grown up together professionally and we are family. You guys have always been an inspiration to me, and I'm so proud of your accomplishments.

Sadly, we lost one of our herpetological family members and one of my dearest friends, Kevin Michael Wright, in 2013. Kevin contributed so much to the field of herpetological medicine. He is present in this third edition because his previous work is so vital that he is the co-author of the amphibian medicine chapter along with his equally brilliant friend and colleague Brent Whitaker. I am thankful to have had Kevin in my life for nearly 30 years, as we met in 1984 at a Society for the Study of Amphibians and Reptiles meeting in Florida as undergraduates. It was an immediate bond because we seemed destined for the same goal, pursuing veterinary school to become herpetological veterinarians. I learned so much from Kevin over the years. He was an amazing human being. He was like a brother to me, and I cherish the time we shared together. Kevin lived life to the fullest, followed his interests and pursuits with passion, and looked for humor in any situation. What a valuable message for all of us. I know the professional goals I have accomplished and many of the opportunities I have pursued are because of his love, support, and friendship. I love you Kevin, and I miss you every day.

In our avian and exotic practice, we have many fourth-year veterinary students spending time learning from our team. I have always felt it is important to help train our future colleagues in this unique discipline. Over 350 students have trained at our clinic, including many international students. I gained a great deal of knowledge from this type of hands-on experience as a veterinary student, and I am grateful to my colleagues who taught me their craft, including Michael Cranfield, Richard Linnehan, Robert Wagner, Walt Rosskopf, Richard Woerpel, Jeff Jenkins, Tookie Meyers, H.J. Holshuh, Lois Roth, Larry Freeman, Michael Leib, Craig Thatcher, Phillip Sponenberg, Alan Adair, Cindy Adair, and many others I may have inadvertently omitted. I want to thank the Virginia-Maryland College of Veterinary Medicine (VMCVM) for allowing me to be a part of the veterinary class of 1989. During my veterinary school interview, I stated that I wanted to be a "snake doctor," and this was before cable television made exotic animal practice a popular choice of applicants today. My undergraduate research involved evaluating the reproductive cycle of the northern copperhead, *Agkistrodon contortrix,* with my mentor Joseph C. Mitchell at the University of Richmond, and this likely made

VetBooks.ir

me an unusual candidate. Thanks for taking a chance on me, VMCVM, and go Hokies!

I am indebted to Dr. Mitchell for taking me under his wing as an undergraduate to work in his herpetological ecology lab and help with research for his book, *The Reptiles of Virginia*. I know he was hoping that I would stay in the field of "true" herpetology rather than pursue veterinary medicine, but he supported my decision and taught me the value of research. Thank you also to the many science professors at the University of Richmond who supported my interest in reptiles and desire to pursue veterinary medicine.

I was known as the "reptile guy" during my years of vet school. Although the program was limited in organized instruction on avian and exotic animal medicine and surgery, the professors and staff were all supportive of me and encouraged my fascination. Thank you to my VMCVM professors for giving me the knowledge and tools to succeed in veterinary medicine and to my 1989 classmates for supporting my unique interests and making the 4 years fun (although, to date, no one has confessed to putting the green peanut M&Ms in Dr. Leib's gallbladder stone specimen jar). Special thanks to my dear friend and vet school roommate, board-certified veterinary surgeon Richard "Hogg" Suess, who had to share his apartment with many "creepy crawlies" over the years. I also want to note that as a veterinary student, I had the opportunity to work with Dr. Robin Andrews in her herpetology laboratory at Virginia Tech. She graciously allowed me to stay close to my herp passion by working with her research lizards and even giving me the opportunity to co-author a paper on reproduction in tropical anolis lizards.

In my first few years of clinical practice, I was lucky to be surrounded by an amazing and supportive group of colleagues who taught me so much about medicine, surgery, and how to be a caring professional. I thank you for the laughs, warm memories, and love Patrick Denny, John Schaff, Jody Clarke, Len Rice, Julia Finlayson, Kelli Rhymes, Andrew Voell, Daniel Morris, and Bill Tyrell (who encouraged me to follow my dream of starting my own specialty practice). Also, early in my career, I worked with numerous enthusiastic and brilliant veterinary associates and technicians. We learned a lot together, and I appreciated their insight. Thank you to Thomas Bankstahl, Carmine Bausone, Patty Bright, Jennifer Stampf, Janice Raab, Carol Canny, Meredith Davis, Ben Haas, Debbie Koth (RIP), Beth Steroitis, and Christopher Normand.

In 2003, I decided to start my own exclusive avian and exotic animal practice, Stahl Exotic Animal Veterinary Services (SEAVS). On opening day at SEAVS, I had one employee, my dear friend Jennifer Hutchins, LVT. Jennifer has been the glue that holds everything together in our practice and has been instrumental to its success. She is a highly skilled veterinary technician, and when she joined me in this adventure, she was coerced into being both business manager and technician. She had no interest in this managerial role, but 15 years later (now a 6-doctor practice, with more than 25 employees) she is still our fearless business manager. Let's face it, she is the real boss of the practice. It's a tough job, and I am so thankful for the sacrifices she has made and for dreaming big alongside me.

I would also like to thank our associates, ABVP avian residents, and interns over the last 15 years: David Crum (our first resident and associate), Lisa Carr, Scott Medlin, Greg Costanzo, Shoshana Sommer, Octavio Romo, Emily Nielsen, and Scott Hammer, for their hard work and dedication. They have all contributed so much and have been integral to the success of our practice. Although some of them have moved on, they will always be part of the SEAVS family. Grasshoppers, I am proud of you. The sky is the limit!

To Greg Costanzo, my previous resident and now senior associate, I'm grateful for your willingness to take on greater responsibilities over the last 3 years because of my abbreviated clinical schedule, which was necessary to allow me to focus on the monumental task of completing this book. Greg knew that contributing to the field of herpetological medicine by co-editing this book would fulfill a professional dream for me, and I am appreciative of his commitment to me and the team. You're a skilled clinician, a great human being, and so important to the success of SEAVS.

Thank you to my second family, the entire SEAVS team, for all your support over the years and especially the last few years during the completion of this book. I am so proud of you all. Your hard work and dedication have resulted in the creation of one of the largest exclusive avian and exotic animal practices in the world! I am especially grateful to my dedicated long-timers (10 years plus!) Alissa Hoklotubbe, Danya Mandery, Kathy Burrier, Anibal Armendaris, and Zach Romeo.

Away from work, my cycling coach and dear friend Jared Nieters helps me maintain some sanity and balance with the demands of life by routinely kicking my butt! Thanks coach.

Finally, my family has always been supportive of me, kept me grounded, and loved me unconditionally, which makes all this hard work and effort worthwhile. As mentioned in the dedication, I owe everything to my parents, Brenda and Dale "Buck" Stahl, who worked hard to provide every opportunity for their kids to pursue their dreams. My interest in reptiles and amphibians, which started at an early age while living on a farm in Maine, was always encouraged. Although I'm sure my parents had some concerns at times when, for example, a presumed male red-bellied snake produced a "surprise" litter of neonates ($n = 10$), an anolis lizard showed up in the mail from Florida (purchased for $1.99 from and ad in the back of a magazine), and numerous "live specimens" escaped in the house over the years! I am grateful to my sister Susie and brother Mark, who survived growing up with these animals around them but still supported me. I love you so much.

None of this would have been possible without the years of support and love from my wife, Stephanie. She has put up with this nonsense (the herps, not me, right?) since we first met when I was a veterinary student and she was an undergraduate at Virginia Tech. More than 25 years later, we still have a house full of reptiles! She has always supported my interest and fascination with these animals. She (and my daughters) have accepted that wherever we travel in the world, visiting zoos and reptile collections and herping in the wild are normal protocol. Being married to a veterinarian is challenging, and this is especially true with one obsessed with contributing to the scientific advancement of a group of animals. Long hours at the office along with writing, putting together lectures, and traveling to teach all reduce family time. Stephanie is the rock that keeps our family grounded, even while pursuing her own full-time career. Honestly, I don't know how she does it all, but I know the world of "content marketing" would be lacking without her input! I am proud of her and her amazing accomplishments in her field. As a writer and editor herself, she has been gracious with her time in helping me with many of my previous writing projects. For sanity reasons and the vastness of this project, I did not ask her to help with editing of this book (I am getting smarter with age); however, she has had to shoulder many responsibilities in the last several years due to my absence while working on this book. I greatly appreciate her making it possible for me to have the opportunity to make this contribution to my field. I love you, Stephanie!

My most important accomplishment of all is being the father to two amazing, smart, and beautiful daughters, Madeline and Macy. I am so proud of them and what they have already accomplished in life. To my loves, I say, "Chase your dreams. I will love and support you wherever life leads!" My co-editorship of this book and the success of Stahl Exotic Animal Veterinary Services is proof that hard work and determination can lead to the fulfillment of your dreams!

Scott J. Stahl

Developing a Successful Herpetological Veterinary Service

Adolf Maas

Building a successful herpetological veterinary service is comprised of two important disciplines: the medicine practiced and the management of the business. Both are intrinsically necessary as one cannot succeed without the other.

The majority of veterinary medicine focuses on domestic species. However, the reptile clade is comprised of nearly 10,000 distinct species that occupy almost every biome on the planet. The evolutionary diversity is staggering; our own species has been present in multiple variants for a few hundred thousand years, while Emydidae (pond turtles) have been essentially unchanged for 45 million years. Furthermore, reptiles are incredibly diverse in their phylogenetic relationships to each other; chelonia are far more closely related to birds and crocodiles than to other reptiles, while geckos and bearded dragons are more distantly related to each other than humans are to rabbits. It is not difficult to understand why a reptile is not a "reptile" and that it is inappropriate to assume that one single therapy or treatment plan should apply to multiple, let alone all, species.

MEDICINE PRACTICED

The majority of herptile diseases have underlying husbandry etiologies; therefore having a strong knowledge of their natural history is essential and is a critical factor in practicing quality medicine. Without the ability to assess a patient's husbandry and determine if it is appropriate for that species, clinicians will have difficulty formulating an effective treatment plan.

The next most important factor for achieving success in herpetological medicine is to gain knowledge in the unique physiology and anatomy, disease syndromes, and therapies utilized in herptiles. This might seem counterintuitive, but, if husbandry and care are not appropriate and/or corrected, an accurate diagnoses and treatment protocol will not be successful.[1] It is not possible to separate natural history from disease management and therapeutics. Natural history and husbandry information can be found in other chapters throughout Sections 1 and 2 of this text, and the reader is encouraged to peruse this critical information.

Managing/Developing the Business

During the process of gaining an important knowledge base in herpetological medicine (an ongoing career process), clinicians must also focus on developing a business and facility that will support practicing this particular subset of medicine.[2] The following components are essential for a successful business:

(A) Attracting clients
(B) Proper organization
(C) Knowledgeable support staff
(D) Appropriate infrastructure
(E) Necessary equipment

(A) Attracting Clients. Herptile-owning clients are not a particular anomaly, even if they are not the most common of pet owners. Zoological medicine and reptile/amphibian medicine are recognized specialties in veterinary medicine, and regardless of whom you ask, herpetological medicine is a small fraction (5%–20%) of their zoological case load. To date, there are no dedicated herptile-only veterinary practices in the United States, despite there being limited numbers of avian-exclusive, exotic companion mammal-exclusive, and even fish-exclusive practices.

However, a rewarding herpetological service can be built with similar approaches utilized to develop other successful services. Three strategies are important.

1. Marketing/advertising your herpetological service. Without a way to reach potential clients, there is no way to get them to consider your practice. Traditional print media has generally gone the way of the dinosaur and been replaced with the internet. One challenge with internet exposure/marketing is holding the attention of potential clients for more than a few seconds, and it becomes critical to "grab their attention" and differentiate your practice from others quickly. Even the practice name plays a role and needs to be focused and descriptive of the patients being targeted so potential clients can see the practice as uniquely filling their needs.

In today's internet age, the practice website has become a significant marketing tool. The website must be dynamic yet easy to use and intuitive. To hold the attention of the viewer, images of herptiles and procedures routinely performed on them can be displayed and discussed to reassure clients that the practice is comfortable with these species. The veterinarian(s)' and staff's credentials and experience can be listed along with continuing education attended. Also, the clinician's curriculum vitae can be posted on the site to show their active involvement in herpetological medicine through publications, lectures, and teaching. Nothing can build a client's confidence more than to see that the practice is contributing to the knowledge base of herpetological medicine. Additionally, the practice's memberships in important associations such as the Association of Reptilian and Amphibian Veterinarians (ARAV), as well as local, national, and international herpetological societies or associations, can be posted. As smartphones are one of the main tools for communication and internet connection, it is critical that websites are designed to be compatible with computers as well as mobile-based browsers.

VetBooks.ir

Search-engine optimization is a skill in and of itself and is critical for more targeted internet placement. As with the development, maintenance, and management of a successful website, companies can be employed to improve the practice's website search-engine placement. This is a worthwhile investment, like the financial investment practices would make in the size and location of a telephone "Yellow Pages" advertisement in the past. This, as well as the inclusion of videos, blogs, regular updates, and changes, will dramatically increase the ever-important website presence.

Social media has become an intrinsic part of our culture and must be utilized to build a successful herpetological service. Facebook, Twitter, Instagram, Snapchat, and Flikr are all social media platforms (with more to follow) that have become popular and effective methods to gain exposure to and connect with potential clients.[3] Herpetological patients are considered interesting to the public, so posting pictures and videos of these animals on social platforms is a great way to promote your expertise as a herpetological veterinarian. A media release form should be utilized to allow the clinic to post pictures of client's animals on social media. Additionally, when their animal shows up on your social media page or in a post, the client will share that image and thus your practice, providing great exposure at a minimal cost.

If your practice has a media savvy employee who can be placed in charge of taking images and posting them regularly, this skill can be utilized. Posting frequently to blogs and social media will increase your standings on search engines; pictures rank higher than text, and videos rank higher than pictures. Use caution, however, as it is possible that too-frequent posting may result in a loss of followers, possibly due to overload.

These social media platforms are efficient, timely, and a preferred method to get information to clients about upcoming events, promotions, products, new employees, public service announcements (i.e., cautioning clients not to overheat pets in cars during summer travel), holiday business hour changes, and more. The timely nature of these social platforms is useful for situations such as emergency closure or other issues that may affect the practice hours.

Another successful form of promotion that is especially worthwhile in herpetological practice is direct exposure, going directly to the source of potential clients. Other than the time commitment, there is little cost. Opportunities abound, especially in urban environments, and attending/becoming a member and/or speaking/exhibiting is a great way to acquire new clients. Examples of such venues/organizations include the following:

- Herpetological societies and meetings
- General and order- or species-specific reptile rescues/shelters (focus on 501c3 organizations)
- Exotic animal shows/sales (may or may not be herptile-specific)
- Reptile subsets of animal rescue exhibits
- Pet shops that carry/sell herptile species
- Reptile hobbyist group (breeder and/or keeper) meetings
- Local/regional VMA groups/meetings

2. Establishing that your practice has herpetological expertise. Once you have reached these new clients, it is important that they perceive the value and expertise your practice can offer compared to others in your region. An excellent way to gain credibility in the herpetological community is by owning and successfully keeping the animals that you treat. Herptile keepers take great pride in their knowledge and often will not respect and/or trust a veterinarian that does not also keep herp species. In addition to gaining the confidence of clients, the knowledge gained by keeping and caring for these animals is invaluable.

Reaching out to and sharing information with owners that you hope to gain as clients is a great way to show your expertise. However, it is important not to diagnose or provide treatment to animals you have not examined. Providing discount services to pet stores and validated rescues (501c3 certification is important) not only allows you access to these cases but can also generate referrals.

3. Establishing yourself as a local expert. Although it can be challenging to find time during a busy practice day, personally taking calls from potential clients as well as from local veterinarians regarding cases will build your credibility in your region as a qualified and approachable herpetological veterinarian.[4] As mentioned above, it is important not to provide too much detailed information without seeing the case yourself. However, providing a list of possible differentials and diagnostic options can help these potential clients or referring veterinarians to see the value that your expertise and practice can offer. It is critical to show that there is more to treating herptiles than a home remedy or a dose of antibiotic. Obtaining a specialist qualification so that you can legitimately call yourself a "specialist" can have many advantages. Likewise, be careful not to give the impression of being a "specialist" if you do not hold a recognized qualification (e.g., DACZM, DABVP[R/A]) in the United States (see Chapter 4).

(B) Proper Organization: Client and Patient Processing

"You have only one chance to make a first impression." Every veterinary practice has standard procedures for addressing clients and their animals when they arrive for an appointment. Most canine/feline patients are socialized as well as socially accepted, and it would be considered an unusual event for another pet's owner to be startled or afraid by their presence. This is not always the case with herps. At a minimum, people that do not own herptiles may be surprised to see them in a practice lobby, and it is not uncommon to have the occasional client in terror. Furthermore, many herptile owners seek the attention associated with possessing an unusual pet and will carry them out in the open.

The reception staff is critical in instructing clients on the policies and procedures of the hospital. This communication must start when the client makes the appointment and be reinforced by the receptionists in person upon arrival. All herptile patients should arrive at the hospital in an appropriate carrying container or cage. During cool weather, owners should be instructed to consider insulated containers and advised that exposure to low temperatures can be damaging to the patient's health, as well as hinder an accurate veterinary evaluation. If there are specific clades or species that the clinician is not willing to take on as patients (i.e., crocodilians, venomous snakes) it should be stated clearly to potential clients at first contact. It would also be advisable for the clinician to research the local jurisdictional regulations regarding potentially dangerous and illegal species and determine the role the veterinarian should play if such species are presented.[5]

Technology can be utilized to easily alleviate potential issues. When the owner is making the initial appointment, along with obtaining the name and phone number of the client, the staff should obtain their e-mail address to send them hospital information and new patient forms. An added benefit of electronic communication is that the "no-show" occurrence rate decreases significantly because of the added communication and increased disclosure. Another system utilized is texting appointment reminders. Once you have the owner's cell phone number, it can be used as a brief reminder to owners regarding upcoming appointments and can even be programmed in advance. The dental profession has been utilizing this system and has had remarkable success, both with helping people keep appointments and encouraging rescheduling an appointment rather than simply not showing up.

Forms sent to the new client should include a summary of clinic policies and procedures, the basic consultation fee, and information regarding restraint and caging of their pet at the appointment, as well as patient health and husbandry questionnaires. To increase efficiency,

VetBooks.ir

new client forms are sent to the owner to read/fill out in advance. Compliance in completely filling out these forms is necessary, and reception staff must review them for completeness at the time of intake.

With the advent of camera phones, owners are encouraged to bring photographs of their enclosures, setups, and supplies. This way, it is easy for the clinician to assess husbandry almost as if they were making an onsite visit. The new client should understand that the more information provided at the first visit, the more accurate the assessment, diagnosis, and treatment plan can be.

The health and husbandry questionnaire can be utilized to help the owner summarize the husbandry and care of the animal they are presenting, as well as increase the efficiency of the technical staff and doctor. Table 1.1 is a condensed general outline of a typical form. While each practice should tailor the questionnaire form to their needs, it is important that the queries are kept simple and brief. The primary goal is to identify general issues rather than specific ones, allowing the clinician to easily investigate potential problems.

Other policies should be determined and documented at the hospital prior to first presentation. As many herptile owners often have multiple animals, a decision should be reached about how additional animals at a visit will be charged. Additionally, charges for large collections (i.e., breeders) might be best based on time and not the number of animals.

Reptiles and amphibians have lower requirements for after-hours emergency care than mammals and birds, but plans should be made in advance regarding where emergent cases should be sent, as well as for times when a herptile-skilled doctor (or specialist) is not on duty. Overnight care plans must be made in advance, as there will be cases that require a higher level of treatment than outpatient care can provide. Having a plan in place for these situations is important to prevent client/staff frustrations and avoid legal liability.

(C) Knowledgeable Support Staff

"You are only as good as those helping you." Recently a t-shirt was seen that said, "Behind every successful veterinarian is an exhausted technician." Not only is that true, but "technician" should also be replaced intermittently with "assistant," "receptionist," and "manager."

Staff are not generally trained in how to process, inquire, and assist a herptile veterinarian, nor is there much coursework available even in accredited technician programs. Although staff education is still primarily the responsibility of the herpetological clinician, there is now specialization through the National Association of Veterinary Technicians in America in "exotic companion animals" or "zoological medicine." Also, many veterinary conferences that incorporate material on herpetological medicine offer continuing education for technicians. There is a veterinary technician group within the Association of Reptilian and Amphibian Veterinarians (ARAV).

Similarly, just as policies need to be established and followed for the herptile-owning client, appropriate guidelines for staff must be in place to ensure each appointment and treatment plan works smoothly and efficiently.

The basic policies involving the front desk staff include those listed earlier, such as providing new clients with forms and hospital procedures in advance. Additional recommendations might include placing reptile-owning clients into exam rooms as quickly as possible (to avoid distressing other clients) and having receptionists learn from teaching tools such as flash cards about the more common species seen in the practice so that basic knowledge and familiarity can be demonstrated to owners. This familiarity builds confidence in the client.

Fear of herptiles is one factor that must be considered when selecting staff that will be encountering these patients. It is critical that all staff are able to approach nondangerous herptile patients (perhaps even be comfortable handling them) when they present in the office. The damage done by an owner seeing a staff member recoil in revulsion is irreparable.

Managers also need to understand the unique issues presented with herpetological medicine. An informal survey of exclusively exotic animal practices in the United States concluded that technical labor needs were nearly 50% higher than domestic animal practices because of the increased time the staff spent working directly with the patients (K. Wright, personal communication). Additional resources were required for these exclusive exotic animal practices, including a commitment to stock specialty medications and unique supplies and equipment. Other important requirements include providing special housing and husbandry materials and unique food resources (insects and rodents), along with additional training of staff. Doctors need to be scheduled appropriately for these patients because more time will be taken to get a complete anamnesis as well as samples for diagnostic testing. Management and accounting must charge appropriately for the increased resources applied to each case.[6]

As stated above, there is usually little instruction available for technical staff to learn to work with herpetological patients until they take a position in such a practice. There are good texts available, continuing education, and internet sources, but the best resource is the experienced herpetological veterinarian(s) in the practice. By taking the time to personally train and educate the technicians and the assistants, the doctor can have them perform the necessary duties as expected by the practice. This also provides a support mechanism for team members to be quizzed, challenged, and have their skills confirmed/corrected. This method of instruction will help them to complete tasks more effectively but also gives them an environment that encourages them to continually advance and improve their skills.

(D) Appropriate Infrastructure

"Better facilities make for smoother operations." Unique infrastructure is necessary to be able to provide quality care to herptiles. These provisions are necessary to accommodate the unique anatomy and physiology that these animals have and will make the practice both easier and more effective.

The lobby requires little more than what is found in any other small animal practice. The entry door should be large enough to facilitate the admission of larger carriers, tubs, and even carts carrying multiple units. Seating is best when there are distinct separate areas, allowing clients with herps to sit away from, or at least out of direct vision of, other clients that might be disturbed by their presence. As with all areas of the hospital, good thermal control is important to avoid exposing these patients to inappropriately hot or cold temperatures.

Making the entrance/lobby appealing to owners is a great way to connect with these clients as soon as they enter your facility. Having decorations that show your interest in these species facilitates comfort, and having reading material, brochures, diets, and other information available communicates to these clients that you take their nontraditional pets seriously (Fig. 1.1).

An exam room needs to have a large work area, both to accommodate larger patients as well as to put the carrying cases or enclosures in which the animals were transported (Fig. 1.2). A sink with running water is essential for the ability to clean off both the patient and the doctor and/or technician. Drawers and cabinets should all close completely and securely, and there should be no gaps or spaces around, under, or behind fixed furniture that might allow a smaller patient an opportunity to hide or escape. For that same reason, the sink should have a permanently mounted mesh drain strainer. Doors entering the exam room work best with automatic closers and should have no more than a 1 cm gap between the bottom of the door and the floor. Any vents or wall perforations should have covers or have only small gaps (<1 cm) to

TABLE 1.1 Reptile History Form

Date: _____

Referring veterinarian: _____

First and last name: _____

Pet's name: _____

Species:_____ Age/DOB: _____

Sex: ____ Male ____ Female ____ Unknown ____

Where did you obtain your reptile? _____

How long have you had your reptile? _____ Is your reptile: Wild caught? ___ Captive bred? ___

Housing

What type of enclosure does your reptile live in? _____

What are the dimensions? H _____ W _____ L _____

Do you use a hygrometer (humidity meter)? YES ____ NO ____ If yes, what is the humidity? _____

How is the enclosure heated (e.g., light, heating pad, heat rock)?_____

What is the temperature? Day: _____ Night: _____ Basking site: _____

Do you use thermometers? YES ____ NO ____

Where are they located? _____

Do you use a full-spectrum UVB bulb? YES ____ NO ____ UNKNOWN ____

What kind of bulb is it? _____

How often is it replaced and when was the last time? _____

How long are the lights on/off? Day: _____ Night: _____

Does your pet spend time outside of the enclosure? If yes, explain: _____

What is the substrate (bedding)? _____

What is the water source? _____

Are there plants, branches, or other climbing structures? _____

Is there a hiding area? If so, what kind? _____

Are there any other reptiles in the same enclosure? YES ____ NO ___ If so, what species?_____

For Aquatic Species:

How often do you change the water completely? _____Partially?_____

Do you use a water heater? ____ YES ____ NO ____ Water temperature: _____

Does the aquarium have a filter? YES ____ NO ____ Do you test water quality? YES ____ NO ____

Diet

Please fill in the percentage of the total diet and types of food in each category that your pet actually eats:

Leafy greens: _____ Legumes/beans: _____ Fruits: _____ Other vegetables: _____

Insects/small rodents: (circle one: live/dead) Pellets: _____ Other (including treats): _____

How often do you offer food? _____

Where do you feed your reptile? _____

Do you add vitamin or calcium supplements to the food? YES ____ NO____

How often? _____ What kind? _____

If insects are fed, are they gut loaded? ____ YES ____ NO ____ UNKNOWN

Miscellaneous

Do you soak or bathe your reptile? YES ___ NO ____ How often? _____

Do they have any seasonal behavior changes? _____

Medical History

Has your reptile ever been checked for intestinal parasites? _____

Has your reptile ever laid eggs? YES ____ NO ____ UNKNOWN ____

How often does your reptile defecate? _____

How often does your reptile shed? _____When was the last shed? _____Any problems?_____

Check any boxes that apply to your pet:

____ mites	____ wounds	____ weight loss	____ weight gain	____ not defecating
____ anorexia	____ diarrhea	____ shedding problems	____ difficulty breathing	
____ lethargy	____ inactivity	____ increased appetite	____ decreased appetite	
____ limping	____ vomiting	____ deformed limbs	____ swollen eyes	

Is there anything else you would like us to know today? _____

FIG 1.1 A reasonable amount of space in the waiting room is an excellent investment to promote nontraditional species care and husbandry but also showcase your herpetological and exotic species practice. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

FIG 1.2 It is critical to have at least one room designed to accommodate herpetological patients. LED lighting, small-size screens over any wall and ceiling perforations, and no inaccessible openings to cabinets or chairs are critical considerations. All surfaces that might come in contact with patients must be solid and easily cleaned.

prevent the escape of small patients. All surfaces (floor, walls, tables, etc.) must be of nonporous, smooth material and easily cleaned, with supplies present.

Lighting is critical for an effective examination but also needs to have the patient in mind when selected. Traditionally, incandescent bulbs were selected to provide both light and heat, but, because they are no longer available, halogen or very high-frequency or constant-light LED bulbs should be utilized. Many species of herptiles have broader spectral ranges of vision than mammals, so the quality of light produced is as important as the quantity. Further information on the LED lights should be obtained from the manufacturer to ensure that they provide a balanced spectrum. Fluorescent lights (CFL included) should be avoided due to the limited spectrum produced (due to the types of phosphors present), as well as the potential strobe effect that they may generate. These lighting concerns should be applied to the exam room, as well as any boarding and/or hospital spaces.

FIG 1.3 To provide quality reptile and amphibian medicine, an appropriate hospital room must be part of the practice. This room provides controlled heat and ventilation, with multiple enclosures available depending on the size and husbandry of the patient. Additionally, this room is well insulated, blocking sounds that might disturb exotic species.

There will need to be hospital space in a designated ward for reptiles and amphibians (Fig. 1.3). The concerns above apply to this space as well (controllable heat, lighting, security, sanitation), along with the ability to isolate patients from each other to minimize intimidation, predation, and disease transmission and to provide optimal husbandry for each patient. Mesh or wire-fronted cages are not appropriate in most cases, so close-tolerance clear plastic or tempered glass doors are advisable. This style also has the added benefit of being able to control heat and humidity so that cages can be optimized for the health of the individual patient. When selecting cage design and materials, consider their ability to have heat sources installed within each unit, their resistance to heat damage and moisture, and ease of disinfection (see Chapter 46).

In the treatment area and critical care ward, it is important to have open floor space with clear lighting. At least one dedicated treatment table with an overhead focused beam exam light (individually controlled) will allow for basic procedures with most animals, whereas the floor will make for an easy exam area for very large individual patients. A large sink or a wet table is necessary for washing, soaking, and even holding some animals, but a clean bathtub will work. Avian/reptile incubators can be an excellent addition to the critical care ward, but they are not all equal. Each model should be considered prior to purchase for oxygen concentration abilities, thermostat accuracy, ventilation, security (e.g., escape proof), and the ability to be easily and completely cleaned and sanitized between uses (see Chapter 46).

(E) Necessary Equipment

"No good carpenter blames his tools." Appropriate materials and equipment kept in the treatment areas are a necessity, and if you have poor-quality tools, you will have poor-quality results. Specific medical equipment is necessary for examinations. Ophthalmoscopes and otoscopes found in any basic practice work well for examining most eyes, ears, and oral cavities; a Doppler monitor is necessary for assessing heart rate and quality; a gram (to the nearest 1 gram or better still 0.1 gram) scale for small reptiles and a cat/baby scale for most others is adequate for getting accurate weights; and a set of sexing probes to determine gender is required. Wooden-stick, cotton-tipped applicators and tongue depressors work well for opening mouths for examination; the soft wood works well for encouraging them to open without damaging sensitive gingiva or teeth. A cordless rotary tool (e.g.,

VetBooks.ir

Dremel) with a diamond grinder bit is preferred for trimming and rounding nails.

Appropriate diagnostic equipment is also imperative to provide quality herpetological veterinary services (Fig. 1.4). Table 1.2 provides a list of recommended equipment needed in different areas of the hospital.

Medical supplies required in a herpetological service are like those required in most veterinary practices. Anti-inflammatories, antibiotics, antifungals, and other medications should be stocked based on current research and known safety data and selected for each patient based on all available information, including patient specificities such as species, condition, husbandry, plasma biochemistries, and culture and sensitivity results. Just as in domestic animal medicine, there is no "one-size-fits-all" medical therapy, and a diversity of therapies must be immediately available. Access to a compounding pharmacy is important.

Table 1.3 provides a short list of some (not necessarily complete) of the most essential medications and drug products necessary for a herptile veterinary service.

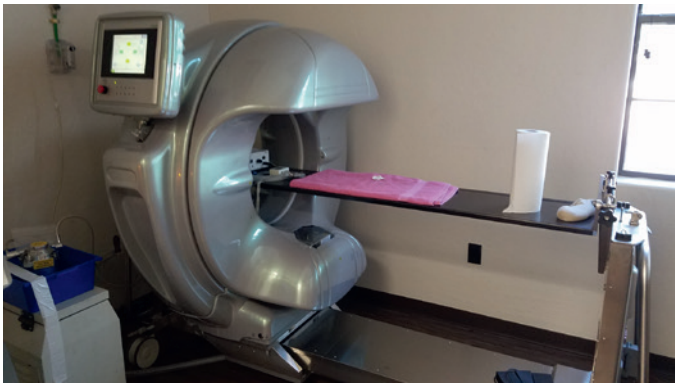

FIG 1.4 An example of a compact, affordable CT scanner (Vimago HDCT, Epica Medical Innovations) now available for private practices, providing advanced resolution and data for the herpetological practitioner.

APPROACH AND ATTITUDE

"A Clear Statement of Our Ignorance Does More to Advance Science Than Does an Assumption of Knowledge."

Probably the single most important aspect of building a successful reptile practice is the approach and attitude the doctor takes in each case managed. The correct approach builds a doctor's reputation, is a measure for success, and can be the inspiration to guide their career. Specifically, the proper approach involves the ability to differentiate what one knows versus what one does not and the ability to build on each. For example, clinicians need to understand that some clients may know more about a specific species than they do. Many owners report disappointment when a veterinarian pretends to have knowledge about a particular species but actually does not. This can be a fatal error in relating to clients and damages the reputation of the clinician. However, clinicians must also be prepared for clients who have spent time on the internet gathering selective "wisdom"; this misinformation spreads through herp-related sites and is presented as absolute certainty, often with no evidence or validation to support the claims. Obviously, clinicians cannot be expected to know all there is about every species and case presented. However, clinicians are obligated to seek out the best (often peer-reviewed journal) information available and utilize this to make evidence-based treatment decisions.

To avoid mismanagement of these cases, as described above, clinicians should complete as much research as possible in advance and never be embarrassed to admit they are not familiar with a species. Additionally, they should willingly defer to the owner's knowledge unless they can readily validate their difference of opinion. In the case of an error, it is best to admit ignorance of a fact or mistake and take action to follow up with the owner after researching the topic.

In this information age, there is constant availability and a never-ending supply of material on almost any subject. A recent Google search for "causes of iguana diarrhea" produced over 130,000 website hits in less than a second. This exemplifies the need to specifically focus such searches and utilize only reliable sources that involve peer-reviewed research. Google Scholar (https://www.scholar.google.com), PubMed

TABLE 1.2 Critical Areas and Basic Equipment Needs for a Practice Seeing Reptiles and Amphibians

Treatment/Lab Area	Hospitalization/Critical Care	Operating Room
Microscope	Oxygen cage/oxygen concentrator	Radiosurgical unit or laser
Centrifuge capable of processing hematocrit tubes, blood tubes, and fecal samples	Programmable incubator(s)	Ventilator (oxygen and room air), programmable for small volume and low tidal pressure
Bacterial and fungal culture supplies	Syringe pump	Endotracheal tube size 1–12 mm
Acid-fast stain kit	Esophagostomy tubes	Doppler
Wright's stain kit	IO and cut-down IV supplies	Surgical loupes or magnification
Gram's stain kit	Blood transfusion supplies	Endoscopy
Radiology, preferably digital, and including horizontal beam capability	Bandaging materials	Bone and external fixator supplies plating supplies
Ultrasonography	Fluid bags and warmer	Microsurgery instrumentation
In-house biochemistry analyzer (or access to a commercial lab)	Blood transfusion supplies	Surgical heaters
Hemocytometer, diluents, and stains for in-house hematology (or access to a commercial lab)		Gas anesthesia
Heparin and EDTA blood tubes		Hemoclips/Ligasure
Digital in–out thermometer		Retractors such as Lone Star retractor
PCR testing supplies, formalin jars		

EDTA, Ethylene diamine tetra acetate; *PCR,* polymerase chain reaction.

VetBooks.ir

TABLE 1.3 Drugs and Other Therapeutic Products Commonly Used in Herpetological Practice

Antibiotics/Antifungals	Antiparasitics	Anesthetic/Analgesic/ Anti-Inflammatory	Other	Nutritional
Ceftazidime	Metronidazole	Meloxicam	Furosemide	Vitamin A
Amoxicillin/clavulanate	Fenbendazole	Ketoprofen	Plasmalyte, LRS, or equivalent	Calcium gluconate
TMP-SMZ	Ponazuril	Butorphanol	Dexamethasone	Vitamin E
Enrofloxacin	Ivermectin	Hydromorphone or morphine, tramadol	Lactulose	Vitamin D
Ceftiofur	Fipronil spray	Lidocaine	Heparin	Vitamin C
Doxycycline	TMP-SMZ	Bupivicaine	Sodium citrate	
Metronidazole	Praziquantel	Isoflurane	Iohexol	
Azithromycin	Permethrin (Provent-a-mite)	Propofol	Barium	
Florfenicol		Alfaxalone	Epinephrine	
Itraconazole		Midazolam	Glycopyrrolate	
Voraconazole		Flumazenil	Allopurinol	
		Ketamine		
		(Dex)medetomidine		
		Atipamezole		

TMP-SMZ, Trimethoprim/sulfamethoxazole.

(https://www.ncbi.nlm.nih.gov/pubmed), and BioOne (http://www.bioone.org) are all excellent search engines for research publications. There are many textbooks and journals (including *Journal of Herpetological Medicine and Surgery*, *Journal of Herpetology, Journal of Zoo and Wildlife Medicine,* and the *Journal of Wildlife Diseases*) available. In general, peer-reviewed clinical trials, studies, and case series are among the strongest and most reliable sources, followed by case reports, roundtable discussions/reports, and conference proceedings. (See Chapter 2 for herpetological reference resources.)

Once information has been researched and reviewed, clinicians must attempt to incorporate substantiated and updated information into the management of the case at hand. If clinical questions can be answered with substantiated information such as research and published material, a specific treatment may be able to be initiated. However, in herpetological medicine, answers are often unclear, and application of evidence-based veterinary medicine, although always the goal, may not always be entirely possible. In these situations clinicians still have an obligation to provide treatment for these unique patients. Subsequently, it is important for the clinician to utilize the *best* available information in managing a case.

Reference Resources for the Herpetological Clinician

Joanna Hedley

Finding reference resources has historically been a challenge for the reptile clinician. Despite published recommendations, reptile medicine has not been well-represented in the core curriculum of the majority of veterinary schools.[1] Thus, in comparison to the more traditional companion animals, there has been a lack of resources available for veterinary students wanting to learn about reptile medicine and surgery. Early literature was based primarily on personal experience, from both clinicians and experienced reptile keepers. Currently, however, as the field of herpetological medicine has developed, there are many more resources available, ranging from textbooks to peer-reviewed research articles. Additionally, a large amount of nonveterinary herpetological literature, including information on taxonomy, anatomy, physiology, ecology, nutrition, and behavior, is available and is relevant to reptiles treated in veterinary practice. Likewise, literature published in other languages should not be overlooked.

With the widespread use of the internet, more resources are available online and even on mobile devices, making access to information easy. Obtaining reliable information, however, can still be problematic and requires the clinician to critically evaluate the quality of reference resources. The advantages and disadvantages of each type of resource will be examined in more detail below.

ASSOCIATIONS AND SOCIETIES

First, for any clinician with a keen interest in reptile medicine, membership in a specialist veterinary association is highly recommended. Membership usually allows access to various resources, including publications, conference proceedings, and an opportunity to network and collaborate with other veterinarians in the field.

The largest association is the Association of Reptilian and Amphibian Veterinarians (ARAV) (http://www.arav.org), which, although primarily based in North America, does have active international involvement and considers itself an international organization. Regular conferences are held in North America and Europe, and members have access to the peer-reviewed *Journal of Herpetological Medicine and Surgery* (JHMS).

Other useful organizations, depending on location, include the American Association of Zoo Veterinarians (AAZV) (http://www.aazv.org) and the European Association of Zoo and Wildlife Veterinarians (http://www.eazwv.org). Many countries also have their own local reptile or zoological veterinary organizations.

Herpetological societies can also be an extremely helpful source of information. The North American–based Society for the Study of Amphibians and Reptiles (http://www.ssarherps.org) is the largest international herpetological society. Other useful societies in North America include The American Society of Ichthyologists and Herpetologists (http://www.asih.org) and The Herpetologists League (http://www.herpetologistsleague.org). Other large international and national organizations include Societas Europaea Herpetologica (http://www.seh-herpetology.org) in Europe, and Australian Society of Herpetologists (http://www.australiansocietyofherpetologists.org), but many countries will also have multiple regional organizations, which can be good sources of information on local herpetofauna.

BOOKS

Textbooks have previously been the standard starting point for those looking for information, and, although they are now often available as online resources, many clinicians still prefer to keep at least some hard copies available for quick reference. Books can provide a good general overview of a topic but may not always be well-referenced or have undergone rigorous review. The reader will therefore need to evaluate the information carefully to decide whether it is based primarily on the author's personal opinion (and whether that author is a recognized specialist in the field) or backed up by references (to material other than previous textbooks).

Many standard veterinary textbooks or exotic pet textbooks contain a section on reptiles, but more reptile-specific literature is now available. Aside from this book (and previous volumes), some useful titles are listed below. This list is limited to the last 20 years because older titles can be harder to obtain. However, the older titles should not be completely disregarded; although some information is outdated, many still contain useful reference material found nowhere else. A classic example would be *Biomedical and Surgical Aspects of Captive Reptile Husbandry*, volumes 1 and 2 (Frye), which contains a wealth of information and high-quality color photographs.

Identification and Husbandry

- Bartlett RD, Bartlett P (2010) *Reptiles, Amphibians and Invertebrates: An Identification and Care Guide* (Reptile Keepers Guide), New York, Barron's Educational series—this basic husbandry manual covers more than 250 commonly kept species, with excellent photographs for identification
- Behler JL, King FW (2013) *National Audubon Society Field Guide to North American Reptiles and Amphibians*, New York, Alfred A. Knopf—this field guide describes all the native and introduced reptiles and amphibians found in North America, with full-color photographs for identification
- Huchzermeyer FW (2003) *Crocodiles. Biology, Husbandry and Diseases*, Cambridge, CABI—a review of the crocodilian species, in particular their biology and captive management

Anatomy and Physiology

- O'Malley B (2005) *Clinical Anatomy and Physiology of Exotic Species*, Philadelphia, Elsevier—a concise, easily read summary of clinically relevant reptile and amphibian anatomy and physiology
- *Biology of the Reptilia*—a 22-volume collection of information, which provides the most comprehensive review of this topic to date; useful for more in-depth reading on a specific topic and now also available for free online at http://www.carlgans.org/biology-reptilia-online

VetBooks.ir

Pathology

- Campbell TW (2015) *Exotic Animal Hematology and Cytology*, 4th edition, Oxford, Wiley Blackwell—an excellent reference guide with good-quality pictures, especially for those routinely performing their own in-house laboratory work
- Fudge AM (2000) *Laboratory Medicine: Avian and Exotic Pets*, Philadelphia, WB Saunders—although some information has now been superseded by newer publications, the reptile chapters provide a useful background in reptile clinical pathology
- Jacobson E (2007) *Infectious Diseases and Pathology of Reptiles: Color Atlas and Text*, Boca Raton, CRC Press—an incredibly detailed reference guide with many useful pictures and further references for the reptile clinician

Clinical Medicine

- Fowler ME, Miller RE (2012) *Zoo and Wild Animal Medicine, Current Therapy*, 7th edition, St. Louis, WB Saunders—the reptile section provides a thorough review of selected topics. The previous six editions also contain sections on different reptile-related topics
- Fowler ME, Miller, RE (2015) *Zoo and Wild Animal Medicine* (vol. 8), St Louis, Elsevier Health Sciences—this revised edition provides an up-to-date overview of reptile and amphibian medicine, including biology, anatomy, and husbandry
- Girling SJ, Raiti P (2004) *Manual of Reptiles*, 2nd edition, Quedgeley, British Small Animal Veterinary Association—this book provides information in an easy-to-use format for the busy clinician
- Jacobson ER (2003) *Biology, Husbandry and Medicine of the Green Iguana*, Malabar, Krieger Publishing—although not as up-to-date as some of the more recent texts, this book is still a valuable source of information, particularly about the biology of the green iguana
- Krautwald-Junghanns ME, Pees M, Reese S, Tully T (2011) *Diagnostic Imaging of Exotic Pets*, Hannover, Schlütersche—a helpful atlas including both normal and abnormal images of a variety of reptile species
- Longley L (2008) *Anaesthesia of Exotic Pets*, Edinburgh, Saunders—the reptile and amphibian sections provide a practical and detailed guide to anesthesia
- McArthur S, Wilkinson R, Meyer J (2004) *Medicine and Surgery of Tortoises and Turtles*, Oxford, Blackwell—a well-illustrated, extremely practical guide for the reptile clinician
- Schneller P, Pantchev N (2008) *Parasitology in Snakes, Lizards and Chelonians*, Edition Chimaira, Frankfurt am Main—a useful reference source for those performing in-house parasitology
- Wright KM, Whitaker BR (2001) *Amphibian Medicine and Captive Husbandry*, Malabar, FL, Krieger Publishing Company—a comprehensive guide to amphibian biology, nutrition, husbandry, and medicine
- Zug GR, Vitt LJ, Caldwell JP (2001) *Herpetology: An Introductory Biology of Amphibians and Reptiles*, 2nd edition, San Diego, Academic Press—a detailed herpetology text
- *Veterinary Clinics of North America* (Exotic Animal Practice)—published three times per year, this journal reviews a different topic with each issue, with contributions from multiple international authors

In addition to the larger textbooks, specific exotic pet formularies are also available, which can provide a quick reference guide for the clinician. These include the *Exotic Animal Formulary,* 5th edition (Carpenter and Marion), and the *BSAVA Small Animal Formulary,* 9th edition, Part B: Exotic Pets (Meredith). In addition to drug doses and some normal blood reference ranges, both of these are well-referenced, so clinicians can assess the evidence (whether based on pharmacokinetic studies or personal communications) before selecting their dosage.

JOURNALS

Both veterinary journals and herpetological journals can be useful sources of information. Peer-reviewed original research articles should provide the most reliable evidence base for reptile medicine. However, articles need to be critically evaluated by the reptile clinician to assess their validity and relevance to clinical cases. Case reports and review articles can also provide valuable clinically relevant information.

The main reptile veterinary journal is the *Journal of Herpetological Medicine and Surgery* (JHMS), published by ARAV and available online for members. However, other veterinary journals are now beginning to include more herpetological articles. These include zoological or exotic animal–based publications, such as the following:

- *Journal of Wildlife Diseases*
- *Journal of Zoo and Wildlife Medicine*
- *Journal of Exotic Pet Medicine* (previously *Seminars in Avian and Exotic Pet Medicine*)
- *Zoo Biology*

Herpetological research and case reports are also now being featured more frequently in mainstream veterinary journals, such as *Journal of American Veterinary Medical Association*, *American Journal of Veterinary Research*, *Veterinary Record*, *Veterinary Journal*, and *Journal of Small Animal Practice*. Publications on more specific reptile topics can even be found in discipline-specific journals such as *Veterinary Radiology and Ultrasound*, *Veterinary Ophthalmology*, *Veterinary Anaesthesia and Analgesia*, *Journal of Veterinary Diagnostic Investigation*, *Veterinary Pathology*, and *Veterinary Parasitology*.

Herpetological journals of interest may include:

- *Journal of Herpetology* (Society for the Study of Amphibians and Reptiles)
- *Herpetological Review* (Society for the Study of Amphibians and Reptiles)
- *Copeia* (The American Society of Ichthyologists and Herpetologists)
- *Herpetologica* (The Herpetologists League)
- *Amphibia-Reptilia* (Societas Europaea Herpetologica)
- *Chelonian Conservation and Biology* (Chelonian Research Foundation)
- *Herpetological Conservation & Biology* (open-access online journal)

It may not be economically feasible to subscribe to all of these journals, and although more journals are now moving toward an open-access online format, many still require substantial subscription fees. In most cases, electronic reprints of articles can be provided for a fee, or alternatively, journals may be accessed via libraries of veterinary colleges or other academic institutions.

ONLINE RESOURCES

As more resources become available online, determining which of these are actually reliable sources of information will be a challenge for the reptile clinician. Searching with a standard search engine such as http://www.google.com provides a basic overview of the information available. Because most websites, wikis, and blogs can be set up or edited by anyone, quality is highly variable. However, these websites can be a helpful insight into the information (often confusing and conflicting) available to clients attempting to research their pet's needs or medical conditions.

For a more focussed search, there are a number of free literature database search engines available. Pubmed (http://www.ncbi.nlm.nih.gov/pubmed) covers primarily biomedical literature and is easy to navigate, whereas others such as Bioone (http://www.bioone.org) include a number of natural history publications that are not available on Pubmed. Google Scholar (http://www.scholar.google.com) covers a wider range of literature types including books, which can result in a more

VetBooks.ir

extended search. However, it has the advantage of providing links to other articles that cite the original, which can be helpful when searching for more current research. Whichever type of search is conducted, it is important to critically assess the information retrieved. This applies whether the resources are books, journal articles, websites, wikis, blogs, or any other format.

Some useful websites for veterinary information and husbandry advice are listed below, although website addresses are subject to change.

- Veterinary Information Network (VIN): http://www.vin.com—a membership fee is charged, but this is an extremely useful resource. Members can access a wide range of information, such as journal abstracts (including several, such as JHMS, that are not listed on Pubmed), conference proceedings, drug formularies, and forums moderated by experienced reptile consultants.
- LaFeber has a website specifically designed for exotic animal veterinarians at http://lafeber.com/vet that provides reviews of many reptile-specific topics in addition to step-by-step guides and videos of procedures
- Reptile Database: http://www.reptile-database.org—this database (originally the EMBL Database) covers current reptile classification and taxonomy for all living species of reptiles and is updated several times per year
- http://www.kingsnake.com—a comprehensive information portal for reptile and amphibian keeping. It contains several hundred links, including breeders, dealers, stores, classified ads, forums specific to various species, organizations, events, care sheets, frequently asked questions (FAQs), and products.
- http://www.anapsid.org—this site contains hundreds of articles on the care of most herpetological species seen in the pet trade, with an exhaustive section on green iguanas. It also lists information on herpetological societies and veterinarians, literature, supplies, and links to other important sites.
- http://www.reptilesmagazine.com—this site provides current news, information, and care sheets on many commonly kept species of reptiles and amphibians.
- World Chelonia Trust: http://www.chelonia.org—dedicated to the conservation and species survival of turtles and tortoises, this website also has many care sheets and images to facilitate species identification.
- Tortoise Trust: http://www.tortoisetrust.org—an easy-to-navigate website containing numerous useful articles on chelonian care, breeding, and conservation
- USDA Nutrient Database: https://ndb.nal.usda.gov—a useful online resource providing complete nutritional information on any human food type
- http://www.herplit.com—a website that offers out-of-print and hard-to-find herpetological literature for sale

As demand for instant access to information has increased, so too has application software (apps) available for mobile devices. These apps can provide quick, concise reference resources, particularly for clinicians working between multiple sites or on the move. Examples include apps such as Merck Veterinary Manual, Veterinary Care of Exotic Pets, and Exotic Pet Vet. Several formularies are also now available as apps, including The Veterinary Formulary, which lists information on drugs and doses for a variety of exotic species. Alternatively, PDF versions of formularies or textbooks may be downloaded onto mobile devices for easy access.

Finally, online veterinary forums such as those run by VIN or Exotic DVM (http://www.exoticdvm.com) can provide clinicians with an opportunity to discuss cases, exchange ideas about topics, and advance their understanding of reptile medicine. Alternatively, more specialist forums are also available, such as the European College of Zoological Medicine (ECZM) forum, although access is restricted to European Diplomates (https://www.eczm.eu).

CONFERENCES

Attendance at conferences is one of the main ways of keeping up to date with advances in the field of reptile medicine. ARAV hosts an annual conference running over several days, concentrating solely on herpetological medicine, although this is often in collaboration with other exotic pet or zoological associations. This conference includes both basic and advanced lecture sessions and wet labs and so provides a helpful learning experience for clinicians at any stage in their career. Other conferences to consider in North America include the North American Veterinary Conference (http://www.navc.com), which usually runs a reptile lecture stream, and the Western Veterinary Conference (http://www.wvc.org). Both conferences take place annually.

In Europe, the International Conference on Avian heRpetological and Exotic mammal medicine (ICARE) runs every other year in various locations around Europe and hosts a reptile stream (including lecture sessions and wet labs) in collaboration with ARAV. The World Congress of Herpetology (http://www.worldcongressofherpetology.org) meets every 3 to 5 years in various locations around the world. Topics include reptile and amphibian biology, ecology, reproduction, and behavior. There are also smaller conferences run by the reptile or zoological veterinary and herpetological associations for each country that may be more accessible for many clinicians and can still provide a good source of continuing education.

Understanding the Human-Herp Relationship

Stacey Leonatti Wilkinson

Reptile ownership represents the fastest-growing population of pets in the United States, and amphibians are becoming more popular as well.[1] At one time, buying a new reptile or amphibian was cheaper than taking an ill animal to the veterinarian, and there was a lack of veterinarians experienced in herpetological medicine. This is simply no longer the case. With the rapid advance in veterinary medical knowledge in exotic pets and the strengthening of the human-animal bond, herp owners are now seeking health care once not even considered an option. Services only available for canine and feline patients are now offered routinely for reptile and amphibian patients.

Veterinarians no longer enter the profession to avoid working with people. In fact, it is well understood that the "people part" of a clinician's job may be the most important. Veterinarians who have poor bedside manner lose out on both the financial and personal satisfaction aspects of this special profession. Preparation for work with owners and caretakers of nontraditional pets takes extra training—training that generally does not come from a classroom. The veterinarian gains this knowledge either in the field through trial and error or from an experienced mentor. This chapter offers veterinary clinicians and technicians a scaffold for building a better understanding of the concerns of these clients and their unique relationships with their nontraditional patients.

THE HUMAN-ANIMAL BOND

Who gets attached to a pet and why? The many answers to this question probably equal the number of clients in a practice. In general, people are attracted to pets for companionship, a sense of security they may provide, unconditional love (free of criticism and judgment), or because of a biological fascination with the species. For many people, experiencing consistent positive feelings with animals is easier than it is with people. Relationships with animals do not take as much emotional work to maintain.

Much truth can be found in the previous statements, even with herps as pets. Depending on the reptile or amphibian in consideration, many owners claim that their pets show reciprocal affection (Fig. 3.1). This affection is a matter of interpretation, and one person's definition likely differs from the next. However, regardless of how the veterinarian rationalizes a particular animal's ability to relate, the owner's emotional interplay is what matters. There is no doubt that certain herps recognize their owners, and many species tolerate handling and interaction very well.

The first step to take with a client and animal, in any situation, is to assume that some degree of emotional investment exists. This emotional investment could be in the form of "my lizard Iggy is deathly ill, and I may lose him" or "my lizard breeder number 14 is sick, and I could be out several hundred dollars." Regardless of the connection, whether an obvious true emotional dependence or a financial dependence, some type of emotion almost always plays a part in the decision making. Three general categories of the human-herp bond are considered in this chapter: the "pet" reptile/amphibian, the "commercial" reptile/amphibian, and the "large collection" group.

THE PET REPTILE OR AMPHIBIAN

To take the position of "pet," the animal generally assumes and fills some niche in a person's life. The relationship may be as simple as the owner dropping some crickets in the animal's cage every morning. Alternatively, it may be more complex, with the owner considering the animal a true part of the family; this may include routine conversations with the pet and even Christmas presents purchased in the animal's name. This bond can affect the owner's relationship with the herp veterinarian. The type and quality of medicine and care offered should not be dictated by the perceived bond between the client and animal. Recommendations should be made based on what is best for the animal, and it is up to the client to decide what they can afford and are willing to pursue. Often one might be surprised by which clients are willing to do whatever is needed for their pet. Part of establishing a trusting relationship with a client is not judging them or their relationship with their animal.

There are some owners who have one or more reptiles or amphibians that are considered members of the family (Fig. 3.2). The pets are typically out of their enclosures, held frequently, and even watch TV with their owners in a similar fashion to how owners spend time with a dog or cat. Owners may buy treats and presents for them and provide intensive detailed care for them such as changing the cage daily. When questioned by clinicians they can often recite their exact environmental temperatures, cage dimensions, type of lighting, food, supplements, and more provided to their cherished pet. These pets are often referred to by people as their "child" or their "best friend," and veterinary recommendations are eagerly accepted, and economics are not of concern. The author often sees this type of bond with green iguanas (*Iguana iguana*), bearded dragons (*Pogona vitticeps*), and large tortoises, among others. The bond between the owner and their herp pets can be profound (Fig. 3.3).

There are also owners who really enjoy their herp pet, love it, and take good care of it but are not as involved with it on a daily basis. They usually do everything correctly in regards to husbandry, but there may be some areas to improve on. When it comes to veterinary care, they are often willing to spend some money but may not commit to expensive diagnostic tests, hospitalization, or surgery without significant thought. They love their pet but may have limits. A common example of this is the college student with a bearded dragon.

Some pets have a more ornamental or decorative value. Reptiles are often used to enhance an image, such as the outlaw biker with the pet

VetBooks.ir

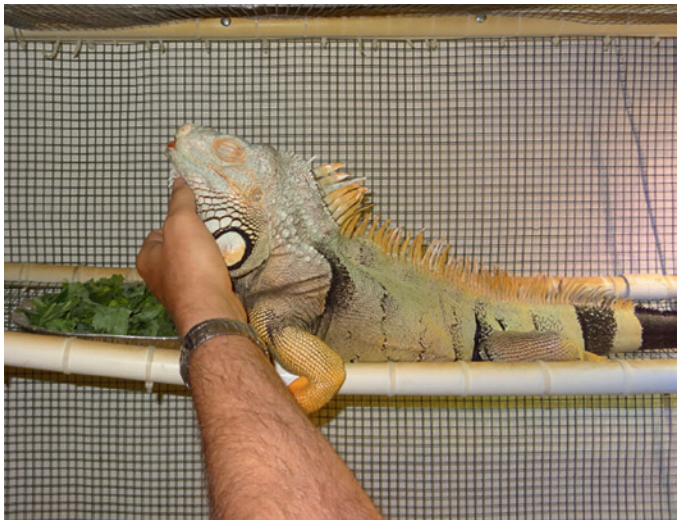

FIG 3.1 A green iguana (*Iguana iguana*) who appears to be enjoying human attention. Closing the eyes can be a defense mechanism (ignoring their surroundings), but in this case the lizard was leaning into the hand as if he is enjoying the attention. (Courtesy of Stacey Leonatti Wilkinson.)

FIG 3.2 A green iguana (*Iguana iguana*) sleeping on blankets with a stuffed animal. (Courtesy of Nanette Gunn.)

rattlesnake, the dancer with the python, or the surfer kid with the pet iguana. These reptiles, although important facets in the lives of these individuals, likely do not take on the same significance as the herp pet considered to be a part of the family.

Veterinarians will also encounter parents of children with pet reptiles or amphibians. Often the child really wanted the animal and the parent agreed, neither understanding the commitment they were making nor the level of care required. Once realizing the care may be challenging, some parents do research on the care required, help their child, and bond with the animal just as much or more than the child; these relationships are often rewarding. However, some parents are discouraged with the extensive care required and may resent the pet. They are not interested in continuing to care for an animal that their child fails to be responsible for or loses interest in. They also resent having to bring it to a veterinarian or spend any money on it at all. They often would prefer to euthanize rather than treat but may do the bare minimum treatment to appease their child. Of course there are variations between these two extremes,

FIG 3.3 A hospitalized red-footed tortoise (*Chelonoidis carbonaria*) being held by the veterinarian so that the owner can speak to it over the phone. (Courtesy of Dan Johnson.)

and some parents are often responsible and actively involved in the care of the pet from the beginning.

Along with the child/parent impulse purchasers, there are adults who purchase reptiles or amphibians with no forethought either, but rather because it "looks cool" or "my friend has one." They do little to no research, buy what a pet store tells them or they find online, and often end up with a sick animal. Many times these owners feel extremely guilty when they realize they have done something wrong and will do whatever it takes to save the animal. If it is beyond saving, they may request humane euthanasia but are willing to learn what they need to do should they get another herp in the future. Although these cases can be frustrating, it is important not to make these clients feel guilty as they are at least seeking veterinary care when realizing there is a problem. Along these same lines, giving a herp pet as a surprise gift is never recommended. These "gifted" pets are often given to people who are not prepared to own a herp and are not aware of the commitment involved. Often the animal is the least expensive part of the purchase; the cage, lighting, heating, food, and more cost significantly more.

THE COMMERCIAL ANIMAL

The commercial animal refers to a reptile or amphibian that is part of a breeding collection (Fig. 3.4). Some professional herpetoculturists have thousands of breeding animals. Breeders with large collections will often vary in their approach to veterinary care depending on the worth of the individual animal and their previous experience with veterinarians. If an individual animal has valuable genetics, they will often be willing to spend money on it, especially if there is a problem that could affect the entire collection. If there is a disease outbreak, they are often willing to sacrifice a critically ill animal for a necropsy in order to obtain a diagnosis. The financial investment generally far outweighs the emotional attachment.

FIG 3.4 An example of commercial animals/large collections. Part of a breeding colony of bearded dragons. In large collections, animals are often kept in rack systems or uniform cages for ease of care and visualization of all the animals daily. (Courtesy of David Freeman.)

Often these clients have been keeping herps for many years, sometimes before there were knowledgeable herp veterinarians available. They often perform their own medical care on their animals. They may still trust other keepers more than veterinarians. The herp veterinarian may have to work hard to prove to this client that they are knowledgeable and offer what is best for the animal. These keepers are often quite experienced, especially with specific species of reptiles or amphibians, and it is important to respect their knowledge while sharing clinical information with them. Often if this is done correctly, a mutually beneficial, respectful relationship can be formed.

LARGE COLLECTIONS

The last general category is the large collection. Examples include animals on display, such as zoo animals or animals in a research colony. In this last category, the bond between caretaker (not an owner but someone assigned to provide daily care for the animals) and the animal often may be just as strong as that between an owner and the pet reptile or amphibian. Caretakers may be asked to spend a significant part of their lives attending to these captive animals. Emotional attachment is not uncommon when one of the animals becomes ill or has to be euthanized, such as in the case of a research setting.

END-OF-LIFE CONSIDERATIONS

Palliative, end-of-life, or hospice care can be a valuable service to offer reptile and amphibian clients. In many cases these animals are as important to a client as a dog or cat may be, and the same standards of care should be offered. Often owners need time to understand or come to accept their pet's diagnosis, and there are frequently palliative measures that can be used to maintain a good quality of life. Often owners will ask if their pet is "in pain" or "suffering," and this can be more difficult to interpret in herps. Although they are not as demonstrative as other species, the same indicators can be used to assess their quality of life, including lethargy, lack of appetite, unwillingness to ambulate, and increased aggression. Remember the owner generally knows their animal best; often what is seen in an exam room is different from what is occuring at home.

Hospice care for reptiles and amphibians usually starts with optimizing husbandry: keep the animal in its preferred optimum temperature zone; provide appropriate lighting; modify the enclosure and furnishings to make it easier for them to move around; provide excellent water quality for amphibians; and generally provide a nutritious, highly digestible diet or modify the diet as needed for the condition being treated. Supportive care may be needed, such as additional soaking, fluid therapy, or syringe or tube feeding for an animal that is not eating. Many times there are medications that can be used to manage conditions being treated, and pain management can be incorporated if necessary.

For the emotionally attached client, regardless of the category, the decision to euthanize a cherished animal is agonizing and heart wrenching. Some people withdraw into a state of denial that gives relief from the psychological pain of a beloved animal in declining health. Many different conflicts and questions must be addressed in each category. An experienced veterinarian (and staff) is a great help to the client in making these difficult decisions.

With pets, regardless of the type of animal, the dilemma is always "treat or don't treat" or "euthanize and replace." Some reptile pets have extended life expectancies. Some of the smaller lizards may only live a few years, but some of the larger snakes and lizards may live much longer, and some tortoises may live more than 100 years. Longevity has an obvious impact on the decision for treatment or euthanasia.

The client who wants heroic efforts made at all costs to keep the terminal animal alive can create resentment in veterinarians and staff members who feel the animal is suffering. Practitioners also may disagree with clients who, in their opinion, prematurely or inappropriately choose euthanasia rather than attempt to treat an apparently correctable health problem. The owner has the right to make the decision to euthanize a pet, and veterinarians have the right to refuse continued therapy if euthanasia is indicated on humane grounds. Owners who feel they are discouraged from or coerced into a euthanasia decision may leave the office feeling misunderstood and manipulated. Euthanasia of a beloved pet can be the single event by which a pet owner judges the veterinary service; one should always be sensitive to an owner's needs in these situations.

In a commercial situation, the decision to treat or euthanize may not be emotional but intellectual and financial (i.e., if the cost of treatment can be recuperated with production profits) or scientific/diagnostic. If an animal is ill and a risk for infectious disease (or other colony danger) exists, then sacrifice of an ill or dying individual for the benefit of the colony is often wise. Even in these situations, a veterinarian should be cognizant of the owner's emotions, because the inherent loss of any animal, commercial or not, may have an emotional impact.

The animals in the large collection category present their own concerns regarding the human-herp bond. The caretaker, and even the general public, develops bonds with certain display animals. The decision to euthanize a charismatic zoo animal requires careful planning and

VetBooks.ir

media announcements to prevent public discourse. In a research setting, the value of an animal to a caretaker/scientist takes on different meanings. Again, caretakers commonly form bonds with long-term research specimens. When one of these animals dies or is sacrificed, an emotional toll may result on the caretaker. From a more objective perspective, if a colony animal is ill and is in imminent danger of dying or may have to be sacrificed, the associated loss of scientific worth (i.e., lost data and future potential data) also brings some consternation. In many cases, the decision for euthanasia or treatment may be a financial one and completely out of the control of the caretaker, which can have a serious effect on their emotions.

COMPASSIONATE EUTHANASIA GUIDELINES

Reptilian euthanasia can be a technically difficult procedure and should not be learned through trial and error in the presence of a client. See Chapter 47 for procedures to follow. Learn the techniques on either non–client owned animals or on patients with clients who do not want to be present.

From beginning to end, all cases of euthanasia should be handled with the utmost sensitivity and compassion. Acknowledge to the client the difficulty of saying goodbye. If possible, reminisce with the client about the animal. Offer at-home euthanasia or a referral for that service.

Give the client the option to be with the animal during the procedure. Many people need to feel that they were at the animal's side until the end. If a practice is not comfortable with this, a referral should be made to a practice where clients can be present during the pet's euthanasia. Many clients appreciate honoring their feelings about being present and remain loyal to the practice in the future.

Take time to educate the client. Talk about the process of euthanasia: the solutions that are used and how they work on the body; the length of time for an animal to die; that twitching, writhing, and elimination can occur; and that animals may die with their eyes open. Because a herp's metabolism is slow, and they can have continued electrical activity in the heart after death, it can take hours for the heart to stop after the euthanasia solution is given. Warn owners about this, and if they wish to take the pet's body home for burial it may be best to return the next day for pickup. Owners who want to be present for euthanasia may wish to stay while the animal is sedated and the euthanasia solution given but then leave once the animal is unaware of their surroundings, as the entire process can take hours. If possible, handle financial matters beforehand. If the client is billed, consider a phrase like "special services" rather than "euthanasia" on the billing statement. Schedule euthanasia when people are not feeling rushed between other client appointments. Some veterinarians worry about crying in front of a client. Getting teary-eyed on occasion is normal. Keep in mind, though, that you have a job to do, so tell yourself that you will take some private time to feel and express emotion after the procedure is completed. Clients appreciate sensitivity and can feel especially supported when the veterinary staff shares in the emotional climate of a particular event or experience.

Once the animal is deceased, allow the client to see the veterinarian check for a heartbeat (using a Doppler monitor in herps). This can be reassuring to some clients who may not be convinced that their animal has actually died. Some clients might appreciate a private moment to say goodbye to their pet. Ask clients who are upset to have someone drive them home, or keep them at your practice until they seem calm enough to drive. One can show support by making a referral to a local pet loss support group or hotline by simply handing the client a brochure telling them that they might be interested in these services because other clients have found them helpful.

Handle the body of a deceased animal with respect and gentleness. Disposal of remains should be discussed with the owner beforehand. If the owner wishes to have the body for burial, use plain boxes or boxes designed for this purpose; do not reuse shipping boxes or those with logos on them. Cremation services should be offered, and many of these services will offer additional mementos such as clay paw prints, poems, or other keepsakes. A sympathy card signed by the employees of the practice should be sent to every owner who loses a pet. Sometimes it is appropriate to send a gift to a client who is very special to the practice, such as one who has been coming there for many years with their pet or recently had a long protracted illness. A plant that the owner can keep in memory of their pet is often much appreciated. Alternatively, a donation can be made in their name to an animal rescue group or animal conservation and research organization.

Update the client's records to reflect the death of the animal so reminders of future examinations, parasite checks, and more, are not sent. If the case was referred, remember to inform the primary practice that the animal was euthanized. It is embarrassing for a well-meaning primary care veterinarian to call the owner to discover what has happened at the referral practice. If applicable, note what examination room was used for the euthanasia and then refrain from using that room for that client who may bring other pets. Providing a photo of the pet to add to a memorial board in the waiting room or web page may give them the courage to return to that practice due to their compassionate care.

COMMON CONCERNS FOR THE CLINICIAN AND THE CLIENT REGARDING ANIMAL LOSS

There are many concerns that both the clinician and the client may have regarding end-of-life care and euthanasia. Delivering bad news is an unpleasant part of the job but is a skill that can be learned. Use a gentle tone of voice, and starting the conversation with a phrase like "I'm afraid I have some bad news" will help prepare the client for what is about to come. Sometimes the client will react with anger, especially if their pet has died unexpectedly. Listen to their concerns and be empathetic and truthful about what happened. It is acceptable to express shock as well. Given time, many clients will be understanding, while some will never be satisfied. Contain feelings of defensiveness when speaking with the client, and document all conversations.

When the decision for euthanasia or not is necessary, often clients will ask the veterinarian "What would you do if you were me?" No perfect answer exists, but one should be careful about answering this question and swaying the client one way or the other; they need to make their own decision for their pet. Review everything that has been done and be honest about the animal's prognosis. Encourage people to think about a definition for a good quality of life; are they still seeing those behaviors? The clinician can often be more objective than the client. Many times people will feel guilty about this choice, feeling they "gave up" too soon or that they waited too long to euthanize their pet. Reassure them that all we can do when faced with tough choices is to make decisions based on the information we have at the time.

Many clients feel unsure about how to talk to their child about the loss of a pet. They may ask you to lie for them because they do not want their child to suffer, but try to avoid this. If you are comfortable you can coach parents about how to talk to their kids, or you can suggest a book on the topic of children and pet loss. Children can benefit from memorializing a beloved pet in their own personal way or by holding a memorial service in which everyone participates.

Older clients often have concerns about what will happen to their pet if something happens to them, particularly when long-lived species are involved. Think about all the people (e.g., friends, relatives, their veterinarian) who would be willing to adopt the animal in case of the owner's death or at least provide short-term care if the owner needs to

VetBooks.ir

be in the hospital for a time. Other possibilities include an animal sanctuary or an arrangement with an informed attorney. Some veterinary schools have programs that provide arrangements for the lifetime care of pets of deceased owners.

CONCLUSION

The profession of veterinary medicine is full of trials, tribulations, and triumphs. It can be demanding when, within the same day, you find yourself sharing the excitement of a client's new pet only to enter the next examination room to deliver bad news about the beloved pet of a familiar client. Euthanasia of animals you have come to know and like also takes its toll on your emotional well-being. Given the emotional challenges you face as a veterinary professional, you need to take care of yourself so that you can maintain patience and a sense of compassion for your clients. Stay current with your medical skills, have confidence in your interpersonal skills, and take good care of yourself physically and emotionally. Many veterinary schools now require self-care classes and more training in client communication in an effort to prepare future veterinarians for some of the challenges of private practice (Kenwright M, http://veterinarynews.dvm360.com/university-tennessee-requires-self-health-classes-veterinary-students).

If you find that you are feeling impatient or you are reacting to people in a cold fashion, you could be experiencing some symptoms of burnout or compassion fatigue. Instead of focusing on the complaints you have about work, think about possible solutions to what you have identified as problems. Do what you can to make constructive changes and accept the aspects of your job you feel you cannot change. If you definitely cannot accept certain things, maybe a different strategy or a new path should be considered.

Working in the veterinary field, especially in a unique discipline such as herpetological medicine, can be a most rewarding experience. Because of the compassion you show, the job is one in which you can truly make a difference in the lives of many animals and the people who love them. Take good care of yourself so you can maintain compassion in all the work you do.

Specialization

Volker Schmidt, Brendan Carmel, Scott J. Stahl, and Stephen J. Divers

Often within any profession there is a drive to "take things to another level," to achieve a higher level of expertise, perhaps with the goal of developing a niche within the profession. Part of this drive is for personal growth; in other cases, it may be more financially driven to develop a "product" for the practice that allows the practice to offer a service not otherwise available within the community. Legally and ethically there are guidelines as to how one may advertise such a product. For example, an American Board of Veterinary Practitioners (ABVP) (avian) specialist cannot advertise as a specialist in reptiles/amphibians and vice versa. While beyond the scope of this chapter, the American Veterinary Medical Association's website (http://www.avma.org) and the European Board for Veterinary Specialization (EBVS) (http://www.ebvs.eu), as well as the Australasian Veterinary Boards Council Inc. (AVBC) (http://www.avbc.asn.au), provides such guidelines for the United States and the European Union, as well as for Australia and New Zealand. Communicating directly with the state veterinary board can also provide guidance as to how to advertise such skills. Ultimately, however, the term *specialist* is considered the gold standard for indicating the highest level of expertise. Because this chapter resides within a herpetological book, the discussion will be directed toward different opportunities for specialization in reptiles and amphibians. The process of specialization will vary depending on which part of the world a veterinarian is eligible to work in, although there are efforts in many areas (unfortunately zoological/herpetological medicine is not one of them) to establish global criteria and reciprocation. A veterinary specialist is a registered veterinarian with an exceptionally high level of skills well above those of a general practitioner in the same discipline. An entry-level specialist must have undergone extensive advanced supervised training, culminating in the passing of a rigorous set of examinations. The specialty must be a branch of veterinary practice having sufficient depth and breadth to allow one to spend a significant time practicing within the specialty. The roles of the American Board of Veterinary Specialization (ABVS), EBVS, and AVBC are simply to maintain the standards established by each specialty. Veterinarians who are eligible to work in the United States have the opportunity to become a Diplomate of the American Board of Veterinary Practitioners with specialization in reptile and amphibian medicine (ABVP R/A) or a Diplomate of the American College of Zoological Medicine (ACZM), which includes reptile and amphibian medicine.[1]

Although many countries offered veterinary specialization, veterinary specialization was not standardized in the European Union until the advent of the EBVS. Standardization on a European level is a central aim of the EBVS. European colleges of different veterinary specialties are established on the European level, for example, a Diplomate of the European College of Zoological Medicine (ECZM) in the subspecialty herpetology would hold the title "European Veterinary Specialist in Herpetology."

The Australian and New Zealand College of Veterinary Scientists (ANZCVS) fellowship is one of the most common pathways for veterinary specialist registration in Australia and New Zealand. The subject *Medicine and Surgery of Unusual Pets* includes native and exotic reptile species legally kept as pets in Australia and New Zealand. *Medicine of Zoo Animals* membership includes reptiles commonly encountered in zoos and so is applicable for veterinarians working in zoos. Membership in the discipline *Medicine of Australasian Wildlife Species* has reptiles included in its learning outcomes. However, the AVBC lists certifying bodies that set the standards acceptable for specialist registration, besides the fellowship, which includes ABVS, EBVS, and The Royal College of Veterinary Surgeons (RCVS), thus a veterinarian who holds a specialist registration from one of these bodies may be registered as a specialist in Australia or New Zealand without having to undergo further examinations. Such reciprocity is generally lacking in Europe and the United States, although some colleges have moved in this direction by allowing diplomates to train residents of either US or EU colleges. In addition, although the ACZM is accepted as a specialist qualification in Europe (e.g., RCVS in the UK) and Australia/New Zealand, the AVBC and ECZM qualifications are not recognized by the ABVS in the United States.

ADVICE TO CANDIDATES SEEKING SPECIALIST REGISTRATION

Before an examination can be taken, a period of 2 or up to 11 years of training is required, depending on whether the training was completed through a structured residency program or an alternative practitioner program. Training programs typically consist of a 1-year internship followed by a 2-year (EU, ABVP) to 3-year (ACZM) residency or 2 to 6 years of comparable general practice experience. Mentors often have the job of motivating residents to undertake research, publish, and study, but mentors and their programs also benefit by having more of their residents take and eventually pass boards. Candidates may be apprehensive about preparation for the specialist examinations. A good course of action is to work on and complete the credentialing process and then focus on studying. Achieving approval to sit for the examination strongly motivates the candidate to focus on study and preparation to pass the exam. For credentialing, some may prefer to work through one case report or submit one publication at a time, whereas others may find it more efficient to work on several simultaneously. Having an online study group to review publications, discuss cases, and test each other can be extremely helpful. The main regulatory bodies offer advice and often provide dedicated short courses to aid candidates in examination preparation. The pass rate for the examinations varies between the examination bodies. Check the relevant organization to access the most current information regarding timelines, credentialing, and recredentialing requirements, and examination structure and content (Table 4.1).

VetBooks.ir

TABLE 4.1 Specialty Colleges and Boards

	ACZM (American College of Zoological Medicine)	ABVP-Reptile/Amphibian Medicine (American Board of Veterinary Practitioners)	ECZM (Herpetology) (European College of Zoological Medicine)	ANZCVS (Australian and New Zealand College of Veterinary Scientists)
Definition	Zoological—A broad spectrum of disciplines involved with the medical problems of invertebrates, fish, amphibians, reptiles, birds, and mammals. Includes all exotic or nondomesticated species, including exotic pets, wildlife, and zoo/aquaria species.	Specialty recognition in the specific animal taxa reptile/amphibian	Herpetology—the veterinary treatment, health care, and preventative medicine of all reptilian and amphibian species Zoo Health Management—veterinary medicine as applied in zoological collections	Membership (MANZCVS) and fellowship (FANZVCS) Fellowship is the college qualification required by those seeking veterinary specialist registration. There are currently no subjects with significant reptile content at fellowship level. It is envisaged that the Unusual Pets Chapter of the ANZCVS, which currently provides a membership level qualification, will consider the introduction of a fellowship level in the future
Foundation	Founded in response to National Academy of Science Committee on Veterinary Medical Research and Education, and the comprehensive PEW report of veterinary education. The majority of diplomates work in institutions (e.g., zoo, universities, state, federal and international commissions and panels). As of May 2017, there are currently 186 diplomates (all examined), with the vast majority (>90%) working in clinical practice.	ABVP recognized a specialty in avian medicine and with strong support and interest, later followed with an exotic mammal specialty. The establishment of these specialties supported the development of the reptile/amphibian specialty, which had its first examination in 2010. As of May 2017, there are 11 reptile/amphibian diplomates (all examined) out of a total of 817 ABVP diplomates.	European Veterinary Specialist College formed under the auspices of the European Board of Specialisation (https://www.ebvs.eu). The ECZM evolved from the European College of Avian Medicine and Surgery (ECAMS), itself a veterinary specialist organization founded in 1993. Herpetology was added in 2009 and zoo health management in 2012. As of May 2017 there are 26 and 41 herpetology and zoo health management diplomates, respectively. The vast majority are de facto (not examined).	Formed in 1971 through the Australian Veterinary Association, it seeks to serve the veterinary profession and reward excellence. College membership signifies that a veterinarian has expertise and competence in a nominated subject area. College fellowship is associated with scholarly and technical excellence in a particular subject. Standards required for training and examination in fellowship subjects meet or exceed the prerequisites for registration as a veterinary specialist in Australia and/or New Zealand.
Official website	http://www.aczm.org	http://www.abvp.com	http://www.eczm.eu	http://www.anzcvs.org.au
Examined areas	Avian Reptiles and amphibians Mammals Fish and aquatic mammals Wildlife	Reptiles and amphibians	Reptile and amphibians	Subjects with a significant component of reptile content: Medicine and surgery of unusual pets Medicine of zoo animals Medicine of Australasian wildlife species
Required training	3-year ACZM-approved residency (100% time allocation) OR 6 years of 100% exotic/zoo/wildlife practice experience	1 year in small animal practice or small animal internship and 2- or 3-year ABVP-approved residency (10+ cases per week) OR 5 years in practice for credentialing application, 6 years prior to sitting for exam. First year may be nonspecialty specific, as with the residency option. There is no % time requirement, but an emphasis on reptile/amphibian medicine with a biannual self-reporting form, including detailed case logs listing, procedures, diagnoses, and diseases seen.	1 year companion animal or zoological species clinical sciences internship in a recognized institution that provides a broad range of clinical assignments or two years in clinical practice, and 2.5 to 3 years approved postgraduate training program (min. 24 hrs per week or 60% time allocation) under supervision of an ECZM diplomate.	Membership: at least 4 years in a full-time veterinary activity between graduation and taking the examination Fellowship: a minimum of 96 weeks of full-time, directly supervised training, or its equivalent At least 25 hours per week working in the clinical and technical aspects of the discipline Specialist registration requires 3 years of work in the appropriate discipline. This is a requirement of the ACRVS, not of the college

TABLE 4.1 Specialty Colleges and Boards—cont'd

	ACZM (American College of Zoological Medicine)	ABVP-Reptile/Amphibian Medicine (American Board of Veterinary Practitioners)	ECZM (Herpetology) (European College of Zoological Medicine)	ANZCVS (Australian and New Zealand College of Veterinary Scientists)
Publications and research	3 first-author, peer-reviewed journal papers, including at least one full manuscript on original research	2 (unpublished) case reports must be submitted OR 1 first-author publication (within 5 years of January 15 credentialing year) in an ABVP-approved scientific journal and 1 (unpublished) case report Must present two 1-hr seminars every year	Herpetology: 2 first-author papers of which at least 1 must be original research (the second can be a case report or case series). Zoo health management: 3 papers, of which 2 must be first author and include at least 1 investigative research project. Resident as first author must have the work accepted for publication in a peer-reviewed, well-established, internationally refereed scientific journal (i.e., mentioned in the Science Citation Index or in the reading list relevant to their own specialty) prior to sitting the examination, second manuscript as first author should also be accepted for publication and can be original scientific research, a case series, or a single case report	Membership: no formal requirements Fellowship: all fellowship candidates as a minimum requirement must submit a total of 2 original, first-author, scientific, peer-reviewed publications in peer-reviewed journals and evidence of presenting at one national or international scientific conference
Examination	Day 1 (qualifying exam, 375 points): 375 multiple-choice on avian, mammals, reptiles and amphibians, fish and aquatics, wildlife. Timed multiple-choice exams, each question has 5 possible answers. Must pass by 65% overall to continue. Day 2 (certifying exam, 300 points): slide (85 points), multiple-choice (75 points), and essays (140 points) in one of the following areas (all of which include herps); Zoological companion animals General zoo Aquatics Wildlife	Day 1 (core examination): 300 multiple-choice on preclinical and basic veterinary sciences 300 multiple-choice questions on reptile/amphibian medicine Day 2 (practical examination): 50–100 multiple-choice questions based on images. May also contain short-answer and essay questions. Timed multiple-choice exams, each question has 3 possible answers.	1-day examination for a total of 370 points, consisting of 100 timed multiple-choice questions, with one correct answer and four distractors, and a practical/written section of the exam is designed to test interpretive skills. Candidates must pass the examination within 8 years of being notified that they have satisfied the credentials process and may sit the examination on 4 occasions only.	College membership: Written paper 1 (2 hours): basic concepts and principles relevant to the subject Written paper 2 (2 hours): the practice and clinical applications of the subject Practical/oral: For most disciplines there is a 45–60 min oral exam A pass will be awarded if the candidate achieves at least 55% in one component (written or oral) AND at least 70% in the other component (written or oral) of the examination, AND achieves an overall average mark of at least 70% College fellowship: Written paper 1 (minimum 3 hours): basic science and principles of the subject. Written paper 2 (minimum 3 hours): practice and clinical applications of the subject. Practical (minimum 1 hour): case presentations, multimedia, problem solving, and theory, for which written answers will be required. Oral examination (minimum 1 hour) Pass mark (70%) in all four components

TABLE 4.1 Specialty Colleges and Boards—cont'd

	ACZM (American College of Zoological Medicine)	ABVP-Reptile/Amphibian Medicine (American Board of Veterinary Practitioners)	ECZM (Herpetology) (European College of Zoological Medicine)	ANZCVS (Australian and New Zealand College of Veterinary Scientists)
Recognition and role (as outlined in published board information)	ACZM diplomates advance competency and scientific progress in zoological medicine, including birds, reptiles/amphibians, mammals, aquatics, wildlife; establish standards for post-doctoral training and experience and to certify veterinarians as specialists in zoological medicine through comprehensive examination; encourage research on the medical, surgical, and management problems of nondomestic species; disseminate information relative to zoological medicine to the veterinary profession DACZM is recognized as a specialist in zoological medicine (including birds, reptiles, mammals, amphibians, fish/aquatics, wildlife)	The DABVP (R/A) advances the quality of veterinary medicine through certification of veterinarians who demonstrate excellence in reptile and amphibian clinical practice	DECZM (herpetology) and DECZM (zoo health management) work primarily as clinicians and can function in academic and research institutions, as well as industry/zoos. The primary objectives of diplomates are to advance the specialties in Europe and increase the competency of those who practice in this field by: (a) Establishing guidelines for postgraduate training; (b) examining and authenticating veterinarians as specialists; and (c) encouraging research and other contributions to knowledge relating to the subspecialties of zoological medicine. A registered specialist shall spend at least 50% (i.e., >20 hours/week) of the time working at the specialist level.	Membership of the ANZCVS is not considered sufficient for application of specialist registration in Australia or New Zealand. Membership candidates are expected to demonstrate a high level of interest and competence in a given area of veterinary activity, which would make the person suitable to give professional advice to veterinary colleagues not similarly qualified on problems or procedures often encountered or used in general practice, in the relevant area of veterinary endeavor. A fellowship level herpetological qualification with reptiles as a significant component does not currently exist but may be available in the future.

REQUIREMENTS FOR CONTINUING EDUCATION IN THE CHOSEN SPECIALTY

Recertification of Diplomate status is required every 5 years in the ECZM and every 10 years in the ACZM and ABVP. Recertification is based on a standardized point system to quantify continued activity within the specialty. These include points awarded for publications and presentations, continuing education, training of residents, active involvement in committees, and annual general meetings of the colleges, as well as preparing questions for the specialty examination.

SPECIALTY BOARDS

The American College of Zoological Medicine

The ACZM website is http://www.aczm.org. In 1983 the ABVS for the formation of the American College of Zoological Medicine (ACZM) was provisionally approved and ratified by the AVMA House of Delegates. The initiating constitution approved by the ABVS stated that the ACZM would be the parent body for three or more sub-groups: (a) Captive Wild Animals, (b) Free-Living Wild Animals, (c) Fish and Aquatic Animals, and (d) such others as might be appropriate in the future. Deliberations between the ABVS and the ACZM organizing committee established that the ACZM would be developed by charter diplomates. An invitation for experienced zoological veterinarians with 10 years or more of experience was made at the October 1983 conference of the AAZV. The ABVS appointed an ad hoc committee to assist in establishing the ACZM. The original organizing committee prevailed upon the ABVS ad hoc committee to determine the number of charter diplomates and to select them from the 22 curricula vitae submitted in response to the call for candidates. The ABVS ad hoc committee chose to limit the charter diplomates to eight and selected Drs. Mitchell Bush, William Boever, Martin Dinnes, Murray Fowler, George Kollias, Kay Mehren, Richard Montali, and Phillip Robinson as ACZM Charter Diplomates. This recommendation was ratified by the ABVS.

ACZM is an international specialty organization for certification of veterinarians with special expertise in zoological medicine. Of note, zoological medicine includes all exotic species, so a Diplomate is not restricted to being just a reptile/amphibian specialist. Six individuals sat for the first examination in 1984. ACZM became a stand-alone college in 1988. As of May 2017, there were 186 active Diplomates in the college (all certified by examination). ACZM is responsible for establishing training requirements, evaluating and accrediting training programs, and examining and certifying veterinarians in the veterinary specialty of zoological medicine. ACZM Diplomates foster high-quality medical care for nondomestic animals and are actively involved in the discovery of new knowledge in the discipline and the dissemination of this knowledge to the veterinary profession and public.[2]

Eligibility for examination can occur either by practicing 100% in the specialty for at least 6 years (or 50% for 12 years, or some combination thereof) or completing an ACZM-approved residency program (minimum of 3 years, 100% dedicated to zoological medicine).

For credentialing the applicant must have at least three senior-authored (first author), peer-reviewed journal publications, and at least one must be original research (hypothesis driven, experimental,

VetBooks.ir

prospective or retrospective). Papers must be fully accepted by the journal(s) before the application deadline—a letter from the editor indicating this may be sufficient proof if a paper is *in press*. Papers must make a meaningful contribution to the literature. Book chapters, review papers, and proceedings papers *are not* acceptable. The ACZM examination occurs over 2 full days, and the total point allocation is 675 points. On Day 1, all candidates take five sections of the test: avian, herpetofauna, terrestrial mammal, wildlife, and aquatics (fish and invertebrates). Continuation to Day 2 is contingent on passing all five Day 1 sections with a score of 65% or higher overall. There are 75 multiple-choice questions for each of the five Day 1 components, and each question has one right answer and four distractors (five options). There are still some encouraging rewards if three or four of the sections are passed. On returning the next year, examinees only need to pass the remaining one or two sections to continue on to Day 2. However, failure to pass those final one or two components will cause the examinee to have to repeat all five sections of the Day 1 examination the next year. The Day 2 examination for ACZM is based on one of four options of a subspecialty—general zoo, zoological companion animal ("exotic pets"), aquatics, or wildlife. Obviously, reptiles and amphibians are a component of each of these four disciplines; however, many examinees choose one of the first two options. Each option has three sections: an essay examination (140 points), a slide examination (85 points), and an advanced multiple choice examination (75 questions). One must pass with 65% or greater. If examinees do not pass Day 2 on the first try, they return the following year for one last try. Failure on the second try for Day 2 requires the examinee to start completely over with passing Day 1, all sections, again.

The American Board of Veterinary Practitioners

The ABVP website is http://www.abvp.com. This specialty is focused more on the private practitioner, although other opportunities are available. Certification provides professional and public recognition of advanced knowledge, skills, and competency in a species category. The organization began in 1978, and the first examination was given in 1981. In 2010 the first reptile/amphibian specialty examination was administered, and five individuals successfully passed the inaugural test. As of May 2017, 11 out of 817 ABVP Diplomates are in the reptile and amphibian medicine specialty. There are no specified % time allocations to be an ABVP specialist or in a residency program, but according to their website the typical caseload is 10 or more herp cases per week.

Two paths are available to qualify an individual for credentialing. One is to practice a minimum of 5 years (6 years prior to sitting for the examination) in any combination of practice that allows the minimal amount of professional exposure and caseload of reptiles and amphibians as required (see table). The first year does not have to be in the recognized veterinary specialty (RVS), but for the subsequent 5 years it is required. The second is to complete a 2- or 3-year ABVP R/A–approved residency program. This often involves a 1-year internship that does not have to be in the RVS, followed by 2 years in the RVS specifically. The applicant should contact the current ABVP R/A regent for up-to-date requirements at the time of application (see Table 4.1). As of 2017 the credentialing process timeline starts with a straightforward first-time application form and fee due by September 1 of each year. The more complex credentials packet, which is described later, is due by January 15 of the earliest year a candidate hopes to sit for the examination. The final evaluation of the credentials packet is completed and notification of acceptance or rejection (complete or partial) of that packet is provided to the candidate by June 1 of the same year. Accepted candidates must decide by September 1 if they will register for that year's examination or wait an additional year. One of the most challenging components of the credentials packet is the case report. An applicant may submit one unpublished case report and a publication or two unpublished case reports. To demonstrate excellence in reptile and amphibian medicine and surgery, it behooves the candidate to show some breadth of expertise in these case reports. Each case report's species should be different. The topic and species of each case should be different from each other. Generally, it is recommended to avoid obscure, new, or uncommon diseases; instead, show expertise at thoroughly working up a standard case. Case reports must have been personally seen and investigated by the applicant within the past 5 years. Applicants should demonstrate their thought processes in the case report: significant presenting signs, diagnostic characteristics, problem lists, pathophysiology, differential diagnoses, treatments, and management options. Additionally, if certain diagnostic or therapeutic steps are not pursued, an explanation for why they were not performed and how they could have been useful in the case must be discussed.

More specific guidelines and example case reports are available on the website (also see Table 4.1). The most common reason for failing to credential is inadequate case reports. It is highly advisable that applicants begin writing their case reports *before* submitting the application and application fee. Study groups and mentors are available through the ABVP and can help with case report guidelines, review, and specialty examination preparation.

For the refereed (peer-reviewed) publication, the applicant must be the first author. The topic of publication must make a meaningful contribution to the literature of the species specialty and must be different from that of the case report. The publication must have been published no more than 5 years before the January 15 deadline in a refereed, ABVP-approved scientific journal. Conference proceedings, online publications, clinical vignettes, short/brief communications, serial features, and review articles will *not* be accepted. Acceptance for publication in a refereed scientific journal does not guarantee that the manuscript will be admissible in lieu of an ABVP-style case report.

The ABVP examination is offered every year in October and is a two-day examination. Day one is broken into two parts; both are timed multiple-choice examinations. The morning is a core examination with 300 questions on preclinical and basic veterinary sciences. The afternoon is a specialty examination on reptile/amphibian medicine. Day two involves a practical examination in the morning with 50 to 100 questions primarily based on slide images. This exam may also include short-answer and essay questions. Multiple-choice questions for both days have one correct answer and two distractors (three options) and are timed examinations. A standard passing score for the ABVP examination is a 70% raw score.

The European College of Zoological Medicine

The ECZM is a European Veterinary Specialist College formed under the auspices of the European Board of Specialization (http://www.eczm.eu). The ECZM evolved from the European College of Avian Medicine and Surgery (ECAMS), itself a veterinary specialist organization founded in 1993. ECAMS was an initiative of the European Committee of the Association of Avian Veterinarians in response to a growing demand for better avian medical and surgical services for birds through specialization and a need to harmonize certification in this area. ECAMS became recognized as a fully functional college in 2005.[3] In 2007 an initiative was commenced to broaden the membership and areas of specialty of ECAMS. The aims were to strengthen the college by increasing membership, provide the opportunity for those working at a specialist level within allied zoological fields to gain recognition, and facilitate greater recognition of the clinical area by the profession within veterinary academia, by governments and by the public. The result was that ECAMS changed to ECZM, and herpetology was added in April 2009. As of April 2016 and according to the ECZM website, there were 26 ECZM

VetBooks.ir

(herpetology) diplomates, including five members from the United States and one member from Australia. In 2012 the zoo health management specialty within ECZM was created and currently has 41 diplomates. As of May 2017 the ECZM (herpetology) and ECZM (zoo health management) qualifications are not currently accepted by the ABVS as a specialist qualification in the United States.

The herpetology specialty encompasses the veterinary treatment, healthcare, and preventative medicine of all reptilian and amphibian species (captive or wild). The zoo health management specialty also includes reptiles and amphibians within institutional and zoological collections. The ECZM website provides detailed information about the ECZM, including the constitution, bylaws, and information brochures on all specialties, including herpetology and zoo health management. The latter contains information about requirements for admission to the college, a profile of the specialties, and application and examination procedures. To become a European specialist in zoological medicine the training period is split into (a) internship (minimum 1 year) in companion animal or zoological species clinical sciences in a recognized institution that provides a broad range of clinical assignments or 2 years in clinical practice; and (b) residency (minimum of 2.5 years, minimum 60% time dedicated to the specialty) program under the supervision of a ECZM Diplomate (i.e., an ECZM resident can spend significant time outside of their specialty). Alternatively, the candidate must have followed a preapproved alternative program, with a minimum of 2 years in general practice (first phase) and 4 years in specialty practice (60% minimum time allocation to the specialty). For the alternate residency route the credentials committee evaluates the suitability of the practice at which the alternative internship period (2 years) was undertaken. The alternative route is intended for clinicians for whom a standard residency would be impossible (e.g., moving to another country). If an alternative residency is proposed, a program must be suggested that is appropriate for the resident, such that they achieve the required standard by the time of completion. All programs must be considered and approved by the ECZM Education and Residency Committee. The alternative training residency must, at the discretion of the Education and Residency Committee, be equivalent to a standard residency. An alternative residency, as with any other, must be approved prior to commencement. At least 20% of the resident's program must be off clinical duty. During this time, residents must fulfil their requirements for research, publications (two journal papers), and presentation engagements. Besides a sufficient case, continuing education, and postmortem log, the resident must complete an investigative project that contributes to the advancement of medicine and surgery of reptiles and amphibians. The resident, as first author, must have the work accepted for publication in a peer-reviewed journal prior to sitting the examination. A second first-author paper should also be accepted for publication and can be original scientific research, a case series, or a single case report. The current ECZM examination structure is composed of only a 1-day examination for a total of 370 points and is the smallest examination of any European specialty college (see Table 4.1).

Veterinary Specialization in Australia and New Zealand

The Advisory Committee on the Registration of Veterinary Specialists (ACRVS) is a standing committee of the AVBC and handles the assessment of applications. The purpose of the ACRVS is to establish uniformity between the registering authorities in terms of the standards applied to assessment of applications for specialist registration. Veterinary registration authorities normally send applications to the ACRVS for assessment, and the ACRVS advises the authority if the application meets the criteria accepted by the AVBC. Eligibility for specialist registration is listed in the AVBC specialist registration information booklet: Section 5 of the AVBC booklet sets out the minimum standards as part of the requirements for registration as a veterinary specialist in Australia and New Zealand, including details of approval of training programs and examinations and selection and roles of supervisors and fees.

College membership of the ANZCVS signifies that a veterinarian demonstrates a high level of interest and competence in a given area of veterinary activity. To become a member of the college, a candidate must have at least 4 years post-graduate experience as a full-time veterinarian and have successfully completed both written and oral/practical examinations in one of the diverse range of subjects offered (see Table 4.1). College fellowship is associated with scholarly and technical excellence in a particular subject. Standards required for training and examination in fellowship subjects meet or exceed the prerequisites for registration as a veterinary specialist in Australia and/or New Zealand. ANZCVS fellowship is one of the most common pathways for veterinary specialist registration in Australia and New Zealand. It is envisaged that the Unusual Pets Chapter of the ANZCVS, which currently provides a membership level qualification, will consider the introduction of a fellowship level in the future for consideration by the AVBC.

The Importance of Herpetological Publication by Clinicians and Academics

Mark A. Mitchell and Sean M. Perry

The majority of the veterinarians or veterinary nurses reading this chapter received minimal exposure to herpetological medicine in their curricula. In the three institutions that the authors have attended or taught at, representing approximately 10% of US veterinary colleges, the herpetological curricula were limited to 1 to 2 elective or graduate courses, consisting of 1 to 3 credit hours, or lectures within a zoological medicine course. Overall, the herpetological medicine course offerings at these institutions represented <2% of the overall curriculum. When compared with the amount of a curriculum that is devoted to two species of small mammals or a few more species of food or farm animals, it is quite obvious that most of us are provided minimal exposure to the >10,000 species of reptiles or >7500 species of amphibians that exist in the world.[1,2] For those that routinely see exotic or zoological medicine cases, this is no new revelation. Veterinary medicine, unlike human medicine, remains a generalists' profession. In human medicine, subspecialization occurs within a specialty and is limited to a single species, whereas in veterinary medicine specialization remains more broad for more than one species (e.g., disciplines such as pathology and zoological medicine) or more restricted to certain species and body systems (e.g., cardiology, dermatology, ophthalmology). The only way for us to move toward greater specialization is to generate evidence-based knowledge that provides insight into the medical and surgical needs of these animals. It is also important to recognize that because of this limitation, we should approach these cases as clinician scientists rather than practitioners (see Chapter 6) to ensure we are generating new questions and problem solving rather than simply moving from case to case without using the knowledge gained to grow the profession.

WHAT IS "HERPETOLOGICAL LITERATURE"?

Herpetological literature includes all written (paper and digital) documentation that encompasses reptiles and amphibians. This can include taxonomy, physiology, husbandry, medicine, surgery, or any topic related to these species. For practical purposes, this chapter will focus on the medical and surgical herpetological literature. When considering herpetological literature, it is generally divided into lay literature, conference proceedings, scientific abstracts, book chapters, and peer-reviewed articles. Each of these will be addressed.

Lay Literature

The lay literature represents an important component to the overall literature. This type of literature is typically associated with husbandry-related information, although examples of medically relevant information are also available.[3] The information provided in these articles is really intended for herpetoculturists and other lay individuals looking to hear the opinion of a specific author on a topic. This type of literature is rarely peer reviewed and thus represents the opinion (good, bad, or indifferent) of the author. The level of review for these types of articles is primarily limited to copyediting, editorial assistants, or an editor; however, these individuals are generally more interested in format than content and may not have a high level of experience with the topic covered. These types of articles have been important in disseminating author experiences on issues such as husbandry and nutrition and will likely continue to do so in the future. They also serve as an important method of educating herpetoculturists on the health and welfare of the animals in their care. These types of articles tend to have wide distribution. Unfortunately, the lack of peer review can lead to the dissemination of misinformation. Thus it is important for veterinarians to remain vigilant when reviewing these types of articles and responding through editorial feedback to ensure best practices. However, the importance of this information cannot be overstated. Much of what we know in our peer-review literature is based on discussions being initiated in the lay literature (e.g., nutrition) and clinician scientists rigorously testing specific hypotheses generated through these writings/discussions.

Conference Proceedings

Conference proceedings are similar to lay articles in their review process but represent a more specific veterinary perspective. Conference proceedings are provided as a supplement to the lectures given to veterinarians and veterinary nurses at continuing education programs; the information gained at these meetings is intended to meet specific continuing education guidelines for state boards. These types of herpetological literature represent the opinions of the author and are rarely peer reviewed; instead, they are copyedited for format. Because there is an expectation that all licensed individuals must obtain continuing education, this type of information is one of the primary mechanisms veterinarians and veterinary nurses use to expand their knowledge. However, a limitation of this "new knowledge" is that it represents the opinion of the author and has not been rigorously tested. In many cases, the information provided is a review of the literature, although it is disseminated through the interpretation of the author/presenter. It is important for veterinarians and veterinary nurses to follow up on the information derived through conference proceedings by delving into the peer-reviewed literature to review and confirm the message being shared. Veterinarians presenting this type of material should, at a minimum, attempt to have this type of material converted to a review paper for publication after peer or editorial review. It is important to convert proceedings material for three reasons: (1) It strengthens the value of the material, (2) there is an increased distribution to members of the profession, and (3) it expands the quantity and quality of literature available for clinician scientists to apply. Indeed, it is for the reasons outlined above that conference proceedings have been essentially removed from the bibliographies of the chapters in this textbook. The editors hope that such a move will help encourage veterinarians to seek journal publication and rely less on proceedings as we have done in the past.

VetBooks.ir

Scientific Abstracts

Scientific abstracts typically represent the first attempt at sharing evidence-based information. These abstracts may include case reports, case series, or hypothesis-driven research. The primary limitations of these types of literature is (1) the length of the material and (2) that it is seldom freely available to those that did not attend the conference (most herpetological abstracts are not printed in journals or available electronically). Most scientific abstracts are limited to 250 words. There are professional organizations that do not limit the word count; however, this is not recommended. The word count limit was primarily established to ensure that the scientific material shared in these settings could still be submitted for publication in the peer-reviewed literature. When word counts are not limited, peer-reviewed journals are less likely to publish the material. The restrictive word count does minimize how much information can be shared with the reader, especially when it comes to study design, analysis, and the conclusions of the author(s); however, the scientific abstract is not intended to serve as the final publication of the material, and thus this should be less of a concern. Another limitation of scientific abstracts is associated with the review process. In some organizations, the scientific abstracts are peer reviewed, whereas in others they are reviewed by the proceedings editor(s). Although these both represent a step up from conference proceedings, there are limitations as to how detailed the review can be because of the limited amount of information provided in the scientific abstract. Ultimately, all clinician scientists who are working with reptiles and amphibians should be contributing at this level. In this book, as an example, such research abstracts published in proceedings have been permitted where they represent very recent information (within the last 1–2 years) but have again been largely avoided because of their limited availability.

Book Chapters

Veterinary textbooks, such as the one you are reading here, remain an important method for disseminating herpetological literature; however, much like the other offering discussed earlier, the information obtained in book chapters is limited to review of the literature and is typically editorially and not rigorously peer reviewed. This by no means limits the value of the material but should remind each of us to delve into the peer-reviewed literature being covered in the book chapter to confirm its value and validity. The authors always review the references or literature cited to determine the source of the information used to generate the book chapter. A it is not uncommon for scientific abstracts to serve as a primary constituent of the references, we are seeing an increase in the number of peer-reviewed papers. It is becoming more routine for some texts to not include any reference that is not from a peer-reviewed journal, and this certainly helps to highlight deficiencies within the peer-reviewed literature. As we noted earlier, all literature has value; it is knowing how much weight each provides that is important. If we take a narrower view of the literature, then books, such as this one, might also be considered nothing more than the opinions of the author(s) without ample peer review to affirm its value. However, textbooks remain an important, readily available source of information for busy clinicians that will continue to serve as an important source of knowledge. Althugh the authors always recommend searching the literature for peer-reviewed articles relevant to a topic of interest, there are times when a quick answer is needed and a book chapter serves that purpose. Book chapters serve as a continuation of the method in which many of us learned veterinary medicine. A lecturer would review and compile the literature and present it to us as students. Book chapters serve the same function, with the author replacing the lecturer. For many of us, our lecturers "knew everything" and were the source of our knowledge. This type of unconscious acceptance that book chapters are all we need to be successful can be dangerous and lead to some instability in the foundation of our knowledge, especially as books are typically 1 to 2 years out of date by the time of publication. Thus, as with the other sources of herpetological literature available to us, we should understand the limitations of the book chapter and always seek peer-reviewed literature when available.

Peer-Reviewed Literature

Peer-reviewed literature serves as the foundation for the evidence we use to practice medicine. The premise behind the peer-review process is that literature is evaluated by individuals within the field to ensure that the hypothesis(es), design, analyses, and conclusions drawn by an author(s) are legitimate based on current knowledge, or what is currently in the peer-reviewed literature. The authors routinely hear colleagues note that peer-reviewed literature is a gold standard; however, although it is true to say that it represents the most reliable source of information, it is important to appreciate that it may not be infallible and should be interpreted using a critical eye. A review of the peer-reviewed literature will show that many studies have flaws and still pass peer review.[4-18] Many authors will acknowledge flaws in their discussion, and that in itself does not negate publication; however, the unappreciated and unacknowledged flaws are more dangerous and can be associated with unanswered hypotheses, poor study design, a lack of or the use of incorrect statistics, and erroneous conclusions drawn based on these shortcomings. Peer review at its core is subjective. It is based on the opinions of the reviewers, experience of the reviewer (i.e., are they an expert on the material and how current are they with the literature?), and state of the literature (i.e., has something been previously published on the subject, and if so, does it have shortcomings?). There are many examples that could be used to show this, but the authors have selected an early publication of the lead editor to reinforce this point.[19] In this article, blood samples were collected from 10 green iguanas (*Iguana iguana*), 7 male and 3 female. Back in 1996, the authors used the term "normal range" throughout the article to describe the results. Of course, the limited sample size and a lack of any statistical analysis of the results beyond descriptive statistics would not be considered acceptable as a reference range by today's standards because the criteria for the establishment of reference intervals were published 16 years later in 2012.[20] However, that was cutting edge for the day. Veterinarians working with reptiles were looking for any help from the literature to better manage their green iguana patients. Interestingly, this article has been cited 58 times, including by articles being published at the time this chapter is being written.[21] What the authors want the readership of this chapter, and scientists in general, to appreciate is that these types of articles, much needed when they were written because there was nothing else, are often dated and flawed by modern standards. Although study design, sample size determinants, and statistical methods were well known in 1996 when this article was published, there were no published standards for normal reference range determination, and therefore the peer-review process was limited. Nowadays, similar "reference range" papers are still being submitted but should not make it through the review process because of established and published guidelines.[20] If they are allowed through to publication, then this represents a failure of the peer-review process. The subjectivity comes in when the reviewers, including the associate editor and editor, allow for these flaws to be published. This remains an issue today because herpetological medical literature is still being produced by a limited number of individuals, the science remains clinical and basic, and many serving as peer-reviewers have limited understanding of study design and statistics. How do we rectify this? (1) By ensuring that recognized system specialists (e.g., clinical pathologists, pathologists, virologists, anesthesiologists, etc.) are paired with

VetBooks.ir

herpetological specialists for peer review, and (2) by having this discussion—it is important for us to challenge ourselves to not believe we are just "practitioners." Instead we must see ourselves as clinician scientists and be prepared to challenge ourselves to learn about these different review processes.

Once we can understand that peer-reviewers can have some inherent flaws, it is important to consciously correct for them and celebrate the value of peer-reviewed literature. We need to take the experiences we gain from working in herpetological medicine and share them with the entire profession. This can take many forms, from case reports and case series to cross-sectional studies, longitudinal prospective studies, and experimental studies. There are experts in our field who can assist with helping guide prospective authors with their work. The Association of Reptile and Amphibian Veterinarians (ARAV) is an excellent resource, and the *Journal of Herpetological Medicine and Surgery* is an excellent medium for peer-reviewed publication.

NEGATIVE RESULTS DON'T EXIST…ONLY HYPOTHESES THAT NEED TO BE TESTED

Negative results are publishable. Unfortunately, there has been some cultural bias against the publication of negative results that has been promoted through the scientific community and also touches herpetological medicine. It is unfortunate that some who are supposed to be objective believe this statement. Evidence-based medicine should be based on hypothesis-driven research. For every hypothesis identified, a null and alternative hypothesis should be generated. A null hypothesis is generally derived by thinking that there will be "no difference" between what is being analyzed, while the alternative hypothesis is the exact opposite; that a difference will exist. An example of null and alternative hypotheses is: Ho (null): there will be no difference in the hounsfield units (generated on computed tomography) of the mandibles of bearded dragons fed a standard non-gut-loaded cricket diet and a commercial diet specifically developed for bearded dragons. The alternative hypothesis is that there will be a difference. This alternative difference can be one-tailed or two-tailed. If the investigators believe that the hounsfield units for one group will be higher than the other, than a one-way directional hypothesis can be used. The benefit of a directional hypothesis is that a smaller sample size can be used. If the authors are unsure of which group will have higher or lower hounsfield units, then the hypothesis should be two-tailed. Regardless of which hypothesis is ultimately accepted, the research answers the hypothesis. The results are not "negative" if there is no difference between the groups; they just reinforce that that the null hypothesis was accepted. It is as important to publish that something is not different as it is when a difference exists, because research is hypothesis-driven, not result driven. In addition, when resources for pursuing research are limited, as they are in the field of herpetological medicine, it is important that we do not repeat research simply because results were not published. This should be a familiar approach to clinicians because it is similar to how we pursue our clinical cases. A "negative" radiograph does not represent a waste of financial resources, instead it serves to rule out a number of potential diseases such as organomegaly, foreign bodies, ascites, etc.

PEER-REVIEWED HERPETOLOGICAL MEDICINE PUBLICATIONS

There are several journals that serve as excellent repositories for herpetological medicine research. The journal that is specific to herpetological medicine is the *Journal of Herpetological Medicine and Surgery* (JHMS). This is the official journal of the ARAV. The journal publishes a variety of editorially reviewed and peer-reviewed articles. Peer-reviewed articles include brief communications, "what's your diagnosis?" reports, case reports/case series, cross-sectional studies, cohort studies, case-control studies, and experimental studies. Brief communications and "what's your diagnosis?" articles are the most basic publications and represent examples of articles that all practicing veterinarians can contribute to. Although these articles are peer reviewed, they are not always accepted by credentialing boards; all of the other articles noted previously are universally accepted. As the authors have stated previously, all clinicians practicing herpetological medicine should feel a professional obligation to share their knowledge and experiences with the profession through peer-reviewed journals (rather than conference proceedings). Additional benefits of the JHMS is that there is no charge to publish, and all images are in color at no additional charge.

The *Journal of Exotic Pet Medicine* (JEPM) is another peer-reviewed journal that routinely publishes peer-reviewed herpetological medicine articles, in addition to exotic small mammal and bird articles. The JEPM accepts the same types of articles noted for the JHMS, has no publishing charge, and has color images at no additional cost. The *Journal of Zoo and Wildlife Medicine* (JZWM) is the official journal of the American Association of Zoo Veterinarians. This journal also accepts the same types of articles but does have a publication charge and does not publish color images. Of course, there are a broad range of journals that will accept herpetological medicine research (e.g., *Journal of the American Veterinary Medical Association*, *American Journal of Veterinary Research*, and *Veterinary Record*) and may be considered by those looking to publish their work.

When selecting a journal to publish in, the authors believe it is important to consider the target audience. Too many times, the impact factor of a journal is considered to be the most important. Impact factors are an objective method of assigning weight to a journal based on its audience size. The audience for the field of herpetological medicine is small. We will never have a high impact value. For that matter, veterinary medicine is a small field and has journals of low impact compared with other scientific fields. The Scimago Journal Rank (http://www.scimagojr.com/journalrank.php?area=3400) for 2016 ranked the *Annual Review of Animal Biosciences* as the highest ranking veterinary journal with a score of 2.4533. Journals 2 to 50 had rank scores of 1.956 to 0.613. The highest ranked journal in the Scimago review is *CA: A Cancer Journal for Clinicians* with a score of 39.285. The previously mentioned top veterinary journal's rank in the overall list is 877/28,606. These findings should reinforce that directing published research to a specific audience is more important than a rank score. These ranks should have no impact on clinician scientists working outside of academia; however, we have had a number of colleagues question publication in certain journals because of either (1) their impact score or (2) their slower review and turnaround times. Science should remain an unbiased and hypothesis-driven endeavor, and those publishing their findings should be focused on distributing it to the audience that will most benefit from it.

BEING AN ACTIVE PARTICIPANT IN PEER REVIEW

For the peer-review process to work, each of us has to contribute. A common problem encountered by the senior author in his role as an editor is getting individuals to accept invitations to review manuscripts and perform the review in a timely manner. In a small field such as herpetological medicine, it is important that everyone feel a sense of responsibility to serve in this role. The peer-review process is at its best when a diverse number of specialists are involved (including those from other specialties such as pathology, anesthesiology, surgery, diagnostic imaging, dermatology, cardiology, and so on). Each specialist brings a unique perspective to the review process based on our understanding

VetBooks.ir

of the literature and the experiences we have gained seeing cases or performing research in the field of herpetological medicine. Manuscript review is typically done using at least two peer-reviewers, and it is the job of the associate editor and editor to pair up reviewers on manuscripts with different backgrounds to ensure a complete review of a manuscript. It is not uncommon for manuscripts reviewed in the JHMS to have a specialist with minimal reptile knowledge but great depth in the specialty (e.g., cardiology, anesthesia, ophthalmology) to be paired with a clinician scientist who has great depth in the field of herpetological medicine and an understanding of the specialty. During the review process it is important for the reviewers to let the editors know of any deficiencies, such as their understanding of statistics or some other aspect of the review. This will ensure that the editors will know of any shortcomings and be sure to obtain additional coverage if needed. Remember, the herpetological literature will only expand if we each contribute to making it so.

CONCLUSION

So in the end what is the point of all this? If you are actively receiving reptile and amphibian cases at your veterinary hospital or teaching institution, you are responsible, nay we say obligated, to contribute to the herpetological literature. The growth of the profession depends on all of its members, especially the recognized specialists. All information, from a brief communication to a well-designed experimental study, has the potential to grow and expand the evidence we use to manage these animals and ensure their conservation. Additionally, each specialist can contribute by reviewing scientific abstracts or peer-reviewed manuscripts when asked. They say knowledge is power. We need to move our profession forward from being the 98-pound weakling to being muscled and fit like editors Steve Divers and Scott Stahl.

Statistics for the Clinician Scientist

Mark A. Mitchell and Sean M. Perry

"Fear not the statistics!" is the primary objective in the syllabus of a graduate biostatistics course taught by one of the authors (M.A.M.). The course is started with this note because the authors have always found it comical that veterinarians, a highly ambitious and intellectual group of individuals, find the idea of learning about statistics or applying them to their research or clinical work a difficult task. However, as it is with all things we learn, if we take the time to understand how and why something is done, it is possible for us to capture and own that knowledge.

There are many things that we need to change in our profession if we ever hope to meet our potential as veterinarians. Because of the limited space available in this chapter, we will focus on two of these needs as they are relevant to the chapter topic. First, we must stop limiting ourselves by identifying simply as "practitioners." Instead, we need to accept that we are clinician scientists. You "practice" some procedure and use it because it works or stop using it because it fails. A scientist is willing to formally test hypotheses and search for new knowledge as to why something works or doesn't. For the scientist, success is met with validation by further review, while failure is met with additional testing to identify why it failed and how to correct it. If we are not providing our clients and patients the latter, we fail them and our profession. The second is using and welcoming rigorous evidence-based science to dictate how we perform our duties as clinician scientists. A large part of this second recommendation is understating the value of statistics in interpreting evidence-based results. There is a general assumption that once a manuscript passes peer-review it is correct and infallible; however, because of this "fear of statistics" I noted earlier, many peer-reviewers are unsure of how to interpret the statistics used to analyze the results of a manuscript they are reviewing. If the associate editor and/or editor are also unsure of what is appropriate, and there is no official statistical review of the manuscript by a trained statistician, then what becomes published may be flawed. This is more common than most of us recognize. It is well documented within the medical literature that statistical errors are common. Study design, data analysis, data reporting, data presentation, and interpretation of data are all areas where errors are commonly made when preparing manuscripts.[1–8] Sometimes these mistakes can result in serious clinical consequences.[9–15] Ultimately, the knowledge each of us gains through reading, listening to lectures, and gaining real-time clinical experience is filtered through our effort to evaluate the truth behind each of these. If we accept them on face value, we may be laying an unstable foundation to our collective knowledge. As it is the focus of this chapter, we will discuss how embracing a basic understanding of statistics can help ensure that when we constructively review a paper we can be sure the statistics were done in an appropriate manner.

HYPOTHESES

Successful research starts with well-defined hypotheses. However, it is only now becoming common for scientists to include the specific hypotheses for their study in their published articles. The reason we see the publication of the hypotheses as important is because they can give us guidance as to the direction of the research, regarding the biological relevance of the work, as well as guide the selection of the statistical tests required to analyze the data. Specific and detailed hypotheses provide insight into the type of data to be collected, which is the first real guide to selecting statistical tests. It is important to recognize that the same basic hypothesis can be answered using categorical, ordinal, or continuous data; however, the level of detail in the answer provided depends on the robustness of the type of data, with continuous data being more robust than ordinal and categorical data, and ordinal data being more robust than categorical data. The concept of using hypotheses to test our scientific opinions regarding our clinical cases is something else we should be doing. The more we think like a clinician scientist, the more likely we are to be more thorough and complete with our cases. For example, every time we submit a diagnostic test to evaluate our hypothesis regarding a specific problem/differential, we are also testing a hypothesis regarding the test method used. When we submit a plasma biochemistry analysis for a tortoise case, we hypothesize what the results are for each analyte measured. If the result for an analyte is what we hypothesized, then we can have more confidence in the direction we are taking the case. However, if the result for an analyte is different from what we expected, then we need to determine whether we are on the right track or if there is some other reason for this difference (e.g., failure of analyzer to correctly perform assay?). A "practitioner" would assume they are wrong and redirect how they are managing the case, such as run another test, whereas a clinician scientist could see that it is possible that they are on the wrong path or that there could be a deficiency in the assay, how the sample was handled, or some other issue. In this latter case, the clinician scientist will reset their hypotheses and do some further investigation.

DATA

When preparing to do a study or interpret the results of a study, it is important to define the type of data used. There are three primary types of data: categorical, ordinal, and continuous. Categorical, or nominal, data represent the most basic data. These data are simply characterized into categories. Many times these data are reported in a binary fashion: yes/no; infected/not infected; present/absent. Ordinal data are assigned a numerical rank, but the assigned numbers have no

VetBooks.ir

TABLE 6.1 Regression Tests Used for Different Types of Data

Data Type	Types of Regression Analysis
Nominal/dichotomous measure of data	Logistic regression
Ordinal/ranked measure of data	Ordinal regression
Continuous/interval measure of data	Linear regression

specific numerical quantity. Examples of this type of data might include a ranking of pathologic lesions from none (1), minimal (2), moderate (3), to severe (4). Each data point represents a qualitative difference, but there is no quantitative value to the difference. Finally, continuous data represents the most robust style of data. It includes data that can be found on a continuous scale, including many of the different types of objective data we use as clinicians to assess our patients, including body temperature, heart rate, body weight, and clinical pathology data (e.g., plasma biochemistry data). These data provide us with quantitative results that can be used for comparison, such as comparing a green iguana (*Iguana iguana*) patient's calcium concentration to a reference interval for captive green iguanas.

It is important to recognize that these three types of data can be used interchangeably to test the same hypotheses (Table 6.1). However, our ability to explain some phenomena improves based on the type of data used. For example, if we are testing a hypothesis that electroejaculation can be used to collect semen from chameleons, we could test the hypothesis by collecting categorical, ordinal, or continuous data. The categorical data would represent a binary outcome: semen yes/no; the ordinal data would include general ranks of data: 0: no semen; 1: <10 sperm/high dry field (hdf); 2: 10 to 100 sperm/hdf; 3: >100 sperm/hdf; and continuous data would count actual numbers of sperm collected in the sample. While the continuous data would provide the most information, with a small sample size and a high degree of variability, it would be difficult to interpret the data. In this example, showing that the technique would produce semen was sufficient to provide proof of concept and serve as a foundation to pursue additional resources (e.g., animals and research grants) for a study where more robust continuous data could be collected. The more robust continuous data could then be collected using a larger sample size to characterize semen concentrations. Those results could then be used to identify the most productive animals for breeding programs.

DISTRIBUTION

The reporting of data can have a significant impact on how we use it as clinician scientists. When reporting continuous data, it is commonplace to report the data by a mean to define the central tendency and the standard deviation to define the variability in the data. However, while these descriptive statistics are considered the "best methods" for presenting continuous data, they are only appropriate when the data is normally distributed. Therefore it is important to always evaluate the distribution of data to determine the best method for reporting it. This is also important for selecting the most appropriate statistical tests for analyzing the data, as parametric statistical testing requires that data be normally distributed. There are a number of different methods for evaluating the distribution of data, much like there are many different methods for treating the same disease; therefore, the authors find it best to identify those tests that provide a consistent result, similar to how we select clinical treatments. The most common methods used by the authors to evaluate the distribution of the data include the Shapiro-Wilk test, skewness, kurtosis, and Q-Q plots. The Shapiro-Wilk test is one of several statistical tests that can be used to determine whether continuous data collected from a group of study subjects meet the assumption of normality. The null hypothesis associated with this test is that the data come from a normal distribution. A test statistic (W) is calculated for this test and a *P*-value generated. If the $P < 0.05$, the null is rejected and the distribution is not normal. Skewness is a measure that evaluates the distribution of the data; it is affected by outliers. A statistic is generated for the distribution that can be positive or negative. The more positive the skewness, the larger the number of outliers to the right of the distribution, while the more negative the skewness, the more outliers to the left of the distribution. Kurtosis describes the shape of the distribution. A normal distribution, or classic bell-shaped curve, has a mesokurtic shape, while a flat shape or peaked shape, both representing nonnormal distributions, are termed platykurtic and leptokurtic, respectively. The platykurtic and leptokurtic distributions are associated with highly negative or highly positive kurtotic values. Q-Q plots represent a visual method of looking at data without a numerical inference. This method is preferred by some for its simplicity but is subject to some personal interpretation. The combination of all four factors in a parallel method ensures the greatest confidence for the authors.

Once the distribution of the data is determined, this information can be used to confirm how the data should be reported. For normally distributed data, the mean (weighted average), median (middle value), and mode (most frequent value) are similar, and it is commonplace to report the mean; however, when the data isn't normally distributed, the median represents the best estimate of central tendency. In addition to reporting the central tendency, it is also important to report the variability of the data. For normally distributed data, the standard deviation serves this purpose; however, when the data isn't normally distributed, this statistic can be confusing to interpret. The authors prefer to use percentiles to describe the variability in the data when the distribution is not normal. In most cases, 25% to 75% or 10% to 90% are used; these represent where 50% or 80% of the data fall. It is now finally becoming common for data to be reported using these methods, although some journals still report these data incorrectly.

SAMPLE SIZE

One of the struggles that clinician scientists face when designing a study or interpreting an article is determining the sample size required to ensure success and minimize the potential for introducing error. This is another reason that the authors believe that hypotheses should be incorporated into an article. By knowing what the specific hypothesis(es) is/are, it is possible to identify the type of data needed and thus the sample size needed. Ultimately, sample size can help determine the risk for introducing Type I or Type II errors into a study. Type I error occurs when a null hypothesis is rejected, when it is true. These types of error are tied to the alpha (or *P*-value). This type of error is less common because the scientific community routinely accepts an alpha or *P*-value of 0.05. In cases where this value is decreased, the likelihood for a Type I error increases; however, this is less common in clinical studies. Type II error is more common in veterinary studies and is the error that we are most concerned about. Type II error occurs when a null hypothesis is accepted, stating there is no difference, when it is false. Because most clinical studies are designed to prove the alternative hypothesis, this can lead to accepting that something isn't significant when it indeed is significant. This type of error is often attributed to small sample sizes; thus, it can be limited or minimized by determining an appropriate sample size before starting the study. As we now understand the importance of preemptive analgesia for controlling pain postoperatively,

VetBooks.ir

preemptively setting a sample size for a study can control poststudy issues. There are a number of different methods available for calculating sample sizes for a study, and to cover them is beyond the scope of this chapter. Instead, the authors recommend that readers of this chapter use available commercial software (MedCalc Software bvba, Ostend, Belgium; http://www.medcalc.org; 2017) or sample size calculators available on the internet. To do so does require some *a priori* information. The *a priori* information is used to estimate sample size. The source of this *a priori* information may come from pilot data, previously published results, or experts in the field. In cases where none of this is available, the authors select values that would have real-world relevance. To start, alpha and beta (1-power [0.8]) values are needed. The standard values for these two parameters are 0.05 and 0.20, respectively. However, if you are concerned about a Type I or II error, you can alter these values to reduce the likelihood of erroneous results. The additional *a priori* information needed will depend on the study. For experimental studies that have a hypothesis that will compare two means, the additional information required includes the "expected difference between the means" and the "expected standard deviations" for each group (e.g., control group and treatment group). In a recent study being conducted by one of the authors (M.A.M) evaluating the impact of ultraviolet B radiation on the plasma 25-hydroxyvitamin D concentrations of leopard geckos *(Eublepharis macularius)*, the authors used the following *a priori* information to determine sample size: an alpha = 0.05, a power = 0.8 (beta = 0.2), an expected difference in the 25-hydroxyvitamin D concentrations of the UVB exposed and non-UVB exposed gecko of 25 nmol/L, and expected standard deviations for each group of 15 nmol/L. The sample size required to detect a difference of at least as big as outlined above is 14 animals, 7 UVB exposed and 7 controls. The authors used pilot data and previously published data in other species of reptiles to generate the *a priori* information. While the authors find estimating a study's sample size *a priori* an excellent way to prepare for a study, it is also important to recognize that many granting agencies now expect researchers to show how they determined their study sample size in order to be given full consideration. As noted earlier, the methods outlined for this study example only represent one study type. Different *a priori* information is needed, other than alpha and beta values, to estimate the sample size for other study types; however, this becomes self-explanatory when using a sample size calculator for a specific study type.

THE *P*-VALUE

The *P*-value is a statistical term known by all but understood by few. The probability of an event occurring, or the *P*-value, is used by scientists to ultimately determine whether or not to accept a null hypothesis. Unfortunately, to most clinician scientists, the *P*-value is a fixed value, .05, and represents a hard line in determining the significance associated with an event. This dogma unfortunately leads us to create evidence-based knowledge that is flawed. The *P*-value selected for a particular hypothesis should not be set at 0.05 for convenience but instead based on the sample size of the study (i.e., is it a small sample size because of resource [animal number, financial] constraints?), the number of comparisons being made in the hypothesis(es), the types of variables being tested, and the risks for Type I and Type II errors, among other factors. Ultimately, the 0.05 value being used suggests that an event occurring would be unlikely to occur no more than 5% or 1 out of 20 times by chance alone. While the authors do find it to be a reasonable value, it is how hard the line is that gives me pause. During peer-review, it is not uncommon for the authors to have reviewers or editors question the significance of a *P*-value that includes 0.05 (e.g., 0.05–0.055). In these cases, individuals have argued that the value is >0.05 and is thus not significant. Is there really that great of a difference in the likelihood of an event happening no more than 4.9% or 0.98 out of 20 times versus 5.1% or 1.02 times out of 20 times? These are the cases where knowledge of what a Type II error represents is important, as well as the power and sample size. Because many of the studies done in herpetological medicine are limited to smaller sample sizes, not addressing these concerns may lead to accepting a null hypothesis and reporting no difference, when indeed there is a difference. One of the ways to officially acknowledge this in a manuscript is to perform a post-hoc power analysis. The authors routinely include a post-hoc power analysis for *P*-values = 0.06 to 0.10. By including post-hoc power and acknowledging the risk of a Type II error in these studies, it guides the reader to consider the limitation associated with the results.

PARAMETRIC VERSUS NONPARAMETRIC STATISTICAL TESTS

Selecting a statistical test to evaluate a hypothesis is no different, and thus should be no scarier to a clinician scientist, than selecting diagnostic tests to rule in/out a disease. While there are entire texts written not only on statistics, but also on select topics in statistics (e.g., logistic regression), it is beyond the scope of this chapter to do anything more than provide a cursory introduction into statistical test selection. However, for the majority, if not all, of the readers of this text, it is not necessary to become an expert in statistics. Instead, we should work to become expert clinician scientists in our field and understand statistics as one of the many tools at our disposal.

The first step in selecting statistical tests is to determine which group of statistics to use. For simplicity, we will divide the statistics into two categories: parametric and nonparametric statistics. Certain assumptions must be met in the study design to properly perform and utilize a statistical test. Two of the most common assumptions, which are needed in both parametric and nonparametric tests, are: (1) data collected for analysis should be obtained from study subjects randomly selected from the population represented in the study, and (2) the individuals and their data should be independent of one another. These represent basic tenets to follow regardless of the statistics used. Note other assumptions must be met for each specific statistical test; the experimental design should reflect these assumptions. A major difference between the two types of statistics is related to the distribution of the data; parametric statistics should only be used on data that meet the assumption of normality, while nonparametric statistics do not have this restriction. Thus, if we simplify this to the types of data, it is obvious that categorical and ordinal data must always be analyzed using nonparametric statistics and that continuous data that doesn't meet the assumption of normality must also be analyzed using nonparametric statistics. The only data type that we would use parametric statistics for are those that meet the assumption of normality. Now, it is important to point out that continuous data that do not meet the assumption of normality can be transformed (e.g., log transformed) to potentially normalize the data. If this transformation is successful, then the more robust parametric statistics could be used to analyze the data; however, it would still be important to report the data by their median and percentiles because the transformed data would not be clinically relevant.

Because veterinarians tend to rely on visual learning aids, we have included Figs. 6.1 through 6.3 as flowcharts that allow us to follow the same hypothetical-deductive reasoning we use to investigate clinical cases. The figures are divided into the three different types of data that we typically use: categorical (Fig. 6.1), ordinal (Fig. 6.2), and continuous (Fig. 6.3). Please note that the flow through each chart is similar and that the only real difference in the type of tests used is based on number of variables. As a refresher, an outcome or dependent variable represents

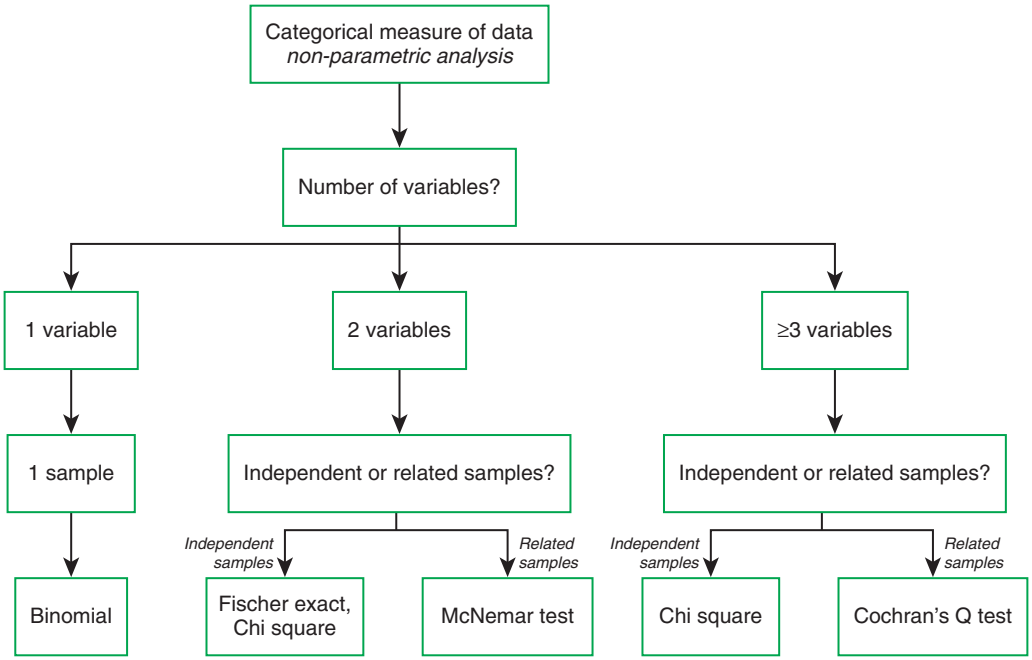

FIG 6.1 Statistical flowchart for categorical data. Independent samples represent the independent variable or predictors, and the related samples represent outcome or dependent variables. These examples are used only to simplify the process, as there are additional tests that can be put into each category; however, the goal of this example is to show commonly used statistical tests and not to overwhelm the reader.

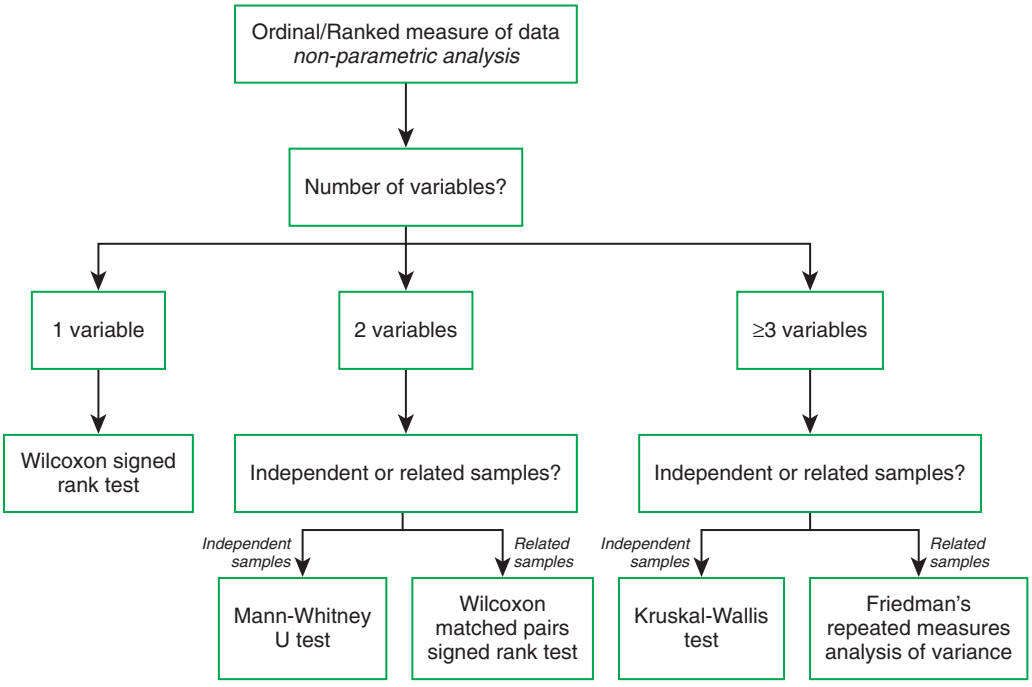

FIG 6.2 Statistical flowchart for ordinal data. Independent samples represent the independent variable or predictors, and the related samples represent outcome or dependent variables. These examples are used only to simplify the process, as there are additional tests that can be put into each category; however, the goal of this example is to show commonly used statistical tests and not to overwhelm the reader.

the data we are measuring, while the independent variable represents the data that may predict or influence the dependent variable. When using the flowcharts, the "related samples" are for those cases where there are two (paired) or three or more (serial) data points for the same outcome variable. For example, if you are measuring 25-hydroxyvitamin D concentrations in leopard geckos (*Eublepharis macularius*) over time and collect a baseline value and a final concentration 30 days later, you have paired data. If you collected samples on baseline (day 0), day 15, and day 30 to evaluate additional samples over time, you have serial data. Paired and serial sampling are excellent methods for reducing

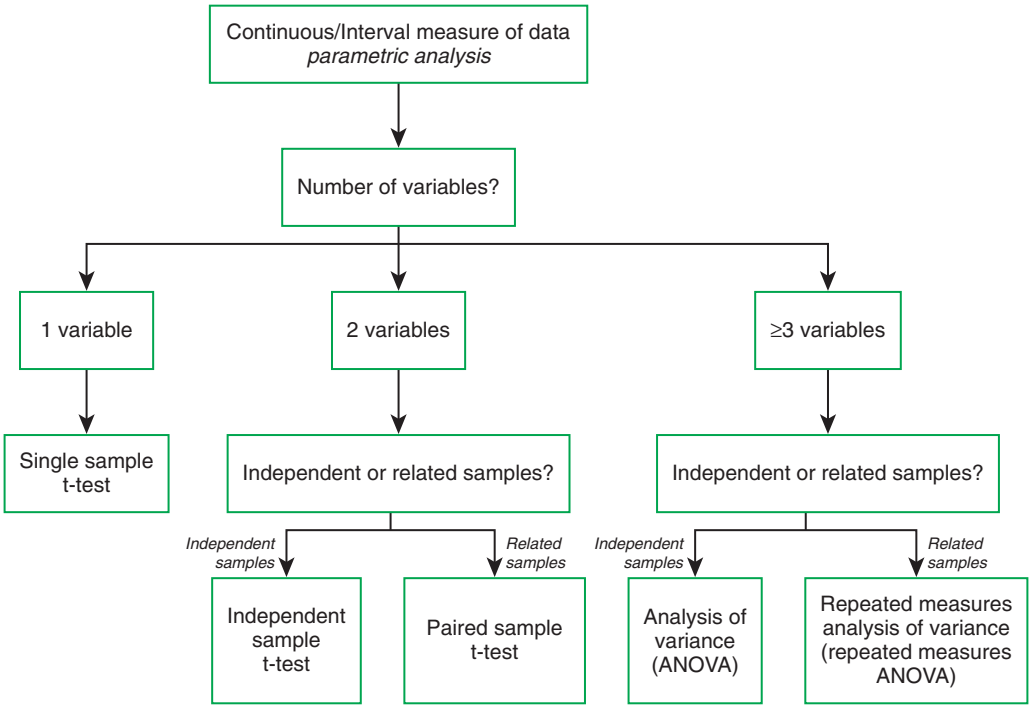

FIG 6.3 Statistical flowchart for continuous data. Independent samples represent the independent variable or predictors, and the related samples represent outcome or dependent variables. These examples are used only to simplify the process, as there are additional tests that can be put into each category; however, the goal of this example is to show commonly used statistical tests and not to overwhelm the reader.

within subject bias and making your analysis more robust. For those looking for an excellent statistical text to pursue additional statistical expertise, the authors recommend *The Handbook of Parametric and Nonparametric Statistical Procedures* by David J. Sheskin.[16]

STATISTICAL SOFTWARE

Statistical software is available that has simplified the process for analyzing data. These software programs come in a variety of packages, from those that require programming to those that don't require programming. The programs that require programming tend to be more robust in what they can accomplish. Examples of these types of programs include SAS (SAS Institute Inc., Cary, NC) and R (https://www.r-project.org/). R is free. MedCalc and SPSS (current version 24.0; IBM Statistics, Armonk, NY) do not require programming, although programming can be done with SPSS when more involved statistical methods are required. The authors use a combination of these programs. For those running very basic statistics, such as chi squared and Fisher exact tests, free calculators are available on the internet. The Centers for Disease Control and Prevention also have a free software program, EpiInfo (https://www.cdc.gov/epiinfo/index.html). Regardless of the software being used, it is important to understand when to select a test (Figs. 6.1 through 6.3) to ensure the analysis is correct, because these software programs will generate results for whatever test is selected, even if it is the wrong test.

CONCLUSION

The field of herpetological medicine is in its infancy, and maturation requires evidence-based knowledge to expand our understanding of these magnificent animals. Evidence-based knowledge requires hypothesis-generated research that is validated using appropriate study design and statistical analysis. Every member of our profession can and should feel an obligation to contribute to the generation of evidence-based science. For it is only through this new knowledge that we can achieve our potential as a true specialty.

Chelonian Taxonomy, Anatomy, and Physiology

Thomas H. Boyer and Charles J. Innis

Chelonians (turtles, tortoises, and terrapins) were traditionally thought of as primitive basal reptiles because of their anapsid skull (without temporal fennestra). Recent morphologic and molecular studies have discarded this notion; chelonians are now thought of as diapsids (having two temporal fennestra) that have secondarily evolved into anapsids.[1–4] As such, chelonians are a sister clade to the Archosaurs (crocodilians, birds, and extinct dinosaurs) and less closely related to the living Lepidosaurs (lizards, snakes, amphisbaenids, and tuataras). Chelonians are the most ancient reptiles, evolving before the dinosaurs over 300 million years ago.[4,5] They survived multiple mass extinctions with little change to their basic body plan; their armored shell served them well until man evolved. Pursuit by man for food, traditional medicine, and pets, as well as introduced invasive species, diseases, anthropogenic trauma, fisheries interactions, habitat degradation, and fragmentation have resulted in population declines for many chelonian species. Chelonians are under siege on a global basis and are the most threatened of any major group of vertebrates—more than mammals, birds, or amphibians.[5] More than half of freshwater turtles worldwide, and 75% of the Asian species, are threatened with extinction. Due to the magnitude of this crisis, concerned organizations and individuals have been developing strategies to conserve chelonians through better education, enforcement, legislation, and international cooperation. Zoos and private individuals can play a role in preserving assurance colonies of threatened species before they are gone. The Turtle Survival Alliance (http://www.turtlesurvival.org) has been effective in prioritizing and coordinating conservation action.

Turtles are near the top in the number and proportion of species that have been known to live more than 50 years in captivity.[6] All species of chelonians can potentially live half a century or more, certain species may exceed 100 years, and fortunate individuals have been known to exceed 150 years.[7] However, in the Anthropocene, death by man is more likely to result in mortality than old age. Anyone who obtains chelonians is encouraged to act responsibly and observe all regulations set forth by the Convention on the International Trade in Endangered Species of Fauna and Flora, in addition to other applicable state, local, and federal wildlife laws. Asking questions about chelonian origin and verification of legal importation are important. Seek captive-born animals.

TAXONOMY

Turtles, tortoises, and terrapins are the only living representatives of the order variously referred to as Testudines, Testudinata, or Chelonia. The two suborders of chelonians are the Cryptodira (hidden-neck turtles) (Fig. 7.1) and the Pleurodira (side-neck turtles) (Fig. 7.2). Cryptodiran turtles can, by a vertical cobralike bending of the neck vertebrae, retract the head and neck straight back into the shell, thereby hiding the neck.[8] Although sea turtles are Cryptodirans, they are anatomically unable to retract their heads into their shells. Pleurodirans are not able to fully retract the neck inside the shell and must fold it sideways hence the common name of side-necks. Currently, approximately 14 families, 97 genera, and 327 species encompass the Chelonia (Tables 7.1 and 7.2), including seven species of sea turtles.[9]

FIG 7.1 (A) Cryptodiran turtles are able to retract the neck straight back into the shell, cobralike, thereby hiding the neck, such as this extreme example (B) in a spotted turtle (Clemmys guttata). (Courtesy of Thomas H. Boyer.)

VetBooks.ir

FIG 7.2 (A) Pleurodiran turtles are not able to retract the neck and must fold it up sideways; hence, the common name of side-necks, such as this common snake-necked turtle (*Chelodina longicollis*) with (B) lateral and (C) dorsoventral radiographs. (D) Note the start of annual scute shedding. (Courtesy of Thomas H. Boyer.)

TABLE 7.1 The Suborder Pleurodira Consists of 3 Families, 16 Genera, and Over 80 Species[9]

Family	Common Names	Example Species
Chelidae (Fig. 7.2 and 7.3)	Austro-American side-necked and snake-necked turtles	Common snake-neck turtle (*Chelodina longicollis*) Mata mata, (*Chelys fimbriata*)
Pelomedusidae (Fig. 7.4)	Afro-American side-neck turtles	African helmeted turtle *(Pelomedusa subrufa*)
Podocnemididae (Fig. 7.5)	Madagascar big-headed turtles, big-headed Amazon river turtles, South American side-neck river turtles	Madagascar big-headed turtles (*Erymnochelys madagascariensis*)

The common names of chelonians vary throughout the world and change from language to language.[10] Tortoise usually refers to terrestrial species, such as members of the family Testudinidae. Australians, however, refer to all but one of their turtles as tortoises, despite the fact that no Testudinidae exist there and all of their chelonians are aquatic. In the United Kingdom, terrapin refers to freshwater/brackish chelonians, turtle refers to marine chelonians, and tortoise refers to terrestrial chelonians. In South Africa, fresh water turtles are also referred to as terrapins. North Americans restrict the use of terrapin to a single species, the diamondback terrapin (*Malaclemys terrapin*), a brackish water species, while all other aquatic turtles are called turtles. Vernacular names such as sliders, sawbacks, or cooters may also be used. The Spanish language refers to chelonians as tortugas, tortugas de tierra (land tortoises), tortugas de aqua (water turtles), and tortugas de mar (sea turtles). One can appreciate scientific names that are the same from language to language. The Turtle Taxonomy Working Group has standardized English common names with generic names by compiling a checklist of turtles of the world, their distribution, and conservation status.[9]

FIG 7.13 The mud and musk turtles, Kinosternidae, are a large group of New World aquatic turtles. This stinkpot (*Sternotherus odoratus*) has musk glands along the bridge that are a predator deterrent. (Courtesy of Stephen Barten.)

FIG 7.15 The desert tortoise (*Gopherus agassizii*) has recently been split into several species and is the most common reptile in the senior author's veterinary practice. (Courtesy of Donal M. Boyer.)

FIG 7.14 The monotypic big-headed turtle (*Platysternon megacephalum*) lives in cool, fast-moving rivers and streams in Southeast Asia and is an excellent climber. Human consumption is rapidly removing it from the wild. (Courtesy of John Tashjian.)

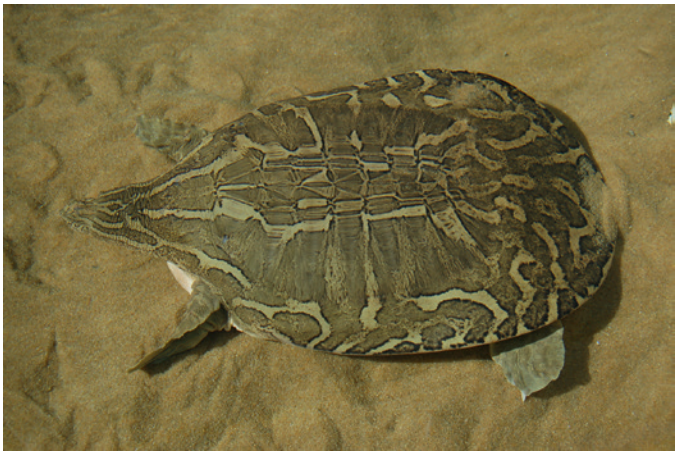

FIG 7.16 Softshell turtles (Trionychidae) are the largest freshwater turtle species, such as this Indian narrow-headed softshell turtle (*Chitra indica*), which has cervical vertebrae at the carapacial junction that can flip 180 degrees. (Courtesy of Donal M. Boyer.)

ANATOMY AND PHYSIOLOGY

Chelonians are vertebrates, but they possess several unique aspects to their anatomy and physiology. Figs. 7.17 through 7.23 illustrate the gross anatomy of the chelonian.

Musculoskeletal System

Chelonians are immediately recognizable by their shell. The shell consists of an upper carapace and lower plastron connected laterally by bony bridges. The carapace consists of some 50 bones derived from ribs, vertebrae, and dermal elements of the skin; the plastron has 9 bones evolved from the clavicles, coracoids, interclavicles, and gastralia (abdominal ribs).

The bony shell is covered by a superficial layer of keratin shields, called scutes (Fig. 7.23). Scutes are staggered so that the seams between them are not directly over bone sutures. Turtles produce new scutes with each major growth period and retain (terrestrial chelonians) or shed (aquatic to semiaqautic chelonians) the scutes from the preceding growth period.[11] Scutes grow outward from their central nucleus, or areola. Each year, a new scute forms beneath the previous year's scute and, if it is larger, its outer edge shows around the perimeter of the older scute in the form of a growth ring (an annulus). If nutrition is compromised, instead of expanding level with the shell surface, the annuli will invert, which is abnormal, but a good indicator of chronic nutritional inadequacy (Fig. 7.24). In some species, annuli can be used to estimate age, similar to growth rings in a tree. This requires considerable expertise and is reliable only when a distinct growth period is present, as in wild temperate turtles.[11] The difficulty of estimating age from annuli is complicated by continuous growth in captivity, without distinct annuli; annuli that are worn off with age, wear, or shedding scutes; or multiple annuli per year. Therefore, contrary to popular belief, the age of most turtles cannot be determined accurately by counting annuli.[12] Scutes and underlying bone are capable of incredible regeneration (Fig. 7.25), such that necrotic bones and scutes are shed, or can be debrided, and eventually replaced by underlying new shell with both bones and scutes.[13] Scute nomenclature is useful to veterinarians to describe shell lesions and surgical sites and to identify species.[11] Scutes are named for their adjacent body portion (see Fig. 7.23).

Shell modifications are numerous. The bones in the shells of leatherback sea turtles (*Dermochelys coriacea*), softshell turtles (Trionychidae), and Fly River turtles (*Carettochelys insculpta*) have been reduced and the scutes replaced with tough leathery skin with α keratin, but no β keratin. All other turtles have both α and β keratin, the latter is hard and brittle.[14] Most hatchling tortoises have fontanelles or fenestrae (openings) between carapacial bones that fuse as the tortoise ages (provided bone growth is normal). Some species, such as pancake tortoises (*Malacochersus torneiri*), adult male and immature giant Asian river turtles (*Batagur* spp.),[15] and softshell turtles retain these fenestrae.

Many chelonians have connective tissue hinges in their shell. These include plastronal hinges in box turtles (*Terrapene* spp., *Cuora* spp.), spider tortoises (*Pyxis* spp.), and mud turtles (*Kinosternon* spp.); a caudal carapacial hinge in hinged-back tortoises (*Kinixys* spp.); and slight caudal plastron mobility in female Mediterranean tortoises (*Testudo* spp.).

Chelonians are the only extant vertebrates in which pectoral and pelvic girdles are within the rib cage, an early evolutionary change first apparent 260 million years ago.[7] The vertical orientation of the pectoral and pelvic girdles buttresses the shell and provides strong ventral anchors for the humerus and femur. With few exceptions, the appendicular bones are typical of other vertebrates. The tripartite rectilinear pectoral girdle consists of a dorsoventral scapula, ventromedial acromium process and ventrocaudal coracoid (procoracoid), which resembles the mammalian scapula, especially on dorsoventral radiographs. Marine species and one freshwater species, the Fly River turtle, have elongated metacarpals and phalanges that form elaborate forelimb flippers so that they can "fly" through water (Fig. 7.26; also see Fig. 7.6).

Chelonians have 8 cervical, 10 trunk, and variable numbers of up to 33 caudal vertebrae. Chelonians have well-developed musculature associated with retraction of the head and neck and the limb girdles and limbs, but because of the shell, they have reduced trunk musculature.[16,17] Appreciating the boundaries of the pectoral and pelvic muscles is important when plastron celiotomy is contemplated.

Integumentary System

The skin of chelonians varies from smooth and scaleless to thickly scaled. A tendency toward thicker scales is seen among the Testudinidae. Injections should be given through finely scaled areas, avoiding the larger, thicker scales that may have osteoderms, which are difficult to penetrate. As with all reptiles, skin is shed periodically, although in a much more piecemeal fashion than in squamates. This is particularly noticeable in aquatic turtles, often misinterpreted by laypersons as a fungal infection.

Respiratory System

The rigid shell makes respiration much different for chelonians compared with other vertebrates with expandable chests. Chelonians are obligate nasal breathers; mouth breathing is abnormal and often indicates airway pathology. Air from the external nares passes over the partial hard palate (there is no soft palate) into the much larger nasal sinus (Fig. 7.27), separated into halves by the internasal septum, then opens into choanae (the internal nares) in the dorsal oral cavity. The nasal sinus is lined with dorsal olfactory and ventral, mucous producing epithelium. The glottis is located at the base of the tongue, and the tracheal rings are complete. In cryptodiran turtles, the trachea is relatively short and bifurcates midcervically into two main-stem, unbranched bronchi that open directly into the entire dorsal surface of the paired lungs. The cranial bifurcation and complete tracheal rings of the trachea enables chelonians to breathe unimpeded when the neck is withdrawn[18] but can also be a hazard if endotracheal intubation is too deep. The dorsal lungs are adherent to the carapace and ventrally separated and weighted by the septum horizontale, which is attached to the liver, stomach, and intestinal tract. No true diaphragm separates the lungs from other internal organs, thus there is a pleuroperitoneal or coelomic cavity. Grossly, the lungs are large, multicameral (partitioned), saccular structures reminiscent of hollow porous sponges. Lungs are divided into 3 to 11 chambers dependent on the family.[19] The lung surface is reticular and interspersed with bands of smooth muscle and connective tissue. Although lung volume is large, respiratory surface area is only 10% to 20% of a comparably sized mammal but adequate for animals with a metabolic rate that is only 10% to 30% of that of mammals.[6,17] Large lung volume provides an obvious advantage as a hydrostatic organ for aquatic turtles.[19] In three-toed box turtles (*Terrapene carolina triunguis*), researchers found relatively small tidal volumes (2.2 ± 1.4 mL/breath) coupled with high respiratory rates (36.6 ± 26.4 breaths/min).[20]

There are five metacarpals, one for each digit. The first and fifth digits have two phalanges, while digits 2–4 have three phalanges. Inset shows close-up of the carpal bones. H, Humerus; U, ulna; R, radius; MC, metacarpal; P1, P2, and P3, first, second, and third phalanges; 1-5, distal carpal bones 1-5; 6, pisiform; 7, centrale; 8, radiale; 9, ulnare. (Courtesy of Charles J. Innis.)

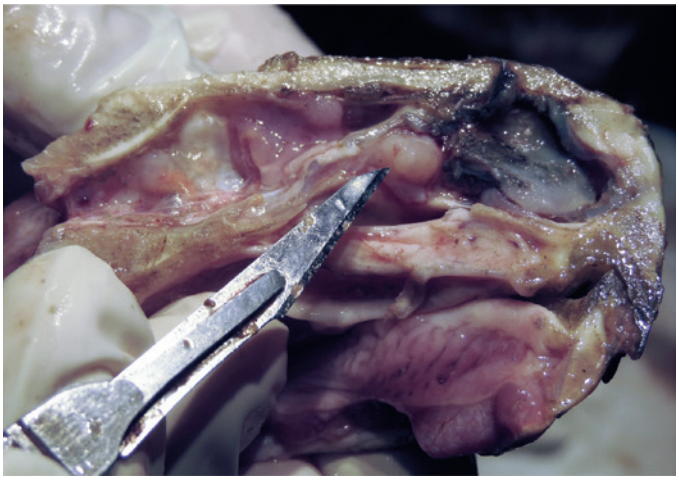

FIG 7.27 Saggital section of the skull of a leopard tortoise (*Stigmochelys pardalis*); note the large olfactory lobes (scapel tip) and anterior nasal sinus. (Courtesy of Brian Horne.)

Intrapulmonary pressure varies from slightly negative to 5 cm H_2O.[19] Peak airway pressures during anesthesia are recommended to be less than 10 cm H_2O.[21]

Antagonistic pairs of muscles essentially decrease or increase lung and visceral volume.[22] This action may or may not be supplemented with limb and head movements and anatomically varies considerably among chelonians. Amphibians and monitors breathe, in part, through positive pressure gular pumping. Turtles are capable of gular pumping, but this assists olfaction, not ventilation (except in some aquatic species that do have gular respiration).[22] In the submerged snapping turtle, inspiration is active and expiration passive because of hydrostatic pressure that affects visceral volume. On land, the opposite is true; inspiration is passive, and expiration is active.[11] Some aquatic turtles have supplemental cloacal, buccopharyngeal, or cutaneous respiration to enable them to remain submerged longer. The Fitzroy River turtle (*Rheodytes leukops*) can extract from 40% (adults) to 73% (juveniles) of their oxygen requirement via highly modified cloacal fimbriated bursae[23] and can pump water in and out of their cloaca 15 to 60 times per minute.[24] Underwater respiration may sustain aquatic turtles during periods of low activity, but when they are active, they still need to surface for air (bimodal respiration).[7] Chelonians are capable of long periods of apnea that makes induction of gas anesthesia by chamber or mask more difficult, especially in cryptodirans, without injectable preanesthetics. Open fractures of the shell, exposing the lung, typically do not result in obvious respiratory distress. Many factors make removing secretions or foreign bodies from the lungs difficult for chelonians. These include termination of the mucociliary elevator outside the glottis, poor drainage through the dorsally located bronchi, compartmentalization of the lungs, large potential space within the lungs, and lack of a complete muscular diaphragm to facilitate coughing.[25] Consequently, pneumonia can be difficult to manage and life threatening in chelonians.

Digestive System

Chelonians have large, fleshy tongues that are not able to distend from the mouth as in squamates. As a general rule, most terrestrial species are herbivorous, whereas aquatic species are carnivorous or omnivorous; however, numerous exceptions exist.[12] Chelonians lack teeth and depend on the scissorlike actions of their horny beak, or rhamphotheca, for biting off pieces of food that are swallowed whole. In captivity, chronic nutritional disease may produce deformity of the rhamphotheca (Fig. 7.28). Salivary glands produce mucus devoid of enzymes to enable swallowing of bite-sized pieces,[24] especially in tortoises. Aquatic turtles eat under water. The ciliated esophagus courses along the neck. Sea turtles have large esophageal papillae to entrap ingested food while expelling sea water (Fig. 7.29). Passing a stomach tube with the neck extended, rather than retracted, is easier. However, in large chelonians, the mouth is easier to open with the head retracted, and it is possible to pass a flexible stomach tube. The stomach lies along the ventral left side, caudal to the liver, and has a gastroesophageal sphincter on the left and pyloric sphincter centrally, as well as greater and lesser curvatures (see Figs. 7.19, 7.20, and 7.21) (Edwards, Proc AAZV, 1991, pp 139–143). The small intestine is relatively short (compared with mammals), mildly convoluted, and absorbs nutrients and water.[27] The stomach, small intestine, and pancreas produce digestive enzymes, while the liver and gallbladder produce and store bile. The pale orange-pink pancreas empties into the proximal duodenum via a short duct or ducts and has functions similar to other vertebrates. The pancreas is in direct contact with the spleen (cryptodirans) or separate in the mesentery along the duodenum (among examined pleurodirans).[17] Tissue amylase and lipase levels have been found to be highest in pancreatic tissue in loggerhead (*Caretta caretta*) and Kemp's ridley (*Lepidochelys kempii*) sea turtles and low in all other tissues.[28,29]

VetBooks.ir

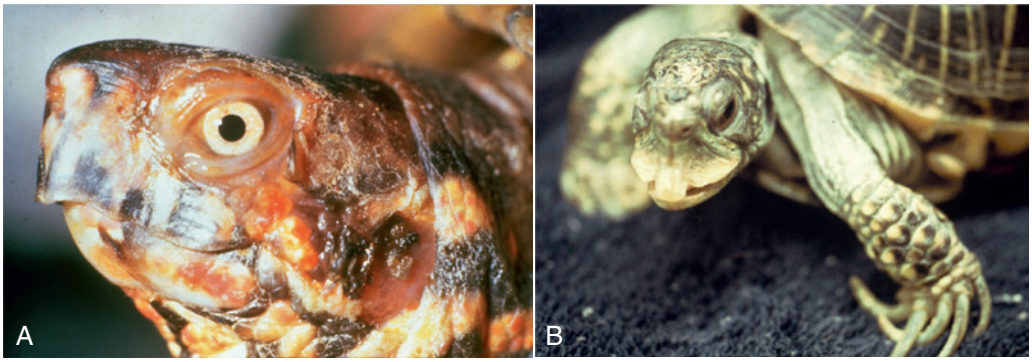

FIG 7.28 The normal rhamphotheca (A) of a box turtle should be vertical. Nutritional disease may produce deformity of the rhamphotheca (B). (Courtesy of Thomas H. Boyer.)

FIG 7.29 Necropsy specimen of a Kemp's Ridley sea turtle (*Lepidochelys kempii*) showing the large keratinized esophageal papillae that are found in all sea turtle species. (Courtesy of Charles J. Innis.)

The liver is a large, ventral, saddle-shaped organ that spreads from side to side under the lungs. It has two major lobes, envelops the gallbladder on the right, and has indentations for the heart and stomach. The liver is dark red to brown, similar to other animals; some chelonian livers may be normally pigmented with melanin (melanomacrophages).[18] Pale yellow to tan color to the liver can be abnormal and an indication of hepatic lipidosis (Fig. 7.30); however, this color change can also be associated with vitellogenesis in females (see Chapter 67). Chelonian bile acids differ somewhat structurally from those typically found in other vertebrates, but 3α hydroxybile acid, the most common clinicopathologic analyte, is conserved. Little is known about the diagnostic use of plasma bile acid concentrations in chelonians, but one study did not detect a postprandial increase in red-eared sliders.[30,31]

The small intestine joins the large intestine at the ileocolic valve. The large intestine, the primary site of microbial fermentation in herbivorous tortoises, includes the cecum, ascending colon, transverse colon, and descending colon (see Figs. 7.19 and 7.20). The cecum is not well developed and not especially distinct; it is more of an expansion of the proximal colon and, fortuitously for the surgeon, lacks mesentric attachments. The ascending and descending colons have short dorsal mesenteric attachments, whereas the transverse colon has a wider mesenteric attachment to the stomach, giving it more dorsoventral mobility.[32] Because of this, heavy ingested material (rocks, sand, metal foreign bodies) sink ventrally in the transverse colon, become entrapped,[32] and accumulate at the descending colon (Fig. 7.31; also see Fig. 7.21). Foreign body removal is facilitated by milking material anterograde into the cecum (which is easiest to exteriorize) from the descending, transverse, and ascending colon, then exteriorizing the cecum for enterotomy and extraction of foreign bodies. The colon terminates in the coprodeum of the cloaca. Gastrointestinal (GI) transit time is affected by many factors, including temperature, species, feeding frequency, food particle size, and water or fiber content of food. GI transit time is shortest in omnivores (e.g., *Trachemys* spp), longer in carnivores, and longest in herbivores (such as tortoises).[32] No digestion takes place below 7°C (45°F), intestinal peristalsis decreases below 10°C (50°F), and extremely slow digestion occurs between 10° to 15°C (50°–59°F).[32] Captive diets generally move faster through the GI tract than natural diets, especially in tortoises. For example, GI transit times for spur-thighed tortoises (*Testudo graeca*), kept at 28°C, varied from 3 to 8 days when fed *ad libitum* lettuce but increased to 16 to 28 days when fed thistles, grasses, and dog food.[33] In Hermann's tortoises (*Testudo hermanni*), diatrizoate (Gastrografin, 100 mg sodium amidotrizoate [sodium diatrizoate] and 660 mg meglumine amidotrizoate [meglumine diatrizoate]/ml, Bayer, Berkshire, UK) mean total transit time was 2.6 hours at 30.6°C (87°F), 6.6 hours at 21.5°C (70°F), and 17.3 hours at 15.2°C (60°F).[34] In loggerhead sea turtles (*Caretta caretta*), radiographic contrast studies documented transit times of 2 to 3 weeks.[35,36] Metoclopramide, cisapride, and erythromycin did not significantly reduce GI transit time compared with water in desert tortoises (*Gopherus agassizii*).[37]

Genitourinary Systems

The retrocoelomic kidneys of chelonians are located deep to the caudodorsal carapace and posterior to the acetabulum, except in marine turtles in which they are usually anterior to the acetabulum (see Figs. 7.22B and C).[18] The kidneys are metanephric. Reptiles cannot concentrate urine above that of plasma because of the absence of the loop of Henle.[27] Urine is not sterile, and, in chelonians, the urinary tract is not easily accessible. Soluble urinary nitrogenous wastes, such as ammonia and urea, require relatively large amounts of water for excretion. This is only practical for aquatic and semiaquatic chelonians. Marine and highly aquatic freshwater turtles (such as *Trachemys*) excrete more ammonia and urea than uric acid (amino-ureotelic); semiaquatic turtles excrete two to four times as much urea as ammonia or uric acid (ureo-uricotelic).[32] Terrestrial chelonians produce more insoluble uric acid and urates that can be passed from the body in a

semisolid state, requiring much less water (ureo-uricotelic to uricotelic).[27] These differences make detection of kidney disease on the basis of mammalian markers, such as blood urea nitrogen (BUN) and creatinine, more difficult in chelonians. Healthy carnivorous sea turtles maintain very high plasma BUN blood urea nitrogen (BUN) concentrations in comparison to most other vertebrates and other chelonians (e.g., often >100 mg/dL), perhaps to aid in osmoregulation in a hypertonic environment as seen in elasmobranchs. Healthy herbivorous tortoises have basic urine, while tortoises in a catabolic state may have acidic urine, but again, this is not specific to renal disease. Urine pH of two healthy captive hawksbill turtles (14 urine samples) was 5.9 to 6.2, as expected for a carnivore.[38]

The urinary bladder opens into the urodeum of the cloaca. A fold separates the coprodeum from the urodeum, which has openings to the ureters, oviducts or vas deferens, the bladder, and, if present, accessory urinary bladders. Terrestrial chelonians have the largest urinary bladders of all chelonians; the bladder is bilobed with a thin, membranous, distensible, ciliated, mucus secreting wall and used for water storage and potassium/sodium ion exchange during drought.[17,18] Aquatic turtles have smaller bladders with thicker walls.[17] The cloaca, colon, and urinary bladder can reabsorb urinary water across a concentration gradient, which can increase urine osmolality but still not above that of plasma.[27] Bladder prolapses are not uncommon with uroliths or colonic foreign bodies and can be reduced endoscopically, if acute.

The paired gonads are located anterior to the kidney. Fertilization is internal in chelonians. Sexual maturity is reached by 15 years in the wild and often much sooner under captive conditions, probably more a function of size than age. Reproductive physiology has been closely studied in *Gopherus* spp. Seasonal patterns for testosterone, estrogen, and progesterone, summarized here, are similar to those reported in other species.[39,40] Spermatogenesis is temperature- and testosterone-dependent, all rising in the spring/summer and falling in the fall/winter. However, spermatazoa may be retained through the winter in the epididymis and released during

VetBooks.ir

the following spring's mating season. In temperate and subtropical species, ovulation occurs in the spring following emergence. Sperm are stored, for months to years, by the female in the albumin gland region within the isthmus of the oviduct, where fertilization occurs. Following fertilization, this same area produces membranes and albumin layers around the developing ovum. Further down the widening oviduct, the shell gland produces shell membranes and the eggshell; the eggs are held here as new eggs are added bilaterally until oviposition.

Each ovary has a hierarchy of follicles at different stages of development.[17] Small white previtellogenic follicles secrete estradiol in response to pituitary gonadotropin. Estradiol stimulates the liver to secrete vitellogenic protein, which is taken up by the maturing enlarging yellow follicles, typically in the fall, sometimes in the spring. Nesting female sea turtles have higher concentrations of total protein, albumin, globulin, calcium, phosphorus, triglycerides, and cholesterol.[41] Testosterone appears to regulate seasonal reproduction in both males and females. Follicular testosterone production increases as the follicles mature and increase in size. In females, there is a biphasic increase in testosterone associated with spring and fall mating. As testosterone falls after ovulation, females become nonreceptive to breeding and avoid males. Ovulation occurs after courtship and mating, then again within days of nesting, associated with luteinizing hormone and progesterone surges. Chelonians may produce single or multiple clutches of eggs in a given breeding season depending on the species. Sea turtles generally migrate to nesting beaches and produce multiple clutches over a several-week period, separated by 2 or more years of nonreproductive activity. Arginine vasotocin peaks during the first oviposition, returning to baseline within an hour. After nesting season, any fully mature follicles that haven't ovulated undergo atresia. Atresia is a process of yolk resorption, and as the follicle reduces in size it eventually becomes a corpora albicans. Repeated folliculogenesis and atresia without production of eggs may lead to egg yolk coelomitis. In temperate species, thyroxine (T_4) levels peak in both sexes following hibernation emergence; males undergo a second peak in late summer as male combat and spermatogenesis return.

Male chelonians possess a single, large, smooth, dark-colored, expansile, spade-shaped phallus (Fig. 7.32). When not erect, the phallus lies in the ventral floor of the proctodeum and is not used for urine transport (no urethra). Females have a much smaller clitoris in the same area. When engorged, the muscular phallus extends from the cloaca and can reach as much as half the length of the shell, with a seminal groove for transport of sperm. Laypersons understandably often mistake an engorged phallus for another organ prolapse. No inversion of the phallus occurs as it does in squamates.[27] The distal proctodeum can entrap uroliths or eggs, which can be broken down and accessed per cloacal manipulation.

Male chelonians often vocalize during copulation or masturbation, causing uninformed owners to suspect that something is wrong with their tortoise. Intermittent cloacal hemorrhage resulting from phallus lacerations associated with breeding or masturbation may require surgical intervention. Under general anesthesia, the phallus is often the last area of the turtle body to be desensitized unless intrathecal local anesthesia is utilized.

Chelonians are oviparous, with either soft flexible eggshells, or, more commonly, hard-shelled eggs. Depending on species, clutches may consist of single or multiple eggs, with some very large species producing dozens of eggs per clutch. Temperature-dependent sex determination occurs in most chelonians, which typically produces females at higher

FIG 7.32 Chelonians have large phalluses (A–D) that, when fully engorged, can span half the plastron. (Courtesy of Thomas H. Boyer.)

VetBooks.ir

temperatures and males at lower temperatures (pattern Ia) during early to mid incubation. However, other species produce females at both high and low temperatures and males at intermediate temperatures (pattern II). With temperature-dependent sex determination the smaller gender typically occurs at cooler temperatures, males for pattern Ia and females for pattern II.[42] Some turtles have genetic sex determination, such as the common snake-necked turtle (*Chelodina longicollis*) and the wood turtle (*Glyptemys insculpta*).[32,42] To produce both sexes, pivotal species-dependent temperatures are somewhere between 27° to 31°C (81°–88°F).

Sexual Dimorphism

Sexual dimorphism is known to occur in most postpubertal chelonians. Where present, differences can be seen in coloration, tail or claw length, size, and shell shape. Perhaps the most obvious form of sexual dimorphism is tail length and shell shape (Fig. 7.33). In many species, to facilitate intromission, mature males have longer, thicker tails, a more distal vent, a curved or concave plastron, and, if present, an anal notch on the plastron that is narrower and deeper than that of the female (Fig. 7.34). In contrast, females have shorter tails that abruptly taper

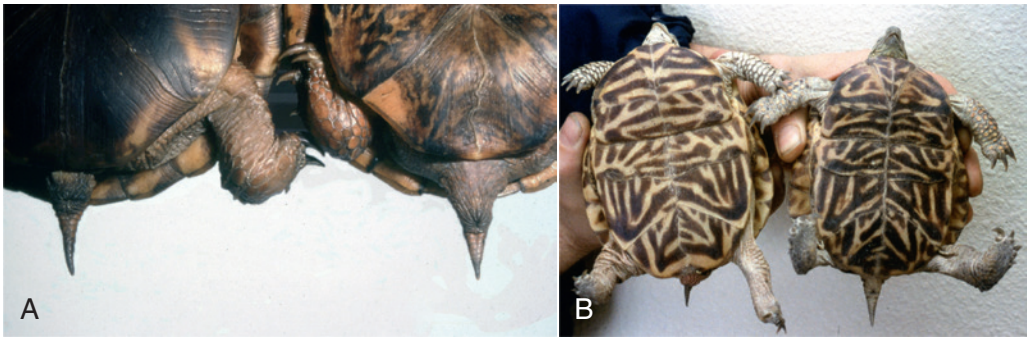

FIG 7.33 One of the most consistent distinguishing characteristics between mature male and female chelonians is the length of the tail. (A) The male (on the right in both photographs) box turtle *(Terrapene carolina)* has a longer broader tail, and the cloacal opening is beyond the margin of the carapace. (B) The female (on the left in both photographs) ornate box turtle *(Terrapene ornata ornata)* has a cloacal opening within the margin of the carapace. These differences are not apparent in juveniles. (Courtesy of Thomas H. Boyer.)

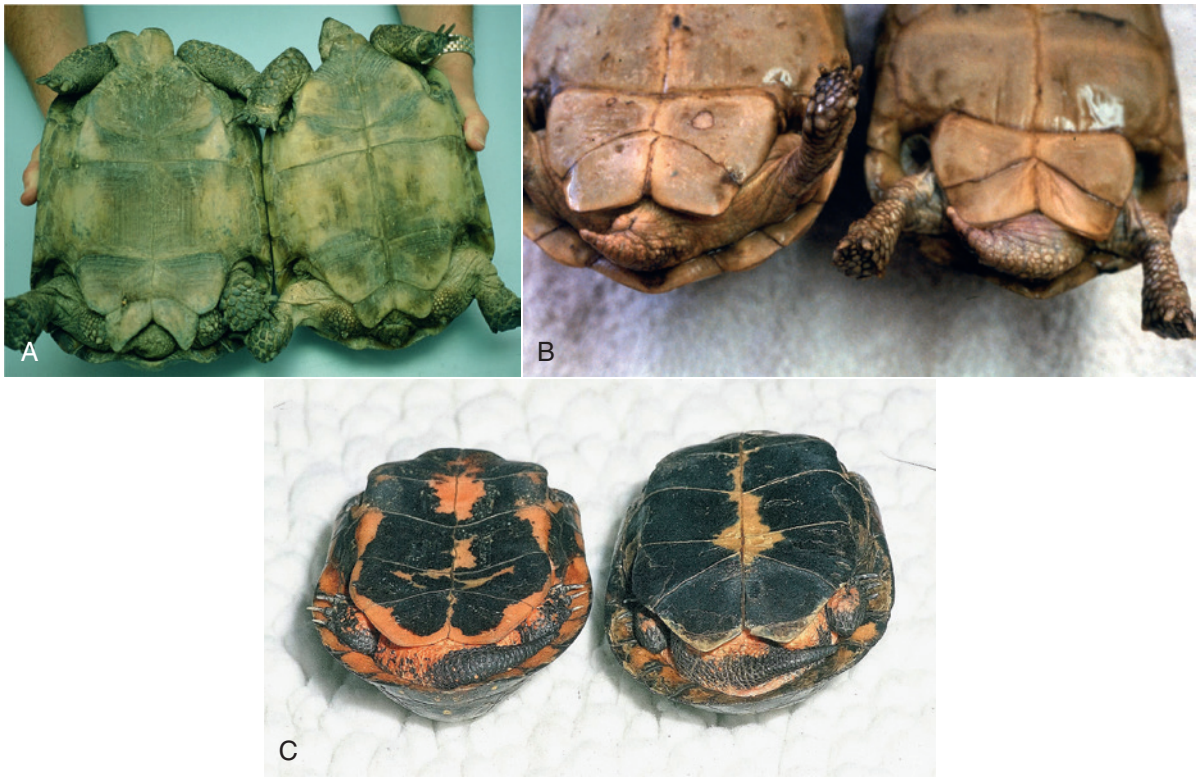

FIG 7.34 (A) In *Gopherus* species, the male (left) has a large epiplaston projection, a deeper V to the anal notch, and a concave plastron. (B) The male Egyptian tortoise (*Testudo kleinmanni*, on right) has a longer thicker tail. (C) Both spotted turtles (*Clemmys guttata*) have long tails, but notice the male's tail touches the rear leg while the female's does not, and the male has a concavity to his plastron (on left). (Courtesy of Thomas H. Boyer.)

FIG 7.35 (A) Sexually mature female leopard tortoises (*Stigmochelys pardalis*) have elongated rear claws, perhaps as an aid to nest digging, and males do not. These claws should not be trimmed. (B) The inner rear claw of the male three-toed box turtle (*Terapene c. triunguis*) is thickened and curved inward to aid clasping the female's shell during intromission. (Courtesy of Thomas H. Boyer.)

posterior to the vent, the vent is cranial to the carapace margin, plastron is usually flat, and the anal notch wider and shallower, perhaps as an aid to oviposition (see Fig. 7.34). With the onset of sexual maturity, these differences may allow for easy sex identification, especially with both sexes present. Often these differences are subtle, and sex identification is very difficult prior to sexual maturity; however, endoscopic sex identification is possible. Males sometimes evert their phallus during defecation or cloacal manipulation.

A difference in size between the sexes is common among cryptodiran turtles. In 70% of 50 taxa examined by Fitch,[43] females were significantly larger, especially in highly aquatic species. Males were larger in 22% of the taxa, and in the remaining 8%, the sexes were equal in size. In general, females are typically larger in smaller-sized species and males are larger in larger-sized species and in terrestrial forms.[32,43]

Many male aquatic turtles have elongated foreclaws that they use to court females. Forelimb claw length is dimorphic in *Trachemys*, *Pseudemys*, *Chrysemys*, and *Graptemys*. Male three-toed box turtles (*Terapene c. triunguis*) have a thickened, curved inner rear claw (Fig. 7.35), and males of some marine species have a hooked claw on the front flipper. These claws allow the male to hold onto the female during copulation. Sexually mature female leopard tortoises (*Stigmochelys pardalis*) have elongated rear claws, perhaps as an aid for nest digging (see Fig. 7.35). Chin (or mental) glands, unique to *Gopherus*, are more developed in males than females, vary seasonally under testosterone influence, and are largest during the fall breeding season (Fig. 7.36). Chin glands ooze long chain fatty acids, which are thought to identify conspecifics and establish rank and territory during courtship and mating.[44]

Sexual dichromatism is especially common among the emydid and geomydid turtles. Mature males and females may differ in coloration of the head, iris, chin, or markings on the head. A well-known example in the box turtle is the bright red iris of males compared with the yellow to reddish brown iris of females (Fig. 7.37). Some of these differences are observable only in males during the breeding season; for example, breeding male batagurids have much more colorful heads than females (Fig. 7.38).

FIG 7.36 Chin, or mental glands, are more prominent in male *Gopherus* spp., enlarge during the breeding season under the influence of testosterone, and are used to identify conspecifics and mark territory. (Courtesy of Thomas H. Boyer.)

Cardiovascular System

Chelonians have four-chambered hearts[45,46] consisting of one sinus venosus, two atria, and one ventricle with three subchambers (cavas), which effectively segregate oxygenated and deoxygenated blood. Heart location moves caudally with neck retraction. The heart is situated on midline except in Trionychidae, which have a more flattened carapace, and, perhaps to make more room for neck retraction, the heart and liver are displaced to the right with the stomach on the left.[45] The heart is bathed in clear colorless to slightly yellow pericardial fluid within the pericardial sac and bordered laterally by the acromium and coracoid processes.[46] Comparatively there is more pericardial fluid than one sees in mammals. A ligamentous gubernaculum cordis attaches from the ventricular apex to the posterior pericardial sac and serves as the anchor for the ventricle.[45,46] The pericardial sac is contiguous ventrally with the coelomic membrane. Surgeons should be aware that a ventral midline, anterioposterior, coelomic membrane incision can inadvertently enlarge into the pericardial sac, which can be repaired or avoided. Deoxygenated blood returns to the dorsally located, thin-walled, but muscular, sinus

venosus, which receives blood from the right and left cranial vena cavas, caudal vena cava, and the left hepatic vein.[47] The sinus venosus has cardiac muscle that acts as a cardiac pacemaker, and size varies considerably between genera.[45] The right atrium is considerably larger than the left atrium and neither has auricles. Three great vessels arise from the ventricle, including two aortas and the common pulmonary artery or trunk. The left-most trunk is the pulmonary artery, which splits into pulmonary arteries to each lung. The middle trunk, the left aorta, supplies blood to the viscera. The third, the right aorta, is obscured ventrally at its base by a brachiocephalic artery or trunk that immediately arises from it. The brachiocephalic trunk, or artery, supplies blood to the head and limbs and bifurcates into the large subclavian arteries, which are good landmarks for the thyroid gland located between them, just anterior to the heart.[46,47] The left and right aortae curve posteriodorsally to rejoin caudal to the heart and form the dorsal aorta.

Chelonians are capable of remarkable apnea (see neurology and pulmonology). During apnea of diving, the heart rate and pulmonary blood flow decrease by 50% and 80%, respectively, with a 150% increase in pulmonary resistance, resulting in a 50% or more intracardiac R-to-L shunt. During air breathing, heart rate and pulmonary blood flow increase two- and three-fold, respectively, which results in a net L-to-R shunt.[48] Baseline mean arterial and systolic pressures, ± SD, of six gopher tortoises (*Gopherus polyphemus*) were 56 ± 10 mmHg and 65 ± 11 mmHg, respectively.[49]

Renal portal systems exist in chelonians, as in other reptiles (see nephrology). The clinical significance of this is debatable; however, drugs are often given in the front half of the body to avoid the potential for renal toxicity or accelerated clearance of drugs excreted by tubular secretion.

Nervous System

Like other vertebrates, turtles have a central nervous system (CNS) consisting of the brain and spinal cord and a peripheral nervous system, which transmits signals between the CNS and the remainder of the body (see neurology). The turtle brain includes the typical vertebrate components, including the olfactory bulb, cerebral cortex, thalamus, hypothalamus, pituitary, optic lobes, cerebellum, and medulla.[50] While in most reptiles the neocortex is lacking, in chelonians, there is some evidence that the dorsal cortex is homologous to the neocortex of mammals.[51] The brain is well protected within the osseous brain case, which is surrounded by the more superficial but very dense bones of the skull. Accessing the brain during postmortem investigation can be challenging, especially in very large individuals. The spinal cord is surrounded by vertebrae as in other species, including the mobile cervical and coccygeal vertebrae, as well as the fixed vertebrae that are incorporated into the carapace. As a result, traumatic midline carapace injuries may affect the spinal cord. The brain and spinal cord are surrounded by two meningeal layers, including the inner leptomeninx and the outer dura mater. Cerebrospinal fluid (CSF) fills the space between these meninges, and this is the space that is targeted for intrathecal injections of analgesics or anesthetics, as well as cerebrospinal fluid collection. Reptiles lack a subarachnoid space. The epidural space is generally rich in vascular supply but does not contain CSF.[50] The brains of some turtle species have evolved a suite of physiological mechanisms to be extremely tolerant of hypoxia or even anoxia.[52] For example, one study found that painted turtles (*Chrysemys picta*) submerged in hypoxic water at 3°C survived for an average of 126 days, with some surviving as long as 177 days.[53]

Chelonians have the typical 12 cranial nerves as seen in other vertebrates, and some authors also include the nervous terminalis, or nerve 0, in the list of reptilian cranial nerves.[50] The cranial nerves are involved with olfaction, vision, taste, hearing, balance, and movement of the eye, facial muscles, tongue, pharynx, glottis, neck, and shoulders. In addition, nerve X, the vagus, has its typical role in regulation of the heart and viscera. Cranial nerve examination and general neurologic examination methods[54–58] are effective for chelonians, although some responses (e.g., olfaction) may be difficult to determine.[55]

VetBooks.ir

Nonreproductive Endocrine System

The thyroid gland is unpaired and located just anterior to the heart. Anterior to the thyroid gland is the thymus. The thymus does not involute as in mammals and is not part of the endocrine system. Chelonians have two pairs of parathyroid glands, one pair within the thymus, one pair near the aortic arch. Parathyroid hormones regulate calcium and phosphorus metabolism. Also found with the caudal parathyroid glands are miniscule paired ultimobranchial bodies, which are homologous with the thyroid parafollicular cells of mammals that secrete calcitonin.[17] The adrenal glands are located retrocoelomically just cranial to the kidneys and produce catecholamines, glucocorticoids, and mineralocorticoids. Increased corticosterone concentrations have been documented in chelonians under physical or physiological stress.[59] The pituitary gland produces nine hormones and is found just below the optic chiasma in the sella tursica of the sphenoid bone.[17] The chelonian pancreas serves the typical vertebrate endocrine functions of insulin and glucagon production.

Special Senses and Salt Glands

Chelonians lack a parietal eye, but do have a pineal gland that may affect behavior, gonadal activity, and thermoregulation.[17] The sense of smell is well developed; terrestrial chelonians have large olfactory bulbs and a modified Jacobson's organ. Chelonians have excellent hearing, especially freshwater emydid species, even though they have no external ears.[7] Chelonians respond to low tones ranging from 100 to 700 Hz,[51] good for sensing ground vibrations and predator approach. Sea turtles appear to be most sensitive to underwater acoustic stimuli below 1000 Hz, suggesting that sea turtles are able to detect much of the low-frequency and high-intensity anthropogenic sound in the ocean, including shipping, pile driving, low-frequency active sonar, and oil and gas exploration and extraction.[60] Chelonians have a large middle and internal ear beneath the tympanic membrane, just caudal to the angle of the jaw, with a large bony case surrounding them. Sound reception involves the tympanic membrane, the attached extracolumella cartilaginous footplate, and the thin osseous columella, which connects to the inner ear. The Eustachian, or auditory tube, connects the inner ear to the oropharnyx.

Freshwater turtles are more far-sighted than terrestrial species, and both react more to movement than shape. Cones are the predominant photoreceptors, typical for predominantly day-active animals. Color vision is especially good for red, yellow, and orange wavelengths, which may partially explain chelonian attraction to colorful foods.[7,32] The retina is avascular but does have a vascular projection from the optic nerve, the conus papillaris. Chelonians have upper and lower eyelids, a nictitating membrane (greatly reduced in Carettochelys) and scleral ossicles surround the globe. The iris is composed of skeletal muscle. Red-eared sliders possess slow pupillary light reflexes (PLRs). Direct pupil diameter decreased by 31% from 36 to 72 seconds, and consensual pupil diameter decreased by 11% from 85 to 120 seconds.[61] Given the small size of chelonian eyes, without specialized testing equipment, PLRs can be difficult to observe. Intraoccular pressure has been measured in several species (see ophthalmology). The craniomedial Harderian and caudomedial lacrimal glands produce the tear film. These glands and ducts are prone to obstruction and cystic enlargement in carnivorous and some omnivorous chelonians with hypovitaminosis A. Herbivorous chelonians can synthesize vitamin A endogenously. Chelonians have no nasolacrimal ducts, so tears spill over lid margins, which is especially pronounced in sea turtles and red-footed (*Chelonoidis carbonaria*) and yellow-footed tortoises (*Chelonoidis denticulata*). Tears are also lost by evaporation or conjunctival tissue absorption.[17]

In sea turtles and diamondback terrapins, the lacrimal gland has evolved into a salt-excreting gland (Fig. 7.39). These glands function along with the kidneys to regulate plasma electrolytes in the presence of a hypertonic environment. Plasma osmolality and concentrations of sodium, chloride, potassium, and magnesium can be influenced by salt gland function.[62]

Snake Taxonomy, Anatomy, and Physiology

Richard S. Funk and James E. Bogan, Jr.

Of the approximately 3400 species of living snakes (see http://www.reptile-database.org/), relatively few are well known in nature, and some are threatened with extinction. For example, the unique Round Island burrowing boa (*Bolyeria multocarinata*) has become extinct in recent times due to soil erosion and general habitat decline.[1] Snake species seen by practicing veterinarians are mainly from three families, the Boidae, Pythonidae, and Colubridae (Fig. 8.1). We cannot assume the anatomy and physiology is the same for all these species, and we must keep in mind that we are extrapolating drug dosages and clinical therapies based on research from relatively few species.

Snakes and lizards are related and classified together in the order Squamata. Snakes are subgrouped into the clade Ophidia, which contains a dozen clades of extinct, prehistoric snakes, as well as the suborder Serpentes, which includes modern snakes.[2] Among the more than 70 anatomical features shared by lizards and snakes are the paired copulatory organs, the hemipenes, located in the base of the tail. Limb reduction has occurred in at least 25 lineages among the Squamata.[3] In pythons the presence of more than 300 precloacal vertebrae, limb loss, body elongation, and loss of axial regionalization are a result of the expression of Hox (homeobox) genes; the Hox genes for thoracic development are expressed but those programming for forelimb development are not.[4,5]

Snakes are limbless with a rigid braincase that has the frontal and parietal bones articulating with the sphenoid bones and a kinetic skull with a joint between the frontals and the nasal region. They lack external ear openings and a tympanum. The ophthalmic branch of the trigeminal nerve enters the orbit via the optic foramen, whereas in other squamates it enters the orbit posteriorly. They have many precloacal vertebrae, from 120 to more than 400, with no regional differentiation posterior to the atlas and axis. Snake eyes have no scleral ossicles and no muscle in the ciliary body, and the eye is covered with a transparent spectacle or reduced and covered with a scale. They have no dermal osteoderms.[5–7] Within a snake's elongated body, paired organs are also elongated and tend to be staggered with one cranial to the other.

Among the snakes are species that mature at less than 10 cm (4 inches) in total length, and those that attain huge proportions of several meters and consume large prey. Much discussion and publicity centers around the so-called giant snakes. Many of the records of truly huge snakes remain dubious and unsubstantiated, because they are poorly documented. A review of the literature on giant snakes lists the four species that probably exceed 6 m (20 ft) in total length: the anaconda (*Eunectes murinus*) of South America, the Burmese python (*Python bivittatus*) of Southeast Asia, the reticulated python (*Malayopython reticulatus*) of Southeast Asia, and the African Rock Python (*Python sebae*) of Africa.[8,9] The two largest species are the anaconda and the reticulated Python, both of which approach 9 m (30 ft), but no valid records are seen of either beyond that length. An anaconda has a greater girth and mass than a reticulated python of the same length.

In captivity many snakes can live for over 20 years, with the record being a 47.5-year-old ball python (*Python regius*) at the Philadelphia Zoo.[10]

This discussion of snake biology focuses on the clinically significant aspects of their lives for an appreciation of their uniqueness and diversity. Few disease conditions are mentioned in this discussion because they are covered elsewhere in this volume.

TAXONOMY

Snake systematics is constantly changing. Difficulties occur when trying to arrange snakes into a meaningful higher classification because of a poor fossil record. Additionally, because snakes have evolved an elongated body adapted to a crawling mode of existence, they have relatively few external features, thus systematists have relied heavily on features of internal morphology. More recently, molecular data have been analyzed to elucidate the relationships among the living snakes.

Snakes are characterized by features that are shared with lizards. Recent trends in phylogenetics, considering both morphologic and molecular data, place the lizards, snakes, and tuataras in the clade Lepidosauria, as a sister taxon to the Archosauria, which includes chelonians, crocodilians, and birds.[5,11–14]

The classification listed here differs dramatically from that presented in the second edition of this text, particularly in recognizing new families and subfamilies. Molecular analyses of snakes reveal major departures from previous phylogenies that were based primarily upon morphology. The most recent and thorough phylogeny is based upon analyzing nuclear and mitochondrial DNA of 4161 squamate species, including all known families and subfamilies of snakes,[11] and appears to be the most accurate reflection of relationships of extant snakes. Table 8.1 summarizes this classification.

A brief listing of the content and some characteristics of the higher snake taxa may be useful in appreciating the diversity of living species. Brief listings are also given of their geographical distributions. The * indicates families most often seen in herpetoculture (Figs. 8.2 to 8.16).

Infraorder Scolecophidia: The Blind Snakes

These snakes have blunt heads, short tails, vestigial eyes with only rods, and a multilobed liver, and the lower jaws are attached to each other anteriorly. They are fossorial and oviparous, have smooth scales with no enlarged ventral scales, and eat invertebrates, especially ants and termites.

Family Anomalepididae: Dawn blind snakes. Four genera, 15 species, Central and South America. These may prove to be a sister taxon to all other living snakes and not be scolecophidians.

Family Leptotyphlopidae: Thread snakes. Four genera, 50+ species. Southwest United Sates through South America, Africa, and Southwest Asia. Unique among vertebrates in having a mandibular mechanism used to rake food into the mouth.

VetBooks.ir

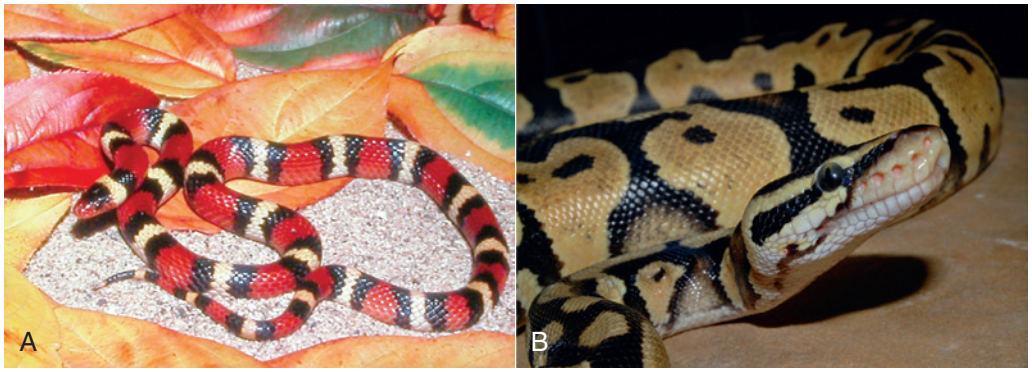

FIG 8.1 The two most common groups of snakes seen by veterinarians in clinical practice are colubrids, such as (A) the scarlet king snake (*Lampropeltis elapsoides*) and boids, such as (B) the ball python (*Python regius*).

FIG 8.2 This adult Sri Lankan pipe snake (*Cylindrophis maculatus*) of the family Cylindrophidae exhibits automimicry with a flattened, elevated tail that is slowly moved in a side-to-side fashion. These viviparous snakes eat relatively large, elongated prey.

FIG 8.3 Sri Lankan shield-tail snake (*Uropeltis phillipsi*) of the family Uropeltidae. The head is the small pointed end. The soil adheres to the robust tail and helps block the burrow from behind.

FIG 8.4 Neotropical sunbeam snake (*Loxocemus bicolor*) was formerly called the "new world python." This oviparous and fossorial snake feeds on lizards, reptile eggs, and rodents.

FIG 8.5 Boa constrictor (*Boa constrictor*), a common pet snake, is generally considered docile. It is now available in a number of colors and patterns. Although these snakes can attain lengths of more than 3 m (10 ft), most do not grow that large.

Family Gerrhopilidae: Blind snakes. One genus, 15 species. Indonesia, New Guinea, Southeast Asia, India.
Family Xenotyphlopidae: Malagasy blind snakes. One genus, Madagascar.
Family Typhlopidae: Cosmopolitan blind snakes. Ten genera, more than 250 species. Worldwide in tropical climes. One parthenogenetic species also becoming worldwide.

Infraorder Alethinophidia

Now defined to include all of the living snakes except the blind snakes. These snakes have a kinetic skull and share other important details of morphology. A diverse variety of sizes and habitats.
Family Aniliidae: South American or red and black pipe snakes. One species. Northern South America.

*Indicates families most often seen in herpetoculture.

FIG 8.6 Juvenile ringed python (*Bothrochilus boa*) from the Bismarck Archipelago. An active species in which adults are brown ringed with black or uniformly brown, with high iridescence.

FIG 8.7 The popular carpet python (*Morelia spilotus variegatus*) is from Australia. This photo shows the typical forked tongue and also, in this case, the labial heat pits. This python typically reaches lengths of 2 m (6–7 ft).

FIG 8.8 Albino house snake, *Lamprophis fuliginosis*, Lamprophiidae. A nonvenomous African snake that is hardy in captivity, producing multiple clutches per season.

VetBooks.ir

FIG 8.9 The dwarf boa (*Tropidophis canus curtus*) of the family Tropidophiidae is a live-bearing snake. Species in this genus have a defensive behavior involving flushing blood across the subspectacular space and out the mouth onto a predator (or human handler). This species possesses a yellowish tail tip that functions as a caudal lure for its prey of frogs and lizards.

FIG 8.10 The yellow-bellied water snake (*Nerodia erythrogaster flavigaster*) is a representative of a group called Natricines, which are mostly associated with aquatic habitats. North American natricines are viviparous, but most old-world species are oviparous.

FIG 8.11 This adult mud snake (*Farancia abacura reinwardti*) is exhibiting parental care, coiling around her clutch of eggs until they hatch. This type of parental care is also seen in some pit vipers and notoriously among pythons, the latter of which thermoregulate to control their clutch's incubation temperature.

FIG 8.12 The copperhead (*Agkistrodon contortrix contortrix*) is a terrestrial pit viper from eastern United States, with a pattern that is cryptic among leaves on the ground.

FIG 8.13 The sidewinder (*Crotalus cerastes laterorepens*) is a species of rattlesnake from the deserts of the southwestern United States. Shown are the rattle on the tail tip, facial heat pit, forked tongue, and supraocular horns that may function to keep blowing sand off the eyes. Rattlesnakes occur only in the New World, and all species are viviparous. A new rattle segment is added with each shed, and rattles may break off. Certain African vipers that sidewind also have supraocular horns.

Family Tropidophiidae: Caribbean wood snakes. Two genera, 25 to 30 species. West Indies and Central and South America. Viviparous small constrictors, most with pelvic vestiges. A unique defensive mechanism starts with ocular (subspectacular) hemorrhage that progresses to oral hemorrhage, the function of which is conjectural. Once placed within the Boidae.

Family Xenophidiidae: Spine-jaw snakes. Two species, Malaysia. They have a large anterior caninelike tooth on their dentary bone.

Family Bolyeriidae: Round Island boas. Two monotypic genera. *Bolyeria* became extinct about 1975. Unique among tetrapod vertebrates in having divided (hinged) maxillary bones. *Casarea* is oviparous. Formerly placed with the Boidae.

Family Calabariidae: Calabar ground boa. One monotypic genus. Central and West Africa. A cylindrical, mostly fossorial, oviparous constrictor with tiny eyes.

*Family Boidae: The boas. Eight genera and about 40 species. Viviparous except two oviparous species of *Eryx*. New World and Madagascar, Africa to southern Asia, and Southwest Pacific Islands. Most have infrared labial receptors. All are constrictors. Cloacal spurs present.

Subfamily Sanziniinae: Madagascan tree boas. One genus and species, Madagascar.

Subfamily Ungaliophiinae: Dwarf boas. Four genera and 5 species, now defined to include the rubber boas *Charina* and the rosy

VetBooks.ir

FIG 8.14 This spectacled cobra (*Naja naja*) is showing the "hood," an extended portion of the neck that can spread by expanding neck ribs laterally. Cobras are highly venomous elapids, and some species can even spit venom at a predator's (or human's) face or eyes. Cobras account for many human deaths and also figure widely in religion and folktales.

FIG 8.15 Western beaked snake (*Rhamphiopus oxyrhynchus*) Lamprophiidae. A mildly venomous terrestrial and burrowing African snake. (Courtesy of Richard S. Funk.)

boas *Lichanura* of western North America. From the United States southward to Colombia.

Subfamily Candoiinae: Pacific boas. One genus, 3 to 4 species. Southwest Pacific Islands. One is quite viperlike in habitus.

Subfamily Erycinae: Sand boas. One genus, 8 species. Central Africa through Asia to China. Viviparous with two oviparous species.

Subfamily Boinae: The boas. Central and South America, West Indies. Includes the anaconda and boa constrictor. Most with labial infrared receptors.

Family Anomochilidae: Dwarf pipe snakes. Sumatra, Bornea, Malaysia. Two species known from less than a dozen specimens. Oviparous. Have yellow or white spots and a red tail band.

FIG 8.16 Adult ball python (*Python regius*) showing the row of facial sensory pits in the upper lip scales. (Courtesy of Richard S. Funk.)

Family Cylindrophidae: (Asian) Pipe snakes. One genus, 8 species. Sri Lanka, Southwest Asia, Indoaustralian Archipelago. Fossorial, viviparous, utilize caudal automimicry.

Family Uropeltidae: Shieldtail snakes. India and Sri Lanka. Eight genera and 50 species. Specialized burrowers with blunt tails and a unique locomotion with the skin in contact with, and pushing off of, the walls of the burrow, while the inner body is moving along relative to the skin.

*Family Xenopeltidae: Sunbeam snakes. One genus with 2 species. Southeast Asia, Burma to the Philippines. Highly iridescent fossorial snakes, constrictors, no pelvic vestiges, oviparous; hinged teeth that change ontogenetically reflecting dietary shifts, bicuspid in juveniles.

Family Loxocemidae: Neotropical sunbeam snake (called New World Python in older literature). One monotypic genus, originating from Mexico to Costa Rica. Similar to Xenopeltidae, they are also iridescent and fossorial/terrestrial constrictors with no pelvic vestiges and oviparous.

*Family Pythonidae: Pythons. Eight genera, 25 species. Africa, South Asia, Indoaustralia, and Australia. Oviparous with maternal care of the eggs. Includes several of the largest known living snakes.

Family Acrochordidae: Wart snakes or elephant trunk snakes. One genus with 3 species. India to northern Australia and Solomon Islands. Aquatic, mainly marine and brackish waters. Scales small and strongly keeled that gives them a sandpaper-like texture, with loose skin; can catch fish with body folds and skin. One species known to be parthenogenetic.

Family Xenodermatidae: Dragon snakes, tubercle snakes. Six genera, 17 species. Southern India, Indochina to Japan, Malaysia to Java, Borneo, and Sumatra. Have small eyes, over 20 maxillary teeth, and are oviparous.

Family Pareatidae: Slug-eating snakes. Three genera, 15 species. Southeast Asia to Borneo, Java, Mindanao. Oviparous slender arboreal snakes with a blunt snout, no teeth on anterior maxillary; able to pull snails from their shells with elongated mandibles and sharp teeth.

*Family Viperidae: The vipers and pit vipers. About 25 genera with 240 species. Basically, worldwide except Australia, New Guinea, and the Pacific oceanic islands. All are venomous, some highly dangerous. Solenoglyph dentition, with fang erection in a posterior-anterior direction. Includes the true vipers, pit vipers, rattlesnakes, moccasins, and their allies. Many habitats and lifestyles, both oviparous and viviparous species, including some rattlesnakes with parental care.

VetBooks.ir

Subfamily Viperinae: Vipers. Thirteen genera and 90 species. Europe, Africa, and Asia. All less than 2 m in length, both oviparous and viviparous species, no loreal pit.

Subfamily Azemiopinae: Fea's viper. One monotypic genus. China, Vietnam, and Burma. Oviparous, no loreal pit.

Subfamily Crotalinae: Pit vipers. Twenty-three genera, 220 species. Southwest and southern Asia and the New World. Have a well-developed loreal pit that is infrared receptive. Both oviparous and viviparous species, some with parental care of eggs or neonates. Bushmasters (*Lachesis,* 3 species) of Central and northern South America are the longest venomous snakes and may reach 3.75 m in length.

Family Homalopsidae: Asian water snakes. Eleven genera with 40 species. South Asia southward to northern Australia. Aquatic with dorsal valvular nostrils and dorsally oriented eyes and tightly fitting labials. Viviparous and venomous with 2 to 3 grooved posterior maxillary teeth.

*Family Lamprophiidae: Stiletto snakes and mole vipers, keeled snakes. About 300 species. Subsaharan Africa and Madagascar. Diverse sizes and habitats, oviparous. Sister group to elapids.

Subfamily Prosymninae: Shovelsnout snakes. One genus, 16 species. Subsaharan Africa. Oviparous, with a diet mainly of lizard and snake eggs.

Subfamily Psamophiinae: Grass snakes. Seven genera, 50 species. Africa, South Asia, southern Europe, and the Middle East. Oviparous. Fast diurnal predators mainly of lizards, and one species purported to be the fastest snake.

Subfamily Atractaspidinae: Stiletto snakes (formerly called mole vipers). Two genera, 21 species. Subsaharan Africa, Israel, and Arabian Peninsula. Highly venomous, envenomate with a lateral and posterior jab; cannot be safely handheld.

Subfamily Aparallactinae: Centipede-eaters. Subsaharan Africa. Two genera with 50 species. Oviparous and viviparous with opisthoglyphic or proteroglyphic teeth.

Subfamily Pseudaspidinae: Mole snakes or mole vipers. Two monotypic genera. Africa, Southeast Asia, Malaysia. Viviparous.

Subfamily Lamprophiinae: House snakes, et al. Eleven genera, 70 species. Subsaharan Africa. Grouping defined mainly by molecular data. Oviparous.

Subfamily Pseudoxyrhophiinae: Malagasy brown snakes, brook snakes. Sixteen genera, 50 species. Subsaharan Africa, Madagascar, Yemen. Oviparous. Includes *Langaha* and *Lioheterodon.*

*Family Elapidae: the elapids, including cobras, kraits, taipans, death adders, mambas, coral snakes, and sea snakes. Sixty-two genera with 350 species. North, Central, and South America; Africa; southern Asia to Australia; Pacific and Indian Oceans. Proteroglyph dentition. All venomous, some not dangerous to humans but some among the deadliest. Most oviparous.

*Family Colubridae: "Common" colubrid snakes. Over 100 genera and 1800 species. Most of the world except Antarctica, Greenland, Iceland, and Ireland. Previous concepts of this family proved to be a polyphyletic assemblage of snakes. As now perceived it is a somewhat smaller but still widespread and diverse grouping. Aside from the boas and pythons, colubrids include most of the nonvenomous snakes we see in herpetoculture, such as king snakes, rat snakes, racers, garter snakes, and gopher snakes. Oviparous and viviparous.

Subfamily Calamariinae: Reed snakes. Six genera, 90 species. India, Southeast Asia, South China, Japan, and Malaysia through Indonesia and the Philippines. Fossorial.

Subfamily Pseudoxenodontinae: Bamboo snakes. Three genera, 13 species. Southeast Asia, Tibet, Taiwan, Indonesia, often at high elevations.

Subfamily Sibynophiinae: Collared or black-headed Snakes. One genus, 6 to 8 species. Southeast Asia, Malaysia, Taiwan. So-called "goo-eaters" feeding on slugs and snails. Oviparous.

Subfamily Grayiinae: African water snakes. One genus, 4 species. Subsaharan Africa, mainly aquatic, oviparous.

Subfamily Colubrinae: Common or colubrid Snakes. One hundred genera, 650 species. Worldwide as for the family. Diverse sizes and habitats, generalists and specialists, oviparous and viviparous. Includes king snakes, rat snakes, racers, and gopher snakes.

Subfamily Natricinae: Water snakes. Thirty-eight genera, 215 species. North and Central America, Africa, Eurasia, East Indies. Many are aquatic. Old World members are oviparous, New World ones viviparous. Includes *Natrix* and *Nerodia.*

Subfamily Dipsadinae: Dipsadine snakes. Ninety-seven genera, 740 species. Most of the New World. Mostly oviparous, diverse in sizes and habitats. Includes several familiar North American snakes, including *Diadophis, Farancia,* and *Heterodon.* Mostly oviparous.

ANATOMY AND PHYSIOLOGY

The following sections refer to Fig. 8.17.

Integument

Snake scales are essentially made of folds of the epidermis and dermis, but the scales themselves are epidermal in origin. Except for the head, they typically overlap each other. A variety of pits, ridges, keels, and tubercles, mostly of unknown function, are present on snake scales. Regional differences occur, with enlarged head shields, a series of rows of small dorsal scales covering the body and tail dorsally and laterally, as well as larger and wider ventral scales that provide support and protection ventrally. Scolecophidians and some sea snakes lack enlarged ventral scales. Most snakes have an enlarged scale or pair of scales that cover the cloacal opening. Dorsal scales are usually in odd numbers or rows, with a maximum number near midbody and fewer rows near the head and cloaca. The keratinized scales and skin protect the snake from abrasions and dehydration.

Almost no skin glands are present in snakes, but paired scent glands are characteristic (Fig. 8.18). These glands are a pair of organs located within the base of the tail, dorsal to the hemipenes in males, and they open into the posterior margin of the cloacal opening. Their unpleasant odor plays a part in defense and may also carry social signals. In captivity, they may become enlarged, impacted, or abscessed. (See Chapters 80 and 171.)

Shedding, or ecdysis, is a complex event histologically.[5,6,15–19] With hormonal input from the thyroid gland, during shedding, a synchronous proliferation of the epithelial cells from the stratum germinativum occurs. This forms a new epithelial generation between the stratum germinativum and the older outer epidermal layer. This younger epidermal layer keratinizes and comes to resemble the (older) outer layer. During separation of these two generations of epithelium, anaerobic glycolysis assists in separating the outer layer, and acid phosphatase helps break down the cementing material. The snake has a dull "blue" look to it as a thin fluid forms between the two layers (Fig. 8.19).

Herpetoculturists call their snakes "blue" or "opaque" at this time. A snake will go blue for several days, then clear up as the fluid is resorbed, and then proceed to shed its entire skin. Healthy snakes shed the entire outer layer as one event, but the older outer layer may tear during shedding especially in larger snakes. The epithelium covering the spectacles (the eye caps) are also shed together with the rest of the skin (Fig. 8.20). During this shed cycle, many snakes refuse food and seek

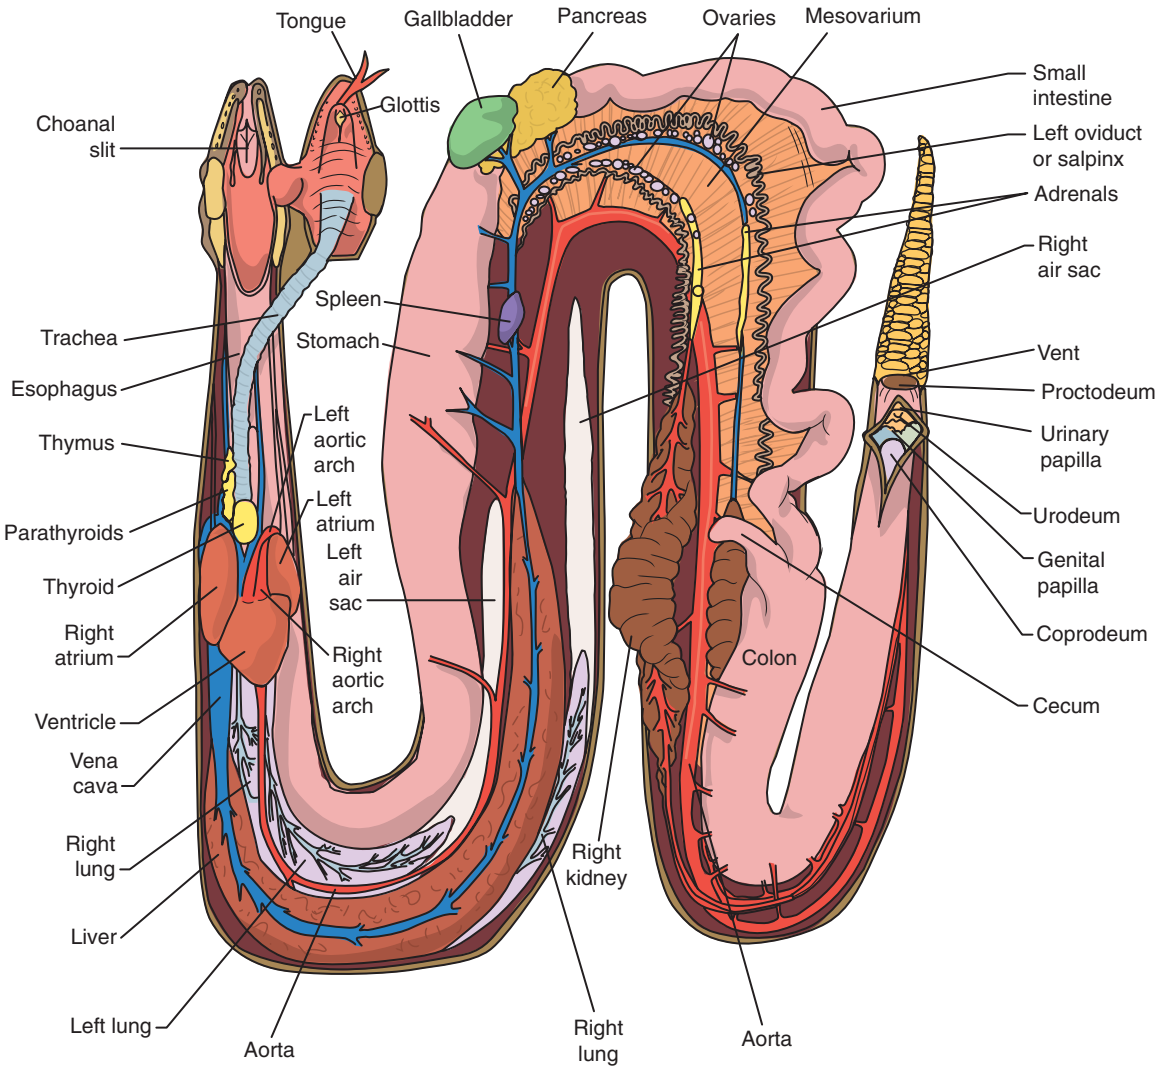

FIG 8.17 Gross anatomy of the snake, ventral view.

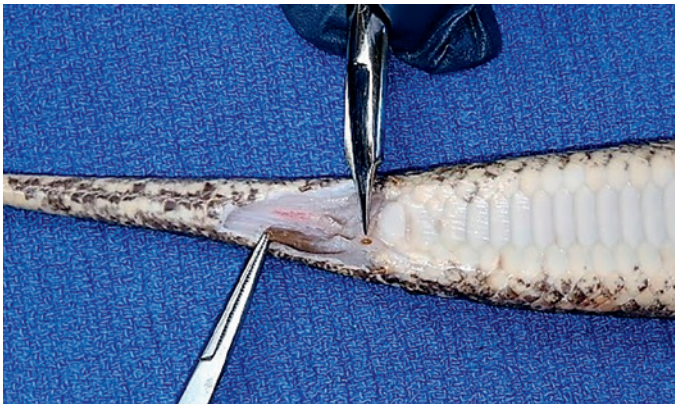

FIG 8.18 Almost no skin glands occur in snakes, but cloacal scent glands are characteristic. A prosection of a female ball python (*Python regius*) showing the location of the paired cloacal scent glands in the tail base. The caudal vent rim and some subcaudal scales have been removed to show the location of the left scent gland (grasped by hemostats) and the opening of the scent gland with scent gland material evident (at the tip of the scissors). (Courtesy of Greg Costanzo, Stahl Exotic Animal Veterinary Services).

FIG 8.19 A shedding snake has a dull blue look to it as fluid forms between old and new layers of skin. Herpetoculturists call their snakes blue or opaque during this time. A snake "goes blue" for several days, clears, and then sheds. Arizona mountain king snake (*Lampropeltis pyromelana*) nearing shedding, showing dulled coloration and bluish coloration of the eyes. (Courtesy of Richard S. Funk.)

VetBooks.ir

FIG 8.20 Shed head and neck skin of a variable king snake (*Lampropeltis leonis*). Note that the skin has also been shed over each eye (eye caps). (Courtesy of Richard S. Funk.)

FIG 8.21 Captive propagation has produced a variety of genetic mutations, including partial albinos and leucistic individuals, and many pattern types, and has contributed to marketing of designer snakes or cultivars. Three neonate ball pythons (*Python regius*) illustrating some of the phenotypic variation being selectively produced in captivity. (Courtesy of Richard S. Funk.)

shelter, often in a moist or humid site. They will often resume feeding immediately after ecdysis.

Dysecdysis is the term for improper shedding and may be caused by incorrect humidity, lack of a proper substrate, improper handling, malnutrition, dermatopathy including ectoparasites, or trauma.

Pigment cells within the skin create the skin coloration and pattern, but microscopic surface structures can yield an iridescence. Ontogenetic color and/or pattern changes occur in some species. Some species, especially in juveniles, have brightly colored tails that are used as caudal lures to attract prey. Coloration may also vary geographically. Polymorphism is unusual, but for example the Turk's Island boa (*Chilabothrus chrysogaster*) and California king snake (*Lampropeltis californiae*) have both striped and blotched or banded individuals within the same populations. Many boas are darker during the day and lighter or paler at night.

In recent years there has been great success in the captive propagation of a variety of snake species with a wide variety of color and pattern mutations. Albinos, leucistics, hypomelanistic, patternless, and even scaleless varieties have become popular. For example, well over 100 "morphs" of the ball python are currently available in the pet trade in the United States.[20] These new mutations are often marketed under unusual names, often coined by the first breeder to produce the morph, for example, the "bumblebee," "clown" and "GHI" (got to have it) ball python morphs (Fig. 8.21). Of course, price varies with pattern and coloration. Such color mutant production often unfortunately necessitates significant inbreeding.

Cardiovascular System

Snakes have traditionally been thought to have a three-chambered heart, but with recent study the sinus venosus has been determined to function as a true chamber, and now many experts consider snakes to have a four-chambered heart. The four chambers include the sinus venosus, a right and left atrium, and a ventricle (see Chapter 68). Although communication exists between the ventricular halves, considerable functional separation exists between the oxygenated and unoxygenated circuits leaving the heart. The heart becomes functionally five-chambered, with the two systemic arches and the pulmonary artery all exiting the ventricle. Further, right-to-left and left-to-right shunting is also possible between the oxygen-rich and the oxygen-poor circuits, under control of several mechanisms.[21] Details of this are complex and beyond the scope of this brief introduction (see Chapter 68). Burmese pythons have been shown to have the remarkable ability to increase the ventricular mass of their hearts by 40% within 2 days of feeding by synthesizing new protein.[22] Once the digestive process has been completed, the cardiac hypertrophy resolves, and the heart returns to its previous size.[23] These findings, however, are often inconsistent and not always reproducible,[23] and the hypertrophy may instead reflect stressed conditions.[24]

The position of the heart within a snake's body varies somewhat with its ecological niche; arboreal snakes' hearts are more cranial, and fully aquatic snakes tend to have a more centrally located heart.[21] The long axis of the heart is oriented craniocaudally with the atria located cranially. With no diaphragm, the heart is somewhat mobile within the rib cage, perhaps facilitating the passage of relatively large prey past it. Two aortae are present, with the right aorta exiting the left side of the ventricle and the left aorta exiting the right side; they fuse caudal to the heart and form the abdominal aorta. The left systemic arch is larger than the right, which is the opposite of most tetrapods. Paired carotid arteries and jugular veins are located anterior to the heart near the trachea. The jugulars may be easily cannulated via a simple cut-down for placement of an intravenous catheter for obtaining samples or administering fluids or medications.

Snakes have been shown to be able to control arterial pressure reflexively, but this control is reduced when the snake's body temperature is higher or lower than preferred.[21,25] Additionally, oxygen dissociation curves of snake blood may also be influenced by temperature.[25] This has not been shown to be true in ball pythons, however.[26]

Snakes have both renal and hepatic portal circulations. For this reason, it has been recommended to administer parenteral medications eliminated from the body via the renal system, in the front half of the body, to avoid potential nephrotoxicity and first pass effects. However, studies have indicated that clearance of drugs via the renal portal system may rely more on how the kidneys clear a drug with tubular excretion affected more than glomerular filtration[27,28] (see Chapter 66 for a thorough discussion of the renal portal system). A ventral coelomic vein courses through much of the coelom, and it should be avoided when making a surgical approach to the coelomic cavity by entering at the edge of the rib cage between the second and third dorsal (lateral) scale rows.

The primary sites for obtaining blood samples in snakes include a ventral coccygeal vein and cardiocentesis. An alternative venipuncture site not commonly used is the jugular vein. The jugular vein is typically located 1/3 to 1/2 the distance between the base of the heart and the base of the skull. A blood sample can be collected by blindly inserting

the needle along the medial rib margins.[29] A cannulated jugular vein may also be used. Venipuncture of the dorsal palatine vein is frequently referenced; however, it is difficult to utilize without sedation and may result in a difficult to manage hematoma at the venipuncture site.

The normal hematocrit (packed cell volume) of snakes is about 20% to 30%. Based on a study in the black rat snake (*Pantherophis obsoletus*), the blood volume is equivalent to about 6% of the animal's body weight.[30] All circulating blood cells are nucleated, and the presence of occasional mitotic figures in the peripheral blood is normal. Azurophils are unique granulocytes that are seen in snakes and other reptiles. Although many snakes seem to lack eosinophils,[31,32] they have been documented in several species, including the king cobra (*Ophiophagus hannah*), puff-faced water snakes (*Homalopsis buccata*), grass snakes (*Natrix natrix*), and Asian vine snakes (*Ahaetulla prasina*)[32–37] (see Chapter 33). Snakes have lymphoid tissue associated with the gastrointestinal tract, and in boas, pythons, and a few colubrids there are tonsil-like structures in the esophagus;[38] these may have clinical significance in the identification of viral infections (Fig. 8.22).

Respiratory System

Although squamates typically have two lungs, in most snakes the left lung is greatly reduced, never more than 85% of the size of the right lung, or absent.[7,39] In boas and pythons the left lung is moderately large. The right lung generally courses from near the heart to just cranial to the right kidney. The cranial portion of a lung is vascularized, functioning in gas exchange, and the caudal portion functions mainly as an air sac (see Chapter 76); these can be termed the vascular lung and the saccular lung, respectively. Air is drawn into the nostrils and delivered to the choana medial to the maxillae, where the epiglottis fits when the mouth is closed.

The trachea has incomplete cartilaginous rings, with the ventral portion being rigid and the dorsal fourth being membranous. In many snakes, the vascular portion of the lung extends cranially into the trachea, with expansion of this dorsal membrane into a "tracheal lung"; in extreme cases the most functional portion of the lung is tracheal.[7,39,40] The wall of the vascular lung is comprised of honeycombed units called faveoli, through which gas exchange occurs; these are not homologous to mammalian alveoli. The Acrochordidae have tracheal air sacs, and in some aquatic snakes the lung extends posteriorly nearly to the cloaca as a hydrostatic adaptation. Variations in lung and tracheal morphology are useful taxonomic characteristics. Snakes lack a diaphragm, and inspiration occurs by muscular expansion of the rib cage to create negative pressure.

The glottis opens in the floor of the mouth caudodorsal to the tongue and is generally easily visualized, making intubation for anesthesia relatively straightforward. When consuming large prey, the glottis is quite mobile and can extend cranial and/or lateral as necessary to facilitate breathing during protracted ingestion. The epiglottal cartilage is quite enlarged and modified to facilitate defensive hissing in bull, gopher, and pine snakes (*Pituophis* spp.) (Fig. 8.23).

Digestive System

The digestive tract is essentially a linear duct from the oral cavity to the cloaca, which also receives products from the urinary and reproductive systems (see Chapters 73 through 75 on gastroenterology). The palatine, lingual, sublingual, and labial mucus-secreting glands in the oral cavity moisten the mouth and lubricate prey. Venom glands are modified labial glands and have evolved independently in several snake lineages. Snake venoms are extremely complex and used mainly for obtaining prey.

Six rows of teeth are generally present in snakes found in the pet trade, with one row on each of the lower mandibular bones and two on each maxillary region. Teeth are generally not regionally differentiated except for modified fangs in some species or in species with specialized feeding habits (none have molars, incisors, etc.). The dentigerous bones include the mandibles, maxillae, palatines, pterygoids, and sometimes the premaxillae. The teeth, including fangs, continue to be replaced throughout life. Usually a membranous flap covers the fangs when not in use. In vipers and pit vipers, the fangs fold caudodorsally and lie sheathed when the mouth is closed. But in elapids and others including colubrids with fangs, the fangs remain erect and cannot fold.

Snake teeth are basically elongated, slender, pointed, and slightly curved posteriorly. Snake teeth are modified pleurodont teeth with a rudimentary socket and are attached to the side of the bone.[41] More primitive snakes have all the teeth the same (homodont), whereas in the more advanced snakes, some teeth may be modified into grooved and hollow fangs. Historically, variations in the maxillary teeth have been classified as follows[41]:

Aglyphous: having homodont maxillary teeth.

Opisthoglyphous: "rear-fanged" with enlarged teeth on the posterior maxilla.

VetBooks.ir

Proteroglyphous: a solitary enlarged fang on the long maxillary bone that does not allow for erection of the fang (elapid type).

Solenoglyphous: the only tooth is a hollow fang on the short maxilla that can be erected by maxillary rotation on the prefrontal bone (viper type).

Many variations occur among these types. In elapids and vipers, the anterior fangs are hollow with a distinctive venom canal. These fangs are shed periodically. It is not uncommon to observe a functional fang and an adjacent replacement fang (destined to replace the currently functional one when it is shed) during examination of the oral cavity. The fangs may be lost as the prey is bitten and pass through the snake relatively undigested and appear in the feces.

Venom glands are modified labial glands, located in the upper jaw below the orbit, and have evolved independently in several snake lineages. The size and shape of the gland varies with the species. Rarely, the venom glands extend far caudally into the body even to the level of the heart (*Causus,* Viperidae; *Atractaspis,* Lamprophiidae; *Maticoura,* Elapidae). Venoms are extremely complex, containing toxic proteins varying from a few amino acids to much higher molecular weight that are used mainly for subduing prey. These toxins have been characterized by their activities: neurotoxins acting at neuromuscular junctions and synapses; hemorrhagins act to destroy blood vessels; and myotoxins act on skeletal muscle. Among the venom toxins are RNAses, DNAses, phospholipases, proteolytic enzymes, thrombinlike enzymes, hyaluronidases, lactic dehydrogenases, acetylcholinerases, L-amino acid oxidases, and others.[42] At least 10 enzymes are found in nearly all snake venoms, and a venom may contain more than two dozen proteins. A particular venom may have a number of receptor sites, and venoms can also have digestive properties. In fact, snake venoms are theorized to have evolved from digestive enzymes.[43] Older classifications of venoms as hemotoxic or neurotoxic are oversimplifications and inaccurate, and some venoms contain mixtures of both. The relative abundance of venom components in a particular species can vary geographically, seasonally, or with age.

Many colubrid and lamprophiid snakes have been reported to have elicited toxic reactions in humans. These reports need to be carefully evaluated; some species, lacking venom glands, may have oral secretions that can elicit an inflammatory reaction when a person is bitten. However, several colubrids are venomous and capable of serious and even fatal human envenomation.[18,44,45] Many colubrids have venoms that are toxic to their prey but not to humans. Individual human reactions can depend on many variables, such as the general health status of the person, the species involved, nature of the bite, the amount of venom injected, the site of the bite, the depth of the bite, and the activity of the venom. A full discussion of human snakebites is beyond the scope of this chapter. Nevertheless, understanding the risks involved is essential before seeing venomous snakes (see Chapter 22). Many jurisdictions have restrictions regarding the possession of venomous reptiles, and legal restrictions must be appreciated. Not all local human hospitals have the appropriate experience or antivenom on hand to treat bites particularly from exotic species. Proper identification of an exotic snake may be difficult. Prevention of snakebite is always preferred to treatment of a bite.

The tongue has a forked tip and lies within a sheath beneath the epiglottis and functions in olfaction, delivering particulate odors to the vomeronasal organs located in the roof of the mouth. Snakes that lose their tongues to trauma or infection may cease feeding.

The esophagus is distensible, and about half its length is largely amuscular. Snakes generally use their axial musculature and skeleton to help transport food to the stomach. Snakes do not masticate food items; rather, they swallow their prey intact. Snakes lack a well-defined cardiac (gastroesophageal) sphincter.

The stomach is muscular and distensible. The process of prey digestion begins in the stomach. The small intestines are relatively uncoiled and straight (compared with mammals, birds, and even lizards). The pancreas is generally located in a triad together with the gall bladder and spleen, distal to the posterior tip of the elongated, spindle-shaped liver. Some species have a splenopancreas.

The small intestine empties into the colon, which in turn empties into the cloaca. The cloaca has three regions and from cranial to caudal the order is coprodeum, urodeum, and proctodeum, and it receives products from the digestive, urinary, and reproductive systems. Urates and feces may be temporarily stored within the colon and cloaca. In boas and pythons a small cecum is present at the proximal colon. The intestines and cloaca play important roles in water conservation.

Fat bodies are present within the coelom, a row on each side of the body cavity and a smaller group cranial to the heart; these may be huge in an obese snake and tiny in an emaciated one.

Reproductive and Urinary Systems

The paired kidneys are located in the dorsocaudal coelom, approximately the last 25% of the snout-to-vent length, with the right kidney situated cranial to the left, far forward from the cloaca (see Chapter 66 Nephrology chapter). The kidneys are lobulated and elongated and arranged in a craniocaudal orientation. The ureters empty into the urodeum. Snakes lack a urinary bladder. Male snakes possess a sexual segment, consisting of distal convoluted renal tubules that hypertrophy during the reproductive season to produce a contribution to seminal fluid (Fig. 8.24). Affected kidneys may appear abnormal because of their increased size and paler coloration, and to the untrained eye, these kidneys may appear diseased (see Chapter 80). Uric acid is the primary nitrogenous waste and appears as whitish to yellowish urates, often voided with the feces. Snake kidneys are unable to excrete urine at a higher concentration than that of plasma.[25]

Male snakes have two paired intromittent organs that are invaginated within pouches in the ventral tail base. Each is called a hemipenis (plural, hemipenes). Hemipenial morphology has proven to be a valuable taxonomic character. During copulation, a hemipenis evaginates into the cloaca of the receptive female. The functional surface of the hemipenis facing her cloacal wall, when not in use, lines the lumen of the cavity in the male's proximal tail. Because of the presence of the hemipenes,

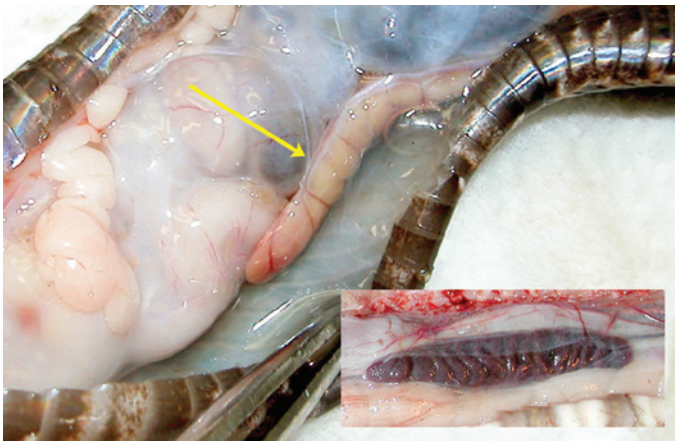

FIG 8.24 Male snakes have a "sexual segment" in their kidneys (yellow arrow), consisting of the distal renal tubules that enlarge during the reproductive season to produce a contribution to the seminal fluid. During this seasonal period, the kidneys appear abnormal because of dramatic size and color change, and this should not be misinterpreted as pathology. Insert shows a normal kidney during the nonreproductive season. (Courtesy of Douglas R. Mader.)

VetBooks.ir

a smooth lubricated (water-soluble) blunt-tipped probe may be carefully inserted into the base of the tail of a snake and into the lumen of the hemipenis to accurately identify gender. The male probes relatively deeply compared with the conspecific female. In many snakes, the tail base of a male is wider and straighter than a female's due to the presence of the hemipenes. With practice, probing is relatively safe and easy, and the authors recommend probing most snakes to ascertain their sex as part of the clinical physical examination.

In males and females, the gonads are situated cranial to the kidneys, with the right one more cranial than the left. The ovaries are located nearer the pancreas. The developing eggs or fetuses in the right uterus are carried cranial to those on the left side. Each oviduct has a separate opening into the cloaca at the urodeum. A few fossorial species have lost one ovary and oviduct. The fusiform testes are intracoelomic, situated between the pancreatic triad and the kidneys, and they enlarge and regress in size as the season changes (Fig. 8.25). Sperm is carried in the Wolffian ducts (vasa defferentia) into the urodeum and to the base of the hemipenis during copulation and travels up the sulcus spermaticus on the outside of the erected hemipenis into the female's cloaca (see Chapter 80).

Some snakes are oviparious (egg-laying) and others are viviparous (live-bearing). Very few snakes (notoriously the king cobra, *Ophiophagus hannah*) build a nest for egg incubation. Egg-brooding has evolved in several lineages (pythons; *Farancia* in the Colubridae; some *Trimeresurus* in the Viperidae); these females coil around their eggs until hatching (see Fig. 8.11). Some rattlesnakes (*Crotalus*) in the southwestern United States are known to exhibit some parental care and remain with their newborn until after they have shed.

No temperature-dependent sex determination has yet been documented in snakes, although it is known to occur in crocodilians, chelonians, and lizards. Where studied, snakes have genetic sex determination, and in advanced snakes the female is heterogametic (ZW) and the male is homogametic (ZZ).[46,47] In more primitive snakes, such as boids and pythonids, the male is heterogametic (XY) and the female is homogametic (XX).[47,48] Sexual dimorphism in coloration or morphology except for size differences is rare in snakes, but in the leaf-nosed snakes of Madagascar (*Langaha* spp.), there is sexual dimorphism in their nasal protuberances. In most species, female snakes attain larger sizes than males.

Most snakes reproduce sexually, although the blind snake *Indotyphlops* (formerly *Rhamphotyphlops*) *braminus* and the file snake (*Acrochordus arafurae*) are parthenogenetic (no males). Rare parthenogenesis has also been reported in several North American snakes and one python; further investigation will prove interesting and likely identify more species with this ability.[26,49]

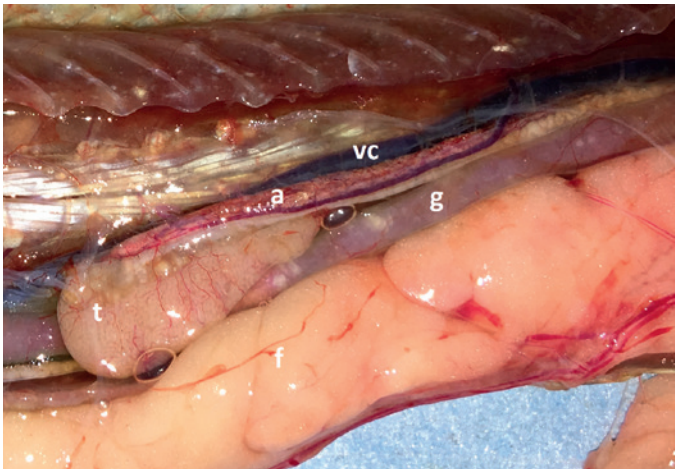

FIG 8.25 Fusiform testes are seen cranial to the kidneys, with the right being more cranial than the left. During breeding season, testes undergo recrudescence, often doubling in size. The pink adrenal gland can be seen in the gonadal mesentery. Cranial is to the left. a, Adrenal gland; f, fat body; g, gastrointestinal tract; t, testicles; vc, vena cava. (Courtesy of James E. Bogan.)

Musculoskeletal System

Snakes show great modifications in their musculoskeletal systems from their lizardlike ancestry. The braincase is solid. However, the skull is kinetic, with the quadrate bones articulating with the lower jaw and the palatomaxillary arch. This facilitates, along with the elasticity in lacking a mandibular symphysis, the ingestion of prey items that are larger than the head or the diameter of the body. The ribs are not joined ventrally, and the body may expand to accommodate prey items that are larger than the diameter of the body. Caudal autotomy, widespread in lizards, is known in only a few snakes and occurs between caudal vertebrae rather than within the vertebral body, and no regeneration occurs (see Chapter 168). Many snakes feed by grasping the prey and ingesting it; others by ingesting it first; and others kill their prey by constriction, suffocating, and/or blocking blood flow to the brain.[22]

Endothermic prey tend to die faster than ectothermic prey when constricted. Snakes do not have thoracic limbs, but a few do have pelvic vestiges, including external spurs, that may be used during courtship, particularly in the boas and pythons (Fig. 8.26).

Locomotion centers around an axial skeletal system of precloacal vertebrae numbering from 120 to more than 400, most of which have ribs, plus axial skeletal muscles with multiple attachments. The ribs and vertebrae lack marked regional differentiation. Snake locomotion has been found to be relatively low in energy expenditure: a garter

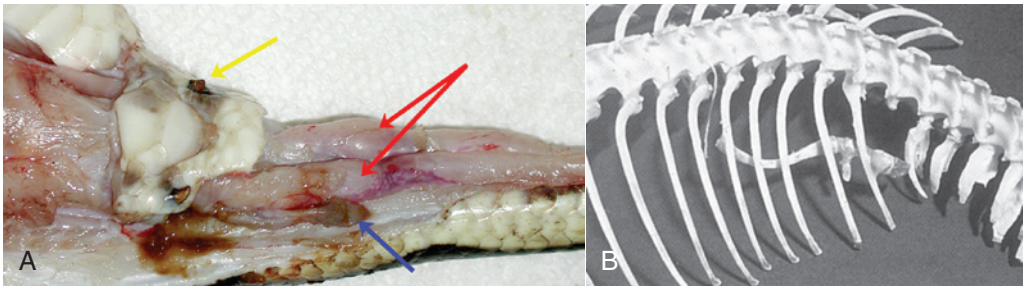

FIG 8.26 (A) Male boids have vestigial pelvic appendages. The yellow arrow points to the "spurs," red arrows highlight paired hemipenes, and the blue arrow points to the scent gland. (B) Skeleton shows relationship of the "spur" to the vestigial pelvis. The tail is to the right in both A and B. (A, Courtesy of Douglas R. Mader; B, courtesy of Richard S. Funk.)

VetBooks.ir

snake expends only about 13% as much energy in locomotion as does a lizard of comparable size.[25] The diversity of snake locomotory types has been classified as follows, although a snake can switch from one form of locomotion to another as it changes habitat, substrate, or activity.[6,25]

Lateral undulation: involves bending the vertebral column laterally, where contractions occur on opposite sides of the body; this is characteristic of most tetrapods. The fastest terrestrial snakes utilize this method.

Rectilinear locomotion: a "caterpillar crawling" in which muscle contractions are bilaterally symmetrical in waves, with the body contacting the substrate at intervals and the progression occurring essentially in a straight line. Common in boas, pythons, and stocky vipers and pit vipers.

Concertina locomotion: the body moves forward by making a purchase and then moving a portion of the body forward to gain a new purchase. Common in arboreal and fossorial snakes; the most energy-expensive method of snake locomotion.

Sidewinding: a difficult mode to describe, much more easily understood when observed; used by snakes on smooth surfaces such as sand or mud; the body essentially contacts the substrate at two points and creates a series of separate parallel straight lines as it progresses. *Crotalus cerastes* and *Cerastes cerastes* are textbook examples.

Nervous System and Special Senses

Snakes have a typical reptilian brain with 11 to 12 pairs of cranial nerves, depending on whether you count cranial nerve 0 (nervus terminalis).[50] Researchers have not yet been able to identify cranial nerve XI in snakes.[51] Snakes have no external auditory opening, tympanic membrane, or middle ear cavity. For years, snakes were presumed to be unable to hear sounds, merely substrate vibrations. However, snakes have been shown electrophysiologically to be sensitive to airborne sound in a low frequency range of 150 to 600 Hz.[52–54]

The eyes of snakes are unique among vertebrates in lacking ciliary bodies. Accommodation occurs by moving the lens toward or away from the retina by means of iris muscle movements. In contrast, other vertebrates use ciliary body muscles to change the shape of the lens.[5,25,55] The eyelids fuse embryologically to form a transparent spectacle that is keratinized, covers the eye, and is continuous with the epidermis. The outer portion of the spectacle is shed during ecdysis, along with the rest of the integument. When a snake is near shedding, the spectacle may appear cloudy or "blue." Lacrimal secretions flow through the subspectacular space between the cornea and the spectacle and drain into the oral cavity at the distal aspect of the medial maxillae. The shape of the pupil varies with habitat and activity. Some fossorial snakes have reduced eyes covered by a scale without a spectacle. Additional details of eye anatomy, clinical examination, and diseases are discussed in Chapter 71.

Independent evolution of specialized infrared receptors has occurred in the heat pits of pit vipers and the labial pits of different groups of boas and pythons[56,57]; they do not appear to be homologous.[58] In pit vipers, one organ occurs on each side of the head slightly ventral to a line drawn between the nostril and the orbit. In boas and pythons these organs occur in labial or rostral scales or both, but the location, arrangement, and number vary with the species. Innervation is via branches of the trigeminal nerve. Pit viper facial pits (also sometimes termed loreal pits or heat pits) have a thin membrane stretched over an air-filled inner cavity. The pit organs are extremely sensitive to infrared radiation changes as small as 0.002°C.[58] These pits provide not only infrared information but also direction and distance, and because these pits are integrated in the brain within the optic region, they provide the snake with both infrared and visual imaging, apparently superimposed.[59,60]

Research shows that many snakes without pits can also detect infrared radiation with other nerve endings in their head. It is theorized that some and possibly many snakes may be able to "see" their environment as well with this infrared system as they can optically.[56,58–62] Snake keepers are commonly bitten when they are feeding cool (e.g., frozen and thawed to room temperature) rodents to snakes because the snakes may smell prey but orient toward the heat source (in this case radiant heat from the "live" keeper's hand).

Snakes have a specialized pair of vomeronasal organs (also called the Jacobson's organs) in the roof of the mouth, which are spherical and separate from the nose, containing a thick sensory epithelium, and are innervated by part of the olfactory nerve. The lacrimal duct enters the duct of the vomeronasal organ. These organs have an olfactory function, and particulate odors are relayed to it by the forks of the tongue.[63,64]

Central nervous system diseases are poorly understood in snakes (see Chapter 77). Boas and pythons with inclusion body disease (arenavirus) show varying degrees of CNS signs, including ataxia and opisthotonos[18] (see Chapter 30).

Endocrine System

The single or paired thyroid glands lie just cranial to the heart (Fig. 8.27). Thyroid function is involved in controlling growth and the shedding cycle. Issues with the skin such as dysecdysis, continual shedding cycles, dermatitis, etc., have suggested links with dysfunction of the thyroid gland. The thymus does not involute in adult snakes as it does in mammals but may be difficult to find in the adipose tissue just cranial to the thyroid(s). Parathyroid glands are paired and often imbedded in the thymus cranial to the heart and thyroid(s) and play a role in calcium metabolism. The adrenal glands are usually located within the gonadal mesentery (see Fig. 8.25). The pituitary gland appears to function as a master gland much as it does in mammals. Melatonin is secreted by the pineal gland. The clinical significance of endocrine function and dysfunction are poorly understood in snakes (see Chapter 79).

BEHAVIOR

Being ectothermic, snakes depend on behaviorally regulating their temperatures by interfacing with their environment. Different species have different preferred body temperatures. Snakes that are ill, gravid, or digesting prey may seek out warmer temperatures. Facultative endothermy is exhibited by brooding females of many python species that are able to maintain their temperatures several degrees warmer than the ambient temperature.[25,65] Both the clinician and the client must understand the thermal physiology of reptiles to ensure success

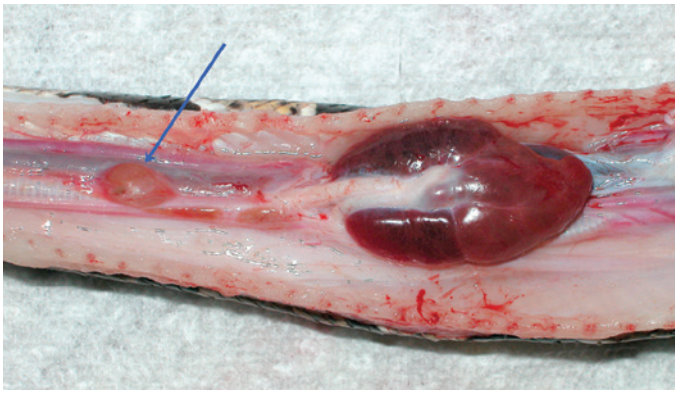

FIG 8.27 Single or paired thyroid gland is found just cranial to the heart.

VetBooks.ir

in captivity. Each species needs to reach its selected (or preferred) body temperature (T_S or T_P), which occurs within the range of physiologically tolerated temperatures or the thermal neutral zone. Herpetoculturists find that their captives thrive better when provided with a thermal gradient that incorporates the T_S for species being maintained. Summary discussions of research on thermoregulation are available.[66–76] Brumation is the term for winter dormancy in reptiles (as opposed to true hibernation).[77,78]

Other snake behaviors, including defense, aggression, courtship, and death-feigning, are covered in behavior-related Chapters 13, 80, 83, and 121.

Lizard Taxonomy, Anatomy, and Physiology

Stephen Barten and Shane Simpson

Ranging in size from the tiny Mount d'Ambre leaf chameleon (*Brookesia tuberculate)* to the giant Komodo dragon (*Varanus komodoensis*) (Fig. 9.1), lizards are arguably the most diverse group of reptiles. They demonstrate a wide range of morphologic, physiological, and behavioral adaptations that have allowed them to colonize an array of environments on every continent except Antarctica.

With such diversity and distribution, it is not surprising that of the over 10,000 known living reptile species, nearly 6200 of them are lizards.[1]

From private reptile keepers to zoo collections alike, lizards offer considerable choice as to what can be kept in captivity. Many species adapt well and can be handled with ease. Similarly, many species have been bred in captivity with great success, and there is no better example of these traits than the most popular pet reptile, the central or inland bearded dragon (*Pogona vitticeps*).

TAXONOMY

Living reptiles, or as they are more correctly referred to, sauropsids, can be divided into three clades. The first reptilian clade is the chelonians (turtles and tortoises), the second is the archosaurs (crocodiles and birds), and the third clade is the lepidosaurs, which consists of lizards, snakes, amphisbaenians, and tuataras (Fig. 9.2).

Common nomenclature recognizes lizards and snakes as two different groups of reptiles. This is not true, however, when classificatory labels are used. Snakes and lizards are collectively known as squamates and have more than 50 shared-derived features that demonstrate their close affiliation with each other. These include skeletal features such as a single fused premaxillary bone and soft tissue features such as males having well-developed, paired copulatory organs known as hemipenes. It should be appreciated that snakes are actually lizards with either reduced limbs or no limbs.[2] Because of this relationship, it is taxonomically incorrect to refer to lizards without also including snakes. Nevertheless, this is exactly the group that this chapter discusses. It is, however, difficult to describe the taxonomy of lizards because there is no clear consensus among taxonomists. The following outline therefore is based on historical thinking in combination with current cladistic theories (Table 9.1).

The first branch of the squamate cladogram divides them into the Iguania and all the others, which collectively are called the Scleroglossa.

Historically Iguania has contained three groups: the Iguanidae, the Agamidae, and the Chamaeleonidae. The family Iguanidae or Iguanids is the dominant group of lizards in the new world and differs from the other two by having pleurodont dentition (teeth attached to the medial side of the jaws without sockets that are regularly shed and replaced) and fracture planes in the caudal vertebrae. There are at least 12 families in this group, and examples include the green iguana (*Iguana iguana*) (Fig. 9.3), green anole (*Anolis carolinensis*), basilisks (*Basiliscus* spp.), horned lizards (*Phrynosoma* spp.), spiny lizards (*Sceloporus* spp.), and West Indian rock iguanas (*Cyclura* spp.).

Together the Agamidae and Chamaeleonidae make up the Acrodonta because of their acrodont dentition (teeth attached to the biting edge of the jaw without sockets that are not shed and replaced). This group also lacks caudal vertebral fracture planes; exceptions include some *Uromastyx*. Because of these similar features, the Agamidae and the Chamaeleonidae are considered to be more closely related to each other than either of them are to the Iguanidae. Members of the family Agamidae are the dominant family of lizards in the old world. Examples include the central or inland bearded dragon (*Pogona vitticeps*), agama (*Agama agama*), frilled lizard (*Chlamydosaurus kingii*) (Fig. 9.4), Chinese water dragon (*Physignathus cocincinus*), Egyptian spiny-tailed lizard (*Uromastyx aegyptius*), and Philippine sail-fin lizard (*Hydrosaurus pustulatus*). The family Chamaeleonidae consists of the old-world, or true, chameleons. Examples include the veiled chameleon (*Chamaeleo calyptratus*), the panther chameleon (*Furcifer pardalis*), and the Parson's chameleon (*Calumma* parsonii).

The relationships between the remaining squamate groups in the Scleroglossa are less certain and are where the greatest amount of conjecture occurs. The following structure is just one proposal and will no doubt raise debate among those with a penchant for taxonomy.

The first main group, the Nyctisaura, contains the Gekkonidae, the Xantusiidae, the Dibamidae, and the Amphisbaenidae.

FIG 9.1 Komodo dragon (*Varanus komodoensis*). The largest living species of lizard, these animals can reach 3 meters in length and weigh up to 70 kilograms. Found only on five Indonesian islands, they hunt and ambush prey such as deer and water buffalo. Human fatalities from Komodo dragon attacks have been reported. (Courtesy of Shane Simpson.)

VetBooks.ir

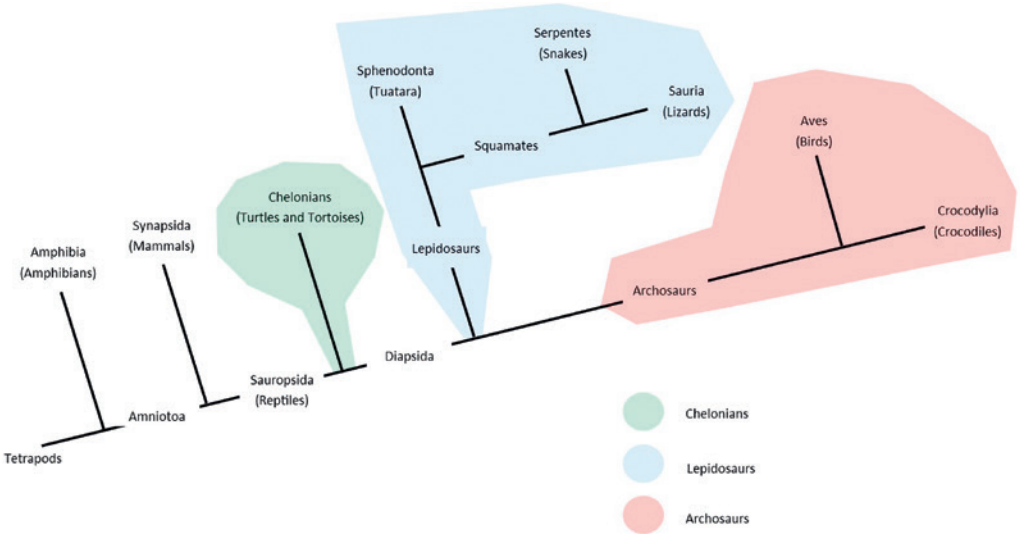

FIG 9.2 A simplified cladogram showing the three extant reptilian clades. There is still much conjecture among taxonomists as to the exact relationships among the reptile groups. Table 9.1 provides an overview of the assorted lizard families.

FIG 9.3 Green iguana (*Iguana iguana*). Dominant males of this species take on an orange coloration as seen in this sleeping specimen. Males also show more developed dorsal spines, larger dewlaps, and larger operculum scales than females. (Courtesy of Shane Simpson.)

FIG 9.4 Frilled lizard (*Chlamydosaurus kingii*). When threatened and during courtship, this predominantly arboreal species will gape its mouth and expand the large ruff of skin that is normally folded back on the neck and head. (Courtesy of Shane Simpson.)

The Gekkonidae family is comprised of the Eublepharidae geckos with movable eyelids and include the leopard gecko (*Eublepahris macularius*); the Diplodactylidae, otherwise known as Austral geckos,[3] of which examples include the three-lined, knob-tailed gecko (*Nephrurus levis*) and the crested geckos (*Correlophus [Rhacodactylus]* spp.); the Gekkoninae, which are the typical geckos including the tokay gecko (*Gekko gecko*) and leaf-tailed geckos (*Uroplatus* spp.); the Phyllodactylidae or leaf-toed geckos; the Sphaerodactylidae or dwarf geckos; and finally the Pygopodinae, which are snakelike without forelimbs and with their hind limbs reduced to flaps of skin containing a few phalanges, such as seen with the common scaly-foot (*Pygopus lepidopodus*) and Burton's snake-lizard (*Lialis burtonis*). The Xantusiidae contain the night lizards (*Xantusia* spp.). The Dibamidae, or blind lizards (*Dibamus* and *Anelytropsis* spp.), also are snakelike lizards with no forelimbs and flaplike hind limbs. The Amphisbaenidae, or worm lizards, are legless, covered with wormlike annular rings made of scales, and all species are fossorial, including the red worm lizard (*Amphisbaena alba*).

The remaining squamates, the Antarchoglossa, contain two diverse subgroups. The subgroup Lacertoiformes includes three families. First is the Lacertidae, or wall and rock lizards. Some examples are the jeweled lizard (*Timon lepida*), rock lizard (*Lacerta saxicola*), and viviparous lizard (*Zootoca vivipara*). Second is the Teiidae, which are the new-world equivalent of the Lacertidae and include the whiptails and racerunners (*Aspidoscelis* and *Cnemidophorus* spp.), jungle runners (*Ameiva* spp.), and tegus (*Salvator* and *Tupinambis* spp.). The final family is the Gymnophthalmidae or spectacled lizards. The other subgroup is the Diploglossa, which contains the remaining lizard groups. One is the family Scincidae or true skinks, familiar species of which include the blue-tongued skink (*Tiliqua* spp.), prehensile-tailed skink (*Corucia zebrata*), five-lined skink (*Plestiodon [Eumeces] fasciatus*), and the

TABLE 9.1 Lizard Taxonomy

Iguania
Agamidae [Agamas]
Chamaeleonidae [Chameleons]
Iguanidae [Iguanas]
- Corytophaninae [Casquehead Lizards]
- Crotaphytidae [Collared and Leopard Lizards]
- Dactyloidae [Anoles]
- Hoplocercinae [Wood lizards and Clubtails]
- Iguaninae [Iguanas and Spinytail Iguanas]
- Leiocephalidae [Curly-tailed Lizards]
- Leiosauridae
- Liolaemidae [Liolaemids]
- Oplurinae [Madagascar Iguanids]
- Phrynosomatinae [Earless, Spiny, Tree, Side-blotched, and Horned Lizards]
- Polychrotinae [Bush Anoles]
- Tropidurinae [Neotropical Ground Lizards]

Scleroglossa
Nyctisaura
- Gekkonidae [Geckos and Pygopods]
  - Diplodactylidae [Austral Geckos]
  - Eublepharidae [Eyelid Geckos]
  - Gekkoninae [Typical Geckoes]
  - Phyllodactylidae [Leaf-toed Geckos]
  - Pygopodinae [Legless Lizards]
  - Sphaerodactylidae [Dwarf Geckos]
- Xantusiidae [Night Lizards]
- Dibamidae [Blind Lizards]
- Amphisbaenidae [Worm Lizards]

Antarchoglossa
- Lacertoiformes
  - Gymnophthalmidae [Spectacled Lizards]
  - Lacertidae [Wall and Rock Lizards]
  - Teiidae [Whiptails, Racerunners, Jungle Runners, and Tegus]
- Diploglossa
  - Cordylidae [Girdle-tailed or Spinytail Lizards]
  - Gerrhosauridae [Plated Lizards]
  - Scincidae [Skinks]
  - Anguimorpha
    - Xenosauridae [Knob-scaled Lizards]
    - Shinisauridae [Chinese Crocodile-Tailed Lizards]
    - Anguidae [Alligator Lizards, Glass Lizards, and Legless Lizards]
    - Varanoidae
      - Helodermatidae [Gila Monsters]
      - Varanidae [Monitors]
      - Lanthanotidae [Earless Monitor Lizards]

crocodile skinks (*Tribolonotus* spp.). Two others are the Cordylidae or girdle-tailed lizards (*Cordylus* spp. and others) and Gerrhosauridae or plated lizards (*Gerrhosaurus* spp. and others). The Diploglossid group also incorporates a lesser subgroup, Anguimorpha, which contains several families. The Xenosauridae or knob-scaled lizards include the new world viviparous xenosaurs (*Xenosaurus* spp.), and the Shinisauridae contains only the Chinese crocodile-tailed lizard (*Shinisaurus crocodilurus*). The family Anguidae are long and snakelike in form. They include the alligator lizards (*Elgaria* spp.), glass lizards (*Ophisaurus* spp.), legless lizards (*Anniella* spp.), the sheltopusik or European glass lizard (*Pseudopus apodus*), and the galliwasps (*Diploglossus* ssp. and *Celestus* ssp.). The final three families in the Anguimorpha are members of the Varanoidae group. The Helodermatidae contain only two species, the gila monster (*Heloderma suspectum*) and the Mexican beaded lizard (*Heloderma horridum*). The family Varanidae consists of the monitor lizards. Australian monitor lizards and certain species from Southeast Asia are often referred to as goannas. Familiar examples include the savannah monitor (*Varanus exanthematicus*), the Nile Monitor (*Varanus niloticus*), and the perentie (*Varanus giganteus*). Lanthanotidae has a single species, the Bornean earless lizard (*Lanthanotus borneensis*).[1–3]

ANATOMY AND PHYSIOLOGY

The following sections refer extensively to Figs. 9.5 through 9.7.

Integument

Lizards have relatively thick, keratinized skin with ectodermal scales formed by folding of the epidermis and outer dermal layers.[4] Epidermal growth is cyclic, and lizards undergo regular periods of shedding or ecdysis, during which the skin comes off in pieces in most lizards rather than in one piece as seen in snakes. Some species eat their sloughed skin. Normal shedding is one indication of good health. The frequency of ecdysis varies with species, size, temperature, humidity, state of nutrition, age, gender, rate of growth, skin damage including surgically induced, state of health, and endocrine factors.[5] Rapidly growing juveniles may shed every 2 weeks, whereas adults may shed three to four times a year.[6] Wounds and skin infections cause more frequent shed cycles.

The skin contains few glands. Many lizards, notably iguanas and many agamids, have femoral pores in a single row on the ventral aspect of the thigh (Fig. 9.8). Many geckos and agamids also have precloacal pores arranged in a V-shaped row anterior to the cloaca. These are not true glands but rather are invaginations of the skin that produce a waxy secretion for territorial marking and social communication.[7] They can be used as a method for sex identification as they tend to be larger and more developed in mature males.

The skin color patterns seen in lizards, like all reptiles, is due to prescence of multiple types of pigment cells referred to collectively as chromatophores. These cells are located in the dermis of the skin. Many species of lizards, such *Chamaeleo* spp. and *Anolis* spp., are able to undergo rapid color changes due to hormonal and neurologic control mechanisms of the chromatophores to alter their size and positioning within the dermis.

Osteoderms are dermal bones that support the epidermal scales. They are present in the Heliodermata, some skinks (such as the shingle-back lizard, *Tiliqua rugosa*) (Fig. 9.9), legless lizards, and girdle-tailed lizards. These are usually confined to the back and sides where they have a protective role. Dewlaps, spines, crests, and horns may be present and often are secondary sex characteristics, being more prominent in males. These all may play a role in defense, protection, and dominance behaviors. The integument can also have a role in locomotion in some species of lizards. Of particular note are the anatomical features of the feet of many gecko species that allow them to seemingly defy gravity. Adhesive setae on the feet of these animals enable them to adhere to smooth vertical and horizontal surfaces.[8]

The integument of lizards not only functions to protect from desiccation and predation but is also innately involved in the synthesis of vitamin D_3. UVB light of the appropriate wavelength striking the skin converts cholesterol to the inactive form of vitamin D as part of the pathway to the ultimate formation of 1,25-dihydroxycholecalciferol.[9] Without such a chemical conversion susceptible lizards may develop secondary nutritional hyperparathyroidism. For further details, see Chapter 69.

VetBooks.ir

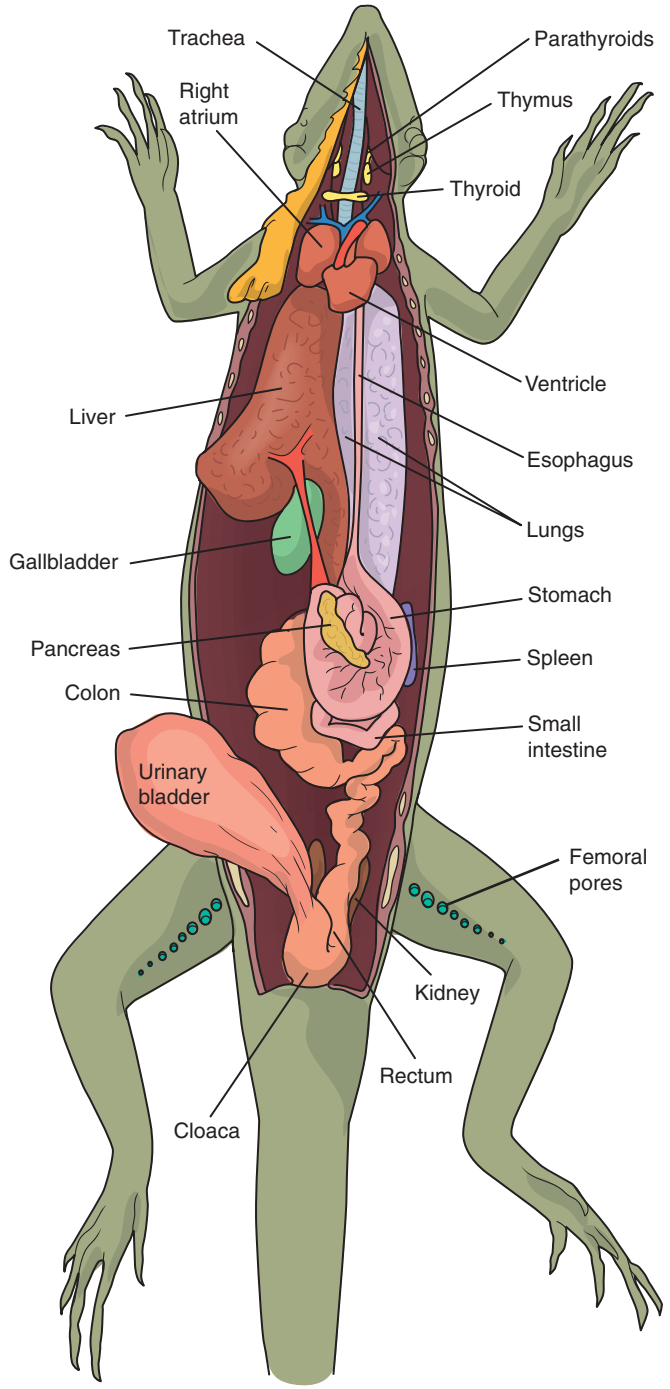

FIG 9.5 Ventral view of a green iguana (*Iguana iguana*). Note the anterior location of the heart between the shoulder joints. Also, note the caudal position of the kidneys within the pelvic canal.

Cardiovascular System

In lizards, the heart is three chambered, with left and right atria and a single ventricle. The ventricle is divided into three chambers: the cavum arteriosum, cavum venosum, and cavum pulmonale.[10] The cavum venosum receives deoxygenated venous blood from the right atrium, and the cavum arteriosum receives oxygenated blood from the left atrium. Blood leaves the heart through the pulmonary artery arising from the cavum pulmonale and the two aortic arches arising from the cavum venosum. All three cava communicate, but a muscular flap and two-stage ventricular contraction minimizes mixing among the three cava. Deoxygenated blood flows from the cavum venosum into the cavum pulmonale. An atrioventricular valve prevents mixing of this blood with the oxygen-rich blood in the cavum arteriosum. Next the ventricle contracts, forcing the deoxygenated blood in the cavum pulmonale into the pulmonary artery. The atrioventricular valve then closes, allowing oxygenated blood to flow from the cavum arteriosum into the cavum venosum and out the aortic arches. Thus the three-chambered squamate heart function is similar to that of a four-chambered heart.[10]

In all lizards the heart lies within the pectoral girdle except for the monitors (*Varanus* spp.) and tegus (*Salvator* and *Tupinambis* spp.), where it is located more caudally in the coelomic cavity. For further details, see Chapter 68.

The renal portal system of reptiles is well documented in the literature for its parenteral therapeutic implications.[10–13] Although the anatomy of the blood vessels varies somewhat from group to group, venous circulation from the tail, and little from the hind limbs, routes directly to the kidneys via the renal portal system.[12] The injection of drugs (that are cleared via tubular secretion) into the caudal half of the body could result in lower than anticipated serum concentrations because of their first-pass excretion from the kidneys before entering the systemic circulation. This practice could also result in increased renal toxicity in the case of nephrotoxic drugs, such as aminoglycosides. Only limited pharmacokinetic studies on the effect of the renal portal system on serum drug concentrations have been done, but the results suggest that the renal portal system has less effect on drug uptake and distribution than was once thought. Moreover, shunts exist that carry blood directly from the renal portal system to the postcava, bypassing the renal parenchyma. For more details, see Chapter 66.

Venous blood from the hind limbs and tail in reptiles drains to the ventral abdominal vein (Fig. 9.10), which connects to the hepatic portal vein and enters the liver.[10] This is in contrast to what occurs in mammals and birds, in which blood drains into the caudal vena cava then to the heart, thus bypassing the liver. Consequently, drugs administered in the caudal half of the reptilian body enter the liver first and are subject to a hepatic first-pass effect. Those drugs that undergo hepatic metabolism or excretion may therefore be rendered ineffective and should not be administered in the caudal half of the body. Given the presence of both renal and hepatic portal systems in reptiles, it would seem prudent to avoid administering drugs in the caudal half of the body to avoid any potential metabolism or excretion effects.

Maintaining adequate blood pressure is important for ensuring appropriate tissue perfusion. Baroreceptor control of blood pressure has been identified in a number of lizard species.[14,15] The level of baroreceptor control in response to hypotension may not be influenced by temperature and is still maintained through periods of reduced metabolic activity such as brumation.[14]

Respiratory System

Nasal salt glands are present in herbivorous iguanid lizards such as the green iguana. Solutions with high concentrations of sodium and potassium can be excreted by these glands, and their importance in osmoregulation in some species is greater than that of the kidneys and is vital for the animal's survival.[10] Generally, lizards sneeze and expel a clear fluid that dries to a fine white powder consisting of sodium and potassium salts. This mechanism allows water conservation and should not be mistaken for an upper respiratory infection. The paired internal nares are anterior in the roof of the mouth and are a common site for discharges to accumulate and a good site for bacteriologic sampling when respiratory infection is present.

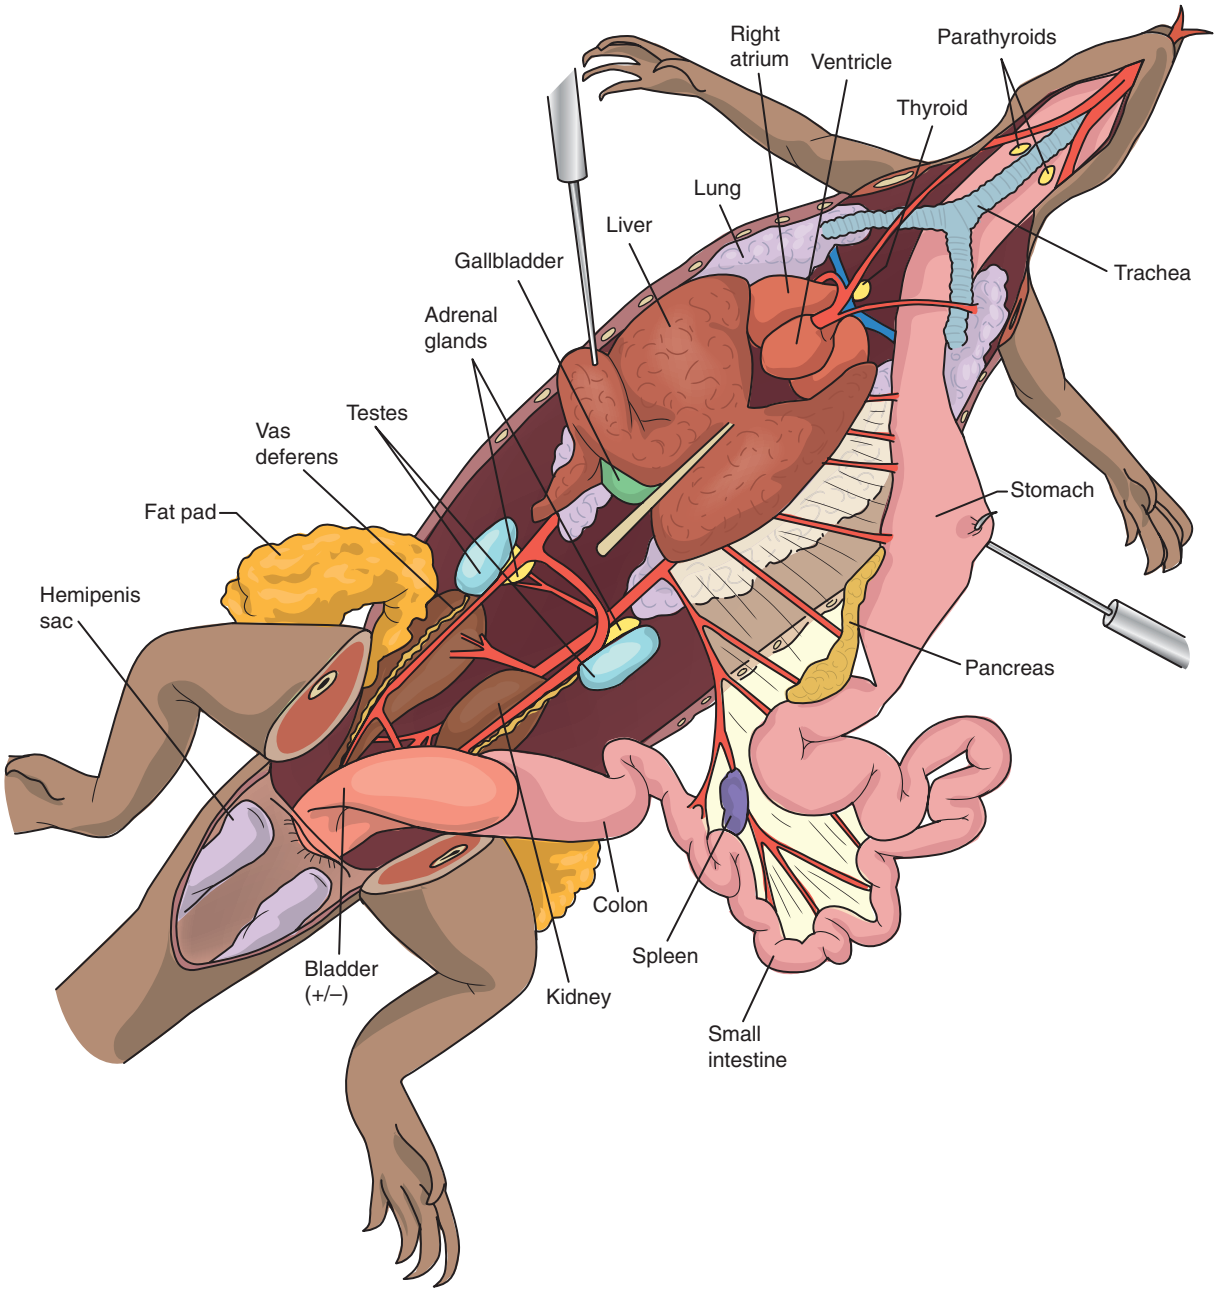

FIG 9.6 Ventral view of a savannah monitor (*Varanus exanthematicus*). Note the more typical location of the heart compared to the green iguana (*Iguana iguana*). Likewise, although the caudal portions of the kidneys extend into the pelvic canal, the cranial portions are within the coelomic cavity, unlike in the green iguana.

The location of the glottis is variable. In some species such as monitors (*Varanus* spp.) it is found rostrally; however, in agamids it is located caudally, behind the tongue. The glottis is normally closed except during inspiration and expiration. Vocal cords are occasionally present, most notably in some geckos, which can produce loud vocalizations. The trachea is composed of incomplete tracheal rings and bifurcates near the level of the heart.[4]

Primitive lizards (e.g., the European green lizard, *Lacerta viridis*) possess so-called unicameral lungs that consist of a hollow single chamber lined with faveoli (small sacs) that are more spongelike than saclike to increase surface area for gas exchange. Some species, particularly skinks (Scincidae), may have large, caudal nonrespiratory sacs that are thin-walled and poorly vascularized.[4,10] In more advanced lizards (e.g., Chamaeleonidae), the lungs are further divided into interconnected chambers by a few large septae, and there is a membrane that connects to the pericardium. Chameleons specifically have hollow, smooth-sided, fingerlike projections on the margins of their lungs that must be identified and avoided during coelomic surgery. These are not used in gas exchange but rather to inflate the body and intimidate would-be predators. Some chameleons also have an accessory lung lobe that projects from the anterior trachea cranial to their forelimbs. This may fill with secretions with infection, resulting in swelling of the ventral neck. Monitors' lungs are multichambered with bronchi that continue to divide until small tertiary bronchi extend toward the pleural surface to form hexagonal

VetBooks.ir

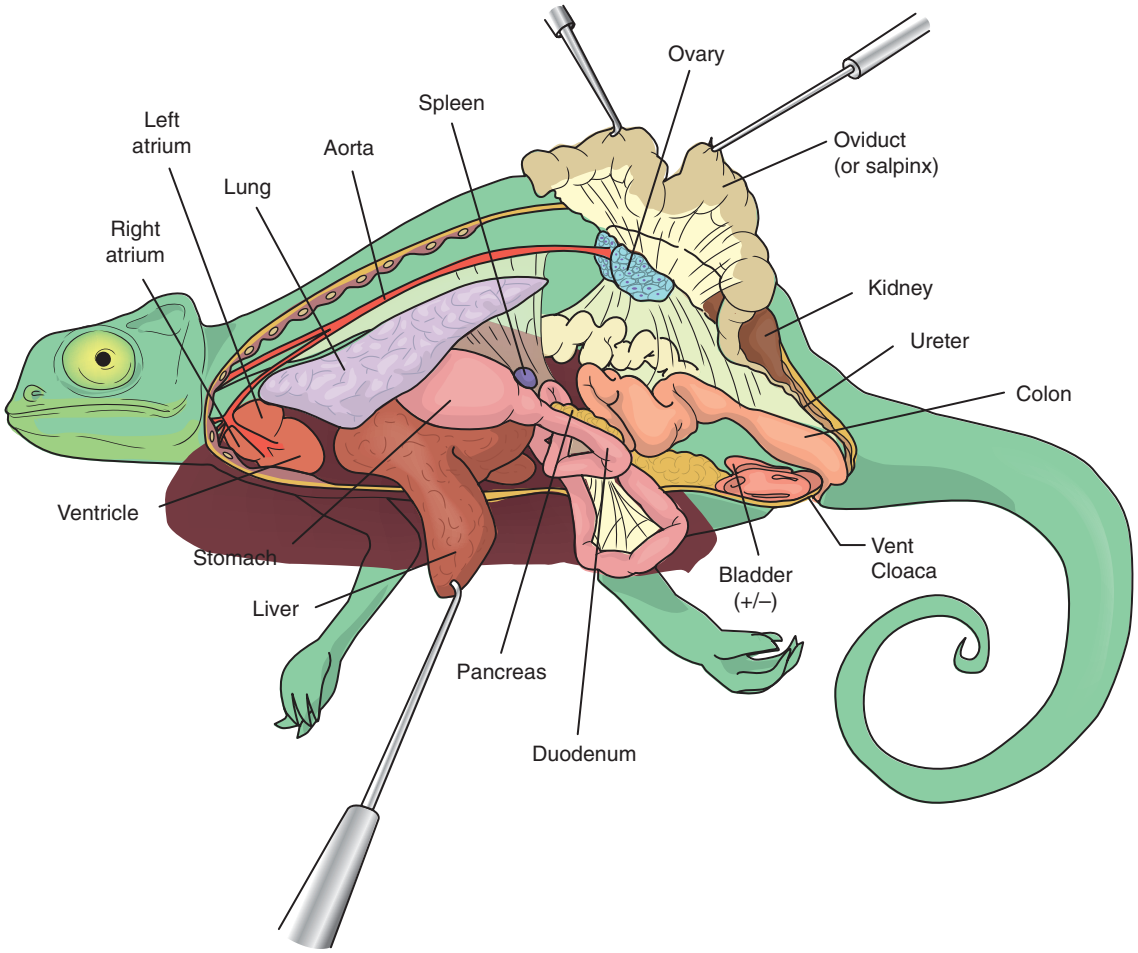

FIG 9.7 Lateral, midsagittal view of a female chameleon. Serosal surfaces in the coelom of many chameleons are starkly melanotic.

FIG 9.8 The femoral and precloacal pores on the ventral aspect of the thighs of this central bearded dragon (*Pogona vitticeps*) indicate that this is a male. Femoral pores of adult male dragons like this one are larger than those in females, although this specimen has an accumulation of secretions in the pores. (Courtesy of Shane Simpson.)

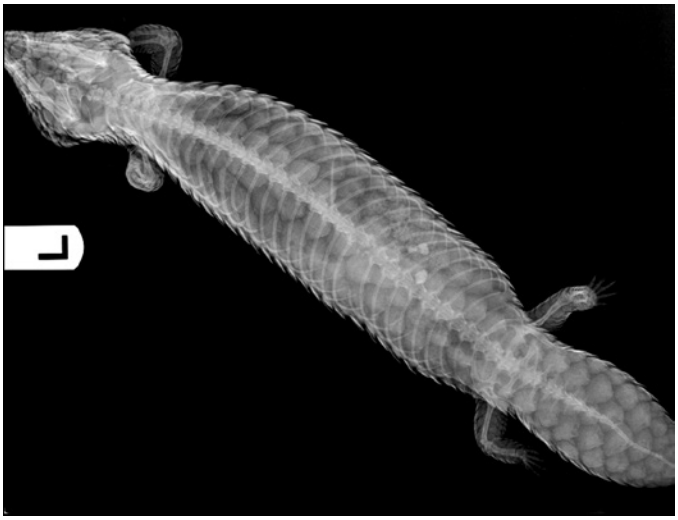

FIG 9.9 The shingleback lizards (*Tiliqua rugosa* sp.) are one of a number of species of lizard that possess bony plates or osteoderms within their scales. Normally confined to the dorsum and sides, they are clearly visible in this radiograph. Notice the vertebral lysis and rib loss in the left mid-body area secondary to neoplasia. (Courtesy of Shane Simpson.)

VetBooks.ir

FIG 9.10 Paramedian coeliotomy incision in a green iguana (*Iguana iguana*). The medial body wall has been elevated to show the large ventral vein as it hangs in its suspensory ligament from the medial aspect of the linea alba. This vessel is best avoided during coeliotomy incisions. (Courtesy of Stephen Barten.)

faveolar parenchyma for gas exchange.[10,16] These lungs most closely resemble the lungs of primitive mammals.

Lizards lack a diaphragm and rely on the expansion and contraction of the ribs using the intercostal muscles, aided by the skeletal muscles of the coelomic wall to move air through the lungs. Given that these muscles are under voluntary control, this has implications when lizards are anesthetized as they will require artificial ventilation. The monitors and gila monsters have an incomplete, post-pulmonary, fascialike septum that divides the coelomic cavity but does not aid respiratory movements.[17] Monitors have been shown to have unidirectional pulmonary airflow similar to that seen in birds and crocodilians.[16] The fluttering of the ventral throat does not result in significant respiration but probably ventilates the oropharynx for olfaction and may play a role in cooling.

Some lizards can revert to anaerobic metabolism during prolonged periods of apnea and will switch to anaerobic metabolism quite quickly with sustained activity due to their limited capacity for aerobic respiration.[4,10]

Control of respiration in lizards is similar to that in other reptile species. CO_2 chemoreceptors and O_2 receptors have been found in the periphery. The dominant drive to breathe in reptiles is an increasing CO_2 concentration in the blood rather than a decreasing O_2 level. In addition, pulmonary stretch receptors act to suppress inspiration and enhance expiration when stimulated. Clinically these methods of control are important to understand, because overventilation with highly oxygenated gas during and after anesthesia can result in apnea and delayed recovery. For further details, see Chapter 76.

Digestive System

The lips of lizards are composed of flexible skin but are not moveable. The teeth of lizards fall into two types. Pleurodont dentition is characterized by teeth attached to the lingual sides of the mandible without sockets and is the most common type of dentition as seen in iguanids and varanids (Fig. 9.11). Pleurodont teeth are regularly shed and replaced. The odd-numbered teeth are shed in one cycle, and the even-numbered teeth in the next, so that a tooth being shed has a functional tooth on either side allowing normal mastication. Agamidae and Chamaeleonidae possess acrodont dentition, where the teeth are attached to the biting edges of the jaws without sockets. Acrodont teeth are not replaced except in very young specimens, although new teeth may be added to the posterior end of the tooth row as the lizard grows. Some agamids

FIG 9.11 Mandible of a green iguana (*Iguana iguana*) showing pleurodont dentition. Teeth are attached to the medial side of the jaw without sockets. Note that alternate teeth have shortened roots with buds of new teeth below them. Teeth are shed and replaced throughout life. Rostral is to the right. (Courtesy of Stephen Barten.)

FIG 9.12 Periodontal disease of the left maxillary arcade of a central bearded dragon (*Pogona vitticeps*). Captive lizards with acrodont dentition such as this are prone to periodontal disease. An improper diet with excessive fruits and lack of abrasive items is thought to be a contributing factor. (Courtesy of Shane Simpson.)

have a few caninelike pleurodont teeth on the anterior jaws, along with the normal acrodont teeth. Care should be taken to avoid damaging the irreplaceable acrodont teeth in agamids and chameleons when opening the mouth with a rigid speculum during physical examination. Peridontal disease has been reported in species with acrodont dentition but not pleurodont dentition (Fig. 9.12).[18] Lizard teeth generally grasp, pierce, or break up food, and, unlike snakes and chelonians, they will chew their food before swallowing. In many monitors, the teeth slice and cut. Mollusc-eating caiman lizards (*Dracaena guianensis*) and adult Nile monitors (*Varanus niloticus*) have broad rounded cheek teeth for crushing shells.

The tongue of the lizard varies with the species. In general, it is mobile and protrusible, being attached to the hyoid apparatus at its base. Taste buds are abundant in species with fleshy tongues, and in these species the tongue has both mechanical and chemosensory function. Taste buds also are found in the lining of the pharynx. In monitors and tegus, the tongue is highly keratinized and has minimal taste buds. Lizards with deeply forked tongues protrude it to bring scent particles to the vomeronasal (Jacobson's) organ for olfaction. The tongue is a projectile for food gathering in chameleons (*Chamaeleo* spp.). In green

VetBooks.ir

iguanas and many Agamids, the tip of the tongue is darker in color and should not be mistaken for a lesion. The paired vomeronasal (Jacobson's) organs have tiny openings in the anterior roof of the mouth, just cranial to the openings to the paired internal nares. Lizards have well developed multicellular mucous glands that line the oral cavity and produce saliva. The saliva lubricates food, allowing it to pass down the esophagus with greater ease.[10,19]

The gila monster and Mexican beaded lizard were considered to be the only venomous extant lizards for many years. These species have grooved rather than hollow teeth, which have no direct connection to the venom glands. The venom glands are sublingual rather than temporal as seen in snakes. Venom flows from the glands along the dental grooves and is injected with the chewing action. Symptoms of envenomation include pain, hypotension, tachycardia, nausea, and vomiting. Work with various varanid and iguanid lizards has since revealed they too possess venom that can have potent effects on blood pressure and clotting ability.[20,21]

The esophagus in lizards is short, thin-walled, and enters the stomach on the left side of the coelom. The stomach of lizards is simple, C-shaped, and not gizzard-like. The stomach can be divided into the fundic (corpus) and parspylorica regions. Some lizard species have prominent cardia regions, and rugae may or may not be present.[19] The swallowing of stones to assist digestion is not a normal behavior in lizards.

The length and complexity of the intestine of lizards depends greatly on the type of diet the animal consumes. In general, herbivores have the longest intestine and carnivores the shortest. In herbivores the distinction between the small and large intestines is often obvious but this is less so in carnivores. A number of vegetarian species have a colon that is divided into sacculations to facilitate hindgut fermentation for more complete digestion. Lizards in this group include the green iguana, prehensile-tailed skink, Egyptian spiny-tailed lizard, and chuckwalla (*Sauromalus ater*).[22]

A cloaca is present and is divided into three parts: the coprodeum, which collects feces; the urodeum, which collects urinary waste and receives the sexual structures (vas deferens/oviducts); and the proctodeum, which is the final chamber before the vent.[23] The cloacocolonic region has an important role in the reabsorption of electrolytes and fluids from the excreted wastes. The vent or cloacal slit is transverse in lizards.

The liver is an encapsulated, bilobed organ in lizards. The right lobe is the larger of the two lobes and usually has the gall bladder closely associated with it. Its exact location in the body cavity can vary in the cranial-caudal direction.[23,24]

The gall bladder of lizards has an important role in digestion, particularly of fats, by acting as a storage organ for bile. Bile emulsifies fat and allows it to be absorbed in the intestine. In most lizards it is attached to the liver, though in some species it may be located some distance from the liver, similar to snakes.[10,23]

The pancreas of lizards is an elongated structure that lies along the mesenteric border of the duodenum.[19,24] For further details see Chapters 73, 74, and 75.

Reproductive System

Lizards have breeding seasons determined by cycles of photoperiod, temperature, rainfall, and availability of food. In males, a corresponding fluctuation is seen in testicular size. Male iguanas and other lizards are often noted to be more territorial and aggressive during their breeding season.

Gender identification can be a challenge in lizards, particularly in juvenile animals. Some species may show sexual dimorphism as they mature. Mature male iguanas have taller dorsal spines, larger dewlaps, and larger operculum scales than do females. They also have bilateral hemipenal bulges at the base of the tail. Male chameleons often have elaborate head ornamentation in the form of horns, crests, and plates that are lacking in females. Many other male lizards have larger heads, bigger crests, brighter colors, erectable dewlaps, or may have a larger body size than females. In addition, males may possess greatly enlarged femoral and precloacal pores. Sexing probes to determine the depth of the hemipenal sac (if present) can be used but is less definitive than is seen in snakes. Female lizards often have hemiclitoral structures that result in similar probing depths as are seen in males. The hemipenes of some species may be temporarily everted with application of gentle pressure to the base of the tail, just caudal to the cloaca. This should not be attempted in species that undergo tail autotomy, such as geckos. Transillumination of the tail base with a strong light source may allow visualization of the hemipenal structures in small or lightly colored species of lizard. The hemipenes of mature male monitor lizards of many species may show calcification of an internal skeleton, termed a hemibaculum, and are demonstrable on radiographs (Fig. 9.13 and Table 9.2).[25,26] The introduction of radio-opaque solutions into the hemipenal sac has been shown to be a useful method of sex identification in eastern blue-tongue lizards (*Tiliqua scincoides* scincoides) (pers. comm., Steven Mallet, 2016). Endoscopy to visualize the gonads may be used to identify gender.[27] Ultrasonography of the gonads or the presence or absence of hemipenes in the proximal tail also may be used to identify the gender of a lizard.[28] See Chapter 80 for more details.

Male lizards have paired testes, epididymides, and vasa deferentia. The testes are located anterior to the kidney, with the right testis positioned more anteriorly than the left in most lizards.[10] The male has paired hemipenes that are saclike and lack erectile tissue; these are an invagination from the cloacal wall and are stored in an inverted position in a pocket in the base of the tail. They may produce noticeable bulges in the ventral proximal tail. There may be considerable morphologic differences in the structure of the hemipenes between different lizard species, with some varanids in particular having very elaborate hemipenal structures. During mating the male aligns his cloaca with that of the female, and one hemipenis everts and penetrates the female cloaca. Sperm runs from the cloaca down a groove in the wall of the hemipenis,

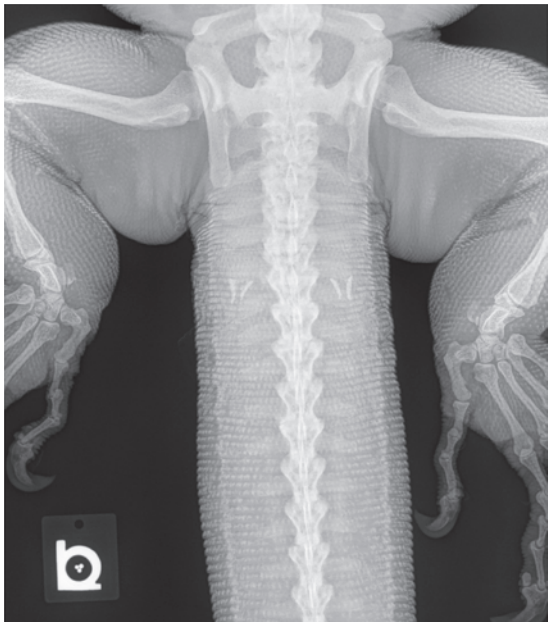

FIG 9.13 Mature male monitors of several species like this lace monitor (*Varanus varius*) can develop ossification of the hemibaculae within the hemipenes. This can be used as a method of identifying the sex of an individual. (Courtesy of Stephen Barten.)

TABLE 9.2 Species of Monitors (*Varanus* spp.) in Which Mineralized Hemibacula Are Present within Hemipenes and the Basic Hemibacula Shape[27]

Mineralization Present

Hemipenal Category	Species	Basic Hemibacula Shape
A	black tree monitor (*Varanus beccari*) emerald tree monitor (*V. prasinus*)	Single, short, parallel sides
B	pygmy desert monitor (*V. eremius*)	Long curved, spike-shaped horn
C	Perentie (*V. giganteus*) Gould's monitor (*V. gouldii*) mangrove monitor (*V. indicus*) yellow-spotted monitor (*V. panoptes*) lace monitor (*V. varius*) peach-throat monitor (*V. karlschmidti*) Komodo dragon (*V. komodensis*) crocodile monitor (*V. salvadori*) Merten's water monitor (*V. mertensi*)	Two components, equal sized, concave centrally
D	ridge-tailed monitor (*V. acanthurus*) striped-tailed monitor (*V. caudolineatus*) Gillen's monitor (*V. gilleni*) Storr's monitor (*V. storri*) black-headed monitor *(V. tristis*) spotted tree monitor (*V. scalaris*)	Two or three components, slightly different sizes, concave at the distal (tail) end
E	Gray's monitor (*V. olivaceous*)	Two components, lateral component much larger

Mineralization Absent

Bengal monitor (*V. bengalensis*)
Dumeril's montitor (*V. dumereli*)
savannah monitor (*V. examthematicus*)
desert monitor (*V. griseus*)
Nile monitor (*V. niloticus*)
roughneck monitor (*V. rudicollis*)
water monitor (*V. salvator*)
Timor monitor (*V. timorensis*)

the sulcus spermaticus, into the female, resulting in internal fertilization. There is no urethral structure. A retractor hemipenis muscle retracts the hemipenis after mating.[25,29]

Female lizards have paired ovaries and oviducts supported by mesenteries, which terminate at the urodeum of the cloaca. In lizards at least, the caudal pole of each ovary is attached to the peritoneum along the ventromedial surface of each kidney. In some lizards with highly modified lungs, such as chameleons, the ovary may extend cranially between the two lungs. The ovaries and oviducts can vary dramatically in terms of size and composition depending on age and time of year in relation to breeding season.[29]

Parthenogenesis is defined as reproduction without fertilization and occurs when the female gamete develops into a new individual without being fertilized by a male gamete. This is the sole method of reproduction in several all-female lizard species, including at least eight *Lacerta* spp.,[30] a number of *Aspidoscelis* spp., and assorted gecko species (e.g., Bynoe's gecko, *Heteronotia binoei*) among others, and is an incidental and anomalous observation in other lizards including the Komodo dragon.[31]

The storage of sperm in the female reproductive tract has been well documented in many vertebrates, and lizards are no exception.[32] Sperm storage has several functions including supporting the sperm to aid in increased fertility, sustaining female fertility duration, and allowing for the choice of the strongest sperm.

Lizards may be oviparous (i.e., egg-laying) or viviparous (i.e., live-bearing). In older literature a third term, ovoviviparous, is referred to and is used to describe the method of reproduction where the eggs are retained within the female until birth of live young. Current studies indicate that even in these species there is nutrient transfer from mother to young, and the appropriate term is viviparous. Some genera of lizards contain both oviparous and viviparous species (e.g., *Phrynosoma, Sceloporus, Rhacodactylus*).[27] See Chapter 80 for more details.

Urinary System

The kidneys are metanephric, paired, symmetric, elongated, slightly lobulated, and flattened dorsoventrally except in chameleons where they are flattened laterally. Depending on the species of lizard, the kidneys may be located deep in the pelvic canal (such as in Agamidae) or in the dorsal coelomic area (as in chameleons and varanids), but as in all reptiles the kidneys are located retrocoelomically.[33] In those species with intrapelvic kidneys, nephromegaly from any cause can result in obstruction of the colon as it passes between the kidneys within the pelvic canal. The posterior segment of the kidney in some male geckos, skinks, and members of the iguana family is sexually dimorphic. This area is called the sexual segment and represents hypertrophy of the distal convoluted tubules. It becomes swollen during the breeding season and contributes to the seminal fluid. The color of the sexual segment may change dramatically during the breeding season and may be misinterpreted as pathology by the untrained eye.

Reptiles can excrete nitrogenous waste as uric acid, urea, or ammonia.[10] Reptile kidneys have fewer nephrons than mammals, lack a renal pelvis, and also lack the loop of Henle and thus are unable to concentrate urine above that of plasma. However, water may be resorbed from the bladder across an osmotic gradient, resulting in the postrenal modification of urine. The excretion of ammonia or urea results in significant water loss, and the excretion of insoluble uric acid allows water conservation. Thus ammonia and urea are excreted in significant amounts only in aquatic and semiaquatic species (Table 9.3).

A thin-walled bladder is present in most species of lizard; however, several species either lack a bladder or develop a vestigial bladder including some agamids (including *Pogona* spp., some varanids, some *Crotophytus* spp., *Scleroporus* spp, teids, and a few geckos). When absent, urine is stored in the distal colon. In some instances, this urate may become desiccated and lead to constipation (Fig. 9.14). Because urinary waste flows from the kidney through the ureter into the urodeum of the cloaca before entering the bladder (or colon in species that lack a bladder), it is not sterile. Urine cannot be concentrated above that of plasma and may change within the bladder, so urinalysis and specific gravity results may not indicate renal function as in mammals.[27] Cystic calculi occur and may be caused in part by water deprivation and diets containing excessive levels of protein. The calculi tend to be singular, smooth-surfaced, layered, and quite large when discovered. For more information, see Chapter 66.

Musculoskeletal System

The skull of lizards is kinetic, resulting in a wide gape and mechanical advantages when closing their jaws. Unlike snakes, the mandibular

FIG 9.15 Chameleons have pincerlike zygodactyl feet with the first through third digits opposing the fourth and fifth in the front feet, and the first and second digits opposing the third through fifth in the hind feet. This veiled chameleon (*Chamaeleo calyptratus*) demonstrates their ability to grasp onto branches as they walk. (Courtesy of Shane Simpson.)

FIG 9.14 A large amount of hardened urates and fecal matter passed by a central bearded dragon (*Pogona vitticeps*). Lizards without a bladder store urate in the distal colon prior to passing it. In cases of dehydration this urate may become hardened and lead to constipation. (Courtesy of Shane Simpson.)

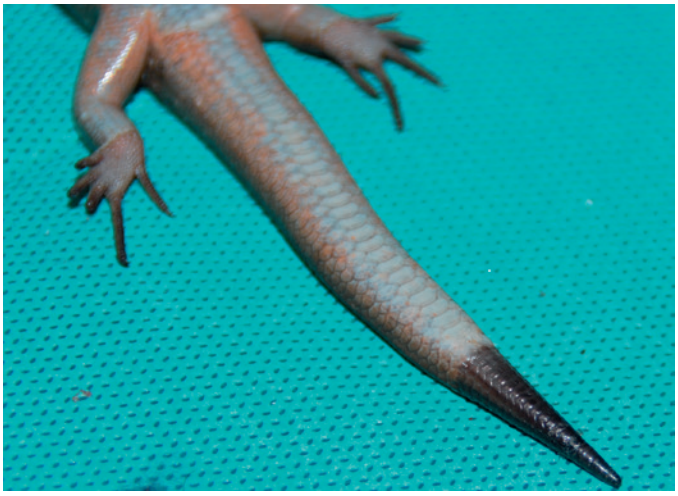

FIG 9.16 Tail autonomy and regeneration is a common trait amongst many lizard species, including the Guthega skink (*Liopholis guthega*). The newly grown tail is normally shorter and darker in appearance than the original one. (Courtesy of Shane Simpson.)

symphysis is fused in lizards. The arrangement of the musculature of the skull results in most lizards having the ability to rapidly and powerfully close the jaws. The backbone of lizards is very mobile and flexible. With the exception of cervical and coccygeal regions, all the vertebrae bear ribs that either join the sternum, the opposite member, or end free in the body wall.[4] The pectoral girdle consists of the scapulae, coracoid bones, and clavicles. The forelimb is composed of a short humerus and the radius/ulna. The hind limb is made up of a short femur and the tibia and fibula along with a patella. The pelvic girdle is comprised of the ilia, ischia, and pubes bones that are firmly braced against the sacrum. Legless lizards have lost the long bones but still retain their pectoral and pelvic girdles. The forefeet and hind feet are usually pentadactyl. The typical phalangeal formula is 2-3-4-5-3 in the forefoot and 2-3-4-5-4 in the hind foot.[2] Chameleons have pincerlike zygodactyl feet with the first through third digits opposing the fourth and fifth in the front feet, and the first and second digits opposing the third through fifth in the hind feet (Fig. 9.15). Bipedal locomotion is seen in some lizards, such as the basilisk and the collared lizard (*Crotaphytus collaris*), and results in great speed.

Many lizards are capable of tail autotomy, or loss of the tail. The advantage of autotomy is to escape from or distract predators when grabbed by the tail. Tails are often brightly colored to attract the attention of predators and wiggle extensively for a few minutes when they detach. Those species that undergo autotomy possess a vertical fracture plane through the body and part of the neural arch of each caudal vertebra. This is a plate of cartilage or connective tissue that develops after ossification. Fracture planes are absent in the cranial part of the tail to protect the hemipenes, fat deposits, and other structures. In iguanas, the fracture plane is replaced by bone during maturation, resulting in a more stable tail in adults. The lost tail is regenerated with a cartilaginous rod for support rather than vertebrae. It generally has smaller darker scales in a more irregular pattern than the original tail and may be shorter and blunter (Fig. 9.16).

Most iguanid lizards, anguids, and many skink genera can undergo autotomy, but most agamids do not. Likewise, the monitors and true chameleons (*Chamaeleo* spp.) do not have fragile tails. Those species with strong tails usually cannot regenerate a complete tail if the original is lost. For more information, see Chapter 81.

FIG 9.17 A monitor lizard (*Varanus* spp.) undergoing ecdysis sheds the outer layer of transparent skin that covers the tympanic membrane. (Courtesy of Stephen Barten.)

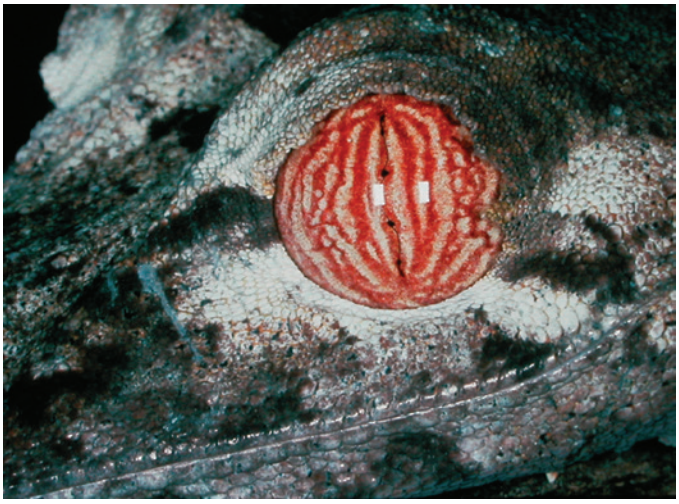

FIG 9.18 Madagascar leaf-tailed gecko (*Uroplatus fimbriatus*). The serrated vertical pupil is completely closed in the bright light used for photography, resulting in a series of pinholes (seen as a vertical line of tiny black dots in the center of the highly ornamented iris). These allow acute vision. (Courtesy of Stephen Barten.)

Nervous System

Like all vertebrates, the reptilian brain consists of the forebrain and the hindbrain. The reptile brain is more advanced, with a larger cerebrum and cerebellum than that of amphibians or fishes. Still, the brain is small, not exceeding 1% of the body mass in its tubular structure. Nevertheless, lizards should not be considered unintelligent; they are capable of learning and benefit from environmental enrichment in captivity. Reptiles are the earliest group of vertebrates with 12 pairs of cranial nerves. The spinal cord differs from that of mammals in that it extends to the tail tip. A subarachnoid space is not present, and as such myelography cannot be performed.

Neurologic disorders are poorly understood and documented in reptiles, but basic neurologic reflexes should be examined during any evaluation. Nutritional requirements and history must also be evaluated, because unbalanced diets may result in neurologic symptoms, such as hypocalcemic tetany. For more information, see chapter 77, Neurology.

Special Senses

Hearing. The ear has both auditory and vestibular functions. The tympanic membrane is generally visible within a shallow depression on the side of the head. It is covered with thin transparent skin, the outer layer of which is shed during ecdysis (Fig. 9.17). In some lizards, such as the lesser earless lizard (*Holbrookia maculata*) and horned lizards, the tympanic membrane is covered with scaly skin. Although mammals have three auditory ossicles, lizards only have two: the slender columnar stapes and its cartilaginous tip, the extracolumella, which are suspended within an air-filled cavity. Airborne vibrations are detected by the tympanic membrane and transmitted via these auditory ossicles across the middle ear to the inner ear. Geckos have the best hearing of all lizards. The inner ear consists of two sacs joined by a broad passage. The dorsal component or utriculus has three semicircular canals arranged perpendicular to each other. This arrangement allows for the detection of movement in three different planes and provides information for the sense of balance.[2,10] Some burrowing lizards have no external or middle ear but transmit sound via bone conduction in a manner the same as snakes. The eustachian tubes connect the middle ear cavities to the dorsolateral pharynx.

Vision. The structure of the reptile eye is similar to that of other vertebrates. The iris contains striated, not smooth, musculature, and common mydriatics therefore have no effect. The lizard pupil is usually round and relatively immobile in diurnal species and is usually vertically slitlike in nocturnal species. Many geckos have a serrated pupillary opening that results in a series of small holes when the pupil is completely closed (Fig. 9.18). The images that pass through these holes are superimposed on the retina, resulting in acute vision even in dim light. The lens does not move for accommodation, but rather muscles in the ciliary body change the lens shape for this purpose. Consensual pupillary light reflex is absent. The cornea does not contain Descemet's membrane. A ring of bony scleral ossicles is present in most species. Eyelids are usually present, except for some geckos and the oscellated skink (*Ablepharus* sp.), which have snakelike spectacle scales. The lower lid is more movable and moves upward to close the eye. In some lizards, the lower lid may be transparent, allowing vision when the lids are closed and the eyes protected. The nictitating membrane is usually present.

The retina is relatively avascular but contains a conus papillaris, a large vascular body that protrudes into the vitreous. The fovea centralis, a depression in the retina responsible for acute vision, is often present in diurnal species. Lizards have good color vision but only a narrow binocular field. This is why they often cock their heads to the side to get the best monocular vision.[4]

A well-developed parietal eye is found on the dorsal midline of the head in some lizards, particularly the Iguanidae (Fig. 9.19). It is a degenerate eye that contains a lens and retina and connects neurologically to the pineal body and is thought to play an important role in regulating circadian rhythms. It does not form images.[10]

Endocrine System

The endocrine system is comprised of numerous glands scattered throughout the body. The gonads produce gametes, but they are also responsible for producing sex hormones. Photoperiod, temperature, and seasonal cycles influence the levels and production of these reproductive hormones. The pituitary gland functions in much the same way as in other vertebrates by producing hormones, such as adrenocorticotropin, prolactin, and follicle-stimulating hormone. These hormones along with others produced by the pituitary gland control such things as growth, water balance, and reproduction.[10]

VetBooks.ir

FIG 9.19 A well-developed parietal eye, like that seen in the center of this central bearded dragon's (*Pogona vitticeps*) head is a degenerate eye that contains a lens and retina. It connects to the pineal body and plays an important role in regulating circadian rhythms. (Courtesy of Shane Simpson.)

FIG 9.20 A male Philippines sail-fin lizard (*Hydrosaurus pustulatus*) with severe rostral abrasion. High-stress species like this can inflict serious damage to themselves with their constant rubbing on the glass walls of the enclosure. (Courtesy of Shane Simpson.)

The pineal body or complex detects the presence and absence of light and as a glandular structure produces the hormone melatonin. This hormone plays a vital role in both daily cycles (or circadian rhythms) and seasonal cycles. It is therefore intrinsically linked with the reproductive cycles of the lizard.[10]

The thyroid gland varies with the species and may be single, bilobed, or paired. The thyroid controls normal ecdysis. Lizards have paired parathyroid glands that control plasma calcium and phosphorus levels. Secondary nutritional and renal hyperparathyroidism are among the most commonly diagnosed diseases in captive reptiles.[4,10] Adrenal glands are suspended in the mesorchium or mesovarium and must be avoided during surgery for neutering.[10] The reptile pancreas has both exocrine and endocrine functions. The beta cells produce insulin, but primary diabetic changes are rare and often are associated with widespread disease. Insulin and glucagon have the same functions in controlling blood sugar levels as they do in other vertebrates.[10]

Despite all the advances in reptile medicine, endocrine disorders are poorly documented and are probably underdiagnosed in these species. See Chapter 79 for more details.

BEHAVIOR

Lizards tend to be alert and responsive, almost inquisitive. Captive-born lizards tend to be tame, docile, and tolerate handling. Wild-caught lizards tend to be shy and wary. They frantically try to escape at the slightest disturbance. Iguanas, monitors, and other lizards may exhibit defensive aggression when threatened. They stand sideways to the threat, swallow air to increase their size, stand high off the ground to look bigger, and lash out at the threat with their tails. Some may gape and threaten to bite if provoked. Some other "normal" behaviors include sneezing in those species with nasal salt glands, color and body size changes in basking animals, and sleeping underwater for semiaquatic reptiles.[34] Many lizards exhibit head bobbing and push-ups when another lizard or human invades their territory. Cage-mate aggression is common in central bearded dragons, and as such they should be kept separate. Offensive aggression is rare and usually involves sexually mature male iguanas during the breeding season. They may attack anyone entering their territory and attempt to bite. These lizards must be confined to their cage during these times.

Iguanas, some geckos, and others frequently defecate in the same spot. If paper is put in that spot, the lizard may become litter-trained. Iguanas loose in the house frequently defecate in the bathtub, which is easy to clean.

A common behavioral problem is rostral nose rubbing. This is most often seen in some of the more "high-stress" species of lizards such as water dragons (*Intellagama lesuerii, Physignathus cocincinus)* and Philippines sail-fin lizards (Fig. 9.20). It can be a frustrating condition to overcome. See Chapter 13 for more details.

LONGEVITY

Owners often question their veterinarian about how long their pet is expected to live. An appreciation of expected lifespans of the various commonly kept lizard species can therefore be useful in answering this question and determining if the patient is nearing its normal end of life.

This can be difficult though because specific and accurate longevity data on assorted species is lacking. Adding to the difficulty is the fact that it can be challenging to estimate the age of reptiles. Reptiles show little outward signs of aging. Body size is not an accurate method due to variations in food amounts and quality that can result in stunting or an increased rate of growth.

In general, it is considered that captive animals are longer-lived than wild relatives due to less exposure to potential dangers

Lizards are relatively long-lived animals when compared to mammals but not when compared with some of the other reptilian groups such as tortoises and crocodilians.

Bearded dragons live 10 to 12 years, with older specimens reaching 14 years. Green iguanas are reported as living 10 to 15 years, but some have been known to live to 20 years of age.[35] Owners should be educated about the difference between record lifespans, which are usually reported in common references, and average lifespans, which often are considerably less than the record for a given species.

Crocodilian Taxonomy, Anatomy, and Physiology

Javier G. Nevarez

Crocodilians are some of the largest reptiles in the world. They can be found through the Americas, Africa, Asia, and Australia in approximately 90 countries. They mostly inhabit tropical and subtropical regions. Crocodilians range in length from 1.5 m for smaller caiman and crocodile species to over 6 meters and over 450 kg for the saltwater crocodile (*Crocodylus porosus*). Most are also long-lived species, although there is no way to determine their true age in the wild. In general, smaller species such as caimans have a lifespan of 20 to 40 years, whereas crocodiles can live 60+ years. As such they require a large enclosure and people committed to their care in captivity. Crocodilians are displayed in zoological institutions, and there are even crocodilian-specific parks that house a majority of the species. Many species are also raised in commercial operations for their meat and hides (see Chapter 177). While they are legal as pets in some states/countries, their large size precludes most individual private owners from providing an adequate environment that is safe for animals and humans alike. Crocodilians have unique anatomy and physiology that separates them from other reptilian groups. Knowledge of these unique features is essential for their proper care in captivity.

TAXONOMY

All living crocodilians belong to the clade Archosauria, which also includes birds and extinct dinosaurs. Crocodilian taxonomy is varied depending on the source and interpretation. The information presented in this chapter is based on currently accepted classification, especially as it pertains to recognition by the International Union for the Conservation of Nature (IUCN) and Convention on International Trade in Endangered Species (CITES), which have important implications for the commercial trade and conservation of crocodilians. Based on this parameter, there are 24 recognized species of crocodilians divided into three families: Alligatoridae, Crocodylidae, and Gavialidae (Table 10.1). Some classifications will include subspecies, but these are not universally accepted. In the future, additional species may be added because recent work suggests *Osteolaemus tetraspis* should be divided into *O. tetraspis*, *O. osborni*, and *O. sp. nov.*[1,2] It is also proposed that *Mecistops cataphractus* (*Crocodylus cataphractus*) be divided into Central and West African subspecies,[2,3] but this has not been universally accepted. *Tomistoma schlegelii*, formerly known as the false gharial, was formerly included in the family Gavialidae, but now it is recognized under Crocodylidae, and the common name Tomistoma is more widely accepted. These taxonomic variations can have important implications for the conservation of the species in their native habitat and selection of animals for captive breeding programs.

ANATOMY AND PHYSIOLOGY

Integument

The skin of crocodilians, like that of other reptiles, is comprised of β- and α-keratin. The outer scales are made up of the rigid β-keratin, whereas the hinge regions are comprised of the more flexible α-keratin. These layers are arranged in alternating lateral distribution as opposed to an alternating vertical arrangement found in squamates and tuataras.[4] This lateral arrangement is responsible for shedding in a gradual, exfoliation pattern more similar to mammals than that of other reptile groups.[4] Despite belief to the contrary, crocodilians do shed their skin, but it is not easily observed grossly as in other reptile species. Crocodilians also have a higher distribution of dermal bones known as osteoderms. The arrangement and number of scales and osteoderms in the dorsal neck region can be used for species identification.[5] The skin over the skull is tightly adhered without a subcutaneous space. While the majority of osteoderms are found in the dorsal skin, some caiman and alligator species have them in the ventral skin, making them less ideal for the skin trade. The tail has a double row of triangular scales that merge into a single row midway along the length.

The skin coloration varies with age. Hatchlings and juveniles often have well-defined bands or spots that will fade as they grow. Adult skin coloration ranges from black-gray to light brown or off-green depending on the species. The ventral and lateral skin tends to be lighter than the back and head.

The skin of all crocodilians possesses intradermal sensory organs (ISO). The distribution of ISOs varies across species. In Alligatoridae, they are strictly found on the head region (Fig. 10.1), whereas in Crocodylidae and Gavilaidae they are found throughout the whole body but are more prominently noted on the ventral skin (Fig. 10.1).[6] These structures have highly sensitive free nerve endings similar to the lateral line system of fish. The function of ISO includes detection of water movement and tactile discrimination.[6] Leitch and Catania report that ISO have a mechanical sensitivity exceeding that of primate fingertips.[6] This is an important consideration when handling crocodilians as it implies their skin is capable of very minute tactile receptivity.

Crocodilians have paired gular and paracloacal glands (Fig. 10.2). The compounds secreted by these glands vary between glands and sexes. Their true function is not fully elucidated but may include mating, defense, and communication.[7]

Cardiovascular System

The cardiovascular system of crocodilians is perhaps the most complex in the animal kingdom due to anatomic features that allow right-to-left

TABLE 10.1 Taxonomy, Geographic Location, and Size of Crocodilians

Taxonomy	Common Name	Location	Average Adult Length
Family Alligatoridae			
Alligator mississippiensis	American alligator	Southeastern United States	4.5 m
Alligator sinensis	Chinese alligator	Eastern China, lower Yangzi river	2 m
Caiman crocodilus	Spectacled caiman	Central and South America	1.5–2 m
Caiman latirostris	Broad-snouted caiman	Argentina, Bolivia, Brazil, Paraguay, Uruguay	2 m
Caiman yacare	Yacare caiman	Argentina, Bolivia, Brazil, Paraguay	2.5 m
Melanosuchus niger	Black caiman	Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Peru	4 m
Palaeosuchus palpebrosus	Cuvier's dwarf caiman	Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Paraguay, Peru, Surinam, Venezuela	1.5 m
Palaeosuchus trigonatus	Schneider's smooth-fronted caiman	Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Peru, Surinam, Venezuela	2 m
Family Crocodylidae			
Crocodylus acutus	American crocodile	Belize, Colombia, Costa Rica, Cuba, Dominican Republic, Ecuador, El Salvador, Guatemala, Haiti, Honduras, Jamaica, Mexico, Mexico, Nicaragua, Panama, Peru, United States, Venezuela	5 m
Crocodylus cataphractus	African slender-snouted crocodile	Central and West Africa	2.5 m
Crocodylus intermedius	Orinoco crocodile	Colombia, Venezuela	4–5 m
Crocodylus johnstoni	Australian freshwater crocodile	Northern Australia	2–2.5 m
Crocodylus mindorensis	Philippine crocodile	Philippines (Busuanga, Luzon, Masbate, Mindanao, Mindoro, Negros, Samar islands)	2–3 m
Crocodylus moreletii	Morelet's crocodile	Belize, Guatemala, Mexico	3 m
Crocodylus niloticus	Nile crocodile	Central-Southern Africa	5 m
Crocodylus suchus	West African crocodile	West Africa	5 m
Crocodylus novaeguineae	New Guinea freshwater crocodile	Indonesia, Papua New Guinea	2–3 m
Crocodylus palustris	Mugger crocodile	Iran, India, Nepal, Pakistan, Sri Lanka	4–5 m
Crocodylus porosus	Saltwater crocodile	Australia, Bangladesh, Brunei, Myanmar, Timor Leste (East Timor), India (incl. Andaman & Nicobar islands), Indonesia, Malaysia, Palau, Papua New Guinea (incl. Bismarck archipelago and other island chains), Philippines, Sri Lanka, Solomon Islands	3 m (females) 5 m (males)
Crocodylus rhombifer	Cuban crocodile	Cuba	3.5 m
Crocodylus siamensis	Siamese crocodile	Cambodia, Indonesia (including Borneo and possibly Java), Laos, Malaysia, Thailand, Vietnam	3 m
Osteolaemus tetraspis	Dwarf crocodile	West and West-central Africa	1–1.5 m
Tomistoma schlegelii	Tomistoma	Indonesia (Sumatra, Kalimantan, Java), Malaysia (Sarawak, Sabah, Peninsular Malaysia)	5 m
Family Gavialidae			
Gavialis gangeticus	Gharial	Northern India subcontinent: Bangladesh, Bhutan, Burma, India, Nepal, Pakistan	5 m

shunting in a way not found in any other taxa. Crocodilians are the only reptiles with a true four-chamber heart. There is a prominent pericardial sac that often contains a large amount of fluid compared to similarly sized mammals (Fig. 10.3). The significance of this fluid volume is unknown. There is a prominent sinus venosus on the right side associated with the right atria. Salient features of the crocodilian heart include a foramen of Panizza, a left aorta originating from the right ventricle, anastomosis between left and right aortas, and cog-teeth-like valves in the right ventricle.[8] The foramen of Panizza is a high septal opening anterior to the aortic valves that connects the right and left aortas. A critical function is the perfusion of the coronary vessels and brain during blood shunting.[8] Because the left aorta originates from the right ventricle, it also plays a significant role in shunting, specifically as it relates to digestion.[9] The anastomosis between left and right aortas lies dorsal to the lungs. Past this anastomosis, the left aorta becomes the celiac artery, and the right becomes the dorsal aorta. The cog-teeth-like valves in the pulmonary outflow of the right ventricle, proximal to the bicuspid valve, help control shunting. These three features combined play a role in right-to-left shunting in crocodilians.[8,10] Shunting occurs as a result of complex anatomical and physiological factors including changes in ventricular pressures, pulmonary pressure, and systemic resistance. The shunting process cannot be predicted or controlled; therefore gas anesthesia alone is not recommended because, if shunting occurs, it can lead to unpredictable levels of anesthesia.

An important role of the shunting process is to allow crocodilians to stay submerged for prolonged periods of time. During diving, an increase in the pulmonary pressure leads to an increase in central pressure due to reduced blood flow from the pulmonary artery. This in turn leads to blood flow through the foramen of Panizza to the left aorta and to the systemic circulation allowing both conservation of oxygen and perfusion of organs.

Respiratory System

The nostrils of all crocodilians are located on a raised area at the end of their dorsal snouts and can be closed with muscular flaps when the animal submerges. Crocodilians lack a choanal slit; instead there is a complete hard palate creating a true division between the oral and pharyngeal cavities (Fig. 10.4). A highly vascular sinus system allows the nasal passage to seal out water when vessels are engorged so that animals do not drown under water. The nasal passage is divided into a vestibulum, nasal cavity (cavum), and nasopharyngeal duct. The nasal cavity has conchae and gives rise to a complex system of nasal sinuses. The internal nostrils open at the level of the glottis in the pharynx.

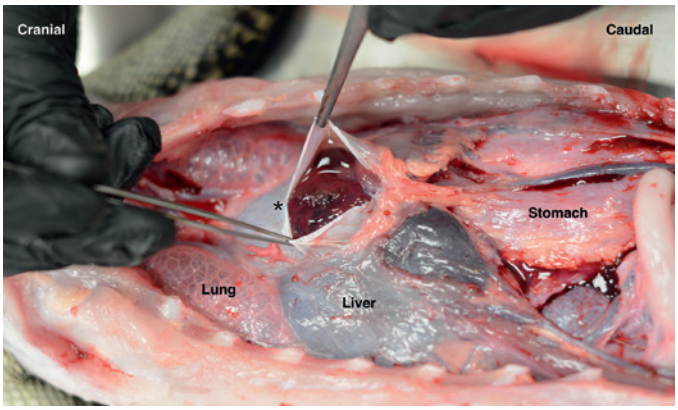

FIG 10.3 Incised pericardial sac (*) of *A. mississippiensis* revealing normal amount of fluid surrounding the heart. It is normal to find a large amount of pericardial fluid and sometimes free coelomic fluid as well, especially in free-ranging alligators. (Courtesy of Javier G. Nevarez.)

There is a gular valve composed of the velum palati dorsally and the gular fold ventrally (Fig. 10.4).[11] The velum palati is a soft tissue extension of the dorsal palate. The gular fold is a cartilaginous extension of the basihyoid cartilage.[11] Together they create a tight seal separating the oral and pharyngeal cavity (Fig. 10.4), which allows crocodilians to grab and hold prey underwater without drowning. Water that is taken into the mouth can be swallowed without being inhaled. They can open-mouth breath in cases of trauma to the nasal passages. Crocodilians have complete tracheal rings and multicameral lungs with a single left and right lung lobe. There is an extensive bronchial tree. The lungs are in direct contact with the liver and extend dorsocaudally within the coelomic cavity. On radiographs, the lungs normally encompass one-third to one-half of the coelomic cavity. Framer et al. have described the airflow through the lungs of crocodilians.[12] Despite the absence of air sacs, there is a unidirectional flow of air similar to birds.[12] Respiration is an active process by the intercostal muscles and the diaphragmaticus muscle, also known as the post-hepatic septum. The diaphragmaticus originates from the ischia and last gastralia and inserts on connective tissue on the caudal aspect of the liver (Fig. 10.5).[13] It is incomplete and more horizontally oriented so it does not create a true separation of the cavity. It is a thin muscle that has often been associated with respiration but also plays an active role in buoyancy.[13,14] Uriona et al. revealed that transection of the diaphragmaticus muscle can lead to decreased submersion times in *Alligator mississipiensis*.[15]

Digestive System

Crocodilians are polyphyodonts with thecodont dentition. As such they have continually replaced teeth that live in a socket. Their teeth are conical, hollow, and without any roots. Estimates are that crocodilians can replace their teeth up to 50 times in their lifespan. Older animals may be missing teeth due to old age and/or damage that has affected tooth growth. There is varied conformation of their tooth arrangement, and some dental formulas have been proposed by Grigg and Kishner.[16] These formulas divide the teeth into premaxillary and maxillary rather than traditional mammalian formulas. Dental disease is usually of low clinical significance in crocodilians.

The tongue is attached to the floor of the mouth along the entire ventral surface, thereby preventing any protrusion of the organ. The crocodilian stomach is divided into two distinct regions, the corpus and the pars pylorica (Fig. 10.6). The corpus or cardiac region is the first compartment and glandular portion of the stomach. Gastroliths and other foreign bodies can sometimes be found in the corpus, leading some to compare it to the ventriculus of birds. However, gross and histologic structure differ from the avian ventriculus. Past the corpus there is a sphincter that opens into a small dilatation, the pars pylorica (Fig. 10.6), before a thick sphincter leads into the duodenum. There is rarely any ingesta observed within the pars pylorica, and its function is largely unknown. The stomach's high acidic secretion is partially controlled by shunting of deoxygenated blood after ingestion of a meal.[9] Crocodilians have shifts in plasma pH levels on a frequent basis.[17] Because of the high production of concentrated hydrochloric acid in the stomach, a shift of chloride ions from plasma leaves a large amount of sodium to react with plasma carbonic acid.[17] This results in large amounts of sodium bicarbonate causing an alkaline tide.[17] Thus a profound plasma alkalemia in crocodilians is associated with food ingestion. The most efficient temperatures for ingestion and digestion are between 25°C and 35° C (77°F–95°F).

The duodenum is thick and U-shaped (Fig. 10.6). The pancreas is closely adhered to the duodenum and runs its entire length (Fig. 10.6). The small intestines have a rather thick wall compared to in other animals, and the mucosa commonly displays a crosshatch pattern. Gut-associated lymphoid tissue is found throughout the intestines. These can sometimes be observed grossly, especially in cases of enteritis. The large intestine is short, thin walled, and with a diameter of approximately twice the

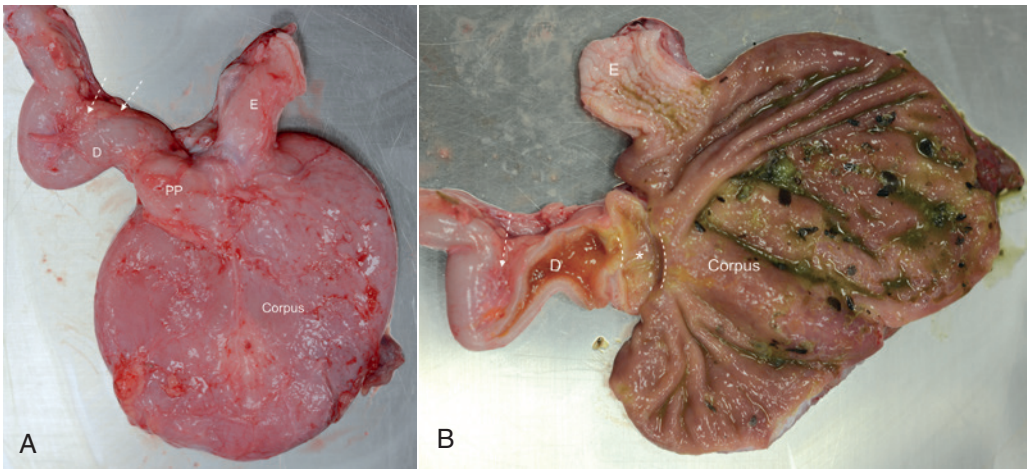

FIG 10.6 (A) The distal esophagus (E), corpus and pars pylorica (PP) of the stomach, duodenum (D), and pancreas (white dotted arrows) of *A. mississippiensis*. (B) Exposed mucosa of the esophagus (E), corpus, pars pylorica (*), and proximal loop of the duodenum (D). The dotted white lines mark the sphincters separating the pars pylorica from the corpus and duodenum. The pancreas (white dotted arrows) is located between the loops of the duodenum. (Courtesy of Javier G. Nevarez.)

small intestines. Urine and fluids are often found within the colon. There are prominent ileocolic and colon sphincters. The small and large intestines are enveloped by an extensive mesentery that creates a true separation between the lungs, liver, stomach, and the rest of the organs. This mesentery in essence creates a bag that encases and/or incorporates the small and large intestines, spleen, kidneys, and gonads (Fig. 10.7).

There are two liver lobes, with the right being larger. A gallbladder is present within the right lobe. A prominent triangular fat pad can normally be found caudal to the right liver lobe. A small fat pad may be indicative of chronic anorexia, particularly in captive animals. The liver lobes are concave medially to accommodate the shape of the heart. On cut surface, the liver tissue is dark brown-red in color. Unlike most reptiles and birds, crocodilians produce bilirubin. The author has observed icterus, elevated bilirubin levels, and liver fibrosis in cases of aflatoxicosis (Fig. 10.8).

Reproductive System

All crocodilians are oviparous. The time of year and length of various stages of the reproductive cycle are somewhat variable depending on the species, habitat, and hemisphere of location, but overall they share common anatomy and reproductive cycles. The testes and ovaries are located ventrally on the craniomedial aspect of the kidneys. Both gonads increase in size during the reproductive season. The reproductive cycle and follicular development of alligators has been described and can be monitored with ultrasonography.[18,19] During vitellogenesis, higher amounts of lipids, phosphorus, calcium, and vitamin E are found in the blood.[20] Blood plasma collected from female alligators at this time of year has a characteristic white appearance as a result of the increased circulating lipids.[19,20] After ovulation, the plasma loses the white appearance and is similar to that of males and nonreproductive females. In the alligator, a hierarchy of follicle groups develops, with each group representing a clutch. The clutch to be fertilized may contain as few as 20 or as many as 80 follicles, with an average of 40 eggs laid per clutch. Alligators and most of the crocodilian species go through a refractory period after ovulation. An exception to this is the Indian mugger crocodile (*Crocodylus palustris*), which produces two clutches per year under natural conditions.

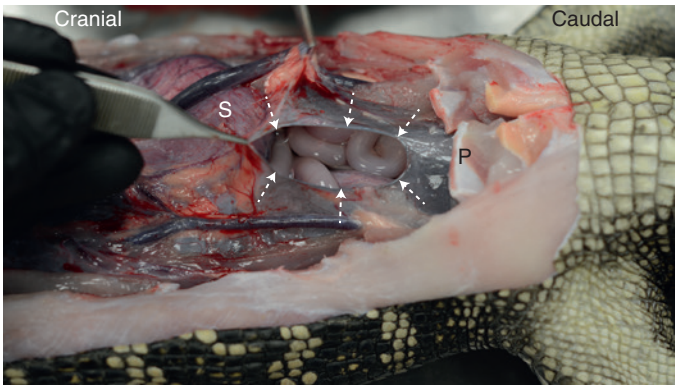

FIG 10.7 View of incision through the mesentery (white arrows) in *A. mississippiensis* revealing intestinal loops. While the intestinal loops come in contact with the stomach (S), they do not contact the lungs or heart. The pubis (P) has been cut for easier visualization. (Courtesy of Javier G. Nevarez.)

Sexing can be performed by examination of the cloaca. Males have a phallus that can be easily everted from the cloaca. The phallus is located on the ventroposterior surface of the cloaca near the cranial opening of the vent, and the dorsal surface has a single open groove that serves for conduction of spermatozoa. Two thick fibrous plates, the crus penis, are located at the base of the phallus. The groove is the result of the fusion of the crus penis. The phallus is primarily cartilaginous and has little erectile tissue. Females have a clitoris that is similar in appearance to the phallus but smaller and will not evert from the cloaca. Therefore when sexing crocodilians, palpating the cloaca is not accurate enough. It is important to attempt to evert the phallus to confirm it is a male, particularly in small animals because the well-developed clitoris is easily confused with a phallus.

Crocodilian gender is a result of temperature-dependent sex determination (TDSD) with an incubation temperature range of 29°C to 34°C (84°F–93°F) being reported as ideal for embryo viability and

VetBooks.ir

FIG 10.8 (A) Icteric cardiac vessels of *A. mississippiensis* diagnosed with aflatoxicosis. (B) Liver from the same animal revealing fibrosis and necrosis (N), replacing the more normal red-colored hepatic tissue. Affected animals were found to have higher bilirubin levels than healthy animals. (Courtesy of Javier G. Nevarez.)

hatching.[21,22] In all species, low incubation temperatures (29°C–30°C; 84°F–86°F) result in all females, and temperatures above 34°C (93°F) result in a high proportion of malformations or embryonic deaths.[22,23] However, the data on mid-range and high-range temperatures vary among studies. While it was proposed that *A. mississippiensis* and *C. crocodilus* followed a female-male pattern (FM) at low and high temperatures respectively,[22,23] Lang and Andrews found a female-male-female (FMF) pattern similar to other crocodilians.[22] In the FMF pattern, females are produced at low and high temperatures while males predominate at intermediate temperatures. It was determined that in *A. mississippiensis*, 100% males are produced at the narrow range of 31.5°C to 31.8°C (88.7°F–89.2°F), which appears to be unique in crocodilians.[22] At 33°C (91.4°F) there is again a shift toward a more-even distribution of male and females, and beyond 33.5°C (92.3°F), females predominate.[22] Based on their results, Lang and Andrews proposed an FMF pattern for *A. mississippiensis*, *C. crocodilus*, *C. palustris*, *C. moreletii*, *C. siamensis*, *C. porosus*, *C. johnstoni*, *C. niloticus*, and *G. gangeticus*. The period of temperature sensitivity at which sex is determined is proposed to be during stages 21 to 24 of the third quarter of embryonic development, which is the period of gonadal development.[21,22] In addition to incubation temperatures, there also appears to be a clutch effect that influences sex ratios.[22]

Urinary System

Crocodilians are both ammoniotelic and uricotelic, with ammonia excretion being predominant.[24] There is no urinary bladder, but urine is often stored in the urodeum and coprodeum.[25] Urine collection via catheter insertion into these chambers has been reported.[25] All crocodilians possess salt-excretory lingual glands, but these are less developed in species that live primarily in freshwater habitats.[26,27] Periodic submergence in water is necessary for all crocodilians to counteract water loss. Water intake consists of incidental drinking and drinking when feeding. Water may also be absorbed through the skin. Small crocodilians such as hatchlings and juveniles may lose up to 20% of body weight per day through insensible losses. Daily movement between land and water is necessary to maintain the correct osmoregulation. Loss of sodium in fresh water is fairly low, and the main route of sodium loss is through the skin. Evaporative water loss occurs from the respiratory tract, the oral cavity, and the skin. The kidney and cloaca are the primary route for the excretion of nitrogenous waste but not for salt excretion. Some salt and water absorption is reported to occur in the cloaca.

Musculoskeletal System

The crocodilian skull is elongated and composed of 30 fused bones. All species of crocodilians have long, flattened, tooth-lined skulls of various sizes and shapes. Both upper and lower jaws have teeth that are set in sockets via connective tissue. The upper and lower jaws articulate at the posterior aspect of the skull, which allows the wide opening of the jaws. The one to two muscle pairs that open the jaw are quite weak, and therefore the jaws can be held closed with a minimal amount of effort.[16] The five to six muscle pairs that close the jaws are very strong, creating an extreme bite force, the highest measured in animals.[16] In adult animals, attempting to open the mouth can be dangerous because of this strength. If one opens the mouth of an adult that has recently died, a point comes where the muscles are stimulated to close with tremendous force. The stimulatory effect may occur up to 24 hours after death.

The approximately 55 to 67 vertebrae consist of 8 to 9 cervical, 15 to 16 dorsal (thoracolumbar), 2 sacral, and 30 to 40 caudal.[16] Crocodilians, like most reptiles, have procoelous vertebrae, which are concave anteriorly and convex posteriorly. This is in contrast to the acoelous vertebrae of mammals, which are flattened on both ends. Exceptions in crocodilians include the atlas and axis, the two sacral, and the first caudal vertebrae, which are all acoelous.[16] There are eight pairs of ribs and an additional eight pairs of gastralia or floating ribs (Fig. 10.9). Gastralia are embedded in the ventral body wall superficial to the rectus abdominis muscles. The so-called sacral ribs are heavy bones that articulate with the transverse

FIG 10.9 Ventral coelom of *A. mississippiensis* with the skin removed to reveal the gastralia (black arrows) and sternum. The eighth gastralia is not visible in the image as it lies within the soft tissues in the caudal coelom. (Courtesy of Javier G. Nevarez.)

FIG 10.10 External auditory meatus of *A. Mississippiensis* showing the large superior (S) and smaller inferior (I) flaps that protect the tympanic membrane. The ear is located caudal to the eye (E). (Courtesy of Javier G. Nevarez.)

processes of the sacral vertebrae. A difference of opinion exists as to whether these are true ribs or merely thickened transverse processes. They are not fused to the vertebrae and so are frequently referred to as ribs. The pelvic girdle has a short ilium, a narrow but elongated pubis, and a short wide ischium. The front and hind limbs are anatomically similar to those of mammals and attach in an analogous fashion. The femur is longer than the humerus and holds the posterior portion of the body higher than the anterior. The front limbs have five digits with claws on the medial three digits, and the webbed hind limbs have four digits that are longer than the front limbs and also have claws on the medial three digits.

Nervous System

Crocodilians have features of the brain and nervous system that distinguish them from other reptiles. They have a cerebral cortex albeit small in size, lack a pineal body, and have a larger cerebellum than other reptiles.[28] They have small brains that account for 0.004% of their total body weight; however, they are still known to have good cognitive and learning capacity.[28] There are 12 pairs of cranial nerves, with a salient feature being enlargement of the trigeminal nerves. It is proposed that this serves the increased sensory function of skin on the face and head, along with the ISO.[28] The dorsal roots of the first two spinal nerves, are absent but do occur on the remaining spinal nerves. The spinal cord of crocodilians extends almost to the tip of the tail. The dorsal and ventral caudal nerves leave the spinal cord in the same way as the body trunk nerves due to the lack of a cauda equina.[29]

Species Senses

Vision. Crocodilians are visually oriented and have eyes that are well suited for both day and night. Because they are located high and lateral on the head, the eyes, like the nostrils, can remain above the surface of the water when the animal is partially submerged. The eyes of caimans and alligators are more prominent than those of crocodiles. The bony orbits of the skull surround the eyes, and if the eyes are pressed, they sink into the orbit. In crocodilians the upper eyelid provides most the movement for closing the eye. The upper lid may also contain a bony structure, or tarsus, which is absent from the lower lid.[30] There is a nictitating membrane with a cartilaginous edge. The third eyelid arises ventral and cranial and moves in a dorso-caudal direction when closing. The nictitans is transparent to translucent in most species. A harderian gland is present and described as discharging on the inner aspect of the nictitans.[30] A lachrymal gland is present on the medial aspect of the orbit.[30] There is a vertical slitlike pupil that dilates in a medial-lateral direction. The pupil position remains vertical with the horizon, even when the head is raised or lowered. It is postulated that when the animal is turned over on its back, it becomes disoriented because of this particular eye configuration. Scleral ossicles are absent, but there is a cuplike scleral cartilage that extends more cranially.[28,30] There is a predominance of rods over cones, an adaptation for night vision. A tapetum lucidum is well developed and located on the dorsal aspect of the retina. This makes it easy to locate the animals at night when a spotlight is used.

The muscles of the eye (the superior rectus, inferior rectus, the internal rectus, and the inferior oblique) serve to allow retraction of the eye into the orbit when the animal is threatened. Almost all crocodilians use vision to capture prey that is out of the water, but such vision under the water is limited, and other senses are used. The lateral placement of the eyes means that the anterior binocular vision is not well developed. In the American alligator, the eyes are oriented to permit 25 degrees of binocular vision and a field of view of approximately 260 degrees.[28] When working with large crocodilians, an approach directly from the front or from behind is advisable and somewhat safer whenever feasible. The poor binocular vision means that the defensive mechanism for the animal is better adapted to lateral approaches. When approached from the side, the rapid defensive movement of the head and tail is directed in the same direction, with an attempt to strike the individual with the head, tail, or both.

Hearing. The external auditory meatus are slitlike openings that are closed by a large superior and smaller inferior flap and are protected by a dorsal shelf of bone (Fig. 10.10).[28] The fibrous flaps serve to close the external opening when the animal submerges. The middle ear is separated from the external ear by a tympanic membrane. Crocodilians have a well-developed hearing mechanism. They have good auditory acuity across a wide range of frequencies from approximately 20 to 2000 Hz.[28] A variety of sounds are used by crocodilians, such as grunts by hatchlings and hissing or snarling sounds when threatened. A characteristic bellowing sound is used during the mating season. Evidence of this is found in their behavior when strange sounds occur and in their ability to respond to vocalizations at specific times, such as during the breeding season or when hatchlings are in the nest. It is not unusual for females to become disturbed when hatchlings are stimulated to make grunting sounds.

BEHAVIOR

Parental care at hatching and post hatching are universal traits in the wild. In captivity, however, some species such as *A. mississippiensis* become accustomed to repeated approaches to the nest and do not

VetBooks.ir

display protective behavior. *C. porosus* is reported to aggressively defend the nest at all times.

Thermophile or heat seeking occurs in all crocodilians after feeding. This increase in body temperature apparently benefits the animal by increasing the rate of digestion and absorption. Even though environmental temperature has an influence on their body temperature, crocodilians select behavior that enhances their activity in relation to the environment. Evidence also shows that the particular temperature of incubation of an embryo may have an effect on selected body temperature later in life.[22] Lang has reported that when *A. mississippiensis* are fed, they select the warmer area in the enclosure.[31] When not fed, the same animals move to a cooler area. Coulson and Hernandez[17] reported that digestion and absorption took twice as long at 20°C as they did at 28°C in *A. mississippiensis*. Diefenbach also reported that passage of food through the digestive system was three times faster at 30°C than at 15°C in *Caiman crocodilus*.[32] This selection in body temperature differential appears to occur in captive *A. mississippiensis* hatchlings and juveniles when given the opportunity. Adults living in the wild or in outside captive facilities also display this selection process. They come out of the water to bask in the sun. At this time, they may lie with their jaws open in an effort to obtain evaporative cooling of the head. Heating and cooling are accomplished by entering and leaving the water.

The requirement for heat is greater in hatchlings and juveniles than in adults. An experimental infection reported by Lang caused an increase in selected body temperature within a short time and returned to normal by day 4.[31] Increases in body temperature ranged from +1.68°C to +7.88°C (35°–46°F). None of the animals showed ill effects in growth or behavior as a result.

In another study, Glassman and Bennett reported that *A. mississippiensis* subjected to an induced infection and held at constant temperatures responded to the infection with increased white blood cells.[33] The animals were maintained at 25°C (77°F), 30°C (86°F), and 35°C (95°F). The animals held at 30°C (86°F) displayed the greatest hematologic response and recovered. Infected animals held at 35°C (95°F) succumbed within 3 weeks, which was attributed to the stress of high temperature and an ineffective immune response.

Behavioral fever, which has been reported in other reptile species, appears to be an important factor in survival. However, an adequate thermal gradient must be available for the optimum immune response, which is temperature dependent.[34] When temperatures are maintained at a constant, the stress combined with a reduced antibody response can lead to stunted growth or a high mortality in the group.

Tuatara Taxonomy, Anatomy, and Physiology

Sarah Alexander

Tuatara (*Sphenodon punctatus*) are unique reptiles endemic to New Zealand and are the only extant members of the order Rhynchocephalia, a once widespread and moderately diverse group. The name "tuatara" is derived from the Maori language, where "tua" means back or far side, and "tara" means spike or spine. This is translated as "peaks on the back," a reference to the tuatara's spiny dorsal crest. The scientific name *Sphenodon* is derived from the Greek words for wedge (sphen) and tooth (odous), describing the wedge-shaped acrodont teeth of tuatara. The species name *punctatus* refers to the large number of spots on the tuatara's body. Tuatara were once widespread throughout New Zealand but effectively disappeared from the mainland following the arrival of Polynesians in AD 1250 to 1300 due to associated land use modification and the introduction of Pacific rats (*Rattus exulans*).[1] The arrival of Europeans and associated predators in the 1840s sounded the death knell for mainland tuatara populations, and today they survive on about 32 offshore islands and several mainland sanctuaries, approximating 0.5% of their former range.[2] The tuatara population today is estimated to number approximately 50,000 animals, and they are listed on CITES Appendix 1.

Tuatara are long-lived reptiles thought to survive for 80 years or more in the wild,[1] although there are several animals in captive institutions estimated to be more than 100 years of age. Adult tuatara exhibit sexual dimorphism. Males are larger than females, have a proportionally larger head, and have more prominent nuchal and dorsal crests and spines. Juveniles may exhibit this to a lesser degree but are more accurately sexed by coelioscopy.[3] Adult tuatara weigh between 200 and 1100 g, with a snout-vent length of 170 to 280 mm. Size varies with geographic location, with animals on larger islands consistently being bigger than their counterparts in more size-restricted habitats, presumably due to differences in food availability.[1] Tuatara are considered nocturnal, though they often emerge during the day in suitable weather, primarily to bask.[4]

TAXONOMY

Tuatara are members of the superorder Lepidosauria, which includes modern lizards and snakes. While tuatara bear a superficial resemblance to lizards, their ancestors are thought to have diverged from snakes and lizards in the early Triassic, an estimated 240 to 250 million years ago (Fig. 11.1).[5] *Sphenodon punctatus* is currently the only recognized species of tuatara, although the Brothers Island subpopulation was briefly classified as a separate species (*S. guntheri*) in the 1990s on the basis of variation in blood proteins.[6] Subsequent molecular studies have confirmed these animals all belong to the single species *S. punctatus*,[7] and they are currently managed as a single species with distinct geographic variants.

ANATOMY AND PHYSIOLOGY

The body shape of tuatara superficially resembles that of terrestrial lizards, but unique anatomic and physiological features set them apart from other squamates.

Integument

The dorsal scales of tuatara are small, granular, and usually an olive-brown color, though green, orange, and gray variants exist. Juveniles often exhibit brighter coloration than adults, and this fades with age (Fig. 11.2). The dorsal surface of the animal is covered in white-yellow spots of varying size, and there is a spiny crest that runs along the dorsal surface of the head and back. The ventral scales are larger than the dorsal scales and are pale gray to white in color. Tuatara slough in a ragged, fragmentary fashion similar to that of lizards, a process that can take up to 1 month and usually takes place once a year in late summer, although it can occur more frequently in juveniles and in captive animals.

Cardiovascular System

Tuatara have a heart structure similar to lizards, with two atria and a single ventricle. The ventricle has a poorly developed vertical septum and muscular ridge; however, functionally there is considerable separation of pulmonary and systemic blood flow, as seen in other squamates.[8] Tuatara have the largest erythrocytes and granular leukocytes of any reptile studied.[9] As in most other reptiles, tuatara lack lymph nodes[10] but have an extensive network of perivascular lymph vessels running throughout the body.

Respiratory System

The trachea of tuatara divides into two very short bronchi, each ending in a thin-walled, single-chambered lung.[11] The surface area for respiration is low compared with similar-sized reptiles, likely a function of the tuatara's low metabolic rate and oxygen demand.[12] Similar to many lizards, tuatara have a biphasic breathing pattern. After inspiration there is a small, incomplete exhalation, followed by a pause, and then active expiration, followed immediately by the next inspiration.[13] Tuatara have limited vocalizations but will make a croaking noise when disturbed or distressed.

Digestive System: Dentition

Tuatara have acrodont dentition, with two upper rows of teeth—a complete outer row attached to the maxilla, and a shorter inner row attached to the lateral edge of the palatine bone (Fig. 11.3). A single lower row of teeth fits into the gap between the two upper rows and moves rostrally relative to the upper jaw, producing a painful crushing bite with a saw-like motion.[14] Tuatara also have a pair of large incisor-like

VetBooks.ir

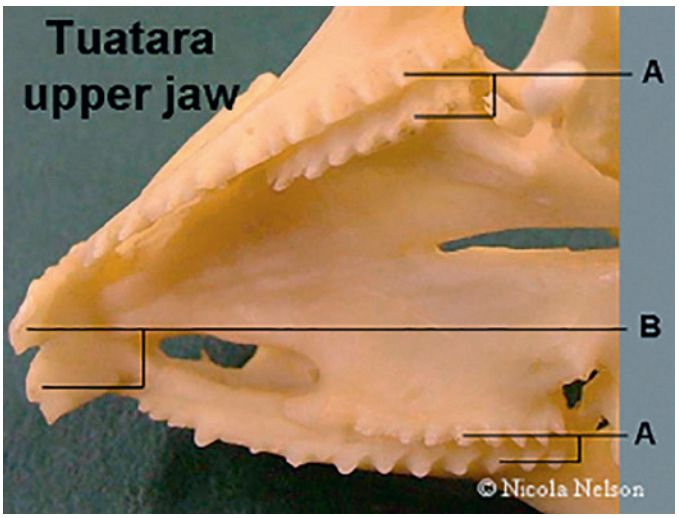

FIG 11.3 Tuatara *(Sphenodon punctatus)* have two rows of teeth in the upper dental arcade: A, wedge-shaped teeth attached to maxilla and palatine bone; B, incisor-like teeth attached to premaxilla. (Courtesy of Nicola Nelson.)

teeth at the front of the upper jaw, attached to the premaxilla. Additional teeth are added caudally as the animal grows.[15]

Liver

The tuatara liver is large, bilobed, and a typical dark red-brown color, extending from the heart to the posterior half of the abdominal cavity. There is a small gall bladder, and hepatocytes produce several types of bile acids, predominantly varanic acid.[16]

Pancreas and Spleen

The tuatara pancreas is pink and bilobed and histologically contains islets of Langerhans and exocrine glands.[10] The spleen is small and elongated with white and red pulp and is the only organ in adult tuatara with discernible lymphoid characteristics.[11]

Gastrointestinal System

Tuatara have a large, fleshy tongue that aids in capturing small prey. The J-shaped stomach contains both fundic and pyloric glands and has several internal longitudinal folds near the pyloric region.[11] The small intestine is longer and narrower than the large intestine,[17] and no cecum has been reported.

Reproductive System

Tuatara reach sexual maturity at 9 to 16 years of age[18–20] and are confirmed to breed into their sixties,[21] although there are anecdotal reports of tuatara reproducing far beyond this age. Male tuatara have paired testes that are closely apposed to the adrenal glands in the middle of the coelom. The testes are not associated with the kidneys, and, unlike squamates, there is no renal sex segment.[22] There is little seasonal variation in testicular size, although testosterone peaks substantially in mating season (March–December, southern hemisphere summer).[23] Spermatozoa are thin and threadlike and are transported from the testes via the epididymis and vas deferens to the urogenital papilla in the cloaca.[24] Male tuatara possess no intromittent organ, and copulation is achieved via cloacal apposition.[25]

Female tuatara have paired ovaries located in the posterior coelom. Vitellogenesis is protracted and can be spread over several years,[26] and eggs are present in the oviduct for 6 to 8 months.[23] Wild tuatara lay eggs every 2 to 5 years,[27] though annual reproduction has been reported in several captive institutions. Females gain a significant amount of weight in late gravidity, and this should not be confused with obesity. Tuatara exhibit temperature-dependent sex determination within a narrow range, with artificially incubated eggs producing all-female clutches below 21.2°C and all male clutches above 22.2°C.[28] Tuatara usually lay between 1 and 18 eggs per nesting event[21]; however, a female at Auckland Zoo has laid 25 eggs in a single clutch. Incubation time is

VetBooks.ir

10 to 16 months in wild populations, the longest of any known reptile,[29] although eggs incubated artificially at 24°C hatched in just over 5 months.[30] Eggs are softshelled and ovoid, and tuatara emerge from them with the aid of a horny shell-breaker, similar to that seen in crocodile and turtle hatchlings.[31]

Male tuatara become increasingly territorial and aggressive during breeding season. In the presence of an intruding male, the resident male will elevate his body off the substrate, inflate the trunk and gular region, and erect the nuchal and dorsal crests.[25] He will then approach the intruder, sometimes swaying the head and neck from side to side, occasionally escalating to jaw snapping and fighting. A similar display is made when courting a female. After making himself look larger, the male will approach and circle the female in a stiff, exaggerated walk known as the *stoltzer Gang*.[32] Mating can last between 15 seconds and 2 hours.[32,33] Multiple paternity has been reported infrequently in both captive and wild tuatara clutches.[34]

Urinary System

Tuatara have two irregularly lobed kidneys located within the pelvis that are grossly and histologically similar to those of other reptiles.[17] A urinary bladder is present, which opens into the urodeum and has no direct connection with the ureters, which transport nitrogenous waste from the kidneys to the cloaca. Tuatara produce uric acid, urea, and ammonia in varying quantities depending on their hydration status.[35] As with other reptiles, tuatara do not possess a loop of Henle and are incapable of concentrating their urine.[11]

Musculoskeletal System

Tuatara share the same basic body plan as lizards, with several distinguishing features. The skull is diapsid with a fixed quadrate bone, contributing to their powerful but relatively slow bite.[36] Like crocodilians, tuatara possess abdominal ribs (gastralia), which are not true ribs but develop within the dermis, probably to provide protection and support for the abdominal organs.[1] Tuatara can autotomize their tails during instances of stress or aggression, though less readily than many lizards. The gait of the tuatara is a diagonal couplet type seen in many vertebrates and has the appearance of a ground-hugging crawl. Tuatara generally move in a fast, jerky stop-start pattern over short distances, presumably tiring quickly as they become anaerobic.[1]

Nervous System and Special Senses

The nervous system of the tuatara is very similar to that of lizards. Tuatara possess a parietal ("third") eye on the midline of the top of their head,[37] which is part of the pineal complex. It is sometimes visible in hatchlings as a dark spot covered by a translucent skin layer. The parietal eye has a lens and retina that contains what appear to be photoreceptive cells and is thought to have a role in regulating basking behavior.[38] Tuatara have two laterally positioned eyes with upper and lower eyelids, as well as a nictitating membrane.[17] The iris is often brightly colored in juveniles but fades with age. Tuatara have good visual acuity and track objects using head and eye movement.[39] Similarly to snakes, tuatara do not have an external ear opening or functional tympanic membrane, and the middle ear cavity is filled with connective and adipose tissue.[40] The inner ear, however, is well developed, and tuatara appear very responsive to sound.

Endocrine System

Apart from male and female reproductive cycles, the physiology of the tuatara's endocrine system is not well studied. The primary androgen is testosterone, which increases during the mating season in both males and females.[23] The roles of estradiol, progesterone, prostaglandin, and arginine vasotocin in female tuatara reproductive cycles have been elucidated,[23,26,41] and oxytocin has been used successfully to induce oviposition. The adrenal glands produce adrenaline and noradrenaline and are anatomically in close association with the gonads.[42] The thyroid is single, transversely elongate, and situated just anterior to the heart, not to be confused with the more cranial, bilobed thymus.[11] There are four parathyroid glands situated in the neck region. The endocrine functions of the pancreas have not been investigated but based on histology are presumed to be similar to other reptiles.[11]

Thermal Physiology and Metabolic Rate

Tuatara are renowned among reptiles for their low metabolic rate and relatively high activity level in cold temperatures. Wild tuatara have been observed to be nocturnally active when their body temperatures are between 5.5° and 20.5°C, and this can increase to 30°C when basking.[1] Sustained body temperatures over 28°C can cause signs of heat stress, and loss of locomotion occurs at 3.5°C.[43,44] The metabolic rate of tuatara at 13°C is similar to that of lizards and some turtles at the same temperature, the difference being that tuatara are active at these temperatures while many other reptiles are not.[45,46] Tuatara can undergo short periods of torpor in cold weather but still emerge periodically to eat and bask in appropriate conditions.[1]

ACKNOWLEDGMENTS

I am indebted to Peter Johnston for providing anatomic interpretation and illustrations, to Auckland Museum for the provision of tuatara specimens, and to Richard Jakob-Hoff and Richard Gibson for their support in preparation of this manuscript.

Amphibian Taxonomy, Anatomy, and Physiology

Frank Pasmans and An Martel

With currently some 7867 described species (Amphibian Species of the World; http://research.amnh.org/vz/herpetology/amphibia/), the number of amphibians known to science has increased by approximately five times compared with the year 1900 and is still steeply increasing.[1] Amphibians inhabit all continents except for Antarctica, the main requirement for their presence being sufficient moisture. The class Amphibia is highly diverse, ranging in size from the tiny frog *Paedophryne amauensis*, the smallest known vertebrate at 7.7 mm in length, to the Chinese giant salamander (*Andrias davidianus*), which reaches a length of 180 cm. Their small size, often attractive colors, and behavior render many amphibians and especially frogs and toads popular terrarium animals. Provided with proper husbandry and nutrition, many amphibians easily live for 10 to 20 years in captivity. Amphibians are being mass bred and collected for human consumption, mainly frogs (the best know example is the American bullfrog *Lithobathes catesbeianus*) but also salamanders (for example the Chinese giant salamander, which is farm bred in China). Due to the global amphibian declines and extinction of more than 200 species, amphibians are emblematic for the current sixth mass extinction event, and amphibian conservation is a hot topic. Amphibians have become the focus of many biodiversity conservation efforts involving zoos, research institutions, and authorities.[2]

TAXONOMY

The class of Amphibia is divided into three orders. With 66829 species described species, the tailless, four-legged frogs and toads (Anura) constitute the vast majority of known amphibian species and occur on all continents except Antarctica. Although species with more terrestrial habitats, drier skin, and a more stocky appearance are generally referred to as toads, there is no scientific delineation between frogs and toads. The Anura comprises 56 families, ranging from being species-rich (e.g., the tree frogs, Hylidae, with 710 species) to families containing a single taxon (the strange Indian frog *Nasikabatrachus sahyadrensis*). Most species kept in captivity belong to the families of the European and Asian fire-bellied toads (Bombinatoridae), the globally distributed true toads (Bufonidae), the South American horned frogs (Ceratophryidae), the neotropical poison frogs (Dendrobatidae), tree frogs (Hylidae), African reed frogs (Hyperoliidae), the Malagasy Mantellidae, the Asian toads (Megophryidae), the narrow-mouthed frogs (Microhylidae), the African and neotropical tongueless frogs (Pipidae), the Afro-Asian tree frogs (Rhacophoridae), and the true frogs (Ranidae).

The 720 species of salamanders and newts (Caudata) are tailed amphibians, mostly with four legs (except for the sirens, Sirenidae, with only two front legs), and are distributed in the Americas, Europe, Asia, and North Africa. With 473 species, the lungless salamanders (Plethodontidae) constitute the most species-rich family, occurring mainly in the Americas, with a limited number of species in Europe and Asia. Most species kept in captivity, such as the "fire-bellied newts" (actually comprising newts of the genera *Cynops, Paramesotriton,* and *Pachytriton*) belong to the true salamanders (Salamandridae) or mole salamanders (Ambystomatidae, to which the famous axolotl *Ambystoma mexicanum* belongs) and to a lesser extent to the lungless salamanders, Asian salamanders (Hynobiidae), and sirens (Sirenidae).

The least-known amphibian order is that of the caecilians (Gymnophiona), with 10 families and 7867 species distributed across the (sub) tropical regions of the Americas, Africa, and Asia. Caecilians are aquatic or terrestrial wormlike amphibians that range in size from 10 cm to more than 1 m. Only very few species are being kept in captivity, notably some aquatic species (Typhlonectidae) and terrestrial neotropical and west African species (Herpelidae, Dermophiidae).

ANATOMY AND PHYSIOLOGY

For an in-depth review on amphibian biology and ecology, readers are directed to reference textbooks.[3,4] An overview of the position of the organs inside the coelomic cavity is provided in Figs. 12.1 and 12.2.

Integument

The skin of frogs and toads, salamanders, newts, and caecilians has a thin outer layer (epidermis) that is not covered by keratinized structures such as scales, hair, or feathers. Few layers of epidermal cells overlay the epidermal basement membrane. A thin stratum corneum covers the epidermis and is shed and eaten periodically. The presence of shed skin (dysecdysis) should be regarded as an anomaly, which is one of the hallmarks of chytridiomycosis. The dermis of salamanders and newts is firmly connected with the underlying tissue, rendering subcutaneous administration of compounds impossible. In anurans, large lymphatic spaces lie under the dorsal skin, with the result that "subcutaneous" injections should rather be considered intralymphatic. Caecilians are the only amphibians with scales in the deeper layer of the skin (the dermis). The amphibian skin is rich in glands, which can be roughly divided into mucous and serous or granular glands. The epidermis can be covered by mucous secretions or can be dry, which is species and often life-stage specific. Assessing skin texture is one of the key parameters for assessing an amphibian's health. The holocrine serous glands secrete a myriad of bioactive molecules, such as antimicrobial peptides, biogenic amines, steroids, alkaloids, and hormonelike peptides. The impressive arsenal of antimicrobial peptides controls microbial populations on the amphibian skin. Many amphibians secrete highly potent and potentially lethal toxins, such as tetrodotoxin,[5] as a defense against predators, notably some widely kept species such as poison frogs (species of the family Dendrobatidae with aposematic coloration; Fig. 12.3) or some newts (*Notophthalmus*, *Taricha, Cynops* sp.). Often, the presence of strong toxins is clearly advertised by amphibians with bright, aposematic colors. In many species such as poison frogs but also Malagasy

Mantella species, these toxins are largely derived from prey items, the lack of which in captivity results in marked loss of toxicity.[6] The amphibian skin is of vital importance for respiration and fluid balance. In many salamander and newt species, gas exchange even takes place entirely through the skin and mucous membranes. Most amphibians never drink through their mouths but absorb water via their skin, in frogs and toads often via a highly permeable region of the skin at the caudoventral coelomic region called the pelvic or drinking patch. Damage or disruption of the skin and its critical functions from diseases such as chytridiomycosis results in loss of homeostasis and death. The

VetBooks.ir

disadvantage of a naked, semipermeable skin is that amphibians become susceptible to desiccation, toxins, and metabolites including nitrogen metabolites (ammonia, nitrite) absorbed from the environment. However, although amphibians are thought to be more susceptible to environmental changes such as pollution or to be useful as early bio-indicators ("canaries in the coal mine"), there are actually few indications that amphibians are any more susceptible to environmental toxins than other vertebrates. Amphibians even seem to adapt to the presence of toxins, and associations between the use of agricultural pesticides and amphibian declines are not clear.[7,8]

Cardiovascular System

Whereas larval amphibians have a two-chambered heart, postmetamorphic amphibians have one ventricle and two atria. Both hepatic and renal portal vein systems are present; the veins of the hind limb and tail combine to form the paired Jacobson's veins, which pass anteriorly on the dorsolateral surface of the kidney. In anurans, the subcutaneous space is largely occupied by an extensive system of lymphatic sacs, which provides an ability to administer medications intravascularly. Lymph fluid is actively circulated through lymph hearts. This also implies that subcutaneous administration in anurans is virtually impossible in practice. The number of accessible blood vessels for venipuncture is limited. A midline abdominal vein is present in most amphibians. In urodeles, a caudal tail vein is present, which is situated ventral to the caudal vertebrae. In anurans, the femoral vein is often used for obtaining blood samples.

Respiratory System

Depending on the species and life stage, amphibians breathe via their skin, mucous membranes, gills, and/or lungs to a varying extent. Skin breathing (gas exchange through the highly vascularized dermis) plays a major role in all species but is of particular importance for those living in the water (aquatic) and obviously for lungless salamanders living on land. Gills are branched structures that are either covered by a skin pouch (most anuran tadpoles, some paedomorphic salamanders) or not (most early-stage anuran tadpoles, all aquatic salamander larvae, and some paedomorphic salamanders). Lungs are present in the majority of amphibians after metamorphosis (but in the minority of salamander species) and present as relatively simple, thin-walled, saclike structures with folding to increase the surface for gas exchange. Most terrestrial amphibians breathe through the nares. Many aquatic amphibians take air in through the mouth. A diaphragm is lacking. Air is forced in the lungs through a force-pump mechanism of the floor of the buccal cavity.

Digestive System

All postmetamorphosis amphibians and larval salamanders, newts, and caecilians are carnivores whose diet consists primarily on live prey items. Although specialist feeders exist (e.g., termites, ants), most amphibians are not picky and will ingest any vertebrate or invertebrate prey that fits into their mouth. Some caecilians (*Typhlonectes* spp.) are known to feed on carrion. In contrast, the diet of larval anurans is extremely variable and ranges from species filtering debris from the water surface, predatory tadpoles, tadpoles that are being fed unfertilized eggs by their mother, or tadpoles that scrape organic substances from surfaces using specialized keratinized mouthparts. In some caecilians, the offspring are fed by scraping off the adult's differentiated skin.[9]

Prey may be caught by grabbing with the jaws, projecting a sticky-ended tongue, or in aquatic species, by sucking the prey into the oral cavity. Teeth are not used for chewing but mainly serve to prevent prey animals from escaping. An epiglottis is lacking. Oral cavity, esophagus, stomach, and duodenum are all separated by sphincters. However, these sphincters can easily be overcome, and the relatively short and broad, cilia-lined esophagus makes the insertion of a gastric tube (for force feeding and gastric flushes) relatively simple to perform. The intestine is relatively short and receives bile from the gall bladder and pancreatic secretions. Since all postmetamorphic amphibians are carnivorous, the intestinal microbiome is likely to be of minor importance. The liver is generally large, bilobate in anurans and elongate in urodeles, contains a gall bladder, and, as in other vertebrates, is dark red/brown in color. The amphibian liver typically contains melano-macrophages (pigment-containing cells), which are thought to increase in size and/or frequency with age, chronic inflammation, and environmental stress.

Reproductive System

The paired testes are either lobed (many urodeles) or not (anurans) and attached to the kidneys by the mesorchium. The paired ovaries are suspended by the mesovarium from the kidneys. Ovulation results in the thin sheath of connective tissue surrounding the follicles, the ovisac, rupturing to release the ova into the coelom. The coelom, with its ciliated epithelium, moves the ova anteriorly to the opening of the oviduct. The gonads are closely associated with the fat bodies, which are suspended from the dorsal wall (anurans) or the gonadal mesentery (urodeles). Copulatory organs are present only in male caecilians and a small number of Anura and Caudata.

The reproduction of amphibians is driven by environmental determinants (temperature and/or humidity). During the mating season, the males will respond to visual, auditive, and/or olfactory cues from females. Only male anurans are able to attract females by means of advertisement calls that are often amplified by one or two vocal sacs. Many amphibian species are sexually dimorphic (Fig. 12.4). In anurans, males are often (but not always) smaller than females; in salamanders and newts males often have a more swollen cloaca region and often show sex-specific coloration and patterns. Males of many amphibian species develop marked secondary sexual characteristics during the breeding season, the most constant being the development of keratinized, darkly colored patches on the skin (nuptial pads) in anurans and a markedly swollen cloaca in salamanders and newts.

Mating can involve either physical contact (e.g., amplexus in many species, actual copulation in caecilians) or not (many species of salamanders and newts). In most anurans and some salamanders and newts, fertilization of the eggs takes place externally. In most salamanders and newts and all caecilians, fertilization is internal. Most amphibians produce eggs that are either deposited on land or in water where larvae or already metamorphosed juveniles hatch. Larvae then pass through an aquatic life stage, whereas metamorphosed juveniles are already adapted for a terrestrial life. Anurans especially have a huge repertoire of reproductive strategies. Parental care is common in salamanders but rare in anurans. The widely kept poison frogs (Dendrobatidae) guard their eggs and transfer the hatchlings to water reservoirs for further development. In some species such as the strawberry frog (*Oophaga pumilio*), the female feeds the aquatic larvae with unfertilized eggs (see Fig. 12.3). A small number of anurans, a large number of caecilians, and several salamanders give birth to a few larvae in an advanced stage of development (ovoviviparity) or even fully metamorphosed young (vivipary).

Neoteny or paedomorphosis describes a phenomenon of incomplete metamorphosis of animals that retain larval characteristics even though they become sexually mature. The best known example for this is the axolotl (*Ambystoma mexicanum*) in which metamorphosis can only be induced artificially by administering thyroid hormones (see Fig. 12.3).

Urinary System

In adult amphibians the paired, mesonephric kidneys are located dorsocaudally in the coelom. The bladder is a ventral outgrowth of the cloaca and is inconspicuous in many urodelans. Most amphibian larvae

FIG 12.4 Sexual dimorphism in amphibians. (A) The presence of keratinized nuptial pads on the fingers of a male European common toad (*Bufo bufo*). (B) A markedly swollen cloaca and the presence of a crest in the southern-banded newt (*Ommatotriton vittatus*). (Courtesy of Frank Pasmans.)

and aquatic amphibians excrete nitrogen as ammonia through urine and gills. Terrestrial species excrete mainly urea. Some arboreal frogs even excrete uric acid, which requires much less water for excretion.

Musculoskeletal System

Amphibians have a skeletal system that is structurally homologous to other tetrapods, though with a number of variations. They all have four limbs except for the legless caecilians and a few species of salamander have reduced or no limbs. The bones are hollow and lightweight but fully ossified. In anurans, the ilium of the well-developed pelvic girdle is attached to the spine by a pair of sacral ribs, and the caudal vertebrae are fused and constitute a single bony structure, the urostyle.

Nervous System

The brain consists of equal parts: cerebrum, midbrain, and cerebellum. Various parts of the cerebrum process sensory input, such as smell in the olfactory lobe and sight in the optic lobe, and it is additionally the center of behavior and learning. The cerebellum is the center of muscular coordination, and the medulla oblongata controls some organ functions, including heartbeat and respiration. The pineal body is involved in hibernation and aestivation in amphibians. Amphibians have 10 cranial nerves, lacking XI and XII. Amphibians can feel pain.

Species Senses

Prey is located by means of scent, vision, and/or touch. The sense of touch can be developed as a lateral line organ in larvae and aquatic amphibians that, like fish, will respond to movements in the surroundings or as the sensitive fingertips of aquatic frogs of the Pipidae. A unique feature of caecilians is the presence of a tentacle below the eye. Most terrestrial amphibians use vision for locating prey and to a lesser extent their sense of smell. Feeding is mainly evoked by moving prey.

Endocrine System

Many amphibians pass through two different free-living life stages, beginning with an aquatic larval stage. Metamorphosis is the transformation from larval form to adult life stage, which involves fundamental anatomical and physiological modifications largely controlled by the thyroid gland.[10] The thyroid glands play a crucial role in amphibian metamorphosis through the production of T_3 and T_4. In Anuran tadpoles, first the hind legs become visible, then the front legs. The tail is resorbed, lungs replace gills, the mostly spiral-shaped intestinal tract of the tadpoles is modified to process prey items, and the jaw and tongue and the mature immune systems develop. Tailed amphibians first grow their front legs and then the hind limbs. During metamorphosis, their external gills disappear and they develop eyelids. In caecilians with a larval stage, metamorphosis includes the loss of the lateral line organ. Overall, metamorphosis is a life stage of increased susceptibility for amphibians with losses from drowning or infectious diseases such as chytridiomycosis. Amphibian declines related to chytridiomycosis are often associated with mass mortality shortly after metamorphosis.[11]

BEHAVIOR

All amphibians are ectothermic. Due to the majority of amphibians being nocturnal, these animals are less exposed to direct solar radiation than diurnal reptiles. Active thermoregulation by basking is observed in many diurnal anurans. In salamanders and newts, it is unclear to what degree they actively thermoregulate. Preferred thermal ranges of amphibians are highly species specific, and for anurans no general rule can be provided. Generally speaking, newts and salamanders prefer relatively low ambient temperatures in a range of 10°C to 20°C. Caecilians generally require much higher temperatures around 25°C.

If ambient temperatures decrease, amphibians from temperate regions will enter a state of dormancy (hibernation). Some amphibian species are well known for their ability to tolerate freezing, even for long periods of times. To survive freezing, these species use antifreeze molecules like glucose or glycerol that prevent the intracellular fluid from freezing.

Natural Behavior

Andrew M. Durso and John C. Maerz

The more than 17,750 species of extant reptiles and amphibians have a wide variety of behaviors that allow them to escape notice, defend themselves, reproduce, obtain food, maintain homeostasis, and otherwise interact with their environment. This chapter is meant to serve as an introduction to the general patterns of behavior seen in reptiles and amphibians. Many behaviors that are normal for a particular species but unfamiliar to hobbyists or clinicians may be misinterpreted as signs of disease or trauma. Unfortunately examples of all these behaviors cannot be presented in a single chapter, and research into the biology and natural history of many species is ongoing. Comprehensive scholarly reviews are available on the behavior of both reptiles and amphibians.[1–3] Throughout this chapter we address general patterns among these two diverse taxonomic groups while highlighting some widespread or special examples. We focus predominantly on anurans (frogs), salamanders, crocodilians, chelonians, lizards, and snakes. Because far less is known about the natural history and behavior of caecilians and tuataras,[4] their coverage here is limited.

The key to understanding amphibian and reptile behavior lies in their reliance on ectothermy and their associated reliance on anaerobic metabolism to produce energy. Pough[5,6] synthesized this understanding in his description of amphibians and reptiles as "low-energy systems." Reptiles and amphibians differ from many mammals and birds in that (1) their metabolic rates are flexible and their resting metabolic rates are nearly an order of magnitude lower than those of birds and mammals;[5,6] (2) as a result, they do not necessarily need food as often as we might assume; (3) the majority of their energy comes from anaerobic metabolism,[5] which leads to rapid exhaustion when active; (4) they spend a lot of their time doing nothing (or appearing to do nothing), with punctuated bursts of activity; and (5) much of their behavior is proximately motivated by regulating temperature or moisture. Frequent and extended periods of immobility or inactivity should not necessarily be taken as a sign that something is medically wrong with an amphibian or reptile.

ECTOTHERMY

As with birds and mammals, amphibians and reptiles operate at body temperatures elevated above the ambient conditions of their environment. The key difference is that amphibians and reptiles do this by absorbing heat from their environment. Therefore behavioral thermoregulation is, arguably, the key activity of all amphibians and reptiles. Behavioral thermoregulation is widely recognized in reptiles but is also demonstrated among amphibians.[5] However, because elevated temperatures accelerate evaporative water loss, many amphibians may be more constrained in their ability to thermoregulate and will choose areas of high moisture over warmer temperatures if both are not available together.[7] As a result of behavioral thermoregulation, many reptiles and some amphibians have relatively stable body temperatures.[5] It is important to recognize that there are no optimal temperatures for an amphibian or reptile species. Rather, amphibians and reptiles need gradients of temperature and the ability to regulate their body temperature behaviorally by moving along that gradient. The inability to behaviorally thermoregulate can cause stress or death, and the absence of behavioral thermoregulation may be an indication of disease or illness.

Because they use ectothermy to elevate their body temperatures, amphibians and reptiles have dramatically lower metabolic energetic demand and higher assimilation efficiencies compared to birds and mammals.[6] Low metabolic demands allow amphibians and reptiles to feed on small, less energetically profitable prey and to take meals less frequently or fast for extended periods when food is unavailable or weather conditions favor estivation or hibernation. A consequence of ectothermy in amphibians and reptiles (and cutaneous gas exchange in some amphibians) is limited aerobic energy production and a reliance on anaerobic metabolism to sustain high activity. Amphibians and reptiles exhaust rapidly and can require hours to recover from only a few minutes of strenuous activity.[5] As a result, most amphibians and reptiles engage in infrequent, short bouts of activity with extended periods of limited activity. During periods of inactivity, amphibians and reptiles will often retreat to cooler areas, and body temperatures often reduce to near ambient temperatures, which reduces energetic demands and improves metabolic efficiency.[5,8] Among amphibians and reptiles there is considerable variation around these generalities. Some larger, often predatory reptiles have higher aerobic capacities that can sustain longer periods of activity, and reptile species that are passive or cruising foragers tend to operate at lower body temperatures for longer periods of time, whereas species that are intensive foragers tend to operate at higher body temperatures for more punctuated periods of time.[6] Body size differences between juvenile and adult amphibians and reptiles often exceed several orders of magnitude. This affects energetics and performance, which in turn affects behavior. Some amphibians (e.g., toads) that are particularly small at metamorphosis are diurnal until they achieve sufficient size to become nocturnal. Among reptiles, juveniles exhaust more quickly after short bouts of activity, and activity endurance tends to increase linearly with size. This phenomenon appears to drive ontogenetic changes in reptile diets. For example, because they can become exhausted when attempting to handle large, live prey, juvenile snakes often take prey that are smaller relative to their body size.

WATER CONSERVATION AND OSMOTIC BALANCE

Both reptiles and amphibians must balance their gain and loss of water and salts. Amphibians absorb water by soaking or extracting it from moist substrates. Through the use of hormones and specialized tissues, amphibians are capable of absorbing water from remarkably dry soils (e.g., water tension below 2 atm), but absorbing water from soils often

takes far longer than from standing water.[9] Reptiles gain water by drinking. Both amphibians and reptiles acquire water from their food and by chemically producing it as a by-product of metabolism. Most reptiles and some amphibians excrete uric acid, and those species are able to retain more of their metabolic water than animals that excrete urea (mammals, terrestrial chelonians, and many amphibians) or ammonia (fishes, crocodilians, aquatic chelonians, most aquatic amphibians). Reptiles and amphibians lose water through urine, feces, evaporation, and their salt glands. Evaporation is the major route of water loss for terrestrial amphibians and reptiles.[2,3] Comparatively, amphibians are more prone to evaporative water loss, but some reptiles are sensitive to evaporative water loss,[10] and water stress can constrain activity.

Amphibians and reptiles generally deal with short-term avoidance of evaporative water loss through altered activity patterns and microhabitat selection. They will be more active during cooler parts of the day or select cooler or wetter microhabitats.[2,7] Many amphibians will concentrate activity around rain events. During periods of inactivity, amphibians will move under cover objects where conditions are typically cooler, moister, and there is reduced exposure to air movement that facilitates water loss. They will assume water conserving postures where bodies are pressed against the substrate, limbs are typically pulled in close to or under the body, the head may be tucked ventrally, and the eyes are typically closed (Fig. 13.1). This reduces their exposed surface area and protects more sensitive tissues from evaporative water loss. Amphibians resting on dry soils may establish a "wetting front," which limits water loss to dry soils.[7,9,11] As water is initially lost from the amphibian to the drier soil, water accumulates between the animal and the soil. When a locally steep gradient of water is formed between a wet region (the amphibian and soil immediately beneath it) and a dry region (the rest of the soil), no water can move from wetter to drier soils. Thus the initial loss of water to establish a wetting front prevents additional, continuous water loss to the soil provided the animal does not move (or is not forced to move by a predator or person).

FIG 13.1 Active (A) and moisture-conserving (B) postures in a waxy monkey treefrog (*Phyllomedusa sauvagii*). (Courtesy of John C. Maerz.)

To deal with more protracted dehydrating environments, amphibians and reptiles may concentrate their activities seasonally or spend extended periods in deeper refugia.[12] Because of their greater reliance on anaerobic metabolism and lower dependence on aerobic metabolism, amphibians and reptiles are capable of burrowing deep in sand and soils where oxygen concentrations are reduced.[5] Body temperatures will cool to near ambient, and metabolic rates are reduced, allowing the animals to remain underground for months or years. Some aquatic and terrestrial amphibians will form cocoons from shed skin to remain moist during protracted droughts.[13]

Marine reptiles, many herbivorous or invertebrate-eating reptiles, and some invertebrate-eating amphibians must excrete excess ions from their diet. Marine reptiles, including sea snakes, sea turtles, marine iguanas, and saltwater crocodiles, dehydrate in sea water and must drink fresh water to survive.[14] They excrete salt through a variety of specialized glands in the eyes, nose, or mouth.[15] Salt glands are about seven times more water-efficient than kidneys at excreting excess salt, although they require more energy for active transport. Species that inhabit hypersaline environments may limit ingestion of high saline water and ingest high amounts of hyposaline water when available. For example, fresh rain water is less dense than hypersaline water and will temporarily form a surface layer. Diamondback terrapins (*Malaclemys terrapin*), which inhabit brackish tidal marshes, will float at the surface during a rain event and drink copious amounts of fresh rain water.[16] Sea snakes exhibit a similar behavior.[17] Freshwater is typically not limited for most temperate and tropical reptiles. Many desert reptiles harvest dew, rain, sleet, and snow off of the ground, plants, or their own bodies.[18,19] For some desert reptiles, such as Gila monsters (*Heloderma suspectum*) and desert tortoises (*Gopherus agassizii*), dietary and metabolic water are sufficient, and these animals rely on seasonal rainfall and inactivity in subterranean burrows to maintain water balance.[20] Some desert reptiles have special morphologic features and associated behaviors that aid in collecting moisture. For example, some lizards (e.g., *Moloch horridus, Phrynosoma cornutum*) have a network of channels between their scales to aid in the collection and transport of dew to their mouth.[21]

SENSORY ADAPTATIONS

Most reptiles and amphibians have good eyesight, hearing, tactile, and chemosensory abilities and exhibit notable sensory exploration behaviors and responses to information. The majority of surface-dwelling species have color vision, and vision plays an important role in amphibian and reptile behavior. Several lineages of snakes have evolved infrared sensory organs that reside in anterior facial pits. The nerves from these organs join the nerves from the eyes before reaching the brain and therefore enhance the detail of objects or allow snakes to see objects outside the field of view of their lateral eyes.[22] Amphibians and reptiles also have extra-optic photoreception for sensing light and dark, and these organs can be important in regulating endogenous biorhythms, physiology, and behaviors.[23–25] Some burrowing, cave-dwelling, or aquatic species that live in murky water have lost much or all of their vision but may still exhibit phototaxis based on extraoptic photoreception. Most amphibians appear to have an optimum level of ambient illumination above which an animal becomes negatively phototaxic and below which the animal becomes positively phototaxic.[26] For many nocturnal species, this manifests as an avoidance of high light environments, and species that occupy caves or burrows often emerge during twilight to forage. Color vision plays an important role in social communication, including

VetBooks.ir

mate assessment,[27–29] location and identification of prey,[30] microhabitat selection,[31] and, for some species, color changing associated with camouflage or social interactions.[23,32]

Hearing is also relatively well developed in reptiles[33] and amphibians,[34,35] though perhaps more variable in capacity and importance than vision. Anurans are widely recognized for their derived ear structure and strong reliance on auditory communication for advertising to mates or rivals, individual recognition, despotic spacing, and release and alarm calls.[2,36] Reptiles also use their hearing for a variety of purposes.[37] Some lizards eavesdrop on the alarm calls of birds.[38] Some geckos use acoustic communication at night.[39] Contrary to popular belief, behavioral, neurological, and physiological experiments have shown that salamanders and snakes can hear both airborne and ground-borne sounds, even though they lack external ear openings.[35,40] Snakes can hear louder and lower frequency sounds more easily; their optimal range is 80 to 600 Hz (compared with 20–20,000 Hz for humans). Saharan sand vipers (genus *Cerastes*) ambush lizards and rodents from a position partially or completely buried in sand and probably rely heavily on hearing or feeling vibration to hunt.[41] Anurans and salamanders are particularly sensitive to seismic vibrations and can use them in communication.[35,42,43] Anurans and salamanders have a peculiar anatomy in which the operculum is attached by a muscle to the suprascapula. In a normal resting position with the forelimbs erect, this anatomy allows the efficient "hearing" of seismic vibrations.[43,44] The lower jaw may also be used in hearing; many reptiles and amphibians press their chin to the ground to amplify ground-borne sounds, and some aquatic amphibians can also sense motion via a lateral line system like that of fishes (e.g., *Amphiuma*). Tortoises have good tactile abilities in their shells.[45]

Along with vision, chemoreception is a dominant sense among amphibians and reptiles. Chemosensing is well developed in almost all reptiles and amphibians and is used extensively in communication and mating, movement, prey location, and predator identification and risk assessment. Salamanders have well-developed vomeronasal tissues and a relatively large portion of the brain dedicated to olfactory stimuli. Salamander species in the family Plethodontidae, which includes approximately two thirds of all salamander species, have unique nasal-labial grooves that carry chemical cues from protrusions on the upper lip to the nares via capillary action.[46] Plethodontid and ambystomatid salamanders frequently engage in nose-tapping behaviors as part of chemosensory exploration.[47,48] Chemoreception in salamanders and other amphibians is important in prey location and recognition,[49] conspecific and heterospecific recognition,[50] recognition of predators,[51,52] homing,[48,53] identifying territories,[48,54] and mate assessment.[55,56] Similar importance of the vomeronasal system and chemical cues are known among reptiles.[57–60] Aquatic turtles rely more on chemosensory cues than semiaquatic or terrestrial species.[61] Snakes and some lizards are well known for their deeply forked tongues and tongue-flicking behavior, which is used to determine directionality when following chemical cues.[62] Scent-trailing is a common behavior for many snakes and other reptiles for both locating mates and prey. Among naïve juvenile snakes, chemicals may be the only cues that can elicit prey-attacking behaviors,[63] although some species can be conditioned to respond to chemical cues of novel prey.[64] Because of the strong effect of chemical cues on amphibian and reptile risk perception and behavior, caution should be taken to minimize stress by limiting exposure to chemical cues associated with predators or rivals and to maintain individual chemical cues when cleaning or changing housing.

FORAGING AND PREDATION

Most reptiles and amphibians are carnivores, and many are ambush foragers. As a result, they can be foraging at almost any time that weather conditions permit, although their energetic requirements are sufficiently low that they do not necessarily spend significant time foraging.[5] Many species (e.g., chameleons, plethodontid salamanders) use projectile tongues in prey capture.[65,66] Many heavy-bodied snakes make use of habitual ambush sites, which they select using chemical cues from their prey.[67] For most amphibians and reptiles, prey strikes are triggered by particular prey movements[68]; however, chemical cues can trigger instinctive or learned strikes, and striking a prey item can induce chemosensory searching behavior in both snakes[69] and lizards.[70] Herbivorous reptiles use both visual and chemical cues to locate and select fruits, flowers, and other parts of plants.[71] Amphibians and most reptiles swallow their prey whole. Many snakes use venom or constriction to subdue large prey.[72] Active foraging is used mostly by diurnal species,[73] and some reptiles and amphibians use additional behaviors to lure prey. Wood Turtles (*Glyptemys insculpta*) stomp their feet to create vibrations in the soil similar to those caused by rain, which lures earthworms to the surface to avoid drowning.[74] Some chameleons use chemical substances derived from their insect prey to lure their food to ambush sites.[75] Several species of frogs (e.g., Argentine horned frogs, *Ceratophrys calcarata* and *C. ornata*), as well as alligator snapping turtles (*Macrochelys temminckii*) and many species of snakes that prey on vertebrates or large predatory invertebrates have specialized toes (amphibians[76]), tongues (snapping turtle[77] and snakes[78]), or tails (snakes[79]) that are wiggled to lure their prey. Some crocodilians appear to use sticks as hunting lures during the nest-building season of their avian prey (Fig. 13.2).[80]

FIG 13.2 A mugger crocodile (*Crocodylus palustris*) luring birds with stick-displaying behavior. (Courtesy of Vladimir Dinets.)

SLEEP AND OTHER ENDOGENOUS RHYTHMS

Sleep appears to be present in all amphibians and reptiles.[81] Periods of rest or quiescence associated with electroencephalogram (EEG) changes similar to those seen in mammalian sleep are clearly present in amphibians, turtles, and crocodilians, but EEG data suggest that they do not exhibit rapid-eye movement (REM or "deep") sleep. Some experiments have found REM-like sleep in lizards,[82] whereas others have not. In experiments where lizards, turtles, and crocodilians were subjected to continuous arousal for 24 to 48 hours, they appeared to get tired, sleeping more afterward and producing more high-voltage EEG spikes. Some reptiles sometimes seem to exhibit sleeplike brain activity when they are awake, perhaps because of sleeplike behavior induced by cold in ectotherms. Crocodilians may sleep one hemisphere of the brain at a time.[83] The single study of a snake[84] reported that an African rock python (*Python sebae*) produced sleeplike brain waves almost 16 hours a day, increasing to over 20 hours following feeding, and that these brainwaves corresponded with slower breathing and heart rate, some

muscle relaxation, and perhaps a lowered behavioral response threshold. There was no evidence for REM sleep in this snake.

COLOR CHANGE

Some reptiles and amphibians can change color for camouflage, thermoregulation, or social communication. Chameleons are well known for their ability to change color, although many lizards can do this. Contrary to conventional wisdom, chameleons and other lizards use their colors primarily for communication, rather than for camouflage, with brighter coloration signaling dominance.[85] Color change is also present in a few snakes,[86] where it seems to be used mostly to aid thermoregulation. Rapid color change is not known from turtles or crocodilians. Color changing in amphibians appears largely related to camouflage and plays an important role in temperature regulation and reducing evaporative water loss. Generally, amphibian color changing occurs more slowly than in reptiles and invertebrates (e.g., octopus); therefore it is unlikely that color changing functions as a rapid antipredator response. Rather, color changing when at rest likely reduces detection of animals and can be used to alter heat absorption, the latter of which facilitates increased control of water loss and more flexible metabolic rates matched to activity.[2] Although some amphibians may use color cues in mate assessment, there is no evidence that color changing in amphibians is used in social interactions.

DEFENSE

Predator Avoidance and Immobility

In the wild, most reptiles and amphibians rely on immobility and cryptic coloration as their primary defense from predators.[87,88] Immobility and cryptic coloration may be accompanied by a reduction in respiration rate to conceal movement associated with ventilation,[89] the selection of substrates that improve camouflage,[2] or positioning themselves partially concealed and where they can quickly retreat to a more secure location. Reducing detection through immobility and crypsis is likely the primary defense of amphibians and reptiles because of their limited endurance for fight-or-flight defenses. Many amphibians also show behavioral responses to chemical cues of their predators or injured conspecifics that clearly function to reduce predatory encounters.[2] Behavioral responses to chemical alarm cues include avoiding substrates containing alarm cues,[51,90–93] increasing use of or delaying emergence from refugia,[93,94] and reducing movement rates.[52]

When predator avoidance has failed and amphibians and reptiles perceive an attack is eminent or they have been attacked, the first line of defense is nearly always an attempt to escape.[1,95] Among amphibians, frogs generally rely on their superior jumping ability to avoid attack. Plethodontid salamanders will jerk violently, causing them to spring away from the predator. Several large lizards[96] (e.g., *Sauromalus ater*, *Uromastyx aegyptia*, Cordylidae) and pancake tortoises[97] (*Malacochersus tornieri*) retreat to rock crevices where they wedge themselves in with their legs, sometimes inflating their lungs or using their tails to block access to their bodies. However, if escape is impossible or if the animal is seized, it may resort to one or more of the following tactics.

Defensive Postures and Displays

Many reptiles and amphibians assume stereotypical defensive display postures when confronted by a predator.[1,2] These postures range from inflating or elevating the body on four limbs to appear larger to displays (e.g., pushups) that signal alertness to the predator and likelihood of escape.[98,99] Some reptile defensive displays include expanding frills or hoods around the head[100] or generating noises by hissing, tail-rattling, growling, scale rubbing, and cloacal popping.[101] Many amphibians also use defensive calls, the exact function of which is debated.[102] Some amphibian and reptile postures may expose or emphasize expendable or durable body parts such as tails, spines, aposematically colored areas,[103] or glands where mucous or chemical defenses are stored, all of which function to deter attack or minimize its impact. Some snakes have specialized nuchal glands on the back of the neck, which they present to predators. The glands contain sequestered toxic compounds from their amphibian prey.[104] Reptiles capable of counter-attacking may turn to face their enemy gaping their mouths.

FIG 13.3 Unken behavior in a rough-skinned newt (*Taricha granulosa*). (Courtesy of Andrew M. Durso.)

The most stereotypical display postures of amphibians are collectively known as the "unken" reflex (Fig. 13.3). Many noxious or mildly poisonous amphibians are generally cryptically patterned with concealed aposematic coloration. More potently poisonous species are often fully aposematic. When disturbed by a predator, amphibians will raise their head, limbs, and tail (for salamanders only) dorsally to expose or accentuate their aposematic coloration. Occasionally salamanders will wiggle their tail as part of their defensive display, which may serve as an additional warning or to direct an attack toward the tail and away from the head or trunk. Most toxic amphibians and some nontoxic species will contract the body with the limbs kept bent and close to the body, eyes usually open, and the head tucked ventrally potentially to present concentrated areas of poison glands positioned dorsally at the base of the head (e.g., toads and ambystomatid salamanders).[2,105,106]

If seized by a predator, many reptiles and amphibians struggle, hiss, urinate, defecate, or discharge their anal/cloacal glands.[1] Salamanders often writhe and coil around predators when seized, which often covers the predator in adhesive or irritating secretions and increases the likelihood of escape.[107,108] Vipers that are eaten by kingsnakes (*Lampropeltis*) use specific defensive postures when exposed to kingsnakes or their scent, including body bridging (a laterally raised loop of the trunk region, with the head and tail held low), inflation, and body flips and jerks, which presumably make them harder to swallow.[109] Colubrid snakes do not exhibit body bridging.[110] A number of lizards and snakes exhibit "death-feigning" behavior (thanatosis), where they flip on their back, the eyes usually remain open, and limbs (if present) remain limp and away from the body.[105] Sometimes death-feigning includes gaping the mouth with the tongue out and defecating, vomiting, or musking on themselves (Fig. 13.4). Although tests in the wild are limited,[111] the function of death-feigning seems to be to deter predator interest or

FIG 13.4 Death-feigning behavior in an Eastern hog-nosed snake (*Heterodon platirhinos*). (Courtesy of Andrew M. Durso.)

inhibit a predator's attack behavior, which allows the prey to slip away unnoticed when the predator's attention decreases.[112] It is often noted that death-feigning in species such as hog-nosed snakes (*Heterodon*) is common in the wild but wanes in captivity, potentially through habituation.

Tail Displays and Tail Autotomy

With the exception of adult anurans, most reptiles and amphibians have tails. Tails are important for balance, gait, and fat storage and are often used in displays with various functions, including luring prey[113] and signaling to predators[114] and conspecifics.[115] Because the loss or damage of a tail is normally not lethal, some reptiles and amphibians use their tails in defense.

Turtles and most snakes do not use their tails in defense, but crocodilians and some large lizards, such as green iguanas (*Iguana iguana*) and mace-tailed lizards (*Uromastyx*), will use their tails to whip or strike their enemies. Most salamanders, lizards, and some snakes can autotomize their tails.[116,117] Tail autotomy is a convergent adaptation among amphibians (salamanders) and reptiles (squamates). Salamander tail autotomy is achieved by a weakness in the skin and musculature between caudal vertebrae, whereas reptiles have fracture planes within each caudal vertebra. Some salamander species only autotomize the entire tail, whereas other salamander species and reptiles can break the tail off at any length. Ease of tail autotomy can vary among species and populations, is often correlated with local predation risk, and can differ between males and females and between previously unbroken and regenerated tails. Tail autotomy is clearly demonstrated to result in higher survival rates among amphibians and reptiles. Although the tail can regrow, there are often nutritional, social, and locomotory consequences to losing a tail.[118] Not all lizards recover well from autotomizing their tails. For example, the consequences of tail loss for leopard geckos (*Eublepharis macularius*) and other fat-tailed geckos, which store more water and fat in their tails than other lizards, can be severe and require more treatment than thin-tailed species such as anoles (*Anolis*) and grass lizards (*Takydromus*). Several groups of salamanders and lizards cannot autotomize their tails, many of which use them for some other purpose (e.g., locomotion, grasping; Table 13.1).[119,120] Many snakes, some amphisbaenians, and some salamanders will conspicuously display their tails when threatened.[108,121] Among reptiles, these species normally have short tails with blunt tips, often with contrasting colors, which probably aid in misdirecting the attacks of predators or in sending aposematic or mimetic signals.[114]

TABLE 13.1 Presence or Absence of Tail Breakage in Lepidosaurs

Squamate Family or Group	Common Name	Tail Autotomy Present?
Agamidae	Dragons and relatives	Some*[118–120]
Amphisbaenia	Worm lizards	Some[114,118,119,202]
Anguidae	Slowworms, glass lizards, alligator lizards, and relatives	Some*[118–120,201]

Counter-Attack

Many amphibians and reptiles use counter-attacks, usually biting, as a last resort defense. For humans and large predators, the bites of most species are incapable of inflicting any significant damage, but some amphibians and reptiles are capable of delivering significant bites. Many reptiles and salamanders will bite and seize a predator to prevent

FIG 13.5 Mouth-gaping defensive behavior in a cottonmouth (*Agkistrodon piscivorus*). (Courtesy of John D. Wilson.)

ingestion.[1,2,107] The predator may have to release the animal, which creates an opportunity for escape.

Reptile venom evolved to accelerate prey digestion and enhance prey capture and therefore functions only indirectly in defense. Venom is energetically expensive to produce, and some venomous snakes do not always elect to use their venom in their own defense.[122] Nonetheless, some species have evolved to advertise their venomous nature through aposematic coloration, tail rattles, or visual displays such as mouth gaping (e.g., cottonmouths, *Agkistrodon piscivorous*; Fig. 13.5). Some reptiles and amphibians can spray their venom (e.g., spitting cobras, *Hemachatus*, and some *Naja*)[123] or poison (e.g., some toads)[124] at an enemy. Northwestern salamanders (*Ambystoma gracile*) have concentrations of poison glands along their tail ridge and will lash their tails to fling or slap irritating toxins into the eyes of a potential predator.[106] Some amphibian species are capable of injecting poisons as a defense.[125,126] Salamanders in the genera *Pleurodeles*, *Salamandrina*, and *Tylototriton* have long, spear-shaped ribs that can penetrate through the animal's skin when it assumes a defensive posture, facilitating the injection of toxic skin secretions into a predator that seizes the salamander.[126,127] Similarly, Greening's frogs (*Corythomantis greeningi*) and Bruno's casque-headed frogs (*Aparasphenodon brunoi*) have bony spines on the skull that penetrate the skin (Fig. 13.6) and can presumably facilitate envenomation of potently poisonous skin secretions.[125]

SOCIAL & REPRODUCTIVE ADAPTATIONS

Courtship

Reptiles and amphibians exhibit a remarkable diversity of courtship behaviors that are beyond the capabilities of this chapter to explore fully.[1,2,60] In many species, male courtship behaviors take the form of ritualized male-male combat or visual or vocal displays intended to advertise mate quality or entice females to breed. Chemical communication is an integral part of courtship for many reptiles and amphibians, and some have evolved elaborate courtship pheromones.

Male crocodilians establish a dominance hierarchy during courtship, and dominant males court females by vocalizing and blowing bubbles at them.[128] Courtship in turtles primarily involves visual and chemical cues. Males of some species turn brighter colors when they are ready to mate.[129] Species that live in murky water, such as mud and musk turtles (family Kinosternidae), rely mostly on pheromonal cues to find

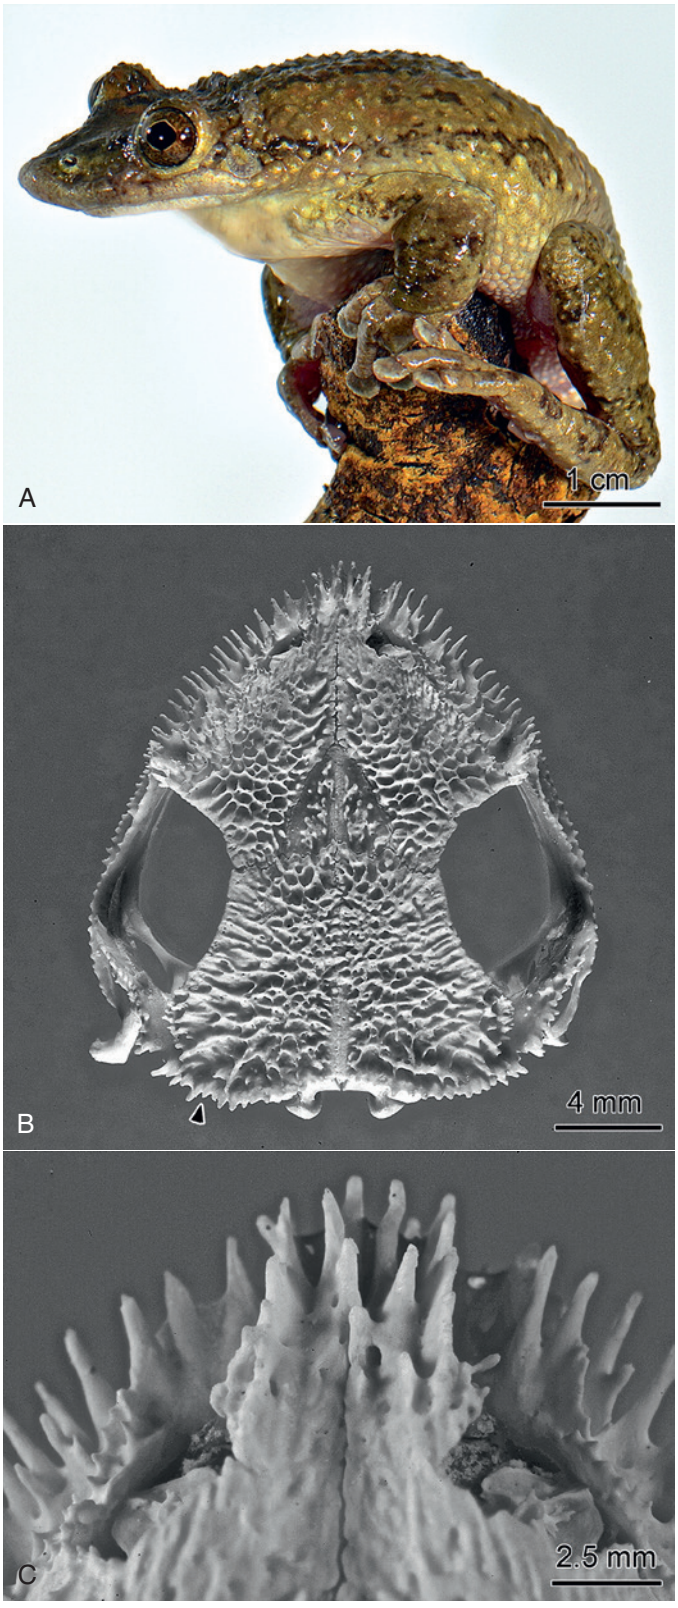

FIG 13.6 (A) The Greening's frog *(Corythomantis greeningi)*. (B and C) Head spines of the Greening's frog. (From Jared C., Mailho-Fontana PL, Antoniazzi MM, et al. Venomous frogs use heads as weapons. *Curr Biol.* 2015;25:2166-2170.)

VetBooks.ir

and choose mates. Males of some turtle species have elaborate displays aimed at female appeasement, whereas others are more brutal and direct.[130] Territorial defense and courtship behavior are often related in lizards and tuataras.[4] Males advertise their quality to one another and to females using bright colors and stereotyped body positions or movements, such as head-bobs, arm-waving, push-ups, tail-flagging, and dewlap displays.[131] Many male lizards also secrete nonvolatile, high protein-content chemical signals from femoral pores on the inside of their upper legs, which probably persist for several days and are used to mark their territories and communicate information about their species, social, and sexual status.[132] Courtship behavior of snakes is usually initiated by males and has three phases: tactile-chase, tactile-alignment, and coitus. Females indicate their receptivity by gaping their cloaca, and intromission follows. Many male snakes perform vertical displays in pairs punctuated by periodic "topping" movements until a "winner" is established. Snakes that can maintain an upright posture for longer are more dominant. The hormones of losing males discourage them from further courtship, while dominant males experience a surge of testosterone following combat that aids them in courting females.[133,134] Male Madagascan boas (*Sanzinia madagascariensis*) use their spurs in combat.[135] Because sperm competition is a major component of sexual selection,[136] males of many species of lizards and some snakes engage in mate-guarding behavior (Fig. 13.7).[137-140]

Wells[2] provides a thorough review of amphibian courtship and mating behaviors. Like reptiles, amphibians use visual, vocal, tactile, and chemical cues in courtship, but the relative importance of those modes differs among major lineages. Male anurans rely strongly on calls to attract females, and females have evolved to prefer very specific call patterns in order to mate. In addition to auditory calls, some male anurans use vibrations transmitted through substrates to communicate and court. Some anurans, especially those from naturally noisy environments such as fast-flowing streams have replaced or enhanced their calls with visual displays, such as waving of limbs in the "Dancing Frogs "of India (*Micrixalus* spp.), Brazilian torrent frogs (*Hylodes* spp.), and Panamanian golden frogs (*Atelopus zeteki*). Visual courtship displays are less commonly known among salamanders except within particular lineages. Males of some species of salamanders such as crested newts (*Triturus cristatus*) have elaborate secondary sexual characters including bold body patterning and enlarged dorsal crests or tail fins that are used in visual displays to attract females. Waving of the tail in aquatic species may also involve the directional dispersal of a chemical pheromone that increases female receptivity.

FIG 13.7 A male (left) broad-headed skink (*Plestiodon laticeps*) guarding a female (right). (Courtesy of Sandy Durso.)

Tactile and chemical signals are very important in the courtship of all salamanders. Ritualized tactile displays occur among a diversity of salamander lineages and involve using the tail to touch the female while delivering a pheromone, touching or bumping the male's head to the female's body, or tail straddle walking, where males position their tail under the female's body, her chin on the base of his tail, and the tail is undulated until the male perceives the female is receptive to mating. Chemical cues are important in locating and recognizing mates. Male newts (Salamandridae) and males of many species in the family Plethodontidae have glands on the head that produce a courtship pheromone. Because these salamanders have external sperm transfer but internal fertilization, these pheromones increase female receptivity to mating and increase the likelihood that she will complete the mating process. Male Eastern newts (*Notophthalmus viridescens*) court females by seizing the female around the neck with their hind legs and placing the glands in their cheek directly against a female's nares. The male uses his tail to create a current that concentrates pheromones near the female's head. Male plethodontids such as those in the genera *Desmognathus* and *Plethodon* have mental-"hedonic" glands in the chin. These species engage in "snapping" behavior that involves scraping or biting the female with their teeth to facilitate application of the pheromone to the female's bloodstream. Some large eastern *Plethodon* species will rub or slap the gland to the female's nares to deliver the courtship pheromone into the vomeronasal cavity. Beyond direct courtship, males of some amphibian species may acquire mates through defense of key resources such as oviposition sites or areas rich in prey resources, and males of many species will engage in direct combat with rivals for mates or key resources. In many species, male combat is enhanced by special morphologic adaptations such as enlarged thumbs, forearms, or specialized teeth or "tusks."

Female amphibians will also engage in courtship or mate assessment behaviors. Beyond selection of male courtship cues, females of some species will directly compete with other females for access to males. For example, male Majorcan midwife toads (*Alytes muletensis*) provide parental care, and females will interfere with matings between a male and another female in an attempt to secure the male for herself. Female Eastern red-backed salamanders (*Plethodon cinereus*) will smash open fecal pellets of conspecifics.[141] Although this behavior appears to function to track prey resources,[56] females may also use the quality of prey in male fecal pellets in mate assessment.[55]

Mating

Fertilization in reptiles and amphibians is either internal or external. Almost all male reptiles have intromittent organs that they use to transfer their sperm directly to individual females. Male turtles and crocodilians have a single phallus, whereas snakes and lizards have two hemipenes, although they only use one at a time. Male tuataras do not have an intromittent organ; sperm transfer is accomplished by "cloacal kissing," as in birds. Amphibians have an enormous diversity of reproductive modes.[2,142] All anurans and salamanders have external sperm transfer, but caecilians have a phallic structure for internal sperm transfer.[143] The vast majority of anurans, as well as salamanders in the families Cryptobranchidae and Hynobiidae, have external fertilization. The vast majority of salamanders have external sperm transfer but internal fertilization. Only a dozen species of anuran are known to have internal

FIG 13.8 Cephalic amplexus in a pair of Eastern newts (*Notophthalmus viridescens*). (Courtesy of Sandy Durso.)

FIG 13.9 Mating in eastern box turtles (*Terrapene carolina*). (Courtesy of Kerry Wixted.)

fertilization.[144] For species with external fertilization, males generally engage in amplexus, where they seize the female from behind using the forearms around the female's waist (inguinal), under the forearms (axillary), or around the neck (cephalic; Fig. 13.8). Other males or females may try to dislodge amplexing males, so grip is often aided with adhesive pores along the male's arms or on enlarged pads on the male's thumbs. External sperm transfer with internal fertilization is accomplished through the deposition of a spermatophore (a sperm packet on a proteinaceous stalk). Male salamanders that deposit a spermatophore will guide females to pick up the sperm packet by tail straddle walking or nudging, and males may continue to use courtship pheromones to sustain female progression through mating.[2] Long-term sperm storage allows many female reptiles and amphibians to become gravid many months or even years after mating[145–147] and to dissociate mating from reproduction, which is useful in highly seasonal or unpredictable climates.

Most male reptiles are aggressive toward other males, and sometimes even toward females, during the mating season. Male crocodilians and many male lizards establish and defend territories around females. Male snakes follow the scent trails of receptive females[148] or scramble to mate with them upon emerging from hibernation.[149] Many male snakes and lizards guard their mates.[150] Actual mating behavior is quite variable. Some species mate very quickly, whereas mating in others takes hours. Most aquatic turtles mate in the water and most terrestrial turtles mate on land. Male box turtles (*Terrapene*) wedge their hind feet into the space between the female's carapace and plastron to prevent her closing her shell on his phallus when it is inserted (Fig. 13.9). Many lizards mate quickly, since their courtship displays make them conspicuous to predators. Overall, the courtship behaviors of most species of snakes are poorly known.[72] Many snakes lay side-by-side, intertwining their bodies, as the male inserts one of his hemipenes into the female's cloaca. Some male pythons use their spurs to titillate the female during mating,[151] and some male colubrid snakes bite the female during mating. Many male vipers exhibit a jerky "tapping" behavior with their chins on the female's back.

Gestation

Female behavior during gestation involves a trade-off between minimizing predation risk and maintaining optimal developmental temperature. Females of some species aggregate in the vicinity of habitat features that offer optimal protection from predators and thermoregulation opportunities.[152] Female reptiles and amphibians are generally less active during gestation than at other times. Many female snakes do not feed during gestation, because there is not enough room for their digestive tract to expand to accommodate a large meal. In temperate regions, they may alternate between feeding in one year and reproducing in the subsequent year.[153] Many female pythons brood their eggs, coiling tightly around them for up to 2 months, and some species can increase the temperature of their clutch by >7°C using muscle contractions ("shivering").[154] The brooding instinct in mother pythons is very strong—lab experiments have shown that they will brood the eggs of other pythons, as well as rocks that are roughly the right size.[155] Female king cobras (*Ophiophagus hannah*) use their coils to build a nest measuring up to 4 feet in diameter out of sticks and bamboo leaves and guard their eggs for 2 to 3 months.[156] Less sophisticated maternal attendance of eggs is widespread in lizards and snakes.[157] Nest-building during or at the end of gestation is also ubiquitous in turtles and crocodilians.

Gestation is not a common focus of behavioral research in amphibians because it appears to be a less important component of their reproductive natural history. Most aquatic-breeding amphibians lay small eggs that expand dramatically when laid, and gravid females may cease foraging shortly before breeding and during migrations to breeding sites. Terrestrial breeding species often have smaller clutch sizes of proportionately larger eggs; therefore females of some terrestrial breeding species may have more prolonged periods where they do not forage while they accommodate their clutches. Live bearing is rare among anurans and salamanders, but the majority of caecilians likely retain eggs for some portion of larval development.[158] Some African toad species (Bufonidae) and *Eleutherodactylus jasper* retain eggs in the oviducts and birth either tadpoles or developed froglets. Some newts (*Salamandra* spp. and *Mertensia* spp.) retain eggs in the oviducts and birth larvae or fully metamorphosed offspring. No special behaviors have been described associated with gestation in these amphibian species. A number of other anuran species have evolved specialized mechanisms for retaining and caring for developing eggs and larvae that are analogous to gestation. Male midwife toads (*Alytes* spp.) carry their eggs wrapped around the male's legs until the tadpoles hatch. Females of several South American anuran species in the family Hemiphractidae carry their fertilized eggs on their back (*Stefania* spp., *Cryptobatrachus* spp., and *Hemiphractus* spp.) or in special dorsal skin pouches (e.g., *Gastrotheca* spp.) until they hatch directly as developed frogs or the tadpoles are deposited in water.

VetBooks.ir

Some pipid species, such as Surinam toads (*Pipa pipa*), also roll their eggs onto the female's back where they are carried in cavities in her skin until the tadpoles hatch.[159] Two of the most exceptional forms of gestation known among amphibians occur among males of the two species of Darwin's frogs (*Rhinoderma* spp.) and females of the two Australian Gastric Brooding Frogs (*Rheobatrachus* spp.), the latter of which are now extinct. After fertilizing the eggs, male Darwin frogs remain with the fertilized eggs until the tadpoles hatch. The male will gather the tadpoles and hold them in thick secretions in his vocal sac where the tadpoles are provisioned by skin secretions for two months until they metamorphose.[160] Female Gastric Brooding Frogs swallowed their eggs after external fertilization and brooded their developing tadpoles in their stomachs.[161] Digestion in the stomach, including the production of stomach acids, shut down and females did not feed for 1 to 2 months. The young would eventually emerge from the mother via the mouth, after which time feeding and digestive processes resumed.

Parental Care

In general, reptiles and amphibians do not exhibit parental care that is as prolonged and intricate as that of many mammals and most birds. However, parental care is found in every major group of reptiles and amphibians,[157,162] has probably evolved multiple times in most groups, is prevalent within specific lineages, and in some groups can be prolonged and intricate.

Crocodilians have particularly well-developed parental care, a trait they share with their closest living relatives (birds), as well as possibly with some dinosaurs. Most chelonians abandon their nests after burying them, although there are exceptions.[163] Hatchling crocodilians and some turtles vocalize from within their eggs to coordinate hatching with their clutch-mates and sometimes with their parents.[164,165] Some lizards guard their eggs against predators,[166] and Australian scincid lizards of the genus *Egernia* live in large aggregations of closely-related individuals and exhibit long-term monogamy and group stability, with up to three annual cohorts of full-sibling offspring living with their biological parents.[167] Parental care is also widespread within certain groups of snakes, such as pythons[168] and vipers,[169] particularly pit vipers, which may remain with their young for several days after they are born. Young pit vipers also seem to follow the scent-trails of their adult relatives to locate preferred hibernation sites[170] and may obtain thermoregulatory[171] and other[172] benefits from aggregating.

Parental care is highly variable within and among amphibian lineages and includes uniparental male or female care and biparental care.[2,173,174] Compared to anurans, which do not generally exhibit parental care, parental care is more common among caecilians and salamanders, particularly among the Plethodontidae. Generally, parental care is most common among terrestrial breeding and direct developing species that have few, large eggs, or among species that have specific constraints on completing their life cycle that require a parent to facilitate. Whether a species will exhibit male versus female parental care is best predicted by fertilization mode; external fertilization is often associated with male parental care and internal fertilization with female parental care.[173,174] Therefore, among anurans that exhibit parental care, males commonly provide the care (though females will as well), and male parental care occurs among external fertilizing salamander species such as hellbenders (*Cryptobranchus alleganiensis*). Among the majority of salamanders and all caecilians, females provide parental care.

Amphibian parental care is most commonly related to egg attendance and defense or egg or tadpole transport.[174] Among terrestrial breeding salamanders (e.g., *Plethodon* spp.), females will remain coiled around their eggs for 2 months or longer, seldom breaking contact with the clutch and often rubbing against and moving eggs around (Fig. 13.10). Egg attendance in these species is known to reduce desiccation and predation risk,[174–177] and females will often consume dead or infected eggs to prevent the spread of fungi to other embryos.[175] It is also hypothesized that female contact with eggs may facilitate the transfer of beneficial microbes that inhibit fungal colonization.[178,179] Upon hatching, young salamanders will remain in contact with their mother for up to 2 weeks, often positioning themselves under her chin or on her back, and juveniles may remain within their parent's territory for several years. Chemical communication between developing embryos and the parent and after hatching has been demonstrated to be important in facilitating parental care behaviors among these species.[180,181]

FIG 13.10 Red-backed salamander (*Plethodon cinereus*) female coiled around her clutch of eggs. (Courtesy of John C. Maerz.)

Beyond the examples of gastric or vocal sac brooding described previously, there are other examples of elaborate parental care in anurans. Tadpole and juvenile transport is documented among several anuran families. Generally, fertilization occurs out of water and males wait with fertilized eggs, or males or females hold eggs on their back or in specialized pouches until the tadpoles hatch, at which time the parent will transport the tadpoles to water. In several species, tadpoles climb on to the parent's back (e.g., *Sooglossus* spp., *Colostethus* spp.) or into skin pouches (e.g., *Assa darlingtoni*) where they will complete their larval development without feeding or ever being deposited in water. Several species of anuran also attend their developing tadpoles. Some species aerate tadpoles by kicking the water around the tadpoles, and some species may facilitate the movement of their tadpoles out of nests or among water bodies by digging channels for the tadpoles to swim between pools.[182] Arguably one of the most advanced forms of active parental care in anurans has evolved in several lineages that breed in or transport tadpoles to small water bodies (e.g., tree holes or bromeliads) where food resources may be limited or competition high. For example, several species of dart frogs (Dendrobatidae) distribute their tadpoles among multiple bromeliads.[183] Males and females will regularly visit the bromeliads to check on their tadpoles, and tadpoles may signal hunger by touching the parent. Females will deposit unfertilized eggs for their tadpoles to consume, and males have been observed signaling females to provide eggs to developing tadpoles. Arguably, this form of parental care is highly derived among amphibians and rivals the complexity often observed in birds and mammals. Finally, arguably the strangest form of amphibian parental care is the discovery of skin feeding in the caecilian *Boulengerula taitana*.[184] Young caecilians were observed feeding directly on the skin of adult females as a means to provision them with nutrients.

NONREPRODUCTIVE SOCIAL BEHAVIOR

Although reptiles and amphibians are generally thought of as nonsocial, many are highly social, even outside of mating. Play behavior has been documented in a number of reptiles and amphibians,[185,186] often in captive settings. All crocodilians are highly social,[128] with a social hierarchy and males that defend territories, females, and juveniles. Although most male turtles are not territorial, they may engage in combat if they encounter one another, even outside the breeding season. Sometimes male and female turtles, such as wood turtles[187] and gopher tortoises,[188] spend time together outside of the breeding season. It has been suggested that tortoises can learn by watching each other.[189] Male lizards are territorial toward one another in general,[190] but some species spend considerable time with females outside of the breeding season (e.g., sleepy lizards, *Tiliqua rugosa*).[191] Great desert skinks (*Liopholis kintorei*) build and maintain elaborate subterranean burrow systems, where they live in cooperative multigenerational family groups.[192] The few other lizard species that form family groups live in rock crevices that require no maintenance.[193] Snakes are generally not social,[194] but rattlesnakes may aggregate outside of the breeding season,[195] and they can use their chemosensory abilities to communicate information about foraging sites even when they are physically distant from one another.[196]

Similarly, social behavior of amphibians outside the context of mating and parental is not widely documented.[2,197] Most species are presumed solitary outside the breeding season, though some species may aggregate for specific purposes such as thermoregulation.[2] A number of amphibian species have been observed huddled during dry conditions, which presumably functions to reduce surface area to volume ratio and evaporative water loss. Many terrestrial salamanders (e.g., *Plethodon* spp., *Aneides* spp.) can be highly territorial in relation to refugia and food resources.[198] The species often engage in scent marking of territories and have visual threat (dominance) and submission displays that are used in territorial encounters. Fights are common among these species, particularly among adults of the same sex and outside breeding seasons, and can result in significant injuries including scarring to the face and the loss of the tail. Female salamanders may also routinely inspect the fecal pellets of other adults as a means to track resource availability.[56]

BEHAVIORS PARTICULAR TO CAPTIVITY

If captive reptiles and amphibians are prevented from thermoregulating or maintaining water balance or are exposed to cues associated with threats, they often exhibit behavioral signs of distress, such as refusing food, difficulty shedding, or weight loss. Some animals engage in "edging" behaviors where they continually push against the walls of their enclosure. This can cause significant lesions, particularly if some aspect of their care is inadequate. Some animals defecate very infrequently, sometimes as little as once per year,[199] but frequent defecation can be induced in captive animals by frequent cleaning of their cages.[200] Some important behaviors may also require stimulation or enrichment in captivity, which is now expected as part of quality husbandry. For example, some species are gregarious when they bask and will not engage in basking when housed individually, and some species or individuals may require live prey to stimulate feeding (which is illegal in some countries). Awareness of important behaviors and the factors that can either result in behavioral displacement or that are needed to stimulate healthy behaviors are important for maintaining animal welfare.

ACKNOWLEDGMENTS

In addition to the numerous references in this chapter, this review is largely possible due to the tremendous review texts produced and edited by F. Harvey Pough et al., Carl Gans, and Kentwood D. Wells, which we have cited throughout this chapter. Their contributions to synthesizing our understanding of amphibian and reptile behaviors cannot be understated. Thanks to P. Zani for reviewing Table 13.1.

Behavioral Training and Enrichment of Reptiles

Michelle L. Skurski, Gregory J. Fleming,[†] Andre Daneault, and Geoffrey W. Pye

Reptiles have historically carried the stigma of being unintelligent, uncharismatic, and easy to care for with minimal husbandry needs. Nothing could be further from the truth. Animal caretakers now recognize a need for all animals, including reptiles, to be able to perform biologically appropriate behaviors. The environment provided should be determined by the animals' natural and individual histories. Training and enrichment are great ways to provide reptiles opportunities to display their natural behaviors, to allow for people who keep reptiles to interact with these animals and observe their behavior close at hand, and to have the reptiles participate in their own veterinary medical care.[1–3]

Animal enrichment and training have become standard practice in most zoological and aquarium facilities and can also be implemented in private homes. The concepts of training and enrichment are interrelated. In recent years, many professional animal care facilities have seen improvements in the health and well-being of reptiles by providing an environment in which reptiles can make choices. For example, natural behaviors such as foraging, climbing, digging, or swimming cannot take place if animals are housed in a barren plastic box. With a small amount of effort, private owners can successfully encourage natural behaviors such as these in their reptiles.

ENRICHMENT

Enrichment is more than just placing a new branch or a plant in a reptile's environment. Although there are many different definitions of enrichment, for the sake of consistency we will follow the definition used by the Association of Zoos and Aquariums (AZA) Behavior Scientific Advisory Group:

> *Enrichment is a dynamic process for enhancing animal environments within the context of the animal's behavioral biology and natural history. Environmental changes are made with the goal of increasing the animal's behavioral choices and drawing out their species-appropriate behaviors, thus enhancing animal welfare.*

In practice, enrichment means encouraging species-appropriate behaviors and providing the animal with choices in every aspect of reptile husbandry, from food presentation to housing. The diversity of reptile habitats, microhabitats, and ecosystems, as well as the range and complexity of their behaviors, can actually increase the opportunities for enrichment to enhance the animals' lives.

Based on the aforementioned definition, there are three main goals for enrichment:

1. To promote species-appropriate behaviors
2. To provide behavioral opportunities
3. To provide animals with choices or control over their environment

All three of these goals require a clear understanding of the animal's natural and individual histories. This information is critical to making the enrichment successful. Useful natural history information includes how the reptile thermoregulates; the optimum body temperature range for the species; normal activity levels for the reptile; diel cycle (i.e., is the reptile diurnal or nocturnal?); natural diet and foraging style; and whether the reptile is arboreal, terrestrial, aquatic, or semiaquatic. This information will help to prepare clients to properly care for a reptile. Based on the natural history, each enrichment initiative should have a behavioral goal. One benefit of setting behavioral goals for enrichment is that it offers a way to measure success. For example, a client may want to encourage an overweight arboreal snake to climb and utilize more of the enclosure. The question the client may ask is, "Did the addition of branches into the snake enclosure encourage the snake to climb and utilize the enclosure?" If the answer is yes, the behavioral goal was achieved. If the answer is no, then other options such as platforms, heat sources, or even different types of branches may be explored to encourage the snake to climb (Fig. 14.1).

Another behavioral goal may be to encourage an animal to forage. One approach might be to utilize natural scents resulting from dragging a prey item through the enclosure to leave a scent trail that can stimulate the reptile to forage. In some cases the scent just needs to be novel to engage the reptile. Animal keepers have successfully utilized a cinnamon scent trail scattered throughout an enclosure to encourage foraging in a Komodo dragon (*Varanus komodoensis*).

Choice of housing, enclosure furnishings, and behavioral opportunity depend on whether the reptile is arboreal, terrestrial, aquatic, or semiaquatic. Something as simple as providing different levels in an enclosure can encourage exploration and foraging. Many species of monitor lizard are known to stand bipedal to forage in the wild. This behavior can be recreated through minor alterations of an enclosure and delivery of food to the animal (Fig. 14.2). Although animals in the wild seem to exhibit this behavior without much effort, a monitor lizard while in human care may need to be encouraged to stand through small and successive approximations of gradually increasing the height at which food is placed. Captive lizards are likely novices at standing bipedal and will need to develop the skills and physical ability to accomplish some behavioral goals.

The way in which food is presented can also provide behavioral opportunity. Multiple behaviors can be encouraged by varying the size of the food item, the placement or location of the food, and the time of day of the feeding. For example, tree pythons are nocturnal; as such, their activity level typically increases at night. During the more active periods, foraging and hunting behaviors will be displayed. Therefore feeding during these periods could encourage active behaviors that stimulate and exercise the snake.

Providing complexity and choices to an environment can be achieved through addition of, or changes to, rocks, branches, plants, light, and

[†]Deceased.

FIG 14.2 A Nile monitor (*Varanus niloticus*) standing bipedal to acquire a food item.

substrate within an enclosure. Providing choices for and control over thermoregulation opportunities is vital for the reptiles. Opportunities for thermoregulation can be provided with the use of lights, under-cage heat pads, water of variable temperatures, and heat-emitting ceramic bulbs. Recently, improvements in technology allow changes in the temperature and humidity of enclosures by the minute. Environmental temperature and humidity may be altered throughout the day, allowing for natural changes in the animal's environment that mimic a natural sunrise or an afternoon rainstorm.

Offering different levels in an enclosure provides reptiles an opportunity to utilize heat and light sources to varying degrees. Understanding the general environment for the reptile in the wild is not enough; a caretaker must dig deeper into the natural history and behavior of the animal to meet its needs. For instance, the animal could come from the desert but spend the majority of its day burrowed underground, escaping from the sun and heat. In this case, the assumption that the animal would need a very warm, barren environment would take into account only a part of its natural history. Providing a way to escape the heat would also be vital to this animal's well-being. Appropriate lighting is essential not only for health but also for enriching a reptile's life.

Encouraging clients to study the natural and individual history of the species they care for will be the first step in the creation of a successful enrichment program for their reptiles. Enrichment done appropriately will improve the health of the animal, enhance their welfare, and assist in facilitating their care. To find some additional examples of enrichment ideas, see Disney's Animal Programs' enrichment website at http://www.animalenrichment.org.[3]

TRAINING

Since the early 1990s, there has been a dramatic increase in the use of operant conditioning techniques to train exotic animals for husbandry and medical purposes. These animal training techniques can assist in facilitating day-to-day care, routine medical procedures, and management of reptiles. The act of training can be enriching for both the animal and its caretaker as they interact. Any reptile brought into clinics, such as bearded dragons (*Pogona vitticeps*), green iguanas (*Iguana iguana*), monitor lizards, boas and pythons, and turtles and tortoises, can be trained to calmly and voluntarily enter a crate instead of being physically restrained for crating. Reptiles can also be trained to accept various veterinary procedures such as ultrasonography, nail clipping, venipuncture, or even being medicated. Reptiles with chronic conditions requiring regular visits and/or treatments can be trained to cooperate for many procedures. This kind of training allows for treatment with reduced stress to the animals and client.

To create a well-thought-out behavioral plan for a reptile, many zoo and aquarium facilities use the "SPIDER" framework[4] taught in several courses given by the Association of Zoos and Aquariums. The SPIDER framework includes **S**etting goals, **P**lanning, **I**mplementing, **D**ocumenting, **E**valuating, and **R**eadjusting (Table 14.1). More information on this process can be found at http://www.animaltraining.org.[5]

The first step *(S)* in the SPIDER process is setting goals. It is beneficial to start a training program by determining the overall behavioral goals (i.e., detailing the specific behaviors to be trained). During this goal-development process, it is important to include all parties involved with the management of the animals. Goals should

VetBooks.ir

TABLE 14.1 SPIDER Framework

Step	SPIDER Framework Details	Example
Setting Goals	Detail the specific behaviors to be trained.	Train the monitor lizard to enter a crate voluntarily and be calm and comfortable in the crate.
Planning	Create a series of steps for shaping the behavior. Plan who will be training the animal, when the animal will be trained, and any equipment or tool needed to achieve the training plan.	Wait for the lizard to move toward the crate; use crickets to reinforce. Continue to reinforce movements toward the crate until the lizard enters the crate. Reinforce calm behavior inside the crate by continuing to provide crickets. Close the door to the crate and continue to provide crickets for calm behavior.
Implementing	Train the behavior over many sessions, advancing only when the animal is ready. Ensure clear communication among participants regarding training steps and timelines.	The lizard's two owners will each train crating for two sessions per week. They will review each other's notes before each session. The crate will not be lifted with the lizard inside until the lizard has successfully entered the crate and remained inside calmly with the door closed for 10 minutes.
Documenting	Create a historical document that tracks the progress of the animal and shows trends in behavior.	Each of the owners will take notes on their training sessions, including a rating of the session and comments on the lizard's progress.
Evaluating	Review the documentation and training plan.	After 3 weeks, the lizard has not yet completely entered the crate.
Readjusting	Make any changes necessary to achieve the behavioral goals.	The owners decide to adjust the plan and begin placing a few crickets at the back of the crate to encourage the lizard to enter completely. Once this occurs, they will continue to provide crickets if the lizard remains calmly in the crate.

be based on the joint needs of owners, veterinary staff, and the reptile. For example, if the monitor lizard can shift into a crate for transport to the veterinarian, the lizard is more easily crated and less distressed when in the crate. This outcome facilitates a better veterinary evaluation. The goals in this case would then be to train the monitor lizard to enter a crate voluntarily and be calm and comfortable in the crate.

The next step *(P)* is planning. This is when a training plan is created for the behavior. The training plan is a series of steps for shaping the behavior. The plan is meant to be a way for the trainer to think through the process before beginning to train an animal. If crate training is used as the example, the first step is to reinforce being comfortable with the presence of the crate itself. This process starts with providing positive reinforcement when the animal merely approaches the crate and then slowly encouraging the animal to enter the crate. The reinforcer or reward for learning to enter the crate could be small bits of a highly desirable food that are delivered as soon as the reptile approaches and/or moves closer to the entry of the crate.

The third step *(I)* is implementing. The behavior should be trained over a number of sessions, and training should advance only when the animal is ready. If more than one trainer is involved, having clearly laid out plans, assignments, and timelines helps to facilitate a smooth process. Defining roles and creating clear avenues of communication among all participants is also important.

Before the training is implemented, a decision should be made regarding how the training sessions will be documented *(D)*. Video recording sessions are an easy way to document and track progress of training. Taking notes, including session ratings and comments, is another useful way to document and track training outcomes. The goals of documenting are to create a historical record that can be used to track the progress of the animal, look for trends in behavior, and facilitate training new animals in the future.

The last two steps of the SPIDER process, evaluating *(E)* and readjusting *(R)*, require reviewing the documentation and training plan and making any changes necessary to achieve the behavioral goals. Often these two steps are occurring throughout the shaping of a behavior. For more information on how to apply this process, visit Disney's Animal Programs website or http://www.animalenrichment.org[6] or http://www.animaltraining.org.[5]

PRACTICAL EXAMPLES OF TRAINING AND ENRICHMENT

Nile Monitor (*Varanus niloticus*)

Providing a pool with cascading water to a Nile monitor's habitat for enrichment will enhance the complexity of the environment. The keeper controls the water level, temperature, and flow rate of the water. Food items such as live fish, crustaceans, invertebrates, cut meat, and deceased whole prey items may also be presented in the pool. This encourages the animal to exhibit natural behaviors, including swimming, soaking, thermoregulation, foraging, and interacting with the cascading water (Fig. 14.3).

Training a Nile monitor to enter a crate on cue may be a safer alternative to physically restraining the reptile. It is certainly less stressful for both the caretaker and the lizard. A Nile monitor can be trained to enter a crate voluntarily for transport (Fig. 14.4). This trained behavior also allows the keepers to clean the enclosure safely.

Komodo Dragon (*Varanus komodoensis*)

A Komodo dragon crate is not only designed for transport but also to facilitate medical examinations and sampling of the animals. Historically, hands-on medical examinations for large Komodo dragons involved the animals being anesthetized. Today, with a solid training program and appropriate crate design, the animal can voluntarily enter the crate to be transferred to the hospital (Fig. 14.5). While at the hospital and during the exams, the animal remains calmly within the crate for multiple procedures. The animal can be asked to move into specific positions in the crate as needed. These exams include evaluation of overall body condition, obtaining weights and body measurements, radiography, ultrasonography, coelomic palpation, and wound evaluation and care (Fig. 14.6). The crate is designed with removable portions to gain safe access to the tail and hind area of the animal for cloacal swabs, nail trims, venipuncture, and hind limb evaluation. Once the examination is complete, the crate and animal are secured and returned to the holding area where the animal is safely released into its enclosure.

Crocodilians

The creation of a training and enrichment program for large crocodilians is an invaluable tool for the animal husbandry and veterinary staff. The

VetBooks.ir

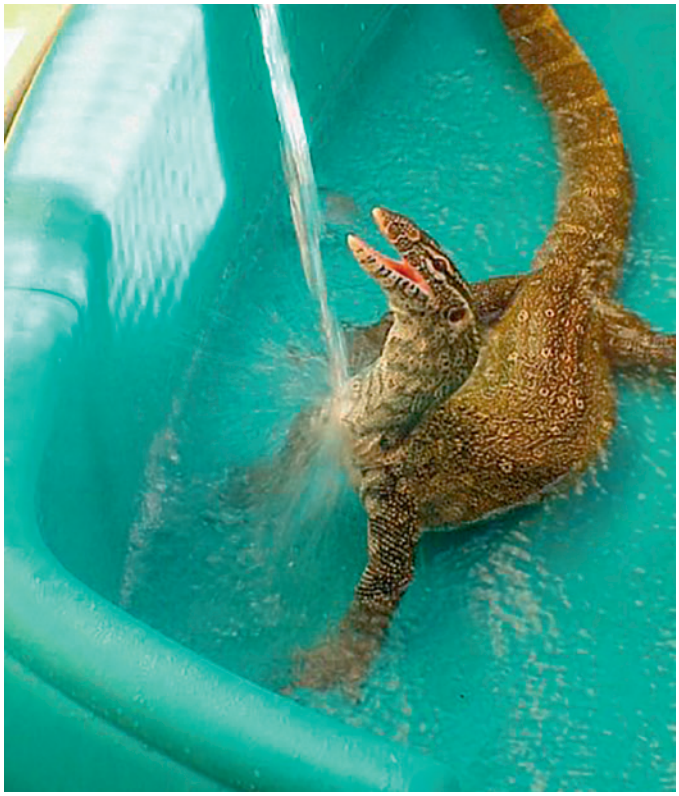

FIG 14.3 A Nile monitor (*Varanus niloticus*) interacting with a water element.

FIG 14.4 A Nile monitor (*Varanus niloticus*) being cued to move into a transport crate.

FIG 14.6 A Komodo dragon (*Varanus komodoensis*) in a crate having an eye exam.

program can facilitate a safe working environment for the staff and animals while providing great care and medical opportunities that would normally not be possible. Traditionally crocodilians were manually restrained and/or chemically immobilized for medical procedures and transport. Crocodiles are trained to shift off exhibit into holding areas where pools and specially designed crates are located. The shift training of the crocodiles facilitates opportunities for the keepers to provide enrichment, opportunities that would not be feasible with the animals being present in the exhibit. Keepers can strategically place enrichment items within the exhibit, manipulate the environment, and control how many animals are in the exhibit at any given time. The act of shifting the crocodiles is enriching as it allows the animals to move and explore other areas and increase activity levels. While in the off-exhibit area the crocodiles can be asked to voluntarily enter crates for medical procedures and examinations that could include transport, obtaining weights and body measurements, venipuncture, radiography, safe injection administration of medications, and wound evaluation and care (Fig. 14.7) (Fig. 14.8). Once the examination and medical procedures have been completed, the crocodile can be safely released back into their holding pool(s) and shifted back into their habitat.

VetBooks.ir

FIG 14.8 A Nile crocodile (*Crocodylus niloticus*) inside a training crate. Once crocodile is in place, pvc poles can be used to minimize movement for procedures. (From Miller RE, Fowler ME. *Fowler's Zoo and Animal Medicine.* Vol. 7. St. Louis: Elsevier; 2012;215. Used with permission.)

Venomous Snakes

Training snakes to shift into a box is helpful, particularly when dealing with venomous species (Fig. 14.9). Once the snake is safely in the holding box, a handling tube can be attached to the box, and the snake can enter the tube. The husbandry staff then detaches the tube from the box with the snake gently restrained by the tube. Using this technique allows safe and humane examination or treatment (Fig. 14.10). The snake does not come into direct contact with the handlers, making the entire procedure safer and less stressful for both the snake and the handlers.

CONCLUSION

The key to creating a successful training and enrichment program with a reptile is to develop the knowledge of the reptile's natural history.

FIG 14.9 A Black mamba (*Dendroaspis polylepis*) has shifted from his enclosure to the holding box. A handling tube is attached to the side of the box. Once this is attached, the door will open and the snake will move into the tube. (Courtesy of Brad Lock.)

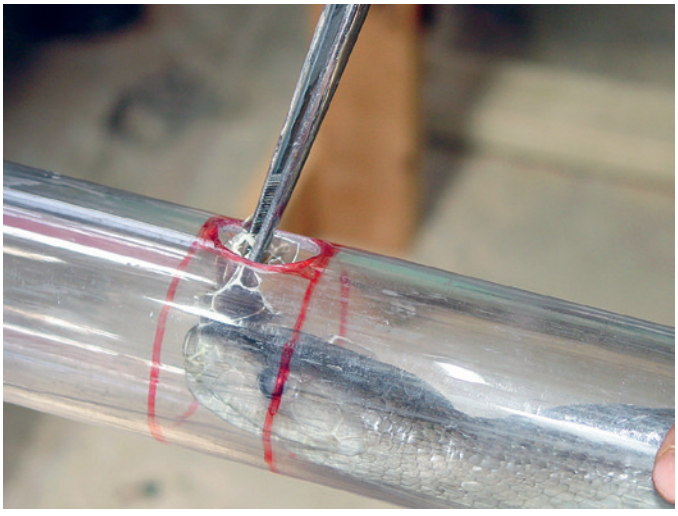

FIG 14.10 Once the snake is in the handling tube, the veterinarian can remove the retained eye cap without sedation. (Courtesy of Brad Lock.)

This is critical for understanding the needs and capabilities of the reptile and, ultimately, improves the reptile's welfare. Consulting with a veterinarian can be helpful in deciding on proper enrichment objectives and appropriate behaviors to train for daily activity and medical procedures. In any case, training and enrichment can benefit both the owner and the reptile by providing a closer relationship and a fuller enriching life for both participants.

Stress and Welfare

Craig J-G. Hunt

Stress may be defined as any physical, chemical, or emotional force that disturbs or threatens homeostasis and the accompanying adaptive responses (the stress response) that attempts to restore homeostasis.[1] When stress results in mental or physical damage the welfare of the animal becomes compromised, thus stress and welfare are inextricably linked.

A stimulus that evokes a stress response is called a *stressor*. Broadly, stressors can be divided into two categories.[2] Physiological stressors affect the animal's ability to maintain homeostasis necessitating physiological changes to cope with such conditions. Contrarily, psychological stressors do not pose a direct challenge to body physiology but rather may be indicative of imminent physiological challenge and can induce a stress response without actual physiological insult. Examples of common stressors are provided in Box 15.1.

Physical and mental well-being are intricately related; any physical injury or dysfunction has the potential to impact behavior, causing mental stress that, in turn, often negatively impacts physical health such as immune function, reproduction, and growth. Maintenance of animals in good condition requires not only an assessment of physiological health but also psychological health.[3]

PHYSIOLOGY OF THE STRESS RESPONSE

The normal stress response is a result of the response of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis with subsequent release of norepinephrine (sympathetic nervous system) and epinephrine (adrenal medulla), preparing the body for fight or flight.[1] The hypothalamus releases corticotrophin-releasing factor, which triggers the release of adrenocorticotropic hormone from the pituitary gland, which then stimulates the release of glucocorticoids from the adrenal cortex. Several other hormones, including prolactin, glucagon, thyroid hormones, and vasopressin, are secreted from other endocrine organs. The overall effect of these two systems is to increase the immediate availability of energy; increase oxygen intake; decrease blood flow to areas not critical for movement; and inhibit digestion, growth, immune function, reproduction, and pain perception. This system works well when responding to discrete short-term stresses.[1]

If the system is chronically activated, the stress response persists and eventually becomes dysregulated. Chronic stress develops when an amimal is unable to adapt to a particular stressor that does not go away. Cardiovascular, metabolic, reproductive, digestive, immune, and anabolic processes can be pathologically affected, subsequently leading to myopathy, fatigue, hypertension, decreased growth rates, gastrointestinal distress, and suppressed immune function.[1]

The predominant glucocorticoid in reptiles is corticosterone,[4] and an elevated serum corticosterone level is often used as an indicator that an animal has experienced stress. Increased corticosterone levels influence whole-body physiology and behavior by acting on numerous target organs. Glucocorticoids potentiate their effect by altering the circulating levels of sex steroid[5–8] and other hormones.[9] Combined, the direct and indirect effect of the sympathetic nervous system, epinephrine, and corticosterone rapidly induces substantial changes in physiological conditions that can be long lasting.

EFFECTS OF STRESS ON THE VARIOUS BODY SYSTEMS

As stated earlier, the role of the stress response is to maximize energy availability to vital body systems. Therefore the stress response stimulates lypolysis and gluconeogenesis[10] and alters cardiovascular function.[11] In addition, the stress response is a potent inhibitor of systems that are nonessential. Specifically, growth[12] and reproduction[13] are oftentimes dramatically inhibited during times of stress since the release of catabolic stress hormones (catecholamines and glucocorticoids) is incompatible with the release of anabolic hormones (growth hormone and gonadal hormones).[14] Although these processes are critical to long-term survival and fitness, they are nonessential for day-to-day survival. The effect of the stress response on the immune system is complex; however, typically the inflammatory response and antibody production are inhibited.[10] Such changes minimize energy utilization and enhance immediate performance, but immune suppression also increases the incidence of disease.

The stress response also has a substantial effect on behavior. Behaviors that are energy demanding such as aggression are usually drastically inhibited; however, behavioral changes can be complex. Corticosterone inhibits reproductive behaviors that consume substantial amounts of energy, such as aggression[7,8] and territory maintenance,[15] yet copulation itself is unaffected.[8] For males, copulation is a relatively low-energy behavior with high fitness value, so with copulatory behavior maintained, stressed males remain able to produce offspring during challenging times. However, without the supportive behaviors associated with male-male competition, such opportunities for reproduction are likely to be reduced.

The role of corticosterone in female reproduction appears complicated. Captivity-induced stress inhibits estrogen and therefore inhibits the production of vitellogenin.[16] However, corticosterone levels are frequently elevated during at least some stages of reproduction in wild female reptiles,[17-19] and this elevation is positively correlated with

VetBooks.ir

BOX 15.1 Common Stressors of Captive Reptiles and Amphibians

Psychological Stressors	Physiological Stressors
Social dominance	Inadequate or excessive environmental temperature, humidity, or photoperiod
Overcrowding	Thirst and dehydration
Confinement	Hunger and undernutrition
Novel environments	Inappropriate diet (malnutrition)
Human-reptile interactions	Oxygen deprivation
Lack of appropriate seclusion	Disease
Excessive differences in the size of cage mates	Trauma
Poorly matched social dominance or sexually established territories	Courtship including male-male combat, production of sperm, eggs, or embryos.

reproductive output.[19] In fact, treatment with exogenous corticosterone implants increases reproductive output.[20] Therefore corticosterone likely plays a constructive role in female reproduction rather than simply reflecting the stressful nature of reproduction.

WHEN DOES THE STRESS RESPONSE BECOME NONADAPTIVE?

Although the stress response is clearly an adaptive process, it also can lead to disease and ultimately the death of an individual. Exposure to stressors is a common occurrence, and the stress response adjusts an individual's physiology to cope with a given situation in the short term. The dramatic physiological effects of the stress response provide a state in which the individual can overcome the stimuli or distance itself from it in a relatively short time frame. However, the extreme mobilization of energy and inhibition of other body systems cannot be supported for a lengthy period without detrimental effects. Repeated exposure to a stimulus leads to long-term adjustments in body physiology and/or perception, and thus tolerance may evolve to a stimulus previously recognized as a stressor.

THE STRESS OF CAPTIVITY

Reptiles live in a vast array of habitats throughout the world, and each species has evolved behavioral and physiological mechanisms that enable them to use the environment to meet both short-term and long-term needs. In captivity, reptiles and amphibians are entirely dependent on their keeper for all of their needs, including provision of shelter, water, food, and access to appropriate environmental parameters. Failure to provide such needs is the cause of a significant percentage of health problems in reptiles and amphibians.[21]

Cowan[22] described a maladaptation syndrome in reptiles and amphibians, which typically results in nonspecific degenerative conditions and diseases attributable to adaptational failures in the captive environment and has been reported to be responsible for an outbreak of salmonellosis in a colony of lizards that were subclinical carriers of *Salmonella*.[23] Signs of stress in reptiles and amphibians may initially be subtle and are often vague and nonspecific and may include ill-thrift, weight loss, increased parasite burdens, inactivity or hyperactivity, and a failure to thermoregulate. There is variation in how individuals perceive a given environmental stimulus or cope with the same environmental change; thus the same environment may cause a greater stress response in one animal compared with another.[1] It is likely that captive breeding over several generations selects individuals that are more adapted to captivity and therefore less likely to suffer stress. Even when reptiles are held in conditions that properly provide for physiological needs, captivity can potentially be stressful. Escape behaviors, foraging activity, and mate-searching activity are all potentially altered by captivity therefore confinement in itself can be stressful.[24,25] However, this effect can be eliminated as the animal acclimates to the confinement.[26]

Another potential stressor that is unavoidable in captivity is handling. In nature, direct restraint is usually closely tied to consumption by a predator, so handling as a stressor of reptiles is not surprising. Handling leads to increases in both corticosterone[27,28] and adrenal catechloamines[29] even in some reptiles that are habituated to humans,[30] although, some can acclimate to handling.[31]

Routine management and cleaning of a reptile's or amphibian's enclosure may cause stress due to the frequent need to handle the animal and by removing important chemical cues.[32] Snakes have been shown to use pheromone on newspaper bedding in order to mark territory,[33] and removal of feces and cage cleaning has been shown to disrupt reproduction in the red-backed salamander (*Plethodon cinereus*).[34,35] Naturalistic enclosures with bioactive substrate may reduce stress by increasing the potential to provide microclimates and natural foraging behaviors; additionally such enclosures require less cleaning resulting in less disturbance. Reptiles in naturalistic environments were shown to be the least stressed when compared with those in more clinical environments,[32] but, if poorly done, there is the potential to increase pathogen and disease exposure.[36] Even in naturalistic enclosures, transparent barriers present a potential stressor as fear responses in snakes and turtles (and probabaly lizards) may be triggered with only visual stimuli.[32]

Psychological stress can also be induced by inappropriate social housing (Fig. 15.1); when kept together in captivity, many solitary or noncolonial animals display some degree of social dominance and territoriality, which may lead to stress.[37] Most reptile and amphibian species are not considered to be social, but there are numerous exceptions, and many exhibit a more social lifestyle at certain stages of life. Some animals come together in large numbers during certain events but remain solitary for the rest of the year, for example, garter snakes (*Thamnophis spp.*) during mating and Komodo dragons (*Varanus komodoensis*) feeding on a large carcass. Australian black rock skinks (*Egernia saxatilis*) exhibit long-term monogamy, stable social grouping, and evidence of nuclear family systems.[38] Group housing in some species such as the red-bellied cooter (*Pseudemys nelsoni*)[39] results in greater food consumption; in others such as hatchling chameleons (*Chamaeleo spp.*),[40] some crocodiles,[41] and snapping turtles (*Chelydra serpentina*),[42] dominance hierarchy discourages some individuals from feeding and limits access to food. Aggression and competition at basking sites has been demonstrated in some species such as the North American painted turtle (*Chrysemys picta*),[43] and dominant male iguanas (*Iguana iguana*) have been shown to grow more rapidly and use supplementary heat sources twice as often as subordinate males.[44] It has been demonstrated that in crocodilians and iguanas isolation from their peers may be stressful in their first year,[45] which suggests that such animals may be best group-housed (with suitable room) as juveniles but kept solitarily when subadults/adults.

Psychological and behavioral compromise due to constraints of a captive environment may result in frequent or constant attempts to escape or in inappropriate prolonged and repetitive locomotory behaviors that often result in self-induced trauma.[37] Reptiles appear unable to perceive the presence of glass as a barrier and may repeatedly rub against or crash into it causing physical injury.[46] Pica, the deliberate ingestion

VetBooks.ir

FIG 15.1 An overcrowded group of juvenile bearded dragons (*Pogona vitticeps*) housed in a barren enclosure with a single basking area. Such conditions are likely to cause psychological stress due to lack of individual space and refuge and physical stress due to an inability of all animals to bask appropriately. (Courtesy of Craig J-G. Hunt.)

of nonfood items, appears common especially in chelonia and may be caused by a lack of, or inappropriate, stimulation.[37]

HOW IS STRESS IMPORTANT TO REPTILE MEDICINE?

Because the stress response leads to a wide range of dramatic physiological changes, veterinarians must understand and consider the role of stress relative to the patient's condition. A thorough understanding of stress and the physiological changes associated with stress is vital for client education and patient treatment. Treatment regimes must incorporate both the immediate treatment of the disease and the reduction or elimination of any stressors in the animal's home environment. Without consideration of both, long-term improvement in the animal's condition is unlikely.

In addition to recognizing the role of stress in the etiology of a patient's condition, veterinarians must recognize the potential for stress associated with medical care. Diagnostic procedures and medical treatment can provide great benefits to an ill reptile, but they also unavoidably include many potentially stressful stimuli. All manipulations associated with both diagnosis and treatment must be evaluated in terms of their potential for inducing stress versus their potential medical benefit, being mindful that physiological changes induced by the stress response can be catastrophic to an already compromised animal.

Proper preparation minimizes the duration of stress associated with handling. All instruments and equipment necessary for physical examination and possible treatments should be ready before an animal is handled. Examination of reptile and amphibian patients in a dedicated room that has been properly sanitized since the last patient is optimal to reduce the potential stress of sounds and odors from other species such as dogs, cats, and ferrets.

ASSESSING WELFARE NEEDS

Animal welfare has been defined as being about how an animal feels about its world.[47,48] The husbandry of captive reptiles and amphibians has a major potential impact on the animals' physical and mental well-being and therefore its welfare in captivity. Appropriate husbandry is the most important factor in keeping captive reptiles and amphibians healthy both physically and mentally, and failure to provide appropriate husbandry is the number one cause of illness in captive reptiles.

In the United Kingdom "The Five Freedoms" were devised as a means by which the welfare needs of farm animals could be assessed; though originally designed for farm animals, their application has been accepted as a guideline for many other species, including those kept in laboratories, zoos, and as pets.[49] In the United States, San Diego Zoo Global developed a five-point animal welfare assessment guideline titled "Opportunities to Thrive" (Proc AAZV 2014, p 18-24), which was derived from and expands on the five freedoms: (1) freedom from hunger, thirst, and malnutrition; (2) freedom from thermal and physical discomfort; (3) freedom from fear and distress; (4) freedom from pain, injury, and disease; and (5) freedom to express normal patterns of behavior. Reptile welfare is protected by law in many countries (see Chapters 184 through 186).

RECOGNIZING STRESS AND ITS IMPACTS ON WELFARE

As previously discussed the causes and types of stress experienced by captive reptiles and amphibians are varied and not always easy to recognize, especially by the inexperienced.

Reptiles and amphibians have evolved mechanisms to mask signs of disease, which in extreme cases can result in an apparently healthy animal showing no signs of illness or distress dying acutely. Such cases are perhaps more likely where animals are kept in "clinical" conditions where the display of the normal repertoire of activities and behaviors is prevented.[50]

Some signs suggestive of stress may be quite obvious and include skin color changes; open mouth; hissing/spitting; coiling; inflating the body, neck, or throat; flattening the body against the ground; broadside posturing; standing more erect; biting; striking; tail whipping; spraying/voiding feces, urine, musk, blood, or stomach contents; retraction into shell; feigning death; tail autotomy; and attempts to escape. Other signs of stress may be much more subtle and/or may mimic other behaviors. Social stress for example may be subtle and is commonly observed when two juvenile reptiles are housed and raised together; in many instances one of the pairs will develop and grow more slowly with a resultant obvious disparity in their adult size. The eventual disparity in size is obvious, but the underlying stress often goes unrecognized (Fig. 15.2).

Hypoactivity with or without seeking out cooler temperatures such as normally occurs during hibernation, aestivation, and brumation is a biological shut-down strategy to avoid the rigors of a hostile environment that in some circumstances can be a sign of stress.[50] Prolonged bathing or basking may occur naturally at certain times of need such as posthibernation and gravidity, respectively; at other times such behavior may indicate stress.

Pain is a significant cause of stress and poor welfare in reptiles and amphians. Signs of acute pain in reptiles and amphibians include flinching, muscle contractions, aversive movements away from the

VetBooks.ir

FIG 15.2 A pair of side-necked turtles (*Macrochelodina rugosa*) reared together in an inadequately sized enclosure with poor water quality. The larger specimen appeared healthy whilst the smaller was undersized and anorexic with poor body condition score (1/5). The potential reason(s) for the smaller specimen's condition are numerous; however, psychological stress due to overcrowding and social stress is likely, in addition to the physical stress from poor environmental conditions. (Courtesy of Craig J-G. Hunt.)

unpleasant stimulus, and attempts to bite. Chronic and persistent pain may be associated with nonspecific signs of inappetance lethargy and weight loss.[51]

CONCLUSION

Although the stress response is an adaptive response that maximizes immediate survival, it jeopardizes long-term survival, especially of compromised individuals. Critical to optimal veterinary care to reptiles is an understanding of the physiology of stress and the potential of seemingly innocuous stimuli to induce a stress response and compromise welfare.

General Husbandry and Management

John V. Rossi

Reptile medicine is a challenging discipline. These unique animals require more than just a diagnosis and treatment to achieve successful medical management. For years experienced reptile clinicians have been aware of the importance of the "third rail" of reptile medicine. This additional evaluation requires establishing the correct physical and biological captive environment for our patients. Indeed, the paradigm of western medicine with regard to the treatment of infectious disease by using antimicrobials alone is being challenged. Questioning these concepts is even more critical in the reptile patient because stimulating a reptile's immune response depends so much on external factors. So what does this mean for the treatment of captive reptiles? Essentially, it means that we need to take a holistic approach to our reptile patients. Providing the correct captive husbandry is the most important factor in encouraging a healthy immune system. Keep in mind that the correct captive environment includes both physical and biological components. Physical factors include temperature, humidity, caging size and materials, substrate, lighting (both quality and quantity), ventilation, water provision, and water quality. Biological factors (or stressors) include competitors, predators, and infectious organisms, with the latter including metazoan, protozoan, bacterial, fungal, and viral diseases. Biological factors also may include symbiotic organisms, such as bacteria that assist in digestion or that may compete with pathogenic bacteria elsewhere on/in the body of a captive reptile.

Along with establishing the proper captive environment, providing the correct diet is critical to maintaining the health of a captive reptile and supporting successful reproduction. The correct diet includes the proper levels of proteins, fats, and carbohydrates, as well as vitamins, minerals, and micronutrients. These lesser minerals often serve as components of enzymes or coenzymes necessary for the immune response, and in many cases, these are deficient in the diet of captive reptiles. Water is also a critical component of the diet, and since many reptiles do not drink readily from standing water sources, the water content of the diet may become an important factor as well. For more detail on nutrition see Chapter 27.

Because there is such a strong correlation between the successful maintenance and reproduction of reptiles in captivity and providing the correct environment and diet, clients must be educated about such requirements and encouraged to research and correct any deficiencies. Reptile clinicians may think of this relationship in terms of a simple equation: $S_R = CE^2$, where *success with reptiles* in captivity (S_R) = both the *correct environment* and *client education* (CE^2). Even with years of research in attempting to understand and gain knowledge in the keeping and breeding of reptiles in captivity, incorrect husbandry and diet are the number one reason for illness in captive reptiles. Therefore clinicians need to be aware of basic reptile biology and husbandry to properly diagnose and treat this group of animals.

Additionally clinicians need to provide their reptile clients with important guidance concerning quarantine, disinfection, regular examination, fecal examinations, and deworming.

In reptile collections disease transmission is an important concern. Reptile keepers often create multi-individual or multispecies enclosures, which increase the likelihood of contagious issues.

There has been a recent shift away from simple enclosures to those that are more environmentally enriched. More complex environments traditionally were considered more difficult to maintain and were not often utilized. However, the benefits of enriched enclosures have become increasingly obvious in recent years (Fig. 16.1). These benefits appear to be both behavioral and physiological. Increased environmental complexity leads to increased activity, which appears to result in leaner, more reproductively active animals. The physiological benefits of microclimates within the enclosure enables the reptile to regulate body temperature and cutaneous water losses accurately (Fig. 16.2). These benefits may prevent illness and allow a reptile to live to an age approximating genetic potential. Another recent advance in herpetoculture involves the use of bioactive substrates in reptile enclosures. Bioactive substrates are believed to encourage the growth of bacteria and fungi that compete with pathogenic bacteria and fungi, thereby protecting the captive reptile from infection. This is discussed in more detail later in this chapter, but examples would include thick layers of natural substrates like cypress mulch or coconut chips. These layers maintain moisture gradients that allow for the growth of beneficial organisms.

The purpose of this chapter will be to associate biology with basic husbandry. Biology will be summarized to help build a foundation for understanding the basic husbandry techniques discussed in more detail in later chapters of this section. The reader is also referred to the Current Therapy chapter on recent updates in herpetologic equipment by Barten and Fleming.[1]

BIOLOGY

More than 10,000 species of reptiles have been divided into three major orders and one minor order. The species vary widely in terms of size,

VetBooks.ir

FIG 16.1 A Brazos water snake (*Nerodia harteri*) in a natural enclosure is more wary and maintains a leaner appearance than those housed in a typical aquarium-style cage. This snake also grows at a rate similar to those found in the wild and maintains oral bacterial flora more similar to a wild snake than one housed in an indoor aquarium-style enclosure.

FIG 16.2 Texas patch-nose snake (*Salvadora grahamiae*) basks on a rock in its cage. Ability to thermoregulate is critical for long-term successful maintenance and reproduction of captive reptiles.

shape, physiology, behavior, and diet. Their captive requirements may vary just as widely. Providing every detail for each of these species is beyond the scope of this chapter. But details of the biology of each group are presented in the previous section, and the husbandry of each group is discussed in more detail in the chapters of this section. However, a basic understanding of the biology of the reptiles a clinician is working with is important when giving guidance on designing an enclosure or attempting to treat a captive reptile. The most important factor is that most reptiles are ectothermic, which means they derive the vast majority of their body heat from outside heat sources. Some reptiles are considered stenothermal, accurately controlling body temperature within a narrow range, and others are eurythermal, allowing body temperature to vary widely according to external temperatures. In general, terrestrial reptiles are more stenothermal than arboreal or aquatic reptiles. There are exceptions, however; large sea turtles, for example, leatherbacks (*Dermochelys coriacea*) are extremely stenothermal because they are primarily endothermic. That means they derive the majority of body heat from metabolic and muscular functions and conserve that heat with a variety of physiological means, including countercurrent multipliers within their peripheral circulatory system. This extremely tight control of internal body temperature is also referred to as homeothermy, which is seen in many birds and mammals. However, all reptiles are believed to thermoregulate to some extent, making use of thermal gradients within their environment. Most aspects of their physiology are intimately tied to body temperatures, and hence, so is their behavior and ultimately their health. The preferred body temperature range of reptiles is referred to as the preferred optimum temperature range or zone (POTR or POTZ); this range is known for most wild reptiles (Table 16.1).

Ambient lighting and photoperiod (both quantity and quality) are important for health and reproduction in reptiles. Knowledge of the light exposure reptiles receive in their natural habitat will be important in providing proper captive lighting. Seasonal reproduction is often strongly influenced by seasonal changes in photoperiod. Some reptiles (e.g., many iguanid lizards and the tuatara, *Sphenodon punctatus*) actually have a light receptor on top of their head called the parietal eye. It is now believed that provision of a light gradient to captive reptiles may be as important as temperature and humidity gradients.

The use of herpetological field studies that describe the natural environment of a species can be helpful for determining captive conditions for that reptile patient. Botanists and gardeners have done this for years. In fact, in the absence of specific information on a species in question, one may refer to maps of solar insolation (hours of sunshine per day or kWh/m^2/day) and temperature zone maps (average minimum and maximum temperatures) for the geographical area that encompasses the natural range of that species. Other maps that indicate average rainfall, elevation, and predominant plant cover may also be used to help determine the environmental preferences of a species. Use of these maps does not take into account the microhabitat selection of a species, but may provide information on appropriate physical parameters to recreate in the enclosure. Lighting is discussed in more detail in the husbandry section of this chapter and in Chapter 17.

Water regulation of reptiles also varies dramatically from one group of reptiles to another and even between species. Generally speaking, reptiles from dry environments are uricotelic, essentially producing the large, relatively insoluble molecules of uric acid in an effort to conserve water at the renal tubule level. Reptiles from aquatic environments generally produce the smaller, more soluble urea, or in some cases ammonia, to eliminate nitrogenous wastes (Fig. 16.3). Many reptiles use various combinations of nitrogenous waste likely related to taxonomy, as well as current environmental factors of the species in question. All reptiles have insensitive cutaneous and respiratory water loss, which may be minimized with microhabitat selection such as seeking an environment with higher humidity. This is properly termed hydroregulation, and all reptiles appear to engage in microhabitat selection and possibly hydroregulation to some extent. The ability to reduce these minute water losses is considered important for long-term health and for reducing the likelihood of developing degenerative renal disease. These microenvironments may also harbor beneficial bacteria and fungi that compete with pathogenic bacteria and fungi, thereby providing other benefits to the reptile. See the subsequent discussion on bioactive substrates.

Behavior is an extremely important factor that is intricately associated with and controls (and/or is controlled by) the physiology of this diverse group of animals (see Chapters 13 and 14). As primarily ectothermic

TABLE 16.1 Preferred Optimum Temperature Ranges for Commonly Housed Captive Reptiles

Common Name (Scientific Name)	Preferred Optimum Temperature Range °C (°F)				
	Day	Night	Winter Cooling*	Underfloor Heat Source	Radiant Heat Source
Snakes					
Boa constrictor *(Boa constrictor)*	27–32 (80–90)	21–27 (70–80)	21–24 (70–75)	Yes	Optional
Rosy boa *(Lichanura trivirgata)*	27–29 (80–85)	21–24 (70–75)	14–16 (58–60)	Yes	Optional
Ball python *(Python regius)*	27–32 (80-90)	21–27 (70–80)	16–21 (60–70)	Yes	Optional
Burmese python *(Python bivittatus)*	27–32 (80-90)	21–27 (70–80)	16–21 (60–70)	Yes	Optional
Green tree python *(Morelia viridis)*	24–28 (75–82)	21–24 (70–75)	16–18 (60–64)	Optional	Yes
Carpet python *(Morelia spilota)*	27–29 (80–85)	21–24 (70–75)	16–18 (60–64)	Yes	Optional
Corn snake *(Pantherophis guttatus)*	25–29 (78–84)	19–24 (67–75)	13–16 (55–60)	Yes	Optional
Yellow rat snake *(Pantherophis obsolete)*	25–29 (78–84)	19–24 (67–75)	13–16 (55–60)	Yes	Optional
Gopher/bull snake *(Pituophis catenifer)*	25–29 (78–84)	19–23 (67–74)	10–16 (50–60)	Yes	Optional
Common king snake *(Lampropeltis getula)*	25–29 (78–84)	20–23 (68–74)	13–16 (55–60)	Yes	Optional
Mountain king snake *(Lampropeltis zonata)*	25–29 (78–84)	19–23 (66–74)	13–16 (55–60)	Yes	Optional
Gray-banded king snake *(Lampropeltis alterna)*	25–29 (79–84)	21–24 (70–75)	14–16 (58–60)	Yes	Optional
Garter snakes *(Thamnophis)*	24–27 (75–80)	18–22 (65–72)	12–15 (54–59)	Yes	Optional
Lizards					
Green iguana *(Iguana iguana)*	29–32 (84–90)	19–25 (67–77)	18–21 (64–69)	Optional	Yes
Basilisks *(Basiliscus)*	28–31 (82–87)	24–25 (75–77)	20–21 (68–70)	Optional	Yes
Leopard gecko *(Eublepharis macularius)*	25–29 (77–85)	18–24 (65–75)	None	Yes	Yes
African fat-tailed gecko *(Hemitheconyx caudicinctus)*	25–29 (78–85)	19–24 (67–75)	None	Yes	Yes
Day geckos *(Phelsuma)*	27–29 (80-85)	24–25 (75-78)	None	Optional	Yes
Leaf-tailed geckos *(Uroplatus)*	27–29 (81–84)	22–25 (72–78)	None	Optional	Yes
Chameleons, montane *(Chamaeleo)*	25–29 (77–84)	13–19 (55–67)	None	Optional	Yes
Chameleons, lowland *(Chamaeleo)*	27–29 (80–84)	21–24 (70-75)	None	Optional	Yes
Bearded dragons *(Pogona)*	29–31 (84–88)	20–23 (68–74)	17–21 (62–69)	Optional	Yes
Blue-tongued skinks *(Tiliqua)*	27–29 (80–85)	19–24 (67–75)	16–18 (60–65)	Optional	Yes
Monitor lizards *(Varanus)*	29–31 (84–88)	23–25 (74–78)	19–21 (66–70)	Optional	Yes
Tegus *(Tupinambis)*	27–30 (80–86)	21–25 (70–78)	16–21 (60–70)	Optional	Yes
Chelonians					
Temperate freshwater turtles (Emydidae)	27–29 (80–84)	18–21 (65–70)	Optional	Optional	Yes
Tropical freshwater turtles, most species	28–30 (82–86)	23–27 (74–80)	Optional	Optional	Yes
Temperate tortoises, box turtles (*Testudo, Terrapene*)	25–32 (78–89)	21–24 (70-75)	10–18 (50–65)	Yes	Yes
Tropical tortoises, most species (Testudinidae)	28–31 (82–88)	21–24 (70–76)	None	Yes	Yes

*Following fasting and with an empty gastrointestinal tract.
Most species probably benefit from the provision of natural sunlight and outdoor enclosures when local climatic conditions permit.

animals, their selection of, and precise control of, body temperatures using primarily exogenous heat sources is absolutely critical for nearly every biochemical reaction. Digestion, reproduction, and immunity are just three of the many functions that are affected by temperature selections. However, reptiles are also behaviorally regulating a myriad of other factors including not just those mentioned above (hydroregulation and lighting selection) but also the biological factors within the environment. Hence, normal behavior should be researched and understood when possible. Often changes in that behavior will provide important indicators of potential problems.

Behavioral changes in captivity fall into three major categories. These are seasonal/hormonal, learned, and medical/pathological. Seasonal/hormonal changes are those normal changes in behavior that occur each year and are associated with the season and/or reproductive behavior. This would include anorexia in males prior to mating or in females after mating. Learned behaviors are random behaviors that are rewarded directly or indirectly and are therefore repeated. This would include such things as approaching an owner for food or making use of another temporary food resource. Medical/pathological changes are those changes in behavior associated with disease, and they are of concern to veterinarians. In reptiles, the most common behaviors associated with disease are excessive wandering and anorexia, followed by inactivity and anorexia. Hence, excessive wandering and anorexia that occurs during nonreproductive times of the year should be viewed with concern. The same is true for inactivity and anorexia that occurs during nonhibernation/nonestivation times of the year. This can make medical problems more difficult to detect at certain times of the year, and it is important to monitor the reptile's weight. Significant weight loss is often pathological,

VetBooks.ir

FIG 16.3 Wood turtle (*Glyptemys insculpta*) is a semiaquatic turtle that is more likely to produce urea as a primary nitrogenous waste product; squamates produce primarily uric acid. This particular turtle is demonstrating corneal edema and conjunctivitis after being placed in chlorinated water. Letting water sit for 24 hours or treating with dechlorinating agents may be helpful for many aquatic turtles.

FIG 16.4 The classic juvenile form of nutritional secondary hyperparathyroidism in a bearded dragon (*Pogona vitticeps*) receiving insufficient calcium in the diet and/or a lack of UVB light. Note the deformed skull shape (an indication of poorly mineralized maxillary and mandibular bones), scoliosis of the spine, pathological fractures, and sternal recumbency.

while normal hibernation/estivation weight loss rarely exceeds 10% of body mass in captive reptiles. In wild reptiles, weight loss may exceed this mark and is usually related to dehydration. Biologists have noted that dehydration is the leading cause of death in hibernating reptiles, not starvation or cold. Hence, behavioral observation and regular weighing and record-keeping are essential as an early warning system for captive reptiles. A common medical reason for behavioral change is parasitism, especially in wild-caught reptiles. The author has observed numerous wild snakes that appeared sluggish or exceptionally docile that were heavily parasitized with ticks or mites. Captive snakes that are normally nocturnal that suddenly displayed more diurnal behavior have been diagnosed with coccidiosis.

The immune response of reptiles appears to vary dramatically on a seasonal basis and is also intricately tied to the temperature range available to the reptile in question. Maximum immune response appears to occur in most reptiles when they are held in or near their POTR. This range needs to be researched for the species in question. Both the humoral and cellular immune responses appear to be measurably lower in winter months, and thus reptiles may be more vulnerable to infection during this time. In fact, it appears that one of the most dangerous times for captive reptiles is at the end of hibernation, or early spring, as they emerge from hibernation. Sudden death of reptiles is common at this time, and it is hypothesized that as they warm up, infectious agents and parasites increase exponentially, while their immune response increases arithmetically. This may leave them with a "posthibernation immunity gap," and susceptibility to infectious agents and possibly death. Hence, clinicians should recommend physical exams, fecal exams, and parasite control prior to hibernation and immediately upon emergence from hibernation.

Certainly, the subject of stress and its relationship to disease in captive reptiles has been discussed in detail by a number of authors. Perhaps the most interesting and detailed report on the subject is that of Cowan.[2] To summarize their discussion, the amount of stress may be directly related to differences between the captive environment and the wild environment. Therefore captive environments that lack suitable temperature, lighting and humidity clines, and secure hiding places or have inappropriate photoperiods are more likely to result in diseased reptiles than those that have these key factors addressed (Fig. 16.4). See Chapter 15 for more details on stress.

BASIC HUSBANDRY REQUIREMENTS

Requirements for captive reptiles are based on their needs in nature. Requirements are summarized in this chapter and in more detail in subsequent chapters in this husbandry section. Unlike domestic animals, most reptiles have not been bred for generations to survive in "human habitations." A reptile's unique dietary requirements and ectothermic nature must be understood and addressed by keepers and clinicians to successfully maintain their health in captivity.

Temporary Housing or Hospitalization

Because the reptile patient has unique requirements, providing temporary housing or hospitalization is often challenging. Clinicians may be forced to provide these patients with just the bare necessities of a thermal gradient and a clean, usually dry, cage. For example a hospital cage may have a heat source, newspaper substrate, a water bowl, and a hiding place. A stable perch, such as a stick or a plastic rod, may be securely wedged into a temporary cage for an arboreal reptile. For species requiring high humidity a humid retreat may be provided if the cage is large enough and well ventilated.

While not ideal, the average veterinary hospital can temporarily house most reptiles for short periods in large plastic bins with secure, ventilated lids, as long as they are maintained in a climate-controlled area or provided with additional heat. For larger reptiles, stainless steel dog cages or runs may be adapted by adding hiding areas and the appropriate substrate for the reptile in question.

Ultimately for most reptiles, making a diagnosis, initiating treatment, and releasing the patient to the owner as soon as possible is beneficial. This reduces stress by allowing a rapid return to their permanent cage. Husbandry issues should have been reviewed and environmental corrections instituted by the owner while the reptile is hospitalized. Some animals must be hospitalized for longer periods of time requiring daily maintenance, such as cage cleaning and soaking or spraying a patient. Chapter 46 includes a more detailed discussion on hospitalization.

The staff may need additional training to care for hospitalized reptiles. A review of handling techniques to prevent injury to staff, clients, and reptiles is important (Fig. 16.5). Many reptiles may be easily injured if dropped, and staff may be bitten or scratched if they handle reptiles carelessly. In addition, cage security is critical. Snakes and lizards are especially good at escaping, and this is unacceptable in a veterinary hospital. In addition to a client's outrage and surprise of being informed

FIG 16.5 Handling reptiles requires additional training in order to avoid injury to the staff or patient. Handling venomous reptiles safely may require sedation or additional equipment. This eastern diamondback rattlesnake (*Crotalus adamanteus*) has been sedated in order to administer medication via a stomach tube.

FIG 16.6 Reptile housing rack system (freedombreeder.com). These mobile units have lightweight, easily cleaned, and heated drawers that can house many reptiles in a relatively small space. A separate rack may be used for quarantine purposes and ideally should be in a separate room.

about the absence of the reptile left in the hospital's care, there are risks that large snakes or lizards may ingest an endothermic patient or frighten clients at the time of reappearance. It is the clinician's responsibility to take every precaution needed to secure reptile patients in proper cages.

Clinics that hospitalize many reptiles should invest in a rack-style system, where small to medium reptiles may be housed in plastic drawers in a rack (Fig. 16.6). These racks are often on wheels and can be conveniently moved from place to place with some degree of ease, and they may be ordered with heat tape included. Unfortunately, this style of cage makes providing a light source difficult, but most reptiles seem to tolerate this for short periods of time. Recently drawer systems (lizard racks, pmherps.com) have been designed with deeper tubs and screen tops to allow lighting for reptiles that require it in a similar space-efficient design (Fig. 16.7). Another company, Freedom Breeder, produces excellent racks for housing snakes (https://www.Freedombreeder.com, Turlock, California).

Ideally one should have separate rooms or at least separate racks for long-term healthy reptiles and those that have been recently captured or been in another collection. This allows a limited hospital quarantine, which is extremely important for reptiles.

An introduction to quarantine, as well as cleaning and disinfection, is found later in this chapter. See Chapters 18 and 19 for a more thorough discussion.

Remember that wild reptiles often show no outward signs of infection or parasitism at the time of capture. In some cases, reptiles may not show signs of a viral disease contracted for up to 6 months.[3,4] Therefore precautions must be taken when handling reptiles of unknown origin. With large numbers of hospitalized reptiles, wearing gloves to handle or examine new reptiles may be beneficial. Temporary identification of hospitalized reptiles with tape or other marking methods is also important and discussed in more detail in Chapter 46.

The handling and hospitalization of venomous reptiles requires strictly followed procedures and protocols; these are discussed in more detail in Chapter 22. This author requires that all venomous reptiles be dropped off in clearly marked, locked boxes with the key handed to the doctor in charge of the case. The reptile is also to be bagged inside of the box. At the time of treatment, the box is unlocked and opened with a pair of snake tongs. The bag is then removed with tongs and placed in an anesthesia chamber. Upon loss of the righting response, the venomous reptile is removed from the bag, again using tongs to lift the bag and slide the venomous reptile out and back into the anesthesia chamber, where it may be further anesthetized or removed for treatment. This discourages handling accidents. Once samples are taken and treatment is administered, the venomous reptile is placed back in the bag, which is knotted, and then placed back in the box, which is then locked. The animal remains in the box until it is discharged at the end of the day. Admittedly, this protocol is extremely weighted toward providing safety for the veterinarian and staff and not on comforts for the venomous reptile while it is hospitalized. But unless the clinician is an experienced venomous snake handler, this protocol is advisable. There is no safe way to house venomous reptiles in the average veterinary hospital, due to the need for additional security measures such as locking cages with detachable shift boxes and preferably a separate locked room. Additionally a highly trained staff, a strict venomous reptile protocol, and warning labels and signs are imperative. See Chapter 22 for more detailed information on working with venomous reptiles.

Temperature

A useable thermal gradient should be provided to every captive reptile. In addition, daily temperature fluctuations and seasonal temperature fluctuations should be provided. Various lamps, heating pads, and heat tapes usually provide a useable thermal gradient for most terrestrial reptiles (Fig. 16.8). These same devices, however, do not provide a useable thermal gradient for aquatic or arboreal reptiles. For aquatic reptiles, a submersible water heater may be necessary, and for arboreal reptiles, a radiant heat source is often necessary to create a hot spot somewhere among the branches in which they reside. There are now radiant heat panels created specifically to provide broad areas of heat to arboreal reptiles (Pro-Heat, Pro-products.com) (Fig. 16.9). Basking areas are considered important for most reptiles, which includes many

VetBooks.ir

FIG 16.7 Lizard/chelonian rack systems (pmherps.com) provide a compact rack concept for efficiently housing reptiles that require overhead lighting and radiant heat sources. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

FIG 16.8 A wide variety of heat sources, vaporizers, temperature and humidity gauges, thermostats, and other tools are now available to help maintain reptiles in their preferred optimum temperature range (POTR) and preferred optimum humidity range (POHR). Thermostats are important because heat lamps/heat sources commonly cause reptile burns. Keepers tend to underestimate the amount of heat they produce and thus fail to provide a proper heat gradient.

aquatic reptiles. The preferred temperature ranges of many commonly kept reptiles are listed in Table 16.1. A simple rule of thumb is to maintain a hot spot in the cage that is near the upper end of the POTR. Then reptiles can achieve the highest temperatures that they would normally seek in nature but also can choose lower temperatures, including those that may be outside the POTR. McKeown[5] defines a primary heat source as that which is used to maintain an appropriate background

FIG 16.9 Radiant heat panel (pro-products.com/pro-heat/). These devices generate a broad area of gentle heat from above without any light. This is beneficial for arboreal reptiles.

temperature in the enclosure. For most, this is the central heating unit in their house. Secondary heat sources are those used to create additional heat in some areas of the enclosure to provide a thermal gradient.[5] If either is insufficient or unusable to the reptile, disease is a likely.

Hot rocks, a source of artificial heat, are commonly used by reptile keepers. These generally provide very focal heat, directed from the ground upward, and generally are not useable except by the smallest reptiles. They often become progressively hotter with age, and larger reptiles frequently burn themselves by coming in contact with focal "hot spots" on the surface, likely trying to reach an optimal temperature. This can be minimized by covering and insulating these heaters, but generally these are not recommended for larger reptiles. Better heat sources include adjustable heating pads placed under the cage and incandescent bulbs placed at various heights above the cage. Ceramic heaters have become more popular because they produce radiant heat with no light emission. However sick reptiles often do not thermoregulate properly, so the background heat must be controlled carefully for these animals. Another group of reptiles at risk are male snakes during breeding season. Male boas and pythons commonly seek out the coolest area of the cage at this time, often staying too cool for extended periods of time resulting in illness. This may be avoided with careful control of the background temperature.

A general guideline for daytime air temperatures to provide for most diurnal reptiles is 80° to 90°F (27°–32°C) with a basking area of 90° to 100°F (32°–38°C). Diurnal desert lizards such as Uromastyx seem to prefer basking areas of 120° to 130°F (49°–54.5°C) for short periods of time. Nocturnal or montane reptiles often do well with daytime air temperatures of 70° to 80°F (21°–27°C) but still seem to benefit by having a warmer area of 90° to 95°F (32°–35°C) present in the enclosure. Field research on the habitat of montane rattlesnakes in southeastern Arizona showed that even though air temperatures in the early morning were barely exceeding 21°C (70°F), the snakes were found basking in areas where the sun had created hot spots of 32° to 35°C (90°–95°F).[6] Nighttime air temperatures for most reptiles should not drop below a temperature of 21°C (70°F) during the active season, although temperate zone reptiles can usually tolerate temperatures lower than this for short periods with access to a heat source. Experience shows that maintaining most reptiles for prolonged periods at temperatures ranging from 60° to 70°F (15°–21°C) is potentially harmful. This temperature range appears to be too cold to allow normal digestion or immune system response and too warm to allow for normal brumation (hibernation). Without

VetBooks.ir

any supplemental heat or the absence of a daytime temperature that rises sharply into the 90° to 95°F (32°–35°C) range, many reptiles kept consistently in this 60° to 70°F temperature range often become ill (Fig. 16.10). In fact, this has been such a common problem in practice that the author has referred to this temperature range as "reptile thermal limbo" for clients so that they can easily remember to keep their reptiles out of this temperature range for any length of time. It commonly occurs when reptiles are housed in air-conditioned rooms at ground level or during the winter when insufficient heat sources are provided.

Brumation (hibernation) temperatures for temperate zone reptiles generally may be maintained between 35° to 59°F (3.8°–15°C) for a minimum of 10 weeks. Montane reptiles or those from temperate climates may need brumation (hibernation) temperatures at the lower end of this range and possibly for a longer period of time. Of course, no feeding should occur at this time (Fig. 16.11). Subtropical reptiles can be brumated (hibernated) at similar temperatures but should have access to some heat source at all times. Tropical reptiles should not be brumated (hibernated) but instead may be exposed to nighttime lows that are lower than those to which they are exposed in the summer, and daytime highs remain similar to those that are provided during the summer. Typically, nighttime low temperatures for tropical reptiles should not drop below 21°C (70°F). Python and boa breeders often attempt to cycle their snakes by dropping the temperatures below this level at night during the late fall and winter to induce breeding behavior and ovulation. This is not necessary for most snakes and is also potentially dangerous, often resulting in respiratory infections. The photoperiod can safely be shortened during this time as discussed below.

Modern thermostats are capable of providing both temperature gradients and daily temperature fluctuations (i.e., diurnal and nocturnal temperatures).

Photoperiod and Light Quality (Lighting)

The amount of light received per day, or photoperiod, is important to reptiles. In general, day length and temperature should be decreased during the winter months for subtropical and temperate species. Failure to do so often results in reproductive failure or disease. Inappropriate photoperiod and temperature fluctuations have been correlated with repeated reproductive failure. Poor reproductive success has been related to abnormal vitellogenesis, chronic resorption of yolk, ovarian cysts, and ultimately ovarian granulomas or tumors (Fig. 16.12).

Obesity is another possible sequela to abnormal photoperiod. Reptiles that are normally inactive and anorectic during the winter months may continue eating when exposed to a consistent photoperiod, even though their metabolism is lower due to a reduction in ambient temperature. In most cases with temperate zone or subtropical zone reptiles, the artificial photoperiod may mimic that which is naturally occurring outside. Modifications may be made depending on the latitude of the reptile's origin and the latitude where the reptile is being housed. For example, seasonal changes can be manipulated appropriately by increasing the day length slightly for tropical reptiles housed in a subtropical area or more so if housed in a temperate zone area. Alternatively, decreasing the day length would be appropriate if housing a northern temperate zone reptile in a subtropical area.

Electric timers are inexpensive and widely available, and lights may be set to mimic the naturally occurring photoperiod or to adjust it in either direction. Not surprisingly, reptiles housed with access to the natural light cycles (i.e., a window or skylight) respond more strongly to the natural light than to an artificial light source. This must be taken into consideration when cycling reptiles for breeding purposes. A general

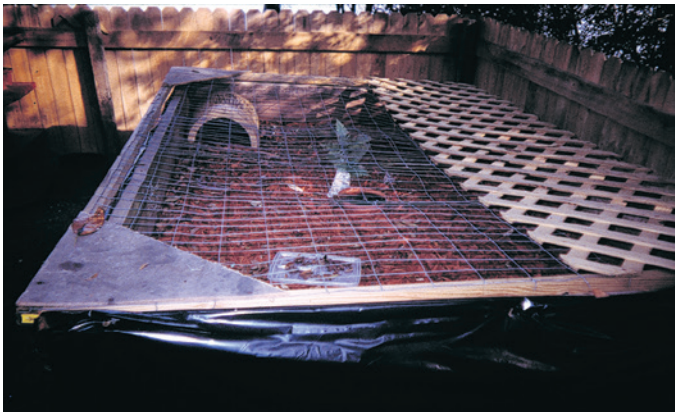

FIG 16.11 This outside turtle enclosure has thick mulch and a plastic barrier as insulation against cold for turtles overwintering. They may not eat for up to 6 months during brumation (hibernation). Such outside enclosures are excellent for housing small and medium-sized chelonians throughout the year but need to be kept covered with wire or hardware cloth to protect the inhabitants against predation.

FIG 16.10 Box turtle (*Terrapene* sp.) with edema secondary to a cardiac abscess. This turtle was maintained at room temperature with little or no access to a usable secondary heat source. Constant exposure to these "middle temperatures" often results in various manifestations of disease.

FIG 16.12 Large ovarian cyst (approximately 500 grams) and necrotic eggs surgically removed from an argus monitor (*Varanus panoptes*). These cysts often progress to neoplasms and are not uncommon in intact, long-term captive reptiles that are not cycled and bred regularly.

VetBooks.ir

guideline relating to photoperiod is to provide about 14 hours of light in the summer and 12 hours of light in the winter. Another author suggested that temperate zone reptiles be exposed to 15 hours of light during the summer, 12 hours during spring and fall, and 9 hours during the winter, with tropical reptiles exposed to 13 hours of light during the summer and 11 hours of light during the winter.[7]

The quality of light is also important, and as with temperature and humidity, a gradient should be created in the enclosure. Some ultraviolet (UVB) light is necessary for most reptiles to manufacture vitamin D_3. Vitamin D_3 is necessary for the absorption of calcium from the intestinal tract. A deficiency of UVB light (290–320 nm) often results in nutritional secondary hyperparathyroidism (NSHP). UVA light, or light in the 320 to 400 nm range, does not assist in converting vitamin D into an active molecule but may have some beneficial effects in terms of behavior (i.e., improved visualization of prey or mates). Infared light is also critical for many reptiles because it provides much of the heat they require as ectotherms. Most curators and experienced herpetoculturists believe that natural lighting is the best light and may even be mandatory for success with some captive reptiles. One study with Hermann's tortoises showed a significant difference in measurable Vitamin D_3 in tortoises exposed to natural light versus two kinds of artificial UV lights, with those in the natural light having higher levels.[8] However, keep in mind that some species have adapted to lower light levels and shorter photoperiods, and for these species, too much or an increased intensity of light may be detrimental. For example, forest-dwelling tortoises, such as red- or yellow-footed tortoises (*Chelonoidis*), box turtles (*Terrapene* sp.), Blanding's turtles (*Emys blandingii*), and wood turtles (*Glyptemys insculpta*), may become anorectic if exposed to high levels of artificial UV light or natural lighting that exceeds what they have adapted to.[9]

As mentioned above, both natural and artificial lighting may be beneficial for these animals. However, two kinds of artificial lights are commonly used. Incandescent bulbs, which are generally bulblike, provide both heat and light. Fluorescent bulbs, which can be tubular or compact, provide a wider spectrum of light but little heat. Popular and widely available fluorescent bulbs that produce light in the proper spectrum are ZooMed's Reptisun lights (http://www.zoomed.com). Diurnal lizards, diurnal snakes, small crocodilians, and basking species of turtles and tortoises do well with the Reptisun 5.0 or 7.0, and amphibians and many temperate zone snakes do well with the Reptisun 2.0. For many diurnal desert reptiles, the Reptisun 10.0 is recommended. Providing both kinds of light (incandescent and fluorescent) for most reptiles is advisable, unless a combination light is used. Mercury halide lamps that are capable of providing both high-intensity light and heat are becoming more popular (e.g., Zoomed Powersun and UV Heat bulbs). There are a wide variety of excellent lights available, and the author does not wish to imply that these are the only useful lights. However, at this time these bulbs are readily available and have been safely utilized. Clinicians also need to be aware that the UV light production from these lights is often very low compared to natural sunlight and decreases over time even though the light still appears to be working. Therefore it is recommended that most lights be replaced at least every six months, whereas Mercury halide lamps may be replaced every 12 months.

Additionally, LED lights (both UVB and non-UVB) are becoming more readily available and popular. More research is needed to determine their effectiveness.

See Chapter 17 on lighting for more types of lights and details on the provision of light, light gradients, light combinations, and measurement of light intensity.

Generally speaking, however, no substitute exists for natural light for many reptiles. It is perhaps one of the most powerful health resources/treatments known in captive reptile management and is a strong argument for maintaining reptiles in outdoor enclosures when weather conditions permit. It is also a potent appetite stimulant for many reptiles and may have many other unknown beneficial effects. However, one must be extremely cautious when utilizing natural lighting. Reptiles should not be placed outside in direct sunlight in glass-sided enclosures. The greenhouse effect has resulted in the deaths of many captive reptiles, and this can occur in minutes! Reptile keepers should consider the construction of outdoor enclosures specifically designed for the reptiles in question. See the discussion on outdoor enclosures in this chapter.

Humidity and Ventilation

Providing a high humidity retreat or a humidity gradient may be difficult. One must remember that the higher humidity areas in the cage must not be created at the expense of total cage ventilation because humidity and ventilation are inversely related to each other. If ventilation is severely restricted (and it often is in many molded fiberglass cages or plastic rack systems), stagnant air often contributes to the growth of bacterial or fungal pathogens. Instead, high humidity zones within otherwise well-ventilated cages should be created. This may be done in confined areas, such as plastic boxes of varying sizes, or with moisture-containing substrates in different parts of the cage. The most commonly used method of providing a high humidity retreat for some reptiles is the use of the humidity box, in which a plastic box is filled with a moisture-containing substrate, such as sphagnum moss or peat moss (Fig. 16.13). A small hole is created in the cover (top) of such a box for snakes, or in the side for lizards and tortoises, to allow the reptile to enter or exit the structure. These boxes often show visible condensation within and provide the moisture needed to aid in ecdysis, or egg deposition, and to prevent chronic dehydration via cutaneous and respiratory water loss. Humidity boxes are now produced commercially in more aesthetically pleasing, naturalistic appearing shapes, such as artificial rocks or logs.

Many reptile keepers use vaporizers, humidifiers, automatic misters, or small fountains to humidify the enclosure directly or indirectly. This is acceptable because it does not interfere with ventilation. Chameleon keepers have been known to place intravenous (IV) drip–type systems or ice above a screen lid to allow water to drip into the environment. A number of keepers of both lizards and snakes simply maintain moistened sphagnum moss at the bottom of the cage. For some strictly arboreal reptiles, the bottom of the cage may be filled with several inches of water. In a well-ventilated cage, this maintains a high and constant humidity. Chameleons and arboreal snakes, such as emerald tree boas

FIG 16.13 A humidity box is a plastic box containing substrate that holds some moisture. The most commonly used substrate for this purpose is sphagnum moss. More naturalistic appearing humidity boxes are now produced commercially.

VetBooks.ir

(*Corallus caninus*) and green tree pythons (*Morelia viridis*) are now successfully maintained in tall, well-ventilated cages with mister systems maintaining the humidity. (Fig. 16.14). These cages and others may also gain increased ventilation via the use of axial fans, where necessary.

Substrate

Perhaps the next most important physical factor in determining the success or failure of a captive reptile is the substrate used. Both artificial and natural substrates may be used to achieve a level of humidity, physical support, and psychological security. Shredded newspaper, butcher's paper, and artificial turf have been popular with many herpetoculturists because of their availability and low price. However, although these materials are satisfactory and readily cleanable substrates for many reptiles, they are not aesthetically pleasing and do not appear to provide microenvironments similar to those found in nature. Certain kinds of wood chips, such as cypress or coconut chips, appear to provide a substrate with all of the features previously listed and an aesthetic appearance. Large, smooth stones have been successfully used as a substrate for many lizards and snakes; small stones and gravel, however, may be ingested. One of the more recent substrates that appears to have worked well is shredded coconut shells, called ReptiChips, and indeed they may prove to be superior to many other substrates for reasons discussed below. Many species of snakes, lizards, and tortoises can be maintained on a variety of substrates; however, refer to herpetocultural sources for specific recommendations on the species in question. Substrates that are too basic, too acidic, too dry, too moist, or dirty may contribute to dermatologic or respiratory conditions in captive reptiles. Substrates that contain irritating aromatic compounds, such as cedar, eucalyptus, or pine shavings, may also result in skin or respiratory irritation and possible secondary infection. Natural substrates that absorb moisture, such as wood chips of any kind, are likely to harbor heavy growth of potentially pathogenic bacteria or fungi if placed in a poorly ventilated cage. Thus wood chip substrates should not be used in plastic shoe box or drawer style cages, unless good (top)ventilation is present. With regard to ventilation, it appears that top ventilation is the most critical factor in determining the usage of natural substrates. Remember that warm (often moist) air rises and is replaced by cooler (often drier) air. Without excellent top ventilation, and often regardless of excellent side ventilation, moisture is often trapped in an enclosure to the degree that natural substrates cannot be used. This ventilation issue may be improved if fans are utilized.

FIG 16.14 A small plastic mesh cage is ideal for many species of arboreal reptiles, because they are tall, light, and well ventilated. However, with excellent ventilation comes the challenge of maintaining proper humidity. Note the vaporizer as well as the UV lights on top of the cage. Chameleons, emerald tree boas (*Corallus caninus*), and green tree pythons (*Morelia viridis*), among others, are often housed in this manner, although mesh cages are usually replaced by tall glass cages for arboreal snakes.

Many tortoises do well on a substrate of rabbit pellets, but occasionally loose footing may lead to splay leg in young tortoises. Also, tortoises such as Burmese mountain tortoises (*Manouria emys*) that need higher moisture substrates do not do well on this substrate. Semimoist cypress mulch or coconut chips work better for these species. It is often placed over cork bark to provide more solid footing and reduce the likelihood of splay leg. In addition, rabbit pellets may also contribute to respiratory disease if the pellets get wet and moldy. Most larger snakes commonly kept as pets do well on shredded newspaper, indoor/outdoor carpet, and wood chips, such as cypress or aspen. Smaller species of snakes generally do not do well on newspaper but may thrive when cypress or coconut mulch is used. Lizards often do well on dry, loose sand or indoor/outdoor carpet. Crushed pecan or walnut shells have been associated with many intestinal impactions in smaller lizards and are best avoided unless they are extremely finely ground. However, crushed pecan or walnut shells have been used successfully with many snakes and larger lizards. Keep in mind however that these substrates often increase exposure to fungal organisms such as *Aspergillis* sp. so if used must be kept clean. Sand may also be ingested and has been associated with impactions in smaller lizards, so it must be used with care. In addition, sand in poorly ventilated cages (i.e., those that lack top ventilation) may retain a large amount of water, which may lead to contact dermatitis. However, loose, dry sands (commercially available children's play sand, calcium-based sands, or Reptisand) have been successfully used as substrates in well-ventilated cages. Commercially available fine color-dyed sand is not recommended because it may become embedded in and color-stain the reptile's skin. This fine "talcum powder style" sand is not a natural type substrate. One must often provide some sand-free areas, such as large flat rocks, on which to feed.

Water itself may be considered a specialized substrate for some reptiles. However, tap water is often a poor substitute for the naturally occurring acidic bacteria-laden water from which many of our freshwater reptiles are derived. Tap water is also not usable for brackish or saltwater reptiles. Aquatic reptiles placed in cages where water is available frequently spend a great deal of time in that medium. However, these reptiles often have skin lesions develop under these circumstances. The neutral tap water is often contaminated with reptile feces, resulting in a suitable medium for opportunistic pathogens such as bacteria and fungi. This water is often devoid of the bacterial milieu and not in the appropriate temperature range found in the reptile's natural habitat, resulting in superficial infections and ultimately in sepsis. The warm acidic bacteria-laden water found in many natural situations is believed to form a bioactive substrate, which interferes with the growth of pathogens on

VetBooks.ir

many of the animals that have evolved to live there (see the discussion on bioactive substrates in this chapter). Attempting to recreate this bioactive milieu by acidifying the water and providing organic material to maintain acid-loving bacteria may be indicated. Some authors have used dilute mixtures of tea; others have added peat to filters, and some have just used swamp mud and live plants.[5,7,8] Commercially available acidifying buffers for tropical fish have also been used successfully for aquatic reptiles. Interestingly, an alternative that seems to help fresh water reptiles avoid skin lesions is the addition of some salt to the water. The addition of 1 cup (approximately 300 grams) of table salt per 20 gallons (approximately 80 L) of water often provides a brackish water solution that reduces the likelihood of infection but does not result in dehydration. This is particularly true if the water temperature is maintained at a warmer temperature than is generally recommended, such as a minimum of 82° to 85°F (28°–29.5°C) with drying/basking areas available in which the reptile can raise its body temperature to more than 90°F (32°C) during the daytime. In some cases, merely a diurnal rise in the water temperature is suitable, and this can be achieved with incandescent lights placed over the water during the daytime. Indeed, this mimics what occurs in nature as the sun warms up the top 4 inches (10 cm) of water in smaller bodies of water during the daytime over much of the earth's surface. Full-strength seawater may be created by purchasing one of the commercially available seawater mixes (e.g., Instant Ocean, http://www.aquariumsystems.com) and following the directions. However, this is only necessary for marine reptiles.

Keep in mind that some reptiles do not follow these general guidelines, and the reader is referred to one of the many references listed for specific information on the species in question.[10–30]

Measuring and Monitoring

In the words of Lord Kelvin, creator of the Kelvin temperature scale, "You don't know what you are talking about unless you count it." This is especially true when creating and maintaining captive environments for reptiles. Not only must one research the physical parameters of the wild habitat of said reptiles, but one must also strive to recreate them as accurately as possible. Aiding in this effort are some of the newer, very accurate digital meters that can measure temperature, humidity, and light levels in different areas of the enclosure and monitor them over time. Remember that the goal is to provide gradients of temperature, humidity, and light and allow the reptile to choose the level required for the particular function required. Data Loggers (Omega model OM-62, Omega.com, works well but there are multiple manufacturers) are typically small devices that can be placed in any area of a cage and record temperature, humidity, or pressure ranges over time (Fig. 16.15). External digital thermostats (Spyderrobotics.com or Vivariumelectronics.com) can also be used with small sensors placed in multiple areas of the cage (Fig. 16.16A and 16.16B). These monitors are also recording humidity. UV light meters (Solartech Inc., Solarmeter.com) are now widely available as well (Fig. 16.17). A detailed description of the available thermostats and their differences is available in Barten and Fleming.[1]

Cage Size and Construction

In general, the larger the enclosure for any captive reptile, the better the reptile fares, with the caveats that a larger cage must be successfully heated to avoid cold areas, humidity must be maintained in the proper range, and that the captive reptile can locate (and in some cases, capture) food and water sources. Larger cages are associated with fewer self-inflicted injuries and better body condition. Captive reproduction is also more likely to occur when larger cages or enclosures are used. One exception is hatchling or juvenile reptiles, which often do not thrive when provided with large enclosures. This is thought to be related to

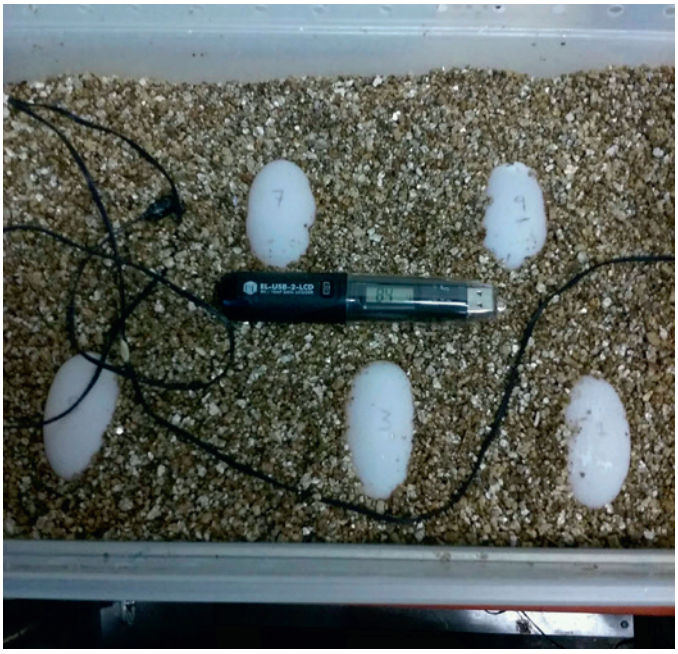

FIG 16.15 A data logger, used here to monitor eggs in an incubator. These small devices can be placed in various locations in reptile enclosures and can measure and record temperature and humidity changes over time.

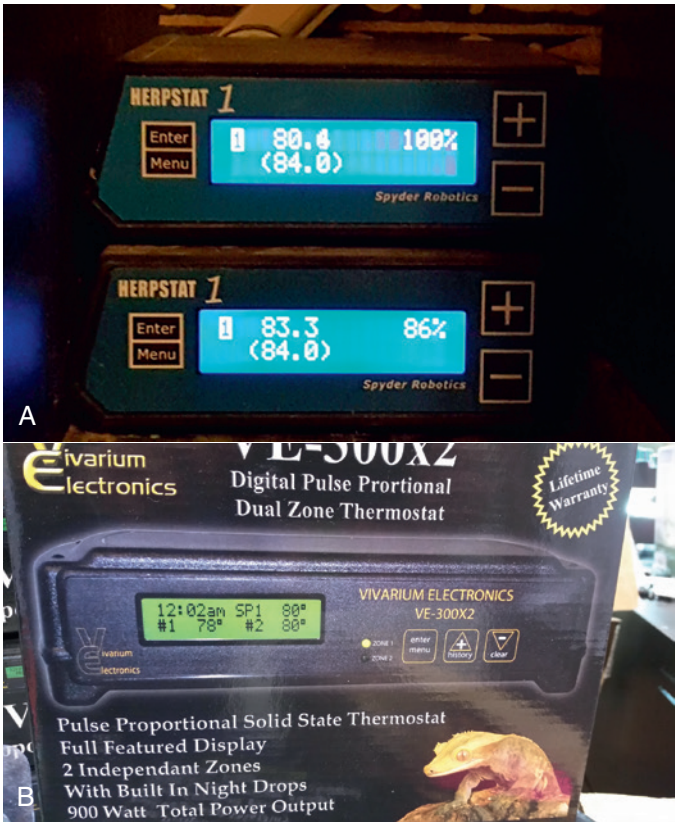

FIG 16.16 (A) A digital thermostat mounted to the outside of the enclosure. These devices take the guesswork out of setting up the thermal and humidity gradients required for different reptiles. (B) Another thermostat commonly used by herpetoculturists that allows for daily, gradual increases and decreases of temperature, as well as thermal gradients.

FIG 16.17 Solar meter. These devices may be used to determine the UVB intensity provided to a reptile.

Table 16.2 Successful Maintenance Areas (SMA) and Ideal Maintenance Areas (IMA) for Reptiles Based on Total Body Length (BL)

	SNAKES	LIZARDS	TERRESTRIAL CHELONIANS
BL m (inches)	SMA/ IMA (m^2)	SMA/IMA (m^2)	SMA/IMA (m^2)
0.1 (4)	0.04/0.12	0.12/0.25–0.50	0.4/1
0.2 (8)	0.08/0.24	0.24/0.50–1.0	0.8/2
0.3 (12)	0.12/0.36	0.36/0.75–1.5	1.2/3
0.4 (16)	0.16/0.48	0.48/1.0–2.0	1.6/4
0.5 (20)	0.20/0.60	0.60/1.25–2.5	2.0/5
0.6 (24)	0.24/0.72	0.72/1.50–3.0	2.4/6
0.7 (28)	0.28/0.84	0.84/1.75–3.5	2.8/7
0.8 (31)	0.32/0.96	0.96/2.00–4.0	3.2/8
0.9 (35)	0.36/1.08	1.08/2.25–4.5	3.6/9
1.0 (39)	0.40/1.20	1.20/2.50–5.0	4.0/10
2.0 (79)	0.80/2.40	2.40/5.00–10.0	8.0/20
3.0 (118)	1.20/3.60	3.60/7.50–15.0

Multiply m × 39.4 to obtain inches.
Multiply m^2 × 35.3 to obtain cubic feet.

an inability to properly thermoregulate and/or find food and water in these larger enclosures early in life.

With regard to the actual amount of recommended space per captive reptile, one is referred to species-specific references in the following chapters in this section of this book. However, formulas for minimum cage sizes for reptiles are presented here.

Many herpetoculturists follow anecdotal cage floor space recommendations put forth by Kaplan (Kaplan M, tank sizes available at http://www.anapsid.org/resources/tanksize.html). These cage size lengths and widths may be determined by using the following formulas: snakes: .75x BL × .33 BL; lizards: 2 to 3x BL × 1 to 1.5 BL, turtles and tortoises 4 to 5x BL × 2 to 3x carapace length, where BL is body length (total length, which equals STL or snout tail length). Cage height recommendations range from 1.5 to 2 × BL. Kaplan stresses that at least 30% to 40% of the cage should be open floor space for the reptile to feed, move about, and defecate. Furthermore, if a naturalistic habitat is used, more space is required to maintain that amount of floor space. For each additional reptile, an additional one-half the amount of floor space is recommended, and even more space is recommended for territorial reptiles. Although these recommendations have been largely successful, it is our goal to enrich the environment, increase more normal activity, and reduce stress, so an analysis of floor space area as determined by the Kaplan formulas was performed.

Assuming that the relationship of area required by a reptile is based on the size of the reptile and that this is a linear positive correlation, one may generate a floor space area required by simply multiplying the BL (body length) of a reptile by a factor that varies with each group of reptile. These factors, as determined by analysis of success by various herpetoculturists, are as follows, where meters squared is represented by (m^2): snakes: .4 m^2/1 m BL; lizards: 1.2 m^2/1 m BL; turtles and tortoises: 4 m^2/1 m BL (in this case, carapace length). These low-end factors, hence referred to as the successful maintenance factor (SMF) for each group, when multiplied by body length (in meters) results in what might be considered a "successful maintenance area" (SMA) (Table 16.2). However, larger areas have been proposed by some herpetoculturists and veterinarians, and at least one peer-reviewed journal publication exists (Table 16.3).[32] They are as follows: snakes: 1.2 m^2/1 m BL; lizards: 2.5 to 5.0 m^2 /1 m BL; turtles and tortoises: 10 m^2 /1 m BL (actually carapace length). These high end factors, hence referred to as the ideal maintenance factor (IMF) for each group, when multiplied by the body length results in what might be termed the "ideal maintenance area" (IMA). Using these factors results in a linear graph of usable areas by the captive reptile (Graphs 16.1, 16.2, and 16.3). Furthermore, any area between the SMA and the IMA will likely be successful for that group of reptiles. Hence, one might refer to areas in this range as the "successful maintenance area range" (SMAR). However, using these factors results in a linear graph of usable areas for reptiles of varying sizes but does not intuitively provide a length, width, or height of the cage. These cage lengths and widths may be approximated by using BL formulas similar to Kaplan's above, which have been calculated to result in an area lying close to or within the SMAR. Using the SMARs for the various groups, the formulas for cage size would be increased over the Kaplan formulas as follows: snakes: 1.25 to 1.5 BL by .5 to .75 BL; lizards: 3 to 10 × BL by 2 to 5 BL; turtles and tortoises: 6 to 12 × carapace length by 3 to 4 × carapace length. Note however that these formulas, like the Kaplan formulas, result in curvilinear (exponential growth) graphs, which may be used to approximate the minimum and maximum areas of a cage within the SMAR. These curvilinear graphs reveal several things. Firstly, that the Kaplan recommendations match fairly well for lizards and turtles, but that snakes require more space. Secondly, that the low-end formulas fail to produce an area that enters the SMAR or even reaches the SMA for medium-sized and small reptiles. Hence, to provide the same usable area for a small reptile, one needs to use a formula of BL toward the top end of the new recommendations. Furthermore, one must remember that the amount of usable area produced by multiplying length times width of the cage is not always

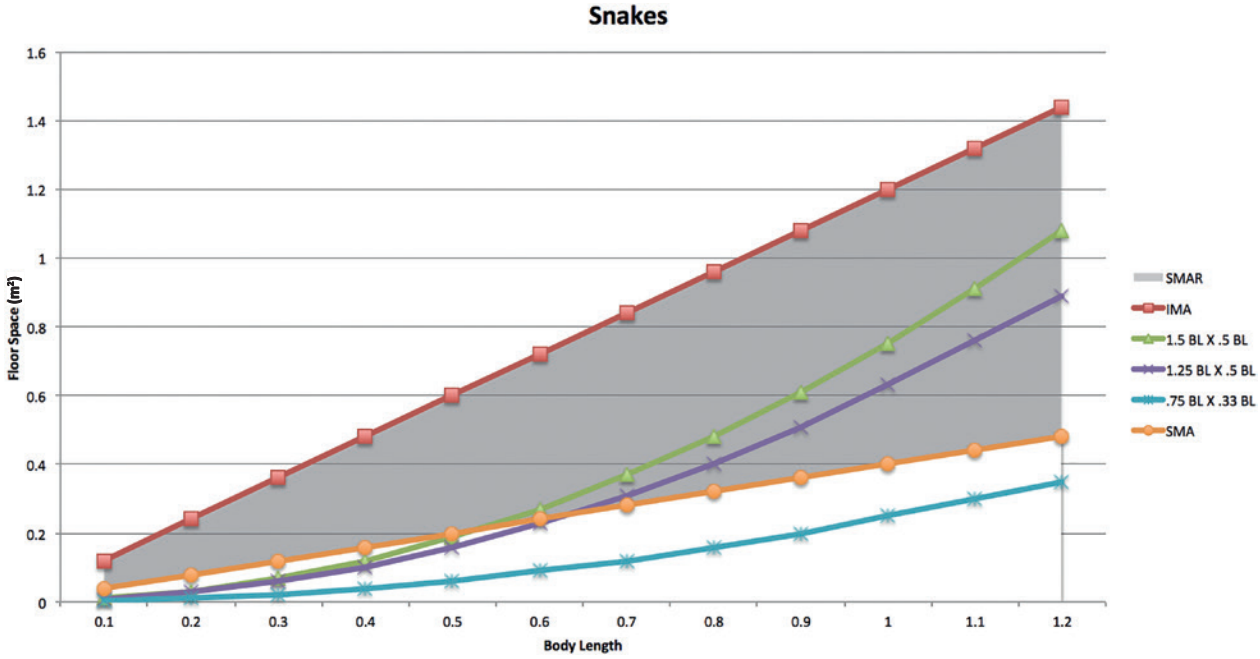
VetBooks.ir

Table 16.3 Recommended Space Requirements for Reptiles[12]

Taxa	Minimum Floor Area or Volume Requirements[a]	Recommended Floor Area or Volume Requirements for Indoor Enclosures[b]
Boas and pythons	0.6 m^2 per m snake	1.2 m^2 per m snake
Kingsnakes, cornsnakes	0.6 m^2 per m snake	1.2 m^2 per m snake
Whipsnakes, racers	1.0 m^2 per m snake	2.0 m^2 per m snake
Arboreal snakes	0.6 m^3 per m snake	1.2 m^3 per m snake
Terrestrial lizards	0.2 m^2 per 0.1 m lizard	0.5 m^2 per 0.1 m lizard
Arboreal lizards	0.2 m^3 per 0.1 m lizard	0.5 m^3 per 0.1 m lizard
Tortoises and semi-aquatic turtles	0.2 m^2 per 0.1 m chelonian	0.5 m^2 per 0.1 m chelonian
Purely aquatic turtles	0.2 m^3 per 0.1 m chelonian	0.5 m^3 per 0.1 m chelonian

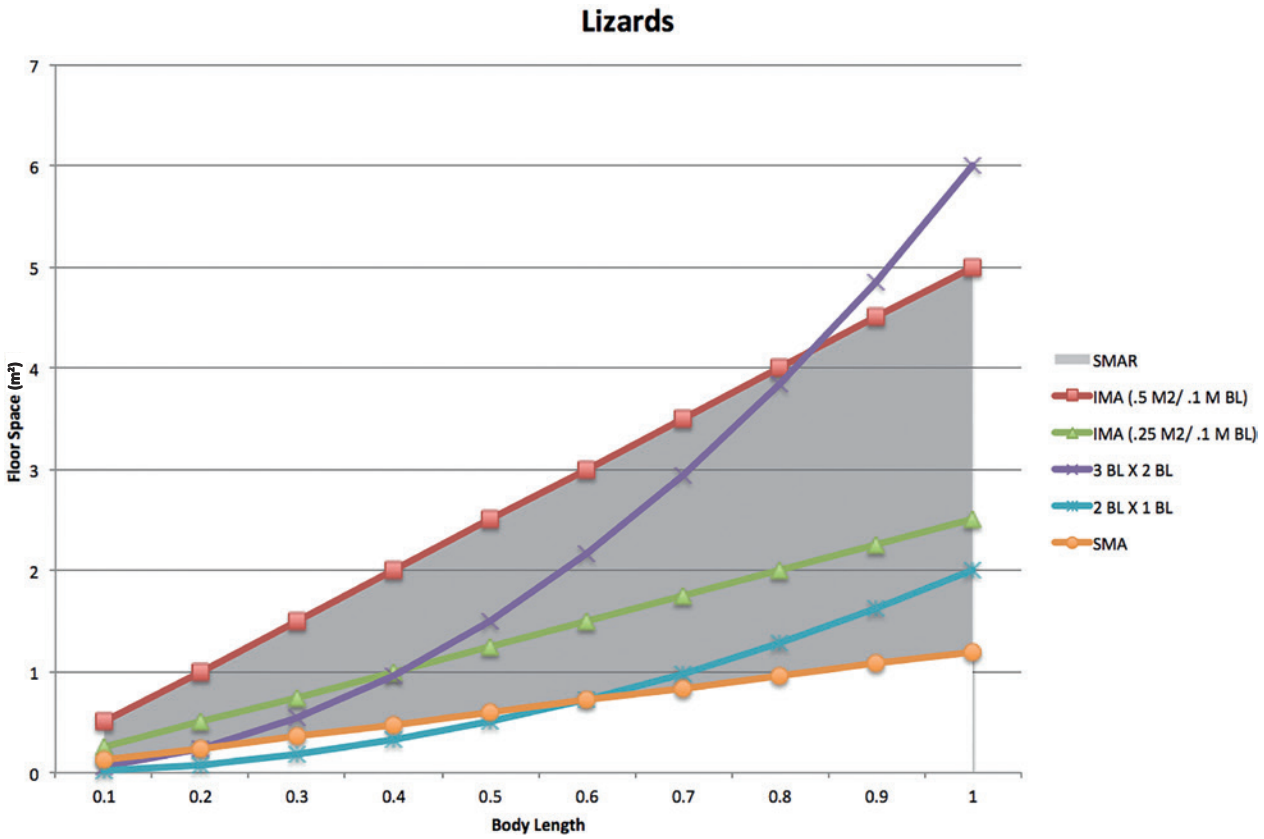
Snake example: A 1.2-m (47″) ball python (*Python regius*) requires at least 0.72 m^2 (7.7 $feet^2$), which could be provided by an enclosure measuring 1.5 m (59″) long × 0.48 m (19″) wide. However, the recommended area is 1.44 m^2 (15.5 $feet^2$), which could be provided by an enclosure measuring 2 m (79″) long × 0.72 m (28″) wide.

Lizard example: A 15-cm (6″) veiled chameleon *(Chamaeleo calyptratus)* requires at least 0.3 m^3 (10.6 $feet^3$), which could be provided by an enclosure measuring 0.55 m (22″) square × 1 m (39″) high. However, the recommended space is 0.75 m^3 (26.5 $feet^3$), which could be provided by an enclosure measuring 0.75 m (30″) square × 1.34 m (53″) high.



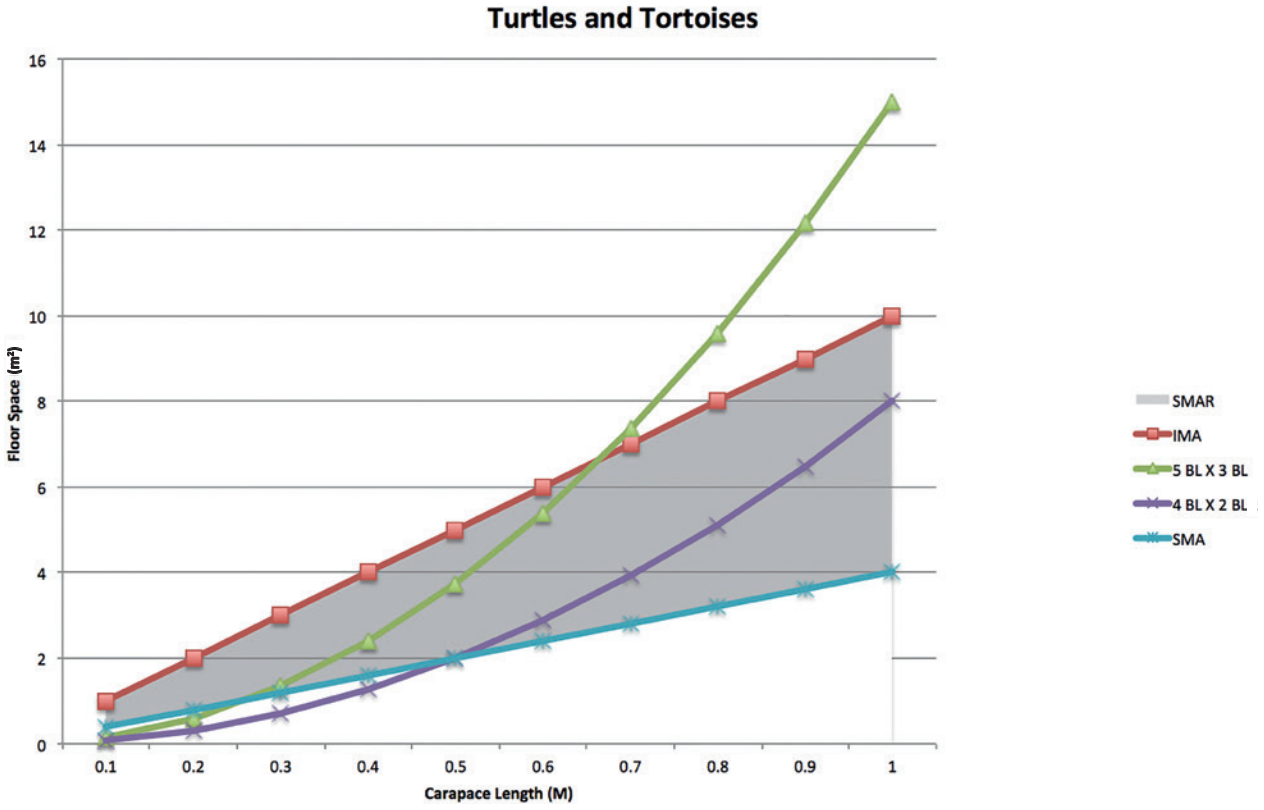
Chelonian example: A 30-cm (12″) Greek tortoise *(Testudo graeca)* requires at least 0.6 m^2 (6.5 $feet^2$), which could be provided by an enclosure measuring 1.5 m (59″) long × 0.4 m (16″) wide. However, the recommended area is 1.5 m^2 (16.1 $feet^2$), which could be provided by an enclosure measuring 2 m (79″) long × 0.75 m (30″) wide.

Quoted animal lengths are total length including tail.



Increasing occupancy does not necessitate multiplying these space requirements by the number of animals as space can be shared; however, increasing enclosure size and resources is important if multiple animals are maintained in the same enclosure.

[a]These minimum space requirements are geared towards wholesalers and retailers.



[b]These recommended space requirements are geared towards private pet ownership; however, in general, the largest enclosure possible should be provided, and larger outdoor enclosures are preferred.

Graph 16.1 Floor space area graph (in meters^2 [m^2]) of successful maintenance area (SMA) vs. ideal maintenance area (IMA) compared to common formulas for cage size in snakes. SMAR = successful maintenance area range. BL = body length = STL (snout total length) in meters.

Graph 16.2 Floor space area graph (in meters^2 [m^2]) of successful maintenance area (SMA) vs. ideal maintenance area (IMA) compared to common formulas for cage size in lizards. SMAR = successful maintenance area range. BL = body length = STL (snout total length) in meters.

Graph 16.3 Floor space area graph (in meters^2 [m^2]) of successful maintenance area (SMA) vs. ideal maintenance area (IMA) compared to common formulas for cage size in tortoises. SMAR = successful maintenance area range. BL = carapace length in meters.

intuitive. For example, if one increases the length of a cage by 10% and decreases the width by 10%, one would think that the area is the same. This is not the case. For example, a tortoise pen that is 10 times the carapace length by 4 times the carapace length of a .1 m tortoise provides a floor space of .4 m^2. A pen that is 9 times the carapace length by 5 times the carapace length is .45 m^2, 8 × 6 provides .48 m^2, and 7 × 7 (a square) provides the maximum floor space of .49 m^2 for a tortoise with a carapace length of .1 m.

Indeed, it is hard to produce a formula for minimum cage size when comparing primarily fossorial skinks or earth snakes to active widely ranging monitor lizards or whip snakes respectively. Although our ultimate goal is to provide for the maximum comfort and welfare of the animals in question, we must be wary of recommending minimum cage sizes that governmental agencies will use to prohibit the average person from maintaining reptiles. Furthermore, the quality of a captive environment is based on more than just the cage size. It includes the environmental enrichment within the enclosure. The author does not mean to malign the Kaplan recommendations. They are an excellent starting point, and they actually align well with the successful maintenance areas. Finally, even though the snake recommendations are slightly lower than the SMA graph for snakes (see Graph 16.1), an interesting observation about juvenile snakes is that they often become anorectic when placed in cages too large. This suggests that the Kaplan recommendations for snakes may actually work very well for small snakes, even though they are mathematically below the newly recommended cage sizes.

As might be expected, some of the recommendations for aquatic chelonians and arboreal snakes are volumetric in nature, with recommendations for aquatic chelonians at 0.75 m^3/0.1 M and for arboreal snakes at 1.6 m^3/1 M of body length. Divers adds the same caveat as above, that active individuals may require more space, while less active reptiles may require less.[32] Be aware that many municipalities and other governmental entities have regulations dictating the minimum cage size for captive reptiles, depending on the length of the reptile and the number to be housed together. The cage sizes recommended above, even successful maintenance numbers for area (SMAs), exceed those minimum recommendations (see Graphs 16.1, 16.2, and 16.3). Hence, a clinician may simply use an SMF to approximate a cage size. For reference, a 5-gallon aquarium has a floor space of .08 M^2, a 10-gallon aquarium has a floor space of .12 m^2, a 20 gallon aquarium has a floor space of .23 M^2, a 40-gallon aquarium has a floor space of .41 m^2, a 75-gallon aquarium has a floor space of .56 m^2, a 125-gallon aquarium has a floor space of .83 m^2, and a 180-gallon aquarium has 1.11 m^2 of floor space. (Note that gallons here and elsewhere in this chapter are US gallons.)

The material from which cages are constructed is also important. Cages should be made of smooth, nonabrasive, and nonabsorbent materials. Examples of such materials are glass, plastic, plexiglass, and stainless steel. One of the most ideal recent materials to be utilized is HDP (high-density polyethylene). This material is extremely smooth, strong, light, and nonporous. All of these materials are less likely to result in rostral abrasions as are rougher materials, and they are easily cleaned and disinfected. Bare wood has notoriously been a problem material used in the construction of large reptile cages. It is abrasive, difficult to clean, and nearly impossible to disinfect. Additionally, eliminating mites from wooden cages is difficult and often requires that the cage be destroyed or at minimum repainted. Melamine-coated, wooden cages do provide a smooth, nonabrasive, cleanable, and disinfectable surface; however, mites may still be difficult to eliminate from such cages.

The most common cage shape used in herpetoculture is the rectangle. These cages are structurally sound and readily available, and they minimize the angles into which a reptile might collide. Unusual shapes such as pentagons, hexagons, octagons, and others often provide less usable space and are associated with more injuries than simple rectangular cages. As mentioned above, a square cage would actually provide the most floor space, but rectangular cages have been far more commonly used and are much easier to produce gradients within. The height of a cage is also an important parameter. For terrestrial reptiles, the "foot space" is more important than the vertical height of the enclosure; however, the top of the cage must not be so low as to allow the reptile to reach it easily and traumatize itself or facilitate an easy escape. For arboreal reptiles, the opposite is true; a cage with increased height provides more usable habitat than a cage with increased foot space. Tall, plastic mesh cages are now available for arboreal reptiles, such as chameleons (e.g., ZooMed Naturalistic Terrarium), and they come in various sizes, including 12 × 12 × 18 in. (30 × 30 × 46 cm = .04 m^3), 18 × 18 × 24 in. (46 × 46 × 61 cm), and 18 × 18 × 36 in. (46 × 46 × 91 cm = .19 m^3) with the latter numbers referring to the height of the cage. Mass-produced aquariums, which are commonly converted to reptile terrariums, use terminology that may be helpful to the herpetoculturist and veterinarian. Aquariums with the maximum floor space are referred to as "long" aquariums, and those of the same volume with a smaller foot space are referred to as "high" aquariums. High aquariums are more suitable for arboreal reptiles because they can use this vertical space.

The use of aquariums for reptile maintenance has been attacked by some well-respected herpetoculturists, stating poor ventilation, poor insulation, and greater exposure. However, the successful use of these structures for years cannot be ignored. With regard to ventilation, they provide nearly perfect top ventilation when utilized with screens instead of the typical light hoods. This is in stark contrast to some of the newer molded plexiglass cages, which have restricted top ventilation, or many of the rack-style cages, which have extremely poor top ventilation. Excellent top ventilation is absolutely critical (see humidity and ventilation discussed earlier in this chapter) when natural substrates are used, as they tend to retain moisture. These substrates provide numerous benefits, including physical support, and even visual security as the reptiles often burrow in them. The fact that they are constructed of clear material, namely glass, has advantages as well as disadvantages. For reptiles that prefer bright habitats, supplemented by natural lighting, this material has a major advantage over many of the more opaque substances. Poor insulation may be a problem compared with some of the newer materials; however, this may be an advantage when primary heat sources (room temperature controls) are utilized to allow the development of a heat cycle for a large number of cages for treatment or hibernation purposes. For reptiles that prefer a high level of visual security and require excellent insulation for narrowly controlled temperature gradients, aquariums may not be the best option. Additionally glass is heavy compared to plastic enclosures, making them more cumbersome and difficult to clean.

On the opposite end of the reptile enclosure maintenance spectrum, compared with the well-decorated terrarium/aquarium, are the popular reptile rack systems or drawer-style enclosures. The newer rack-style cages are constructed of HDP (high-density polyethylene), reasonably ventilated, often wired to provide a thermal gradient, and frequently have molded places to prevent water bowls from tipping over. They are often filled with a satisfactory substrate, such as newspaper or aspen bedding, and by their nature provide good visual security. The individual cages/drawers are light, strong, smooth, and easily cleaned and disinfected. In short, they are very effective at providing the requirements necessary for snakes and many other reptiles. The size of individual cages in such a rack varies from a "shoe box" size, 19 × 8 × 3.5 in (48 × 20 × 9 cm) or approximately .1 m^2 of floor space, to the "boa box" size, which is 51 × 25 × 8 in (130 × 64 × 20 cm) or approximately .8 m^2 of floor space.

VetBooks.ir

Note that the cage size numbers are listed as length by width by height and that there is very little height to these cages. However, the low height issue does not appear to be a problem for the successful maintenance of most species of snakes commonly kept by herpetoculturists at this time. In fact, multiple generations of many species have been maintained and bred in such enclosures. In spite of the success of these rack-style cages, the author is intuitively "dissatisfied" with this style of caging as a permanent, final enclosure for a captive snake. It is not aesthetically pleasing to see a snake housed in an opaque "box." Hence, this explains the encouragement of the more enriched, well-decorated aquarium/terrarium-type enclosure. However, there is no scientific evidence at this time that snakes or other reptiles require more intellectual stimulation than what they receive in these "boxes," and indeed many snakes commonly maintained are semifossorial, or are nocturnal/crepuscular, and thereby may be comfortable and secure in dark, relatively small spaces.

Quarantine

Isolating reptiles from each other during their initial entry into a collection is critical. Often parasitic or infectious diseases have been introduced into a collection because of a lack of proper quarantine. A recommended period of 3 months is advisable for most reptiles. Some experts have suggested that reptiles be quarantined for up to 6 months because of the risk of viruses.[2,3] Isolation should theoretically be accomplished in separate rooms that do not exchange air with each other. However, this is not often practical or possible with hospitalized reptiles. Under these circumstances, prevention of direct contact or fomite spread is often what can be achieved. Animals that will enter a reptile hospital area or bank of cages should be carefully examined first for any evidence of external parasitism. Snake mites and lizard mites may rapidly travel from cage to cage in a rack-style arrangement. Snakes with mites are not housed in the same room as other reptiles. After the newly arrived reptile has been placed in its new enclosure, the bag or box used to transport that reptile should either be disinfected or discarded.

Also, reptiles from different areas of the world should never be housed together because organisms that may be commensals for reptiles from one area may be pathogens for reptiles from other areas. Healthy animals, or long-term hospital patients, should be serviced and treated first, and new arrivals, or quarantined animals, last. In some cases, reptiles of the same species, captured in the same area and shipped at the same time, can be quarantined in a communal cage. However, this should only be attempted if the species in question is not cannibalistic and all of the previous conditions are met. Reptiles housed together may compete with each other for food and basking sites, so care should be exercised when housing communally. See Chapter 19 for a thorough discussion of quarantine procedures.

Cleaning and Disinfection

Disease is often considered an opportunistic event. A potential pathogen is given the "opportunity" to invade an organism, and it enters and reproduces. Microbiologists have turned this possibility into an equation, $D = V \times E \div I$, where D is disease; V is virulence of the invading organism; E is Exposure, or how many potential pathogens are involved; and I is the immunity of the organism invaded. There is generally little that the clinician can do to change the virulence of the invading organism. Immunity however, is increased by providing the correct environment and diet as discussed. Increased immunity, of course, reduces the risk of disease. But it is exposure that we are attempting to control with disinfectants. Heat and certain kinds of UV light (especially in the UVC range) may act as disinfectants, but generally, the word disinfectant refers to a group of chemicals known for their ability to kill pathogenic organisms. There are several groups of disinfectants, including the halogens (bleach and povidone iodine), phenols or coal tar derivatives (such as Lysol, Pine Sol, and Amphyl), and quaternary ammonium compounds (e.g., Roccal and DiQuat). Of these groups, the halogens and quaternary ammonium compounds are generally the most effective and safest for reptile enclosure disinfection. No disinfectant should be used in a soiled cage (i.e., cages should be cleaned with soap and water prior to disinfection). See Chapter 18 for a detailed discussion on disinfectants.

Use of disposable paper towels instead of a single cleaning sponge/cloth is imperative when cleaning from cage to cage. Keep in mind that no disinfectant is 100% effective against all pathogens; therefore one should dispose of towels after use in a single cage. Only clean paper towels are dipped into the chosen disinfectant bucket. In this manner, the disinfectant solution itself does not become contaminated. Hands should also be washed between cages with a suitable antibacterial soap or perhaps some of the disinfectant solution in a separate container from that used to disinfect the cages. A common, inexpensive, and effective disinfectant is household bleach (sodium hypochlorite), which can be diluted to a concentration of one part bleach to 30 parts water (30 mL per liter of water or ½ cup per gallon). Full-strength bleach is not necessary and has been associated with the destruction of respiratory epithelium and death of reptiles when used in their cages. A 5% ammonia solution is effective against coccidia and cryptosporidia, but remember that bleach and ammonia when mixed produce toxic fumes.

Another commonly used and effective disinfectant is Roccal-D. This is a quaternary ammonium compound that has a broad spectrum of activity against common reptile pathogens. McKeown[5] recommends a dilution with water of 1:200 to 1:400 for reptile cages and bowls.[5] Remembering that disinfection cannot occur without first physically removing the organic debris. Cleaning is defined as the removal of organic material from the cage or pen. Thus, the clinician should advise herpetoculturists, zookeepers, and technicians to thoroughly clean a cage first and then disinfect it. Cleaning should occur daily unless a bioactive substrate is being used, in which case, nonpathogenic bacteria breaks down the fecal matter. See the discussion on bioactive substrates. It is also important to remember that most disinfectants work best above 20°C (68°F).

Ideally, hospitals that treat reptiles benefit by having foot pump water faucets and soap dispensers. This helps prevent cross contamination of hands and cages and cage accessories at the sink/faucet level. An important point to remember about cleaning these cage accessories, including water bowls, hide boxes, and artificial plants, is to avoid placing them together in the same water-filled sink. Even when soap and a disinfectant are added, certain infectious agents may not be eliminated and instead spread from dish to dish within the ineffective soapy solution. For example, if one placed a water bowl contaminated with coccidia in a sink filled with bleach water, all other dishes in that sink may be contaminated with coccidia because sodium hypochlorite is an ineffective disinfectant against coccidia. See Chapter 18 for a more detailed discussion on disinfectants and disinfection.

Examinations

Careful examination of reptiles entering a facility where other reptiles are housed is critically important in protecting that collection. (See Chapter 42 for a more detailed discussion on performing a physical examination.) Any signs of illness, including nasal or ocular discharges; excessive sneezing or wheezing; loose, mucous, or bloody stools; neurological signs; or skin lesions should alert the clinician to isolate such an animal immediately. It is not uncommon for large stable collections to have drastic losses after a new "unquarantined" animal was introduced.

VetBooks.ir

A collection of reptiles that does not admit new animals is referred to as a closed collection.

A fecal examination is advisable for all reptiles immediately after acquisition and again 3 months later. Annual or semiannual fecal examinations are advisable after that.

Hematology and blood chemistry may also be helpful in determining the apparent health of a reptile. Often a reptile appears healthy outwardly but has a disorder that is only revealed with a complete blood cell count (CBC) or chemistry (see Chapters 33 and 34). A blood smear evaluation may reveal parasites in wild-caught reptiles (see Chapter 32). Normal blood values for numerous species of reptiles have now been published and are readily accessible (see Chapter 35).[33,34]

Parasite Control

Parasites and commensal organisms are extremely common in captive reptiles. Problems associated with parasites include diarrhea, constipation, obstruction, colitis, perforation of the intestine, peritonitis, bloating, bleeding from the cloaca, anorexia, cachexia, anemia, and death. Commensal organisms are organisms that live in or on a reptile but do not result in any damage. Symbiotic organisms may also be present, and these may actually help reptiles digest their food or possibly compete with potential pathogens. When performing a fecal exam it is often difficult to distinguish pathogens from symbiotic organisms, particularly in herbivorous reptiles. Hence, evaluating fecal exams and determining a treatment protocol must include evaluating the overall health of the reptile in question. A moderate amount of protozoans in an otherwise healthy herbivorous reptile may be normal, whereas any protozoans in an anorectic snake or carnivorous lizard should be viewed as potential pathogens, and the clinician must consider treatment to reduce or eliminate these organisms. In spite of the difficulty determining the pathogenicity of organisms discovered on a fecal exam, all recently captured reptiles or reptiles that are new to a collection should be suspected of parasitism. Repeated fecal examinations should be performed during the first several months in captivity and then regularly thereafter. The eggs of many parasites may not appear immediately in the first fecal examination performed on a recently captured reptile; they often appear on fecal examinations performed 3 to 6 months later. This was observed in numerous species of North American snakes after their capture.[6] The cause of this is not known. Presumably, the parasite infections are present at the time of capture, but either they are not yet reproductive and need time to mature and produce ova or the stress of captivity may suppress the immune response of the captive reptile and allow the parasites to increase in numbers. Thus, fecal examinations performed on reptiles after recent capture or importation are important screens to evaluate for a heavy parasite load but not as definitive tests to rule out parasitism. Fecal analyses should be performed both at the beginning and the end of the quarantine period.

Once parasitism is diagnosed, appropriate parasiticides should be administered at the doses recommended elsewhere in this book (see Chapters 32 and 120). Some authors recommend a routine deworming be performed even in the absence of positive fecal examination results. Furthermore, those parasites with direct life cycles are particularly difficult to eliminate, even in a single animal enclosure, so a regular deworming schedule may be indicated even for some long-term captives. Examples of parasites that are extremely difficult to eliminate are cryptosporidia in many species of snakes and lizards and coccidia in bearded dragons. Grazing tortoises present a unique problem in reptile parasite control. Following a deworming, grazing reintroduces parasites (as well as commensals and symbionts) back into the gut. Hence, their parasite control may be considered similar to that of other grazing animals such as horses and cattle, in which regular deworming in combination with rotational grazing is recommended.

Parasites and other infectious agents may be brought into a collection by wild rodents, birds, insects, and other arthropods. Mosquitoes are well-known vectors for certain blood parasites, and flies can serve as mechanical vectors for many pathogenic bacteria. Thus, a simple but extremely effective method of disease control is to maintain insect screens over and between all cages. Flies, mosquitoes, and roaches are not able to move easily from cage to cage with this protection. Unfortunately, most insect screens do not inhibit movement of fruit flies, gnats, or mites, and other methods are necessary for the control of these pests.

Snake mites (*Ophionyssus*) and lizard mites (*Hirtstiella*) are frustrating parasites for herpetoculturists to manage. Once in a collection, they are extremely difficult to eliminate, so major efforts should be made to prevent their entry into a collection. Usually all new reptiles should be quarantined for at least 3 months and probably longer to visualize a potential infection. If the newly acquired animal is found to have these ectoparasites, treating this individual is far easier than treating an entire collection. Food items and humans (such as caretakers, especially those working around other groups of reptiles) may also serve as vectors for mites.

Food items such as live mice have also been incriminated in transferring snake mites into collections. Pet shops often maintain rodent cages near snake cages, and when the snakes have mites, they often get into the rodent cages. Thus, an unsuspecting owner may carry home mites with a live prey item. The clinician should warn owners of this potential risk. This problem may be eliminated by purchasing rodents from clean reputable sources where reptiles are not housed near rodents or by purchasing frozen rodents. Freezing prekilled rodents appears to eliminate snake mites; however, freezing is not effective for eliminating pathogenic bacteria or protozoans. Keep in mind that feeding live prey items is illegal in some countries, states, provinces, or municipalities. Hence, purchasing humanely euthanized, frozen rodents will eliminate the risk of mites from this source. See Chapters 32 and 120 for more details on parasite identification and control.

As mentioned previously, insects, including prey insects, may also serve as vectors for the transmission of parasites or other pathogenic organisms. Prey insects arriving from a supplier with flies, maggots, or the larvae of other insects should be suspect, and one might want to consider recommending a different supplier.

Lastly, keep in mind that a substrate intended for use in the bottom of an enclosure may harbor mites as well, particularly if purchased from a vendor that also carries reptiles. A simple solution is to freeze the substrate for several days (or, if nonflammable, oven bake for a short time) prior to using.

Control of Disease Transmission in Closed Collections

A closed collection is a group of reptiles where new specimens are not permitted to enter. This arrangement has tremendous advantages in the prevention of disease. The only reason to allow a new animal into a closed breeding colony is to add more genetic diversity to the group. This reduces the likelihood of inbreeding and associated diseases.

Multi-Individual and Multispecies Enclosures

Recently, herpetoculturists have made efforts to house reptiles in naturalistic enclosures that mimic not only the naturally occurring physical environment but also the biological environment of the animals. Numerous species of plants and animals that coexist with the species may be considered for the captive environment, if the cage is suitably sized and complex enough to provide the proper habitat for all species considered. However, if two or more species are to be considered for cohabitation, the relationship to each other must be determined. Will

VetBooks.ir

they compete with each other for food and habitat? Will they prey on each other? Do they carry any diseases or parasites that may negatively affect each other? What is a suitable population density for the species? Are the species being considered somewhat social in nature or entirely independent from each other and potentially cannibalistic? These and other questions need to be answered to safely house different species of reptiles together. For many years, we have correctly advised clients to house reptiles alone when they are using small cages. Only in this way can feeding be monitored and competition for food reduced. Larger, more complex cages may house more than one individual of the same species, but they must be monitored closely. Clients frequently misinterpret reptiles maintaining close proximity to each other under basking lights as a positive social indicator. A frequent comment is that "they are buddies because they hang out on each other." To which the author responds, "so do people in a lifeboat." Indeed, there is a great risk for two or more individuals of the same species to compete heavily for limited basking sites, food, water, and even hiding areas. The stress of such competition may be detrimental to both the submissive and dominant reptile over time. Usually this competition manifests itself first in the submissive individual. Unable to bask effectively, limited in feeding, the submissive individual begins to lose size and body condition relative to the dominant individual. As the size difference increases the dominance of one individual over another appears to increase, and often the submissive individual ends up with an infection from opportunistic pathogens. Typically, it will succumb in exactly the same environment, and consuming the same diet, where the dominant reptile is thriving. This has been referred to as "big reptile, little reptile syndrome," and it is extremely common (see Fig. 16.18). It has been observed in captive squamates (both snakes and lizards), chelonians, and crocodilians. Indeed, this may be one of the best demonstrations of the effects of biological stress on an individual, given that all physical factors in the environment and the diet offered are the same for both reptiles involved. The best way to avoid this "syndrome" is to either house reptiles separately or increase the size and complexity of the cage, such that there are multiple basking areas, feeding areas, and hiding areas. Tortoise keepers have been known to create a feeding stall arrangement so that tortoises in the same enclosure can eat without disturbance from other tortoises yet gain the benefit of social contact. See the discussion on stress in this chapter and in Chapter 15.

Generally, reptiles from different geographic areas should not be maintained together because of the risk of introducing disease into a susceptible (immunologically naive) population. Hence, clinicians should strongly advise their clients against this practice. As mentioned above, two individual rodent-eating snakes maintained in a small enclosure or two groups of rodent-eating snakes in a large enclosure may not be compatible. Similarly, two species of tortoises that feed on the same food at the same time of the day may compete directly or indirectly. Also, chelonians and crocodilians appear to naturally carry a number of commensal protozoans that may be pathogenic for some snakes and lizards (e.g., Entamoeba). Thus, chelonians and terrestrial snakes should not be housed together in small enclosures. Crocodilians, of course, are likely to eat snakes and small chelonians, thereby making their cohabitation ill-advised.

In a large, outdoor enclosure maintained by the author, six species of snakes were maintained. These included water snakes (*Nerodia harteri harteri*), queen snakes (*Regina septemvittata*), hog-nosed snakes (*Heterodon simus*), rough green snakes (*Opheodrys aestivus*), fox snakes (*Pantherophis vulpinus*), and ribbon snakes (*Thamnophis proximus*) (Fig. 16.19). Theoretically, these snakes should have been able to cohabitate on the basis of their differing food preferences. Their preferred foods included, respectively, fish, crayfish, toads, insects, rodents, and small amphibians. However, the ribbon snakes also preyed on small fish, effectively competing with young water snakes. The fox snakes and green snakes contracted amoebiasis, presumably from drinking water contaminated by the heavy population of water snakes and queen snakes, for which the amoeba appeared to be nonpathogenic commensals. The hog-nosed snakes were preyed on by large local birds. Thus, it became evident how difficult it can be to maintain health in these multiple species enclosures. Even when predation was controlled, the water snakes increased rapidly to such a number that parasitism, fungal disease, and even cannibalism became significant factors for these snakes housed outdoors.[35,36] See the discussion on outdoor enclosures to follow.

Environmental Enhancement and Outdoor Enclosures

As a small boy visiting the large cat enclosure at a zoo in the early 1960s, I was struck by the constant activity level of the caged cats. In small concrete-bottomed bare cages, they appeared to pace back and forth incessantly. Reptiles caged in similarly stark cages appear to show similar

FIG 16.18 Measuring stress in a captive reptile is difficult but important as stress plays a major role in survival, longevity, and reproductive success. These two tortoises were raised together in exactly the same environment and offered the same diet. Their size difference is likely a manifestation of stress, probably from competition for food or thermal resources. This is referred to as "big reptile, little reptile syndrome."

FIG 16.19 A large outdoor enclosure allows reptiles to establish territories, forage, and avoid confrontations with cage mates. These behaviors are not often observed in those reptiles housed indoors.

VetBooks.ir

stereotypic behaviors, and generally, reptiles that pace are more likely to have health problems in captivity. A direct observation that may be associated with pacing is rostral abrasion, which often leads to stomatitis, anorexia, and rapid decline. However, a constantly pacing reptile likely is under stress and all the sequelae of that stress, including immune system suppression and ultimately disease. Ideally, one should observe that a captive reptile finds certain areas within its enclosure and stays in one of those areas for periods of time, rather than constantly wandering.

Numerous hiding, resting, and activity areas should be provided. Activities might include foraging for food or water, seeking mates, thermoregulating, or seeking more suitable shelter. Admittedly, some energy may be directed toward escaping from an enclosure, but in a large well-designed enclosure, this activity should be minimized. In open outdoor enclosures, some reptiles establish territories and defend them. They may exhibit normal escape reactions when approached and normal defensive actions when approached closely or picked up (e.g., they may bite, flail wildly, or defecate on the keeper). In short, they may live like and behave much more like wild reptiles than captive ones.[35] All of those factors that affect them in nature may affect them in a large outdoor enclosure (i.e., competition, predation, parasitism, disease, starvation, dehydration, cold exposure). However, these animals are not wild but rather captive reptiles in elaborate naturalistic cages. They may become more heavily parasitized than their wild counterparts, because they are confined to much smaller areas, thereby increasing exposure to parasites. They may become obese because of reduced activity associated with confinement. And they may exhibit unusual behaviors not seen in wild reptiles of the same species. But in spite of all of the potential problems, it is interesting to note that in the study with snakes conducted by the author mentioned above, snakes housed in a large outdoor enclosure were anatomically and physiologically more similar to their siblings released back into the wild in a number of measurable parameters than those raised in aquariums. These parameters included length, weight, defensive behavior, and oral bacterial cultures (see Figs. 16.1 and 16.19). Large outdoor enclosures have been used successfully for years with crocodilians and tortoises; only recently have they become more popular for lizards and snakes.

Bioactive Substrates

Some advances in herpetoculture may seem counterintuitive regarding the way we keep reptiles in captivity and think about their captive requirements. DeVosjoli[37] discusses in detail the use of bioactive substrate systems (BSS).[37] The basic theory behind these substrates is that they provide an environment where beneficial bacteria compete with pathogenic bacteria and fungi to support a healthy microhabitat for the captive. Stirring the substrate is apparently the key. Stirring mixes the competitive bacteria in lower layers with fecal bacteria and others at the surface, thereby inhibiting their growth. Successful creation of the bioactive substrate, according to DeVosjoli, requires that the substrate is at least 6.5 cm (2.5 in) deep and that it allows for good oxygenation and moisture retention. If the substrate dries out, it does not work. This system has been tested primarily on snakes, but theoretically it is useful for many captive reptiles.

The moisture-containing substrate mentioned previously probably has other benefits as well. Lillywhite[38] and others have recently commented on cutaneous water loss that captive snakes endure when they are placed in completely dry cages. This chronic water loss is suspected of being a major factor leading to the premature demise of captive snakes; by contributing to renal damage. Thus, a moist substrate may create a microhabitat that protects a captive reptile from both dehydration and infection. Indeed, the author has seen many small species of snakes do well in moist substrates or where moist substrates are offered as one of the choices available. An example of a bioactive substrate is a thick layer of cypress mulch, which has been regularly misted with water and stirred occasionally. Typically, this will result in layering of humidity within the substrate, with the driest areas on top and the moister areas near the bottom. Beneficial bacteria are encouraged within this acidic medium, and these appear to compete with pathogens in a well-ventilated cage. The author has successfully used this substrate for over 5 million snake hours (hours in which over 90 species of captive snakes have been housed in this substrate).

Other substrates successfully utilized are finely shredded coconut husks (coir), sphagnum or peat moss of varying particle size, and natural soil (baked or not). Each one of these substrates has potential for being successfully used as a natural (and bioactive) substrate. However, each substrate has its unique qualities of pH, moisture retention, air pocket size, compressibility, and the amount of physical support it provides to the reptile in question. Those substrates that are naturally less compressible will retain more air and less moisture (e.g., aspen bedding) will also tend to stay looser and provide less physical support. While this may be ideal for larger terrestrial reptiles, it is not a good substrate for smaller, semifossorial reptiles. Indeed, it appears that recommendations for substrate particle size may be correlated (loosely), with the size of the reptile in question. For example, larger reptiles generally do well on larger particle size substrates, which are less compressible and retain less moisture. Whereas smaller reptiles generally do well on smaller particle substrates that are more compressible and more moisture retentive. Any time a natural substrate is used, it is critical that enough top ventilation is provided or moist stagnant air will lead to the development of an unhealthy, fungal-laden environment.

Regarding the use of natural soil, some have questioned the value or necessity of baking the soil first before using. Some argue that baking the soil before use kills the naturally occurring bacteria and reduces its quality as a bioactive substrate. Others argue this is not the case. Indeed, natural soil may contain a variety of potentially symbiotic bacteria. However, there is also a risk that it may contain pathogens, including soil arthropods, nematodes, fungi, bacteria, and viruses that may opportunistically invade a reptile in close contact for an extended period of time, and thus baking is advisable.

Water

Water should be available at all times for most reptiles. However, exceptions do exist. The constant presence of water in poorly ventilated cages often becomes a health hazard for many reptiles. Unable to escape the excessively humid air in such a cage, these animals become susceptible to dermatitis or respiratory disease. The situation may be aggravated by excessive substrate moisture. However, with suitable conditions in a well-ventilated cage, the presence of a clean reliable source of water is extremely important to most captive reptiles. As mentioned previously, definite cutaneous and respiratory water losses must be compensated for or the captive reptile suffers either acute or chronic dehydration. This concept of chronic dehydration, and possibly associated kidney disease, has captured the interest of some physiologists and zookeepers recently.[38] Some have suggested that merely providing sufficient drinking water cannot prevent chronic dehydration and kidney disease if the reptile does not have access to a suitable microenvironment that reduces cutaneous and respiratory water loss. See the discussion on basic husbandry requirements.

How water is provided is also important. An arboreal reptile, such as a vine snake, a tree boa, or a chameleon, may rarely come to the ground level. Therefore a water bowl on the floor of the cage may be futile as a method of providing drinking water. However, misting the branches on a regular basis or providing a tree-mounted water bowl may be effective. Modern herpetoculturists have responded to this requirement

VetBooks.ir

by creating naturalistic water bowls and hiding areas that can be mounted high in the enclosure with the use of magnets. Desert reptiles may also benefit from misting rocks in their enclosure on a regular basis, as they often lap water from these rocks but may not always use a water bowl. Conversely, some may sit in their water bowls for excessively long periods of time if these are provided, sometimes resulting in associated dermatitis. Many tortoises seem to need a daily rain to thrive, but the substrate should not stay excessively moist on a continual basis. Water intake may also be increased significantly by soaking or misting food prior to feeding it to captive reptiles.

The size and shape of a container is another factor that should be considered. Steep-sided water containers may prevent easy entry or exit by many chelonians, resulting in dehydration or drowning. Terrestrial chelonians and even some aquatic species are not strong swimmers and may easily drown if the water is deeper than their legs are long, and thus chelonians should not be put in water deeper than this. Even the most aquatic of reptiles, including crocodilians, chelonians, and certain snakes, need a resting area or "haul out" where they can climb out to bask or rest. In many cases, they must be able to raise their body temperatures significantly and dry the skin completely during the basking process or dermatitis may occur.

Be aware that daily soakings are an important maintenance requirement for many terrestrial chelonians. It is recommended to soak hospitalized tortoises for at least one half hour daily in shallow water. The tortoises may drink at this time, but often the soaking merely facilitates defecation and appears to encourage activity and alertness. Furthermore, bathing and the manual scrubbing or removal of debris or old skin may be healthful (Fig. 16.20).

Additives to reptile water have been the subject of many discussions during the last 10 years. Several commercial vitamin and mineral formulations are presently available, but the values of these products are largely unknown. The dosing of such products is purely empirical. Some authors have recommended the use of dilute bleach in the drinking water to control bacteria. At 1 to 5 mL per gallon (4 L), this addition is both safe for the reptile and efficacious against some bacteria. This addition is probably unnecessary for most captive reptiles; however, it may be helpful in cases where a particular bacterial organism may be thought to be spreading through a group of reptiles in the same cage. Conversely, chlorinated water may be a problem for aquatic turtles because it may cause conjunctivitis, so dechlorinating additives may be used or the water should be allowed to sit for 24 hours prior to use (see Fig. 16.3).

FIG 16.20 Hospitalized tortoises should be soaked in shallow water at least every other day. This author recommends soaking every hospitalized tortoise for at least a half hour every day. Bathing tortoises and turtles is also advisable as needed to help remove debris or old skin. Here a technician uses a soft bristle toothbrush to remove old skin from a juvenile snapping turtle (*Chelydra serpentina*).

Feeding

Poor nutrition is as common as an inadequate environment for causing disease in captive reptiles (see Chapter 27). Together, these factors are likely responsible directly or indirectly for more than 80% of illness in captive reptiles.

Both the quantity and quality of food is important. Feed reptiles the highest quality food items possible. When possible, feeding fresh food items is ideal. "Old" food items or those that have been stored improperly may be contaminated with various fungi or bacteria.

Items that have been frozen for more than 6 months often lose nutritive value. Nevertheless, short-term freezing of most food items is an economical and convenient way to store food. Freezing may actually increase the digestibility of certain plant materials by rupturing the cell wall and thereby making the cell contents more accessible at an earlier stage in the digestive process. Unfortunately, the freezing process has also been associated with a reduced thiamin content in certain species of fish (see Chapter 27).

Cooking some vegetables accomplishes the same function of breaking down cell walls as freezing but does not reduce the thiamin content, and this process may be helpful in softening hard vegetables, such as sweet potatoes. Recently steaming and canning insects and other foods for reptiles has become popular. The preservation of nutritive value with this process appears to be excellent and provides a reliable food source, if accepted by reptiles. (Fig. 16.21) Under normal circumstances, however, most herbivorous reptiles should be fed uncooked green leafy vegetables. Mustard greens, collard greens, turnip greens, dandelion greens, escarole, endive, and watercress are all excellent foods. Other nutritious vegetables to offer include squash, snap peas, and carrot tops. Vegetables to avoid in large quantities include cabbage, Brussels sprouts, cauliflower, broccoli, kale, bok choy, and radish because they contain goitrogenic substances (i.e., iodine-binding agents); however, these vegetables are safe when fed in moderation. Another group, including spinach, beets, and celery stalks, contain oxalic acid in a sufficient quantity to interfere with normal calcium uptake and metabolism but again can be safely fed in moderation. Many fruits are nutritious but are low in

FIG 16.21 A wide variety of commercially prepared reptile foods are now available. Canning insects stabilizes the nutrient value and provides a reliable food source.

VetBooks.ir

calcium or have a poor calcium to phosphorus ratio or both. Bananas and grapes also contain tannins, which can interfere with protein metabolism in reptiles. As with birds, avocados are generally considered toxic to reptiles, although it is not uncommon to see wild iguanas eating avocados that have fallen from trees. Rhubarb and eggplant are also believed by some to be toxic for reptiles. If concern exists over the safety of a food item, it is best left out of the captive diet.

Some flowers are considered safe and nutritious. The most notable and common among these are dandelions, hibiscus, and roses. Flowers that are toxic and extremely dangerous are azaleas, oleander, daffodils, and tulips. Marijuana is also toxic to reptiles (see Chapter 88 for more information on toxins).

The use of live prey food has been discouraged in the last few years, only utilized if necessary, and remains illegal in many countries. Reasons for this include the increased risk of injury to the captive reptile and the inhumanity associated with placing a frightened prey animal in with one of its predators. The latter observation notwithstanding, some benefits may exist to feeding live prey. First, the energy spent hunting and subduing food in a large enclosure represents a significant percentage of total energy expenditure for some reptiles. Second, the act of hunting may represent a series of necessary intellectual stimuli for the maintenance of normal behavior. Certainly, it is a survival skill that is needed if a reptile is to be released back into the wild. The combination of physical activity and intellectual stimulation helps to maintain a predatory reptile in "better fitness" than a stationary, stagnant, and stimulus-free environment. The same may be said for herbivorous reptiles, although the hunting behavior is limited to finding suitable forage.

Food may also serve as a vector or fomite for parasites, bacteria, fungi, or viruses. Clients must be advised to avoid wild-caught food and not to transfer food items from one cage to another.

The preferred foods of many reptiles are discussed in Chapter 27 and in detail in many references.[6,13,20,33,34,39] Generally, however, all snakes are carnivores, with foods ranging in size from insects, slugs, and earthworms to mammals the size of capybaras, deer, and antelope. Most snakes seen in practice are rodent or rabbit eaters, but a small percentage eat birds, fish, or other vertebrates (see Chapters 20, 22, and 27). Many lizards and turtles are also carnivorous, with foods ranging from insects to large rodents, birds, fish, and small deer. The entire family Varanidae (monitors), with a few rare exceptions, are carnivorous. The most commonly seen captive species (e.g., savannah, water, and Nile monitors) all are primarily small vertebrate feeders. The family Teiidae, commonly known as whiptails and tegus, occupy the same niche in the western hemisphere as the monitors do in the eastern hemisphere and eat primarily insects and small vertebrates. Certainly most members of the five other lizard families are insectivorous, namely the Scincidae (skinks), Chamaeleonidae (chameleons), Iguanidae (new world anoles, fence lizards, swifts, chuckwallas, and iguanas), Agamidae (old world lizards occupying the same niche as the new world iguanids [e.g., agamas, water dragons]), and Gekkonidae (geckos). Other species of lizards are herbivorous or omnivorous, including many of the species commonly kept as pets (e.g., green iguanas, bearded dragons) (see Chapters 21 and 27; for tuataras, see Chapter 26).

Most tortoises and turtles are herbivorous, but many are omnivorous and a few are primarily carnivorous. Box turtles (*Terrapene* sp. and *Cuora* sp.) and hingeback tortoises (*Kinyxis* sp.) are examples of chelonians that are primarily carnivorous. Among aquatic turtles, carnivorous or scavenging species include mud turtles (family Kinosternidae), chicken turtles (*Deirochelys reticularia*), and snapping turtles (*Chelydra serpentina* and *Macroclemmys temmincki*) (see Chapters 23, 24, and 27).

Crocodilians are all carnivorous, with adults preferred prey varying from fish in some species to mammals and birds in others. The young of all species of crocodilians may consume some insects but rapidly switch to vertebrate prey, which has a higher calcium content (see Chapters 25 and 27).

Knowledge of these basic diets is helpful in establishing guidelines for captive and hospitalized reptiles. In an emergency situation, leafy greens or a high-quality pelletized rodent food may be used for herbivorous reptiles, a (quality) canned dog food may be used for an omnivorous reptile, and a (quality) canned cat food may be used for a carnivorous reptile. The latter two options, however, may be too high in protein for long-term use in many reptiles. Gout or renal disease can result from such diets. Better nutrition for hospitalized reptiles can be provided by utilizing diets prepared specifically for this purpose. These include the Critical Care Diets (Oxbow Pet Products) or Emeraid Critical Care Diets (LaFeberVet).

Be aware that concentrated pelletized diets, if used as the primary diet of a reptile, even those marketed as "balanced" diets, may lead to nutritional disorders. A variety of foods that may include some pellets is always preferable to any monotypic diet.

Fruits may have limited nutritional value but are often added to diets to stimulate consumption for herbivorous reptiles. Reptiles are capable of seeing color. Brightly colored fruits such as strawberries, tomatoes, bananas, and melons often attract the attention of many herbivorous lizards and tortoises and invite consumption. These are particularly valuable in many cases to entice recently captured or ill animals to eat, and they contain large quantities of water. Yellow (summer) squash and cooked sweet potato are also brightly colored and can be valuable additions to the diet of many herbivorous reptiles. Some lizards, such as *Uromastyx*, consume significant quantities of seeds in the wild, so a variety of seeds should be included as part of the captive diet.

Monoculture insects raised in captivity are also often of questionable value as a balanced diet. Captive raised crickets and mealworms often have a low calcium content and must be "fortified" to improve nutrition. Perhaps the most widely accepted method of raising the calcium content is to "dust" these food items with calcium powder; however, feeding the insects a high calcium diet for 24 hours or more before feeding them to a reptile has been shown to be more efficient at providing the needed calcium to the reptile.[40] This is referred to as "gut loading" in the herpetological vernacular. Current recommendations are to gut load and dust to provide maximum levels of calcium (see Chapter 27).

Regarding gut-loading diets, there are several commercially available. However, all gut-loading diets are not the same. Many feature powdered calcium in the metallic form, mixed with a food source (e.g., oatmeal). Only a small percentage of calcium in this form is absorbable by the reptile, whereas calcium in the chelated form, as found in green leafy vegetables, is highly absorbable. Hence, gut-loading insects with shredded turnip greens (7/1 calcium to phosphorus ratio), collard greens (3/1 calcium to phosphorus ratio), or other greens is preferable to a powdered gut-load diet. Furthermore, the cubed (gel) calcium supplements are not by themselves a satisfactory gut-load meal. In one study performed by the author, hatchling insectivorous snakes (ground snakes, *Sonora semiannulata)* were fed crickets gut loaded with turnip greens or calcium gel cubes. Those that were fed crickets gut loaded with turnip greens developed normally, while those fed crickets gut loaded solely with calcium gel cubes developed multiple kinks in the spine. In addition, numerous juvenile lizards have been presented to the author in practice with signs of nutritional secondary hyperparathyroidism, where the history included being fed crickets gut loaded solely with these cubes.

Mice and rats raised in captivity are usually considered to be a good quality food source. However, the nutritional quality of these rodents is affected by what they have been fed. Rodents fed a diet exclusively of dog food have a tendency to be fat and "greasy," and

VetBooks.ir

snakes and monitors that have eaten rodents fed this way also have a tendency to become obese. Many rat and corn snakes (*Pantherophis*) that develop lipomas have a common history of primarily feeding on a diet of ex-breeder mice or mice fed primarily a dog food diet. Feeding reptiles young lean mice that have been fed a high-quality, plant-based rodent chow provides a healthier diet. Additionally a high-quality food should be available to the rodents until the time they are fed to the reptile. These gut contents probably contain valuable nutrients and roughage, and thus, multivitamin and mineral supplementation for rodent feeders is usually not considered necessary, because properly fed rodents represent a complete diet (entire rodent ingested). In fact, one study showed no significant difference in size, weight, or bone density in two groups of hatchling corn snakes fed supplemented and nonsupplemented mice (Backner B, personal communication, 1991).

Herbivorous reptiles need a quality vitamin and mineral supplement. However, the vitamin and mineral requirements for most reptiles have not been determined, and most recommendations are anecdotal. Oversupplementation has occurred when vitamins, especially fat-soluble vitamins, are administered too frequently or in large quantities. Also, oversupplementation does not always balance an otherwise deficient diet (i.e., appropriate vitamin and mineral intake in the absence of sufficient roughage may still result in an unhealthy reptile). As in mammals, sometimes oversupplementation of one nutrient may result in a deficiency of another. In most cases, calcium dusting should occur with every meal, while multivitamin and mineral supplementation once weekly or every other week is usually sufficient (see Chapter 27).

Stress

Stress is an important factor for captive reptiles (see Chapter 15). Stress is difficult to define but may be thought of as the increased energy required for a reptile to maintain itself, compared with that which is required in the normal habitat (see Fig. 16.19). Reptiles generally can survive for prolonged periods in captivity and may reproduce if they are maintained in low-stress environments. Clean adequately sized cages with the proper substrate, thermal gradients, light quality and photoperiod, ventilation, and humidity are considered important physical requirements to reduce stress in the captive environment. Predators, competitors, parasites, and pathogens are biological factors that must be controlled to reduce stress, but these factors act independently to increase the morbidity and mortality of captive reptiles in high-stress environments.

Constantly changing cages, substrates, cage accessories, or cage mates adds stress to the life of a captive reptile. Adding or interacting with a cage mate is likely the most stressful factor in a confined captive reptile's environment. See the discussion on "big reptile, little reptile syndrome" in the section on multi-individual and multispecies enclosures. Even a change of keepers may add stress. However, many reptiles, once they adjust to a certain routine, adapt well to captive maintenance.

Other factors that may contribute to stress include handling or disruption. In addition, placing a cage in a high traffic area with associated vibration can be stressful. We often advise our clients not to handle any anorexic reptile until the animals have adapted and are feeding regularly.

CONCLUSION

Reptile clinicians should be aware that reptiles are not domestic pets. Even though some species are bred extensively in captivity, millions of years of evolution cannot be erased in a few generations of captive propagation. As wild animals in captivity, they need a recreation of many of the physical and biological features of their natural habitat. Successful management of reptiles in a contrived environment requires veterinarians to become familiar with the habitat (particularly the substrate likely to be found where the reptile lives), diet, and preferred temperature range of the species in question. We need to approximate those parameters as close as possible in the captive setting. The same is true for biological factors. Will competition with other animals negatively impact them or stimulate normal activity? Are the animals in question social in nature or asocial (i.e., only interacting with the same species during mating season)? If there is any doubt, it may be safer to house reptiles alone.

Some reptile species appear to be more adaptable than others. Those which occupy large geographic ranges in nature with a broad diet may be considered more adaptable. Many of these adaptable species have the ability to tolerate a wide range of captive habitats. As clinicians we need to be aware of ideal temperature, lighting, and humidity range for our patients so that we can guide our clients. For all captive reptiles, whether the natural history is well known or not, the safest and best way to prevent problems is to provide environmental gradients. Not only should a thermal gradient be provided but also a humidity and lighting gradient. In this manner, the reptile may choose the microenvironment that best suits it for the function at hand, such as digestion, reproduction, or immune system stimulation.

Finally veterinarians and herpetoculturists must strive to go beyond just providing the correct environment. Attempts should be made to provide an enriched environment.[41] In recent years, herpetoculturists have developed a variety of inventions to help reduce stress in captive reptiles by enriching the captive environment. Some of those recent innovations are illustrated in these figures (Figs. 16.22, 16.23, and 16.24). Ultimately reptile enclosures should be large and enriched to allow the reptile to have "needs fulfilled" and practical enough for the keeper to be able to keep that reptile "healthy" (see Fig. 16.25).

Inappropriately housed reptiles may survive but not thrive. This difference between ideal and a deficient captive environment can result in stress, and chronic stress leads to reproductive failure, disease, and death.[42]

To summarize, the first step in successfully treating reptiles is the examination of the captive environment and the second step is educating the client on how to correct errors in the captive environment. Thus, as mentioned early in this chapter, success with maintaining captive reptiles involves both client education and correcting the environment ($S_R = CE^2$).

FIG 16.22 Magnetized devices are available that allow ledges, hiding areas, and water sources to be placed at elevated locations in aquariums for arboreal reptiles.

FIG 16.23 The substrate or bottom material is an important component of the captive reptile environment. Herpetoculturists may select from a wide variety of naturalistic substrates, which vary in texture, particle size, absorbency, and the physical support that they provide to a reptile. Many substrates also provide additional hiding areas, which can reduce captive stress.

FIG 16.24 Misting devices have become increasingly popular and are adaptable to a variety of cage sizes.

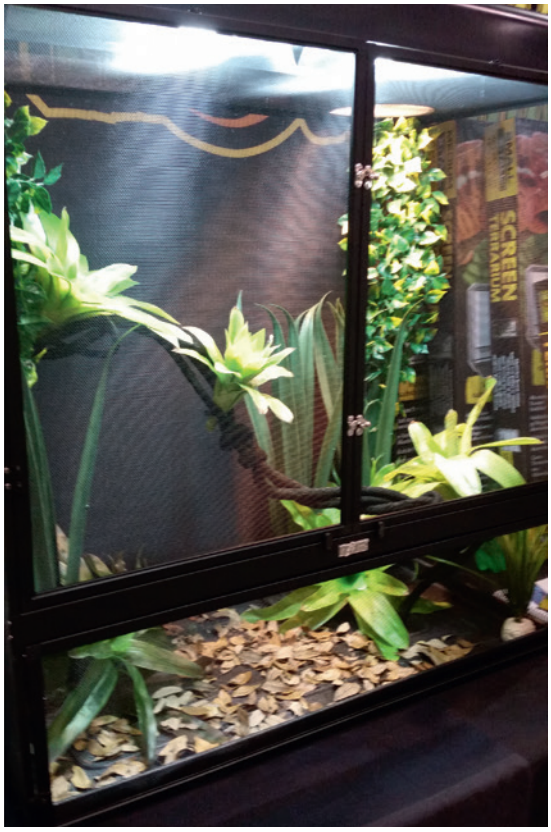


FIG 16.25 The "ideal" reptile enclosure provides all of the requirements discussed, including correct size, excellent ventilation, lighting, temperature and humidity control (and gradients), a naturalistic substrate suitable for the species in question, and environmental enrichment.

ACKNOWLEDGMENTS

I would like to thank the late Sean McKeown for setting the standard for this chapter in the first edition and all of his guidance in so many areas of herpetoculture. I would also like to thank Brian R. Eisele, senior reptile curator at the Jacksonville Zoological Garden, as well as Chris Lechowicz, director of wildlife habitat management at the Sanibel-Captiva Conservation Foundation, for sharing their experiences. Vic Morgan and Michael Pilch, experienced herpetoculturists, also provided me with some excellent suggestions. In addition, I would like to extend thanks to the staff of Riverside Animal Hospital in Jacksonville, Florida, for their suggestions on practical solutions to common reptile problems.

Environmental Lighting

Frances M. Baines and Lara M. Cusack

In nature, sunlight interacts with features of a reptile's environment, creating a microhabitat with superimposed gradients of heat, light, and ultraviolet (UV), extending from full sun into full shade. Reptiles utilize these gradients for thermoregulation and, at least in some cases, for UV photoregulation[1,2]; they do so by self-regulating their exposure to solar radiation. Deviations from the optimal range are likely to act as stressors, with negative repercussions on health. Providing a suitable photo-microhabitat in captivity is, however, challenging. To date, very few field studies have recorded the daily light and UV exposure of wild reptiles of any species; this work has been pioneered by Drs. Gary Ferguson and William Gehrmann and colleagues at Texas Christian University.[3,4] Natural sunlight varies constantly, its spectrum and radiance determined by the solar altitude (the height of the sun in the sky) and the degree of cloud cover, as well as the degree of shading from features within the landscape. In a typical vivarium, a lamp is either on or off, and its spectrum and radiance vary little, if at all, over the course of a day. However, it is possible to utilize combinations of lamps to create full spectrum gradients from ultraviolet to infrared. Although artificial lighting cannot replicate natural sunlight it can, when used properly, make a huge contribution to reptile husbandry.

NATURAL SUNLIGHT

Free-living reptiles, even crepuscular and nocturnal species, utilize every part of the solar spectrum from ultraviolet to infrared (Fig. 17.1). Their exposure levels are determined by their microhabitat and their daily activity patterns. Sunlight includes short-wavelength infrared (IR-A), so-called visible light (visible to humans) and ultraviolet (UV), subdivided into UVA and UVB from around 290 to 295 nm (depending on solar altitude). Earth's atmosphere blocks hazardous shorter wavelengths (UVB below 290 nm and UVC) from reaching the surface.

Infrared

Short-wavelength infrared (IR-A) is responsible for the warming effect of sunlight. Sunlight reaching the earth's surface passes through water vapor, which absorbs certain infrared wavelengths. This "water-filtered IR-A" passes through the epidermis, reaching the internal organs of small-bodied reptiles, without excessively heating water molecules in the tissues.[5,6] IR-A also warms the surface of the earth, which reradiates in longer wavelengths (IR-B and IR-C). Long-wavelength infrared does not penetrate the epidermis, but transfers all of its energy as heat,[7] which is conducted or carried by convection in bodily fluids to deeper tissues. Infrared is invisible to humans and most reptiles, although some snakes can perceive the longer wavelengths (above 3000 nm) through their facial pit organs.

Visible Light and UVA

Most reptiles have full color vision, in which UVA is a vital component, with wavelengths from 350 nm (within the UVA band) to those at the boundary with infrared being visible. The presence of UVA-reflective markings on many animals and plants aids in the recognition of conspecifics and food. Some nocturnal reptiles even have good color vision in dim moonlight, in which humans see no color at all.

In addition to enabling conscious vision, sunlight reaches nonvisual photoreceptors in the reptile retina, pineal body, and parietal eye (when present), and even deep brain photoreceptors that respond to light filtering through the skull.[8] Information is relayed to a complex neuroendocrine network controlling daily and seasonal behaviors, including activity levels, thermoregulation, the immune system, and the reproductive cycle, and which is mediated via hormones secreted by the pituitary (Fig. 17.1).

UVB

The amount of UVB in sunlight depends on the solar altitude, because the earth's atmosphere absorbs and scatters UV light, affecting the shortest wavelengths most strongly. When the sun is low in the sky, near dawn or sunset, the sun's rays have a longer path through the atmosphere, so more filtering occurs, leaving only traces of UVB in the spectrum. As the sun rises, the total UVB rises, reaching a maximum with the sun directly overhead. The dose of UVB received by a reptile therefore depends on the time of day when sun exposure occurs. A wild reptile's photo-microhabitat may bear little resemblance to solar data collected by meteorological stations; climate data is rarely indicative.

UVB and warmth are required for cutaneous vitamin D3 synthesis in reptiles. A cholesterol in the epidermis, 7-dehydroxycholesterol (7DHC), is converted to previtamin D_3 when exposed to short-wavelength UVB (range 290 nm–315 nm). This undergoes a temperature-dependent isomerization into vitamin D_3, which enters the bloodstream. This process has been demonstrated in both diurnal and crepuscular lizards and snakes. The vital vitamin D pathways (endocrine, autocrine, and paracrine)[9] are summarized in Fig. 17.1. For more details, see Chapters 27, 79, and 84. Overproduction of vitamin D_3 is prevented by the conversion of excess previtamin D_3 and vitamin D_3 in the skin into inert photoproducts by UVB and short-wavelength UVA (range 290 nm–335 nm). UVB in sunlight also has direct effects on the skin: it acts as an effective disinfectant, modulates the immune system, improves skin barrier functions, and upregulates melanin synthesis.

Utilizing Natural Sunlight

Many reptiles, especially basking species, benefit from outdoor enclosures where they can experience natural sunlight. Ambient temperatures must

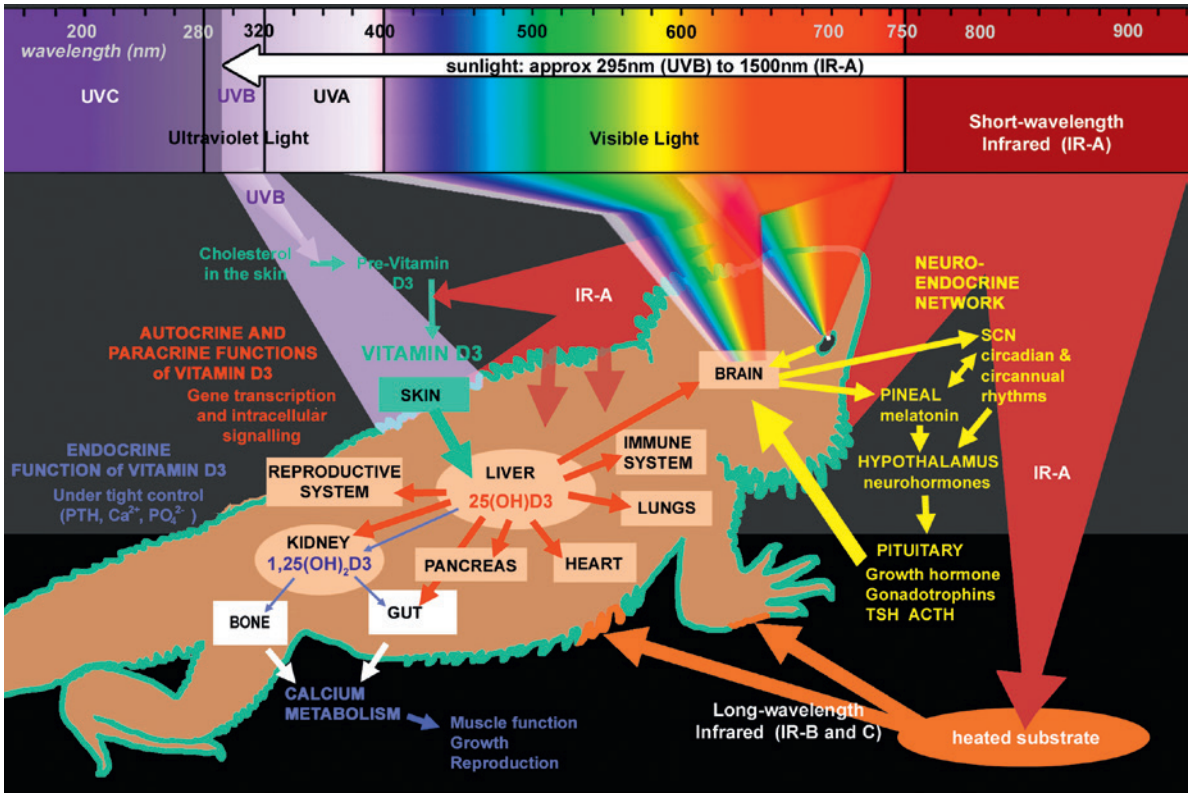

FIG 17.1 Reptiles utilize every part of the solar spectrum. (Courtesy of Frances M. Baines.)

be suitable, and the amount of direct sunlight required will depend on the species. All enclosures must provide areas of full shade and shelter. "Greenhouse"-type shelters may be glazed with special UV-transmitting acrylic sheets ("sunbed acrylics"), allowing up to 80% transmission of UVB, or low iron glass, which may allow 50% transmission. Horticultural UV-transmitting plastic sheeting, with up to 65% UVB transmission, can be used to create covers for more temporary outdoor shelters and polytunnels. Care must be taken to avoid excess heat buildup caused by direct sunlight through glass or plastics into restricted airspaces. Glass tanks and vivariums should never be placed in direct sunlight as lethal temperatures can swiftly develop. Natural sunlight can rarely be utilized inside unmodified buildings. Ordinary window glass and most plastics block all UVB and some UVA.

ELECTROMAGNETIC RADIATION

To be successful, vivarium lighting must create superimposed heat, visible light, and UV gradients similar to those found in nature. Sun-basking species will require a basking zone with a gradient into full shade, allowing the reptile to self-regulate its exposure. It is virtually impossible to simulate sunlight using just one type of lamp, but combining simple incandescent bulbs ("basking lamps"), lamps emitting additional visible light, and specialist UV-emitting products can be very effective.

Infrared

Ceramic Heaters, Panel Heaters, and Heat Mats. These emit only long-wavelength infrared (IR-B and IR-C), which can put an excessive heat load on the upper epidermis and increase the risk of thermal burns. They make excellent background or nighttime heaters but are not suitable for basking zones. The absence of a visible light output is also a significant disadvantage, as many reptiles use light as a cue for locating a basking area.

Incandescent Lamps. Basic tungsten or halogen lamps are widely used to create basking zones. Their spectrum contains no UVB and very little blue or UVA. Orange and red visible light and short-wavelength infrared (IR-A) predominate, but this IR-A includes the wavelengths removed from natural sunlight by atmospheric moisture. They also emit longer-wavelength IR-B and some IR-C. Intense exposure may overheat the skin surface and water molecules in the epidermis before deeper structures reach optimum temperatures. To minimize the risk of thermal burns, the basking zone must cover an area at least as large as the whole body of the animal, and the radiation must be evenly distributed, with no focal hot spots. "Flood" bulbs (with beam angles of 30 degrees or more) are essential. Basking zones for large reptiles are best created with a cluster of several lower-wattage bulbs rather than with one high-wattage lamp.

Thermal imaging (Fig. 17.2A and B) demonstrates the contrast between the uniform body temperature of a reptile basking in natural sunlight and the extremely localized heating provided by a "spot" basking lamp. The head and limbs of the animal may remain at ambient (air) temperature. Such abnormal heating of a tortoise carapace may contribute to localized dehydration and development of pyramiding deformities in captive tortoises.[10] A reptile may remain under such a lamp long enough for serious burns to occur, typically over the shoulders and cranial coelomic spine (Fig. 17.2C). For further details, see Chapters 69 and 169.

Incandescent lamps should be controlled using dimming thermostats. Surface temperatures underneath basking lamps need to be measured directly, as they are very different from ambient (air) temperatures. Noncontact infrared thermometers (so-called "temperature guns") are ideal for this purpose.

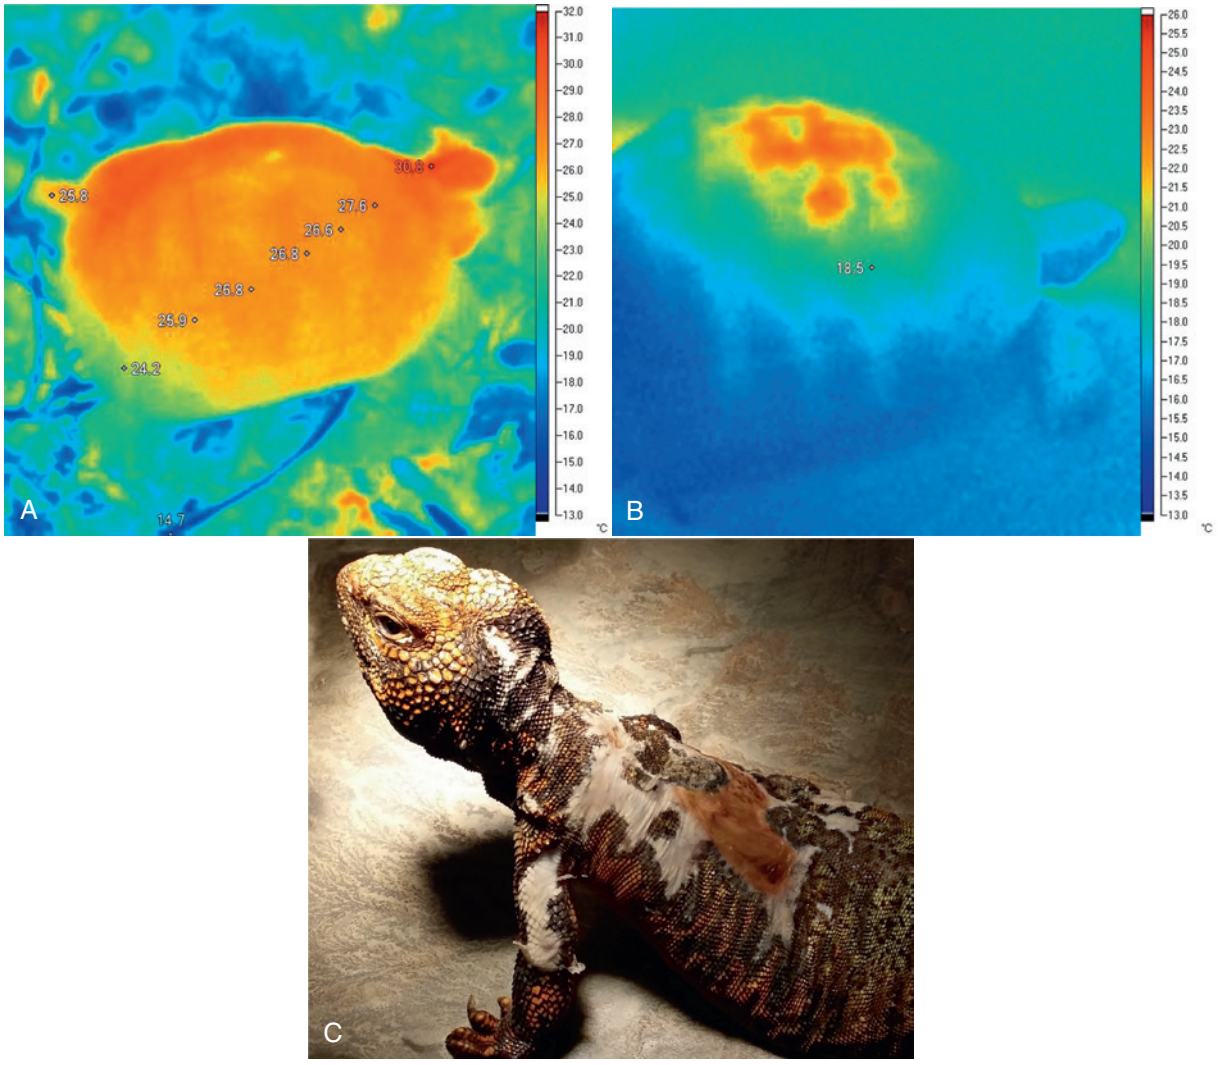

FIG 17.2 (A) Thermal image: Wild *Testudo graeca*, basking in natural sunlight, Murcia, Spain. (B) Thermal image: *Testudo graeca* in captivity, basking under a 100-watt "spot" lamp. (C) Moroccan Uromastyx (*Uromastyx acanthinuris*) recovering from severe thermal burns from inappropriate "spot" basking lamp. Note typical location of burned skin. (A and B, Courtesy of A.C. Highfield; C, courtesy of D. Chatham.)

Visible Light

"Daylight" Fluorescent Tubes and Compact Lamps. Sometimes misleadingly called "full-spectrum," these emit no UVB and very little UVA but can be useful for improving general light levels in cooler areas of a vivarium.

Metal Halides. High-quality "daylight" metal halide lamps, such as those used for freshwater aquaria and display lighting in store windows, can reproduce the full brilliance of sunlight, including UVA (but no UVB) and significant infrared. These are high-intensity discharge (HID) lamps requiring external ballasts and cannot be used with a proportional/dimming thermostat. Positioning them directly above the vivarium is crucial because ocular damage can occur if they are placed in an animal's direct line of sight.

LED Lighting. There are two types of LED currently available:

(1) "White" LEDs, which use a blue LED and a phosphor to simulate white light. The spectrum of these contains no UVA or UVB and is deficient in cyan and red.

(2) LEDs that emit just one color, in a very narrow band of wavelengths. "White" is created using a combination of red, blue, and green LEDs in a single bulb. However, this light will not appear white to any reptile, owing to their different visual range from humans. Neither type of LED should be the primary light source in a vivarium. However, they may be suitable for supplementary lighting or for enhancing plant growth.

In the near future lamps may be developed that utilize multiple LEDs covering a wide range of wavelengths from UVB to infrared, creating a more sunlike spectrum. A recent trial of a prototype

VetBooks.ir

UVB-emitting LED lamp by one of the current authors (L.M.C.) has shown promising results with regard to cutaneous vitamin D_3 synthesis in bearded dragons (*Pogona vitticeps*).[11]

Colored Lamps. These should be avoided, since reptiles need full-spectrum, white light during the day for normal color vision and nonvisual perception. Neodymium coatings do not improve the spectrum of an incandescent bulb; they merely absorb some yellow wavelengths so that the light appears more "blue" to a human observer. The use of red and blue lamps at night is also extremely unnatural as reptiles can see both colors. Reptiles should not be illuminated at night; their circadian rhythms require regular periods of darkness and daylight.

Ultraviolet

There are five main types of UVB-emitting lamps that are commonly available, all of which also emit significant UVA and visible light (Fig. 17.3).

Regular T8 UVB fluorescent tubes (diameter 25 mm) have a low, well-diffused output (Figs. 17.3A and 17.4A). T5-high output (T5-HO) UVB fluorescent tubes (diameter 16 mm) can have a much higher output, especially when used with a reflector (Figs. 17.3A and 17.4B) Very wide UVB coverage can be obtained for large vivaria and zoo enclosures using multiple T5-HO tubes in reflective fixtures.

Compact fluorescent UVB lamps (Figs. 17.3B and 17.4C) have a well-diffused but very steep UV gradient and limited range. They are only suitable for use in small vivaria.

Mercury vapor UVB lamps (Fig. 17.3C) are self-ballasted HID lamps, which do not require a ballast. They can have a high UV output, but all have a poor visible spectrum. Lamps with clear front glass produce very narrow beams, creating "hot spots" of either UV or infrared; these must be avoided in favor of those with coatings diffusing and widening the beam.

UVB-emitting metal halides, a relatively new development (Figs. 17.3D and 17.4D), produce intense visible light, UVA and UVB. Many brands have fairly narrow beams, however; wide flood versions should be chosen to create large basking zones. Like all metal halides, these need external ballasts; "kits" are available that include a lamp, a matching ballast, and a lamp-holder. Both mercury vapor and metal halide bulbs produce sufficient heat to contribute to basking zones but cannot be controlled by a proportional/dimming thermostat, so previously discussed cautions regarding infrared radiation apply.

Brands vary widely in their UVB output. High-quality products from well-known brands should be chosen to ensure suitable spectra, output, and longevity although even these will show some individual variability. Manufacturers' recommended distances should be carefully observed. Independent test results for a range of lamps are available on the internet (e.g., http://www.uvguide.co.uk) but only provide rough guides, since UV at the level of the reptile is affected by external factors such as the presence of reflectors, which can greatly increase the irradiance beneath a lamp, or mesh screens, which physically block 30% to 50% of visible light and UV. The effect of aluminum reflectors and a typical mesh "vivarium screen top" on the output of a T5-HO UVB fluorescent tube is shown in Fig. 17.5. Lamp output also declines with use, mainly due to solarization of the glass: most lamps show a sharp initial fall in UVB output over the first few days of use (the "burning-in period") followed by a much slower loss over weeks and months. Ideally, owners should purchase a UV meter and test their lamps *in situ* at the closest lamp-to-reptile distance, repeating the tests monthly to monitor decay. Some veterinarians offer a lamp testing service, but care must be taken not to expose staff to a UV-radiation hazard. The most suitable meter currently available is the Solarmeter 6.5 UV Index Meter (Solartech Inc., Glenside, PA), also sold

FIG 17.3 Examples of specialist UVB-emitting lamps used in reptile husbandry. (A) Fluorescent tubes: regular T8 (2.5 cm diameter) and high-output T5-HO (16 mm diameter). (B) Compact fluorescent lamps, available as coil- or bar-type lamps in a range of styles. (C) Self-ballasted mercury vapor lamps. (D) Metal halide lamps, sold with matching external ballasts and lamp-holders. (Courtesy of Frances M. Baines.)

FIG 17.4 Creating UV, light, and heat gradients. Overlaid iso-irradiance charts visualize the UV index gradients. (A) Shade method using regular T8 5% UVB fluorescent tube and diffuse halogen lighting for leopard gecko (*Eublepharis macularius*) vivarium. (B) Sunbeam method using T5-HO 12% UVB fluorescent tube with aluminum reflector, twin halogen floodlamps, and non-UVB compact fluorescent lamps for *Uromastyx yemenensis* vivarium. (C) Shade method using 6% UVB compact fluorescent lamp and halogen reflector, both above mesh, for gargoyle gecko (*Rhacodactylus auriculatus*) vivarium. (D) Sunbeam method using 150W PAR38 flood UVB metal halide with PAR38 halogen floodlamp and non-UVB metal halide for chuckwalla (*Sauromalus ater*) vivarium. (A, C, and D, Courtesy of Frances M. Baines; B, courtesy of M.J. Versweyveld and Frances M. Baines.)

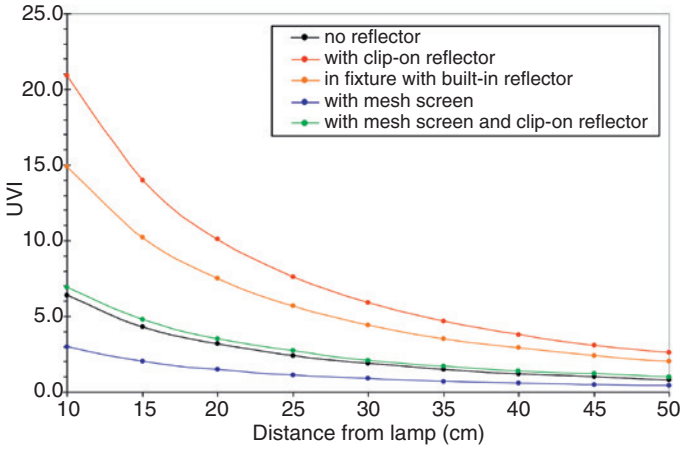

FIG 17.5 The effect of reflectors and mesh upon UV irradiance in the vivarium. UV index recordings made at increasing distances directly beneath the midpoint of a T5-HO UVB fluorescent tube (Arcadia T5 D3+ 12%UVB 24 watt lamp; Arcadia Products plc., Redhill, UK). When the tube was fitted with a clip-on aluminum reflector (Arcadia T5 Reflector; Arcadia Products plc., Redhill, UK) readings increased by 218%. Mounting the tube in a fixture with an integral aluminum reflector (Sunblaster T5 fixture; FHD Europe, Tyne & Wear, UK) increased readings by 138%. Placing a thick flyscreen mesh vivarium screen (Komodo screen top cover; Happy Pet Products Ltd., Syston, UK) under the tube reduced output by 52%. However, use of the clip-on reflector counteracted the effect of the screen. (Courtesy of Frances M. Baines and Lara M. Cusack.)

under the brand name ZooMed Digital UV Index Radiometer (ZooMed Laboratories Inc., San Luis Obispo, CA). The sensitivity response of this meter follows the action spectrum for vitamin D_3 synthesis fairly closely, making this meter suitable for estimating UV from both sunlight and lamps. Cheap "sun-smart" UV index meters should not be used; typically they do not register short wavelength UVB and are unable to give accurate readings with reptile lamps.

The Solarmeter 6.2 UVB meter is another handheld meter that has been popular for many years. This gives a readout in microwatts per square centimeter ($\mu W/cm^2$) and measures the total UVB output (from 280 nm–320 nm). However, this is a less helpful measurement when comparing the output of reptile lamps with each other and with natural sunlight, because the photobiological activity of UV is wavelength-dependent. Short-wavelength UVB is far more effective than long-wavelength UVB in enabling vitamin D synthesis—and in causing cellular damage. So if a lamp has a greater proportion of its UVB output in the shorter wavelengths, then less total UVB will be needed to have the same biologic effect as another lamp (or sunlight), which has a greater proportion of its output in the longer wavelengths. Most reptile lamps do have a significantly higher proportion of short-wavelength UVB than sunlight; total UVB readings from sunlight cannot therefore be used as a guide to suitable UVB levels from reptile lamps, because overirradiation may result.

However, the Solarmeter 6.5 has a sensitivity response weighted toward the shorter wavelengths. If any UVB lamp gives a reading of UVI 3.0, for example, with a Solarmeter 6.5 then its "strength" is likely to be similar to sunlight of UVI 3.0 regardless of the total UVB recorded.

UV index (Solarmeter 6.5), total UVB (Solarmeter 6.2), and lux meter (SkyTronic LX101-600.620) readings from individual samples of reptile lamps and natural tropical sunlight. (Numbers in brackets: UV Index/lux too high–lamp is unsuitable at this distance.) Lamps all in use for 100 hours before testing; measurements taken after 30 minutes warm-up. No mesh, glass, or plastic between lamp and meter; no reflectors used except where indicated.
Source: Frances M. Baines (unpublished data).

Table 17.1 gives examples of UVI, total UVB, and visible light (lux) meter readings from a range of lamps on sale at the time of writing, with solar readings for comparison.

Estimating the UV Requirement: the Ferguson Zone Concept. Ferguson and colleagues recorded the daily UV exposure of 15 reptile species and placed these into four sun exposure ranges or "zones," since designated as "UVB zones" or "Ferguson zones" (Fig. 17.6).[3,4] They suggested that knowledge of any species' microhabitat and basking behavior enables an estimate of its range of UV exposure, with the average daily exposure used as a suitable "midbackground" level of UV and the recorded maximum UVI used as the upper acceptable limit for the UV gradient in captivity. This concept has been used to develop a living document estimating suitable UV ranges for more than 250 species of reptiles and amphibians.[12]

Two methods of providing UVB are described. A "shade method" provides low-level "background" UV over a large proportion of the animal's enclosure, with a gradient to zero in shade (Fig. 17.4A and C). This would be suitable for shade-dwelling reptiles and occasional baskers, that is, those in Zones 1 and 2. Provision of UVI up to approximately 1.0 would seem appropriate. Fluorescent T8 UV tubes may be used if the animals will be close to the lamps; other sources may be suitable if positioned at greater distances.

A "sunbeam method" provides a higher level of UV for species known to bask (Fig. 17.4B and D). The aim is to provide UV similar to that which the animal would experience when in direct sunlight *during a typical early to midmorning period* when most reptiles bask. This higher level needs to be restricted to the basking zone ("like a sunbeam") with a gradient to zero in shade. T5-HO UV tubes fitted with an aluminum reflector, UV metal halide, and mercury vapor lamps can be used. This method would seem appropriate for reptiles in Zones 3 and 4; a maximum of UVI 7.0 at reptile level is suggested. Zone 2 (occasional baskers) in larger enclosures that can accommodate a high-output lamp would probably utilize this type of UV gradient as well, with a maximum UVI around 3.0.

Excessive UV Exposure/Nonterrestrial UVB and UVC

All guidelines to date are still very experimental. It is vital to watch the animals' responses and adjust the UV levels immediately if problems are seen. Albino and hypomelanistic animals may be at increased risk of UV-induced skin damage and cancer and likely need much lower UV levels than normally-pigmented conspecifics.

Zone	1	2	3	4	Suggested method of UVB provision
Characteristics	Crepuscular or shade dweller	Partial sun or occasional basker	Open or partial sun basker	'Mid-day' open sun basker	
Species in original study (Ferguson et al. 2010)	**Cottonmouth water moccasin** *(Agkistrodon piscivorus)* **Texas rat snake** *(Elaphe obsoleta)* **Jamaican brown anole** *(Anolis lineotopus)* **Broad-banded water snake** *(Nerodia fasciata)*	**Western ribbon snake** *(Thamnophis proximus)* **Green anole** *(Anolis carolinensis)* **Jamaican blue-pants anole** *(Anolis grahami)* **Yellow-bellied water snake** *(Nerodia erythrogaster)*	**Desert side-blotched lizard** *(Uta stansburiana stejnegeri)* **Eastern fence lizard** *(Sceloporus undulatus hyacinthinus)* **Cuban brown anole** *(Anolis sagrei)* **Texas spiny lizard** *(Sceloporus olivaceous)*	**Lesser earless lizard** *(Holbrookia maculata)* **Sagebrush lizard** *(Sceloporus graciosus)* **Northern prairie lizard** *(Sceloporus undulatus garmani)*	
UVI Zone range (all-day average)	0 - 0.7	0.7 - 1.0	1.0 - 2.6	2.6 - 3.5	**Shade Method** (Fluorescent UVB) UV Index up to approx 1.0
Maximum UVI recorded (one-off maximum)	0.6 - 1.4	1.1 - 3.0*	2.9 - 7.4	4.5 - 9.5	**Sunbeam Method** (Mercury vapour, metal halide or T5-HO Fluorescent UVB) UV Index up to approx. 7.0
Species typical of Zone commonly held in captivity	**Leopard gecko** *(Eublepharis macularius)* **Crested gecko** *(Correlophus cilliatus)* **Corn snake** *(Pantherophis guttatus guttatus)* **Burmese python** *(Python bivittatus)*	**Redfooted tortoise** *(Geochelone carbonaria)* **Monkey-tailed skink** *(Corucia zebrata)* **Chinese water dragon** *(Physignathus cocincinus)* **Boa constrictor** *(Boa constrictor)*	**Bearded dragon** *(Pogona vitticeps)* **Spur-thighed tortoise** *(Testudo graeca)* **Red-eared slider** *(Trachemys scripta elegans)* **Standing's Day Gecko** *(Phelsuma standingi)*	**Saharan Uromastyx** *(Uromastyx geyri)* **Chuckwalla** *(Sauromalus ater)* **Rhinoceros iguana** *(Cyclura comuta cornuta)* (NB: shade is vital even for these)	* Zone 2 reptiles in a larger enclosure would probably utilise gentle "sunbeam" UVB up to approx. UVI 3.0

FIG 17.6 UV index estimates based on the Ferguson zones. The original 15 species of reptiles studied in their natural habitat in Jamaica and south and west United States were allocated to one of four zones according to their basking behavior and recorded UV range. Other species, such as the examples given, may also be assigned to these zones based upon their known basking behavior, and this also acts as a guide as to choice of shade or sunbeam methods of UV provision. (Modified from Baines et al., 2016.)[12]

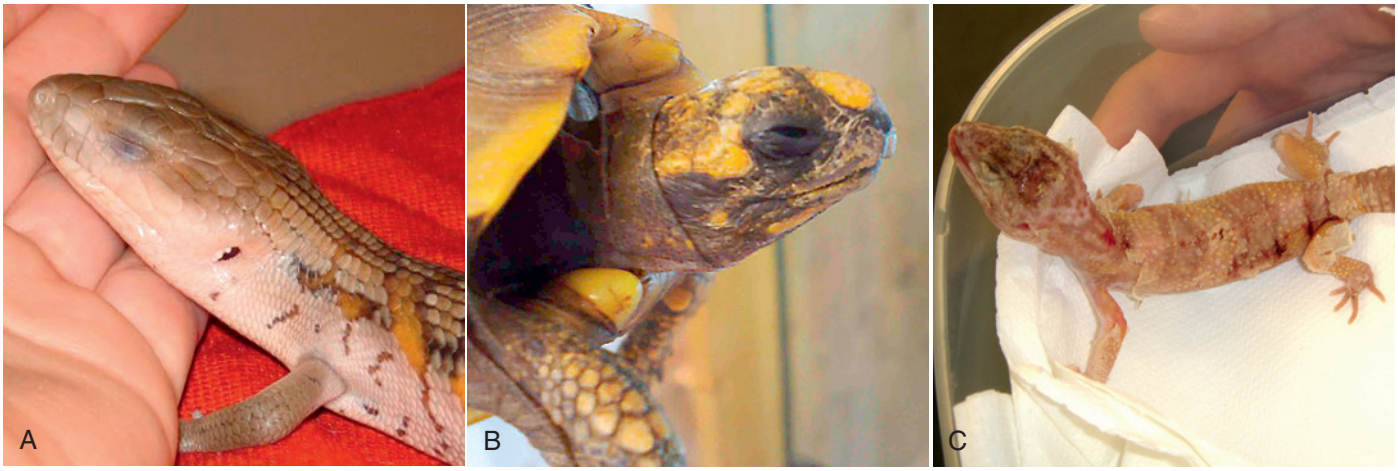

FIG 17.7 Effects of hazardous, abnormally short-wavelength UVB from "problem" UV lamps marketed in 2006 to 2007. (A) Juvenile blue-tongue skink (*Tiliqua scincoides intermedia*) with photo-kerato-conjunctivitis. (Courtesy of A. Murphree.) (B) Yellow-footed tortoise (*Chelonoidis denticulata*) with photo-kerato-conjunctivitis. (Courtesy of M. Buono.) (C) Leopard gecko (*Eublepharis macularius*) hatchling with very severe UV "burns," which proved fatal. (Courtesy of M. Buono.)

VetBooks.ir

A few brands of reptile lamps, found to emit hazardous, very short wavelength UVB and UVC, have caused photo-kerato-conjunctivitis, severe photo-dermatitis, burns, and death in a significant number of cases[13] (Fig. 17.7). These were withdrawn from sale but similar products may inadvertently be marketed. In mild cases, recovery is spontaneous following removal of the lamp.

Excessive doses of "solar" UVB and UVA can also result in eye and skin damage and, in mammals, can lead to the formation of skin cancers. Squamous cell carcinomas have been reported in captive reptiles, but their association with use of artificial UV lighting is, as yet, undetermined.[14]

Disinfection

Craig J-G. Hunt

Disinfection is an essential tool to help provide a healthy environment for amphibians and reptiles in the home environment and veterinary clinic by helping to reduce pathogen loads, disease transmission, and postoperative infections. Although often used interchangeably, cleaning, disinfecting, and sterilizing are not the same. Cleaning refers to the physical act of removing organic matter and solid debris (dirt, grease, feces, body fluids, etc.) and must always precede disinfection and sterilization in order to eliminate infectious microorganisms.[1] Disinfection reduces the pathogen load but does not eliminate it; a properly disinfected surface may still harbor a low level of potentially pathogenic bacteria, fungi, and viruses, but the pathogen level is usually so low as to not cause problems for otherwise healthy inhabitants.[2] Sterilization, as opposed to simple cleaning or disinfecting, kills all life (bacteria, fungi, and viruses). Exposure to steam at high pressures and certain chemicals such as ethylene oxide gas, peroxide, or formalin may be used. These methods require special equipment and safety considerations.

TECHNIQUES AND PRODUCTS

Disinfection techniques differ depending on specific needs. Maintenance of hygiene in a single, private-home cage versus a large breeding colony, pet store, or quarantine facility can vary dramatically. Veterinarians must properly advise clients with specific instructions for specific needs. Many disinfectants are on the market, and choosing the right one can be confusing. One must take the time to read labels to choose the right disinfectant and to use appropriate personal protection equipment such as gloves, aprons, and masks. In choosing a disinfectant, one should keep in mind that it should be safe, easy to use and effective against target pathogens, be fast acting, and have predictable risk to animals in the vivarium and not leave toxic residues. More than one disinfectant may be needed to kill all target organsisms.

Good housekeeping is the best ally against disease. Cleaning and disinfecting on a scheduled basis prevents the buildup of potential pathogens and reduces the spread of disease. Few disinfectants work effectively in the presence of organic debris (blood, feces, and urine), therefore thorough cleaning with a mild detergent followed by a thorough rinse in hot water before disinfection is essential. Dish soaps work well because they are easily rinsed and generally effective against grease. Washing should be performed in a dedicated area away from food preparation areas, and disposable gloves should be worn as a minumim.

Disinfectants should be mixed following the manufacturer's directions. Too dilute a concentration is ineffective, and too strong may be toxic, hard to rinse, and expensive.

Some disinfectants may not be compatible when mixed; ammonia and bleach for example can produce toxic, potentially lethal fumes. Some plastics and rubber may retain chemicals such as disinfectants, and if they are not thoroughly rinsed and soaked, can leech out back into an animal's environment, water, or substrate with potentially toxic effects. Stoskopf[3] reported a case of iodine toxicity, resulting in the death of several individuals in a group of red and black poison arrow frogs (*Dendrobates histrionicus sylvaticus*), which had been temporarily housed in styrene plastic containers previously disinfected with povidone iodine solution.

There may be individual variation in tolerance to disinfectants and particular care should be exercised when using disinfectants in different species. For example, two red-bellied short-necked turtles (*Emydura subglobosa*) developed partial flaccid paralysis and death when bathed for 45 minutes in a 0.024% clorhexidine solution.[4] In one study a 0.75% chlorhexidine solution used as presurgical skin preparation in African clawed frogs (*Xenopus laevis*) was associated with erythema, skin ulceration, and death in some individuals, whereas 0.5% povidone-iodine was associated with minimal reaction.[5]

Ammonia and bleach are both excellent, inexpensive, and readily available disinfectants. Ammonia can be used undiluted (full strength), and bleach should be diluted to a working concentration of 1% to 5% (1:50 to 1:10 dilution).[6] Both of these solutions are adequate to kill most common pathogens. Contact time is the key to effectiveness, and items should be soaked for a minimum of 5 to 30 minutes depending on the pathogen(s) of concern and which disinfectant is used (Table 18.1). Placement of disinfectants in spray bottles is an excellent way to disperse the material. Some disinfectatants should be rinsed following application to prevent toxicity and/or damage to treated surfaces and should subsequently be allowed to air dry. Ammonia can be rinsed with water, and chlorine bleach can be neutralized with the addition of a dechlorinator to the rinse water or with placement of the items in direct sunlight for a few hours, which deactivates the chlorine. Other disinfectants may have residual activity and are preferably not rinsed for optimal effect.

Extra bowls and cages allow rotation of items through this cleaning process, with minimal stress to the occupants. Substrates that cannot be effectively cleaned, such as paper towel, aspen, soil, and coco bedding, should be replaced when soiled. Porous items such as wood may be impossible to disinfect and may be best discarded, preferably by incineration, in quarantine facilities or in the event of a disease outbreak.

Nine broad categories of disinfectants exist. Each has a different spectrum of activity, advantages, and disadvantages, and each is used for a variety of applications (see Table 18.1).

In addition to disinfection of enclosures, food bowls, and furnishings, good hand hygiene is extremely important in preventing spread of potential pathogens between animals and between animals and humans (see also Chapter 19). In one study, less than half of the respondents

VetBooks.ir

TABLE 18.1 Characteristics of Common Disinfectants

Type	Examples	Dilutions	Spectrum of Activity	Comments	Common Uses	Contact Time	Mode of Action
Iodophore solutions	Betadine Povidine-iodine Pevidine Tamodine	10%–100% solution	B+/-, (s), tb, m, (f), ev, nev	Inactivated by organic debris and alcohol. Stains skin and porous material.	Wound antiseptic, preoperative scrubs	1–5 min depending on concentration used.	Denature proteins and disrupt nucleic acids
Chlorines	Sodium hypochlorite Bleach	2%–10% solution	B+/-, (s), tb, m, (f), ev, nev	Corrosive, irritant, fumes irritant to mucous membranes. Must be rinsed well. Inactivated by organic debris, high water ph, and UV light. Inactivated by some soaps.	Hard surfaces	10 min	Denature proteins
Chlorhexidine	Nolvasan Chlorhexiderm Hibitane Savlon Virosan	0.5%–2% solution	B+(-), m, (f), (ev), (nev) (not effective vs. *Pseudomonas spp.*)	Not inhibited by organic matter or alcohol. May be affected by alkaline ph. Generally safe when in contact with animal but potentially toxic in baths, especially to amphibians.	Instruments, cages, and all hard surfaces. Preoperative scrub; may not be suitable for amphibians	10 min	Alter cell membrane permeability
Quaternary ammonium compounds	Roccal-d Parvosol Disintegrator Ark-klens Anistel F10 (combined with a biguanide) Benzalkonium chloride	0.5%–1%	B+/-, (s), (tb), (m), (f), (ev), (nev) (may not be effective vs. *Pseudomonas spp.*)	Inhibited by organic matter. Inactivated by soaps. Poor activity in hard water. Can be toxic to amphibians. F10 has been used in some amphibians and appears safe in those species.[9,10,11]	Instruments, rubber equipment, and hard surfaces. Used as bath and aerosol in some species to treat environment with animals in situ	5–10 min	Denature proteins, disrupt cell membrane, inactivate enzymes
Alcohols	Ethyl alcohol Isopropyl alcohol	70%–90%	B+/-, (s), tb, (f), ev, (nev)	Good skin antiseptic. Inactivated by organic matter. Fumes may be irritating.	Instruments and skin	20 min	Cell lysis, precipitates proteins, and denatures lipids
Phenolic compounds	Lysol Synphenol-3	Follow data sheet	B+(-), tb, f, (ev), (nev)	Not inactivated by organic material. Irritating and corrosive to skin; must be rinsed well. Potentially toxic to reptiles and amphibians.	Hard surfaces, floors, foot baths, laundry rinse.	10 min	Alter cell membrane permeability and denature proteins
Aldehydes: glutaraldehyde, formaldehyde	(Formula h)	Follow data sheet	B+/-, s, (tb), m, f, ev, nev	Not inactivated by organic material. Corrosive, toxic, and irritating to the eyes, skin, and respiratory tract. Toxic to humans/animals.	Endoscopy equipment, empty cages, and furnishings. A fixative for electron microscopy.	20 min	Denature proteins and alkylate nucleic acids
Peroxide	Hydrogen peroxide, peroxygen compounds	3%–6%	B+/-, (s), tb, (f), ev, nev	Toxic gases form when in contact with chlorine and bi-sulfites. Dilute always by adding acid to water. Stable and effective when used on inanimate surfaces. Breaks down very quickly when contaminated with impurities.	Endoscopy equipment instruments and used to fog rooms	10–30 mins	Denature protein and lipids

B = bacteria, s = bacterial spores, tb = mycobacteria, m= mycoplasma, f=fungi, ev = enveloped viruses, nev = nonenveloped viruses; parentheses indicate partial effectiveness.
Data from references 1, 2, 8, and 12.

VetBooks.ir

(76 of 182 [41.7%]) reported washing their hands regularly between handling patients.[7] Environmental contamination is known to be an important factor in the transmission of hospital-borne infections and surfaces with regular hand contact are most at risk of contamination.[6] Alcohol-based hand rubs remain the initial choice for hand hygiene in human medicine, unless the hands are visibly contaminated with dirt and organic material, in which case liquid soap and water is recommended.[8]

Glutaraldehyde-based disinfectants are commonly used to sterilize instruments such as endoscopes that may not be easily or safely sterilized using heat or steam-based protocols; a 2% solution used for a maximum of 30 minutes is recommended.

Quarantine

Sam Rivera

Quarantine is defined as the period in which a new arrival to a collection is kept isolated for observation, habituation to its new environment, disease testing, and subsequent treatment or relocation if required. The inadvertent introduction of an infectious pathogen into an established reptile collection can have devastating consequences, both emotional and financial due to associated animal disease and loss. The goals of quarantine are to prevent the introduction of infectious diseases into an established collection, provide a recovery period from shipment, and allow an animal the opportunity to adapt to new husbandry procedures and protocols with minimal stress. Additionally, it has been well-documented that transport and exposure to a novel environment can be stressful and may result in animals being both more susceptible to, and more likely to, shed infectious agents. Therefore it is important to separate newly acquired animals from the established collection during this quarantine period to mitigate disease transmission.[1,2]

Traditionally quarantine has been defined as a period of time to isolate a newly acquired animal from an established collection. The parameters of this quarantine period were based on the origin of the animal (captive-born vs wild-caught) and/or resources available at each individual facility. The current concept of quarantine has evolved, however, and the principles of disease risk assessment and management are now specifically tailored for both the species involved and the individual institution. The inherent goals are to optimize the resources available to properly isolate new animals while minimizing risk to the established collection.[3,4]

Disease risk assessment requires having an intimate knowledge of the new arrival's previous environment and health history, as well as that of the collection of origin. In many cases, performing a thorough disease risk assessment may allow for modifications in the quarantine period, resulting in reduced labor cost and ease of transition.[4] Compared with a traditional quarantine, the disease risk assessment approach can be more efficient and effective. With this approach, if a new animal originates from an institution that can provide detailed medical records for review prior to acquisition then modifications to a traditional quarantine may be permissible.[3] In contrast, when acquiring animals with an unknown health history, a traditional quarantine becomes an important tool to protect the health of the individual animal and the collection animals at the receiving institution.

DISEASE RISK ASSESSMENT

The goals of disease risk assessment are to estimate presence, exposure, and consequences of introducing an infectious disease of concern.[5–7] Reviewing medical and pathology records from both the sending and receiving institutions is a crucial part of assessing the risk of disease presence and potential for exposure. A disease risk assessment is a method by which the likelihood and consequences of an adverse effect are calculated.[5,6] In the case of quarantine, the most devastating consequences would involve the introduction of an infectious disease agent with high morbidity/mortality to a naive or healthy population.

A proper disease risk assessment involves reviewing current knowledge about the diseases of concern, reviewing medical records from the sending institution regarding both the animal in question and the relevant collection, reviewing pertinent historical data of both the animal and collections involved, and finally reviewing important natural history information.

To complete such a disease risk assessment, four interconnected steps must be considered and performed. These include (1) hazard identification, (2) risk assessment, (3) risk management, and (4) risk communication.[5–7] For hazard identification, diseases of concern must be identified. This is accomplished by performing a thorough review of the medical history of the individual animal to be acquired and the original collection/source. In many zoological collections, comprehensive preventive medicine and pathology programs can provide essential information about the presence of diseases of concern. This identification of hazards, or diseases of concern, should start with consideration of the species involved and the diseases to which those species may be particularly susceptible. Table 19.1 lists important diseases per taxa that should be considered when performing the disease risk assessment. This list is dynamic, and recent literature should be reviewed on a regular basis to stay current on the ever-increasing body of knowledge regarding infectious diseases in reptiles and amphibians. It is also important to review the animal's history regarding temperament, nutrition, and enclosure requirements to identify potential noninfectious hazards prior to acquiring the animal.

Risk management helps to develop and implement policies and procedures that decrease the likelihood of specific diseases being introduced into an established collection. These actions may include refusal to accept an animal, extending the quarantine time period, additional disease testing, euthanasia of an animal based on results or necessity, or acceptance of an animal if the disease in question is already present in the collection. It is arguable that the risk management step is the most important component of the disease risk assessment process, because it integrates the identification of a specific pathogen with the actions needed to minimize its introduction into a naive collection.[6,7] Risk communication involves keeping all relevant individuals and departments informed and updated on the progress of the disease risk assessment and the plans and outcomes of the actions taken.

QUARANTINE DURATION

The results of the disease risk assessment are then utilized to determine the length of the quarantine period and requirements for specific infectious disease testing. An animal with no exposure to a disease of concern could potentially bypass a lengthy quarantine period and enter the collection after a shorter acclimation and observation period. The

length of the quarantine period can be difficult to determine when the health history is unknown. Currently, at Zoo Atlanta, reptiles originating from unknown sources and/or suspected to be wild caught are quarantined for a minimum of 90 days. This period overlaps with or exceeds the incubation period of the majority of pathogens of concern, although there are an ever-increasing number of novel pathogens being identified for which we have little or no epidemiological information. Reptiles arriving from known institutions with well-documented health history and without hazards identified during the disease risk assessment may have a quarantine period as short as 14 days.

During quarantine, there are some important principles to be followed. The space allocated for quarantine should be separate from the established collection, ideally in a separate building with a separate air-handling system. The greater the distance, the less likely a disease agent may be transmitted or transported by fomites. Quarantine care and husbandry routines must be completed in a manner that minimizes cross-contamination within the established collection. In the ideal world, the person taking care of quarantined animals is not the same person taking care of the established collection, but this may not always be possible. Alternatives may include providing hands-on care on alternate days or caring for quarantined animals after working with the animals in the established collection.

Animals in quarantine must be housed in an enclosure that meets their husbandry needs with regard to size, thermal gradient, hiding areas, and climbing structures balanced with ease of cleaning and disinfection (Fig. 19.1). Setting up a quarantine enclosure, which is based on a good understanding of the animal's natural history, minimizes stress and eases the transition period. Paper makes an ideal substrate for quarantine purposes because it can be easily replaced, is relatively inexpensive, and allows for observation and collection of fecal samples for analysis. Porous surfaces should be avoided, because they are difficult to clean and disinfect, but if they are used they should be disposable. Dedicated tools and equipment should be designated for quarantine use only and should be cleaned and disinfected on a regular basis during the quarantine period (Fig. 19.2). Adequate disinfection of quarantine space, tools, and equipment is paramount to minimize disease transmission (see Chapter 18).

FIG 19.1 A newly arrived spiny-tailed skink (*Egernia epsisolus*). The animal is housed in an enclosure adequate for its size. Note that all cage furniture is disposable or easily disinfected, and newspaper is used as a substrate during this quarantine period. (Courtesy of Stephanie Earhart, Zoo Atlanta.)

QUARANTINE EVALUATION

When an animal arrives into quarantine a thorough physical examination should be performed as soon as possible. Record the entry weight, body condition score, and any distinguishing external characteristics (i.e., scars, missing digits, shell notches). If not already present, some form of permanent identification, such as microchip placement, should be established. Photographs of individuals are an easy and convenient way to identify animals when dealing with large groups. Chelonians can be temporarily identified by painting a number on the shell.

During quarantine note the animal's behavior and demeanor, appetite, defecation frequency, and fecal consistency. Any deviation from these normal baseline observations may be an indication of illness and may require further diagnostic investigation. Abnormal clinical signs that should alert the clinician that something is wrong include vomiting/regurgitation, diarrhea, anorexia, weight loss, dysecdysis, lethargy, lameness or abnormal locomotion, and dehydration. If problems are identified during quarantine, quarantine duration may need to be extended to accommodate for treatments or diagnostics to be performed and results obtained.

Screening for infectious agents, especially if the health history is unknown, is critical to the goals of quarantine.[1] Intestinal parasites, while common in some species, must be monitored and controlled in many cases. Certain parasites such as oxyurids and *Nyctotherus* sp. can be commensal organisms and under normal circumstances

VetBooks.ir

FIG 19.2 The quarantine area should have a dedicated set of tools that are easily disinfected and kept separate from the tools used for the established animal collection. (Courtesy of Stephanie Earhart, Zoo Atlanta.)

are nonpathogenic. On the other hand, direct life-cycle ascarids and strongyles can be pathogenic, and an attempt should be made to eliminate infestation or keep the parasite load as low as possible. Keep in mind that reptiles kept on the same substrate, especially when housed in naturalistic exhibits, will have an increased exposure to higher parasite concentrations in their environment that can be extremely detrimental to their health. Other parasitic infections such as cryptosporidiosis, intranuclear coccidiosis, and amoebiasis must be kept from entering the collection. Screening for these agents requires molecular techniques such as a polymerase chain reaction (PCR) test (*Cryptosporidium* sp. and intranuclear coccidiosis) or frequent fecal examinations and special stains (amoeba). The decision to test for a specific parasite is largely based on the results of the disease risk assessment.

Serology screening for infectious diseases can be challenging due to the limited availability and poor reliability. Serologic assays are available to screen for ophidian paramyxovirus in snakes and *Mycoplasma agassizzii* and *Mycoplasma testudineum* in chelonians. These assays if positive are indicative of infection by the pathogen, but a negative result does not exclude exposure or early infection, and the test may need to be repeated. Furthermore, cross-reactivity among closely related strains may limit their usefulness. Molecular assays, such as PCR, may be helpful but are of limited value when screening healthy animals that may not be shedding the infectious agent's nucleic acid at the time of sample collection.

All animals coming into a new collection should be screened for ectoparasites, particularly if the animal's origin is unknown. Ectoparasites such as snake mites (*Ophionyssus natricis*) can be easily missed during quarantine if the infestation is mild. Multiple attempts should be made to identify mites on both the animal and in the enclosure before the animal is released from quarantine. Ticks are common in reptiles, especially in wild-caught animals, and can pose a risk as reservoirs of infectious agents.[8,11] The African tortoise tick (*Amblyomma marmoreum*) was identified in Florida outside importation facilities where it had become established.[9] Further investigations found that at least eight premises in Florida had been infested with this tick, including reptile importation facilities, reptile breeding operations, zoos, and wildlife theme parks.[10] Studies confirmed that *A. marmoreum* was a vector of heartwater, an acute rickettsial disease of domestic and wild ruminants.[11] At Zoo Atlanta's quarantine facility, we have identified tick species found on illegally imported tortoises that were from the tortoises' countries of origin.

It is often difficult, unrealistic, or impractical to screen for every potential pathogen. In some cases, there are unknown or emerging pathogens that pose great danger to an established collection. As an example, a confiscated group of Sulawesi tortoises (*Indotestudo forstenii*) illegally imported into the United States exhibited a high mortality rate, and subsequent studies revealed a novel adenovirus.[12] These animals had been screened for the majority of commonly recognized pathogens of tortoises, and the results were negative. These tortoises either died or became severely ill shortly after being placed into quarantine, thus demonstrating the importance of establishing and adhering to a quarantine period as an effective tool to identify signs of illness and take appropriate action.

Ideally, once an animal enters quarantine, no other animals should be allowed into quarantine until these specific animals leave quarantine. However, this is not always feasible. Some institutions have an all in/all out policy where animals from different institutions are brought into quarantine around the same time and complete their quarantine period simultaneously. In cases where animals are brought into an occupied quarantine space, it is ideal to extend the quarantine period on the basis of the time the last animals arrived.

Quarantine serves a vital role in preventing the introduction of a potentially fatal infectious agent into an established collection. There is value, however, in rethinking the traditional concept of quarantine by utilizing a disease risk assessment. Such an assessment can help to design and implement an optimum plan that is tailored for each new acquisition with the benefit of maximizing resources and minimizing risk to a collection.

Snakes

Richard S. Funk and Scott J. Stahl

Snakes are among the most fascinating, beautiful, and wonderful animals inhabiting our planet. During the past 3 decades, they have steadily increased in popularity in the pet trade. An increasing variety of species is becoming available every year. The most commonly kept species include the boas, pythons, and colubrids, many of which adapt well and will readily reproduce in captivity.

In choosing a snake, clients should closely examine the individual for alertness, good body strength and muscle tone, body weight and conformation, any open wounds or scars, oral lesions, signs of respiratory disease, stool quality, and evidence of external parasites. Captive-bred animals are preferred because they originate in captivity, are generally well established and feeding, usually lack parasites, and are less likely to have the poor adaptation issues commonly associated with wild-caught snakes. Additionally, captive-breeding reduces pressures on wild populations. Many snakes are purchased through Internet sales, and, although most are healthy, the health status of some may be misrepresented, and buyers must be cautious. Legislation concerning reptile ownership exists in many jurisdictions and is constantly changing, and this may prohibit the ownership of certain species in some areas, such as large constrictors, native or endangered species, and venomous snakes. Both the keeper and the clinician must be aware of applicable regulations. See Section 15.

Newly acquired snakes should always be quarantined away from other captives in the home or facility. Ideally, a separate room or even a separate building should be used. During quarantine, the new snake is observed for normal activity, feeding, shedding, stool quality, and general health. Medical problems are identified and addressed during quarantine. A quarantined snake should be managed only after the resident snakes have been cared for, and equipment used in quarantine should be carefully disinfected and remain with the quarantined animal. See Chapter 19 for more information on quarantine.

RESTRAINT

Venomous snakes should only be handled by trained, experienced individuals using appropriate equipment (e.g., tongs, snake hooks, plastic tubes, large transparent viewing containers). The remaining discussion focuses on nonvenomous snakes (see Chapter 22 for details on handling venomous species).

The head of an aggressive snake or snake of unknown disposition should be identified and restrained before opening the transportation bag and removing the animal. In general, the head is held behind the occiput using the thumb and middle finger to support the lateral aspects of the cranium. The index finger is placed on top of the head. The other hand is used to support the serpentine body. By restraining the snake's head in this manner greater support can be given to the cranium-cervical junction, which, having only a single occiput, is more prone to dislocation with rough or inappropriate handling. Upon removal from the transportation bag, the snake should be supported using one or two hands depending upon size. The largest pythons and anacondas can exceed 5 m and 80 kg and are powerful and potentially dangerous. When dealing with large, even docile, boas and pythons, an additional handler is recommended for each meter of snake. An assessment of demeanor can usually be quickly done. A healthy individual that is permitted to wrap a coil around the handler's wrist while the head is allowed to hang down should be able to raise its head to the level of the tail. Nervous or aggressive (nonvenomous) snakes can be restrained using plexiglass tubes or in clear plastic viewing containers.

SPECIFIC HOUSING REQUIREMENTS

Snakes are quite adept at escaping from enclosures, so the first consideration for any vivarium or cage is security; it must be escape-proof when properly closed. Cages may be plastic shoe boxes, sweater boxes, modified aquaria, or homemade from wood. Commercially manufactured cages now can be purchased specifically for snakes and are typically made of fiberglass or acrylonitrate-butadiene-styrene (ABS) plastic (Fig. 20.1). Cages can be solitary or part of a rack system, where multiple plastic tubs slide in and out of openings; many professional breeders utilize rack systems (Fig. 20.2A and B). Table 20.1 lists the minimum requirements for snake caging. See Chapter 16 for more detailed information on appropriate cage sizing.

Lighting requirements for captive snakes are not as well understood as they are for lizards. However, attention to the photoperiod promotes good health and successful reproduction in snakes. Many successful breeders provide only subdued artificial lighting for their snakes and have excellent results. UVB lighting is not documented to be necessary for successful husbandry and breeding, but keepers who provide diurnal snakes access to UVB lighting report these snakes will exhibit some degree of increased activity and basking behavior.

One concern for cages kept in dim light is that snakes may not be cleaned as routinely or as thoroughly because excrement is not as easily observed. Fresh water should always be available and changed frequently. Some keepers use disposable plastic cups that fit into premolded holders in the tubs of rack systems to improve sanitation and cleaning efficiency (Fig. 20.3). Arboreal species may appreciate an elevated water bowl. Water bowls should be cleaned and disinfected at least once weekly.

Humidity varies geographically and seasonally. During the winter, when forced air heat is utilized to maintain appropriate temperatures, the drying effect (with reduced humidity) may cause problems such as dysecdysis and respiratory disease. Alternatively, too much humidity may be harmful to a desert-adapted species. Many snakes do well if the humidity is between 50% and 70%, but this must be maintained while still providing adequate ventilation, or the humidity inside a cage will rise dramatically and air quality will be adversely affected. Desert or xeric-adapted species should be maintained with less humidity than

riparian or semiaquatic species. Snakes kept in aquaria or plastic sweater boxes, with only substrate, a water bowl, and a hide, may have the essentials but are being housed more like laboratory animals rather than pets (see Fig. 20.2A and B). A recent trend is to use larger cages or *vivaria* with cage furnishings such as plants, rocks, and tree branches. Most clients feel that their snakes are more fulfilled in these environments, even though more maintenance may be necessary (Fig. 20.4). This type of vivarium provides the snake with environmental enrichment, which may help to minimize captive stress and provide more enjoyment in maintaining snakes for the keeper as well.[1]

The authors prefer a newspaper or paper substrate for hospitalized patients unless their needs dictate otherwise, such as with fossorial or aquatic species (see Fig. 20.2A and B). For clients, simple (spartan or barren) cages may also work well. But many species, especially fossorial or more sensitive species, need more attention to cage setup, including some attempt to duplicate more natural conditions. Woodland burrowers generally will not thrive in dry sand and vice versa for desert burrowing snakes. Among the most popular substrates utilized are aspen shavings or chips; they are relatively dust free, may be spot-cleaned, are inexpensive, and allow snakes traction and some burrowing ability. Aspen is a popular substrate used in rack systems. Newspaper is inexpensive but does wrinkle and fold and is less absorbent. Nonprinted paper with varying absorption abilities and specifically cut (for cage size and if desired with a cut-out for molded water cup holders) for certain rack systems are commercially available and help with efficiency and sanitation in large collections of snakes (Fig. 20.5). Pelleted and shredded paper products are available and are more absorbent than flat paper. Well thought out vivaria with naturalistic setups may utilize sand, gravel, soil, or mixtures and may include living plants.

Briefly, several different styles of caging for snakes are as follows:[2]

- *Basic enclosure setup:* One type of substrate, with a water bowl, a hide box, and perhaps with a plant or tree branch added.
- *Wet-dry enclosure setup:* Like the basic, but this type has one or two types of substrate, with a moist area and a dry area, providing a horizontal moisture gradient.

FIG 20.1 Commercially manufactured modular, stackable cages made of ABS plastic with locks placed on the horizontally sliding glass doors. Individual lighting is present within each cage. This is a private collection of rattlesnakes (*Crotalus* spp.). (Courtesy of Richard S. Funk.)

TABLE 20.1 Minimal Requirements for Snake Caging

Escape-proof with latch or lock
Easy access for cleaning, feeding, and monitoring occupant
Avoid design/materials that allow for ectoparasites or uneaten prey to hide
Easy to clean and disinfect
Appropriate substrate both for snake's needs and for serviceability
Hide box or shelter(s)
Constructed to prevent water or feces absorption
Appropriate lighting, ventilation, and humidity
Large enough to accommodate the snake and allow some activity
With multiple captives, uniform or modular cages are conducive to good husbandry (see Figs. 20.1 and 20.2A and B)

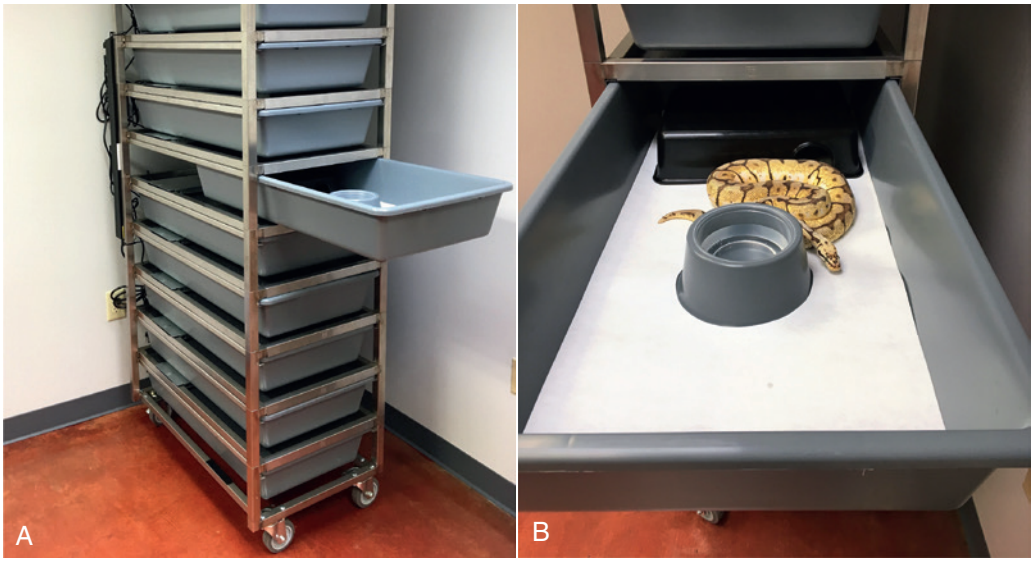

FIG 20.2 (A) Commercially produced rack systems are available for housing snakes efficiently utilizing multiple plastic tubs that slide in and out of tight openings that do not require tops (https://www.freedombreeder.com). Heat tape controlled by a thermostat is then utilized along the back of the tub system to establish a temperature gradient for the snakes. This rack is on wheels to allow mobility of the entire system. (B) A "bumblebee" color morph ball python (*Python regius*) is housed in one of the tubs showing the molded water holders and a plastic hide box provided over the heated area. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

FIG 20.3 Some keepers use disposable plastic cups that fit into pre-molded holders in the tubs of rack systems to improve sanitation and cleaning efficiency. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

FIG 20.4 Commercially manufactured, vivarium-type cage, housing a single snake. The cage is decorated for esthetics and to provide environmental enrichment for the inhabitant. (Courtesy of Richard S. Funk.)

- *Three-layer enclosure setup:* Three layers of substrate are used; from bottom upward they are gravel, sand, and then mulch. The gravel can be moistened, and a vertical moisture gradient achieved.
- *Desert enclosure setup:* Basically, a thick layer of sand for the substrate. Small water bowl, good ventilation, and in some situations, depending on species housed, occasional moisture in a small focal area.
- *Swamp tea setup:* Rarely used, primarily for swamp snakes, with a dilute solution of tea for the water environment.
- *Natural setups and outdoor enclosures:* Indoor vivaria are often naturalistic and esthetically pleasing, but they must also be functional.

FIG 20.5 Nonprinted paper with varying absorption abilities and specifically pre-cut (for cage size and if desired with a cut-out for molded water cup holders) for certain rack systems are commercially available and help with efficiency and sanitation in large snake collections. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

Unfortunately, difficulty in maintaining these enclosures often relates to their degree of complexity.

Outdoor enclosures can be rewarding, as they allow the snake to experience a true natural environment, but the environment must be similar to their native environment. However, being housed outside has inherent risks that must be avoided. The enclosure must be escape-, vermin-, and vandal-proof, and meeting these requirements can be challenging. See Section 3 for more information on cage setups.

THERMOREGULATION

Snakes, like other reptiles, are ectotherms. In a captive setting, providing a thermal gradient to allow the snake to move in and out of preferred temperature zones (similar to the temperatures they would experience in the wild) will allow proper thermoregulation. A variety of commercially available products exist to give the herpetoculturist an opportunity to provide such a regimen. Heat tapes are popular and effective and may be used with thermostats (Fig. 20.6). Light bulbs and hot rocks are inefficient and dangerous heat sources that and are not recommended; they may lead to thermal burns if a snake has prolonged contact. Shine provides a discussion of behavioral thermoregulation in wild diamond pythons (*Morelia s. spilotes*), describing variations in their activity based on seasonal and gender differences.[3] Both the clinician and the client must understand the thermal biology of reptiles (Fig. 20.7). Each species needs to reach its selected (or preferred) body temperature (T_s or T_p), which occurs within the range of physiologically tolerated temperatures or the thermal neutral zone (TNZ). Snakes that are ill, gravid, or digesting food often seek out

VetBooks.ir

FIG 20.6 Snakes, like other reptiles, are ectotherms. In a captive setting, providing a thermal gradient to allow the snake to move in and out of preferred temperature zones (similar to the temperatures they would experience in the wild) will allow proper thermoregulation. Sophisticated thermostats to control heat tape are available (https://www.freedom-breeder.com), with multiple features including day and night temperature control and alarm systems to warn keepers if temperatures are out of a preset temperature range. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

situations that allow them to achieve a slightly elevated body temperature. Captives thrive better when provided with a thermal gradient that incorporates the T_s for each species. Summary discussions of research on thermoregulation in snakes have been published.[4–6] Also, see Section 3 for more information on captive thermal considerations in snakes.

FIG 20.8 Adult rosy boa (*Lichanura trivirgata*) constricting its prey even though the mouse was offered already dead. (Courtesy of Richard S. Funk.)

FEEDING AND NUTRITION

All snakes are carnivorous. Some species may eat a wide variety of prey, some primarily endothermic prey, some only invertebrates, and some have specialized diets (e.g., slugs, eggs, frogs, fish, eggs, termites). Therefore it is critical for both the clinician and the client to understand the appropriate diet for a snake species (Table 20.2). One of the most common reasons for anorexia in snakes is offering the incorrect prey. Species with specialized diets are difficult to maintain and require a dedicated owner. Most pet trade species feed on captive-reared rodents, which are whole (dietarily complete) animals, therefore nutritional problems are not often seen in feeding snakes. However, rodents must be fed a nutritionally complete commercial rodent diet to be a balanced diet for snakes. Similarly, if a client is feeding insects or fish to a snake, these prey items should be fed a nutritionally sound food to improve their dietary quality before feeding them to the snake. It is preferred to feed dead rodents to snakes to avoid possible bite wounds and injury to the snake but also for humane considerations for the rodents (Fig. 20.8). Rodents can be offered fresh-killed or purchased frozen and then thawed and rewarmed just before offering to the snake. Dead prey items should be placed in the enclosure or if simulated movement is necessary, offered from long forceps or tongs instead of by hand. The "live" human hand tends to radiate more heat than the warmed prey item, and keepers are frequently bitten when feeding snakes by hand, as the snake is confused where to strike. If a snake is not feeding, the natural history and husbandry for that species should be reviewed and changes made to provide a diet, timing, and strategy for feeding that more closely resembles that in the wild. Snakes may become anorexic if appropriate environmental temperatures are not provided for the species. Additionally, it is normal for most snakes not to feed during an active shed cycle. Underlying illness could also be a cause of anorexia, and a health evaluation should be performed if other etiologies are ruled out. Frequency of meals varies with the age and species of snake. Many juvenile and adult rodent-feeding species thrive and grow well with once-weekly feedings, but babies may need two feedings per week. Very active species may need more frequent feedings. For example, garter snakes (*Thamnophis* spp.*)* fed primarily fish do poorly if fed only once weekly and must be fed more frequently. Most keepers increase the feedings for female snakes as the breeding season approaches. Many gravid female

snakes will not feed during gestation, and actively breeding males may also have reduced appetites. See Chapter 27 for a thorough discussion of nutrition in snakes.

BEHAVIOR

If the cage is opened primarily for feeding, the snake is likely to exhibit a feeding response every time the cage is opened. Sometimes snakes can be conditioned to a "feeding" experience if the keeper repeats an action at feeding time. For example, tapping on the enclosure with metal forceps (recommended to feed snakes) before feeding can train the snake that a prey item is soon to be presented. If the snake is large and potentially dangerous to the keeper, feeding it outside the cage (within another enclosure) may be safer. Many social behaviors observed in captive snakes are related to reproductive activities, and these courtship-related interactions can be quite dramatic and variable among species. Pheromones along with visual and tactile cues are often involved in these complex behaviors. During the mating season, the behavior of some snakes is completely different, sometimes becoming aggressive, and courtship, mating, and combat can occasionally result in injuries. Most clients can recognize behavioral changes in snakes as the mating season arrives, and they can track when a female is ready to oviposit or give birth. See Chapter 80 for more information on reproduction in snakes. In most circumstances, housing captive snakes singly is preferable. If housed in groups, they must be monitored closely, especially during feeding times or during the breeding season to avoid injuries or even cannibalism. For example, if two snakes attempt to swallow the same prey item, a larger snake may eventually ingest both the prey and the other snake (Fig. 20.9A and B). Before interacting with a snake, hands should be washed, especially after handling prey species such as rats and mice, or after handling predator species such as cats, ferrets, or king snakes. Otherwise, the snake may become confused and react to these odors by biting the hand in a feeding or defensive response. Having an ophiophagus (snake-eating) snake, such as a king snake (*Lampropeltis getula* or *L.californiae*), housed in an adjacent cage, or having just treated one on the same examination table, can affect the behavior of another snake likely in response to pheromone production.

BRUMATION

Brumation is the proper term for winter dormancy in reptiles (as opposed to true hibernation).[7–9] Many temperate zone snakes must be brumated to induce successful reproduction. For successful, safe brumation snakes are fed well during the summer and fall, then feeding is stopped, and the snakes can pass stool (empty the gastrointestinal tract) before the cooling cycle. The cage temperature is slowly dropped over a period of several weeks. Dropping the temperature 2.8°C (5°F) every few days for a total drop of 10°C to 14°C (20°F–25°F) "conditions" the snakes to enter the brumation period. They are maintained in the dark with water available but no food for about 3 months, then slowly the temperatures are increased again. Feeding may begin 2 to 3 weeks later. Unlike temperate colubrids, most tropical boas and pythons do not require as drastic a temperature drop. Usually a 5°C (10°F) temperature reduction suffices, and often this may only need to occur at night, and total darkness is not required. These tropical snakes are prone to respiratory or neurologic disease if kept too cool. Neonate temperate zone snakes that are not yet feeding, if in good physical condition, can be brumated, which may induce them to feed after the brumation period. No snake, regardless of age, should be brumated if it is not in good physical condition or if it is showing evidence of illness.

FIG 20.9 (A) It is recommended to feed snakes separately if they are housed together, as cannibalism may occur. A juvenile corn snake (*Pantherophis guttatus*) was presented for ingesting its cage mate (another juvenile corn snake) after prey items were offered in the same enclosure. Radiographs identified the cage mate was ingested tail first. (B) The ingested snakes head was visualized in the cranial esophagus and gently pulled out, but the ingested snake was no longer alive. Pictured here is the patient and its extracted cage mate "meal." (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

LONGEVITY

Clients frequently ask about the life expectancy of their snakes. A ball python (*Python regius*) set the longevity record at 47.5 years in the Philadelphia Zoo.[10] Table 20.3 lists longevity records for a number of commonly kept snakes, showing many snakes can potentially live a long life in captivity. Little is known about longevity in nature, but experts doubt that many snakes reach these ages in the wild. Many herpetoculturists believe that female snakes, bred repeatedly for high production, may have a shorter lifespan because of reproductive activity.

Lizards

Stephen Barten and Shane Simpson

Great advances have been made in the captive care of lizards, in part from our increased knowledge of their ecology and natural history but also due to the global dissemination of information through internet-based resources. Unfortunately, this information is not always accurate and must be critically interpreted. Keepers acquiring a new lizard species should be familiar with the natural history and any special husbandry requirements necessary for that species. Thorough research should include speaking with people who keep or have kept the species; reading reference material from as many different, reliable sources as possible; and speaking with a reptile veterinarian. Unfortunately, many acquire the lizard first and do research later, often to the detriment of the animal.

Despite advancements in the captive management of lizards, veterinarians are still frequently presented with animals suffering from medical conditions related to poor husbandry.

RESTRAINT

Lizards may need to be restrained for a number of reasons including environmental management, examination, diagnostic procedures, or therapeutic delivery. No matter the reason, the method of restraint should always be performed with care to avoid injury to both the animal and the handler. Never assume that because someone owns an animal they know how to handle it safely.

Although many captive reptiles seem calm and relaxed when handled, they are not domesticated. Therefore restraint methods should allow appropriate control with minimal stress and handling time.[1]

Small lizards may simply be caught and held in bare hands. If needed towels and blankets should be available. These can be placed over the head and/or body of the lizard to avoid being bitten or scratched, as well as to provide some comfort for the animal. Covering the head reduces light and visual stimulation, and most lizards will relax and become motionless when this is performed. In short-bodied species such as skinks, a thick sock can be used over the body to restrain the animal to allow for examination of the head and oral cavity (Fig. 21.1). Equipment such as catching poles and tongs may be required in larger, faster species, although care should be taken to avoid injury to the animal.[2] In fieldwork circumstances a fine noose has proven to be an effective method to capture lizards and could be used in a captive situation if deemed necessary and appropriate. If a large, uncooperative lizard needs to be restrained for accurate morphologic measurements, the construction of a restraining tray using Velcro straps and a plastic base may be considered.[3] Clear, plastic tubes that are more known for the handling of venomous snakes are very effective in restraining lizards for procedures such as radiology (Fig. 21.2). For the short-term restraint of small lizards, a clear ziplock bag can be used.[4] Some species, such as the eastern water dragons (*Intellagama lesuerrii* spp.), can be placed in a hypnotic-like trance when positioned on their backs, with their throat and ventral coelomic area gently stroked. This relaxed state allows for minimal procedures such radiology and ultrasonography to be performed. Once placed back in normal recumbency they return to their normal state.

The use of the ocular vasovagal response has been reported as an effective short-term method of restraint for iguanids,[5] monitors, and other large, hyperactive lizards. This method requires applying gentle pressure on the eyes (through closed eyelids) to stimulate the vagal nerve and cause a reduction in the heart rate and, through vasodilation, a subsequent drop in blood pressure. This can be achieved using digital pressure or, alternatively, soft gauze placed over the eyes and held in place with self-adherent bandage material. Pressure is applied for 30 seconds to 2 minutes to achieve the effect. Unfortunately, not all patients respond, and the technique may only allow for several minutes of restraint. If there are excessive external stimulants, such as noise and movement, this method is less successful. It can be repeated but is often less effective on subsequent applications unless a suitable time interval is allowed. The simple process of covering the eyes may also calm the animal due to a reduction of external stimuli.

In some cases, the use of physical restraint can actually be avoided all together. When radiographing small lizards, they can simply be placed in a radiolucent box for images to be taken. This is considerably less stressful for the animal and is often adequate to obtain satisfactory diagnostic images.

Another method for reducing the need to restrain and handle lizards is training (see Chapter 14). While once thought impossible, several successful training outcomes with reptiles, including lizards, have been reported.[6] Target training and visual and auditory cues can all be utilized to aid the handler.

Utilizing the ectothermic nature of reptiles may also aid in the restraint of lizards. Allowing a lizard to cool to below its preferred optimum body temperature will result in a less active animal and one that may be easier to handle. This can be achieved by handling animals in the cooler parts of the day or simply not providing any supplemental heat for a period. Animals should not be actively cooled by artificial means (e.g., placing in the refrigerator) to achieve this. Different species have particular defensive behaviors of which handlers should be aware. Iguanas and monitors are proficient at tail whipping and can deliver a nasty blow if the tail is left unrestrained. If a single person is holding such an animal the tail can be pinned gently between the holder's hip and a table while the head and body are restrained. Probably the most common defensive behavior is biting. Large lizards can cause serious

VetBooks.ir

FIG 21.1 Large skinks such as eastern blue-tongue skinks (*Tiliqua scincoides*) can be well restrained in a thick sock. This is particularly useful for allowing radiographs to be taken and for examination of the head and mouth structures. (Courtesy of Shane Simpson.)

FIG 21.3 Larger lizards, such as this eastern water dragon (*Intellagama lesueurii lesueurii*), may be adequately restrained by grasping behind the head to reduce the chances of being bitten. The pelvis and hind legs are supported in the other hand while the tail is pinned against the handler's body to prevent being whipped. (Courtesy of Shane Simpson.)

FIG 21.2 Clear plastic tubes normally used for restraining snakes can be used just as effectively to immobilize lizards, particularly small, flighty species such as this Hosmer's skink (*Egernia hosmeri*), for procedures such as radiography. (Courtesy of Shane Simpson.)

damage, so it is vital that the method of restraint minimizes this risk. The head can be controlled by holding it firmly behind the mandible with the thumb and index finger. The front feet can be controlled by holding them against the body with the remaining fingers. The rear legs can be grasped with the other hand and held against the lizard's body or tail just below the pelvis (Fig. 21.3).[7] Never reach over an iguana or other large lizard that is not being restrained, because they may bite and claw. This is particularly so in arboreal species, and it may be prudent to clip nails prior to an examination or procedure to minimize the risk of injury to the handler. Lizards do not tolerate leashes well. They do not walk to follow an owner. When the leash is tugged, the lizard usually spins becoming tangled in the leash, which often results in injury.

Care must be taken to prevent tail autotomy in species that possess this ability. These include most iguanids, skinks, geckos, and anguids but not monitors, chameleons, or agamids (refer to Chapter 9). They must never be grasped by the tail, and it is advisable to inform owners that there is a risk of tail autotomy prior to any restraint or procedure. Small geckos, such as *Phelsuma* spp., have delicate skin that can tear during handling and may best be captured with a soft net. Other geckos of the *Strophurus* genus possess a series of tail glands that can exude a sticky amber fluid. The secretion is quite pungent and can be an irritant to the eyes and mucous membranes of the handler. Some species are able to explosively eject this fluid up to 50 cm.[8] Special considerations should be taken when handling the two species of venomous lizards that are dangerous to humans, gila monsters (*Heloderma suspectum*) and beaded lizards *(Heloderma horridum*).

Regardless of the method of restraint used, lizards are best controlled with a light touch. The more pressure that is exerted, the more lizards tend to struggle. When necessary, lizards can be chemically sedated or anesthetized (see Chapters 48 and 49).

IDENTIFICATION

In both zoological collections and with private keepers, individual animals may need to be permanently identified. The appropriate method of identification will depend on many factors, including the species involved, size and temperament of the lizards, the length of time identification is required, the actual reason for the identification, and whether the lizard is in a captive situation or wild.

Photo-identification of lizards is a method of identifying animals based on their natural markings and other features present on one or more parts of the body. It is an excellent noninvasive method of identification that has become more accessible with digital cameras and imaging software. High-resolution, standardized photographs of predefined regions of the lizard can be taken and stored for future comparisons. Disadvantages for this method include excessive handling to obtain adequate photos, accuracy issues in those species in which natural markings change over time, and limited use in species that lack distinguishing marks.

A simple, cheap, and fast method of identification that is particularly useful for field situations is to use a felt-tip permanent marker or paint pen to write a number or other mark on the lizard's side. These identification markers can be seen from a distance, especially with binoculars, thus minimizing stress to the animals. The amount of marking should

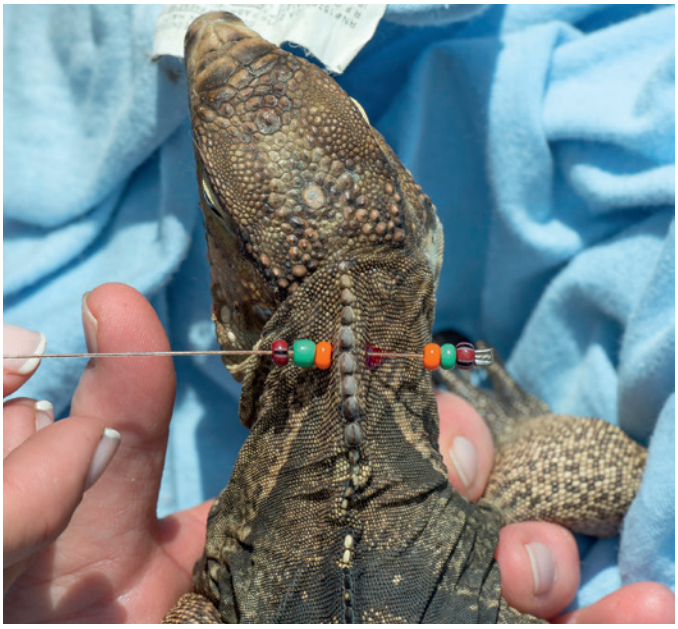

FIG 21.4 Colored beads threaded onto wire that is inserted through the nuchal crest of lizards can be used as a means of identification. By using different color combinations and repeating this on both sides of the animal, it can be easily identified from any angle, such as in this Sister Islands iguana (*Cyclura nubila caymanensis*) from Cayman Brac. (Courtesy of Stephen Barten.)

be kept to a minimum to avoid an increase in mortality from predation. Unfortunately, markings will only last until the lizard sheds its skin. Spray paint can also be used and is a great tool for mark-recapture studies estimating population size over time. If lizards are seen on subsequent days, researchers can mark them with different colored paint each day. The nontoxic, water-based paint is applied as minimally as possible but in a manner that allows the animal to be identified from any angle. Using a spray device means the animal may not have to be captured for the paint to be applied.[9] Different colored nail polishes and highly reflective paints applied to the animal's body and/or its nails have also been utilized.

The use of colored beads provides a more permanent method of marking and identification. Colored beads can be sutured into the tail musculature or crests of the neck using thin wire or nylon suture (Fig. 21.4).[10] A combination of colors and patterns can be used to create a unique code. When the neck is used, it is common for the same bead combination to be placed on either side to allow the animal to be identified from any direction. This method is more stressful for the animal, and some practice is required to perform the "beading" quickly.

Visible implant elastomers (VIE) are biologically inert solids that can be injected just beneath areas of translucent skin where they remain externally visible. Available in multiple colors, including some that fluoresce under ultraviolet light, they can be injected into different positions on the body to create an inordinate number of unique combinations. Unfortunately, these implants are not visible from a distance and so the animal must be restrained to allow accurate identification.

Visible implant alpha tags (VI Alpha Tags) are biologically inert, implantable tags with a letter and number combination printed on a fluorescent background color. When implanted under translucent skin the combination is visible when the animal is restrained.

TABLE 21.1 Microchip Implant Sites in Lizards

WSAVA Guidelines[12]	
Lizards >12.5 cm snout to vent length	Subcutaneously in the left inguinal region
Lizards <12.5 cm snout to vent length	Intracoelomic
British Veterinary Zoological Society[13]	
Lateral aspect of the left femoral area, over the quadriceps muscle, or subcutaneous on the caudal half of the left flank if too small or legs too skinny or absent	

WSAVA, World Small Animal Veterinary Association.

For times when identification is only required for a short period of time the use of bee tags has been reported.[11] These cardboard tags come in 5 colors and are numbered 1–99. Used for the identification of queen bees in a hive, the tags can easily be glued to a small lizard in appropriate locations.

The most common method of animal identification known to veterinarians is the microchip. More correctly referred to as passive integrated transponder (PIT) tags or passive radio frequency identification (RFID) tags, these small devices are used extensively for permanent identification in dogs, cats, and other animals. PIT tags can also be used to identify lizards, whether in captive or wild populations. Standardization of microchip implantation sites is essential for integrity of the system, and recommended sites have been developed (Table 21.1).

Another classic method of identification for small vertebrates is toe clipping. By clipping toes in different combinations on different limbs lizards can be identified. Although toe clipping is a permanent identification method for lizards, there is a high prevalence of lost toes in wild populations. Thus this method could lead to errors and misidentification of lizards. Loss of toes in captive populations is less likely; however, toe clipping is invasive, and in some species of lizards the procedure has had a negative impact on survivability.[14,15] In addition there is always public concern for the humane treatment of animals in research, and toe clipping is a contentious issue.[16] Other methods of lizard identification involving permanent modification of body parts include tail notching and clipping of dorsal body spines. Researchers using identification techniques that involve alteration or removal of body parts must keep the animals' welfare in mind and consider alternatives when possible. In general toe/spine clipping and notching should only be performed under a research license and cannot be recommended for clinical practice.

Other temporary identification methods used by field researchers that can be utilized in captive lizards include colored cloth tape around the tail, aluminum leg rings around the upper thigh, collars, and subcutaneous tattooing with ultraviolet fluorescent tattoo ink.[17]

SPECIFIC HOUSING REQUIREMENTS

Design of captive lizard enclosures basically can be split into two broad categories. Reptiles were once considered quite basic animals, and so traditionally spartan, easily cleaned cages were recommended and popular. Bare cages with newspaper substrate, a single branch if needed, and a water bowl were considered adequate. The advantage was ease of maintenance at the cost of stimulation and enrichment for the cage inhabitants. The other category, naturalistic, is one that has become more popular over recent years, particularly with keepers taking on

VetBooks.ir

FIG 21.5 Zoos, wildlife parks, and other establishments with reptiles on display need to have animals presented in naturalistic settings. Such enclosures need to be well planned with respect to providing the animals with all their requirements, as well as being suitable for the viewing public. (Courtesy of Shane Simpson.)

lizards as pets. These keepers want more lush, complex, naturalistic vivaria to show off their animals and provide them with a more realistic setting in which to live. Many of these enclosures become part of the decor in the home and become a talking point among friends and family. Keepers will literally spend thousands of dollars on creating mini-landscapes for their animals to enjoy. They often take great pride in not only having a healthy animal but one that is living as it would in the wild (or as close to that as possible). Naturalistic enclosures are a must for display systems at zoos and wildlife parks (Fig. 21.5). The visiting public like and demand to see animals represented as if they were taken directly out of the wild. These facilities often need to balance the wants and needs of the animal with the need for the paying public to see the animal. Although these vivaria are more aesthetically pleasing for both the owner or member of the public and the pet, they do not come without cost. Such cages are labor intensive to maintain, and, if inadequately done, bacteria and fungi build up to levels that result in illness for the cage inhabitants. Few but the most dedicated and experienced hobbyists do an adequate job of maintaining hygiene in such complex cages. If a keeper cannot properly maintain a complex vivarium, then a simpler setup is a better choice.

Cage Size and Orientation

In general, lizards need large cages to accommodate their active behavior. As another generality, most keepers provide cages that are too small or of inappropriate dimensions for the species being kept. Not all space is created equally when it comes to the highly diverse lizard group. An enclosure that is perfectly suitable for an arboreal lizard is likely to be totally unsuitable for a terrestrial one. Keepers need to keep this in mind when deciding what species they wish to keep so that appropriate space can be planned for and allocated. It has been recommended that for lizards the cage length should equal 1.5 to 2 times the total length of the lizard housed within and the cage width at least half that length.[18] These dimensions are very conservative, and others have suggested even more space, quantifying requirements as 0.2 m^2 cage space per 0.1 m total length for terrestrial lizards and 0.4 m^3 cage space per 0.1 m total length for arboreal lizards.[19] That equals a cage two times as long and one time as wide as a terrestrial lizard is long or two times as long, two times as high, and one time as wide as an arboreal lizard is long. For example, a 1 m–long iguana should have a cage measuring 2 m long, 2 m high, and 0.5 to 1 m wide, and a 2 m long one needs a cage measuring 4 m long, 2 m high, and 1 m wide, almost the size of a whole room. Few commercial cages exceed 1.2 m in length, so once a lizard reaches a length of 0.8 m, it needs a custom-built or room-sized cage. This is only one example why green iguanas (*Iguana iguana*) are not the most ideal pet for most reptile keepers. Aquariums often sold for juvenile iguanas and monitors are rarely adequate for more than a year. Chameleons need proportionately even more space, and cages varying from 1 m × 0.5 m × 0.6 m high for dwarf species to 1.3 m × 0.6 m × 1.3 m high for large species are minimum standards.[20] All these measurements are purely minimums, and attention needs to be given to how the cage furniture is arranged to make appropriate use of the space for species being housed. Additionally, the larger an enclosure the more microhabitats can be created using temperature, light, and humidity.

Terrestrial lizards need a horizontally oriented enclosure. Enclosure height is not a priority for these species, although they often use rocks and branches for climbing. These also are essential to allow the lizard to move closer to and further away from overhead heat and light sources. Arboreal lizards need height in their enclosures, and many species fail to thrive if denied the opportunity to climb at will. To achieve this, the enclosure should be fitted throughout with both vertical and horizontal climbing structures of varying widths and textures that are securely anchored to prevent falling and causing injury to the cage inhabitant. This will allow the animal to access all the environmental zones.

All lizards should be housed within a suitable enclosure, because lizards allowed to roam free in the house are subject to hypothermia, trauma, ingestion of foreign material (Fig. 21.6), and escape.

Construction Materials

A multitude of materials are available. Glass, acrylic, timber, assorted plastics, fiberglass, and wire may all be utilized. Each has its pros and cons, and the correct material is used to meet the unique husbandry needs of the species.

Keepers must be aware of these needs for each species of lizard being housed. An enclosure for a larger chameleon should be constructed of plastic-coated, wire mesh with timber or metal framing. The mesh should be no smaller than 10 mm × 10 mm square, because this provides good ventilation and protection yet is still a physical barrier. Aluminum window mesh should be avoided because there is a risk of trapping and removing toes and claws. Medium to large chameleons should not be housed in glass or plastic aquariums. First, the lizard's reflection in the glass may cause stress for these solitary animals. Second, this type of enclosure is also not ventilated well enough to provide adequate air exchange and can lead to eye, skin, and respiratory infections.[21] Semiaquatic lizards such as caiman lizards (*Dracaena* sp.) need a large bathing area that allows them to fully submerge and swim. A simple bowl of water is not sufficient for these species. As such the enclosure base needs to be constructed of glass or plastic to accommodate water and handle the humidity associated with it. Wire mesh for the enclosure walls should be avoided when housing highly stressed or active animals

VetBooks.ir

FIG 21.6 Lizards should not be allowed to roam freely outside of their enclosure. They can be inquisitive animals and will use their tongue to sample their surroundings. This can often lead to the ingestion of inappropriate items such as screws, as seen in this radiograph of an eastern water dragon (*Intellagama lesueurii lesueurii*). (Courtesy of Shane Simpson.)

FIG 21.7 A smooth knob-tailed gecko (*Nephrurus levis levis*) necropsy showing severe sand impaction in the lower regions of the intestinal tract. (Courtesy of Shane Simpson.)

like basilisks (*Basiliscus* spp.) and water dragons (*Physignathus* spp., *Intellagama* spp.). These animals often rub their noses on the walls of their enclosures in an attempt to escape. The wire mesh acts like coarse sandpaper and can inflict severe damage to the rostral area. Ideally these animals should be housed in enclosures with opaque walls and a smooth surface to minimize damage. Geckos with adhesive lamellae on their feet prefer solid surfaces to screening. Glass provides poor visual security and is a poor insulator. Many reptiles are escape artists and can squeeze through narrow cracks; thus cages must be secure, with tight-fitting lids.

Substrates

There is possibly no single subject that creates more debate amongst reptile keepers than that of substrates. With such diversity in the lizard group and with animals coming from such a broad range of habitats and lifestyles, it is not unexpected that there is controversy. As herpetoculture has grown, so has the boundless number of different substrates available in the market place. Keepers must balance the natural history requirements of their animals with the ability to adequately maintain hygiene and minimize other risks associated with using particular substrates. An ideal substrate is one that is inexpensive, aesthetically pleasing, easily cleaned, absorbent, and digestible or easily passed if swallowed. Examples of commonly used substrates include newspaper, unprinted paper sheets, outdoor or marine carpet, bark chips, assorted mulches and commercially available wood shavings, soil, ground coconut fiber (coir), vermiculite, recycled paper, and compressed wooden pellets. Like construction materials, each substrate has its good and bad qualities. Newspaper is easy to keep clean and is cheap to obtain but is not aesthetically pleasing. Carpets require regular washing and replacement. Bark made from redwood and cedar should not be used because there are anecdotal reports of the toxic aromatic oils in them causing respiratory and dermatological issues. Soils containing fertilizers should be avoided in case of accidental ingestion. Recycled paper pellets are a popular substrate because they are absorbent, contain minimal dust, and if swallowed are digestible. Additionally, from an environmental standpoint many of these products, with the exception of carpet, are compostable. Sand or a mixture of soil and sand may be used for desert species. However, color-dyed fine desert sand made for reptiles often results in discoloration of the skin.

Of greatest concern with most lizards kept on particulate substrates is the risk of accidental ingestion and gastrointestinal impaction. Cases of this have been reported in animals kept on fine bark chips, crushed corn cob, clay kitty litter, crushed walnut shell, shredded coconut husk, and calcium carbonate sands marketed as digestible among others (Fig. 21.7).[22] There are anecdotal stories of obstructions occurring in lizards housed on other sands (e.g., washed play sand and sand sold as "red desert sand"), but actual documented reports in the literature are scarce. Regardless of the particulate substrate used, there is always a risk of ingestion, especially at feeding time, or associated with pica due to mineral-deficient diets. The risk of ingestion can be minimized by feeding an appropriate, balanced diet from a large, flat food bowl or feeding the animal in a separate enclosure free from particulate substrates. Chameleons are best kept in an enclosure free of substrate or a non-particulate substrate such as outdoor or marine carpet. This will minimize the risk of ingestion of foreign material should the chameleon's tongue miss a prey item at feeding time.

Some fossorial species prefer substrates that hold their moisture and allow burrows to be made, whereas others such as sand skinks (*Scincus scincus*) prefer a looser sand mix that they can "swim" through.

Both public and private displays sometimes use natural-appearing, artificial rock substrates and walls made of concrete or gunite. These surfaces can be excessively rough and result in open sores and granulomas on the ventral surfaces of the body and feet of inhabitant lizards. If such lesions occur, case management must include smoothing out the surfaces, for instance, using an epoxy-based top coat.

Cage Furniture

The extent and type of enclosure furnishings used for lizards should keep the natural history of the species in mind. Some keepers prefer minimalistic setups that allow easy cleaning and visibility of the animal.

VetBooks.ir

Others like a more naturalistic approach that provides environmental enrichment for the animal and encourages natural behavior.

There is a vast array of natural and artificial products that can be used in enclosures. These include hides, branches, backgrounds, and plants. What and how these products are utilized will be dependent on budget, the species being kept, and the imagination of the keeper.

Many species such as the frilled lizard (*Chlamydosaurus kingii*), helmeted iguana (*Corytophanes cristatus*), and Boyd's forest dragon (*Hypsilurus boydii*) need vertical or strongly inclined branches on which to perch and become stressed and anorectic if these are not available.[23]

Live, nontoxic plants that lack spines and slick surfaces and are big enough to bear the weight of the lizard are recommended. Live plants should be potted to facilitate cleaning and easy replacement if needed. Plants with small, easily swallowed pieces should be avoided. Plants, whether live or artificial, act as cage furniture, provide shelter, and visually enhance an enclosure. Live plants have the additional benefits of adding humidity and providing egg-laying sites. An array of realistic-looking artificial plants is also commercially available.

The provision of at least one hide area and preferably two is essential to ensure ongoing health. Lizards may become stressed if they are unable to seek refuge from heat, light, and other stimulation outside the enclosure. Hide boxes can be made from a cardboard box, terra cotta pottery, cardboard tubes, PVC tubes, corrugated black plastic drainage tubes, sheets of cork bark, or the saucer that fits under a flowerpot. The latter is inverted, and a hole is cut through the top or side to allow access. Arboreal species should be provided with real or artificial plants in which to hide. Many animals may refuse to eat and become stressed if they lack a secure hiding place. If a lizard does not use a particular hiding place, a different size or shape should be tried.

An additional benefit of providing a hide box is that they can be used to create a humid microclimate within the enclosure. Certain species may benefit from this when undergoing ecdysis.

An alternative to a hide box is a Retes stack. This multilayered type of hide allows the lizard to hide and thermoregulate at the same time, as the lizard can move from the lower layers to upper (near the heat source) layers of the hide.

OUTDOOOR ENCLOSURES

Where climatic conditions allow, many lizard keepers use outdoor enclosures to take advantage of natural sunshine, humidity, and weather. Escape and exposure to potential predators is prevented by the use of wire mesh walls and ceiling, or, for some species, smooth, nonclimbable walls made of corrugated tin or similar material. These should be buried deep enough to prevent the lizard from tunneling to freedom. Nontoxic plants, climbing branches, and a water source should be utilized. A shelter to provide refuge from direct sun and inclement weather is essential.

Thermoregulation

Reptiles are ectothermic and need supplemental heat in captivity. The preferred body temperature (T_p) is a behavioral choice and is the temperature range a reptile selects when placed in a thermal gradient. The optimal body temperature (T_o) is a physiological constant that represents the temperature at which performance is maximized. T_o is necessary to optimize metabolic processes, including digestion, growth, healing, reproduction, and immune system function. T_p and T_o usually overlap.

Keepers should be aware of the difference between overhead and substrate heat sources. Radiant heat sources are the preferred method for heating most species of lizard. Overhead radiant heat sources include spot lamps (such as incandescent, mercury vapor, metal halide, and dichroic), ceramic heaters, and radiant heat panels. When radiant heat sources are used, direct contact must be prevented to avoid burns. This can be achieved through the use of wire guards. Examples of substrate heat sources include heat cables and heat mats. These must be used in accordance with the manufacturer's instructions to avoid potential fire hazards.

Heat sources should be used in conjunction with a thermostat so that the temperature in the cage can be precisely controlled. A number of models designed for use with reptile heating systems are commercially available. The simplest form is the on/off thermostat. This type simply turns off the supply of electricity when the temperature in the enclosure reaches a set point. Similarly, the electricity is turned on if the temperature gets too low. These types of thermostats have a degree of swing in the temperature since the enclosure needs to cool below the set point for the heater to be turned back on. Proportional thermostats allow much finer control over the temperature; rather than shutting off the electricity completely they adjust the flow based on the temperature at the probe. The thermostat or its probe should be positioned in close proximity to the basking area within the enclosure to control what will be the hottest area. This reduces the risk of overheating. As a consequence of this, thermostats that are able to register higher temperatures are more useful. If they cannot, then they will need to be positioned further from the basking site.

Even with a thermostat in use, temperatures within the cage must be monitored with a thermometer. Digital and analogue thermometers are available as are infrared temperature "guns." These should be positioned and used to monitor the temperatures at both the basking site and cooler end of the enclosure to gain an appreciation of the thermal gradient present.

Thermal gradients must be provided. In nature, the environment consists of multiple microenvironments with varying temperatures and humidity levels. Reptiles in the wild control their core body temperature to within a few degrees of their T_o via thermoregulation—they move all or parts of their bodies into or out of direct sunlight. A thermally complex environment is recommended for captive reptiles to allow them to adjust their body temperature behaviorally as they would in the wild. A thermal gradient on both a horizontal and vertical axis is ideal. This can be created by providing a focal hot spot on one side of the cage with a combination of substrate and radiant heat. This area should reach the T_o for the species being housed. A captive lizard can heat up in the morning by sitting in the focal hot spot and move out of the hot spot when it exceeds its T_o. Having the entire cage maintained at a uniform temperature is unnatural.

Diurnal temperature fluctuations occur between day and night in the wild, so heat sources should not be left on 24 hours a day. Daily fluctuations in temperature seem to be important for lizards. Timers can be used to turn the heaters off at night. Should temperatures drop too low at night, supplemental heat should be provided by using non-light-emitting radiant sources such as ceramic heat emitters or heat mats. The particular needs of a given species should be researched, because some require hotter or cooler temperatures (Table 21.2).

Stressed, sick, or injured reptiles need to reach their T_o to optimize immune system function. Drug uptake and distribution is influenced by temperature, and reptiles should be maintained at their T_o when receiving medications or anesthetics.

Once commonly used as a heat source, so-called "hot rocks" are inappropriate because most lizard species derive external heat from basking in the sun (radiant heat) and not from lying on rocks heated by the sun (conductive heat). Hot rocks also do not heat the air adequately to increase the ambient temperature. Hot rocks can also be dangerous because they allow direct contact with the heat source. They also have the ability to short circuit and can progressively get hotter with age,

VetBooks.ir

TABLE 21.2 Preferred Optimum Temperature Ranges for Common Captive Lizards

Common Name	Scientific Name	Preferred Optimum Temperature Range (°C/°F)		Basking Site Temperature (°C/°F)
		Day	Night	
Bearded dragons	*Pogona* sp.	29–31/84–88	17–20/63–68	35–40/95–104
Green iguanas	*Iguana iguana*	29–32/84–90	19–25/66–77	35–37/95–99
Leopard geckos	*Euphapharis macularius*	25–29/77–84	18–24/64–75	31–32/88–90
Crested geckos	*Correlophus ciliatus*	26–28/79–82	21–23/70–73	Not required
Chameleons (montane)	*Chamaeleo* sp.	25–29/77–84	13–19/55–66	28–29/82–84
Chameleons (lowland)	*Chamaeleo* sp.	27–29/81–84	21/70	29–35/84–95
Blue-tongue skinks	*Tiliqua* sp.	27–29/81–84	19–24/66–75	32–35/90–95
Monitors	*Varanus* sp	29–31/84–88	23–26/73–79	40–45/104–113
Tegus	*Tupinambis* sp.	27–30/27–86	21–26/70–79	39–42/102–108

FIG 21.8 The surface of a hot rock can become extremely hot and lead to serious burns as seen in this western blue-tongue lizard (*Tiliqua occipitalis*). (Courtesy of James Haberfield.)

resulting in dangerous surface temperatures. This can lead to severe burns when lizards come in contact with these hot spots (Fig. 21.8) (see Chapter 16).

Lighting

The full spectrum of natural light, specifically the ultraviolet wavelengths (UV), is important for vitamin D synthesis and calcium metabolism in diurnal lizards that do not eat vertebrate prey (see Chapter 17).

No artificial UV source matches the sun, but certain precautions must be taken before exposing captive lizards to direct sunlight. First, window glass filters out UV rays, so sunlight through a window is of no benefit. A reptile in a glass cage should never be placed in direct sunlight, or overheating and death may occur. Reptiles should be in a screen or mesh cage to allow sunlight to enter, but at the same time prevent the escape of the lizard. Part of this enclosure must be shaded with an overhang or plants to allow the animal to get out of direct sun. Basking outside should not be allowed if the ambient temperature is excessively high or low. Even 15 to 30 minutes of direct sunlight a week can be quite beneficial.

A number of artificial UVB light sources for reptiles are commercially available. Traditionally, fluorescent tubes have been used but other lamps such as mercury vapor and metal halide bulbs that provide UVB and heat in a single bulb are excellent alternatives in the right enclosure. These latter lamps get very hot and must be used with caution and only with larger lizards.

There should never be glass or plastic between a UV light source and the reptile because it will filter out the beneficial UV rays. Follow manufacturer recommendations for distance between the lamp and the reptile and how frequently to replace the bulb.

Caution should be taken to avoid human exposure or eye contact with the UV rays because these have been associated with skin cancer and cataract formation.[24,25] Artificial UV light sources should mimic natural photoperiods and be turned off at night.

Artificial light sources cannot replace natural sunlight, and reptiles with access to the sun in outdoor enclosures, even on a screen porch or patio, invariably have better growth, health, behavior, reproduction, and longevity than those kept exclusively indoors.

With advances in technology, LED (light-emitting diode) products made for the reptile hobby are entering the market. These LED lights can provide an energy-efficient and economical method of providing visible light in an enclosure. They do not provide any additional heat. At the time of this writing, few if any provide UV light, and they should not be relied upon as a UVB source. However, as the technology advances and costs come down, UVB-emitting LEDs are likely to become available in the future.

WATER PROVISION, HUMIDITY, AND OSMOREGULATION

Pseudomonas spp. bacteria grow rapidly in water bowls, so bowls should be changed and disinfected or washed in hot soapy water daily.[26] Alternatively, using disposable plastic water bowls is another way of maintaining hygiene in large collections. Arboreal species, such as Old World chameleons, geckos, and anoles, only lap dew from leaves. These species need daily misting of the cage or a drip system.

Tap water usually is adequate, but filtered or bottled water might be used where the tap water quality is in question. Aging the water for dechlorination is generally not necessary.

Humidity is an important but often overlooked factor when keeping lizards. In general, tropical species need higher humidity and desert species lower humidity. Most species do well at humidity levels around 50%.

Low humidity levels result in skin issues such as dysecdysis, because the shed skin dries back onto the animal before it has had the opportunity to be shed. Dysecdysis is most common in winter months when humidity

VetBooks.ir

FIG 21.9 A Madagascar day gecko (*Phelsuma grandis*) with a tear in its skin over the right shoulder area. These lizards have very fragile skin, and handling them should be avoided. (Courtesy of Shane Simpson.)

FIG 21.10 Many species of lizard, such as central/inland bearded dragons (*Pogona vitticeps*), are territorial and should not be kept together. They tend to fight often, resulting in injuries to the legs and feet. Avascular necrosis often develops from these crush injuries, necessitating the amputation of the foot, leg, or tail. (Courtesy of Shane Simpson.)

in the average home can get as low as 10%. Low humidity can be corrected by placing damp sponges or clean cloths in the hide boxes or by using a so-called humidity box. This is made by cutting an access hole in the side or top of a plastic storage container and partially filling it with damp but not soaked sphagnum moss. Frequent spraying with a plant mister is also effective to maintain a higher level of humidity but is more labor intensive. Commercial fogging and misting machines for reptile enclosures are increasingly available in the pet trade. Fogging machines are best used in small enclosures, whereas misting systems are generally preferred for larger ones. Manufacturer recommendations for use should be followed. These machines can be controlled by timers. For more precise control, higher end thermostats are available that contain a channel to be used with a hygrometer probe; this triggers the mister whenever the humidity level drops below a preset level. Some misting system models can be directly plumbed into the building water supply. Room humidifiers or vaporizers may be more efficient for controlling humidity in collections with numerous cages; however, care should be taken to ensure hot steam is not directed at housed lizards. All these misting and humidity systems must be monitored for bacterial growth and should be periodically cleaned and disinfected. Decreasing ventilation to maintain humidity is inappropriate. Without adequate ventilation, high humidity and temperature can result in rapid growth of bacteria and mold. Adequate drainage must be provided to avoid flooding of enclosures.

COMMUNAL HOUSING AND HANDLING

Pet stores often display lizards for sale in crowded community enclosures, suggesting these are social animals. Additionally, dealers and breeders may encourage customers to purchase multiple animals. However, many lizard species, especially males, are highly territorial and are stressed by the presence of conspecifics.[27,28] Hormone fluctuations, and thus territoriality, are seasonal and are manifested most acutely during the breeding season.[29] Chameleons are especially territorial, and when two or more are kept together, the larger or more aggressive individual may physically attack and inflict serious wounds on the subordinate one (Fig. 21.9). Often the signs of chronic social stress are subtler where subordinate lizards are merely denied free access to food, heat sources, and hides. This results in "failure to thrive syndrome" for these subordinate cage mates. Symptoms include slow growth, emaciation, poor muscle tone, lethargy, poor coloring, and susceptibility to opportunistic infectious agents. Keepers often interpret lizards lying together as a compatible behavior; however, in nonsocial lizard species, stress is likely present, even in the absence of overt aggression. Separating the lizards to individual enclosures often solves these issues.

If providing each lizard with its own cage is not possible, then at least housing same-sized members of the same species together, with adequate resources, is acceptable. However, placing males together should always be avoided.

For these communal cages a large cage is necessary, with enough spatial complexity that lizards are able to stay out of sight of one another while still having access to heat, UV light, water, and food.

Human nature is to be enthused with pet lizards, especially newly acquired ones, and to handle them frequently. However, unless a pet lizard is tame and acclimated to captivity, this practice may cause stress and lead to anorexia.[30] In general, the relatively large species, such as iguanas and monitors, tolerate handling and are less prone to panic and flight behavior. Bearded dragons (*Pogona* spp.) and plated lizards (*Gerrhosaurus* spp.) are especially docile and easily handled. Small, high-strung species and juvenile lizards of any species are readily startled and stressed with handling. They are commonly injured by jumping and frantically trying to escape. Day geckos (*Phelsuma* spp.) have fragile skin that is torn even with gentle restraint and should not be handled (Fig. 21.10). Generally, excessive handling of lizards should be avoided. One should strive for a balance, with enough contact to train the lizard to tolerate gentle handling without stress, but not so much as to induce stress. For instance, a monitor that is never handled can become a wild, aggressive animal. Another factor to consider is that during handling, the lizard is at room temperature and humidity, away from its basking sites. Because lizards may be carriers of zoonotic diseases. Handlers should wash their hands thoroughly after interaction.

FEEDING AND NUTRITION

No other group of reptiles shows the diversity of diet that lizards do. Although some species have quite specific dietary requirements, others show more flexibility in what they will eat. Nutrition of reptiles is a complex and ever-changing topic. The guidelines listed below are only

VetBooks.ir

very basic recommendations, but please refer to Chapter 27 for more detailed information. Many keepers provide a diet based on what the lizard prefers, but, as with humans, this has no relationship to nutritional value. Diets appropriate to the biology of the species in question must be used.

Herbivores

Green iguanas are herbivorous for their entire lives and in the wild feed almost entirely on leaves of trees and vines.[31] They do not have gizzard-like stomachs and do not need grit or gravel to help digest their food. In fact, intestinal obstruction with gravel is a common problem when iguanas are kept on this substrate. Iguanas, like most herbivores, use microbial fermentation in the hindgut to digest high-fiber diets as efficiently as ruminants. However, this requires suitable environmental temperatures. Newly hatched iguanas lack the microbes necessary for hindgut fermentation and obtain them in the wild by eating the feces of adult iguanas.[32] Other species of herbivorous lizards, such as the Caicos rock iguana (*Cyclura carinata*) and Gray's monitor lizard (*Varanus olivaceus*), do undergo an ontogenetic change from a carnivorous diet as juveniles to an herbivorous diet as adults. Ground iguanas (*Cyclura* spp.), the prehensile-tailed skink (*Corucia zebrata*), spiny-tailed iguanas (*Ctenosaura* spp.), spiny-tailed lizards (*Uromastyx* spp.), and chuckwallas (*Sauromalus* spp.) are herbivores with hindgut fermentation like green iguanas and, in general, do well with similar nutritional provisions.

In captivity, herbivorous lizard diets should be based on a variety of chopped, dark green, leafy vegetables. The use of greens that contain high levels of oxalates, like spinach, or goitrogens, like kale, is controversial, but such items can be fed in moderation. Fruit should be minimized, not because it is toxic but because it dilutes the beneficial nutrients of the other ingredients. Commercial iguana diets can be used as part of a varied diet but vary in quality and palatability.[31,33] We can approximate a nutritious diet, but most formulations are based on anecdote, experience, and speculation rather than scientific feeding trials. See Chapter 27 for more details.

Insectivores

Crickets (*Acheta domestica*), like those that are readily available in pet stores, are in general overused in lizard diets. Crickets by themselves are low in protein and calcium.[34] Many pet stores do not feed the crickets before sale to reduce mess and clean up, but this practice results in less nutritional value. Commercial cricket foods are available and should be fed to the crickets for at least 4 days before their use as prey items to improve nutritional value (gut loading).[35] Nevertheless, crickets should not be more than 50% of the diet. The remainder of the diet can consist of a variety of wild-caught and captive-raised insects and other prey items, including but not limited to mealworms (*Tenebrio molitor*), king or super mealworms (*Zophobas morio*), wax worms (*Achroia grisella, Galleria mellonella*), earthworms, butterworms (*Chilecomadia moorei*), horn worms (*Manduca sexta*), phoenix worms or soldier fly larvae (*Hermetia illucens*), silk worms (*Bombyx mori*), cockroaches (including Dubia [*Blaptica dubia*], hissing [*Gromphadorhina portentosa*], and speckled [*Nauphoeta cinereal*]), flies, cicadas, grasshoppers/locusts, field crickets, stick insects, caterpillars (smooth-skinned, lacking any hairlike covering that can be irritating), and newborn pinkie mice. "Sweepings" are obtained by sweeping a butterfly net through a grassy field to collect a variety of insect life. Porch lights attract a variety of nocturnal insects. Certain insect species such as fruit fly (*Drosophila melanogaster*) and springtails (*Collembola*) can be cultured to feed to tiny or hatchling insectivorous lizards.

However, fireflies or lightning bugs (family *Lampyridae*) and some butterflies can be potentially toxic, and lizard deaths have resulted from the ingestion of a single firefly.[36] Many caterpillars with bushy, hairlike, or spikey appendages are toxic or irritating.

Multivitamin and calcium supplements may be applied to the insect prey with a salt shaker or by shaking the insects in a plastic bag with a small amount of supplement powder. Supplement particle size affects the bioavailability with smaller particle size resulting in higher blood levels. Insects groom themselves and remove this powder, so they should be offered immediately to the lizard. Young growing lizards should receive vitamin supplements once or twice a week and calcium supplements daily, and adults should receive vitamins every other week and calcium two to three times a week. Insects should be presented in a controlled manner such as a plastic tub so that the appetite can be monitored and insects are not wasted. In addition, insects such as crickets may begin to feed on the lizards themselves if left in an enclosure.

When possible, chameleons should be hand-fed. The insect may be held in front of the chameleon or may be placed in a smooth-sided bowl suspended in the climbing branches. Juvenile chameleons must be fed several times a day, and a single daily feeding suffices for adults.

Commercially prepared insectivore diets are available in a number of forms, including pelleted, powdered, dried, frozen, and canned. The formulations of the pelleted diets vary with respect to ingredients used and nutrient levels available. There is little to no regulation to control their production, ingredients, and the claims of being complete and balanced nutrition. The powdered diets are most often mixed with boiling water and allowed to set as a gel before feeding. Because data is lacking on the exact nutritional requirements for individual species of lizards, these diets may be deficient in essential nutrients and as such should be incorporated into a varied diet rather than being fed exclusively. Similarly, dried, frozen, and canned insects can be used as part of the diet should they be accepted by the animal.

Many species of lizards, particularly the agamids and skinks, are omnivorous in food preferences. These animals will readily take insects, fruit, vegetables, and meat if presented.

Many keepers are falsely led to believe that central/inland bearded dragons are predominantly insectivores as juveniles and change to predominantly herbivores as they reach adulthood. Adults should be considered as dietary generalists and opportunistic predators. Although recent research shows that free-ranging adult bearded dragons do maintain a high level of insect intake as adults, in captivity a much less active adult diet should include plant material to reduce the common occurrence of obesity and hepatic lipidosis.[37] Because of their acrodont dentition, central/inland bearded dragons, similar to other agamids and to old world chameleons, are predisposed to the development of periodontal disease (see Chapter 161). Feeding proportionally more hard-bodied insects such as cockroaches and locusts along with fibrous vegetables such as pumpkin, sweet potato, and green-leafed vegetables aids in keeping the teeth clean and avoids periodontal disease. Diets with higher fruit content increase the risk of developing periodontal disease and as such should be minimized.[38]

Carnivores

Carnivorous lizards should be fed prekilled whole prey (either thawed or fresh killed). Rodents are preferable to chicks, and chicks are preferable to fish due to more balanced nutrition and firmer stools produced. Live rodents should never be offered as a food source. Not only does this prevent rodent bites to the lizard, but it is also more humane for the prey. In many jurisdictions, it is also illegal to feed live rodents to predators. Appropriate-sized prey should be offered to prevent trauma during swallowing or subsequent impaction or regurgitation. Juveniles should be fed once or twice a week, and adults every week or two. Obesity is common in adults, and these animals should be fed smaller

VetBooks.ir

amounts and/or less frequently. Alternatively, the amount of rodents fed can be reduced and replaced with cockroaches and stick insects.

If whole rodents and chicks make up the bulk of the diet, vitamin and mineral supplementation is not necessary. Newborn pinkie mice have less total calcium than do adult mice, and calcium should be supplemented if these are used.

Other items may be offered to help reduce feeding costs, but these are less optimal than whole prey items and should always be less than 50% of the diet. These include chicken parts, ground beef, dog food, cat food, and trout food. It should be noted that none of these are designed or formulated for reptiles and should be considered nutritionally inadequate.

Nectivore

Once considered rare in captivity, nectar-eating lizard species such as the crested gecko (*Correlophus [Rhacodactylus] ciliatus*), gargoyle gecko (*Rhacodactylus auriculatus*), and New Caledonian giant gecko (*Rhacodactylus leachianus*) have exploded in popularity. Much of this stems from the fact they can be easily fed using commercially available powdered nectar and fruit diets such as Crested Gecko MRP (Repashy Ventures, Oceanside, California) and Pangea Fruit Mix With Insects (Pangea Reptile LLC, Hudsonvile, Michigan). Although insects can be supplemented into the diet, these lizards can be fed exclusively on these products.

DISINFECTION

Cages and bowls must be cleaned frequently. It is important to remove all organic waste using something such as hot, soapy water. The cage and its furniture must be rinsed thoroughly before returning a lizard to the cage. Solutions of bleach or one of many commercial disinfectants can be used periodically, after treating a sick lizard and before a new lizard is placed in a cage previously occupied by a different lizard. Keepers must wash their hands thoroughly after cleaning each cage and not transfer water bowls, uneaten food, or climbing branches between cages without disinfecting them first (see Chapter 18).

QUARANTINE

New reptiles to a collection must be kept in a separate area from the main collection until they can be appropriately monitored and screened for health problems. New arrivals should have physical examinations, recorded body weights, fecal examinations, parasite treatment, and monitoring for appetite, normal behavior, and symptoms of illness. At the very least, the owner should inspect new arrivals. The main collection should be fed and cleaned first and the quarantined animals second, with no transfer of animals, cages, food and water bowls, uneaten food items, or cage furniture between the two. Keepers must wash their hands and consider clothing changes after working with either collection to prevent the inadvertent transfer of pathogens. Ideally, different keepers should care for the two collections. The farther apart the two collections are physically, the less likely an epizootic will occur. No transfer of air should occur between the two groups. When multiple animals are quarantined, they should enter and leave the quarantine area as a group (see Chapter 19).

Venomous Species

Robert Johnson

Approximately 450 species of venomous snakes and two species of venomous lizards exist, many of which are kept in captivity. The effects of venom are sometimes categorized as neurotoxic, myotoxic, and coagulopathic, with each victim having a unique clinical picture because of the wide range of effects produced by the various venom components.[1] Venomous reptiles are kept at most zoos, at a few aquariums, and by some hobbyists. Although bites from captive animals are rare, developing, implementing, and following appropriate emergency protocols can help to minimize the likelihood of permanent disability or mortality from an accidental envenomation.

Globally, snake bites are an important public health problem in rural and developing communities, particularly in poor, tropical, and subtropical areas.[2] As many as 4.5 to 5 million snake bites occur every year, causing 2.5 million envenomations, 125,000 deaths, and perhaps three times that number of permanent disabilities.[3] In the United States in a study of calls to poison control centers on animal bites from 2001 to 2005, an annual average of 6803 calls were reportedly due to snake bites.[4] An average of five deaths occur from reptile bites each year in the United States.[5] Three families of venomous snakes are native to Australia, including Colubridae, Homalopsidae, and Elapidae. Nearly all clinically significant bites are from elapids. There are around 2000 bites each year in Australia, and an average of two deaths per annum according to Commonwealth Serum Laboratories (CSL) data (Morgan, unpublished data). The most common snakes to cause severe clinical signs and death are the Eastern brown snake (*Pseudonaja textilis* [Fig. 22.1]), Coastal taipan (*O. scutellatus*) and Mainland tiger snake (*Notechis scutatus*).

DEVELOPMENT OF EMERGENCY PROTOCOLS FOR THE MANAGEMENT OF VENOMOUS ANIMAL BITES[6]

Emergency protocols for handling venomous reptiles should be developed and implemented before the acquisition of a venomous animal or before deciding to provide veterinary services for venomous animals (Fig. 22.2). These protocols include specific plans for venomous animal escape/recovery, venomous animal bite, first-aid procedures for a venomous animal bite, and medical treatment protocols. Sources of information that may be useful in the development of these protocols include direct contact with other zoos or aquariums and the American Association of Zoos and Aquariums Resource Center (http://www.aza.org), where emergency plans developed by several zoos have been published. In addition, the Antivenom Index published and updated periodically by the American Zoo and Aquarium Association and the American Association of Poison Control Centers (https://www.aza.org/antivenom-index) lists the amount and location of available antivenom for most venomous species.

In the United States, venomous reptiles are classified as Code 1 and Code 2 animals (Table 22.1). The venom of a Code 1 animal is capable of causing death, long-term illness, or permanent disability, and the venom of a Code 2 animal is unlikely to have severe or long-lasting effects. The protocols developed must be specific for the type and number of venomous reptiles in the collection. For each protocol, contact information for responsible staff and outside consultants must be readily available. It should be emphasized that the guidelines in this chapter may not be applicable, economical, or practical for all facilities. It is recommended that a physician knowledgeable in the treatment of venomous reptile bites be consulted in the development of protocols for venomous animal bites. Once developed, these protocols should be given to authorities at the medical facility that will be responsible for treating an envenomation.

CLASSIFICATION OF VENOMOUS REPTILES

Venomous snakes occur in the following families: Viperidae, Elapidae, Lamprophiidae, Homalopsidae, and Colubridae. A revised phylogenetic classification of squamate reptiles at the family and subfamily level has been suggested.[7] There are two species of venomous lizards (Gila monster, *Heloderma suspectum,* and the beaded lizard, *H. horridum*), with no recorded human deaths occurring from bites. The multilobed venom glands are located on the lower jaws, whereas in venomous snakes the glands are in the maxillary region. Studies have also reported the presence of venom toxins in two additional lizard lineages, monitor lizards and iguanids.[8,9]

VENOMS

Venoms are key evolutionary innovations in the animal kingdom that have evolved independently in multiple taxa.[10] Venoms allow predators such as snakes, with their lack of limbs, to feed on a far wider range of prey items than would otherwise be possible. Venom is also an effective defense for an otherwise vulnerable animal. The favored terminology is "venom gland" for the venom glands of viperids, elapids, and atractaspidids, and "Duvernoy's gland" for the venom glands of all other colubrids.[11] There is strong developmental evidence that both originate from dental glands, which are present in most squamates.[12] Snake venoms are chemically complex mixtures of proteins, including peptides, polypeptides, enzymes, and glycoproteins, which together produce a variety of pharmacological activities in prey animals. Ranging from a molecular mass of 6 to 100 kD,[13] venoms may contain 30 to 100 protein toxins, with no two venoms identical.[14] Many of these proteins have enzymatic properties. The peptides in venom appear to bind to multiple receptor sites in the prey. For example, components of pit-viper venom affect almost every organ system; therefore some sources claim it is

TABLE 22.1 Classification of Venomous Reptiles in the United States

Family	Code 1	Code 2
Viperidae (Crotalinae: pit vipers)	Rattlesnake, cottonmouth, copperhead, lance-headed pit viper, Fer-de-lance, bushmaster, and Asiatic pit viper	
Viperidae (Viperinae: true vipers)	African, European, and Middle Eastern vipers	
Elapidae	Cobras, mambas, kraits, coral snakes, and most venomous snakes of Australia	
Hydrophiidae	True sea snakes	
Colubridae	Boomslang, bird or twig snake, and red-necked keelback	Brown vine snake, Amazonian vine snake, and cat-eyed snake
Laticaudidae	Sea kraits	
Atractaspididae	African and Middle East mole vipers	
Helodermatidae	Gila monster and Mexican beaded lizard	

inaccurate to label a venom according to the body system affected, that is, as a neurotoxin, hemotoxin, cardiotoxin, or myotoxin. Accordingly, the most deleterious effects are seen in the cardiovascular, hematologic, respiratory, and nervous systems.[15] Recent studies have used molecular techniques of high throughput proteomics and transcriptomics, aiming to characterize further the components of snake venom.[16]

Hemotoxic Effects

Venoms may interfere with blood clotting, either by procoagulant or anticoagulant activity. Procoagulants (prothrombin-activating enzymes, serine proteases, and PLA_2) produce disseminated intravascular coagulation (DIC) defibrination and bleeding. Anticoagulants produce anticoagulation without fibrin depletion. Bleeding may occur from the nose and gums, skin (petechiae and echymoses), intravenous catheter sites, urinary tract, gastrointestinal tract, and the intracerebral space. Thrombotic microangiopathy is a more recently recognized condition that is always associated with a venom-induced consumption coagulopathy (VICC) and is characterized by thrombocytopenia, microangiopathic hemolytic anemia, with fragmented red blood cells, and acute renal impairment.[17] Analysis of blood films reveals fragmented red blood cells (microangiopathic hemolytic anemia) and a thrombocytopenia, accompanied by a rising creatinine level (>120 mmol/L), which may lead to renal impairment or even acute renal failure requiring dialysis.

Neurotoxic Effects

Both pre- and postsynaptic neurotoxins exist. Postsynaptic neurotoxins (neurotoxic peptides "3 finger toxins") bind competitively to acetylcholine receptors. They are readily reversed by antivenom and may be reversed by physostigmine. The venom of the death adder (*Acanthophis antarcticus*) is mainly postsynaptic. Presynaptic neurotoxins (neurotoxic PLA_2) cause structural damage to nerve terminals either at the level of the cell membrane or synaptic vesicle. They respond poorly to antivenom and are found to a variable degree in all Australian elapids. The venom of the coastal taipan, *Oxyuranus scutellatus*, is mostly presynaptic (Fig. 22.3). Symptoms include a descending flaccid paralysis that initially involves the eye muscles (ptosis, diplopia, and blurred vision), followed by bulbar muscles, respiratory muscle paralysis, and limb paralysis.[17]

Myotoxic Effects

Phospholipases (PLA_2) produce rhabdomyolysis and only affect striated skeletal muscle. Symptoms include generalized muscle pain and tenderness; muscle weakness and edema; myoglobinuria, hyperkalemia, and renal failure; and local pain and tissue destruction. For example, common and abundant components of *Bothrops* spp. (Central and South American vipers) venoms are myotoxic phospholipases A2 (PLA_2) and play a major role in the pathogenesis of local tissue damage. These myotoxins are responsible for local myonecrosis, inflammation, and pain.[18]

LD_{50}

The lethal dose of venom required to kill 50% of mice injected is termed the LD_{50}. For example, the inland taipan, *Oxyuranus microlepidotus* (0.025 mg/kg), and the eastern brown snake, *P. textilis* (0.053 mg/kg),

VetBooks.ir

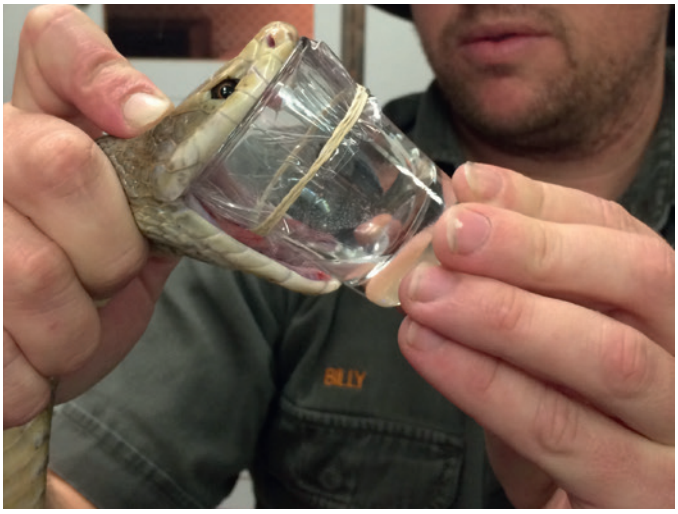

FIG 22.3 Venom collection in a Coastal taipan (*Oxyuranus scutellatus*) yields a large volume compared with many other elapids. (Courtesy of Robert Johnson.)

FIG 22.4 Snakebite on the arm of a veterinarian from an eastern brown snake (*Pseudonaja textilis*). Only a small volume of venom is delivered by the bite of this small-fanged but highly venomous snake. (Courtesy of Robert Johnson.)

deliver a much smaller volume to achieve the LD_{50} compared with the king cobra, *Ophiophagus hannah* (1.8 mg/kg), and the eastern diamond-backed rattlesnake, *Crotalus adamanteus* (11.4 mg/kg) (Australian Venom Research Unit: http://biomedicalsciences.unimelb.edu.au/departments/pharmacology/engage/avru). However, grading venomous snakes by comparing the LD_{50} is not of great benefit because many other factors determine whether a snake is termed "dangerous," for example, the volume and manner in which the venom is delivered, the fang size, and the behavior of the snake.

MEDICAL MANAGEMENT OF SNAKEBITE

Every bite is unique and depends on human factors: age, weight, sex, preexisting conditions, bite site, and first aid (time and quality); and snake factors: species, degree and number of bites, and the age and size of the snake (Fig. 22.4). Not all patients bitten will have been envenomated, and antivenom is not needed in every case. Each patient presented for treatment for a suspected snakebite should be rapidly triaged, with management of any cardiovascular or respiratory impairment taking priority. It should not be assumed that medical or nursing staff are familiar with assessing snakebite victims or recognizing symptoms. Consequently, treating staff should be instructed to monitor specific signs such as ptosis, dysarthria, weakness, diplopia, persistent bleeding from a bite site or venipuncture wound, or dark or discolored urine (myoglobinuria, hematuria).[19]

In summary, the treatment of snakebite may be divided into two components: management of tissue damage and supportive care and neutralization of the venom using antivenom. The time to onset of symptoms depends on the size and species of the snake, the number of bites, the size and health of the victim, the activity of the victim after the bite, and whether adequate first aid was administered in a timely manner (Morgan, observation). Symptoms usually develop over hours, and deaths usually occur after 24 hours. Common nonspecific symptoms are headache, abdominal pain, back pain, nausea, vomiting, and dizziness.

Snake Venom Detection Kit (SVDK)

The Snake Venom Detection Kit (SVDK; CSL, Commonwealth Serum Laboratories, Parkville, Melbourne, Australia), based on the immunoassay of venom enzymes, may assist in regions of Australia when the identification of a snake is not known and where the range of possible snakes is too broad to allow the use of monovalent antivenoms.[17] The optimal sample is a swab from the bite or urine. Blood yields unreliable results in the SVDK.

Antivenom

Any venomous snakebite should be considered a medical emergency, and antivenom is the only effective antidote for a venomous snakebite; however, in some cases antivenom administration can cause anaphylaxis and delayed serum sickness. For these reasons antivenom use is usually reserved for cases that decompensate or deteriorate despite supportive measures. Dry bites may occur, wherein no venom is injected.

Antivenoms can be classified as monovalent (when they are effective against the venom of a single species) or polyvalent (when they are effective against a range of species or several different species at the same time). Antivenom is a hyperimmune serum containing antibodies (immunoglobulin G) that bind to the venom molecules, rendering them inactive. The IgG molecule is divided into two main fragment types; the Fc is involved in mounting a cellular response to antigens and in complement fixation and two antigen-binding fragments, Fabs, which recognize and bind to foreign substances.[20] Currently in North America, the most widely used antivenom in humans is CroFab Crotalidae Polyvalent Immune Fab (Ovine) (BTG International, Inc., http://www.crofab.com). In Australia, species-specific equine IgG antivenoms are available for black snakes, tiger snakes, taipans, death adders, brown snakes, sea snakes, or polyvalent snakes. The World Health Organization maintains a list of antivenoms available on the world market (http://www.who.int/bloodproducts/snake_antivenoms/en/).

HANDLING AND TREATING VENOMOUS SNAKES IN THE VETERINARY HOSPITAL[21]

Venomous snakes should be expertly restrained for the physical examination, preferably by the keeper, wildlife rescuer, or owner and not the veterinarian or veterinary technician, leaving them free to treat the patient. It is recommended that only experienced reptile veterinarians examine and treat venomous species and that they are fully aware of

the legalities involved (Box 22.1). Veterinarians are liable for any injuries that occur under their supervision. Equipment required for the safe handling of venomous snakes includes the following: jiggers, hooks, pinning sticks, hoop bags with sewn corners, clear plastic tubes (Fig. 22.5), pads (foam rubber), secure containers, and holding facilities. If possible, it is preferable to treat venomous snakes on site or as outpatients. If hospitalization is necessary, ensure that a locked, labeled enclosure is available in a secured room. Access should be restricted to authorized and fully trained staff only. Snake hooks, jiggers, and tubes should be easily accessible. Protective eyewear and gloves should be worn when handling anesthetized or dead snakes, as envenomation may still occur. Care should be taken when dissecting the venom gland. To minimize the chance of envenomation it is often safer to decapitate the dead snake or encase the head in a crush-proof container before commencing the postmortem examination (Fig. 22.6). Place the head directly into decalcifying formalin solution.[21]

BOX 22.1 Legal Issues for Consideration When Treating Venomous Snakes[21]

- Legal responsibilities of the veterinarian should be considered when handling venomous snakes.
- Who is responsible in the event of a bite—rescuer, handler, staff, or veterinarian?
- Does the veterinary hospital have a protocol for the handling of venomous snakes?
- Has the insurer been informed that venomous snakes are handled at the veterinary hospital?
- Veterinarians treating venomous snakes should have a good understanding of the legal and licensing issues of owning or keeping exotic venomous reptiles in private collections.
- Understand and consider the legal requirements involved in possessing a venomous reptile.
- Understand and have a commitment to maintaining a safe work environment. Ensure that there is a plan for emergencies and access to a local hospital and antivenoms.
- There should be a written protocol in place for handling and for emergency snakebite.

Venomoid Snakes

Venomoid snakes are snakes that have undergone surgery involving the sectioning of the venom duct or ablation of the venom gland. This practice is viewed by most reptile veterinarians and herpetologists as a disfiguring surgery and, in many countries, is illegal and considered professional malpractice. Venomoid snakes can never be guaranteed as "de-venomed." Concerns include an incomplete, or incorrectly performed (often by nonveterinarians), surgery. It is apparent that there are considerable legal and liability issues associated with this practice. In addition, there is the subsequent risk of people being bitten by apparently venomoid snakes that may still have remnants of venom gland tissue and/or patent venom ducts. Venomoid snakes should always be regarded as venomous.

VENOMOUS ANIMAL BITE PLAN (UNITED STATES)[6]

In the United States, venomous reptiles are classified as Code 1 or Code 2. Example protocols are provided for the response to Code 1 (Box 22.2) and 2 (Box 22.3) venomous animal bites. Routine emergency drills are important to ensure that personnel are prepared and alarms are working properly. Appropriate antivenoms, if available, must be acquired, properly stored, and replaced when expired.

VENOMOUS ANIMAL ESCAPE PLAN[6]

Every facility that holds venomous reptiles must have a plan for recapturing escaped animals (Box 22.4). A well-developed plan is critical for management of escape. The plan must include procedures for managing an escape into both public and contained areas and a course of action if the animal cannot be located.

FIRST-AID PROCEDURES

Veterinarians treat venomous snakes at their own discretion and should be acutely aware of the risks involved. These notes are meant as a guide only, and the advice contained within may change with time. Veterinarians are also advised to familiarize themselves with snake identification and make their own enquiries. Veterinary hospitals should ensure that there is always a fully trained first aider in attendance when venomous snakes are being handled or treated.

FIG 22.5 Tubing a red-bellied black snake (*Pseudechis porphyriacus*) is usually a gentle and stress-free procedure for the snake and safe for the handler and veterinarian. (Courtesy of M. Wilson.)

FIG 22.6 Enclosing the head of a venomous snake in a crush-proof receptacle prior to necropsy or disposal is a safe alternative to decapitation. (Courtesy of M. Wilson.)

VetBooks.ir

BOX 22.2 Protocols for Code 1 Venomous Animal Bites

Victim

Leave area
Secure area to prevent animal escape
Activate emergency bite alarm
Notify others in area of the bite, type of animal, and whether the animal is secured
Remain calm; remove all jewelry to prevent further injury from swelling

First Assistant

Call 911; report that a venomous animal bite has occurred and give address
Call for further assistance
Ensure jewelry has been removed and keep victim calm
Administer first aid
When help arrives, ensure that the antivenom, Antivenom Index, and other reference documents accompany victim to hospital

Second Assistant

Enlist trained staff to recapture venomous animal, if necessary
Gather antivenom, AZA Antivenom Index, and other documents needed to accompany victim to hospital

BOX 22.3 Protocols for Code 2 Venomous Animal Bites

Victim

Recapture and secure animal if easily done
Leave area and close door
Request assistance from staff
Remove all jewelry to prevent swelling-associated injuries
Begin first aid

Assistant

Treat as a Code 1 venomous animal bite if victim is in severe pain or shows signs of shock or other systemic effects
If available, request an emergency medical technician; otherwise, take victim directly to a medical facility for treatment
Notify appropriate staff of injury

BOX 22.4 Example Protocols for the Recapture of Venomous Animals

Contained Escape (i.e., in a secured area)

Alert appropriate staff of the escape, including the type of animal and its location, via radio, pager, or telephone
Alert any personnel in the immediate vicinity of an animal escape
For Code 1 animals, secure the area and wait until a minimum of two trained staff members arrive before recapture is attempted
Code 2 animals may be recaptured by one trained staff person
If alone or untrained in the capture of venomous reptiles, secure the area and monitor the animal from a distance until trained staff arrives
Recapture and secure animal
Report incident to appropriate staff

Public Area Escape

Report escape to appropriate staff, including the type of animal and its location, via radio, pager, or telephone
If members of the public are present, evacuate them from area
Secure area. This may include:
  Closing doors, windows, or other escape routes
  Shutting off escalators and elevators
Recapture and secure animal
Maintain communication with appropriate staff, such as the head of visitor services, security, and other departments that need to ensure public and staff safety

Missing Venomous Animal

Report to appropriate staff that an animal is missing; include the type of animal and location of escape
Once the animal has been confirmed missing, appropriate actions are determined by:
  The species of animal
  The area involved
  The potential risk to visitors or staff

FIRST-AID PROCEDURES FOR A VENOMOUS REPTILE BITE (UNITED STATES)[6]

First aid for bites by a Code 1 animal should be administered immediately after activating the venom alarm and calling 911 (see Boxes 22.2, 22.3, and 22.5). Do not activate the venom alarm or call 911 for Code 2 animal bites unless the victim is in severe pain or shock. Previously, the Sawyer Extractor was recommended to aid in the extraction of venom from viperid and crotalid bites. The effectiveness of this device has not been proven, and its use in North America is no longer recommended, although these kits are still readily available. Apart from being ineffective there is also evidence that these devices can aggravate or facilitate tissue damage at the bite site.[22] The technique of lancing bites and sucking out venom is ineffective and may result in greater tissue damage and possible infection. The use of a tourniquet or an ice pack is contraindicated.[22] Pressure bandages are not recommended if the venom has proteolytic properties, which cause tissue necrosis. A pressure wrap is recommended for bites by sea snakes, sea kraits, or other animals with venom that has primarily cardiotoxic or neurotoxic effects. Many types of venom may cause respiratory failure; therefore maintenance of an airway is a top priority.

ELAPID SNAKEBITE (AUSTRALIA)

In regions where pressure immobilization is indicated to slow uptake of neurotoxins/hemotoxins, appropriate measures should be used.[1] A pressure bandage should be applied as soon as possible over the bite site and then around the limb from below the bite to the top of the limb (except in the case of rattlesnake or viper bites). The limb is splinted and placed in a sling if appropriate. Both pressure and immobilization must be used to reduce the rate of venom absorption and movement from the bite site. Do not wash, clean, cut, or suck the bite site. Do NOT use a tourniquet (Box 22.6).

PRESSURE/IMMOBILIZATION

Other than those from Australasia and North America and all viper species, the use of measures to reduce local venom uptake in elapid snakes is not formally agreed upon, and first aid measures used vary widely. Pressure/immobilization (PI) should be considered for envenomation by any lethally potent coagulopathic or neurotoxic species. However, pending further research, it should not be used for species known to cause serious local tissue injury.[1] A review of the treatment of snakebite in Australia has shown that PI is safe for Australasian elapid

VetBooks.ir

BOX 22.5 Snakebite First Aid (United States)

What to Do if You Are Bitten by a Snake

- Keep still and calm; do not panic.
- Call the poison center immediately by dialing the national, free Poison Help number at 1 (800) 222-1222. If the person who was bitten is having trouble breathing or losing consciousness, call 911 immediately.
- If you are in a remote location and do not have mobile phone service, ask someone to drive you to the nearest emergency medical facility. Only drive yourself as a last resort.
- Keep the part of your body that was bitten straight and at heart-level unless told otherwise by the specialist at the poison center.
- Remove all jewelry and tight clothing.
- Wash the bite with soap and water and cover the bite with a clean, dry dressing, if available, and if doing so does not cause delay.
- Being able to describe the snake to medical professionals can help them decide on the best treatment for you. Only take a photograph of the snake if you can do so from a safe distance.
- Note the time the bite happened.

What Not to Do

- DO NOT pick up, attempt to trap, or kill the snake.
- DO NOT apply a tourniquet or attempt to restrict blood flow to the affected area.
- DO NOT cut the wound.
- DO NOT attempt to suck out the venom.
- DO NOT apply heat, cold, electricity, or any substances to the wound.
- DO NOT drink alcohol or caffeinated beverages or take any drugs or medicines.

From American Association of Poison Control Centers. https://aapcc.s3.amazonaws.com/pdfs/releases/2016_AAPCC_BTG_Press_Release_Updated_with_PH.pdf. Accessed June 30, 2017.

BOX 22.6 Snakebite First Aid (Australia)

What to Do

1. Follow DRSABCD, which stands for:
   a) **D**anger—always check the danger to you, any bystanders, and then the injured or ill person. Make sure you do not put yourself in danger when going to the assistance of another person.
   b) **R**esponse—is the person conscious? Do they respond when you talk to them, touch their hands, or squeeze their shoulder?
   c) **S**end for help—call triple zero (000). Don't forget to answer the questions asked by the operator.
   d) **A**irway—is the person's airway clear? Is the person breathing?
   e) **B**reathing—check for breathing by looking for chest movements (up and down). Listen by putting your ear near to their mouth and nose. Feel for breathing by putting your hand on the lower part of their chest. If the person is unconscious but breathing, turn them onto their side, carefully ensuring that you keep their head, neck, and spine in alignment. Monitor their breathing until you hand over to the ambulance officers.
   f) **C**PR (cardiopulmonary resuscitation)
   g) **D**efibrillator—for unconscious adults who are not breathing, apply an automated external defibrillator (AED) if one is available. Some AEDs may not be suitable for children.
2. Reassure the patient and ask them not to move.
3. Apply a broad crepe bandage over the bite site as soon as possible.
4. Apply a pressure bandage (heavy crepe or elasticized roller bandage) starting just above the fingers or toes of the bitten limb and move upward on the limb as far as can be reached (include the snake bite). Apply firmly without stopping blood supply to the limb.
5. Immobilize the bandaged limb with splints.
6. Ensure the patient does not move.
7. Write down the time of the bite and when the bandage was applied. Stay with the patient.
8. Regularly check circulation in fingers or toes.
9. Manage for shock.
10. Ensure an ambulance has been called.

What Not to Do

DO NOT wash venom off the skin.
DO NOT cut the bitten area.
DO NOT try to suck venom out of wound.
DO NOT use a tourniquet.
DO NOT try to catch the snake.

Signs and Symptoms

Signs are not always visible but may be puncture marks, bleeding, or scratches.
Symptoms developing within an hour may include headache, impaired vision, nausea, vomiting, diarrhea, breathing difficulties, drowsiness, faintness, problems speaking or swallowing.

Disclaimer

St John Ambulance Australia first aid protocols are for the Australian market only. All care has been taken in preparing the information but St John takes no responsibility for its use by other parties or individuals.

From St John Ambulance. http://stjohn.org.au/assets/uploads/fact%20sheets/english/ FS_snakebite.pdf. Accessed June 30, 2017.

snakebite; however, PI is still not used correctly in the majority of snakebites in Australia.[23] Immobilization is critical in addition to pressure bandaging. It is not known to what extent PI retards venom absorption in the snakebite patient. The timing of PI application appears critical, especially for bites involving species such as the brown snake (*Pseudonaja* sp.), where venom may be absorbed rapidly via the capillary venous system.

MEDICAL TREATMENT

In the event of a venomous snakebite the patient should be referred immediately to the nearest hospital with appropriate facilities for the treatment of snakebite. It is not within the scope of this chapter to expand further upon the current medical treatment of snakebites in humans.

ACKNOWLEDGMENTS

The author acknowledges the work of Drs. Whitaker and Gold in the previous edition and thanks Dr. Richard Funk for his input in the production of this chapter.

Tortoises, Freshwater Turtles, and Terrapins

Thomas H. Boyer and Donal M. Boyer

HANDLING

Temperament varies considerably among the chelonians. As an overgeneralization, terrestrial forms rarely bite, whereas aquatic forms typically will. Handle chelonians by their shell, not their appendages or tail. The main hazards are from bites and scratches, although being urinated, defecated, or musked on can be unpleasant. Large species may require several people to safely handle. In large tortoises the rear limb can withdraw, trap, and crush an unwary handler's finger in the prefemoral fossa. Avoid this risk when moving large species (Fig. 23.1). Some turtles can inflict a serious bite with a surprisingly fast and long reach. The head may be blocked, with a thick folded cloth towel, and the turtle held posterior to the bridge of the shell. Placing a tongue depressor in front of the head of smaller turtles allows safe front limb access.

LIGHTING

Chelonians require ultraviolect light (UVB, 290–315 nm); natural sunlight is the best source (see Chapter 17 for more information). There should be no light at night and a photoperiod of 12 hours light for tropical chelonians year round. For temperate chelonians an annual photoperiod should be followed.[1] All lighting should be controlled by timers for consistant photoperiod regulation and adjustment.

TEMPERATURE

Most chelonians are heliotherms; they obtain radiant heat by basking in the sun. The nonlethal temperature range for all chelonians is 8°C (46°F) to 45°C (113°F). The optimal for terrestrial species is 28°C (84°F) with a range of 22° to 30°C (72°–86°F),[2,3] with exceptions. At temperatures less than 15°C (59°F), chelonians are inactive and anorexic; at less than 10°C (50°F), chelonians are hibernating.[2] Sudden freezes, especially in late winter or early spring, are a major cause of mass mortalities in box turtles (*Terrepene*), even though box turtles are the largest freeze-tolerant taxa.[4] Some montane species, such as impressed tortoises (*Manouria impressa*), do poorly above 30°C (86°F). Above 35°C (95°F) chelonians actively seek cooler areas, such as burrows or burrowing in the mud, and may aestivate.[2] Temperatures of 39° to 43°C (102°–109°F) are within the lethal or critical thermal maximum for most chelonians; 45°C (113°F) is rapidly lethal for all species.[2,5] A drop in temperature at night is beneficial and may help lessen pyramidal shell growth.[6] Larger chelonians have much more thermal inertia than small chelonians. Small chelonians are more prone to temperature fluctuations because of their high ratio of surface area to volume. Perhaps this is one reason pneumonia is much more common in young turtles.[7]

In captivity, a temperature gradient within the preferred optimal temperature zone or range (POTZ, POTR) is best so that the chelonian can regulate its own body temperature. Basking areas can be created under various incandescent light bulbs, infrared heat lamps or porcelain heating elements, or self-ballasted mercury vapor flood lamps with reflector hoods. In addition, one can place a heating pad underneath the cage in the basking area, or even better, a radiant heat panel overhead (see the tortoise barn discussion later in this chapter). Chelonians should not be within the 18-inch focal heating range of infrared fixtures or severe burns could occur. Chelonians need not stay within their POTZ; a nighttime drop in temperature preserves natural circadian rhythms. Ambient temperatures should be regularly monitored with minimum-maximum thermometers. Indoor-outdoor varieties allow ambient and basking temperature monitoring. Noncontact temperature measurement guns (Raytek Ranger ST, Total Temperature Instrumentation Inc, Williston, VT) are also useful to spot check temperatures throughout enclosures.

HIBERNATION

Hibernation (or brumation) is part of the normal physiology for many temperate chelonians. It precedes reproduction, utilizes stored glycogen and fat, and can be an essential component of husbandry. With colder temperatures thyroid values plummet, and most hibernating species become anorectic. All temperate chelonians should be hibernated if in good health. Most *Gopherus* and *Testudo* tortoises hibernate, with the exception of African *Testudo* tortoises (Greek tortoise spp. *T. graeca graeca* and the Egyptian tortoise *T. kleinmanni*). In contrast, none of the tropical tortoises (e.g., leopard, African spurred, red-footed, yellow-footed, star, radiated) hibernate. Most temperate zone terrestrial and freshwater turtles hibernate. Of the North American box turtles, all hibernate except for the Gulf Coast (*Terrepene c. major*) and Florida box turtles (*Terrapene c. bauri*). Some other commonly kept species that should hibernate are wood turtles (*Glyptemys insculpta*), spotted turtles (*Clemmys guttata*), common snapping turtles (*Chelydra serpentina serpentina*), northernly distributed eastern mud turtles (*Kinosternon subrubrum*), stinkpots (*Sternotherus odoratus*), red-eared sliders (*Trachemys scripta elegans*), and painted turtles (*Chrysemy picta*).

Hibernation onset is primarily governed by falling temperatures, which inhibits appetite. In the wild, this drives chelonians toward their hibernaculi. Hibernaculi are areas that are slightly warmer than the surrounding environment to avoid freezing and provide some moisture to protect against dessication.[3] Glycogen and fat stores in the liver and body are the main energy source during hibernation. Metabolism slows down considerably as temperature and thyroid levels plumet, resulting in reduced energy expenditure.[3] Emergence is triggered by rising temperatures, not photoperiod.[3]

Only healthy chelonians should hibernate, which means they have been eating and are in good body condition. Sick, convalescing, or underweight turtles should not hibernate. A physical examination, weight-to-length ratio, complete blood count, plasma chemistry panel,

VetBooks.ir

FIG 23.1 When handling large tortoises, be sure your finger doesn't get drawn into and crushed in the prefemoral fossa.

and, if possible, survey radiographs are recommended in late summer to early fall, before hibernation. Low body condition, weight loss, edema, hypoalbuminemia, hypocalcemia, hyperuricemia, anemia, diarrhea, or other signs of illness, such as nasal discharge or hepatic lipidosis, are some of the indications not to hibernate. If the chelonian does not have sufficient body reserves, it will catabolize its own tissues and may die. There is no one clinical parameter regarding hibernation; clinical acumen and keeper judgment are needed.

Body condition scores have been described for desert tortoises,[8] with 1 to 3 being poor or in undercondition, 4 to 6 in good condition, and 7 to 9 obese or in overcondition. Jackson's ratio[9] compares body weight with midline, straight carapace length and is a simple partial estimation of normal or healthy body condition for *Testudo graeca* and *T. hermanni* (but not applicable to other *Testudo*). Sick tortoises often exhibit a reduced body condition (low weight for a given length), while obese tortoises are well above normal weight for a given length. However, the presence of uroliths, coelomic exudates, or intestinal gravel can elevate body weight of ill tortoises.[10] Mader and Stoutenberg (Mader et al, Proc ARAV, 1998, p 103) charted maximum carapace length, width, and height (volume) against weight, as another estimation of the health status of desert tortoises. More charts should be produced for other species of chelonians, along with some already available on the internet or in research papers.[12–14]

Supplemental food should be discontinued several weeks prior to hibernation; larger animals may require 3 or 4 weeks, smaller turtles 1 or 2 weeks. Backyard grasses, weeds, or leaves can still be consumed. Water should be available, and soaking prior to hibernation is recommended. Most chelonians enter hibernation in the fall/autumn when nighttime temperatures drop to 8° to 21°C (40°–60°F), and the days are cooler. However, there is great individual variation in the timing and duration of hibernation. Onset of hibernation in northeastern Mojave desert tortoises is from late October to early November, and they emerge 4 to 5 months later in mid-February to late April. Mean temperatures of hibernaculi were 11° to 16°C (52°–61°F), with minimum temperatures of 7° to 10°C (45°–50°F).[15] Hibernaculi often maintained higher temperatures than the surrounding open environment, with less temperature variation.

Hibernaculi can be indoors or outdoors, with outdoors preferred for species that naturally hibernate in a given geographic area. Outdoor hibernation is not advisable in areas with severe winters or in areas outside the species' normal geographical distribution. For desert tortoises, an outdoor burrow, or tortoise barn, works well. Temperatures should be between 7° to 15°C (45°–59°F), ideally around 13°C (55°F), and always above freezing. Ensure that burrows can't flood during winter rains because wet and cold conditions are dangerous. Indoors, tortoises can be hibernated in cool areas, such as an unheated garage, storeroom, closet, or even in modified refrigerators.[1] A Styrofoam box, or a cardboard box insulated with thick layers of newspaper, within a larger cardboard, plastic, or wooden box can be used. The box should be large enough for the tortoise to turn around in, lined with newspaper and filled with shredded newspaper, or humid substrate, covered with blankets and kept dark. Do not put the box directly on cold concrete, unless it is too warm. Insulation minimizes temperature swings. Indoors low humidity can dehydrate tortoises; juveniles should be soaked every 2 to 3 weeks and adults every 4 to 6 weeks. Soak for 15 to 30 minutes in shallow lukewarm water during the day and allow the tortoise to dry before returning to the hibernaculum. Contrary to popular belief, disturbing turtles during hibernation is not harmful.[16] Low humidity is generally not a problem outdoors, but turtles should still be encouraged to drink if active on warmer days. During warm periods tortoises may be active only to return to hibernation as it cools again. As overnight temperatures stay above 18°C (65°F), and days warm, the tortoise will start to move around and can emerge from hibernation. Soak the tortoise and watch to see if it urinates. Healthy tortoises will start eating and urinating within a week of emergence; make sure they stay above 18°C (65°F) at night.

Box turtles (*Terrapene* spp.) and *Testudo* tortoises can tolerate much colder hibernation temperatures, ideally from 2° to 9°C (36°–48°F).[1] They generally dig into outdoor substrates but do not use burrows, except for ornate box turtles (*Terrapene ornata*) and Russian tortoises (*Agrionemys horsfeldii*). Eastern box turtles (*Terrapene carolina carolina*), hibernate near the surface, whereas ornate box turtles dig down into the soil.[4] A simple outdoor hibernaculum can be constructed in an area sheltered from the wind, near a foundation or wall. Excavate an area 2.5 ft by 4 ft, about 2 ft deep, and line it with stacked masonry blocks to about 6 inches above ground level, with several openings that turtles can enter through. Spread a mixture of mulch and soil, with a leaf layer on top, to the top of the block wall. Place marine-grade plywood on top of the hibernaculum, bury the entire structure in soil, and clear tunnels into the openings. Once the turtle enters in the fall, after a week or so, the entrance can be sealed shut with masonry blocks until the following spring. Compost piles are not suitable for hibernation. Some box turtles and Russian tortoises can survive freezing, but it is not recommended and can result in blindness, damage to extremities, or even death.[1]

Postemergence turtles and tortoises are often dehydrated, immunocompromised, and vulnerable to disease. Suboptimal nutrition, as well as suboptimal hibernation conditions, can result in a dehydrated, malnourished chelonian with major organ system failure upon emergence. Tortoises should lose no more than 6% to 7% of their body weight over hibernation.[17] Under ideal conditions *Testudo* spp. lose less than 1% body weight.[1]

Aquatic turtles housed outdoors that hibernate will cease feeding in late fall/autumn if they have no supplemental heat. Aquatic turtles can hibernate under water, in terrestrial environments, or both. If hibernating indoors one can use a stock tank in a garage or unheated room. Multiple turtles can be hibernated together if they are compatible

VetBooks.ir

species. Reduce feeding in preparation for hibernation so that when temperatures are 15°C (59°F) feeding has ceased. Water level depth should cover shell by about 6 inches. A few blocks or rocks can be added to allow the turtle easy access to the surface but not allow them to emerge from the water. A filter should be run to help keep the tank clean, circulate water, and keep it oxygenated. Allow water temperature to fall into the 4.4° to 10°C (40°–50°F) range and provide reduced lighting, less than 10 hours per day, or no lighting. Turtles may still move about, but they should not be disturbed. A more controlled hibernation is possible with refrigeration units or incubators that can be programmed to cool. Feeding can be started again as it warms in the spring. Watch for signs of pneumonia such as asymmetric lateral floating, inability to submerge, discharge from the nostrils or mouth, or closed eyes. If any signs of illness are present during hibernation, warm the turtle up to 27°C (80°F) over 24 to 48 hours and perform diagnostic testing, including culture and sensitivity, before beginning antibiotic treatment.

PREDATORS AND OTHER HAZARDS

Predators, especially dogs, are fond of chewing on chelonians' shells and appendages and can wreak havoc in a short time (Fig. 23.2). Small chelonians can be devoured without a trace. Small carnivores (e.g., raccoons, opossums, foxes, skunks, coyotes) and large birds (e.g., raptors, ravens, sea gulls, and wading species) may enter yards to prey on turtles, especially aquatic turtles. Ponds should have sufficient depth and underwater shelters to allow turtles to seek cover and prevent predators from easily wading in. Rats can chew on the limbs and heads of turtles, even indoors. Smaller terrestrial and aquatic chelonians should always have screened outdoor cages.[18] Fire ants (*Solenopis* spp.) and Argentine ants (*Linepithema humile*) can attack and kill small chelonians. Eggs should always be removed for incubation to avoid predation by an even larger suite of predators.

Tortoises will eat anything that falls into their enclosure. Enclosures must be regularly screened for trash (Fig. 23.3). Produce is often bound

FIG 23.2 Predators, especially dogs, are fond of chewing on turtles and can cause a tremendous amount of damage (A–E) in a short time. Raccoons can smell aquatic turtles and will travel large distances to prey on them at night.

VetBooks.ir

FIG 23.3 Chelonians will eat anything in their enclosure. This tortoise ate carpet, rubber bands, rubber erasers, twist ties, string, and metal foil, which resulted in several colonic prolapses before resolution.

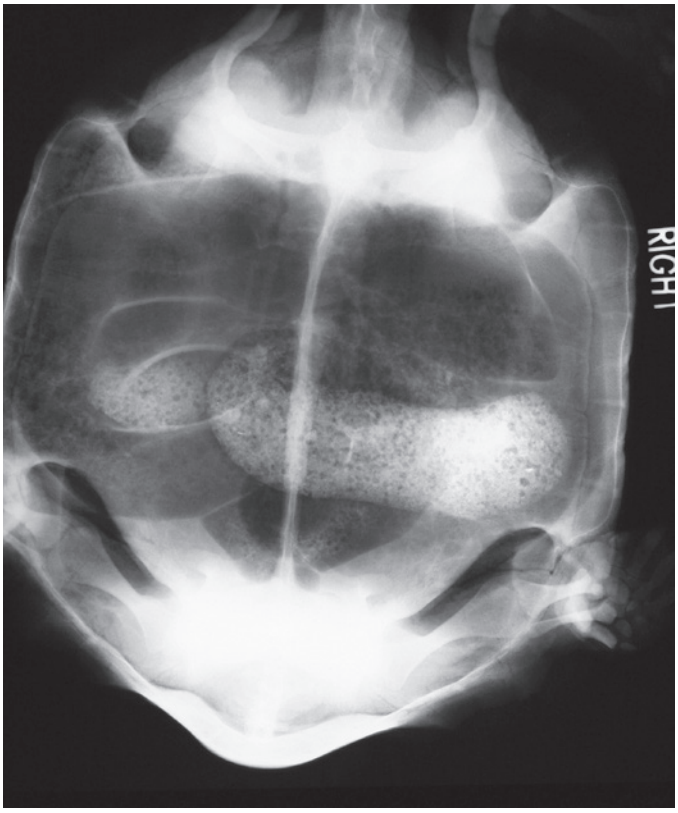

FIG 23.4 Large amounts of ingested sand or gravel can cause colonic impactions, chelonians should not be housed on dry sand or gravel.

with wire ties or rubber bands, so be sure to remove these from salad mixtures or they may be eaten (see Fig. 23.3). Tortoises will also consume small rocks, gravel, decomposed granite, pumice, pebbles (perhaps if they don't have enough calcium in their diet), and sand. These are rarely cause for concern unless large quantities are consumed. Large amounts of ingested sand or gravel can cause intestinal impactions (Fig. 23.4). Another potential hazard is pesticide spraying; do not spray tortoise enclosures with pesticides. Theft is an unfortunate reality as well.

ANNUAL EXAMINATIONS

Annual examinations are important to discuss overall care and feeding, educate owners, compare weight to species' normals, and screen for parasites and diseases. After a year, review of husbandry is again indicated, to get back to healthy habits. Reliance on diagnostics, especially hematology chemistry panels, fecal analysis (both direct and fecal flotation), and three-view survey radiographs are vital for the early detection of abnormalities. If an owner thinks something is wrong with the chelonian, there generally is. Do not delay diagnostic investigation; often the chelonian has been sick for weeks to months and adopting a wait-and-see attitude is often catastrophic.

IDENTIFICATION

Microchips are an accurate, permanent way to identify turtles and tortoises. The chip should be scanned first to ensure it is working and then injected subcutaneously in the skin fold over the left dorsal femur. All CITES Appendix I chelonians over 6 cm need to be microchipped as part of registration for a CITES Transaction or Specimen Specific Certificate, which allows them to be sold. Another method of identification is by using 5-minute epoxy to apply the patient's name, address,

FIG 23.5 Microchipping is a permanent identification method; however, most chelonians are lost and found locally but not scanned for a microchip. Applying a tiny identification tag to a caudal central costal scute, covered with 5-minute epoxy, may help get the chelonian back to its home.

and phone number, in 8-point print, in the center of a costal scute, not overlapping a seam—a service most tortoise owners appreciate (Fig. 23.5). Most tortoises are lost locally and often not scanned for microchips; visible identification makes it easier to find the owner. Wildlife biologists will often notch marginal scutes to provide a unique number identifier.

VetBooks.ir

While this system is appropriate for fieldwork when performed appropriately, it is not recommended for captive-owned pets. Inappropriate notching can result in damage to the sensitive underlying bone.

ACCLIMATIZATION

Wild-caught adult chelonians adapt poorly to captivity, and their purchase should be actively discouraged. Wild-caught temperate chelonians should be established in spring or early summer; late summer and fall does not allow them time to acclimate and feed enough prior to hibernation. Prior to obtaining chelonians, review the natural history and pertinent literature on captive care. All new arrivals should be quarantined away from the main collection to allow for veterinary diagnostics, parasite treatment, and establishment of a feeding regimen for 3 to 6 months. This basic safeguard should not be overlooked because diseases are easy to introduce into a collection but difficult and costly to eliminate. If healthy, new arrivals should be set up in as large a cage as possible or placed outdoors if the weather is favorable. Most chelonians are naturally secretive animals, and frequent handling or disturbance deters them from settling into captivity. Try to minimize disturbance and provide the turtles with plenty of security with low shelters they can retreat under, with proper cage substrates, broad-spectrum lighting, and basking areas. For finicky eaters try enticing them with preferred foods. For carnivorous species this means live prey, such as insects, worms, fish, or pink mice (taking into account legislative restrictions on feeding live vertebrate prey). For herbivorous species, red, yellow, or orange-colored foods, and fresh dark leafy greens, such as dandelions, are often favored (refer to Chapter 27). Rainstorms often increase activity; thus spraying the enclosure can stimulate appetite. Never release tortoises back into the wild; it is illegal, they rarely if ever survive, and more importantly they are likely to pose a serious health threat to the endemic chelonian populations.

TORTOISE AND BOX TURTLE CARE

Tortoises and box turtles are popular backyard pets. Many of these species are commonly treated by veterinarians, including Mojave desert tortoises (*Gopherus agassizii*), Sonoran desert tortoises (*G. morafkai*), Texas tortoises, (*G. berlandieri*), Greek tortoises, (*Testudo graeca spp.*), Hermann's tortoise (*Testudo hermanni*), Russian tortoises (*Agronemys horsfieldii*), and the African spurred tortoise or sulcata (*Centrochelys sulcata*). Several subspecies of box turtles were common, especially in the U.S. pet trade, including the Eastern box turtles (*Terrapene carolina spp.*), and the ornate box turtles (*Terrapene ornata spp.*). Some species may be controlled by international or national legislation (see Chapters 183 and 184 on legislation).

Outdoor Housing

Whenever possible, house tortoises and box turtles outdoors, in as large an enclosure as possible, even if only for a small portion of the year. This allows them space to exercise, graze, and bask. Hatchling and juveniles should be kept above 21°C (70°F). Adult tropical tortoises can be housed outdoors when morning temperatures are above 18°C (65°F) and midday temperatures exceed 24°C (75°F). Bring them in at night when temperatures are below 18°C (65°F) or provide a heated tortoise barn (Fig. 23.6). Adult temperate species tolerate temperatures 3°C (5°F) less than those listed for tropical species provided it warms up to 24°C (75°F) during the day or if a heated barn is present. Many *Terrapene*, *Testudo*, and *Gopherus* spp. do well from 20° to 32°C (68°–90°F); tropical tortoises benefit from less variability, from 22° to 28°C (72°–82°F).[1] Temperatures above 38°C (100°F) are too hot, and greater than 43°C (110°F) is critically dangerous for all box turtles and tortoises.

In most areas it is often too cold for tortoises without supplemental heat, especially at night. All tortoises benefit from heated shelters (e.g., the tortoise barn, Fig. 23.6), which can be constructed of plywood with a hinged, sloped, insulated, slightly overhanging, and heated inner roof. The floor is open to the dirt to boost humidity and ease cleaning or can be floored in colder areas. Hinging the roof makes it easier to clean; waterproofing the plywood will extend its lifespan. A 12-inch by 36-inch Kane pig blanket (Kane MKG, Inc., Des Moines, IA) or waterproof radiant heat panel, suspended loosely from the solid inner roof insulation, provides heat, and temperature can be controlled with a rheostat or thermostat. A dusk-to-dawn timer will keep heat on at night and off on warmer days, or it can be run continuously. The doorway should be just large enough for tortoises to fit through and left open to provide an avenue to escape heat should the timer fail. The doorway opening can be covered with heavy gauge clear vinyl strips, which allows for

FIG 23.6 A heated waterproof insulated tortoise barn (A, B) is advantageous for tortoises. The insulated roof reflects heat down from the heat pad. Hinging the roof makes cleaning easier, and a dusk-to-dawn timer turns on heat at night and off on hot days.

FIG 23.7 Tortoise solariums boost ambient heat to provide a basking area so the tortoise can better thermoregulate.

easy tortoise access but traps heat. On really cold nights a waterproof wrap or space blanket can increase heat retention.

Another way to boost heat and allow better thermoregulation is to make a solarium, with 1/4-inch safety glass, leaned up at a 45-degree angle against a sun-facing wall and secured on the other side by quarter round on top of two or more stacked 4-inch by 4-inch landscape timbers, drilled through and secured to the ground with rebar spikes. Leave this structure open at both ends (Fig. 23.7).

Burrowing species (e.g., desert tortoises, African spurred, Russians, ornate box turtles) may excavate a burrow to escape cold or hot temperatures. Be sure the opening cannot flood during heavy rains, either by berming around the entrance or providing drainage away from the entrance. Artificial burrows can also be constructed (see the Arizona Game and Fish Department website).[19] Do not allow African spurred tortoises to burrow near foundations; they can do extensive damage.

When planning outdoor enclosures, several factors should be considered to suit the needs of species. An understanding of the species microhabitat use and environment will be useful in designing the enclosure. Desert species can tolerate higher temperatures and drier enclosures than can tropical rainforest species. For grassland or desert species, such as *Gopherus*, *Testudo*, sulcatas, leopard tortoises (*Stigmochelys pardalis*), Indian star tortoises (*Geochelone elegans*), and ornate box turtles (*Terrapene ornata* spp.), enclosures can be more sparsely planted with shrubs and grasses. For tropical forest forms, such as red- and yellow-footed (*Chelonoidis carbonaria* and *C. denticulata*), Burmese tortoises (*Manouria spp.*), hingeback tortoises (*Kinixys* spp.), *Indotestudo* spp., Eastern box turtles (*Terrapene carolina* sspp.), provide densely planted enclosures with shelters they can retreat under and shallow pools they can cool off in. Loose mulch piles in shaded areas will allow additional refuge to burrow under. All enclosures should have sun areas, as well as shade. The strategic use of rocks, boulders, hollow logs, branches, and varied topography can provide a more complex and enriched environment.

Outdoor enclosures must have secure, solid perimeters. Tortoises pace perimeters and constantly try to get through perimeters they can see through. If there is a way over, under, or through, the turtle or tortoise will find it. Solid barriers, such as wooden fencing, block walls, or smooth concrete, are far more preferable to open fencing. Open fencing should be small, or large, enough that turtles or tortoises cannot entrap and cut an appendage. Materials will vary in size from hardware cloth to welded wire, depending on species size. Small tortoise species can climb chain link. Fencing should be buried 12 inches to 24 inches and be at least two to three times the carapace length in height. Large powerful species, such as African spurred, Aldabra, and Galapagos tortoises, or giant yellow foots, require more substantial containment barriers of welded pipe or concrete/block construction. Tethering a tortoise by a leg, or through a hole in the shell, is unacceptable, inhumane, and potentially disastrous if a leg gets entrapped.

Indoor Housing

Indoor housing is usually required for a good portion of the year, except in subtropical to tropical areas. The combined shell size of all turtles/tortoises present should not exceed a quarter of the floor surface area available to the tortoises (Mader et al, Proc ARAV, 1998, p 103), or at minimum, 0.4 m^2 per 0.1 m carapace length and recommended is 1.0 m^2 per 0.1 m carapace length.[12] Provide as much space as possible. Aquariums, plastic or metal livestock troughs, or plastic containers can be used for small turtles/tortoises. Large commercially available plastic tubs are waterproof, easy to clean, and much more suitable for larger tortoises than aquariums (Vision Products, Tubs, Canoga Park, CA, or Waterlandtubs). Cages can also be constructed out of plywood for larger tortoises. The inner cage surfaces should be caulked and sealed with several coats of polyurethane, which facilitates cleaning. Allow the cage to dry out thoroughly and any varnish smell to completely dissipate before placing any tortoises inside. To prevent chilling, the cage bottom should not be in direct contact with cold concrete; a gap of several inches is advisable, such as resting on 2 inch by 4 inch (5 cm × 10 cm) wood blocks. Ambient indoor temperature should be 24° to 32°C (75°–90°F) depending on the species. Rooms can be heated with thermostatically controlled space heaters, radiant heat panels, and basking lights to provide a thermogradiant.

Substrates

Tortoises vary in environmental requirements from desert to tropical forest. More xeric-adapted tortoise species can be maintained indoors on alfalfa pellets or newspaper. As they graduate to larger cages, a mixture of medium to large rice hulls, newspaper, indoor-outdoor carpeting (be sure to avoid frayed edges), or corrugated cardboard can be used. Forest tortoises and box turtles will fair better on humid substrates such as a mixture of conifer bark nuggets and peat moss, coconut coir, or soil (which is a good source of cellulolytic bacteria). Remove fecal material from the enclosure several times per week and replace the substrate several times per year. Avoid sand, gravel, cat litter, crushed corncob, or walnut shells.

Water

Water should be regularly available for indoor and outdoor chelonians (Fig. 23.8). Shallow plastic plant saucers work well for most tortoises, with the exception of desert tortoises. Chelonians often defecate in their water; thus water bowls should be changed frequently and whenever visibly soiled. Desert tortoises, and other species outdoors, will also drink from standing water. An alternative to the water bowl is to soak the desert or xeric species in chin-deep water every 1 to 2 weeks.

Feeding

What to feed tortoises is an evolving empirical science and fraught with misconceptions (Box 23.1, Tortoise Diet; see also Chapter 27).[16,18,20] Most desert tortoises in the backyards of southern California suffer from chronic protein and fiber deficiency, as well as carbohydrate

VetBooks.ir

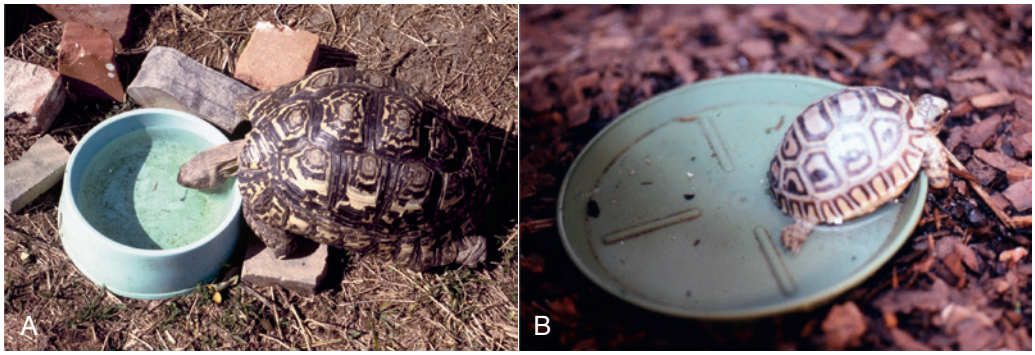

FIG 23.8 Water should always be available for chelonians, such as these leopard tortoises *(Stigmochelys pardalis),* either by water bowls (A) or soaking (B).

BOX 23.1 Tortoise Diet[18,20]

Adults should be fed three times per week, and hatchlings fed daily. If pelleted commercial tortoise foods are used, calcium and multivitamin supplementation isn't needed. If not feeding pellets (not recommended) every feeding, dust food with calcium lactate, carbonate, citrate, or gluconate and multivitamins once or twice a month.

Majority—50% to 80% good quality commercial pelleted tortoise diets and grass hays (Bermuda, timothy, buffalo, brome, tall fescue, orchard grass but not alfalfa hay or Kentucky bluegrass). See Chapter 27 for more information.

Minority—20% to 50% native plants consumed by tortoises in the wild: backyard weeds (especially dandelions, clover, burclovers, purslane, spurges, crabgrass, cheese weed, creeping wood sorrel, and others), spineless prickly pear cactus pads and fruits *(Opuntia ficus-indica),* dark leafy greens (collards, mustards, turnip tops, bok choy, kale, spinach, cabbage, endive, Romaine lettuce), flowers (roses, nasturtiums, hibiscus, carnations, geraniums, primroses, ice plant, and cactus flowers), leaves (mulberry, grape, hibiscus, squash) can also be fed. Very little to no fruit should be fed.

excess, and many have calcium deficiencies. The same is likely true in other areas.

Most wild tortoises consume a wide variety of plants (over 200 for *Gopherus morafkai*), switching diet species to obtain the freshest plants until only dry senescent plants are available.[21] Commercial tortoise diets, grasses, and grass hays tend to have better calcium levels and nutrient profiles similar to what tortoises naturally consume. Getting tortoises to eat hay and commercial foods can be a challenge. Much like a dog content with table food, a tortoise will eat pellets and hay once hungry enough, but not if better tasting or more familiar foods are available. Use good quality hays, not stems or stalks that smell stale or moldy. Chopping the hay with scissors, or a food processor, and sprinkling or spraying the hay with water to moisten it helps, or it can be soaked in water for several minutes. Soaking too long will leach out nutrients. Mixing the normal food in or under the hay also helps. Pellets can be soaked in water until just soft and mixed into the greens. Be patient and persistent, and tortoises will switch over to hay and commercial pellets, as fruits and vegetables are gradually reduced. Feeding less or less often will encourage turtles and tortoises to try new foods. For information on native plant species naturally consumed by desert tortoises, see the websites of AZ Game and Fish Department[22] and the CA Turtle and Tortoise Society.[23] Similar resources probably exist in other countries.

Be aware of several persistent widespread misconceptions. Members of the vegetable family Brassica (cabbages, kale, mustard greens, broccoli, cauliflower, Brussels sprouts) do not cause thyroid problems (goiter) and are completely harmless in moderation as part of a balanced diet. Foods rich in oxalic acid, such as spinach, beet greens, collards, Swiss chard, Brussels sprouts, prickly pear cactus, and purslane, do not contribute to calcium oxalate uroliths. The adverse effects of oxalates must be considered in terms of the oxalate:Ca ratio of food (see Chapter 27). Diets low in Ca and high in oxalates are not recommended, but occasional consumption of high oxalate foods as part of a nutritious diet does not pose any particular health problem. Tortoises commonly form uric acid stones but very rarely calcium oxalate stones, which were considered an incidental finding in wild desert tortoises.[24,25] Plant poisoning is rare in tortoises. Tortoises either avoid poisonous plants or are more resistant to their effects, unless no other forage is available. Some toxic plant exceptions include rhododendrons (grayanotoxins cause flaccid paresis), oleanders, chinaberry trees, tree tobacco, and poisonous mushrooms. Tortoises love fruits and will consume them preferentially over more nutritious foods; however, most species are not frugivorous. Red and yellow-footed tortoises are more frugivorous than other tortoises and can be offered more fruit, but no more than 20% of the entire balanced ration. Fruits, in general, are mineral poor, yet high in sugars and can disrupt the normal gut flora and may lead to hepatic lipidosis. Limit fruits to a small portion of the diet, more of an occasional treat than a staple, or do not feed them at all.

Tortoises should be fed on a flat board, metal or plastic trays, or newspaper. Wash, or dispose of, these after use. Do not feed tortoises on loose substrate or they will incidentally ingest it. Feed as much variety as possible! The majority of the diet should be commercial tortoise chows, hay, grasses, weeds, and flowers (see Box 23.1, Tortoise Diet). Adults should be fed a minimum of three times per week and hatchlings daily. If the diet consists largely of commercial pellets, then supplemental calcium and multivitamins are not needed. It is easier to achieve proper shell growth with commercial pellets than a fresh vegetable diet (Fig. 23.9). If not using commercial pellets or natural foods, every feeding should be lightly dusted with calcium carbonate, lactate, citrate, or gluconate for juveniles, and weekly for adults. If vitamin-fortified tortoise foods are not being consumed, twice a month lightly dust food with multivitamins. If the tortoises are exposed to unfiltered sunlight or indoor ultraviolet (UVB) lights, vitamin D supplements are not needed or desired.

Box turtles are quite predatory, eating whatever they can catch, consequently, moving prey appeals to them.[4] Box turtles are opportunistic omnivores that consume a wide variety of invertebrate and small vertebrate prey along with a diversity of plants. See Box Turtle Diet (Box 23.2)[20,26] and Chapter 27 for information on captive feeding.

VetBooks.ir

Reproduction

Males of bowsprit tortoises (*Chersina angulata*), chaco Tortoises (*C. chilensis*), African spurred tortoises, and *Gopherus* spp. will fight relentlessly, may kill one another, and should be housed singly. Females may be housed together separate from males. It is no longer recommended to breed desert or African spurred tortoises as there is an overabundance of them in captivity. Celioscopic-assisted prefemoral oophorectomy,[27] or orchiectomy,[28] or phallectomy is recommended to reduce unwanted numbers of these tortoises. Orchiectomy is difficult as the testicles are deep in the coelom. Phallectomy will not change the male's belligerent mating behavior.

Courtship behavior and breeding season varies. Posthibernation rising temperatures and increasing daylength stimulate temperate chelonians to breed. Tropical species may respond to the onset of the rainy season. Storms and associated changes in barometric pressure seem to stimulate breeding activity in many species. Courtship behavior involves visual, tactile, and olfactory cues including trailing, smelling, biting, ramming, male/male combat, female copulatory posture (presentation), and male vocalization.[29] Female tortoises must be in prime condition before egg production, including a well-balanced diet with adequate calcium. Additional calcium should be provided for females that produce large or multiple clutches. Chelonians are known to be able to store sperm up to 4 years.[30] Gravid females feel heavier than normal and tend to be more active, often pacing in the enclosure. Eggs can be palpated in the prefemoral fossa and can be readily demonstrated by radiography and ultrasonography. Some females may excavate several nests before actually laying eggs. Eggs should be carefully excavated and removed for incubation. Fertile eggs, when candled, develop a dorsal chalk spot, or band, that slowly spreads ventrally as the extraembryonic membranes develop, and blood vessels may be visible, whereas infertile eggs have neither (Fig. 23.10).

Neonatal Care

Once the neonate has pipped the eggshell with its caruncle, or eggtooth, it emerges from the shell within 1 to 4 days. During this time, the neonate's shell begins to unfold, facilitating yolk absorption. As the neonate's shell straightens and the tortoise begins to move, the eggshell

FIG 23.9 Juvenile leopard tortoise (*Stigmochelys pardalis*), raised primarily on commercial pellets, dark leafy greens, weeds, flowers, and no fruit. A nighttime drop in temperature, and humid substrate or hidebox, may also help prevent pyramidal shell growth.

BOX 23.2 Box Turtle Diet[20,26]

Items listed in italics often entice anorexic animals to eat. Adults should be fed three or more times per week in the morning, and juveniles fed daily. Juveniles tend to be much more carnivorous than adults. If pelleted foods are not a large part of the diet, lightly dust food with calcium lactate, carbonate, citrate, or gluconate every feeding and give multivitamins twice monthly. Provide variety.

>50% Pellets or animals—commercial good quality box turtle or aquatic turtle pellets (see Chapter 27 for more information), earthworms, crickets, grasshoppers, slugs, snails, pill bugs, cicadas, whole-skinned chopped mice, baby mice (pinkies), mealworms, waxworms, silk moth larvae, and other insects.

<50% Plants—25% fruits and 75% vegetables

25% Fruits: tomatoes, strawberries, raspberries, blackberries, mulberries, blueberries, apples, grapes, cherries, peaches, pears, plums, nectarines, figs, melons.

75% Vegetables: mushrooms; dark leafy greens (mustard, collard, radish, beet and turnip greens or tops, kale, cabbage, dandelion leaves, stems or flowers, spinach, bok choy, pak choi, broccoli rabe); red leaf or romaine lettuce (be careful not to overfeed lettuces); Swiss chard; steamed chopped squashes; sweet potatoes; shredded (not chopped) carrots; thawed frozen mixed vegetables (peas, corn, carrots, green beans, lima beans); alfalfa, radish, clover, or bean sprouts; soaked alfalfa pellets; bell peppers; broccoli; green beans; peas in the pod; okra; and prickly pear (*Opuntia* spp.) cactus pads (be sure to shave off spines).

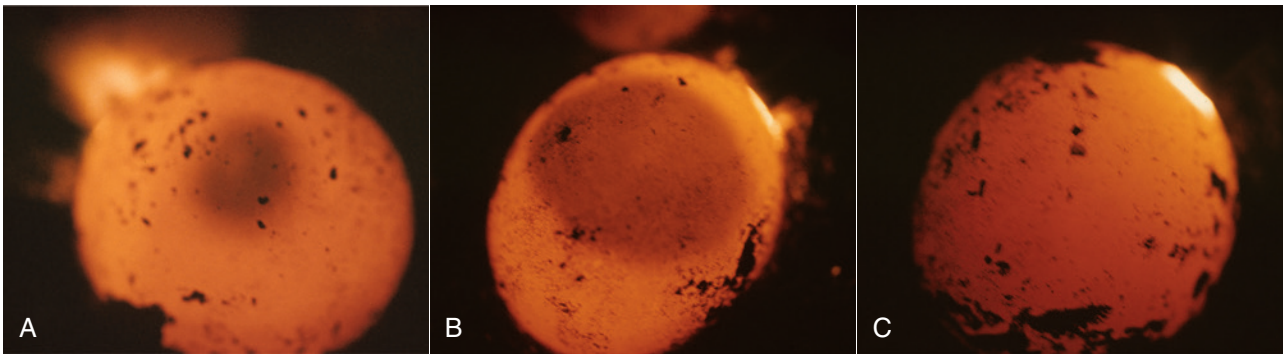

FIG 23.10 Fertile eggs, when candled, have a dorsal chalk line (A) that spreads slowly ventrally during development (B), whereas infertile eggs do not (C).

VetBooks.ir

breaks further. Once out of the egg, the neonate may still have a considerable yolk sac (Fig. 23.11). The hatchling should be carefully rinsed off and transferred to a small plastic container, and kept on clean moist paper towels at the same temperature as the incubator. Replace and remoisten towels as the yolk sac slowly absorbs over the next few days (Fig. 23.12). Once the yolk sac is fully absorbed and the umbilicus sealed, the neonate can be transferred to a cage with previously mentioned substrates.

Hatchlings usually begin feeding within 1 to 14 days of leaving the egg. Hatchlings are prone to dehydration; therefore shallow water bowls should constantly be available (see Fig. 23.8B). An alternative is to soak neonates in shallow water several times a week. A drop in ambient temperature at night,[6] provision of humid substrate,[31] or humidity box, and feeding pelleted commercial pellets seems to reduce pyramidal shell growth. Ambient temperature should gradually warm to 30°C (85°F) during the day, with a thermal gradient. Hatchlings should develop a firm shell in the first year.

FIG 23.11 Once out of the egg, neonatal chelonians, such as this leopard tortoise *(Stigmochelys pardalis),* may still have considerable yolk sac. The hatchling should be carefully rinsed off and transferred to a small plastic container and kept on clean moist paper towels, at the same temperature as the incubator, until the yolk is absorbed.

AQUATIC TURTLES

Aquatic turtles are popular pets, yet among the most labor intensive of all reptiles to maintain properly.[32] Improper husbandry often results in health problems, such as skin and shell infections, pneumonia, hypovitaminosis A, and shell deformities. An understanding of proper captive care helps to avoid these issues. Keep in mind that there are many species-specific differences, and no substitute exists for knowledge of natural history to direct captive care. The most common aquatic turtle seen by veterinarians is the red-eared slider or terrapin (*Trachemys scripta elegans*).

Housing

Housing requirements vary according to the size of the turtle and the number being kept. A variety of enclosures can be used from glass aquaria, plastic tubs, livestock watering tanks, and pond liners to elaborate outdoor ponds. Waterland Tubs, ZooMed, and Vision Cages all make commercially available turtle enclosures (Fig. 23.13). Outdoor enclosures should have some shade available. Never place a plastic or glass aquarium in full sun because it could easily overheat. A rule of thumb, for minimum cage size, is the combined shell size of all residents should not exceed 25% of the cage's accessible space for turtles,[33] or 0.25 m^3 per 0.1 m carapace length and 0.75 m^3 per 0.1 m carapace length is recommended.[34]

Temperature

Water and air must be warm; 24° to 28°C (75°–82°F) are recommended for most species. A combination heat and broad-spectrum lighting (including UVB), with reflector, directed toward the basking area creates

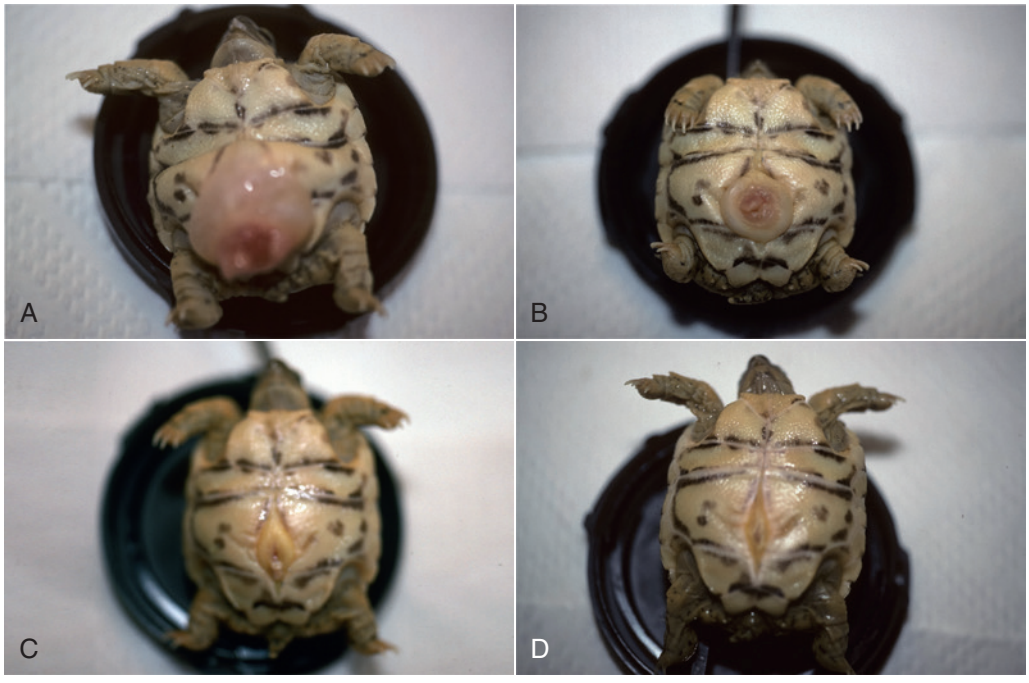

FIG 23.12 Leopard tortoise (*Stigmochelys pardalis*) hatchling on days 1 (A), 3 (B), 5(C), and 8(D) as it rapidly resorbs its yolk sac and the umbilicus closes.

VetBooks.ir

a hot spot for basking. Submersible aquarium heaters (Eheim Jager, Deizisau, Germany, makes good, durable ones) will keep the water warm; this is especially important for hatchlings. Provide barriers around submersible heaters to prevent contact burns on the turtle. In larger setups, an inline heater can be plumbed to the filtration system. Alternatively, one can keep the room temperature within this range, without heating the water. Some species such as mud and musk turtles, common snapping turtles (not alligator snapping turtles), and big-headed turtles (*Platysternon megacephalum*) prefer it cooler; the latter may need an aquarium chiller to cool the water.

Water Quality

Clean water is crucial to prevent skin and shell infections in turtles. Warm water promotes bacterial, fungal, and parasitic growth. Water laden with bacteria, feces, and urine is malodorous; clean water should have little to no odor. Likewise, turtles should have no odor, unless they are overly excited and express their musk glands. Water should be kept clean by frequent water changes and/or sufficient filtration.

FIG 23.13 A variety of commercial aquatic turtle enclosures are available, such as this Waterland Tub.

Small aquatic turtles can be kept in simple, small, closed water systems that afford more freedom from water conditioning because reptiles are not dependent on ultraclean water for respiratory needs as for fish.[35] The bacterial nitrification cycle that converts ammonia in urine to nitrites, then to less toxic nitrates, is much more important for delicate fish gills. Being less sensitive, full water changes (as opposed to partial water changes) are regularly needed to keep bacterial levels low, unless filtration is profound and well maintained. Dechlorination of water is also not normally necessary for turtles; however, it should be performed if biologic filtration is used or fish are present. A common misconception of inexperienced turtle owners is that the mechanical and biologic filtration recommended for specific water volumes for fish will keep a similarly sized turtle tank clean. However, the much greater biomass of turtles in the same volume necessitates considerably greater filtration.

How often the water needs to be changed depends on several factors, including stocking density, water volume, temperature, feeding frequency, and available filtration. One can keep the water cleaner by feeding in a separate container, because most foods foul the water quickly and promote bacterial growth, but this is not essential. Initially some turtles may be reluctant to feed in the separate container but can be acclimated to this over time. Using the same water from the home container helps.

Full water changes are easier if no substrates, or easily removable substrates, are present. Sand and gravel are harder to clean, and aquatic turtles can ingest gravel, which can cause intestinal obstruction (Fig. 23.14). Some species (e.g., soft shells, Trionychidae), however, like to burrow into sand and gravel. Keep in mind that cleaning areas are a potential source of zoonosis, such as Salmonella. Avoid food preparation, or infant bathing areas, when cleaning turtle cages.

For larger enclosures, too heavy to move, make it as easy as possible to dump and fill water. By far the easiest way to drain a tank is to install a PVC bulkhead fitting (http://pentairaes.com) and valve that attaches to a hose. Use a hole drill bit to cut through plastic and a diamond hole saw (http://www.grainger.com) to cut through glass, or buy a predrilled aquarium before installing a PVC bulkhead fitting. The next easiest method of drainage is portable electric submersible pumps (e.g., Little Giant Water Wizard model 50500 5-MSP, http://www.lilgiantpump-products.com). Be sure to purchase a bottom suction pump, not a side suction pump. When in use, make sure a turtle doesn't get caught in the pump's suction, panic, and drown. Alternatively, one can use a siphon to drain the water into a toilet, floor drain, or outdoors to water plants. Siphons take longer than pumps. After draining, the empty tank

FIG 23.14 Aquatic turtles can ingest small pebbles and gravel, this anorectic red-eared slider (A) responded to food and fluids through an esophagostomy tube and was able to pass these stones (B).

VetBooks.ir

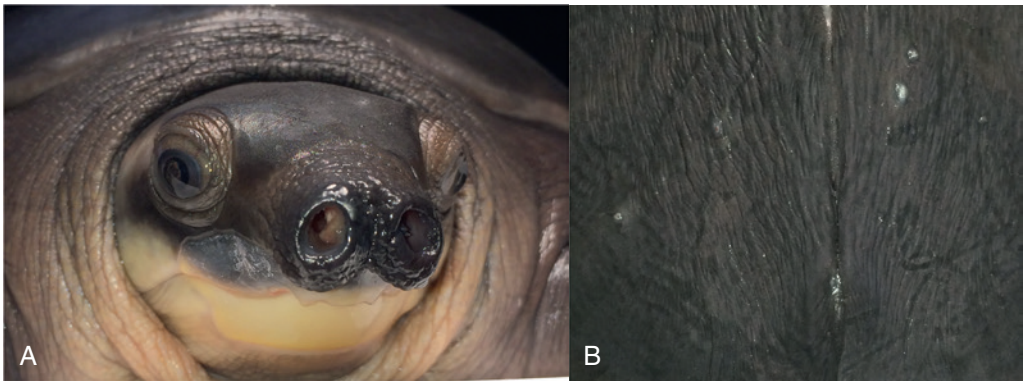

FIG 23.15 Multiple acid-fast granulomas in the nostril (A) and on the shell (B) of a Fly River turtle (*Carettochelys inscuplta*) that resolved after adding a simple external canister filter with ultraviolet disinfection designed to eliminate algae.

can be rinsed out, and occasionally even scrubbed out, but need not be disinfected. When refilling be aware that abrupt changes in water temperature can kill turtles, especially hot water; make sure the water temperature refilling the tank is similar to what it was prior to cleaning. Thermometers facilitate this; with experience, one can gauge this by hand.

Proper filtration makes aquatic turtle care easier. The best filters for turtles are large external canister filters, such as those designed for Koi, or rapid sand filters. A weir tank, fed from the holding enclosure, increases water volumes and can allow for prefiltering of the water through a floss pad. Sterilizing ultraviolet (UV, 254 nm) filters irradiates pathogens and is an easy way to eliminate algae and as an adjunct to managing infectious disease (Fig. 23.15). Ozone is even better at water disinfection but much more expensive and has the potential for harm if not accurately monitored and controlled. Aeration of water is important to support aerobic bacterial growth in biological filters. Under-gravel filters need a deep gravel bed, 7.5 cm or more, or the turtle may dig and expose the filter plate.[16] Once exposed, water will bypass the gravel as it follows the path of least resistance, and the benefits of biological filtration will be decreased. For small enclosures with low biological load, internal submersible filters are gaining in popularity but need to be cleaned frequently. Foam rubber filters are generally inadequate as a sole method of keeping water clean.

Water should be at least as deep as the width of the turtle's shell at the widest point so that if overturned the turtle will be able to right itself and avoid drowning. For the most part, turtles can be maintained in water with neutral pH, except for some South American blackwater species, such as red-headed river turtles (*Podocnemis erythocephala*), snake-necked turtle (*Hydromedusa tectifera*), red side-neck turtle (*Phyrnops rufipes*), and other *Phyrnops* spp., which need more acidic conditions.[16] There are numerous aquarist buffer systems available to maintain such conditions. Diamondback terrapins live in brackish water and require the addition of two tablespoons of aquarium salt and mineral mix per gallon of water (5 g per L).

Haul Out and/or Nesting Area

A dry haul out or nesting area should be present so that turtles can crawl out of the water, dry off, and bask. A broad spectrum (including UVB) basking light that provides heat should be directed toward the basking area to create a hot spot (<35°C, 95°F). Basking areas can be as simple as a flat rock resting on submerged bricks, a cinder block, or fixed pieces of cork, hardwood driftwood, or plastic platforms. More elaborate platforms can be built above water level with access via a plastic or wooden ramp or branch (Fig. 23.16). Snapping turtles (*Chelydra*

FIG 23.16 A haul out area is important for aquatic turtles to dry off, bask, thermoregulate, and for vitamin D synthesis via ultraviolet light.

and *Malaclemys* spp.), matamatas (*Chelus fimbriata*), and Fly River turtles (*Carettochelys insculpta*) do not need basking areas.

Nesting areas, which double as a basking area, should be provided for adult females, even if males are not present. If sufficient nest area is provided, dystocia may be avoided and oviposition stimulated. Temporarily rigging a nesting area, or shifting a gravid female to a cage with a nesting area, is far less successful than keeping a nesting area present year round.[36] The nest area should be approximately four to five times larger than the female, and twice as deep as the carapace length. Nest medium should be a mixture of 50% moist sand mixed with potting soil or peat moss. Nest area containers can be made from a variety of plastic tote containers, with wet sand weighing down the bottom, which prevents the nest area from floating and tipping over. Some aquatic turtle enclosures, such as those from Waterland Tubs and Zoo Med, have built in basking/nest areas, with a ramp coming up out of the water (see Fig. 23.13).

Feeding

The majority of the diet should consist of soaked, softened, commercial fish-based aquatic turtle pellets (Box 23.2). Patience and persistence is

VetBooks.ir

BOX 23.3 Aquatic Turtle Diet[20,26]

Feed adults one to three times per week, and hatchlings daily. Feed as much variety as possible. If a balanced commercial pellet is provided, multivitamin and mineral supplementation is not required.

- Majority of the diet—Commercial, good-quality, soaked, fish-based aquatic turtle pellets (see Chapter 27 for more information), or whole animals (mice, rats, earthworms, tubifex worms, slugs, snails, fresh whole shrimp [with shells, not freeze dried], thawed frozen guppies, trout, bait fish, freshwater (not saltwater) smelt.
- Minority of the diet—Insects (crickets, wax worms, mealworms, flies, moths, and grasshoppers), in moderation, if properly gut loaded with calcium-enriched diet (>8% calcium). Desiccated insects are nutritionally inadequate and should not be fed.
- In older omnivorous species (many sliders and pond turtles), gradually increase dark leafy greens (kale, spinach, dandelion greens, romaine lettuce, cabbage, watercress, endive, bok choy, escarole), yams, carrots, duckweed, water lettuce, and algae.

required with commercial diets because acceptance can take several weeks. See Box 23.2 for other options. Whole fish are better than gutted fish and can be fed chopped or whole. Ideally, fish should be well fed prior to being fed to turtles. Freezing for more than three days may eliminate transfer of some, but not all, parasites. Wild-caught sticklebacks, mosquito fish, and goldfish should not be fed because they are natural vectors for several serious parasites[37] and mycobacteria. Most aquatic turtles will readily consume mice, from pinkies to chopped, skinned adults. Mice and rats are skinned to reduce indigestible keratin. Older mice have more mineralized bone, which is preferable for shell growth, whereas mouse liver is an excellent source of vitamin A. A variety of gut-loaded insects can also be fed as a minority of the diet (Box 23.3). Mineral or antibiotic blocks in the water do not help nutritionally, or medically, and should be discouraged.

Commercial gel diets are also available. Cut gelatin into bite-sized pieces or strips. The strips can be tightly wrapped in plastic wrap, placed in self-sealing polyethylene plastic bags, and frozen for up to a month. Remove as much air as possible before freezing to minimize freezer burn. Do not refreeze the ration once thawed. Refrigerated gel diet should be discarded after a week.

Neonatal Care

Hatchling aquatic turtles can be a challenge to raise, and overcrowding must be avoided. Hatchlings may be shy and scramble for cover at your approach and can be reluctant to feed. Provide hatchlings with cover to retreat under such as floating pieces of cork, clay flower-pot pieces, plastic leaves (large enough that they cannot be ingested), or a board or flat rock over bricks. Be certain that cage props are stable so that they do not shift and trap young turtles underwater and drown them. Live plants such as cuttings of pothos (*Epipremnum aureum*) or java moss (*Vesiclaria duyana*) work well for cover and can thrive in shallow water. The tank can be tilted by placing a small block of wood under one end, providing a gradual taper from shallow to deep. Nontransparent plastic containers are easy to clean and may offer additional security.

To coerce young turtles to feed, try feeder guppies (taking into account national welfare legislation); small live insects such as two-week-old crickets, mealworms, wax worms, chopped pink mice or earthworms; frozen krill; or soaked, softened, pelleted fish-based diets. Live small worm species such as black worms (*Lumbriculus variegatus*) or tubifex (*Tubifex tubifex*) often initiate feeding. As the hatchlings begin to feed with more vigor, try a wider variety of foods. Broad spectrum (including UVB) lights, proper temperature, and a wide variety of foods are important to prevent nutritional disease, improper growth, and imprinting on a single food.

Species Interactions

Some turtle species, such as snapping turtles, large softshell turtles, mud and musk turtles (*Kinosternon* and *Sternotherus* spp.), big-headed turtles, and Hamilton's pond turtles (*Geoclemys hamiltonii*) are aggressive toward other turtles, and cannibalism is known to occur. They can cause severe trauma and even kill other species, and should only be kept with others of the same species and size. When establishing groups of turtles watch for evidence of aggression, including bite marks along rear shell margins, neck, or tail, and be ready to separate if necessary. If a turtle refuses to enter the water, aggression from another turtle may be the cause. Many turtles can be carriers of *Entamoeba invadens*, which can cause serious gastrointestinal disease in chelonians and other reptiles.[38]

Sea Turtles

Craig A. Harms and Jeanette Wyneken

Seven species of sea turtles are found worldwide (Table 24.1). All are listed in Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES; https://cites.org/eng/app/appendices.php), signifying the species' risk of decline and extinction, with international trade permitted only in exceptional circumstances. Six species are listed in whole or as subpopulations with designated status by the International Union for the Conservation of Nature and Natural Resources (IUCN; http://www.iucnredlist.org) red list of threatened species. Status identifies those with too little information to rank (data deficient: the flatback [*Natator depressus*]) and those designated as vulnerable to critically endangered: leatherback (*Dermochelys coriacea*), Kemp's and olive ridley (*Lepidochelys kempii* and *L. olivacea*), hawksbill (*Eretmochelys imbricata*), loggerhead (*Caretta caretta*), and green turtle (*Chelonia mydas*). Those same six species are listed in whole or in distinct populations segments (DPS) as threatened or endangered under the US Endangered Species Act (ESA; https://www.fws.gov/endangered/), and the flatback is listed as vulnerable by the Australian Department of Environment and Energy (https://www.environment.gov.au/biodiversity/threatened/publications/flatback-turtle-natator-depressus-2008). Generally, listings agree, yet there is also some divergence. For instance, leatherbacks are listed as endangered, wherever found, under the ESA, but some subpopulations are designated of least concern and others as critically endangered by IUCN. It is, however, safest to assume that some level of regulatory protection applies when working with any sea turtle species.

Pressures from interactions with humans (industry and recreation), poaching, predation, habitat encroachment and degradation, and infectious and noninfectious diseases together contribute to the worldwide decline in sea turtle populations. Veterinarians working along coastal regions may be presented with opportunities to provide veterinary care to these animals. Sea turtles also are popular exhibit animals and can convey a powerful conservation message to visitors (Fig. 24.1). Because of the legal implications of working with protected species, which vary greatly from location to location, veterinarians must communicate with federal and local authorities regarding medical intervention with these animals.

This chapter is intended to give the veterinary professional a working background for understanding basic sea turtle biology and species identification, as well as husbandry and management in human care. Assessing medical problems and providing treatment are covered in Chapter 176.

SEA TURTLE SPECIES AND IDENTIFICATION

Sea turtles are taxonomically separated into the leathery-shelled (dermochelyid) and the hard-shelled (cheloniid) species. The key characteristics include the presence or absence of complete longitudinal ridges along the carapace versus a hard-keratinous shell (Dermochelyidae versus Cheloniidae, respectively). The family Dermochelyidae is represented by just one extant species. Within the Cheloniidae, the six species can be distinguished by the number and patterns of specific scales on the head (prefrontals), jaw form, the number of claws, and the numbers and patterns of the plates or scutes on the shell. The plastron also has distinct scute patterns, but these scutes are used most often as landmarks for internal structures rather than for species identification. Inframarginal (bridge) scutes are found between the

TABLE 24.1 Conservation Status and Distribution of Sea Turtles

Common Name	Scientific Name	Distribution	ESA Status (IUCN)
Loggerhead	*Caretta caretta*	Tropical and subtropical Atlantic, Pacific, and Indian Oceans; Mediterranean Sea	T/E (LC to CE)
Green turtle	*Chelonia mydas*	Tropical and subtropical Atlantic, Pacific, and Indian Oceans	T/E (E [LC Hawaii population])
Hawksbill	*Eretmochelys imbricata*	Tropical Atlantic, Pacific, and Indian Oceans; Black Sea	E (CE)
Kemp's ridley	*Lepidochelys kempii*	Western Atlantic, Nova Scotia south to Mexico	E (CE)
Olive ridley	*Lepidochelys olivacea*	Tropical and subtropical Atlantic, Pacific, and Indian Oceans	T/E (V)
Leatherback	*Dermochelys coriacea*	Atlantic, Pacific, and Indian Oceans; north to Alaska and south to Australia; Mediterranean Sea; Great Britain to South Africa	E (LC to CE, and two DD)
Flatback	*Natator depressa*	Tropical and subtropical Australian waters	[V] (DD)

Conservation status as listed under the United States Endangered Species Act (ESA) and in parentheses, by the International Union for Conservation of Nature (IUCN). Some species are divided into distinct population segments (ESA) or subpopulations (IUCN) with different conservation status assignments. CE = critically endangered, DD = data deficient for determination, E = endangered, T = threatened, LC = least concern, V = vulnerable. The flatback turtle has no listing under the ESA but is listed as Vulnerable by the Australian Government, Department of the Environment and Energy.

FIG 24.1 Green turtle (*Chelonia mydas*) in a large multispecies exhibit tank at a public aquarium. (Courtesy of North Carolina Aquarium at Pine Knoll Shores.)

carapace and plastron.[1] Inframarginal counts usually range from three to four but can be highly variable and hence are of limited use as diagnostic characters.

Scutes of the carapace are the marginals, laterals (= costals), and vertebrals (= centrals). The first marginal caudal to the neck is the nuchal. The most posterior marginal scutes on each side are termed supracaudals (= postcentrals). The paired scutes of the plastron (listed cranial to caudal) are the gular, humeral, pectoral, abdominal, femoral, and anal; unpaired intergular and interanal scutes sometimes are not present (Fig. 24.2). Supernumerary scutes are common in species that incubate under very warm or very dry conditions.

Leatherbacks lack distinct head scales as adults, lack claws, and have a thin keratin covering on the jaws. The cheloniid sea turtles are characterized and distinguished from one another by the prefrontal scales on the head, carapace shape and scute pattern, inframarginal scute characteristics, the numbers of claws on the flippers, and details of the robust keratinous covering of the jaws (rhamphotheca). Most species have two claws associated with digits I and II. The claw I on digit I is usually larger than claw II; in adult males, claw I is enlarged and strongly curved ventrally. The number of claws on the front and hind limbs is the same. Fig. 24.3 compares the distinguishing features of all seven species.

The hard-shelled sea turtles have keratinous scales on the dorsal and lateral head that are used in identification of species. The prefrontal scales are a key characteristic. They occur in pairs on the snout. Green turtles and flatbacks have one pair of prefrontal scales. The other species all have two pairs and may have one or more supernumerary scales along the midline that separate the pairs. Other head scales are not diagnostic.

The rhamphotheca may be used for species identification. Most species have sharp cutting edges or crushing plates. In green turtles, the rhamphotheca has serrated edges for cropping sea grasses (Fig. 24.4).

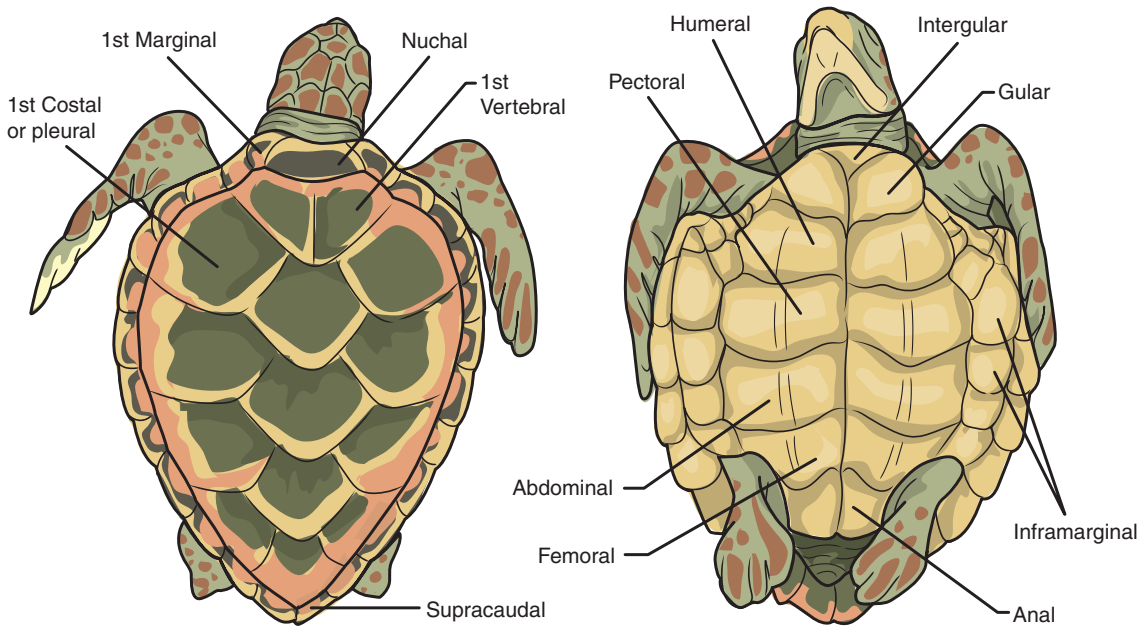

FIG 24.2 The scutes of the carapace and plastron are keratinous. Their pattern and number can be diagnostic in determination of species. Scutes in different parts of the carapace, bridge, or plastron are named here. (With permission of Jeanette Wyneken, 2001, "Guide to the Anatomy of Sea Turtles," NMFS Tech. Publication NOAA Tech., Memo NMFS-SEFSC-470.)

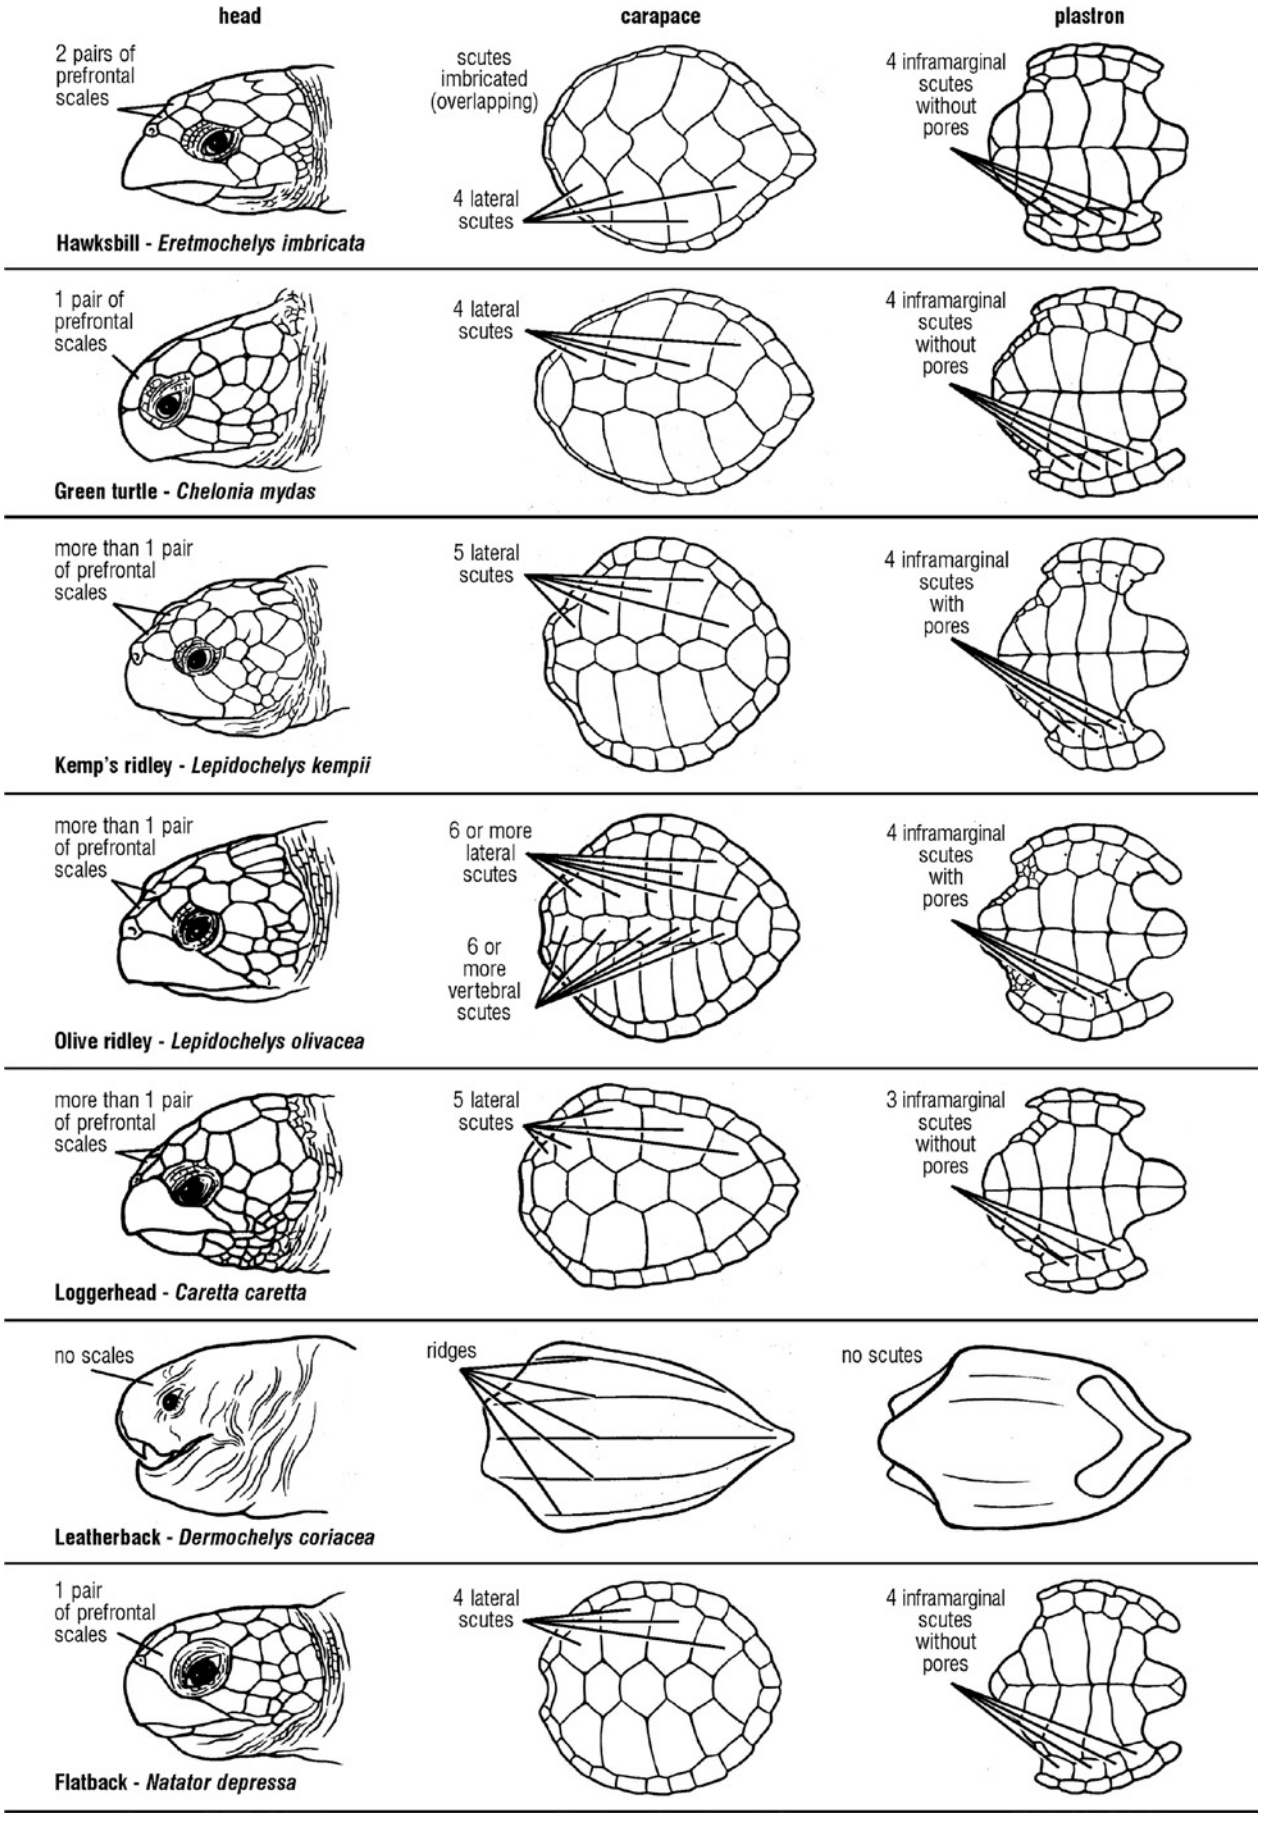

FIG 24.3 Key to sea turtle species. (Modified from Jeanette Wyneken, 2001, "Guide to the Anatomy of Sea Turtles," NMFS Tech. Publication NOAA Tech., Memo NMFS-SEFSC-470.)

VetBooks.ir

FIG 24.4 Sea turtles lack teeth, as do other turtle species. The upper and lower jaws are covered by keratinous rhamphothecae. Most species have sharp, cutting edges on crushing plates (top); however, the herbivorous green turtles (*C. mydas*) (bottom) have serrated edges on the rhamphothecae. (Courtesy of Jeanette Wyneken.)

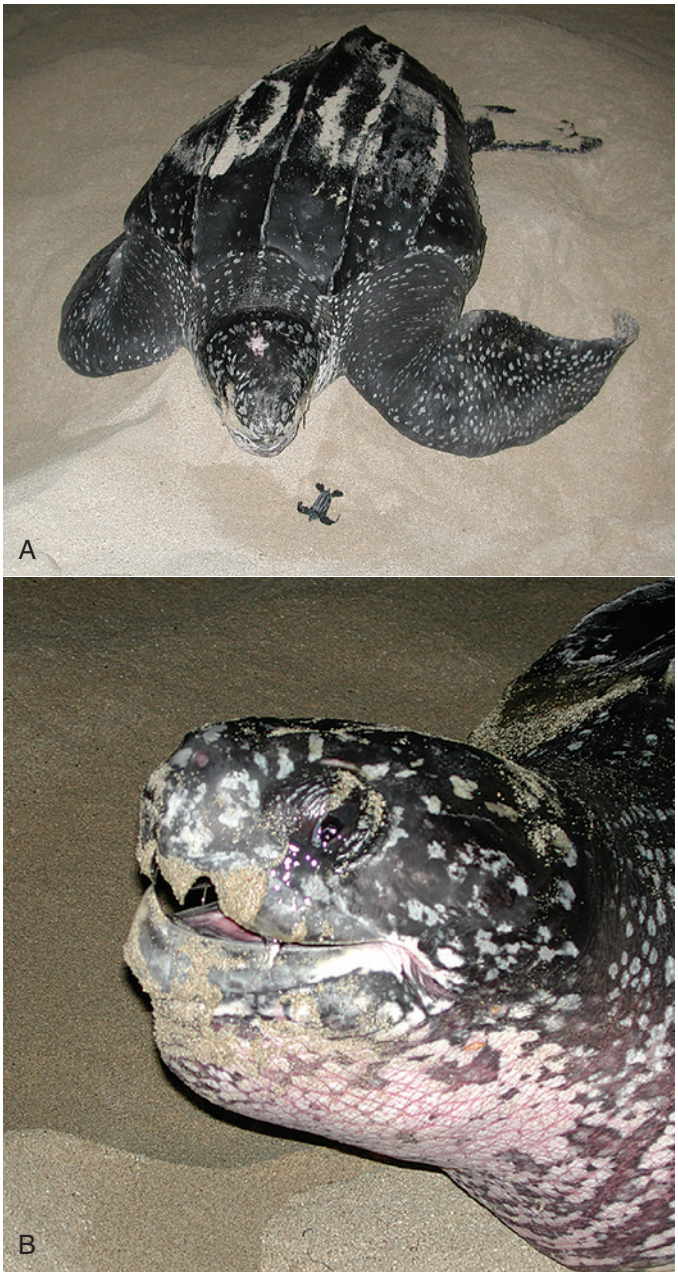

FIG 24.5 A The leatherback (*D. coriacea*) is the largest of all the sea turtles and is black with white stripes (young) or white spots (juveniles and adults). The hatchlings have scales that are lost in the juveniles. The carapace has five longitudinal ridges running its length. (B) The jaws have little keratin, and a characteristic notch is seen in each side. (Courtesy of Jeanette Wyneken.)

Just one dermochelyid species exists: the leatherback (Fig. 24.5). It is black with white speckling. Five dorsal ridges run the length of the carapace, two ridges form the margins, and ventral ridges are seen in hatchlings but are usually not obvious in adults. The upper jaws have a notch in each side. The flippers and hind feet lack claws.

The six cheloniid species can be distinguished geographically in some cases (see Table 24.1).[2] The flatback is endemic to Australia; Kemp's ridley (both described subsequently) is restricted to the North Atlantic. All can be distinguished from one another with external characteristics, starting with the prefrontal scales and the carapacial scutes (see Fig. 24.3).

The green turtle and the flatback each have one pair of prefrontal scales. The green turtle has a smooth carapace that lacks keels and four pairs of lateral scutes (Fig. 24.6). Carapace color changes with age. It is black in hatchlings and then turns brown and tan in juveniles; in adults it is olive or gray-green, sometimes with speckles of yellow and brown. The plastron is white in hatchlings. It turns creamy yellow, sometimes pink or gray in juveniles, depending on the population. Adult green turtles have a creamy yellow plastron except in more melanistic Pacific green turtles (referred to as black turtles) that have a gray plastron. The green turtle has one claw on each limb.

The flatback is distinct from other cheloniid species (Fig. 24.7). Flatback hatchlings are light gray, and each carapacial scute is rimmed with dark gray. The marginal scutes caudal to the flippers form a serrated edge. As flatbacks grow, the carapace becomes solid gray; the carapacial scutes are thin and appear softer than in other cheloniids and feel waxy. The body is not as tall as in other cheloniids; however, the carapace is not flat as the name implies. The lateral margins of the carapace curl slightly upward. The plastron is white or pale yellow. The flippers and hind feet typically have one claw.

The remaining cheloniid species (*C. caretta*, *L. olivacea*, *L. kempii*, and *E. imbricata*) each have two pairs of prefrontal scales, and, as young, they have keels (ridges) on their shells. All have two claws on each flipper or foot. The loggerhead (Fig. 24.8) has a large head and brown

VetBooks.ir

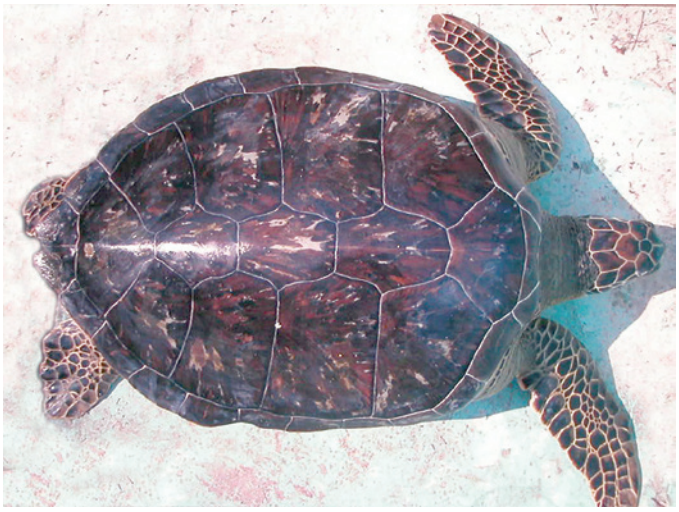

FIG 24.6 The green turtle (*C. mydas*) lacks keels on its smooth shell. This species changes colors dramatically from hatchling (black carapace with white ventral surfaces) to adult (brown, tan, or olive gray). (Courtesy of Douglas R. Mader.)

carapace with five (sometimes four) lateral scutes. The nuchal scute (the marginal just dorsal to the neck) is in contact with the first lateral scute on each side. In hatchlings, the carapace is brown with various shades of dark gray (see Fig. 24.8). The plastron of hatchlings is light tan to brown. In juveniles and adults, it is cream to tan. The carapaces of juveniles often develop streaks of yellow and tan, and sometimes the scutes slightly overlap at their caudal margins. In adults, no overlap of scutes is seen. The carapace is primarily brown, with occasional individuals retaining some tans or even black. The shells of juvenile and adult loggerheads often host large epibiont communities. Loggerheads have two claws on each limb.

Hawksbill hatchlings have carapace and plastron colors that range from medium to dark brown. The head of the hawksbill soon elongates so that, even in turtles as small as 15 cm SCL, the head is nearly twice as long as it is wide, and the rhamphothecae form a long, narrow, distinctive beak (Fig. 24.9). The carapaces of juveniles and adults have distinctive patterns of yellow, black, tan, and brown radiating through scutes that overlap at their margins (Fig. 24.10). This color persists through adulthood. The nuchal scute does not articulate with the first lateral scute in hawksbills. The plastron of adults is light tan. Each plastral scute may retain a spot of dark color in juveniles.

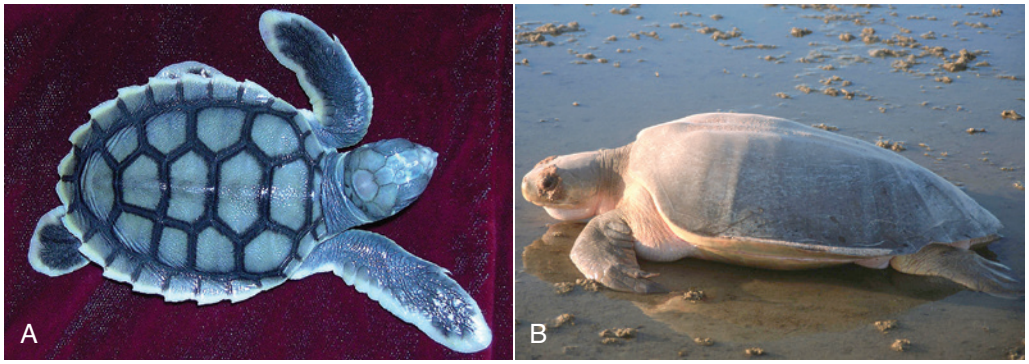

FIG 24.7 Flatback sea turtles (*N. depressa*) are endemic to Australia. (A) This species has dark pigment around each scute in hatchlings. (B) As a juvenile or an adult, it is primarily gray or gray and tan dorsally and white or light tan ventrally. The carapace of the adult flatback has upturned lateral edges. This species has thin keratinous scutes and scales, so the skin is pliable and the carapacial scute pattern is not easily discerned. The flippers retain more flexibility in the digits than many other cheloniids. The flatback has powerful jaws and can have a contrary disposition. (A, Courtesy of Jeanette Wyneken; B, courtesy of K. Pendoley.)

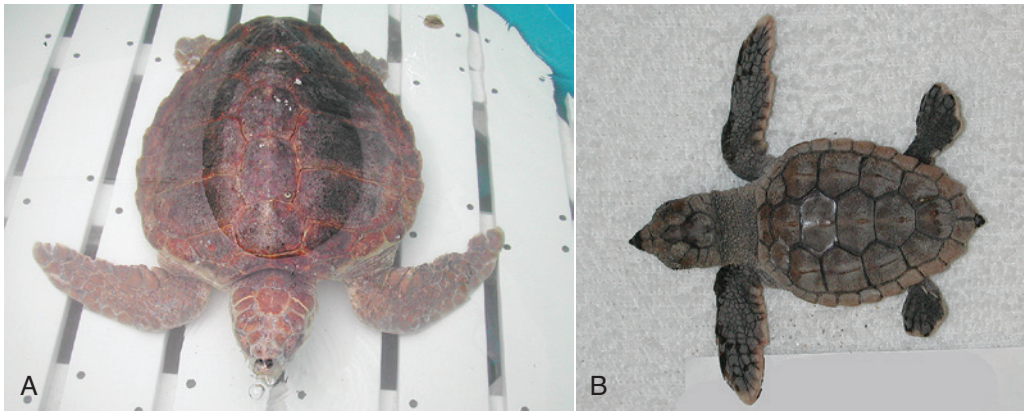

FIG 24.8 (A) The loggerhead (*Caretta caretta*) is a brown turtle with an obviously proportionately larger head than the other cheloniid species. It has two pairs of prefrontal scales and two claws on its limbs. (B) Hatchlings, juveniles, and adults are mostly brown with gray and tan coloration. (A, Courtesy of Douglas R. Mader; B, courtesy of Jeanette Wyneken.)

VetBooks.ir

FIG 24.9 The head of the hawksbill (*E. imbricata*) is elongated so that, even in turtles as small juveniles, the head is nearly twice as long as it is wide, and the rhamphothecae form a long narrow distinctive beak. (Courtesy of Douglas R. Mader.)

FIG 24.10 Hawksbills (*E. imbricata*) have overlapping scutes at most life stages. The beautiful epidermal scutes on the carapace and plastron are the source of the "Tortoiseshell" used in jewelry. These colors differ little between juvenile and adult stages. (Courtesy of Jeanette Wyneken.)

The remaining two species of sea turtles that occur in U.S. waters are both members of the genus *Lepidochelys* (Fig. 24.11). Both are primarily gray. The Kemp's ridley occurs in the Gulf of Mexico and East Coast waters. The olive ridley occurs in Pacific and South Atlantic waters (but occasionally strays into North Atlantic regions). The hatchlings of both species are gray-brown. The carapace grows more rapidly in width than length for some periods so that both species are nearly round in dorso-ventral silhouette. Much of the width increase is due to growth in the marginal scutes, which become wide. Olive ridleys typically have more than six normally aligned lateral scutes, six or more normally aligned vertebral scutes, and many supraoccular scales on the head. Kemp's ridleys, in contrast, have four (sometimes five) lateral scutes and just five vertebrals. In both ridley species, often four (sometimes three) inframarginal scutes characteristically each have a pore (Fig. 24.12).

FIG 24.11 Both species of the ridleys are primarily gray, and the carapace is nearly round in outline. (A) The olive ridley (*Lepidochelys olivacea*) has many more vertebral and lateral scutes than the Kemp's ridley *(L. kempii)*. (B) Kemp's ridleys have four or five lateral scutes and just five vertebrals. (A, Courtesy of Jeanette Wyneken; B, courtesy of Douglas R. Mader.)

NATURAL HISTORY

Sea turtles are long-lived and late maturing. In most species, longevity records are limited and often are best estimates. Life spans are estimated to be in the range of 50 to 75 years, based on long-term mark-and-recapture studies and captive records.

The sexes can be differentiated from one another by external characteristics only at puberty, which, depending on species, ranges in age from 8 to 20 or more years. Mature males have long, prehensile tails that extend well beyond the carapace margins (Fig. 24.13), and the cloacal opening is closer to the tail tip than to the most caudal part of the plastron. The tails of mature females (and immature turtles) are short and seldom extend beyond the carapace except in adult leatherbacks. The cloacal opening is close to the plastron in females.

The age to maturity is becoming better understood in several species through skeletochronological approaches using lines of arrested growth (LAGs) in the humerus or scleral ossicles on histologic sections, although considerable variability probably exists. Age estimates in adult females may also be independently assessed using DNA fingerprinting and mark-and-recapture techniques. Age to maturity within the same species may vary by the ocean basin in which it lives. Maturity in cheloniid species have estimates of roughly 25 to 50 years, with the younger estimates primarily coming from Atlantic populations and the older estimates from Pacific populations.[3,4] Kemp's ridleys appear to mature

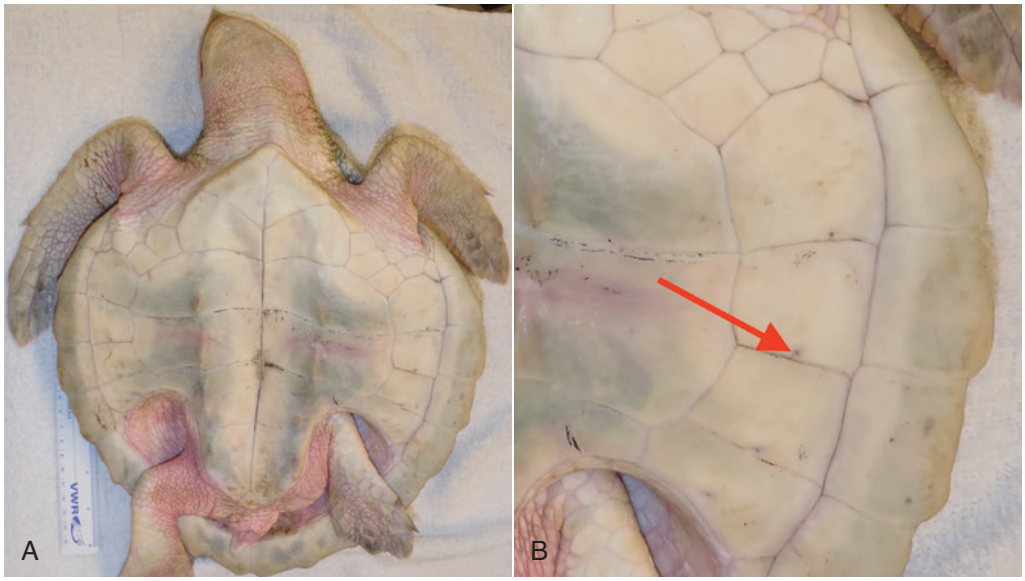

FIG 24.12 (A) This ventral view of a Kemp's ridley (*Lepidochelys kempii*) shows the almost round outline of the shell, the wide marginal scutes, and the pores (B, arrow) in the inframarginal scutes that are characteristic of this genus. (Courtesy of Craig A. Harms.)

FIG 24.13 Dorsal view of an adult male loggerhead (*Caretta caretta*) shows the tail extending well beyond the carapace margin. (Courtesy of Craig A. Harms.)

at younger ages, around 10 to 12 years.[5] There is some disagreement in the literature regarding age at maturity in leatherbacks, with early estimates at 13 to 14 years[6] and later estimates of 20 to 25 years.[7] Adult body weights vary by species and within species by location. Table 24.2 lists approximate adult size and weights.

Members of the genus *Lepidochelys* exhibit a coordinated nesting event known as an "arribada." Kemp's ridleys and some populations of olive ridleys mass nest for several months of the year. This occurs mainly at night for olive ridleys and during the night and day for Kemp's ridleys. Solitary nesters occur as well. The synchronous emergence of 100 to 10,000 females to oviposit occurs over a 1-to-3-day period and repeats approximately every 30 days for the season.[8] Decades of egg and turtle harvesting during these events combined with heavy incidental mortality in fisheries and other industry-associated threats have taken a toll on the Kemp's ridley population, which has improved over decades but remains endangered.

For centuries, sea turtles have been exploited for meat, oils, leather, and shell for jewelry. Green turtles and hawksbills, with their beautiful shells, were killed for curios. The sea turtle industry has been banned in the United States and other countries. In many places, possession or trade in sea turtle artifacts is illegal. Illegal harvest still occurs in many countries, and legal harvest (particularly for indigenous peoples) or even farming occurs in some countries (see Chapter 177). Current threats to sea turtles include accidental capture by fishing nets and long lines and entanglement in fishing, lobster, or crab trap lines. Trauma from boats, personal watercraft, fishing gear, and dredging equipment accounts for many of the calls to rehabilitation facilities. Environmental pollution (chemical, agricultural run-off) may debilitate, and in-water pollution (plastics, plastic bags, other trash) may kill animals before they are found. Habitat destruction, loss of nesting beaches, disorientations of hatchlings or nesting females from artificial lighting, predation, and natural disease take a toll on sea turtles.

PERMIT CONDITIONS FOR SEA TURTLE CAPTIVE CARE AND REHABILITATION

Permit conditions for captive care and rehabilitation of sea turtles vary by country. In the United States, permits are issued by the US Fish and Wildlife Service (US FWS).[9] These directives cover a wide range of topics related to husbandry and management of sea turtles, including transportation conditions, tank size and depth, public display and educational messaging, water quality, lighting, temperature, quarantine and biosecurity, environmental enrichment, nutrition, veterinary care and release determination, among others. They allow a certain degree of latitude based on the medical judgment of the attending veterinarian to meet the needs of turtles undergoing treatment and rehabilitation, and for specific research needs. Although US FWS permit conditions are specific to the United States, general principles are applicable to sea turtle captive care anywhere. Major points are included below, but direct reference to country-specific permit conditions is recommended, and as more information is learned about sea behavior and habitats, adjustments may need to be considered.

VetBooks.ir

TABLE 24.2 Size, Weight, and Diet of Sea Turtles

Species	SCL Hatchling	SCL Adult	Weight Range*	Natural Diets
Loggerhead (*Caretta caretta*)	38–55 mm	70–125 cm	170–182 kg	Omnivorous-carnivorous: mollusks, crustaceans, algae and sea grass
Green turtle (*Chelonia mydas*)	45–57 mm	59–117 cm	96–186 kg	Hatchlings omnivorous; juveniles and adults herbivorous: sponges, jellyfish, algae, and sea grass
Hawksbill (*Eretmochelys imbricata*)	39–50 mm	63–94 cm	78–91 kg	Hatchlings omnivorous; adults omnivorous or spongivorous
Kemp's ridley (*Lepidochelys kempii*)	38–46 mm	58–75 cm	32–49 kg	Omnivorous: vegetation, crustaceans, and mollusks
Olive ridley (*Lepidochelys olivacea*)	40–50 mm	56–78 cm	35–45 kg	Omnivorous: vegetation, crustaceans, tunicates, and jellyfish
Leatherback (*Dermochelys coriacea*)	56–63 mm	114–176 cm CCL	200–916 kg	Gelatinivorous: jellyfish, cnidarians, and tunicates
Flatback (*Natator depressa*)	56–66 mm	81–97 cm	80–90 kg	Omnivorous: echinoderms, crustaceans, and sea grass

*Adult female.

HANDLING AND TRANSPORTATION

Sea turtle handling is usually straightforward, constrained mainly by the size and strength of larger individuals, however, hazards to personnel must be considered. Sea turtles typically are not actively aggressive and have a limited range of motion with their heads, but with extremely powerful jaws capable of crushing shellfish, they have the capacity to inflict serious injury if mishandled (Fig. 24.14). Forelimbs (flippers) can slap forcefully enough to bruise restrainers, and claws can scrape exposed skin. Handlers must always be aware of their position relative to the turtle's mouth and should lift sea turtles from the sides. In most cases, lifting adults and large juveniles requires more than two people. The edges of the carapace at the neck and near the rear flippers provide convenient and secure grasping sites for safely lifting the turtle with less risk of joint damage than lifting by the limbs (Fig. 24.15). Sea turtles with shell fractures may be lifted and transported by sliding a strong tarp or board underneath the plastron and lifting that instead of the shell. A custom-made turtle stretcher with Velcro straps (http://wmblanchardco.com/custom-sewing/) can be useful for lifting and carrying larger injured or refractory turtles (Fig. 24.16). Humeral fractures and glenohumeral luxations can occur if foreflippers are restrained improperly with either too much force on the joint or by immobilizing the distal flipper while allowing proximal flipper movement.

Sea turtles are surprisingly responsive to tactile stimulation through their carapace, and many respond by becoming calm when scratched or patted. Covering the eyes with a dry towel may also calm some sea turtles, although patting the carapace or covering the eyes occasionally agitates rather than calms a turtle. Resting the plastron on a tire or other padded elevated surface where flippers cannot gain traction provides convenient nonrestrictive restraint for examinations and minor procedures (Fig. 24.17).

Sea turtles must be protected from heat and cold and kept moist during transport, ideally between 21° to 27°C (70°–81°F). One exception is cold-stunned turtles, which should be kept near the temperature at

FIG 24.16 Restraint stretcher useful for carrying large injured sea turtles. Time of complete physical restraint in the stretcher should be minimized. (Courtesy of Craig A. Harms.)

FIG 24.17 Loggerhead (*Caretta caretta*) restrained on a tire while mayonnaise is used to remove adhered tar. (Courtesy of Craig A. Harms.)

which they stranded or started on a very slow rewarming en route to a rehabilitation facility.[9] Moisture can be provided by covering with a wet towel at temperatures above 24°C (75°F) or with a thin layer of water-based, water-soluble lubricant at lower temperatures. Eyes can be protected with ophthalmic gel for longer transports. Use rigid, covered crates with padding, ventilation holes, and sufficient room for normal flipper and head positioning. Transporting more than one turtle per container is sometimes unavoidable but adds risks of bite wounds. Face the turtles in the direction of motion to reduce agitation from abnormal acceleration backward or sideways. A container with moist sand substrate is recommended for transporting hatchlings, which mimics the beach environment, keeps them from dehydrating, and avoids initiating the swimming frenzy. Hatchling turtles typically undergo a period of hyperactive swimming that distances them from the shore. Hatchlings that are placed in a pool or bucket of water usually cease vigorous swimming prematurely, may fail to reach offshore nursery areas, and deplete yolk reserves.[9] Sand can cause irritation, particularly to the eyes and umbilicus, during the jostling of transportation, so some facilities prefer transporting hatchlings and post-hatchlings on a damp cloth instead. If transporting a turtle by air, follow International Air Transport Association (IATA) Live Animals Regulations (http://www.iata.org/publications/store/Pages/live-animals-regulation.aspx).

HOUSING

US FWS tank size requirements are provided in Table 24.3. These are based on the size of the largest turtle in the tank and are intended to provide adequate room for unimpeded swimming and diving. Tank size requirements for larger turtles are difficult to meet in rehabilitation settings. For example, calculated tank size minimum for a 99 cm SCL (straight carapace length) and 77 cm SCW (straight carapace width) loggerhead would be 8.9 m long × 1.5 m wide × 1.2 m deep. Smaller tanks are allowed, however, to facilitate medical treatments or for short-term management, such as while arranging for release after complete recovery or during mass stranding events. The intent for turtles undergoing rehabilitation is that once medically cleared, they should be released within 2 weeks, so that the duration of holding in smaller tanks is brief. Tank sizes should increase when holding more than one turtle, but permit conditions do not allow for housing hatchlings together, and, even when permitted, caution is warranted to prevent trauma from tank-mate aggression (Fig. 24.18). Green turtles are generally, though not always, more amenable to short-term cohabitation than loggerheads and Kemp's ridleys, although dominance hierarchies develop, and biting increases with time in all species, particularly in the absence of abundant space and hiding places afforded by some large exhibit

TABLE 24.3 Tank Size Requirements (US Fish and Wildlife Service 2013)[9]

Turtle Size (SCL)	Minimum Surface Area	Minimum Width	Minimum Depth cm (ft)
Hatchlings and post-hatchlings up to 6 cm	5x SCL by 2x SCW	>2x SCW	30.5 (1)
6–50 cm	7x SCL by 2x SCW (increase by 50% for each additional turtle)	>2x SCW (>2x the sum of SCW for more than one turtle)	76 (2.5)
50–65 cm	7x SCL by 2x SCW (increase by 50% for each additional turtle)	>2x SCW (>2x the sum of SCW for more than one turtle)	91.5 (3)
>65 cm	9x SCL by 2x SCW (increase by 100% for each additional turtle)	>2x SCW (>2x the sum of SCW for more than one turtle)	122 (4)

Exceptions include allowing smaller tanks to facilitate treatments and short-term management situations. Hatchlings and post-hatchling must not be housed together. Pairings and groupings of larger turtles need to be monitored for compatibility in order to avoid trauma from aggression.
SCL, Straight carapace length; *SCW,* straight carapace width.

FIG 24.18 Floating plastic baskets are used to keep loggerhead (*Caretta caretta*) post-hatchlings separate to avoid intraspecific aggression, while taking advantage of the stability and water quality management of a larger tank system.

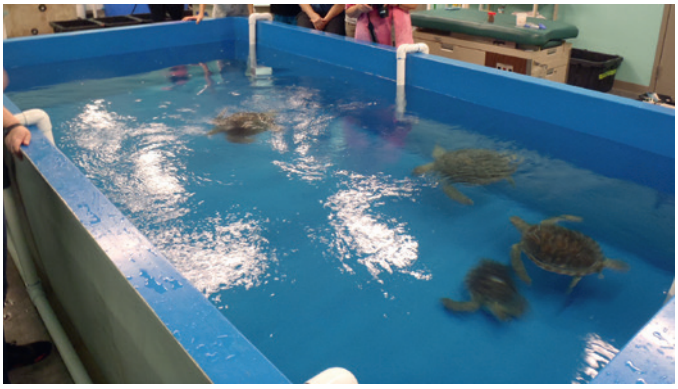

FIG 24.19 Large pool with multidirectional jetted currents used to stimulate swimming for physical therapy. Small green turtles (*Chelonia mydas*) can swim together under observation with relatively low risk of conspecific aggression, and grouping them together also promotes increased activity. (Courtesy of Craig A. Harms.)

FIG 24.20 Sand in the intestines of a loggerhead (*Caretta caretta*). This turtle was managed with mineral oil in food items to help clear the sand from the intestines and changing the tank substrate to eliminate the ingestion hazard. (Courtesy of Craig A. Harms.)

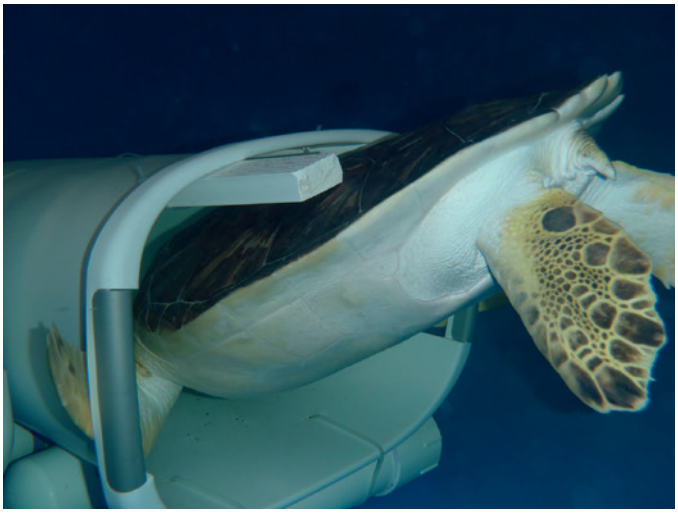

FIG 24.21 A weighted plastic clothes hamper modified by an extension to expand a ledge, and removing the bottom to allow swim-through, provides a mechanism for a positively buoyant green turtle (*Chelonia mydas*) to remain comfortably submerged. (Courtesy of Craig A. Harms.)

tanks. A tank with directed or haphazard currents (e.g., a commercial jetted lap pool or custom-designed currents) can maximize swimming within limited space (Fig. 24.19).

Besides size minimums, additional conditions of tanks should include smooth surfaces that will not abrade turtle skin; nontoxic coatings; use of only finished concrete; and avoiding foreign body ingestion hazards (Fig. 24.20), entangling material, and potential entrapment hazards that could prevent surfacing to breathe. Additionally, using barriers to prevent the public from reaching into tanks is important.

Weak, debilitated, or seriously injured turtles may require dry-docking or shallow wet-docking (water level below the nares) temporarily. Provide padding and keep the turtle moist with wet towels or a sprinkler system when they are not allowed to immerse. Even shallow water can help with hydration, provide some buoyant support, and reduce pressure on the plastron. If wounds are above water, cover the enclosure with insect netting and dress the wounds to protect the turtle from myiasis. Sea turtles need to be submerged for normal voluntary feeding, so ultimately water depth needs to be increased to facilitate adequate nutrition for convalescence and wound healing. After an initial phase of healing, wounds can tolerate water exposure well, as long as good water quality is maintained, and in conjunction with continued topical and systemic treatment. A false bottom made of mesh or a fenestrated platform that can be raised or lowered within a fixed volume intensive care tank can be used gradually to adjust the water depth a turtle can manage, and to raise the turtle with minimal handling for wound treatments.[10]

Environmental enrichment is encouraged to facilitate normal swimming, feeding, and resting behaviors. Ledgelike items are used for submerged resting and back scratching to remove epibiota and loose keratin scutes[11] and are particularly useful to help positively buoyant turtles to remain submerged (Fig. 24.21), although they should not be a risk for entrapment. Enrichment devices including various configurations of PVC pipes (Fig. 24.22), water cooler jugs, jugs and PVC pipes containing food items to simulate foraging (Fig. 24.23), and falling

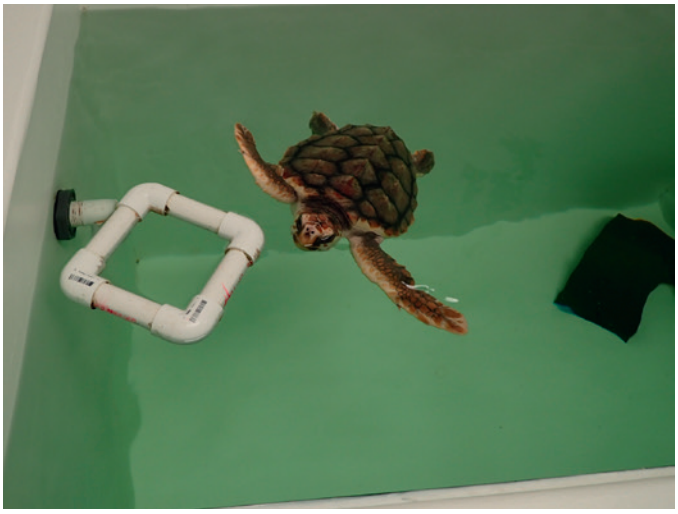

FIG 24.22 Floating PVC-pipe square and submerged half-pipe ledge provide basic enrichment in a tank for a small loggerhead (*Caretta caretta*). (Courtesy of Craig A. Harms.)

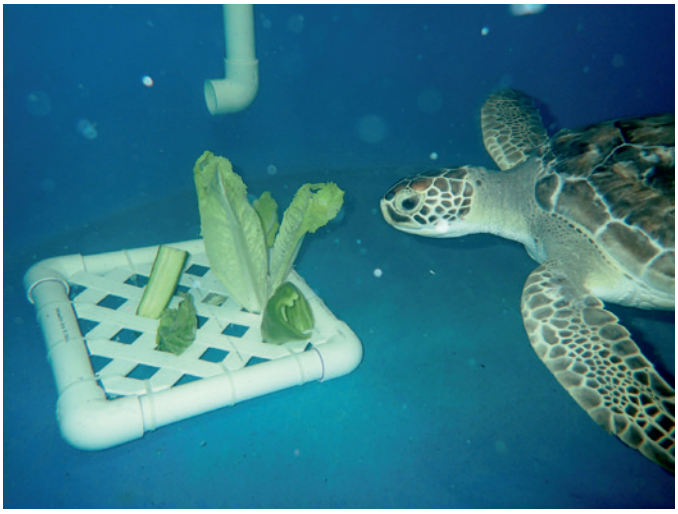

FIG 24.23 Green turtle (*Chelonia mydas*) feeding on fresh cucumber, green pepper, and romaine lettuce anchored in a custom-made weighted PVC-pipe-framed feeding tray. (Courtesy of Craig A. Harms.)

water (e.g., from a hose) are important to provide. (However, some turtles ingest bubbles and may develop positive buoyancy if the water flow produces a stream containing bubbles.) Enrichment devices increase random swimming and focused behavior while decreasing resting and pattern swimming in captive sea turtles, indicating that effective environmental enrichment can be provided for sea turtles similarly as with other animals in human care.[12] Feeding seafood or vegetables in ice blocks is another way to simulate more active foraging behavior and to help prevent rhamphothecal overgrowth. Conch or whelk shells also stimulate biting activity and promote tomial wear if suitably sized, that is, small enough to serve as a source of calcium and roughage without causing obstruction or large enough to prevent ingestion. Sea turtles also are amenable to basic behavioral training for such things as positioning for weighing and examination and separation from mix-species tank mates for focused feedings.

Appropriate water quality and composition are important for maintaining skin and ocular health and avoiding infection of healing wounds. Recommended water quality parameters are listed in Table 24.4. Use these recommendations in conjunction with knowledge of the species, life stage, and habitat from which a turtle is rescued and make adjustments gradually. Additionally, water clarity must be adequate for easy viewing of sea turtles. Freshwater or reduced salinity water can be used therapeutically short-term for rehydration and epibiota/ectoparasite removal, but caution and monitoring of behavior and plasma electrolytes are warranted to prevent hyponatremia, particularly in smaller turtles. Nitrogenous waste products (ammonia, nitrite, nitrate) are more of a concern for fish and are important to monitor if fish are kept in a mixed species exhibit with sea turtles but are not specifically addressed for sea turtle permit conditions. Ammonia and combinations with halogen disinfectants (chlorine, bromine) can be irritating to mucous membranes, however, so maintaining low concentrations of nitrogenous wastes is advisable, even if systems contain only sea turtles. Similarly dissolved oxygen and total dissolved gas tension are of greater concern for fish cohabiting with sea turtles, but adequate dissolved oxygen is necessary for biofilter function (minimum of 5–6 mg/L), and there are anecdotal reports of gas emboli in sea turtles from inhabiting gas supersaturated water.

When sampling for water quality testing, be consistent in timing and locations to ensure reproducible results for monitoring changes, and be strategic about sampling to obtain desired information. For instance, sampling from filtration outflow into the tank provides an indication of filter function, while sampling from mid-water column of the tank shortly after feeding provides an indication of what may be the least optimal water quality the turtle experiences in a 24-hour period.

Water quality is maintained by filtration or water turnover, or a combination of the two. Recirculating systems with filtration, flow-through systems with variable degrees of filtration, and periodic complete water change (dump and fill) systems all can provide either excellent or substandard water quality conditions, depending on rates of filtration or water turnover and properly functioning filters. Water quality being equal, however, dump-and-fill systems, in which all water is removed and replaced at one time and left static between water changes, are discouraged except on a short term, such as in managing a higher number of cases than usual or during power outages.[9]

Filtration includes four basic functions—mechanical, biological, chemical, and disinfection—and multiple filter types are commonly used together.[11,13] A single filter can perform more than one function. Mechanical filters remove suspended particles based on size and type of filter media and include sand, canister, and bag filters. The surface area of mechanical filtration media supports a biofilm that contributes

TABLE 24.4 Acceptable Water Quality Parameters for Systems Housing Sea Turtles (US Fish and Wildlife Service 2013)[9]

Water Quality Parameter	Acceptable Range
Salinity	20–35 ppt (or g/L)
pH	7.2–8.5
Temperature	20–30°C (68-86°F)
Chlorine	<1.0 ppm
Redox potential (ozonated system)	<400 mV
Coliform bacteria	<1000 MPN (most probable number)/100 ml

Exceptions include lower salinity under veterinary supervision for rehydration and for epibiota removal and lower temperatures being raised gradually for cold-stunned turtles.

VetBooks.ir

to biologic filtration. Foam fractionators and skimmers remove a film of organic waste from the surface of the water (skimming) or bubbles (foam), along with some particulates and hydrophobic chemicals, so these filters can be considered mechanical and chemical filtration. Biologic filters combine large surface areas and aeration to promote growth of bacteria that convert ammonia to nitrite and nitrite to nitrate. Activated carbon is used to remove a wide range of chemicals from the water and some suspended particulates.

Disinfection using ozone, UVC light, or chlorine can reduce microbial loads (including pathogens) in the water column, but true sterilization is not feasible or desirable for tanks holding living animals. Ozone and UV light are applied to water flowing through chambers separate from the holding tank, whereas chlorine is applied to the whole system, including the inhabitants. All filtration and disinfection systems require regular monitoring and maintenance, cleaning, or replacement to remain effective. Water should be changed daily in dump-and-fill systems. Feeding 1 to 2 hours before water change and cleaning minimizes the time turtles spend in fouled water, because sea turtles often defecate soon after a new meal. Physical removal of feces and uneaten food with a dip net is labor intensive but dramatically reduces the burden on the filtration system, limits bacterial proliferation, and slows deterioration of water quality in static systems.

Wastewater disposal must follow local, state, and federal regulations. Water discharged from sea turtle facilities may contain a high nutrient load (nitrogen and phosphorous compounds), microbes, drugs and their metabolites, and high salt content. Municipal sewer systems may be an option, but local rules apply. Tertiary wastewater treatment systems can effectively reduce bacterial and nutrient loads, but drugs may pass through unaltered, and some systems may not tolerate high volumes of salt water, necessitating limits on discharge volumes. If discharge directly back into the environment is allowed, some pretreatment is advisable to destroy pathogens (e.g., ozonation, chlorination/dechlorination with sodium thiosulfate), break down or absorb drugs (e.g., ozonation, carbon filtration), or absorb nutrients (e.g., designed wetlands).

Lighting must be adequate for easy viewing of sea turtles in all areas of the tank, with a seasonally appropriate photoperiod. Shaded areas must be provided to give turtles the option of choosing light levels and degree of visual exposure and for outdoor tanks to prevent water from overheating and to allow behavioral thermoregulation. If artificial lighting is the primary light source, full-spectrum UVB bulbs have been mandated for vitamin D production and calcium metabolism.[9] Exposure of sea turtle tanks to adequate UVB by artificial lighting is challenging.[14] The close proximity needed is at odds with electrical appliance splash safety, tank access, and keeping the light (or light guard) surface free of spray and salt caking that can interfere with light transmission. Because of the close proximity of the lights to water, all fixtures should be wired with ground-fault circuit interrupters (GFCIs). Bulb variability, and diminished performance over time, make monitoring UVB exposure important. A commercially available UV radiometer can be used to ensure lighting at the water surface is adequate. The need for UVB lighting to maintain normal vitamin D and calcium metabolism in sea turtles is not entirely clear. Plasma 25-hydroxyvitamin D concentrations decreased over 4 to 5 months in green turtles housed indoors without natural sunlight and continued to decline over a 6 to 8 year period, although clinical signs of vitamin D deficiency were not evident.[15] No significant differences in plasma 25-hydroxyvitamin D concentrations were found between green turtles housed at least 75 days in a rehabilitation facility lacking a UVB source and a wild cohort from the same region.[16] Despite the lack of a clear demonstration of UVB requirement in these limited studies, replicating a complete natural diet in managed care is challenging, and UVB may compensate for dietary deficiencies and imbalances in vitamin D, calcium, and phosphorus. Therefore provision of UVB light by some means is advisable, especially for hatchlings and juveniles that have requirements for growth. Smaller turtles are also easily moved, and rotating them outside periodically for brief exposure to natural sunlight under favorable weather conditions is likely to be more effective than artificial lighting.

Water temperature should be maintained between 20° to 30°C (68°–86°F),[9] although 25° to 30°C (77°–86°F) may be more suitable for maintaining appetite and promoting healing and immune response. Cooler temperatures are required initially for rehabilitating cold-stunned turtles (see Chapter 176). Rapid temperature changes should be avoided, preferably no more than 2° to 3°C over 24 hours.

Hatchlings intended for immediate release from shore should not be kept in water, because they will undergo a swimming frenzy that is essential to propel them to offshore currents and floating vegetation, depleting their energy reserves. Once hatchlings end their frenzy, it will not resume, and they will require a boat ride for release to favorable currents. Hatchlings should instead be kept moist in a quiet, low-light container. If they are held for treatment (e.g., dehydration, superficial wounds from failed predation attempts), keeping them in water is necessary, but they will need to be released offshore in suitable habitat, because they will lack the energy reserves for the swim from shore. Post-hatchlings that have washed back to shore require similar release considerations after rehabilitation.

Mixing of adult male and female turtles is prohibited under USFWS permit conditions to prevent breeding, and if an adult female deposits eggs in the tank, consultation with USFWS within 24 hours is required to discuss the best course of action for the turtle and her eggs.[9] Special considerations for housing and treating leatherbacks are addressed in Chapter 176.

QUARANTINE AND BIOSECURITY

Biosecurity for a facility keeping sea turtles comprises all measures taken to prevent the spread of infectious agents among sea turtles within the facility, to wild turtles from released or translocated turtles, to wildlife from discharge water, and to personnel. Biosecurity measures (including quarantine) can be effective in minimizing transmission of known and, perhaps even more importantly, unknown pathogens. Water supply can be a source of pathogen introduction into a facility, so incoming water should undergo some level of filtration (e.g., particulate, ozone, UVC). Using sea salt mixtures with municipal or well water minimizes the risk of environmental pathogen introduction, though at greater expense than natural seawater. If discharge into adjacent surface waters is allowed, intake pipes should be separated from discharge as much as possible. Indirect transfer of pathogens can occur in water (tanks on the same system, splashes from tanks, and drips from carried seawater), in aerosols, in improperly handled food, and on fomites (e.g., feeding utensils, scrub brushes, towels, enrichment items, clothing, unwashed hands). Physical separation of tanks and water handling systems provides an important barrier against waterborne pathogen transfer. Quarantine is an important measure to prevent introduction of disease to turtles already under care. Sea turtles admitted to a rehabilitation facility are in some state of debilitation and so are more likely to be shedding infectious agents, as well as more susceptible to infection. Quarantine tanks should be on separate water systems from those holding turtles under long-term care and ideally in separate rooms with dedicated air handling, cleaning, and feeding utensils. Minimize personnel traffic in the quarantine area. If staffing levels permit, have individuals dedicated only to quarantine, or if not, service the quarantine area after the nonquarantine areas. Any duration of quarantine can reduce the risk of pathogen introduction; the US FWS specifies a 60-day quarantine period for juvenile and adult turtles.[9] Completion of a quarantine period

VetBooks.ir

is not a prerequisite to release from the rehabilitation facility. During mass stranding events such as cold stunning or oil spills, space limitations may make adherence to the all-in-all-out principle of quarantine difficult or impossible, but some batching may be possible as groups progress through quarantine. Releasing turtles promptly after they are medically cleared minimizes overlap of healthy recovered turtles with compromised recent admissions and alleviates overcrowding that can foster cross-contamination.

After a turtle has vacated a tank, the tank should be cleaned, disinfected (e.g., bleach, quaternary ammonium compound), and well rinsed before occupancy by another turtle. If a turtle dies, following postmortem examination to ascertain likely cause of death, the carcass should be incinerated/cremated or buried deeply to avoid transfer of drug residues or pathogens to scavengers and the environment.

Preventing zoonotic disease transmission to staff is a priority. Sea turtles are not particularly high-risk animals from a zoonotic perspective in husbandry and rehabilitation settings, but they do harbor many gram-negative and gram-positive bacteria that have been documented in infections of humans, including *Vibrio* spp., *Enterococcus* spp., and others. Some of these bacteria may be resistant to multiple antibiotics even before selection by antimicrobial therapy in rehabilitation,[17,18] which could complicate treatment in the event of a human infection. Reasonable hygienic and personal protection measures are warranted when working with sea turtles as with any animal. These include, but are not limited to, nonsterile examination gloves, hand washing, eye protection when irrigating wounds, not immersing cuts or open sores in tank water, changing soiled clothes, and showering after working with sea turtles.

NUTRITION

Food should ideally replicate or mimic the natural diet for species and life stage (see Table 24.2), although this can be difficult to achieve for herbivorous green turtles, gelatinovorous leatherbacks, and spongivorous hawksbills. Animal-based feed is easier and more economical to provide to green turtles and is readily accepted, but it is not suitable for long-term maintenance. Green turtles can be adequately maintained with a mix of calcium-rich greens, even though terrestrial-source vegetation does not match the nutritional profile of sea grasses they normally consume. Even for omnivorous-carnivorous loggerheads and ridleys, fish and shellfish available commercially in economical quantities may be higher in fat (e.g., herring, mackerel) and deficient in calcium (e.g., squid) compared with their natural diets, risking obesity, hepatic lipidosis, or calcium/phosphorus imbalance. Food must be high quality, uncontaminated, and unspoiled (Fig. 24.24). To minimize nutrient loss and bacterial growth, frozen food should be thawed under refrigeration, finishing thaw shortly before feeding, and should never be refrozen.[19] Live food has the advantages of freshness and being stimulating to the appetite but can also transmit parasites and be more active and effectively defensive than a debilitated turtle can manage, and it is better reserved for prerelease conditioning. A floating pellet diet for fish has long been used with good success in a sea turtle–rearing facility and mimics pelagic-phase feeding,[20] but it may not be readily accepted by sea turtles in rehabilitation. A homemade gel diet listed in Table 24.5 can be modified based on available ingredients and monitoring turtle growth and plasma biochemistry values and used as a vehicle for delivery of oral medications.[21] A commercial gel diet for sea turtles is also available (http://www.mazuri.com/seaturtle-aquatic.aspx). Without gelatin (i.e., meal diet for the commercial product), these may also be used as a tube-feeding formula for anorexic turtles. Feeding rates vary by life stage, with younger, faster growing turtles requiring a greater amount. Good growth rates using a dry feed have been achieved starting at ~2% body weight per day, scaling down to 1.2%.[20] Wet gel foods would be about five times that amount by weight.[20] For maintenance in a healthy subadult to adult turtle, feeding rate could be as low as 1% wet feed per week.[20] Regular weighing of sea turtles is required to assess and adjust feeding rate.

Restoring a positive plane of nutrition is essential for adequate wound healing and immune response. For weak debilitated turtles, feeding rate must start slow to avoid impaction and to prime the gastrointestinal system, which may have developed ileus during prolonged inanition. After verifying digestive function and defecation, the above rates can be increased to allow normal maintenance or growth and recovery of

FIG 24.24 Food preparation cart with fresh greens for green turtles (*Chelonia mydas*) and fresh fish and shellfish for loggerheads (*Caretta caretta*) and Kemp's ridleys (*Lepidochelys kempii*) measured out in individual sanitized dishes and feeding trays. (Courtesy of Craig A. Harms.)

TABLE 24.5 Gelatin Diet for Sea Turtles

Ingredient	Weight (g)	Percent of Diet
Staple diet		
Trout chow	425	8
Fish, various species	565	10.6
Squid (viscera removed)	282	5.3
Peeled shrimp	282	5.3
Carrots (fresh, washed)	142	2.7
Spinach (fresh or frozen)	142	2.7
Gelatin (unflavored)	450	8.5
Water	2800 mL	53
Supplements		
Sea tabs (Pacific Research Labs, Inc, El Cajon, Ca) #4	500 mg tabs	0.04
Amino acid complex 1000 #4	500 mg tabs	0.04
Spirolina (Lightforce, Santa Cruz, Calif)	50 mL powder (28 g)	0.5
Rep-Cal (Rep-Cal Research Labs, Los Gatos, Calif)	200 mL powder (180 g)	3.4

Diet can be modified based on available ingredients and can be used as a vehicle for oral medications.
Modified from Whitaker BR, Krum H. Medical management of sea turtles in aquaria. In Fowler ME, Miller RE, editors. *Zoo and Wild Animal Medicine 4*. Philadelphia: WB Saunders; 1999:217–231.[21]

VetBooks.ir

body condition. Rehydration and correcting electrolyte imbalances also helps ensure digestive system function. Softer highly palatable foods (e.g., fish fillets, debeaked squid) are appropriate in early stages of rehabilitation to provide essential protein and calories and reduce chances of impaction. However, once a turtle is feeding well, transition to a more balanced whole food diet for carnivores and to a primarily plant-based diet for green turtles is recommended. Debilitated turtles may require some level of assisted feeding initially. This can range from tong feeding to gently lifting the beak and placing food in the oral cavity or pharynx (with tongs) to tube feeding. Overly aggressive assisted feeding may lead to impactions. Tube feeding is a stressful procedure but in some cases is unavoidable. Tube-feeding formula is easily regurgitated by sea turtles, so they must be tilted head up during tube feeding and for a period afterward. The volume for tube feeding may start at 0.5% of body weight and gradually increase to 3%, once or twice daily. Continue trying to transition to less aggressive forms of feeding in between tube-feeding sessions. If a turtle is too weak to remain in water continuously, it may still be placed in water supervised for short periods to encourage voluntary feeding. Once a turtle no longer requires assisted feeding, cease hand or tong feeding as quickly as possible and transition to broadcast or bottom feeding to discourage habituation and promote natural feeding. Parenteral nutrition has been used successfully in recent years during the initial recovery phase for emaciated, debilitated sea turtles that are not amenable to enteral assisted feeding.[22]

CONCLUSION

The ability of sea turtles to recover from major injuries and serious medical conditions, given adequate time and supportive care, make them incredibly rewarding patients to treat. The population-level impact of rehabilitating sick and injured sea turtles is unclear, even considering their threatened or endangered status,[23] but the opportunities afforded for education, research, and environmental advocacy are invaluable. Release of a successfully rehabilitated sea turtle is a celebration with potential to inspire greater stewardship of the entire marine environment (Fig. 24.25).

Crocodilians

Javier G. Nevarez

Crocodilians are among the largest reptiles in the world. They range in length from 1.5 meters for smaller caiman and crocodile species to over 6 meters and more than 450 kg for the saltwater crocodile (*Crocodylus porosus*). Most are also long-lived species, but there is no easy way to determine their true age in the wild. A general rule is that smaller species such as caimans will live a shorter life (20–40 years) than the larger crocodiles (60+ years). Therefore, with their size and longevity, they require large enclosures and people committed to their long-term care in captivity. Crocodilians can be found in zoos, aquariums, commercial farms/ranches, breeding facilities, and under private ownership. Commercial farming/ranching is discussed in Chapter 177. While it is certainly possible for some private individuals to properly maintain crocodilians in captivity, the large size and aggressive nature of some species makes them less suited for this scenario. In addition, not all states or countries allow private ownership of crocodilians. Crocodilian exhibits help educate the public about both the importance of protecting these reptiles and the dangers of not respecting them in their natural environment. In general, crocodilians are fairly low-maintenance animals with respect to need for frequent veterinary care; however, when required it can be daunting for all involved. Proper habitat design can help provide ease of capture, allow separation of sick animals, and make it easier to perform daily observations. As a group, crocodilians have unique husbandry and management requirements that are key for the safety and well-being of both crocodilian and personnel alike.

RESTRAINT

The methods and requirements for handling and restraint vary, depending on the size, species, and the procedure to be accomplished. Crocodilians are powerful animals, and their physical capture and restraint should always be performed by experienced personnel. Contrary to popular belief, crocodilians are quite astute and very observant of their surroundings. They will quickly be aware of a change in routine, leading them to be on high alert. Alligators and most caimans tend to be more defensive in nature whereas crocodiles are more aggressive and can take an offensive stance when threatened. Therefore capture and restraint plans must be carried out in a careful but swift manner. Crocodilians will lunge forward and can move their heads quickly side to side but are not very fast crawling backward. They can, however, turn around very quickly. Approaching a crocodilian is best performed from behind the animal, never from the front or the sides. It is also important that all personnel are committed to follow through in synchrony once contact has been made with the animal, otherwise a small number of individuals will quickly be overpowered, which increases the risk of injury.

A minimum of one person is required for every meter of body length (tip of snout to tip of tail) for animals up to 2 m. Beyond 2 m, there should be two persons for every additional meter. Manual restraint can be safely performed for crocodilians up to 3.5 m in length. Physical restraint of animals larger than 3.5 m should be reserved for only the most experienced of crews. In the absence of such a crew, or when dealing with aggressive animals, chemical immobilization is the only safe option (see Chapters 48 and 49). Large crocodiles of any species are extremely dangerous to handle (more so than alligators). They are faster and more aggressive than alligators or caimans.

The first goal of manual restraint is to control the head, followed by the tail and limbs. The muscles used to open the mouth are relatively weak, so the mouth can be easily held closed. Care must be taken when working around the head, because the teeth that are exposed even when the jaws are closed can cause injury to the handler (Fig. 25.1). The tail must be controlled at all times to prevent vigorous lashing that can cause injury. The limbs must be controlled to prevent them from rolling and attempting to escape. Staying as close as possible to the animal will minimize the risk of injury, because the tail cannot travel as far, thereby minimizing the damage of a tail strike. When collecting diagnostic samples, one should work in line with the long axis of the animal and avoid working beside them to avoid injury from the head or tail. Hands should be kept as far away from the mouth as possible (Fig. 25.2). Applying pressure over the eyes helps decrease visual stimulation and also induces vagal tone to help calm the animal (Fig. 25.3).

Hatchlings and juveniles up to 1 m can be physically restrained with one hand to hold the mouth closed and the other hand to control the lower body and tail. Once the mouth is taped, control can be maintained by grasping the cervical area and supporting the tail (Fig. 25.4). An effective grasp for animals up to 1 m is to bring their body close to the handler, support their neck, and simultaneously hold the rear limb facing away from the person's body at the base of the tail. By holding the limb and tail, the animals are less likely to attempt rolling.

Animals between 1 and 3 m can be caught by hand or with the aid of a catchpole or snare. The metal cable of the snare should be encased in plastic to prevent injury to the animal. Again the animal should be approached from behind, and the handlers must commit to reaching out to grab the animal. Any hesitation can provide the animal enough time to turn around, possibly causing injury to the personnel. Their nature is to roll or twirl once the snare is around the neck. One must be prepared to rotate the snare to prevent injury or strangulation of the animal. The tail should be grasped as soon as possible because this serves to immobilize the animal to some extent until the mouth can be securely closed. However, one must remember they are capable of turning around, and holding the tail does not guarantee personal safety. The head can be swiftly moved from side to side even with a snare around the neck. One can then pin the head manually and secure the mouth with tape. Placing a towel, rag, or taping over the eyes tends to help keep the animal calmer (Fig. 25.5). This can be done before or after restraining the head.

For animals over 3.5 m, physical capture and restraint can be as simple as all crew members forming a single line to approach the animal

VetBooks.ir

FIG 25.1 Morelet's crocodile (*Crocodylus moreletii*) with tape around the mouth and still revealing prominent mandibular and maxillary teeth. These teeth are very sharp and can cut a handler's hand. (Courtesy of Javier G. Nevarez.)

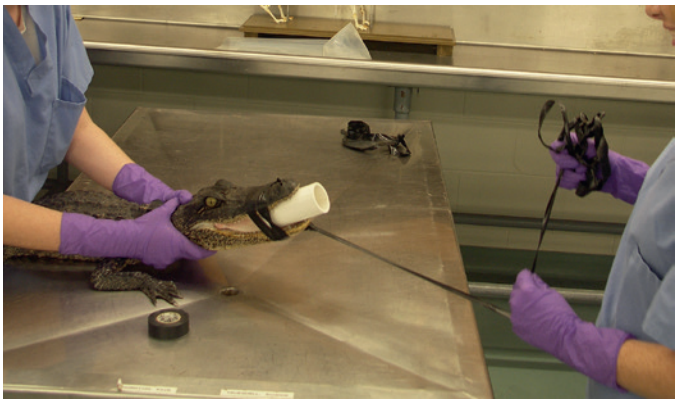

FIG 25.2 Removal of tape that was securing the mouth of an American alligator (*Alligator mississippiensis*). Notice the handler is leaning over the animal to secure the rear limbs and tail while holding the neck of the animal. The person removing the tape is working directly in front of the alligator and taking advantage of slack in the tape to remain a safe distance from the head. (Courtesy of Javier G. Nevarez.)

from behind and then quickly landing on top of the animal in synchrony. For larger and more aggressive animals, special nets and ropes should be used to secure them before any attempt is made to tape the mouth. For large crocodiles, roping the jaws shut and then taping is advisable. Multiple ropes can be used to restrain the head, tail, and limbs before any hands-on contact with the animal. A pole snare or ropes around the neck and another around the jaw plus control of the tail and feet are necessary before tape can be applied to the jaws. The selection of technique will vary with individual and species demeanor, animal accessibility (enclosure design, animal in vs out of the water), personal experience, animal's activity level, and more. Regardless of the technique, the head, tail, and hind limbs must be controlled. If the animal must be transported or restrained for a period of time, both the front and hind feet may be secured to the body by tying over the back (see Fig. 25.5), or the animal can be tied/taped to a wooden board. Care must be taken to ensure the limbs are not tied too tight or for long periods of time to avoid injury to the animal.

Transportation of these animals can be accomplished in either burlap sacks, custom crates, or cages, depending on the size and circumstances.

FIG 25.3 Restraint for supravertebral venipuncture in an American alligator (*Alligator mississippiensis*). Notice the eyes are being covered by the handler's hand to decrease visual stimulation and elicit vagal tone to calm the animal. The person holding the animal has a firm hold on the neck while putting slight downward pressure. The tail is controlled between the handler's legs; however, the rear limbs of the alligator are on the table, which would provide leverage if it attempted to roll. It would be better to have the limbs off the table for added safety. (Courtesy of Javier G. Nevarez.)

FIG 25.4 Restraint of an American alligator (*Alligator mississippiensis*) after its mouth has been taped. The neck and tail are held in order to both control and support the animal. The animal is kept close to the handler's body. Aggressive species (e.g., crocodiles) would require a more secure grip. (Courtesy of Javier G. Nevarez.)

One must use caution because overheating is possible, especially if the animals continue to thrash about with the mouth closed. Removal of the tape from the eyes or mouth can also be dangerous. The usual procedure is to place a tie or rope around the tape on the ventral side of the jaws between the mandibles. A quick pull from a distance, after the other restraints have been removed, allows the animal to move away. Occasionally an animal escapes after all the restraints except the mouth tape are removed. In these instances, the animal must be recaptured to remove the tape to prevent starvation. Recapture is usually much more difficult.

Operant conditioning is also recommended to train crocodilians to perform var ious procedures, including moving within the enclosure,

FIG 25.5 Anesthetized *Crocodylus niloticus* with a rag taped around the head and eyes, and the limbs taped across on the dorsum. Notice the head and tail as still being held by personnel to ensure the safety of all present. (Courtesy of Javier G. Nevarez.)

getting into a crate, tail access for venipuncture, and more. Engaging enthusiastic personnel in this repetitive activity is key to ensure successful training.

Finally, electrical stunning has been used in commercial crocodile farms in Australia and South Africa to safely immobilize and transport *Crocodylus porosus* and *C. niloticus*.[1,2] In *C. porosus*, the stunned animals had a lower stress response versus restraint with ropes. Stunned animals had no increase in corticosterone or glucose levels.[1] In. *C. niloticus*, blood lactate levels were significantly higher in animals captured with a noose versus those captured via stunning.[2] The author has evaluated electrical stunning in alligators with similar results. These data suggest that electrical stunning could be a useful technique to reduce the stress of restraint and improve safety for both animals and personnel.

IDENTIFICATION

Identification of individual animals in a group of captive crocodilians is frequently advantageous. The use of collars, bands, or tattoos is considered unsatisfactory in most instances because collars and bands are frequently lost during normal animal activity. Tattoos are often difficult to read and fade away. Tags and transponders are better alternatives.

Metal swine ear tags can be used as toe tags for crocodilians. These tags can be placed on the web of the feet (Fig. 25.6). These are not permanent identification but could last for over a year in small animals. Placing tags bilaterally also increases the possibility of longer-term identification. The use of plastic cattle or swine ear tags has been accomplished in the dorsal area of the mid-tail of larger animals. Although animals can be identified, they must be out of the water to do so. The tags can also be lost or bitten off by other animals.

Another method that has been successfully used in some facilities is the placement of a tag on the head (see Fig. 25.6). The numbered half of a common swine tag can be attached to the head by passing a stainless steel surgical wire around the jugal bone midway between the eye and the auditory meatus. The jugal bones are elongated bones that form the lateral borders of the orbits. Each forms a part of the postorbital bar that separates the orbit from the lateral temporal fossa. The advantage of this method is that the tags are inexpensive, easily attached, and visible from a distance of up to 20 ft (6 m). The variety of tag colors allows the left or right side of the head to be used, depending on parameters of gender, clutch group, or age. The disadvantage of the head-tagging method is that the wire must be securely fastened or the tags come off. Also, if the wire is too tight, the jugal bone is weakened and scarred. Identification methods using exposed tags may not be not ideal for animals in zoological institutions, as they are readily visible to the public.

A more permanent identification method is the use of implanted passive integrated transponder (PIT) microchips, commonly known as PIT tags. These are cost effective and are available from a number of manufacturers. The main disadvantage of the smaller (approximately 8×2 mm) full duplex PIT tags is that the scanner must be within a few centimeters of the microchip; however, larger (approximately 23×4 mm) half-duplex PIT tags provide greater range. PIT tags can be implanted in just about any muscle, but placement posterior to the dorsal plate of the head or in the tail provides easier access for reading (see Fig. 25.6). These sites also have a decreased subcutaneous space, which limits migration of the transponder. When possible, the entry point of the needle should be closed with surgical glue or suture to decrease the risks of infection and the transponder migrating out of the animal.

Finally, a permanent identification method is the use of tail notches. The distal tip of the tail scutes are cartilaginous and do not contain any bone. There is blood supply, but bleeding is minimal after notching. Both the paired lateral and single dorsal scutes of the tail can be used to create a numbering system (see Fig. 25.6). In young animals, the scutes are easily cut using a scalpel blade or sharp knife. In older/adult animals, the tissue is more fibrotic; hence, notching takes slightly more effort, but it is still plausible. In either case, no more than 50% of the scute should be notched. This prevents cutting deeper into the tissue, which is likely to be more painful. Tail notching is commonly performed in farmed American alligators before being released to the wild. They appear to tolerate this well, and there are no reported cases of detrimental effects associated with tail notching. However, this technique may be more acceptable for farmed or research animals rather than exhibit animals.

SPECIFIC HOUSING REQUIREMENTS

In a zoological institution, the facilities are aimed at exhibiting the animals in the most appropriate artificial environment possible. While having a naturalistic enclosure is ideal, this may not always be possible. Priorities include water quality, appropriate diet, and enough space to accommodate the growth and number of animals. A rear holding area should also be considered. The size of the enclosure will largely depend on the species of crocodilian and their purpose in captivity. One should have a general understanding of their biology and natural behavior in order to design an appropriate enclosure for display versus breeding. If in doubt, you should contact an institution housing the species for advice on what has or has not worked for them.

When designing an enclosure, first consider the species of interest. Some species grow larger than others and may be more territorial, necessitating a larger enclosure. Also consider how many animals will be kept in the enclosure and their gender. Both males and females can become aggressive during the reproductive season, and keeping them separated should be a consideration if enough space is not available in the primary enclosure. This is often not taken into account, and many crocodilian exhibits do not have any separations or back holding areas. The lack of separate holding areas makes management of aggressive and ill crocodiles challenging.

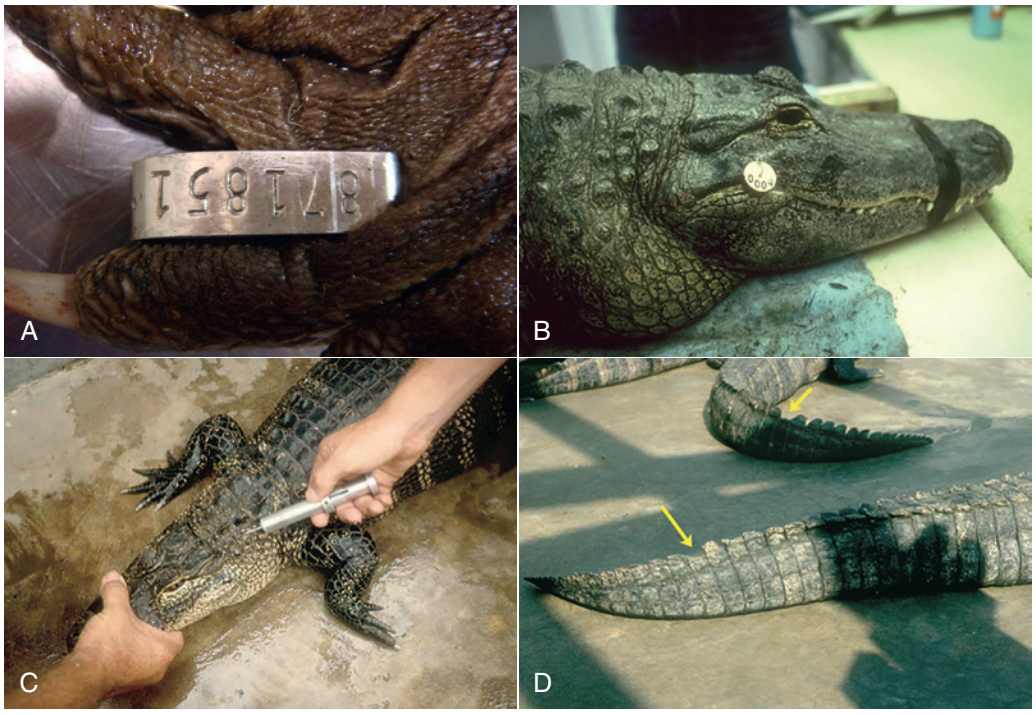

FIG 25.6 Crocodilian identification methods. (A) Metal ear tag used to identify a crocodilian by placing it in the webbing of the feet. Tags with the same number can be placed on multiple feet to create redundancy in case a tag is lost. (B) A head tag placed by passing stainless steel surgical wire around the jugal bone midway between the eye and the auditory meatus. (C) Location for implantation of microchip on the neck region. (D) Tail notching (*arrows*) is a permanent method but cannot be easily visualized when animals are in water.

Exhibits can be outdoors, indoors, or a combination thereof. Outdoor exhibits will likely mimic the natural environment more closely, but also present their own challenges for maintaining water quality and enclosure hygiene. Geographic location will also play a role in the value of outdoor exhibits, because not all species of crocodilians can tolerate cold weather. Finally, some species can create large burrows or tunnels and may escape an exhibit that does not have suitably deep footings. Crocodilians are also adept at climbing; therefore chain-link and horizontal fencing must be avoided.

The temperature and humidity requirements for crocodilians vary with species. As a general rule, 25°C to 32°C is optimal for the growth and well-being of most species. Animals maintained constantly at higher temperatures (e.g., indoor farmed crocodilians) may be more susceptible to certain diseases that are normally restricted to mammals (e.g., West Nile virus). In an enclosure, the water temperature can be maintained via heating elements contained within concrete slab or in-line water heaters and a recirculating system. The water temperature must also be maintained during the wash and refilling period to avoid a drastic temperature change that could lead to cold shock. Relative air humidity should be approximately 40% to 60%. The provision of circadian variations of both environmental temperature and light cycle to mimic the natural environment is recommended.

The UVB requirement for crocodilians is unknown. As true carnivores it might be expected that they can thrive with minimal exposure to UVB as long as they are offered whole prey or a commercial diet supplemented with vitamin D_3. Studies with 5-month-old broad-snouted caimans (*Caiman latirostris*) identified immune activity alterations and genotoxic effects after exposure to 30% UVA 5% UVB Sylvannia Reptistar lights.[3,4] These are the first studies to evaluate the deleterious aspects of ultraviolet radiation (UVR) in reptiles and conclude that provision of UVR must be carefully planned.[3,4] However, natural photoperiods of natural sunlight were associated with greater growth than any artificial lighting regime or darkness.[3] The clinical implications of these findings are not clear at this time. Most captive crocodilians are not offered artificial UVR within large enclosures. For young animals exposed to artificial UVR, a gradient must be provided to allow them to hide from the light as needed. Provision of natural sunlight must be done concurrently with the provision of shaded areas so the animals can seek shelter from the sun.

FIG 25.7 Outdoor enclosure for *Crocodylus acutus*. An artificial pond with sloped concrete leads to a natural soil and grass area. Notice the condition of the tall grass indicating little use of this area of the enclosure.

The two main areas in a crocodilian exhibit will be water and land. Soil, grass, sand, and concrete can be used for land surfaces (Fig. 25.7).

VetBooks.ir

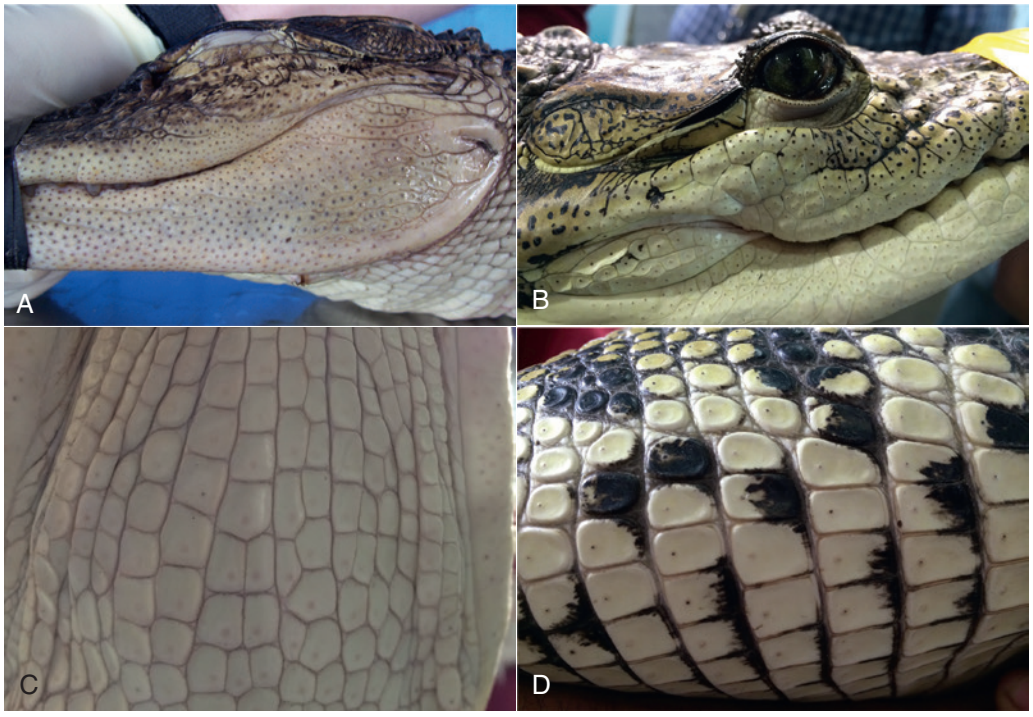

FIG 25.8 Intradermal sensing organs (ISO) (*gray dots*) on the lateral aspect of the head of an alligator (A), crocodile (B), the ventral mandible of a crocodile (C), and the lateral and ventral skin of a crocodile (D). These ISO allow crocodilians to sense water movement and prey proximity, allowing them to hunt even in murky water. (Courtesy of Javier G. Nevarez.)

All-concrete flooring is the least ideal because it can lead to pressure sores and irritation of the skin on the feet and legs. Concrete ramps leading in and out of the water should slope over a distance of 1 to 2 m to minimize haul-out efforts and reduce the risk of skin abrasions. An important consideration for the design of water features is the presence of intradermal sensory organs (ISO) (see Chapter 10), which are highly sensitive free nerve endings similar to the lateral line system of fish (Fig. 25.8). ISO are reported to have mechanical sensitivity exceeding that of primate fingertips.[5] For these reasons, waterfalls and other features creating surface water movement may serve as a source of overstimulation and stress in species that naturally inhabit calm waters. The behavior of animals in these enclosures must be monitored closely to determine if they appear to avoid areas of high water movement. Currently no studies have evaluated this as a potential stressor for captive crocodilians.

FEEDING AND NUTRITION

As true carnivores, crocodilians require a high-protein, high-fat diet that is low in fiber. Their feeding habits in the wild vary with age and food availability. The diet of juvenile animals is often comprised of small invertebrates, amphibians, and reptiles. As they grow, they pursue larger prey of the same type and may add fish and birds to their diet. As adults, they will usually prey on mammals as well. There are various commercial feeds available for captive alligators. A variety of whole prey foods, such as chicken, nutria, and fish, may also be used as part of an overall nutritional plan. Lead toxicosis has been reported in alligators fed nutria killed with lead shot.[6] Lead ingestion was also suspected to affect reproduction in captive alligators.[7] Similar effects have not been observed in *C. porosus* after ingestion of lead shot,[8] suggesting there may be species-specific sensitivity to the toxic effects of lead. If feeding frozen fish, thiamine supplementation may be needed to prevent thiamine deficiency because thiaminases are released from the fish tissues upon thawing. Obesity is a common problem of captive crocodilians due to overfeeding combined with a sedentary lifestyle. Feeding amounts and frequency should be tailored to the age, size, and activity level of the species. Young crocodilians may require feeding three to four times per week whereas adults may only have to be fed once weekly to maintain their body condition. Gastrointestinal foreign bodies can be a common problem, and it is important to prevent the public from throwing coins and trash into exhibits. Hoses, buckets, and other tools must also be stored securely outside of exhibit areas.

Tuatara

Sarah Alexander

Tuatara *(Sphenodon punctatus)* are widely held in captivity in New Zealand and have historically contributed to reintroduction programs. At the time of writing there are six institutions outside New Zealand that house tuatara for display and education purposes. Tuatara superficially resemble lizards, their husbandry is accordingly similar, with a few significant exceptions, and many of the restraint and identification methods used in lizards are also applicable to tuatara.

RESTRAINT

Physical restraint of tuatara is best accomplished by one person. Tuatara are most at ease when lightly restrained horizontally and will often sit comfortably on a handler's forearm with the tail partially wrapped around the arm for security (Fig. 26.1). Vertical restraint may be required for physical examination or blood sampling; in these situations the tuatara is held firmly behind the head with one hand, and the pelvis is supported with the other hand, as in medium-sized lizards. We have found this to be the best method for restraint of captive animals for blood collection from the ventral tail vein, although other methods involving a single operator have been described.[1] A head bandage can be utilized to reduce visual stimulation and induce a vasovagal response, although we have found this method to be of varying success in tuatara. Tuatara can inflict painful bites and may be reluctant to release their grip, in which case placing the tuatara on the ground may encourage it to let go. Their sharp claws can also result in scratches and damaged gloves. Although Salmonella has been infrequently detected in tuatara,[2,3] gloves and appropriate disinfection protocols should be routinely utilized. Tuatara have the ability to autotomize their tails, and this can be caused by tail trauma or improper restraint during handling. This is not a common occurrence, even in conscious animals, when properly handled.

Chemical restraint of tuatara has similarities with other reptiles, but special consideration is given to the tuatara's low metabolic rate, which can result in prolonged recovery times when injectable anesthesia is used. Ketamine hydrochloride should be avoided in tuatara, because prolonged apnea and recoveries ranging from 3 to 12 hours have been documented with doses from 4.5 to 70 mg/kg IM. Alfaxalone (Alfaxan, Jurox NZ Ltd., Auckland, New Zealand) administered IM or IV at 5 mg/kg did not produce appreciable sedation but did prolong recovery from subsequent inhalational anesthesia, whereas at 10 mg/kg IM or IV it produced deep sedation to light anesthesia, with recoveries taking up to 2 hours. The anesthesia agents of choice at Auckland Zoo are isoflurane (Isoflurane-Vet, Merial NZ Ltd., Auckland, New Zealand) and sevoflurane (Sevorane, Abbott, Botany, New South Wales, Australia). Tuatara often breath-hold when administered isoflurane, but this can be reduced by using a tight-fitting facemask to allow partial ventilation, using medical air rather than oxygen on induction, increasing the isoflurane concentration slowly, and gently compressing the cranial coelom or squeezing a toe to encourage ventilation. Similar problems have been experienced with sevoflurane induction, although often to a lesser degree. Several animals have been successfully induced with sevoflurane, with the aid of a darkened induction chamber. After anesthetic induction, the tuatara is intubated in the same manner as a lizard and maintained on the preferred inhalational anesthetic in oxygen. Intermittent positive pressure ventilation (IPPV), typically at 1 to 6 breaths/min, is frequently needed to supplement respirations and maintain anesthesia. Heart rate is easily monitored by use of a Doppler probe placed on the cranioventral coelomic area over the heart. Changing from oxygen to medical air before the end of the procedure may speed return to spontaneous ventilation and anesthetic recovery. Using this protocol, recovery times of 10 to 30 minutes can be expected.

IDENTIFICATION

Adult tuatara are reliably identified by microchip, implanted subcutaneously in the left inguinal region. However, at Auckland Zoo several juvenile tuatara (<2 years of age) have expelled their microchips when implanted in this region or over the lateral coelomic wall, despite appropriate placement and closure of the resulting wound with tissue adhesive. Juvenile tuatara can be visually identified by the placement of beads on nonabsorbable monofilament suture material that is threaded through the nuchal crest (Fig. 26.2) or temporarily by permanent marker or correction fluid on the dorsum. Photographic identification can be sufficient in small groups of animals. Toe clipping is still used as a means of identification in juveniles in field situations if other methods are not available or practical, but it should be avoided in captivity where less-invasive options are available.

SPECIFIC HOUSING REQUIREMENTS

Tuatara are cold-adapted reptiles and should be housed in conditions that mimic those in their natural environment as closely as possible. Temperatures should be carefully monitored and not be above 25°C (77°F) or below 4°C (39°F) for prolonged periods. It has been recommended that ambient air temperature be kept between 4°C (39°F) and 15°C (59°F) in winter and 10°C (50°F) and 25°C (77°F) in summer,[1] with the provision of an artificial heat source for basking in indoor enclosures. In the absence of access to direct sunlight, appropriate UVB supplementation should be provided. Recommended levels are as for other native New Zealand reptiles and are 50–200 uw/cm^2 of UVB 290–315 nm or UV index 1–4 (Gibson R, 2016, personal communication). At Auckland Zoo artificial UVB lighting is provided using Reptisun 10.0 UVB T5 lamps, with output measured regularly using a UVB meter. Humidity levels should be maintained above 60% in the enclosure and above 80% in burrows with the aid of misting if required. Temperature, humidity, photoperiod, and UVB supplementation should be varied seasonally in indoor enclosures to match natural conditions, and adequate ventilation should be provided to achieve good air exchange.

FIG 26.2 Identification of juvenile tuatara *(Sphenodon punctatus)* using beads on suture material placed through the nuchal crest. (Courtesy of Auckland Zoo.)

Enclosures should have a minimum of 3 m^2 of floor space for each adult animal if housed alone and at least 5 m^2 if housed in a group situation (Gibson R, 2016, personal communication). Enclosure substrate should drain freely and be deep enough to allow tuatara to dig their own burrows and nests for egg-laying. Leaf litter is an ideal surface layer, with the remaining substrate comprising soil with the addition of coarse sand or fine pumice for drainage. Substrate should be replaced as necessary to prevent the build-up of waste products. Artificial burrows should also be provided; these can be in the form of partially buried hollow logs, appropriately sized plastic pipes, or purpose-built wooden boxes with hinged lids to allow inspection and capture of their inhabitants (Fig. 26.3). Cage furniture such as low-growing shrubs and rocks provide shade and visual screens between animals. A shallow water dish provides a water source and aids in preventing dysecdysis; tuatara will also often pass urates and feces in water. Like many reptiles, tuatara can develop rostral abrasions by rubbing their noses on the walls of enclosures; this can be prevented by ensuring enclosures have smooth, nonabrasive walls and sufficient space for all animals. Tuatara are vulnerable to predation, and off-display areas should be fully enclosed with wire mesh or similar.

FIG 26.3 A partially buried artificial burrow that allows inspection of its inhabitants (Courtesy of Auckland Zoo.)

Young tuatara should be housed separately from adults to prevent predation. Newly hatched animals can be housed in large groups, but from 6 months of age juveniles can become territorial, so incompatible animals should be separated.[1] At 12 months of age, juveniles can be moved to enclosures that are similar to but smaller than those housing adult tuatara.

FEEDING AND NUTRITION

Tuatara are primarily insectivorous, and wild tuatara subsist primarily on a variety of invertebrates, including darkling beetles (*Mimopeus* sp), weevils, spiders, earthworms, adult moths, and tree weta.[4] Wild adult tuatara also occasionally consume vertebrate prey, most commonly fairy prion (*Pachyptila turtur*) chicks, seabird eggs, reptiles including juvenile tuatara, and crustaceans if available.[4] Tuatara rarely intentionally consume plant material, but they do appear to have a preference for ripe kawakawa (*Macropiper excelsum*) berries.[5] The captive diet of tuatara should mimic the nutrient composition of the wild diet as much as possible[6] and should include a variety of invertebrates and appropriate vitamin and mineral supplementation. At Auckland Zoo, tuatara are primarily fed live field crickets (*Teleogryllus commodus*) and locusts (*Locusta migratoria*) dusted with a vitamin and mineral supplement (Calcium Plus, Repashy Superfoods). They are also offered woodlice (*Porcellio scaber*), mealworm beetles (*Tenebrio* sp.), and cockroaches (*Celatoblatta* spp. and *Drymaplaneta semivitta*) when available and forage for other invertebrates in their naturalistic enclosures. Kawakawa berries are offered when in season. Captive tuatara can become obese, and careful attention should be paid to weight and body condition relative to similar-sized wild counterparts. Secondary nutritional hyperparathyroidism has been diagnosed in captive tuatara and is caused by insufficient UVB and/or inadequate calcium provision,[7] as in other reptiles.

ACKNOWLEDGMENTS

Many thanks to Richard Gibson and Richard Jakob-Hoff for their contributions to these chapters and to Wayne Boardman and Barbara Blanchard for their previous work on this subject.

Nutrition

Thomas H. Boyer and Peter W. Scott

Inadequate nutrition is a leading cause of morbidity and mortality in herpetological medicine because owners, as well as most veterinarians, are often not well educated about the nutrition needs of these animals. Much less is known about herpetological nutrition compared with domestic animal nutrition. Therefore veterinarians must be a dependable source of information for reptile and amphibian owners, otherwise, they will seek advice from the internet, pet stores, or outdated literature, usually with highly variable, and sometimes dangerous, results.

Always evaluate the reptile patient's diet as part of any detailed medical history. Never assume the owner has good nutritional knowledge, regardless of their experience. Keeping a reptile alive for years is no guarantee that it is healthy. Chronic nutritional disease, often with environmental components, remain common, including nutritional secondary hyperparathyroidism (NSHP), hepatic lipidosis, protein deficiency, hypovitaminosis A, hypervitaminosis A, pyramidal shell growth, renal disease, urocystoliths, thiamine deficiency, vitamin E/selenium deficiency, steatitis, corneal lipidosis, obesity, loose stools, and starvation (see Chapter 84).

As veterinarians we need to take a proactive approach to reptile and amphibian nutrition rather than treating an endless stream of nutritional disease. The goal of this chapter is to educate veterinarians so they are competent and confident in evaluating, reformulating, and implementing herpetological diets.

WATER

Water is the most important of all nutrients. All animals need water, it is the most essential nutrient, and there is enormous diversity in methods utilized to obtain it. Mammals can survive loss of most fat and glycogen reserves, and half of their bodies' protein, but a 10% to 15% water loss is life threatening. Water remains of critical importance to reptiles, even desert species, which can withstand greater losses but still require water.

Three sources of water are available to animals: dietary water (in food), metabolic water (formed from cellular metabolism), and environmental water. Few animals are able to survive without environmental water, and those that do are generally herbivores consuming plants with a high water content. Their dependence on, or independence from, environmental water is not well understood.[1] Many desert species can behaviorally conserve water by retreating to a humid underground burrow, but this may not be available in a cage or yard with low relative humidity. In captivity, it is safest to assume all reptiles depend on environmental water. Some reptiles are not adept at drinking from water bowls. Many terrestrial species (e.g., desert tortoises, *Gopherus agassizii* and *G. morfakai*; bearded dragons, *Pogona* spp.; spiny-tailed lizards, *Uromastyx* spp.) seem to prefer to walk into shallow water to drink or to have water dripped on their head; while arboreal species (e.g., anoles, *Anolis* spp.; chameleons, Chamaeleonidae; day geckos, *Phelsuma* spp.; arboreal vipers, *Atheris, Bothrops, Bothriechis, Trimeresurus* spp.; boids, *Corallus* spp., *Morelia viridis*; green and ribbon snakes, *Thamnophis, Opheodrys* spp.) imbibe water droplets from foliage or their skin. The thorny dragon or devil (*Moloch horridus*) is an Australian lizard with hydroscopic channels within its skin that channel water (from dew condensation at night or rainfall) via capillary action from all over its body to its mouth. This same system, first reported by Gans et al.,[2] has now been shown in a number of agamid and iguanid lizards.[3] All these species need water, whether misted, sprayed, dripped, or provided as free-standing water. Some need water provision several times daily (e.g., misting), while others may only need water to be provided a few times each week.

COMPLETE MANUFACTURED DIETS

The goal is to feed captive reptiles a balanced diet, although in the wild state reptiles likely balance their diet over long periods of time. A balanced diet is one that leads to no net gain, or loss, of nutrients from the body, allowing the body to maintain a state of metabolic equilibrium. The important factors are nutrient content, energy content, digestibility, and the species-specific requirements, which may change with age, gender, season, and reproductive status.

Major differences in mammalian nutritional requirements have been identified, for superficially similar species, or even the same species, such as humans. We simply do not have the same body of knowledge for any reptile species that we have for the more familiar domesticated animals. Nevertheless, manufactured diets are available, and while some have reasonably long-term feeding data, most do not. Much more work is needed in this area, especially in relation to the many reptile species being kept.

The main advantage of appropriately processed or manufactured diets is they can contain all of the nutrients for a given species, assuming we know what they are. The disadvantages are that if any nutrients are omitted or included at inappropriate levels, the consequences can be substantial.[4] The data and research to formulate complete herp diets are not currently available; however, companies may falsely claim to have data. No regulatory agencies oversee reptile diets or advertising claims, so veterinarians should be cognizant of a wide variation in quality and be prepared to evaluate the diets themselves before making recommendations. In general, manufactured foods use the National Research Council (NRC) guidelines for some species (such as laboratory rats and domestic carnivores) as a starting point, or known nutritional studies from herps, where they are available. Some complete diets are from feed manufacturers with PhD nutritionists, or veterinarians, on staff to provide professional input, while others are from pet suppliers with little training or expertise in diet formulation. Meats used may be human grade in Europe, but not in the United States. Routinely offals are used. National guidelines exist in different countries for declarations

and layouts on labels, although these may be limited to the familiar domesticated species.

Reading a Product Label

Protein is the most costly component, and therefore manufactured diets will often use less expensive plant proteins in combination with smaller quantities of mammalian or fish proteins. Examining ingredient lists may help estimate digestibility since plant materials are generally less digestible by carnivores. Reviews of how to "read" labels are available.[5]

The best way to read a product label is to start with the guaranteed analysis. If ingredients are listed without a guaranteed analysis, then readers are advised to be skeptical of nutritional adequacy. The more nutritional information provided, the better. The water content of foods varies, so for direct comparison, diets are compared on a dry matter basis (DMB), with water removed, and not by the nutrient levels on the label (which are as fed, or AF). For example, suppose three foods (frozen, canned, and pellets) had a label guaranteed analysis of 15% protein as fed. Do they have the same protein content? The moisture content is 80% for the frozen food, 75% for the canned food, and 12% for the pelleted food. On a DMB the frozen food contains 75% protein, the canned food 60% protein, and the pelleted food 18% protein. So no, the protein content is not the same on a DMB, but they look the same on the label, or on an AF basis. By removing water, diets can be more accurately compared to one another. See Box 27.1 for an explanation on how to calculate the DMB of a food. See Tables 27.1 through 27.3 for nutritional information for various herbivorous foods, and Tables 27.4 through 27.7 for tortoise, iguana, box turtle, aquatic turtle, and bearded dragon manufactured diets.

Metabolizable Energy

Another way to look at foods is by metabolizable energy (ME) or kcal ME per unit volume (e.g., cup) or weight. For carnivores, which consume variably energydense foods, ME estimates can be useful. ME estimates are calculated using Atwater calculations. In cats and dogs, estimated digestibility coefficients determined in humans overestimated ME in pet foods, so modified Atwater calculations are preferred.[9] Using guaranteed analysis data from four current commercial diets, the calculations allow some comparisons (Table 27.8). In general, juvenile reptiles require higher dietary ME than adults.

Protein

Overall growth rate in animals is protein driven, although food intake can be controlled somewhat by energy intake. As animals mature, active growth slows and less protein is needed in relation to energy. The consumption of excess calories resulting in a maximal growth rate is not compatible with optimal skeletal development and may result in skeletal deformities in juvenile reptiles.

A protein:energy ratio (P:E ratio) can also be calculated for a diet; this is not something that directly relates to an established "need" but is a useful "descriptor" of the nutritional quality of a diet. It represents the proportional contribution of dietary protein to total dietary energy. In general, the P:E ratio needed by an animal changes throughout its life, with a higher proportion of protein to energy needed as animals are growing. It also varies depending on activity and reproductive status.

BOX 27.1 Converting a Nutrient Analysis From "as Fed" to "Dry Matter" (DM)

To calculate DM, first determine the percentages of protein, fat, fiber, moisture, ash, and carbohydrate listed as fed, fresh-weight basis, or as sold (all the same). Carbohydrate is not included in the guaranteed analysis but is equal to 100 – (% protein + % fat + % moisture + % ash). Note that fiber is not included because it is a carbohydrate. Next, remove the moisture or water content to give the % total dry matter (TDM). Then divide each nutrient % by % TDM and multiply by 100 (DM = 100 [% nutrient/% TDM]).

For example, the guaranteed analysis lists:

Protein 15%, fat 3%, fiber 18%, moisture 12.5%, ash 8%, Ca 1.2%, P 0.65% AF

The carbohydrate content would be 100 – (15+3+12.5+8) = 38.5%

Next, remove water, TDM = 100 – 12.5% (moisture) = 87.5%

For DM basis protein, 100(15/87.5) = 17% protein

DM basis for the others are: 3% fat, 21% fiber, 44% carbohydrate, 1.4% Ca, 0.74% P

Protein/energy	0.10	0.06	0.10	0.07

Currently we have no in-depth knowledge of the actual needs of herps, but we can assess effects clinically. Animals short of energy will use protein as an energy source, whereas a physiological excess of protein tends to be stored as fats. The metabolism of excess protein in this way can lead to excess nitrogenous waste excretion. Looking at levels of declared calcium (Ca) and phosphorus (P) is also useful. The diets listed in Table 27.8 provide close to "ideal" vertebrate ratios of Ca:P if nothing else is fed. If live foods or greens are used in addition, then the ratio may become inadequate without additional calcium supplementation.

MULTIVITAMINS AND CALCIUM SUPPLEMENTS

Multivitamins

Multivitamins marketed for reptiles and amphibians can be broken down into multivitamins with and without Ca (Tables 27.9 and 27.10). Ca supplements are typically used on a daily or regular basis. Some argue that multivitamins with Ca should not be used as a daily Ca source, because they may not contain sufficient Ca to prevent NSHP (thus giving owners a false sense of adequate Ca supplementation), and long-term inclusion of fat-soluble vitamins (particularly A and D) or trace minerals (such as copper, iron, or zinc) may lead to oversupplementation; however, taking calcium supplements with iron or zinc compromises the absorption of these minerals. Others believe that properly formulated supplements containing multivitamins (including low level D_3) and calcium are required daily. Such opinions and controversies probably stem from the variable quality, availability, and experience of using supplements and are unlikely to be resolved until definitive research is published.

For most animals, the presumed maximal safe levels of vitamins A and D_3 for long-term feeding (>60 days) is 4 to 10 times the recognized dietary requirement.[10] Unfortunately for herps, we still do not know their dietary requirements for either A or D, nor any other vitamins. In green iguanas (*Iguana iguana*), the risk of oversupplementation of vitamin A was thought to be especially great in supplements with vitamin A levels >1100 IU/gm.[4] The estimated daily vitamin A requirements of green iguanas was 56 IU/kg, and long-term intake of vitamin A 2 to 3 times the recommended dietary level of 8000 IU/kg feed could produce hypervitaminosis A.[4] Using human-formulated products should be done with great care, as it may be impossible to subdivide a tablet into small enough portions for safe dosing.[4] If multivitamins are used, the amount provided should be restricted to that amount that supplies the daily requirement for vitamin A, but at this level many supplements are poor sources of other vitamins and trace minerals.[4] One author (Boyer) has had empirical success recommending multivitamins once or twice a month for diets lacking vitamin A, and no multivitamins if commercial gut-loading diets, or dry, formulated feeds with vitamin A, are used. Vitamin deficiencies typically arise from a total lack of the vitamin in the diet; small amounts of the vitamin, with a balanced diet, generally avoid deficiencies.

Multivitamins without Ca should be evaluated to see if they are true multivitamins (all vitamins A, B, C, D, E, and K, as well as trace minerals). Insectivores, such as chameleons (Chamaeleonidae), leopard geckos (*Eublepharis macularius*), toads, and some frogs (Anura), need vitamin A in their diet because of poor conversion of β-carotene precursors into vitamin A. All herbivores seem capable of vitamin A synthesis. Carnivores typically avoid vitamin A deficiency because liver in whole animal diets is an excellent source of vitamin A. Emydid turtles, such as box turtles (*Terrapene* spp.) and sliders (*Trachemys*), cooters (*Pseudemys*), and painted turtles (*Chrysemys*) often develop hypovitaminosis A; however, it is not clear if this is from a dietary deficiency or if they are poor converters of β-carotene precursors. An informal survey of popular reptile multivitamins showed that about a third contained no vitamin A but instead list β-carotene, and half are not true multivitamins (see Table 27.9). This could be an issue for insectivores if not fed properly gut-loaded insects, or for emydid turtles, if their diet were vitamin A deficient. The ratio of A:D:E should be roughly 100:10:1. Essential amino acid supplementation should not be necessary if insects, whole animals, or a nutritionally complete commercial diet are fed, as these foods all have adequate essential amino acids.

The vitamin D content must also be considered; vitamin D enhances Ca absorption. As we have discussed, Ca is often used on a daily or regular basis. Vitamin D is a fat-soluble vitamin or hormone, and excess may be retained in fat. Large doses of vitamin D can be toxic (hence, its widespread usage as a rodenticide), although these doses far exceed levels used in most supplements. Not all reptiles (especially *Iguana* and *Cyclura* spp.) seem to be able to efficiently utilize dietary vitamin D.[4,11] If adequate UVB light exposure is available, there is less need for dietary vitamin D_3 in Ca supplements, especially if multivitamins or fortified foods containing vitamin D_3 are already in use. It is important to note that reptiles are thought to only utilize D_3, many human products use D_2 but "mathematically convert" the D_2 into the equivalent D_3 for their label information using the known rate of human conversion. Reptiles cannot convert D_2 to D_3. The important point is that clinicians evaluate the vitamin label (see Table 27.9 or online resources) to make sure the product is appropriate.

Calcium Supplements

Ca supplements are listed in Table 27.10. Ca supplementation is needed on a regular basis (daily to every other day) for all growing herps not consuming whole vertebrates regularly. Once adults have fully formed skeletons, Ca demands decrease, but there is still a need, especially in reproductive females. Most calcium salts are better absorbed with food and help to competitively inhibit P absorption. Ideally, Ca supplements should be independent of multivitamins (other than vitamin D) and contain little to no P. Most insects have a 1:10 Ca:P ratio, therefore a Ca supplement with a 2:1 Ca:P ratio (common with bone meal products) will never achieve a positive Ca:P ratio until the mass of the supplement is greater than the mass of the insect. Also heavily dusting salads adds

TABLE 27.9 Alphabetical Listing by Manufacturer of Multivitamins Marketed for Reptiles and Amphibians

Manufacturer, Name	Vitamin A Present?	All Multivitamins Present?	Ingredients
Dendrocare, Vitamin/ Mineral Powder	Yes	No	Vitamin A (450,000 IU/kg), Vitamin D_3 (120,000 IU/kg), Vitamin E (10,200 mg/kg), Vitamin B_1, Vitamin B_2, Pantothenic acid, Niacin, Vitamin B_6, Copper, Iodine, Iron, Manganese, Zinc, Cobalt, Sodium, Magnesium, Potassium, Calcium 22%, Phosphorus 8.8%
Exo Terra, Multi-vitamin Supplement	No	No	Seaweed Meal, Yeast, Oyster Shell Flour, Dextrose, Beta-Carotene (8980 IU/kg), Menadione Sodium Bisulfite Complex (Source of Vitamin K Activity), Biotin, Inositol, Choline Chloride, Salt, Calcium Phosphate, Calcium Carbonate, Potassium Chloride, Manganese Oxide, Ferrous Fumarate, Calcium Sulfate, Manganous Oxide, Zinc Oxide, Copper Sulfate, Potassium Iodate. Calcium (4.4%–4.6%), Vitamin D_3 (21,954 IU/kg), Vitamin E (100 IU/kg)
Fluker's, Liquid Vitamin Electrolyte Spray	No	No	Vitamins: Niacin, Dl-Alpha Tocopheryl Acetate, Vitamin D_3, Calcium Pantothenate, Ascorbic Acid, Riboflavin, Menadione Sodium Bisulfite Complex, Pyridoxine Hydrochloride, Thiamine Mononitrate, D-Biotin, Folic Acid, Vitamin B_{12}. Minerals: Sodium Bicarbonate, Potassium Chloride, Magnesium Sulfate, Manganese Sulfate, Zinc Sulfate, Copper Sulfate, Ethylene Diamine Dihydriodide. Amino Acids: L-Glutamic Acid, L-Aspartic Acid, L-Leucine, L-Valine, L-Serine, L-Lysine, L-Alanine, L-Phenylalanine, L-Arginine, L-Isoleucine, L-Threonine, L-Tyrosine, L-Proline, Dl-Methionine, Glycine, L-Cystine, L-Histidine, L-Tryptophan.
Fluker's, Repta Boost Insectivore/Carnivore High Amp Boost Reptile Supplement	Yes	Yes	Egg Product, Wheat Flour, Starch, Isolated Soy Flour, Corn Oil, Brewers Yeast, Kelp, Calcium Carbonate, Dicalcium Phosphate, Pollen, Dextrose, Sodium Chloride, Potassium Sorbate, Dl-Methionine, Lecithin, Choline Chloride, Potassium Chloride, Spirulina, Manganese Sulfate, Mixed Natural Tocopherols, Zinc Sulfate, Magnesium Oxide, Ascorbic Acid, Beta Carotene Supplement, Niacin, Vitamin E Supplement, Copper Sulfate, Vitamin B_{12} Supplement, Vitamin A Acetate, Calcium Pantothenate, Vitamin D_3, Pyridoxine HCl, Menadione Sodium Bisulfite Complex, Riboflavin, Thiamine Mononitrate, Ethylene Diamine Dihydriodide, Biotin Supplement, Folic Acid, Sodium Selenite.
Fluker's, Reptile Vitamin with Beta Carotene Reptile Supplement	Yes	Yes	Dibasic Calcium Phosphate, Kelp Flour, Oyster Shell Flour, Calcium Carbonate, Bone Ash, L-Glutamic Acid, L-Aspartic Acid, L-Leucine, Iron Sulfate, Beta Carotene, L-Valine, L-Sarine, Choline Chloride, L-Lysine, L-Alanine, L-Phenyfalanine, L-Arginine, L-Isoleucine, Canthaxanthin, L-thereoline, L-Tyrosine, L-Proline, L-Methionine, Glycine, L-Cystine, Niacin, L-Histindine, Potassium Chlorine, Ascorbic Acid, Inositol, L-Tryptophan, Manganese Sulfate, Sodium Chloride, Zinc Sulfate, Thiamine Mononitrate, Para-Aminobenzoic Acid, Pyridoxine Hydrochloride, Apo-Carotenal, Rutin, Vitamin B_{12}, Magnesium Oxide, Copper Sulfate, Riboflavin, Calcium Pantothenate, Dl-Alpha Tocopherol Acetate, Vitamin A Acetate, Sulfur, Calcium Iodate, Folic Acid, Hesperidin, Vitamin D_3, D-Biotin, Menadione Dimethylpyrimidinol Bisulfite.
National Geographic, Reptile Multivitamin Supplement Powder	Yes	Yes	Dicalcium Phosphate, Soy Protein Isolate, Calcium Carbonate (Ca 21%–25%, P 9%), Oyster Shell Flour, Calcaxanthin, Choline Chloride, Beta Carotene, Ferrous Sulfate, Kelp, Niacin, Potassium Chloride, Ascorbic Acid, Inositol, Vegetable Oil, DL-Methionine, Manganese Sulfate, Salt, Zinc Sulfate, Thiamine Mononitrate, Para–Aminobenzoic Acid, Pyridoxine HCl, Mixed Tocopherals, Rosemary Extract, Citric Acid, Magnesium Oxide, Riboflavin, Copper Sulfate, d–Calcium Pantothenate, Vitamin B_{12}, Vitamin E, Vitamin A (23,129 IU/kg), Vitamin D_3 (5,124 IU/kg), Vitamin E (49 IU/kg), Sulfur, Ethylenediamine Dihydriodide, Folic Acid, Natural and Artificial Flavoring, Neohespiridin Dihydrochalcone, Biotin, Menadione Sodium Bisulfite Complex Biotin, Vitamin B_{12}, Ascorbic Acid, Inositol
Nekton-Rep, Vitamin Mineral Supplement for Reptiles	Yes	No	Dextrose, Calcium Carbonate, Silicic Acid, Vitamin A (6,600,000 IU/kg), Vitamin D_3 (10,000 IU/kg), Vitamin E (6600 mg), Vitamin B_1, Vitamin B_2, Pantothenic acid, Nicotinamide, Vitamin B_6, Folic acid, Vitamin B_{12}, Vitamin C, Vitamin K_3, Menandione sodium bisulfate, Iron Zinc, Manganese, Copper, Iodine
Nekton, Multi-Rep	Yes	Yes	Dicalcium phosphate, Dextrose, Calcium Carbonate, Magnesium Carbonate, (Ca 21.3%, Phosphorus 7%), Vitamin A (200,000 IU/kg), Vitamin D_3 (40,000 IU/kg), Vitamin E (2,000 mg/kg), Vitamin B_1, Vitamin B_2, Pantothenic Acid (calcium-D pantothenate), Nicotinamide, Vitamin B_6, Folic Acid, Vitamin B_{12}, Biotin, Vitamin C, Selenium, Carnitine, Taurine, Choline Chloride, Iron, Zinc, Manganese, Copper, Iodine

Zilla Food Spray Calcium Supplement	No	No	Water, Calcium Gluconate, Calcium Carbonate, Calcium Chloride, Potassium Sorbate, Sodium Benzoate, Xantham Gum
ZooMed, Repti Calcium with or without D3	No	No	Calcium Carbonate, Vitamin D_3 or Calcium Carbonate
Zoo Med Tortoise Calcium Block	Yes	Yes	Calcium Sulfate, Nopales (Spineless Opuntia Cactus), Carrot, Alfalfa, Dicalcium Phosphate, Niacin, Vitamin C, Thiamine HCl, D-Calcium Pantothenate, Pyridoxine Hydrochloride, Biotin, Beta-Carotene, Artificial Tropical Fruit Flavor, Yellow 5, Blue 1, Calcium 23.0%–28.0%

TABLE 27.11 Type of Calcium Can Be Important as not All are Absorbed Equally; Calcium Carbonate and Calcium Citrate are Best Absorbed

Ca Salt (1 gram)	Elemental Calcium (mg)	Percent Calcium Salt Absorbed or Elemental Ca Available
Ca carbonate	400	40%
Ca citrate	211	21%
Ca lactate	130	13%
Ca gluconate	93	9.3%
Ca glubionate	66	6.6%

a mildly salty, sour, or chalky taste (for humans), which may reduce palatability for herps. Therefore any herp Ca supplement should be P free or have a very high Ca:P ratio (>20:1). Furthermore, there are a number of similar-sounding products that make distinguishing Ca powders more confusing. For example, Rep-Cal (Rep-Cal Research Labs, Los Gatos, CA), ReptaCalcium (Flukers, Monroe, LA), and Repti-Calcium (Zoo Med, San Louis Obispo, CA), all have P-free Ca with and without vitamin D. Reptical (Aristopet, Brisbane, Australia) is a P-free Ca supplement with vitamin D, and ReptoCal (TetraFauna, Blacksburg, VA) has dicalcium phosphate with vitamin D (phosphate is a source of P). Note that one of these products has Ca and P, the other four do not. It is often difficult to distinguish among these products, therefore owners should bring supplements with their animal to the veterinarian's office and compare them to Tables 27.9 and 27.10.

The type of Ca used is also important as different kinds of Ca salts have different amounts of elemental Ca available for absorption and utilization. One gram of Ca carbonate has 40%, or 400 mg elemental Ca, available for absorption, followed by 1 gram of Ca citrate with 211 mg (Table 27.11). You would have to use almost three times as much Ca lactate to equal Ca carbonate in elemental Ca. Fortunately, Ca carbonate is the most commonly used Ca salt in Ca powders.

How well the product adheres to the insect depends on electrostatic properties and the fineness of grind. Finer particles adhere better than coarser particles. Companies manufacturing these supplements regard component particle sizes as commercially sensitive, but often the ingredients other than the calcium will be larger and will adhere for a much shorter time. Particle sizes can be appreciated on gross examination of most supplements.

NUTRITIONAL BIOLOGY

Although some particularly interesting exceptions exist, caecilians generally feed on earthworms and other invertebrates; frogs, toads, and salamanders feed almost exclusively on insects (at least as adults, tadpoles are detritivores); crocodilians feed largely on other vertebrates; turtles feed on a combination of plants and animals; and squamates feed largely on invertebrates or vertebrates.[12] Herbivory is uncommon, generally the exception within groups rather than the rule, except for Testudinidae, Iguanidae, and Leiolepidinae (Butterfly agamids).[12] Adult amphibians and reptiles do not necessarily eat the same prey as larvae or juveniles; ontogenetic shifts in diet are probably common but not well studied.[12] On a very simplistic level, reptile and amphibian diets can be categorized as insectivores, carnivores, herbivores, or omnivores. These can all be regarded as simply a means of obtaining the necessary amino acids, fatty acids, carbohydrate components, and more that make up a diet. Many reptiles have specialized dietary needs that require extensive appreciation of natural history. Some will have needs for certain components not yet identified. The following information serves as a foundation for most common species in captivity.

Insectivores

This group includes many lizards, most amphibians, some turtles, and a few snakes. Many obligate carnivorous adults may be insectivores as growing juveniles. Insectivory is a broad term that also includes consumption of arachnids, annelids, and crustaceans.[13] Nutrient levels of insects are listed in Table 27.12. Nutritional requirements of most insectivorous reptiles are unknown, so nutritionists often extrapolate from better-known species, such as the rat, or other carnivores, that have known NRC requirements.[14,15] Although these comparisons are unlikely to be appropriate for all insectivores, they do provide a basis for comparison. Deficiencies by nutrient (percentage of samples deficient vs. NRC rat growth requirements on a DMB) for fasted adult and nymphal house crickets (*Acheta domesticus*), superworms (*Zophobas morio* larvae), larval and adult mealworms (*Tenebrio molitor*), giant mealworms (*Tenebrio molitor* mealworm larvae treated with juvenile hormone to prevent them from molting into adults), waxworm larvae (*Galleria mellonella*), silkworm larvae (*Bombyx mori*), and earthworms (*Lumbricus terresstris*), were as follows: calcium (100%), vitamin D_3 (100%), vitamin A (89%), vitamin B_{12} (75%), thiamin (63%), vitamin E (50%), iodine (44%), manganese (22%), methionine-cystine (22%), and sodium (11%).[15] Simply put, as dietary items, insects are Ca and multivitamin deficient. All invertebrates are a good source of protein and meet or exceed NRC requirements for growth in rats.[15] It is true that some of the protein nitrogen may be chitin, which forms the cuticle (exoskeleton) of invertebrates and may not be nutritionally available. However, some

insectivores have chitinases, while others rely on gut bacterial chitinases.[13] Invertebrates contain little or no carbohydrates except silkworms fed a high (60%) carbohydrate diet.[15] Larval insects (except silkworm larvae) have high fat content (35%–60% DMB), especially mealworms, waxworms, and butterworms (*Chilecomadia moorei*).[22] If these larvae constitute a substantial portion of the diet, this may lead to disproportionally high fat content.[13] Earthworms, silkworms, false katydids (Phaneropterinae), adult fruit flies (*Drosophila*), wood louse (Oniscidea), termites (Isoptera), and krill (Euphausiacea) have lower fat content.[23] Insects contain significant quantities of fiber, highest in mealworms and lowest in silkworms and earthworms.[15] Invertebrates appear to be a good source of essential amino acids (except for superworms and waxworms, which are limited only in methionine and cysteine)[15] and adequate sources of trace minerals copper, iron, manganese, and zinc.[14]

Calcium and vitamin A and D levels of insects are below the NRC requirements for rat growth[15,22] and carnivores.[14] Consequently Ca and vitamin A deficiencies are the most common nutritional diseases of both reptiles and amphibians. One study found that juvenile veiled chameleons (*Chamaeleo calyptratus*) fed locusts (*Locusta migratoria*) with adequate artificial UVB developed symptoms of NSHP (if no supplemental Ca, vitamin A, or vitamin D_3 was provided to locusts) within 152 to 186 days, and even faster if no UVB was present (within 110 to 146 days).[24] When Ca, vitamin A, and UVB were supplemented, chameleons did not develop NSHP, and the best results were in chameleons supplied with Ca, vitamins A and D, and UVB. Healthy Ca to P ratios for most vertebrates are generally 2:1 to 3:1 but may be higher for growing herps. For example, rapidly growing juvenile saltwater crocodiles (*Crocodylus porosus*) eat insects, amphibians, crustaceans, small reptiles, fish, and rats, with an overall Ca:P ratio of 6.7 to 1, primarily because of the calcium-rich crustacean shells. Adult saltwater crocodiles consume more mammals and fish but fewer crabs and shrimp, and consequently the Ca to P ratio of their diet drops to 1.85 to 1.[25] Ca:P ratios of commonly fed insects are as follow: 0.2 crickets, 0.1 mealworms and waxworms, and 0.06 super mealworms. All analyzed insects are Ca deficient, with few exceptions. Cocooning eastern tent moths (*Malacosoma americanum*), stone flies (Plecoptera), and black soldier fly larvae (*Hermetia illucens*, sold as Phoenix worms) all have a higher Ca content,[14,18] but only the last is commercially available. When fed to mountain chicken frogs (*Leptodactylus fallax*) the calcium digestibility of whole soldier fly larvae was only 44%, compared with 88% for soldier fly larvae that had been "mashed" to expose calcium in mineralized exoskeletons.[18,26]

So, for client discussions, it is appropriate to say all insects are severely Ca deficient (Fig. 27.1). Earthworms, night crawlers (*Lumbricus terrestris*), and terrestrial crustaceans (Isopods), such as the wood louse (*Porcellio scaber*) and pill bugs, or roly-polies (*Armadillidium* spp.), all have positive Ca:P ratios.[15,22] Crustacean shells are good sources of amorphous calcium carbonate, which is reported to have higher bioavailability than crystalline calcium carbonate.[23]

All analyzed insects are vitamin A deficient with the exception of false katydids (e.g., greater angle-wing katydid, *Microcentrum rhombifolium*), migratory locust (*Locusta migratoria*), termites (*Nasutitermes* spp.), silkworms, and four other wild-caught species of lepidopteran larvae, which may be able to convert β-carotene to vitamin A.[15,22] Insects are also vitamin D deficient,[15] which is not a problem because most insectivores are kept under UVB lights and should also receive Ca dusted and gut-loaded prey (discussed later). Interestingly, nocturnal geckos, such as the leopard gecko, have the ability to utilize UVB light but also appear to thrive utilizing only dietary vitamin D.

Compared to NRC requirements for growing rats, most invertebrates contain sufficient vitamin E (except mealworms and superworms) and trace minerals, except superworms, giant mealworm larvae, waxworms, and silkworms, which are deficient in iodine.[15] Vitamin B_{12} is below the NRC requirements for growing rats for all larval insects. Thiamine is below the NRC requirements for growing rats in crickets, superworms, and giant and adult mealworm larvae.[15]

From this discussion it is obvious that commercially available invertebrates and annelids are nutritionally incomplete.[15] Feeding herps store-bought crickets and mealworms without supplementation will result in calcium or vitamin A deficiencies and may induce obesity and hepatic lipidosis. Improving insectivore nutrition is a simple triad of feeding a nutritionally complete, calcium-rich diet to insects, dusting insects with calcium (and, less frequently, multivitamins), and feeding a wide variety of insects, crustaceans, annelids, and rodent pups. Both gut loading and dusting are recommended to provide more balanced nutrition and boost Ca. One case of hypovitaminosis A in a panther chameleon (*Furcifer pardalis*) resulted from refusal of the chameleon to eat multivitamin-dusted insects until 2 hours after they had been offered, enough time for the insects to groom off the multivitamins (Boyer, personal observation). Providing a gut-loading diet resolved the problem.

Gut-Loading Insects. Originally, feeding a Ca-rich diet to improve the insect's Ca content was called gut loading.[27] Early studies in feeder insects demonstrated that feeding high Ca diets (≥8% Ca DM) increased the Ca content and developed a positive Ca:P ratio after 24 hours (mealworms), 48 hours (crickets), or 72 hours (waxworms).[27-29] Higher Ca levels (12%) result in poor viability of mealworms, and Ca levels begin to decline after a week of high-Ca diets.[30] Unfortunately, over time, the term gut loading has lost its original meaning and degenerated into just feeding crickets, often with foods rich in β-carotene (even though crickets and some insectivores do not convert β-carotene to vitamin A). For instance, feeding mealworms and crickets a 3% Ca DM diet with a 2.8 Ca:P ratio for 72 hours resulted in a mean Ca:P ratio of 0.19 for mealworms and 0.26 for crickets (i.e., negative Ca:P ratios).[30] Not all cricket diets designed to boost Ca content are equal. In one study, three out of four commercial calcium-fortified dry diets designed for feeder crickets contained no more calcium than unfortified diets.[31] Despite claims on their labels, only one diet actually increased the calcium content of the crickets (T-Rex Calcium Plus Food for Crickets).[31] Calcium-fortified, high-moisture cricket waters or high-moisture foods (gel water cubes) are also ineffective at increasing calcium content.[32] A typical cube has 600 ppm Ca or 0.06% Ca, about twice the content of tap water. One study noted that as fed, gel water cube labels claimed 0.1% to 0.12% Ca but when analyzed were found to have only 0.01% Ca and caused some mealworms to asphyxiate. Another problem with gel water cubes is that insects, as well as reptiles, will consume them preferentially over high-Ca diets. Instead of gel water cubes, offer water, such as a water-soaked cotton ball in a bottle cap (for crickets and roaches) or damp paper towel (for mealworms or superworms) (Fig. 27.2). One of the reasons cubes became popular is that insects drown in standing water. The same study found that by day 3 mealworms on a Ca-fortified insect diet and offered either apple slices or gel water cubes had a mean negative Ca:P ratio of 0.62 and 0.91, respectively. Presumably, the mealworms ate more apples and gel cubes and less Ca-fortified diet (see Fig. 27.2). Therefore do not offer fruit, vegetables, or gel water cubes as a water source to feeder insects. Additionally, fruit and vegetables tend to mold and may result in aflatoxin ingestion by the insects and accumulation by herps. Assume store-bought insects are nutritionally inadequate at purchase. Mealworms are typically shipped and sold in 100% wheat bran, with 0.14% Ca and a Ca:P ratio of 0.12, or even worse, inedible saw dust. Only mealworms and superworms fed a high-calcium cricket feed met NRC dietary calcium recommendations for nonlactating rats; those fed wheat millings, avian hand-feeding formula, or organic avian mash diet

**= Calculated from values in Finke 2002.[15]
GE = Gross energy, determined in the lab rather than calculated using Atwater.
Crude protein (marked *) has been calculated by total nitrogen x 6.
ADF-N is considered to be chitin-bound nitrogen and so is unavailable to many species; crude protein (adjusted) may be more accurately calculated by deducting ADF-N from total nitrogen.
Insect exoskeletons contain not just chitin but also sclerotized protein, fat, and other compounds. Some species have chitinases.
Thiaminase has been reported in a wide range of genera, freshwater and marine, vertebrate and invertebrate. It has been demonstrated to vary through the year.

To convert a nutrient analysis from "as fed" to "dry matter," see Box 27.1

Thiaminase has been reported in a wide range of genera, freshwater and marine, vertebrate and invertebrate. It has been demonstrated to vary through the year.

- 1 mg alpha tocopherol = 1.1 IU, and 0.3 μg retinol = 1 IU vitamin A activity
  mg/kg = μg/g
- Gross energy (GE) calculated by adding the product of % crude protein x 5.43 kcal/g to the product of % crude fat x 9.11 kcal/g.[4,21]

VetBooks.ir

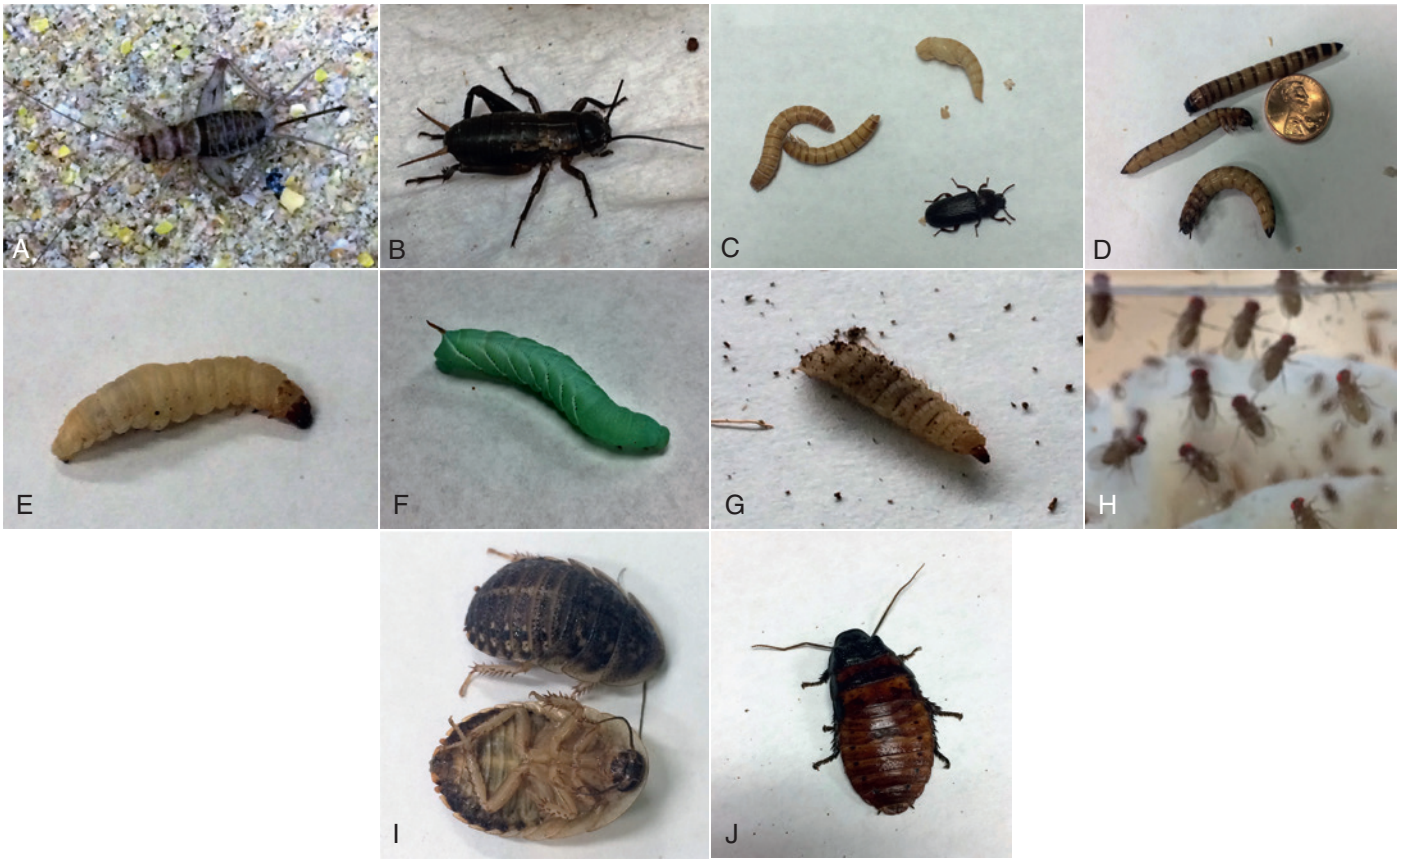

FIG 27.1 Practically speaking, almost all insects are calcium deficient (approximately 1 Ca:5 to 10 P for most insects) and must be fed a diet greater than 8% Ca to develop a positive Ca : P ratio. Note that gut loading does not mean mere feeding; it entails providing a diet fortified with high levels of calcium, as well as multivitamins and trace minerals. Common feeder insects include (A) house or gray crickets (*Acheta domesticus*); (B) black field crickets (*Gryllus bimaculatus*); (C) mealworms (*Tenebrio molitor*), larvae, instar, and beetle; (D) superworms (*Zophobas morio* larvae); (E) waxworm larvae (*Galleria mellonella*); (F) tobacco hornworms or goliath worms (*Manduca sexta*); (G) black soldier fly larvae or Phoenix worms (*Hermetia illucens*); (H) fruitflies (*Drosophila melanogaster* or *D. hydei*) and cockroaches; (I) dubias (*Blaptica dubia*); and (J) hissing cockroaches (*Gromphadorhina portentosa*).

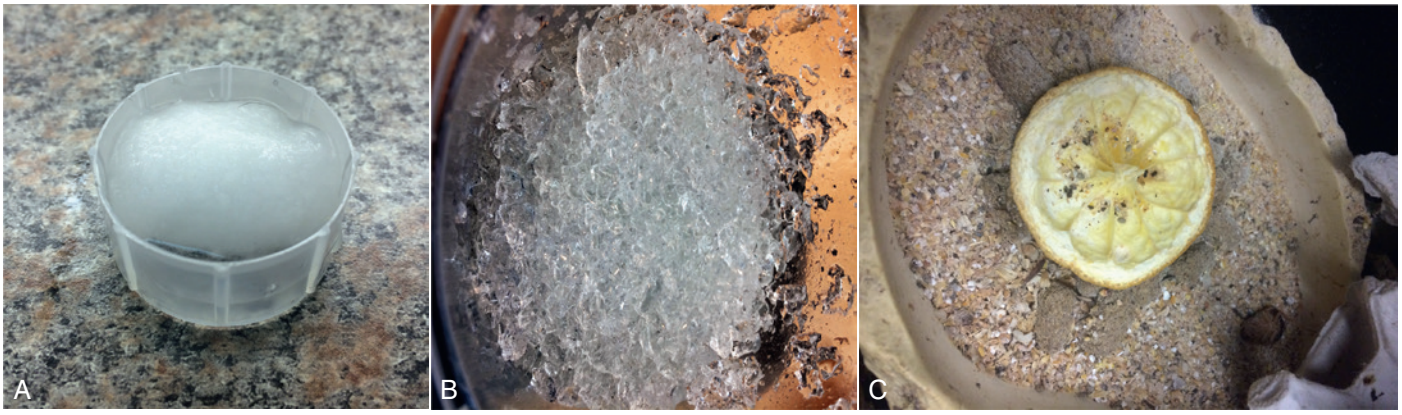

FIG 27.2 (A) All insects need water; a cotton ball in a bottle cap works for crickets and cockroaches, a damp paper towel on the surface of the gut-loading diet works for mealworms and superworms. (B) Cubes are not recommended because they are consumed preferentially over gut-loading diets, do not change the nutritional profile of the insect, and some insects can choke on them. (C) When gut-loading insects, offer only water (not cubes) and the gut-loading diet, nothing else. Good gut-loading diets have a high Ca content and probably reduced palatability. If better-tasting foods are available, such as fruits or vegetables, the insects will eat them, avoiding the gut-loading diet.

VetBooks.ir

did not.[33] Owners should purchase a high-quality, gut-loading diet (such as Mazuri Hi Calcium Gut Loading Diet) or veterinarians should buy, stock, and supply such products. Food products should be appropriately stored in a cool dry area, refrigerator (4°C, 39°F), or freezer (−20°C, −4°F) and discarded after expiration dates (varies with manufacturer but typically 6–12 months).[27] Crickets, mealworms, superworms, and Dubia cockroaches (*Blaptica dubia*) can be maintained on cricket high-Ca (≥8% Ca DM) diets, even though these diets are not intended as maintenance diets, and Ca content of feeders declines after a week. Newer commercial gut-loading diets can produce a positive Ca:P ratio as quickly as 12 hours, compared with experimental diets that required several days. Be sure to use a Ca-enriched diet (such as Mazuri Hi Calcium Gut Loading Diet, 8%–9% Ca) and not a maintenance diet (such as Mazuri Cricket Diet, 1% Ca). Remember, water is the most essential nutrient, and insects will die rapidly without it. Feeder insects should not be refrigerated; they should be maintained at their preferred optimum temperature zone, when in doubt, around 27°C (80°F). Refrigeration merely extends shelf life without essential nutritional supplementation. Feeding starved insects will result in a malnourished reptile, even though the reptile is still eating. For crickets, a temperature range of 26°C to 34°C (79°F to 93°F), with a vertical temperature gradient from top to bottom is desirable (easily provided with egg flats or other cage furniture), and a relative humidity of 20% to 50%.[34,35]

Many of the gut-loading studies produced variable results on final nutrient content (especially Ca:P) because of variations in insect age (crickets do not feed readily in the last week of life), food or insect size (smaller insects cannot consume larger food particles, gut capacity is slightly higher relative to body weight for nymphal stage vs adult crickets), or developmental stage (where the insect is in its instar; see later), temperature (higher or lower temperatures may adversely affect food intake; optimum temperature maximizes food intake and growth), sex (female crickets develop faster than males), water sources or lack of water (water cubes, produce, or fruit decreases consumption of gut-loading diets, as does a lack of water), humidity, and, of course, palatability.[34,35] Perhaps the most important is developmental stage. All insects grow through various life stages by shedding their exoskeleton. The time between sheds is called an instar, or growth period. Crickets begin feeding about 6 hours after shedding, then feed well until about mid-instar, at which point they have filled their exoskeleton and reached their critical weight to get through molting. At this stage, they reduce feeding until after the next molt. Instars can last days (at 35°C or 95°F) to weeks (at 28°C or 82°F), last longer in older crickets, and have obvious implications on how well the insect can be gut loaded.[34,35] Practically the best way to minimize these variables is to gut load all insects, with the hope that short-term deficiencies will be corrected over the long term. Additionally, it is important to consistently dust insects and provide a variety of different species. If insects are left in the cage for more than a few hours, a gut-loading diet and water should always be available.

Dusting Insects. An additional essential method of improving Ca, or vitamin content, is dusting insects with calcium or multivitamins (Fig. 27.3). To dust, insects and the Ca, or multivitamin powder, are placed in a plastic bag, or deep plastic cup, and lightly shaken or swirled, until the insects are coated. This method can produce variable results depending on the type of calcium or multivitamin used (e.g., particle size and electrostatic properties). One study found crickets would groom off 50% of either multivitamin/mineral or calcium/vitamin D powder within 90 seconds of dusting.[36] A larger study involving two cricket species (*Gryllus bimaculatus* and *G. assimilis*), and multiple life stages, found dusting with Ca boosted Ca:P ratio above 1:1 for 5.5 hours (endpoint of study).[37] There were no statistically significant differences between the dusting powders, but there were differences between cricket species and life stages. Overall, adult black field crickets (*Gryllus bimaculatus*) were the least effective at delivering calcium, with Ca:P ratio barely exceeding 2:1 immediately after dusting and eventually declining to just below 1:1, whereas hatchlings of both species were the most effective, with Ca:P ratios remaining above 4:1 for at least 5.5 hrs. Other instars of both species were intermediate.[37]

FIG 27.3 Dusting insects with Ca is recommended every feeding, in addition to gut loading, to further boost Ca content. Insects can be dusted with multivitamins once or twice per month. Some insectivores will avoid multivitamin dusted insects for several hours until the insects have groomed off the multivitamins, thus gut loading is also important.

Dusting insects in environments with high humidity is less effective and generally ineffective for aquatic insectivores unless they take insects off the water surface.[38] Multivitamins do not contain enough Ca to prevent NSHP, regardless of what the label claims. Calcium carbonate has the most elemental Ca (see Ca discussion earlier) and is most useful. Little to no P should be present in the Ca supplement as insects are already high in P; vitamin D is generally not required if appropriate UVB is present. Dusting can be effective in raising calcium; however, unless the other component vitamins in the product are of equal size and electrostatic charge, they may not adhere to the insects for long.

Insect Variety. The third vital aspect of feeding insectivores, in addition to gut loading and dusting, is to offer a wide variety of insects (see Fig. 27.1). Senegalese chameleons (*Chamaeleo senegalensis*) maintained on grasshoppers (*Scuderia* spp.) developed a statistically significant preference for crickets (*Acheta domestica*).[39] Jamaican anoles (*Anolis lineatopus*) experienced significantly higher growth rates when they ate a variety of insect larvae species compared to just a monoculture diet.[40] Insectivores naturally consume a diverse diet. Individual chameleons that steadfastly refuse crickets may immediately take a novel insect. Store-bought insects such as crickets, waxworms, mealworms, super mealworms, and Dubia cockroaches should be supplemented with commercially available silkworms, black soldier fly larvae (Phoenix worms), tobacco or tomato horn worms (*Manduca sexta* and *M. quinquemaculata*), bean beetles (*Callosobruchus maculates*), fruit flies, springtails (Collembolands), and

VetBooks.ir

wood lice (e.g., European wood lice, *Porcellio scaber*; dwarf tropical wood lice, *Trichorhina tomentosa*), as well as wild-caught, seasonally available insects such as moths, cicadas, flies, grasshoppers, bees (remove stingers), cockroaches, and crustaceans. Insects are easily collected at night around lights, with funnel traps or by children, and pill bugs accumulate in damp soil under a piece of shaded plywood. Owners often are overly concerned about pesticide hazards, but this is rarely ever a problem. Fireflies (*Photinus* sp.) contain toxic lucibufagins, and deaths have been reported in bearded dragons (*Pogona vitticeps*), a panther chameleon (*Furcifer pardalis*), Derjugin's lizard (*Darevskia derjugini*) and a White's tree frog (*Litoria caerulea*) following ingestion.[41] Many insectivores can be trained, or naturally take, baby mice and annelids, which are excellent dietary supplements. It is recommended that owners feed as wide a variety of invertebrates as possible, not just two or three varieties.

In summary, veterinarians should advise insectivore owners that almost all insects are deficient in Ca and vitamins A and D, and larval insects can have inappropriately high fat levels if fed exclusively. Broad-spectrum lighting including UVB is recommended for all insectivores. Gut-loading insects (i.e., feeding a nutrient-dense diet with ≥8% Ca DM, for 12 hours to 5 days, but no longer than 7 days) is essential. Proactive veterinary involvement, such as stocking a good gut-loading product, may be required to ensure compliance. Calcium dusting of insects is a good way to boost Ca and is recommended to augment gut loading.[35] Multivitamins must have, but are also limited by, their vitamin A content. Multivitamins are regularly needed for all reptiles (especially insectivores) not eating dry formulated feeds or whole vertebrates. A wide variety of foods is necessary to keep insectivores healthy.

Carnivores

This group includes all snakes, crocodilians, adult amphibians, and most aquatic turtles and lizards. Carnivores require high levels of protein (25%–60%) and fat (30%–60%) and low levels of carbohydrates (<10% DM).[8,42]

Snakes. One reason snakes remain popular is that rodents are a completely balanced diet and are easily procured. Therefore snakes are easier to provide a healthy, well-balanced diet for, and nutritional diseases are uncommon. See Table 27.13 for nutrient levels of whole vertebrates. Nutritionists consider whole vertebrate animals nutritionally complete foods that do not require supplementation.[43,50] Most pet stores, as well as numerous online vendors, sell frozen mice and rats, in all sizes. Veterinarians should be aware of different rodent life stages as owners often ask what size rodent to feed (Fig. 27.4). Pinkies are neonatal rodents (*Mus musculus* and *Rattus norvegicus*) without fur and have been found to have an almost even Ca:P ratio (slightly negative to slightly positive). After 5 to 9 days mice develop fur to become fuzzies, and from then on have a positive Ca to P ratio. After 2 to 2.5 weeks, mice open their eyes and are known as hoppers (because of their propensity to jump when startled). By 21 to 25 days they wean and are known as weanlings or small adults, then on to large and extra-large adults. Rodents and other whole animal prey should be frozen in moisture-impermeable plastic or vacuum packed to reduce dehydration during storage.[43] Frozen whole animals should be completely thawed and warmed before feeding to prevent a bacterial bloom in the prey's gut. This also occurs commonly if rodents are allowed to thaw over several hours at room temperature. Feeding cold or partly frozen prey is not recommended, as it can cause gastrointestinal dysfunction and slow digestion. For the die-hard reptile breeder still producing their own rodents, it is recommended to feed commercial pelleted rodent diets, not seed mixes or dog food (which can pass on nutritional deficiencies to the predator). Feeding live prey, although legal in the United States, is ethically unacceptable in most countries and should be avoided. The feeding of live prey has been the subject of much discussion; see Cooper[51] for the welfare and ethics of feeding live prey. Prey should be killed (cervical dislocation or gassed with CO_2) prior to feeding.[52] Serious trauma can be inflicted by a live rodent on a reptile (Fig. 27.5). Given the choice, boids and colubrids may prefer thawed mice over freshly killed ones.[53] Rabbits, hamsters, gerbils, chicks, lizards, snakes, frogs, toads, or fish are also appropriate food items. It is important for owners to appreciate the natural history of the species to identify food preferences. Muscle meat and viscera lack bone and therefore have little Ca. For example, Ca:P ratios of chicken meat (0.08:1), hamburger (0.06:1), chicken liver (0.14:1), and gizzards (0.1:1) are all inadequate for bone growth or maintenance.

FIG 27.4 Rodents come in a variety of sizes from pinkies, fuzzies, hoppers, and small and large adults and can be purchased frozen from most pet stores. From left to right, fuzzies, pinkies, and small adult mice. (Courtesy of Don Boyer).

An interesting digestive strategy has been noted in pythons.[54] As digestion of a meal begins, the snake's metabolic rate rises dramatically as a result of the energy requirements of digestion, known as the specific dynamic action (SDA). The python selectively digests the protein components first, releasing amino acids for oxidation (even if the prey has been through a blender). These amino acids provide the immediate needs of the SDA, with digestion of lipids occurring more slowly. Previously, it was assumed that the needs of the SDA were met from endogenous stores. The fatty acids released are then stored and used as an energy source during times of the prolonged fasting, which is common in these ambush predators.

Hatchling snakes often refuse pinkies, and several sequential tricks can be used to induce feeding. Handling should be curtailed, and at least one hide box should be present in the enclosure. A pink mouse can be left in the cage overnight. Washing, to remove all rodent scent, and/or then scenting a pink mouse with the preferred natural prey (such as lizards for king snakes and milk snakes [*Lampropeltis* spp.]; toads for hognoses [*Heterodon* spp.]; or fish for garter, ribbon, [*Thamnophis* spp] or water snakes [*Nerodia* spp]). Scenting involves rubbing, or attaching a small amount of skin, or limb, from the preferred prey onto the pink mouse, especially around the head. "Braining" also works well, even in snakes that have steadfastly refused pinkies. Brain material is forced out the pink mouse's nostrils or through a skull incision, onto

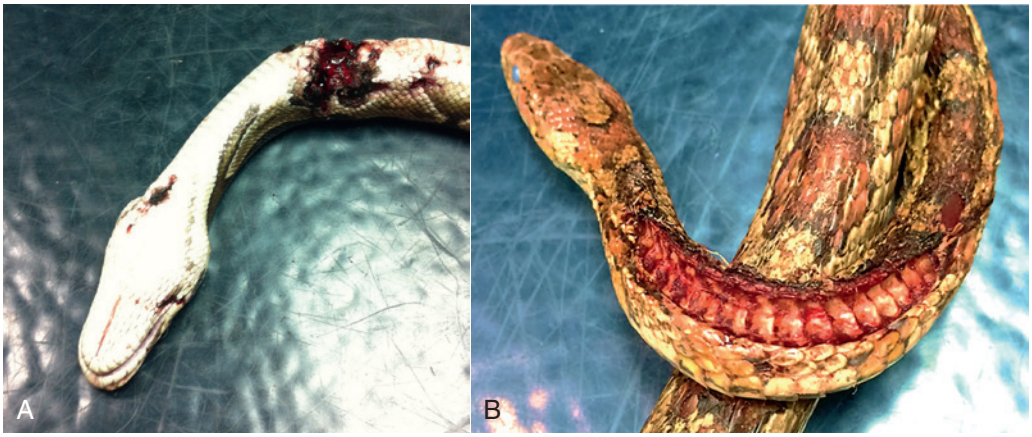

FIG 27.5 (A, B) Live prey should be humanely killed by cervical dislocation or gassed with CO_2, prior to feeding. Alternatively, rodents can be purchased frozen and thawed completely before feeding. Feeding live prey can result in serious injury to reptiles.

the snout, and presented close to the snake, or left in the cage overnight. Tongue flicking by the snake of the pinky brain seems to be a super optimal stimulus releaser for feeding.

Fish is often used as a food for snakes, turtles, and crocodilians. Whole fish are relatively good sources of most nutrients except for thiamine and vitamin E.[48] Thiaminases, enzymes that destroy or inactivate thiamin, are present in many marine animals, such as clams, herring, smelt, and mackerel.[48] The recommended supplementation is 25 mg to 30 mg thiamine per kg of wet fish. Trout and most freshwater fish do not contain thiaminases and do not require thiamin supplementation. Vitamin E is abundant in fresh fish, but oxidation of fish lipids while frozen can deplete vitamin E content.[50] Much of the vitamin E can be destroyed after a few weeks of freezing, and frozen fish should be used within 4 to 6 months.[48] The recommended level of supplementation is 100 IU of vitamin E per kg of wet fish. Many freshwater reptiles will not eat saltwater fish. The types of fish fed should be varied, and many piscivores will also eat rodents, snails, slugs, earthworms, shrimp, krill (frozen, not freeze dried), or pelleted commercial diets. Aquatic turtles do well on fish-based aquatic turtle pellets (see Table 27.6), earthworms, waxworms, mealworms, crickets, whole fish (freshly killed guppies or minnows, chopped trout, and freshwater smelt [Fig. 27.6], whole shrimp, and pinkies or chopped skinned mice. Goldfish are not recommended due to frequent infection with *Mycobacteria*. Many sliders and cooters will take dark leafy greens as they get older.

FIG 27.6 Freshwater smelt (not saltwater smelt), and chopped, skinned whole mice, can be fed to aquatic turtles that will not consume aquatic turtle pellets.

Crocodilians. Nutritional studies of saltwater crocodiles (*Crocodylus porusus*) reveal average diets to be 70% water, 13% to 15% protein, 3% to 4% fat, and with a Ca:P ratio of 2–7:1, which are similar to other crocodilians.[55,56] Crocodilians are generalist opportunistic carnivores, which eat a wide variety of prey. Gharials (*Gavialis gangeticus*) are the singular exception, being largely fish specialists. Hatchlings feed mostly on small prey items such as insects, spiders, crustaceans, fish, and amphibians; adults feed mainly on larger prey (fish, crustaceans, mammals, reptiles, and birds). Small crocodilians typically stay in shallow, warmer water. Hatchling American alligators (*Alligator mississippiensis*) have metabolic rates 25 times that of large adult males. Consequently, they need about 25 times more food per unit of body weight, have faster digesta transit times, and higher food conversion rates.[56] Food is not chewed by crocodilians but swallowed whole or as large chunks; however, food may be crushed by the powerful jaws. If the prey or food item is too large to be swallowed or attached to a large dead animal, the crocodile bites and rolls its body in an attempt to tear off smaller pieces. Crocodiles are ambush predators and active scavengers (but will not take putrid prey), can be cannibalistic, and some occasionally even feed on fruits.[56] Small captive crocodilians can be fed gut-loaded insects, rodents, and whole fish or shrimp. Larger crocodilians can be fed larger prey, such as crustaceans, fish, rodents, rabbits, chickens, pigs, nutria, cats, dogs, and sheep. Crocodilian farms often utilize waste food, or byproducts, unfit for human consumption, which works if animals are culled young, but can be lethal to long-term zoo captives.[55] Rancid fish, or fish high in polyunsaturated fatty acids, can cause steatitis (see Chapter 84). As a general rule, juveniles should be offered food 2 to 3 times/week, subadults 1 to 2 times/week, and adults 1 time/week to every 2 weeks.[55] In the wild, juveniles eat 3% to 4% of their body weight/week, while adults consume 0.5% to 1% body weight/week. Farms encourage

There are many sources of these figures that differ in detail; it is useful to recognize trends and ideally work with one set.
Often sources are regionally varied, dependent on food source and sampled in small numbers, so using the data requires some caution.
Some of these analyses do not show corresponding Ca and P; there is a basic assumption that these are present in healthy vertebrates in a classic ratio of approximately 1.5–2.0:1
Diet of the prey species has some variable effects on nutrients.[46]

- Pinkies, fuzzies, and crawlers have only fed on milk from the mother; other sizes receive commercial rodent diets.
- Vitamin E as alpha tocopherol, and A as retinol.

To convert a nutrient analysis from "as fed" to "dry matter," see Box 27.1.

Thiaminase has been reported in a wide range of genera, freshwater and marine, vertebrate and invertebrate. It has been demonstrated to vary through the year.

- 1 mg alpha tocopherol = 1.1 IU, and 0.3 μg retinol = 1 IU vitamin A activity
  mg/kg = μg/g
- Gross energy (GE) calculated by adding the product of % crude protein x 5.43 kcal/g to the product of % crude fat x 9.11 kcal/g.[4,21]

VetBooks.ir

growth by feeding juveniles and subadults 20% of their body weight/week. All crocodilians can be fed commercial crocodilian extruded biscuits, such as Small or Large Crocodilian Diet or Crocodilian Gel Diet (Mazuri, PMI Nutrition International, LLC, St. Louis, MO). See Chapter 25 and Britton reference for more information.[55]

Herbivores

Herbivores average dietary composition is 15% to 35% protein, less than 10% fat, and 50% to 75% carbohydrates, of which 15% to 40% is crude fiber (DM).[8,42] Herbivores are the greatest challenge to feed correctly. Extant herbivorous reptiles are found in the Cheloniidae, Testudinae, and some Agamidae and Iguanidae. Only three other herbivorous lizard species exist outside the latter two families, including the Solomon Island prehensile-tailed skink (*Corucia zebrata*). Thus herbivory in lizards is limited to only about 50 species, and folivory is unique to the green iguana.[4,57,58] However, herbivorous species are popular and a large portion of the reptile veterinarian's caseload. Herbivores are typically generalized grazers and browsers. Some species are only herbivorous as adults and insectivores, carnivores or omnivores as juveniles, such as the bearded dragon and Emydid turtles, including *Chrysemys*, *Pseudemys*, *Trachemys*, and *Terrapene*.[59] All herbivores require UVB light. Green iguanas and rock iguanas (*Cyclura*) seem to utilize dietary vitamin D relatively inefficiently and are far more dependent on UVB radiation.[4,11] Herbivorous reptiles are hindgut fermenters with an enlarged cecum or colon, particularly well developed and partitioned in herbivorous iguanids and agamids but not in chelonians. The hindgut contains symbiotic microbes (bacteria, protozoa, and fungi) that anaerobically ferment plant material to produce proteins, vitamins, and volatile fatty acids.[57] A common misconception is that herbivores will select a balanced diet from the foods offered. While this may be true for free-ranging herbivores, this is not the case in captivity. Complex natural diets of herbivores are only slowly beginning to be appreciated. For example, Sonoran desert tortoises (*Gopherus morafakai*) consume well over 200 plant species, and this dietary diversity is probably true of many species.[60] Plants vary seasonally, annually (dependent on rainfall), phenologically (freshest plants eaten first, dry senescent plants last), and ecologically. Consumed plants in Arizona upland habitat included 55% forbs (herbaceous flowering nongrasses), 22% woody plants (especially desert vine, *Janusia gracilis*), 18% grasses, and 5% succulents (*Opuntia* cactus). In contrast, in more xeric habitats, tortoises consumed 50% to 90% woody plants, 3% to 29% forbs, and 13% to 19% grasses.[61] Dietary overlap between two desert tortoise species (*G. agassizii* and *G. morafkai*) was less than 25% of diet plants found in both the Mojave and Sonoran deserts. Thus there is much intraspecies and interspecies variability, even between closely related species. One researcher commented that the abundance and diversity of annual plants varied so much from year to year and site to site that it was difficult, if not misleading, to characterize an average desert tortoise diet.[62] Nonetheless, captive desert tortoise diets should attempt to emulate the nutrient composition of wild diets, with a goal of ≤15% crude protein, 2% to 4% fat, and 25% to 30% fiber (% DM).[6,62] Captive herbivore nutrition is more of an art than a science, primarily because of the scarcity of nutritional information. Nutritional studies are difficult and tedious. Consider, for example, studying the green iguana. Green iguanas are tough to observe in the field because they are arboreal folivores and wary of humans. They are also inactive 90% of the time[63] and spend little time foraging (0.6% of total observation time in one study).[59] Once you observe them foraging, arboreal plants consumed must be collected and nutritionally analyzed. However, one must be careful to collect exactly what they consumed. In another study, iguanas never ate mature leaves with ≤20% DM crude protein content but always selected younger leaves with higher crude protein contents of ≥25% DM.[64] It is therefore understandable that we still know so little about the nutrient composition of wild iguana diets. Nutritionists, working on captive propagation of green iguanas for decades, have produced some valuable estimates.[4] For green iguanas, the recommended DM nutrient levels are 26% gross protein for hatchlings to 6 months, 22% gross protein after 6 months, 15% to 17% gross protein for nonreproductive adults, as well as 3% fat, 6% to 10% crude fiber, and a 2:1 Ca:P ratio (% DM).

Salad-type diets are problematic in that commercial fruits and vegetables produced for humans typically are too low in Ca, fiber, trace minerals, and some vitamins; too high or too low in protein; and too high in simple carbohydrates for herbivorous reptiles (see Tables 27.1 and 27.2).[4] It is no surprise that captive herbivores commonly present with calcium deficiencies, difficulty laying eggs, cystic calculi, renal diseases, and loose stools. In southern California, chronic nutritional disease is endemic in tortoises fed backyard grasses, weeds, and grocery store fruits and vegetables. Most suffer from chronic protein, calcium, and fiber deficiencies and simple carbohydrate excess, with many dying from hepatic lipidosis. Captive iguanas typically die from calcium deficiency, hypovitaminosis D, or renal failure. Nutritional analysis of the most frequently consumed plant species reported from four studies of free-ranging desert tortoises,[6,7] and a recommended nutrient profile for green iguanas,[4] are compared to commonly fed greens (see Table 27.1) and fruits and vegetables (see Table 27.2). It is difficult to provide a balanced range of necessary nutrients with greens, vegetables, and fruits. That is not to say that they have no place in herbivorous reptile diets, but, by themselves, are often poor alternatives to wild foods.[4] Another problem with salads is that animals can be selective in favor of fruit and other food items that are nutritionally incomplete. The USDA nutrient database (https://ndb.nal.usda.gov/ndb/) is an online, searchable database that enables veterinarians to obtain complete nutritional information on any human food item.

Attempts to compensate for nutritional inadequacies in salad diets by supplementing with vitamin-mineral supplements is difficult without knowing what they need, how much they need, and how much they are consuming, and does not correct nutritional excesses. This also applies to natural foods planted for browse in the herbivores exhibit. In the wild, they consume dozens to hundreds of species, although they may concentrate on a few. Most backyards or exhibits simply are too space limited to support a wide variety of plant species, and herbivores often overgraze whatever is in their exhibit. This is not to say that native palatable species should not be offered, but rather that it is hard to provide a nutritionally complete diet in such a manner.

There is a difficult trade-off to be made between trying to mimic a reasonably normal diet while accepting that the actual components are nothing like those encountered in the wild, against using a totally abnormal commercial diet based on in-house extrapolation with little to no validation. The former presumably fills more of the nonnutritional behavioral needs of the animal, which will not be experienced by eating uniform pellets. Some prefer to attempt to simulate normality in the types of food items presented often with the choices dependent on availability of suitable natural or commercial foodstuffs. Others believe providing a high-quality commercial pelleted diet as a large portion of the diet probably offers a superior dietary alternative to what the typical owner can accomplish.

Most grasses and hays (except for Kentucky bluegrass and alfalfa) approach or meet the nutrient profile for desert tortoises, except some are low in Ca (see Table 27.3).[6,65] Clover (*Trifolium* spp.) and alfalfa (*Medicago sativa*) have more Ca but are also higher in protein. Alfalfa is a nitrogen-fixing legume hay that has higher crude protein than grass hays. Early season vegetative alfalfa has a 23% crude protein content that drops to 17% crude protein by full bloom,[65] all levels above what desert tortoises naturally consume and therefore may be excessive.

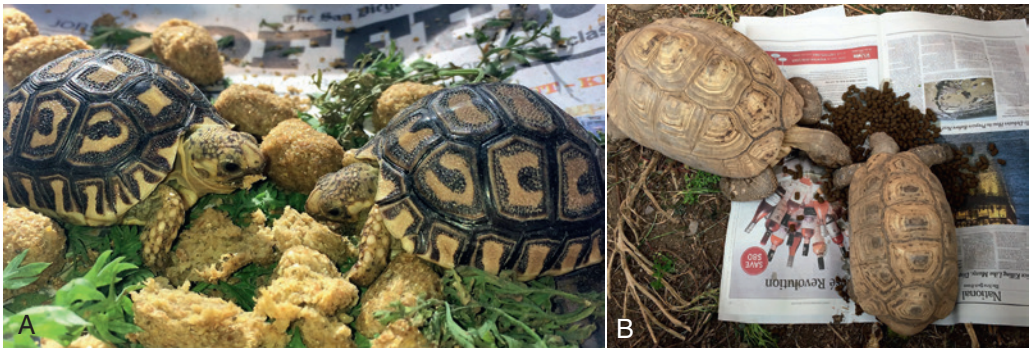

FIG 27.7 Chronic nutritional deficiency, such as anemia, hypoalbuminemia, and hepatic lipidosis is prevalent in backyard tortoises fed grasses, weeds, flowers, and grocery store produce. Better alternatives include commercial pelleted mixes, grasses, grass hays, and plant species normally consumed in the wild. Converting reptiles to pellets and hay is much like getting a dog off table scraps and onto dog food; patience, persistence, and feeding less often will eventually convert them.

Commercial diets are also compared to nutritional analysis of the most frequently consumed plant species reported from free-ranging desert tortoises[6,7] in Table 27.4 and recommended nutrient levels for green iguanas[4] in Table 27.5. On a DM basis, there is a great deal of variation in these diets, and some are better than others in approaching free-ranging nutrient profiles. Overall, they appear better than greens, fruits, or vegetables. However, a diet for juvenile iguanas with a 13% protein DM is not only inappropriate for juveniles but for adult iguanas as well. Only two of the tortoise diets had the recommended 3.2 to 5.8 Ca:P ratio, so additional Ca supplementation may be needed, and all tortoise diets were high in carbohydrates. Scores were assigned based on whether the diet met the free-ranging nutrient profiles (for tortoises, protein, fat, fiber, carbohydrates, and Ca:P; for iguanas, the same, except carbohydrates were not listed by Allen and Oftendal[4]). Not all diets had Ca or P listed, which was reflected in their lower scores. The diets in Tables 27.4 and 27.5 are listed from highest to lowest scores.

Getting tortoises to eat hay and commercial foods can be difficult (Fig. 27.7). Much like a dog content with table food, a tortoise will eat pellets and hay once hungry enough, but not if better-tasting foods are available. Feeding less frequently will often encourage the reptile to try new foods. Use good-quality hays, not stems or stalks, and ensure it is not stale or moldy. Chopping the hay with scissors, or a food processor, and sprinkling, spraying, or briefly soaking the hay with water improves palatability. Soaking too long will leach out nutrients. Short hay segments may decrease colonic obstructions. Mixing greens in or under the hay also helps with acceptance. Pellets can be soaked in just enough water to be absorbed and soften and then mixed into the greens. Be patient and persistent, tortoises and iguanas will switch over to commercial pellets, or hay (for tortoises), once hungry enough. African spurred tortoises (*Centrochelys sulcata*), as well as other giant tortoise species, grow so large and eat so much that reliance on grass hays often becomes a practical necessity.

Diluting commercial diets with natural foods and creating an unbalanced ration should be avoided. By definition, complete diets are intended as sole diets, unless the feeding instructions specify they are formulated to be fed with natural foodstuffs. Some manufacturers have anticipated this, and Mazuri recommends feeding their pelleted tortoise diets with good quality grass hay, and, if desired, up to 5% fruit and 20% vegetables by total diet weight.

Misconceptions. Be aware of several persistent and widespread misconceptions. Members of the Brassica family (cabbages, kale, mustard greens, broccoli, cauliflower, Brussels sprouts, bok choy) are thought, but not proven, to cause thyroid problems (goiter) if fed exclusively long term but are harmless in moderation as part of a balanced diet. Goiters appear exceedingly rarely in tortoises, and goiter association with feeding Brassicas has never been validated in tortoises. Galapagos and Aldabra tortoises may have enlarged thymuses in their ventral neck, but these should not be confused with goiter. Massively enlarged thyroid glands are generally tumors, not goiter (see Chapter 79).

Many greens contain oxalates, which can bind Ca in the intestinal tract and decrease calcium absorption. The adverse effects of oxalates must be considered in terms of oxalate:Ca molar ratio of food.[66] Spinach, beet greens, sorrels (*Oxalis* and *Rumex spp.*), and purslane (*Portulaca spp.*) have oxalate:Ca ratios >2, therefore they have no utilizable Ca and possess excess oxalate, which can bind Ca in other foods eaten at the same time. They are not good sources of Ca despite their apparently high Ca levels.[66] Other foods, such as prickly pear cactus (*Opuntia ficus indica*), collards, Swiss chard, dandelions, kale, turnip greens, Brussels sprouts, and parsley, have oxalate:Ca ratios <2, indicating that they are good sources of Ca. Diets low in Ca and high in oxalates are not recommended, but occasional consumption of high-oxalate foods, as part of a nutritious diet, does not pose any particular health problem.[66] Indeed, it is recommended to feed these greens, just not exclusively. Cattle and sheep, as well as humans, possess a bacterium, *Oxalobacter formigenes,* that can metabolize oxalic acid, and perhaps herbivorous reptiles do as well.[66] Another unfounded concern with oxalates is that they can cause urocystoliths, probably because they may contribute to renoliths in humans. Reptiles form urate stones, not Ca oxalate stones. There are only two reports of Ca oxalate stones in tortoises, one in a Moorish tortoise (*Testudo graeca graeca*, the cystourolith was only 20% calcium oxalate)[67] and one in a deceased wild desert tortoise with renoliths.[68] The latter study concluded that oxalates in desert tortoises were an incidental finding and nonpathogenic.[68] In contrast, humans do get Ca oxalate stones, yet oxalate-rich foods are still widely and safely consumed and only restricted in people predisposed to Ca oxalate stone formation.

Plant poisoning is extremely rare in tortoises. Leopard tortoises (*Stigmochelys pardalis*) and tent tortoises (*Psammobates oculifer*) regularly eat the invasive African species, goat's head (*Tribulus terrestris*), which causes staggers (limb paresis) and death in livestock.[69,70] Leopard tortoises are known to consume more than six plant species suspected to contain toxic substances, including oxalates.[69] Most of the plants consumed by Russian tortoises (*Agrionemys horsfeildii*) are notorious for their

VetBooks.ir

toxicity to herbivorous mammals.[71] More than 10% of plant species regularly consumed by Hermann's tortoises (*Testudo hermanni*) contained toxic alkaloids.[72] Tortoises will typically avoid poisonous plants, dilute their effects with other foods, or are resistant to their effects. Some exceptions include rhododendrons (*Rhododendron* spp., grayanotoxins cause flaccid paresis), oleanders (*Nerium oleander*), chinaberry trees (*Melia azedarach*), tree tobacco (*Nicotiana glauca*), and toadstools (Agaricomycetes).

Given the previous discussion, it is apparent that making recommendations for an appropriate herbivorous reptile diet can be challenging. However, some important points for guidance are summarized here. All herbivores require UVB light to assist with Ca requirements, and it must be routinely provided with either exposure to unfiltered sunlight or appropriate lighting. Regarding diet for both tortoises and iguanas, it is important to concentrate more on dietary variety than limiting foods. For tortoises, grasses, grass hays, native plants and good-quality commercial tortoise diets should make up at least 80% of the diet. The remaining 20% can be dark leafy greens, Mulberry tree leaves, grape leaves, backyard weeds, and nonstarchy vegetables, as well as calcium-rich flowers (roses, *Rosa* spp., nasturtiums, *Tropaeolum* spp., carnations, *Dianthus caryophyllus*, cactus flowers). For iguanas, produce should be no more than 50% of the diet, on an AF basis, with the remainder being a rationally formulated commercial diet.[4] Produce should be limited to dark leafy greens and nonstarchy vegetables. Commercial fruits and starchy vegetables should be avoided.[6] Additional multivitamins are not needed for iguanas or tortoises, as long as they consume commercial foods formulated for them but ensure that Ca levels are acceptable, or additional supplementation should be used. If the commercial diet is supplemented with produce, or grass, then additional calcium supplementation may again be required.

Omnivores

Omnivores' average dietary composition consists of 15% to 40% protein, 5% to 40% fat, and 20% to 75% carbohydrates.[42] Many aquatic turtles, box turtles, wood turtles, forest tortoises, sea turtles, and lizards consume both plant and animal material. Many omnivores consume more animals as juveniles to fuel increased demands for protein and fat than as adults.[8]

Box Turtles. Box turtles are more carnivorous than initially thought, and they eat whatever stimulates them and whatever they can catch; moving prey especially appeals to them.[73] Box turtles are opportunistic omnivores that consume beetles, insect larvae (caterpillars, grubs, maggots), cicadas, crickets, cockroaches, flies, grasshoppers, termites, millipedes, centipedes, land snails, slugs, earthworms, spiders, dragonfly larvae, sowbugs or pillbugs, crayfish, carrion, fish, frogs, tadpoles, toads, small mammals, birds, salamanders, lizards, snakes, smaller turtles, and all types of carrion, as well as plant material, such as mushrooms (even poisonous ones), strawberries, raspberries, blackberries, blueberries, elderberries, mulberries, persimmons, sea grapes, tomatoes, apples, grasses, leaves, shoots, buds, roots, mosses and Opuntia fruits, pads, and flowers.[73] Again fruits should be limited, and good-quality commercial diets designed for box turtle or aquatic turtles should make up a large portion of the diet (see Table 27.6).

Bearded Dragons. One study of the stomach contents of 10 bearded dragons found a wide variety of arthropods (9 orders, 80% Isopterans [termites]) but a larger volume of plant matter. The diets were high in crude protein (41%–50% DM), and fatty acid content was 14%–27% of the DM intake. Mealworms most closely resembled the nutritional profile of termites, and the authors concluded a diet with a variety of insects and dark leafy greens would closely resemble the natural diet.[74] Another study showed adult bearded dragons consumed 90% plant material, whereas juveniles consumed 50% plant material and 50% animal material.[75] Bearded dragons are also lizard eaters and cannibalistic if size disparity is present. Suitable vegetables include calcium-dusted dark leafy greens (kale, collards, mustards, turnip or beet tops, spinach, dandelions, cabbage, bok choy, broccoli rape, and lettuces such as romaine, red leaf, green leaf, or boston lettuces but not iceberg lettuce), carrots, squash, zucchini, peas, and beans. Flowers such as roses, nasturtiums, carnations, and hibiscus are also good. Dragons should be fed a wide variety of insects, including mealworms, crickets, super worms, waxworms, Dubia cockroaches, black soldier fly larvae, locusts, silkworms, butter worms, grasshoppers, and tomato hornworms. Insects should be gut loaded and dusted before becoming prey. Commercial pelleted (not cubed) bearded dragon foods can also be fed (see Table 27.7). Baby mice can be offered several times per month. Even though bearded dragons enjoy fruits, they are not recommended. Overfeeding and obesity are major problems in captivity. Growing juveniles can be fed daily, while adults should be fed 2 to 3 times weekly. Growing dragons need more calcium than adults. Calcium is provided in calcium-rich insect gut-loading diets, dusted on insects or sprinkled on plant food. If multivitamins are not included in the gut-loading, dusting preparation, or fortified foods, multivitamins can be given twice a month.

Sea Turtles. Sea turtles can be carnivorous, herbivorous, or omnivorous, and most undergo a change in diet as they age.[12] Adult leatherbacks (*Dermochelys coriacea*) are gelatinovores; their diet consists of jellyfish, tunicates, and sea squirts. Sea turtles have large caudally directed papillae in their oropharynx and esophagus to help them swallow soft food (see Fig. 7.29). Their fondness for jellyfish can also lead to fatal consumption of plastic bags. Adult hawksbills (*Eretmochelys imbricate*) eat sponges primarily but also feed on soft corals, tunicates, shrimp, and squid. Kemp's ridley sea turtles (*Lepidochelys kempii*) are also carnivores that eat crab, fish, jellyfish, shrimp, and mollusks. Green sea turtle hatchlings (*Chelonia mydas*) are carnivorous until juveniles, when they switch to eating sea grasses, especially turtle grass (*Thalassia testudinum*) in the Caribbean, as well as red, green, and brown algae, jellyfish, mollusk eggs, and sponges. Near the coast of Peru, invertebrates are much more common in green sea turtle diets, and some fish are taken.[12] Adult loggerheads (*Caretta caretta*) are carnivorous, eating crabs (especially horseshoe crabs) and mollusks, while hatchings are omnivores. Olive ridley sea turtles (*Lepidochelys olivacea*) are omnivores, eating crabs, shrimp, lobster, urchins, jellies, algae, and fish. Flatbacks (*Natator depressus*) are also omnivores, eating sea cucumbers, jellyfish, soft corals, shrimp, crabs, mollusks, cuttlefish, fish, and seaweed. In captivity, all sea turtles can be maintained on a carnivorous diet. Mazuri (PMI Nutrition International, LLC, St. Louis, MO) makes a meal form product (Sea Turtle Meal Diet for Carnivorous Turtles) that may be fed via gavage, as well as a gel diet (Sea Turtle Gel Diet for Carnivorous Turtles). See Chapter 24 for more information.

Freshwater Turtles. Many large emydid turtles, including *Chrysemys, Graptemys, Pseudemys*, and *Trachemys* spp. undergo an ontogenetic shift in diet as they mature.[76] The red-eared slider (*Trachemys scripta elegans*) starts out predominantly carnivorous when juvenile, inhabiting shallower warmer waters that are rich in invertebrate and animal prey (the latter are good sources of protein and Ca). As they get older and larger, they cannot maneuver in shallow water and move into deeper, cooler water (typically 5°–6°C lower) where prey is more dispersed, and so they shift to eating more plant material (with lower protein content), such as duckweed (*Spirodela polyrhiza*) and hydrilla (*Hydrilla verticillata*).[76] See Table 27.6 for an alphabetical list of freshwater turtle manufactured diets.

VetBooks.ir

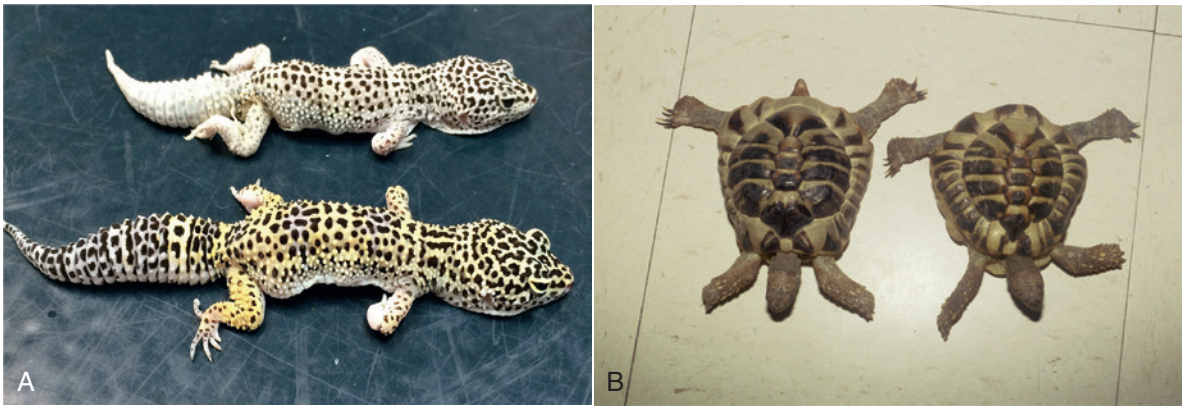

FIG 27.8 Always consult with your reptile and amphibian owners (from novice to breeder) about nutrition. As their veterinarian, you are their best knowledgeable source for this vital information. If you do not provide it, they may acquire the information from questionable sources, often leading to disastrous results, as illustrated here in these stunted and nutritionally unsound reptile patients (A) leopard geckos *(Eublepharis macularius)* and (B) tortoises *(Testudo),* that can be completely preventable.

CONCLUSION

Veterinarians have been trained in animal nutrition. The herp veterinarian must evaluate dietary history on a regular basis to keep their reptile and amphibian patients healthy. Information within this chapter covers the majority of reptiles and amphibians seen by veterinarians in private and zoological veterinary practice. With basic information and as vocal advocates for good nutrition, veterinarians can have a tremendous impact on the health of captive herps (Fig. 27.8).

Amphibians

Frank Pasmans and An Martel

Captive propagation of amphibians has gained increased attention due to the global amphibian crisis, which renders amphibians the most severely threatened vertebrate class on earth.[1] Indeed, ex situ captive breeding programs are far from ideal; however, they may prove to be the only available measure to prevent extinction of amphibian species from global threats such as chytridiomycosis (Fig. 28.1).[2,3] Although amphibians are currently being kept in fairly large numbers in different settings (e.g., zoos and aquaria, research laboratories, private collections), principles for keeping these animals healthy in a sustained way are widely applicable. For example, avoiding pathogen pollution and the establishment of invasive alien species, securing amphibian welfare and conservation, and avoiding negative effects on public health all apply within these settings. Because issues with infectious diseases are especially prominent in amphibian conservation and relevant in most aspects of amphibian captive management, veterinarians play a key role in the sustainability of captive amphibians.

RESTRAINT

Restraining amphibians should be kept to the absolute minimum, for example, for collecting blood or cloacal samples or administering therapeutics. In general, the smaller the amphibian, the less it will tolerate prolonged periods of contact with the warm and relatively salty human skin. Manipulation can result in severe signs of (heat) stress and even death. Signs of distress are excessive production of skin secretions, cramps, and in some urodelan species caudal autotomy (tail loss). Many critically important clinical parameters can be assessed visually in amphibians without the need for manipulation (posture, skin texture, presence of dysecdysis, body condition, appetite). Parasitologic examination is preferably done on fresh feces instead of cloacal lavage.

Wearing vinyl (nonpowdered) gloves is highly recommended when manipulating amphibians. The use of latex gloves is discouraged, given the potential adverse reactions of amphibians, especially after repeated manipulation.[4] Changing gloves between animals is advised, not only to prevent disease transmission but also to prevent intoxication by skin secretions that adhere to the glove. Frogs and toads can be restrained by grasping the animal firmly just cranial to the hind legs (Fig. 28.2). Most salamanders and newts can be carried easily on the open palm of the hand. For restraining these animals, the same techniques as for lizards can be used. Amphibians with particularly slippery skin may be restrained by using a wet towel, tissue, or a dip net. Some amphibians (for example, large and slippery salamanders or caecilians) can only be properly manipulated with sedation. Most amphibians will not attempt to bite when grasped, with very few exceptions, such as some large anurans (notably horned frogs, *Ceratophrys* sp., *Lepidobatrachus* sp., and African bullfrogs [*Pyxicephalus* sp.]) and some, mostly very large salamanders (large sirens, amphiumas, and giant salamanders but also some smaller species like *Aneides lugubris*). All amphibians should be considered to contain several skin toxins that may cause irritation or (in very rare cases and invariably after ingestion) intoxication. Notoriously toxic taxa include the popular pet species like poison dart frogs (family Dendrobatidae) or Malagasy poison frogs (genus *Mantella*) but also many urodelans (e.g., the genus *Taricha*), many of which are aposematically colored (with warning colors) and secrete defensive alkaloids. However, at least in anurans, much of this toxicity is commonly derived from prey items,[5–7] which are generally not available in captivity and, hence, toxicity of these species is reduced over time in captivity. Intoxication by amphibian skin secretions can be easily avoided by wearing gloves. A very small number of amphibians such as the frequently kept frogs of the genus *Trachycephalus* may cause mucosal irritation even without contact[8] (Fig. 28.3) or by active spraying of poison from skin glands (*Salamandra*).

Alternatives to oral and parenteral application should be preferentially used where applicable, for example, by percutaneous drug administration, which is possible for several frequently used antiparasitic drugs (metronidazole, levamisole). Only in rare cases do these authors utilize force feeding. Opening an amphibian's mouth can be done by gently forcing a nontraumatic device (e.g., credit card, double-folded piece of paper) in the mouth.

IDENTIFICATION

Identifying individual amphibians for research or legislation purposes (e.g., CITES) may pose some challenges given the small size of many species. Methods to identify individuals include toe-clipping (amputation of one or several toes), branding, tattooing, implantable polymers, pattern mapping, and transponders.[9] For reasons of animal welfare and technique reliability, only the use of polymers, pattern mapping, and transponders will be discussed. Passive integrated transponder tags (PIT tags or microchips) are widely used and provide long-term, unambiguous identification. The only limitation is the size of the animals, the minimum size for frogs and toads being some 4 cm and the minimal snout-vent length for salamanders and newts being approximately 5 cm (but depending on the animal's girth) when using 1.4 mm × 9 mm transponders. In anurans, transponders can be placed either in the coelomic cavity or in the dorsal lymphatic sac (Fig. 28.4). In salamanders and newts, transponders can be placed in the coelomic cavity or, in very large species, intramuscularly in the tail. For some species that are difficult to handle, sedation is recommended to prevent trauma from the PIT tag applicator. Potential complications are the loss of transponders (often reported but actually, when performed secundum artem, loss of transponders is very limited) and the potential of causing trauma in

small animals. PIT tags should be applied by trained persons only. The insertion site should be gently wiped clean with a sterile gauze or cotton-tipped applicator. These authors prefer not to disinfect the insertion site to avoid possible irritation or even intoxication.

High-quality detailed photographs of amphibians against a contrasting background and with indication of size can be used for pattern mapping in species with unique patterns that remain stable with age. For several amphibian species, software has been developed for quick matching of a given pattern with a pattern database. Finally, colored or fluorescent polymers (e.g., elastomers) are widely used in amphibians, mainly in field studies. These are injected subcutaneously. The technique is cheap, allows a large number of individual identifications (by alternating dyes and application sites), and is applicable to very small amphibians, including tadpoles. Disadvantages are loss of visibility of the tags and the lack of unique code combinations, rendering this technique limited for CITES and other legal purposes.

SPECIFIC HOUSING REQUIREMENTS

Before acquiring any amphibian, the relevant literature should be consulted to identify the species husbandry and nutritional needs. Indeed, given the often highly species-specific requirements, it is impossible to provide general instructions that meet all species' needs. Ample literature is easily available,[10,11] and a wealth of high-quality monograph booklets

VetBooks.ir

have been published on most of the commonly kept species. Most amphibian enclosures are constructed from glass or plastics. Only glues and sealants, such as silicone-based or two-component epoxy glues, that are safe for use in fish aquaria should be used. Newly glued materials should be thoroughly dried and rinsed with water. All amphibians need moisture in at least part of their terrarium to maintain their fluid balance. Amphibians typically do not drink, but rather absorb fluid through their skin (such as the drinking patch on the ventral coelom of many anurans). Depending on their life history, amphibians should be kept in aquaria or terraria, the latter containing an aquatic part, the size of which depends on the amphibian species. It is of vital importance to keep the water quality in any amphibian enclosure optimal (see below) to avoid intoxication. Most amphibians can easily overcome the glass sides of their enclosure and should be prevented from escaping by securing a tightly fitting lid covered with fine mesh. For many salamanders and newts a frame of overhanging strips of at least 5 cm will prevent the inmates from escaping, although some species, notably plethodontid salamanders, are capable of walking around on glass sheets upside down (Fig. 28.5). An abundance of shelters, provided by PVC tubes, piles of flat stones, bark, or similar should be available.

Fully aquatic species can be housed in escape-proof aquaria (Fig. 28.6) that can be otherwise designed similar to aquaria used for ornamental fish. A water level of 15–20 cm will be sufficient in most instances, and potable tap water will be fine for most of the commonly kept amphibians, as long as chlorine levels are low or absent, acidity (pH) is between 6–8, and overall hardness of the water is moderate to high (8°dH–18°dH, 2.9–6.5 meq/L). The pH values below 4 or above 11 are lethal and must be avoided. Water hardness, expressed in degrees of German hardness (°dH), reflects levels of dissolved calcium and magnesium and is an indirect measure of the alkalinity of the water, that is, the amounts of dissolved carbonates and bicarbonates. The lower the hardness, the lower its capacity for buffering, with the potential of severe pH fluctuations. Chlorine can be removed from tap water by leaving the water in a bucket for at least 24 hours, preferably with aeration. The use of chloramine-treated water for amphibians is discouraged. Chloramine is more stable and requires the use of dechlorinators for removal. Only a limited number of amphibian species require a more specific water quality. One of the most crucial parameters that should be monitored is the level of nitrogen metabolites and especially ammonia, nitrite, and nitrate. Total ammonia nitrogen consists of NH_3 and ionized NH_4^+. The latter is far less toxic. The rate NH_3/NH_4^+ increases with increasing pH and temperature. The maximum levels for these metabolites are for ammonia: 0.02 mg/L, nitrite: 0.1 mg/L, and nitrate: 50 mg/L, but for ammonia and nitrite, values should be zero.[12,13] Ammonia is continuously being produced by aquatic amphibians but also by decaying organic matter, such as leftover feed items. In a well-conditioned aquarium, ammonia is quickly metabolized to nitrite and further to nitrate by bacteria. When these bacteria are lacking (typically in newly installed tanks or following inappropriate antibiotic use in the environment) or do not have the capacity to break down ammonium and nitrite, buildup of these metabolites causes overt disease and death (Fig. 28.7).[14] This "new tank syndrome" is an often overlooked but very frequent cause of death in captive amphibians. Accumulation of nitrates

FIG 28.6 Aquarium for a pair of stream-dwelling salamanders (*Necturus lodingi*). The substrate consists of coarse gravel, aquatic vegetation of cold-tolerant Java moss, and hiding places of PVC tubes. Water is circulated, aerated, and filtered by a submersible filter. (Courtesy of Frank Pasmans.)

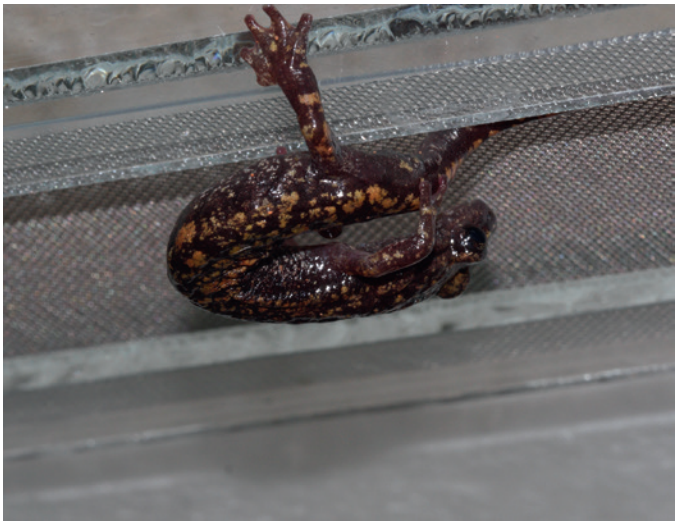

FIG 28.5 Cave salamander (*Speleomantes strinatii*) clinging to the glass ceiling of the terrarium (Courtesy of Frank Pasmans.)

FIG 28.7 Mortality in a colony of painted frogs (*Discoglossus pictus*) due to elevated nitrite concentrations in the water container, despite the water looking rather clean to the naked eye. The dark pink coloration on the test strip demonstrates the very high levels of nitrogen metabolites. (Courtesy of Frank Pasmans.)

causes more subtle clinical symptoms such as anorexia. Buildup of toxic nitrogen metabolites is an important cause of disease and death in both larval and adult amphibians. It is important not only in aquatic settings but also in terrestrial species kept on substrates with a poor capacity to metabolize waste products (e.g., tissue paper), and a water-quality check should be part of any routine veterinary evaluation. A weekly water-quality check by the owner using commercially available testing kits is highly recommended. Optimal water quality can be maintained by proper water filtration to eliminate ammonium and nitrite, combined with regular, partial water changes to remove excessive nitrates. Anaerobic filters and resins to remove nitrate from the water are commercially available. Charcoal or activated carbon can reduce the amount of toxins or chemicals. Thus, when medication is applied to an aquarium, charcoal should be removed from the filter. The surface for nitrogen converting bacteria should be maximized, for example, by including special substrates (e.g., ceramic tubes, filter foam) in the filter compartment and by providing an aquarium substrate of sand or gravel. Likewise, a proper substrate increases the surface for bacterial growth. Generally, sand (which does not contain sharp particles) or gravel is used as substrate. Sand generally allows the roots of aquatic plants to anchor easily but has the disadvantage of easily accumulating large amounts of detritus. Gravel must be preferably smooth and of such a size that, if ingested, it will not cause foreign body impaction. Small- to medium-sized gravel generally works well. Aquatic plants not only add to the aquarium's aesthetics but create environmental enrichment for the inmates, spawning substrate, produce oxygen during the day and remove metabolic waste products such as nitrate from the water. A newly set up aquarium should be left to establish an efficient nitrogen cycle before the amphibians are added. This process takes at least 6 weeks but can be shortened by adding substrate and/or filter material from a mature aquarium to the new tank. Living aquatic plants use nitrate as fertilizer and help keep nitrate levels low. A sufficiently high concentration of dissolved oxygen in the water is particularly important for amphibian species or life stages that breathe mainly via gills and the skin but also for the proliferation of aerobic bacteria that metabolize amphibian waste products. The amount of dissolved oxygen in the water should be at least 5 mg/L (ppm). However, oversaturating the water with oxygen may cause "gas bubble disease" (Fig. 28.8).[15] The oxygen content of the water may be raised by creating a water current and, during the daytime, by the presence of aquatic plants. Even though most stream-dwelling amphibians prefer at least some water current, this does not mean that they prefer to be exposed to strong currents continuously. In fact, many stream-dwelling amphibians inhabit stream sections with weak currents.

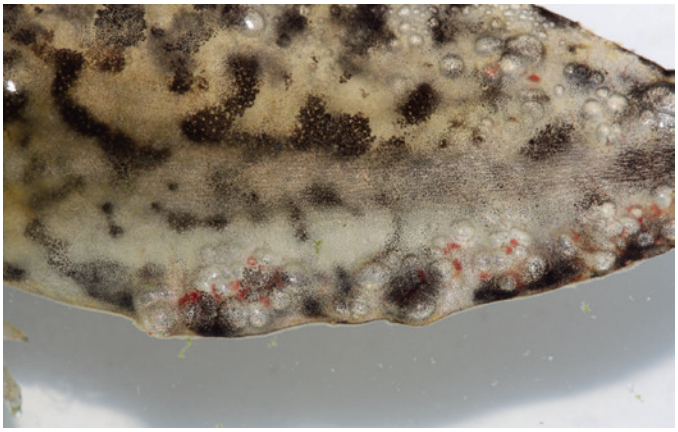

FIG 28.8 Gas bubble disease in a salamander (*Ambystoma andersonii*), visible as gas bubbles in the tissue of the tail. (Courtesy of Frank Pasmans.)

The majority of terrestrial amphibians are best kept in well-structured terraria with a moisture gradient and a water container, the size and depth of which depend on the life history of the species kept. The shape of the terrarium should reflect the species' behavioral preferences; for example, most arboreal species appreciate climbing opportunities in a terrarium as high as possible. Easy access into and exit out of the water container is vital to prevent drowning, especially in metamorphing juveniles but also many adult terrestrial amphibians that are poor swimmers. For these aquatic sections, the same requirements with regard to water quality apply as discussed above, especially with small water containers, which are prone to pollution with feces and drowned feeder insects. A constantly wet substrate without the opportunity to retreat to drier places is detrimental to the skin of many terrestrial species. A drainage layer below the actual substrate, for example, from expanded clay balls or foam mats, can prevent stagnant moisture. Comparable to the importance of a heat gradient in reptile enclosures to facilitate thermoregulation, a moisture gradient in the amphibian terrarium is necessary. This can be accomplished by stacking layers of bark on the substrate or by keeping only part of the substrate moist by regular misting. The substrate used must be nontoxic and easy to keep clean. When using inert substrates (e.g., paper toweling), these must be regularly exchanged to avoid buildup of toxic metabolites. The use of bleached paper towels is under debate, but actual evidence of resulting health problems is lacking. Organic substrates that allow the development of metabolite-degrading bacterial communities (e.g., loam, forest soil) can be used as well. However, regular cleaning (removal of feces, dead prey items), removal, and replacement are recommended to prevent buildup of metabolites and parasites. Commercial topsoils should be avoided because many contain fertilizers or chemical additions that might prove toxic for amphibians. Live moss is esthetically pleasing but is often not long-lived in the terrarium environment and must be frequently replaced. Mulch can be used as well, if not derived from trees that produce toxic or irritating substances (pine trees, cedar). Peat can be used for species that tolerate acid soil. We discourage the use of tree fern substrate in terraria since this is often not harvested in a sustainable way. Nontoxic foam (e.g., filter mats for garden ponds) can be used but should also be regularly cleaned. Fossorial species require a substrate similar to that in their natural habitat. Notably for fossorial species, which often defecate below the surface, the substrate should be replaced regularly and a drainage layer (filter mat or clay balls) used to avoid the buildup of excessive moisture and prevent anaerobiosis of the substrate (with the production of H_2S). The use of dead leaves (we prefer oak or beech leaves, which are less prone to fungal overgrowth) on the substrate provides additional hiding places and moisture gradients. When materials are being used from amphibian-rich forests, prior decontamination (heating for 30 minutes at 80°C) will kill most potential pathogens, such as ranaviruses, *Batrachochytrium* sp., many bacteria, and trombiculid mites.[16–18] For all amphibians, it is vital that proper shelters are provided, with at least one shelter per animal. The type of shelter depends on the species' requirements: many arboreal species rest on or between leaves or branches. Many terrestrial species seek shelters that fit their body dimensions and prefer contact of the roof of the shelter with their back to feel secure. Shelters can include bark, PVC pipes, shells from clay pots, roof tiles, and more. Some "sit and wait" predators that rely on camouflage (e.g., *Ceratophrys* sp.) partially dig in the substrate to blend with their environment and should be given the opportunity to do so. When heavy objects are used in the terrarium (rocks, branches, water bowls), they must be securely attached to avoid trauma to amphibians that may try to dig underneath. Adding plants to the terrarium offers additional niches for the inmates. Many

VetBooks.ir

FIG 28.9 Live or plastic plants are important cage enrichment for many amphibians, for example, providing opportunities to lay eggs for these tree frogs (*Agalychnis annae*). Eggs are deposited on leaves overhanging water, and when the tadpoles hatch, they fall in the water beneath. (Courtesy of Frank Pasmans.)

arboreal species appreciate the opportunity to rest on leaves, and many species (e.g., many poison dart frogs) breed in the axils of plants, such as bromeliads, or deposit eggs on leaves overhanging water (e.g., *Agalychnis* sp., Fig. 28.9). Alternatives to these axils can be provided using dark-walled, nontoxic canisters, for example, film containers (although increasingly hard to come by) or amber plastic pill pots. When living plants are used, their leaves should not have sharp edges or spines. The relative humidity of the air should, in general, be kept high, at least at 80%. This can be achieved by regular misting using manual or automated misting systems. Either rainwater or demineralized water should be used to prevent mineral depositions. Variations in moisture should reflect seasonal moisture variations of the species concerned and are important to cycle reproductive behavior. For example, in many species, mimicking the onset of the wet season by increased misting of water or transferring the animals to a rain chamber will trigger reproduction. A limited number of species (e.g., certain *Phyllomedusa* sp.) do not tolerate a continuously high relative humidity.

Temperature

The endothermic amphibians require a taxon-specific temperature range in which they function optimally. In the case of species undergoing marked seasonal temperature differences in nature, captive conditions should reflect these thermal needs, for example, by providing a period of hibernation where appropriate. Providing these natural seasonal fluctuations is an important key to inducing amphibian reproduction. In contrast to reptiles, most amphibians do not require the presence of a thermal gradient for active thermoregulation. Providing a temperature within the range that is consistent with the species' thermal preference and taking natural day/night fluctuations into account often suffices. However, species that exhibit basking behavior such as many diurnal anurans (e.g., the widely kept fire-bellied toad, *Bombina orientalis*) or tree frogs, do benefit from access to a basking area, which can be provided by a low-power spotlight or ceramic heater. The use of high-power heat mats in amphibian enclosures to create basking areas is not recommended because accidents resulting in quick desiccation of the terrarium and inmates can occur. Providing general temperature recommendations is not possible, and we recommend looking up thermal requirements of a given species in the relevant literature. Many species such as poison dart frogs appreciate a circadian thermal regime, with cooler nights (Table 28.1). One important temperature-related consideration is that the majority of the urodeles require temperatures that are cooler than those in most modern households. Many urodelan species do not tolerate temperatures higher than 20°C, and when kept at these higher temperatures tend to develop secondary infections including chlamydiosis.[19] A limited number of widely available species (e.g., *Tylototriton shanjing*, *Cynops ensicauda*) are notable exceptions. Cooling and heating devices are readily available commercially.

Lighting

Lighting is less of an issue for keeping healthy amphibians healthy than is the case for reptiles. A preference for a high light intensity is only appreciated by a limited number of diurnal amphibians that voluntarily expose themselves to sunlight. Although not as well understood in amphibians as in reptiles, these (partially) diurnal species likely benefit from UVB radiation for calcium metabolism to prevent secondary nutritional hyperparathyroidism, and also for color rendition.[20] Most amphibians have been bred successfully over generations without providing any UVB radiation. For nocturnal species, lighting serves the purposes of stimulating plant growth, and many species prefer dim light conditions—some are even markedly photophobic. Care must be taken not to use light sources that emit heat, which could result in overheating; fluorescent bulbs or LED lights are often recommended. Likewise, amphibian terraria should be kept from direct insolation to prevent overheating. Illumination of the terrarium should follow a photoperiod experienced by the free-ranging species. The seasonal variation in photoperiod (when appropriate) is an important reproductive stimulus in many species. Mimicking the natural photoperiod can be done stepwise, for example, with 1 hour increases or decreases of light every 2 weeks.

Outdoor Enclosures

When kept in a climate similar to that of their region of origin, many amphibians do well in outdoor enclosures, especially when provided with a pond and underground retreats to escape from heat, drought, and frost. Captive breeding of species in their home range in outdoor enclosures (e.g., for conservation purposes) mimicking the species' habitat is often successful and is far less time-consuming than breeding attempts indoors (Fig. 28.10). Such outdoor enclosures must be well fenced to prevent entry of predators (rats, cats, birds, rodents, mustelids, etc.) but also to prevent escapes. One major drawback is that outdoor enclosures for amphibians render regular health checks difficult, and major health issues, including mass mortality, can go unnoticed. Escape and direct or indirect contact of captive amphibians with native amphibians should be avoided to prevent pathogen pollution of the environment (or the inverse: infection of inmates from wild amphibians) or establishment of invasive alien species. Unless strict biosecurity can be enforced, the housing of exotic pet amphibians in outdoor enclosures should be discouraged.

QUARANTINE AND DISINFECTION PROCEDURES

Often overlooked, proper quarantine procedures are mandatory to minimize the risk of introducing infectious diseases by newly acquired amphibians (see also Chapter 19).[21,22] Independent of the source, all amphibians should be kept in quarantine for a period of at least 6 weeks, and until they appear to be healthy (or are euthanized). This determination includes no anomalies upon clinical examination (including parasitological examination of feces), normal appetite and behavior,

Anura					
Ceratophrys ornata/ Bell's horned frog	10–12 cm/Male smaller, with darker throat and nuptial pads on fingers	Sit and wait predator buried in leaf litter, nocturnal/ forest floor terrarium/25°C–28°C/20°C–22°C	Drier and cooler (20°C) period followed by wet and warm period (rain chamber).	Spawn up to 2000 eggs, tadpoles carnivorous and cannibalistic	High/bred in large numbers, often carrier of *B. dendrobatidis*
Dendrobates auratus/ green poison frog	25–60 mm/Finger disks in males larger	Ground dweller, diurnal, lowland to premontane rain forest/forest floor terrarium/24°C–27°C/19°C–20°C	Breeds throughout year, alternating drier periods provides a resting period and stimulates breeding	Clutch of 6–10 eggs on land, tadpoles are carried on the male's back to the water and should be raised individually or in large containers	High/bred in large numbers in several color morphs, frequent carrier of *B. dendrobatidis*
Dendrobates tinctorius/dyeing poison frog	34–60 mm/Finger disks in males larger	Ground dweller, diurnal, lowland rainforest/forest floor terrarium, due to intraspecific aggression, pairwise keeping recommended/24°C–27°C/19°C–20°C	Breeds throughout year, alternating drier and wetter periods stimulates breeding	Clutch of 2–16 eggs on land, tadpoles are carried on the male's back to the water and should be raised individually or in large containers	High/bred in large numbers in several color morphs, frequent carrier of *B. dendrobatidis*
Phyllobates vittatus/ Golfo Dulce poison dart frog	26–31 mm/Females larger	Ground dweller, diurnal, lowland rainforest near brooks/forest floor terrarium, can be kept in groups/25°C–27°C/19°C–20°C	Breeds throughout year	Clutch of 7–21 eggs on land, tadpoles are carried on the male's back to the water and can be raised in groups	High
Oophaga pumilio/ strawberry poison frog	17.5–24 mm/Males of some populations have darker throats	Ground dweller, climbs regularly, diurnal, lowland rainforest/forest floor terrarium with sufficient height (>60 cm) for climbing. males very territorial/25°C–27°C/19°C–20°C	Breeds throughout year, drier period provides resting period.	Clutch of 3–10 eggs on land, tadpoles are carried on the female's back to bromeliad axils and fed with unfertilized eggs	Intermediate/extreme, locality-dependent color and pattern variation
Litoria caerulea/green tree frog	10–12 cm/Male with darker, wrinkled skin on throat	Nocturnal, forests, cultivated landscapes/large and high terrarium with ample climbing opportunities/23°C–28°C/20°C	Breeding induced in rain chamber after a drier period	Eggs deposited in small clumps, in total up to 2000 eggs	High
Rhinella marina/cane toad	To 24 cm/male smaller with nuptial pads on fingers	Nocturnal, forests, highly adaptive/very large surface terrarium/21°C–28°C/20°C	Breeding can be induced using hormones	Eggs in long jelly strings, up to 36,000 eggs	High/highly invasive species
Bombina orientalis/ oriental fire-bellied toad	To 6 cm/male with extensive foot webbing and nuptial pads on fingers	Diurnal and nocturnal, near shallow parts of brooks/ terrarium with large and shallow water part/20°C–25°C/15°C–20°C	Hibernation at 5°C; with increasing temperature in spring, animals come in breeding condition	Eggs in clutches up to 100 eggs	High/most specimens available as wild-caught animals from mass importations, frequent carrier of *B. dendrobatidis* infection
Xenopus laevis/ African clawed frog	4.5–15 cm/Male smaller, with nuptial pads, female with skin fold above cloaca	Nocturnal, in all kinds of water bodies/ aquarium/18°C–22°C	Cool period at 7°C–14°C; with increasing temperature, animals come in breeding condition.	Up to 17,000 eggs deposited singly or in small groups, tadpoles are filter feeders	High/common laboratory animal, highly invasive species, many breeding colonies infected by *B. dendrobatidis* and/or mycobacteria

TABLE 28.1 Key Husbandry Requirements of Frequently Kept Amphibian Species—cont'd

Scientific Name/ Common Name	Total Length/ Sexual Dimorphism	Life History/ Terrarium/ Temperature (Day/Night)	Breeding Induction	Reproduction	Suitability/Remarks
Hymenochirus boettgeri/Zaire dwarf clawed frog	32–41 mm/Male smaller, with whitish to pinkish spot in the post axillar region	Nocturnal, rainforest ponds/ aquarium/22°C–27°C	Breeds throughout year	Up to 1000 eggs, tadpoles are predators	High/commonly sold for tropical aquaria
Dyscophus guineti/ tomato frog	60–95 mm/Males yellowish, females orange-red, Males smaller	Nocturnal, lowland rainforest ground dweller/Forest floor terrarium, Burrows in soil/23°C–28°C/20°C–22°C	After a drier period, breeding can be induced in a rain chamber	Up to 15,000 eggs per clutch, tadpoles are filter feeders	High
Mantella aurantiaca/ golden Mantella	19–31 mm/Males smaller	Diurnal, rainforest, ground dweller in swampy areas/ forest floor terrarium, especially froglets are extremely sensitive to stress/18°C–22°C/12°C–14°C	After a cooler and drier period, breeding can be induced by increasing temperature and humidity	Up to 60 eggs produced, eggs laid on land, tadpoles are flushed to water by rain	Low/critically endangered in its native range in Madagascar
Urodela					
Cynops orientalis/ Chinese fire-bellied newt	Up to 9 cm/males smaller with shorter tail and cloaca more pronounced	Nocturnal on land, nocturnal and diurnal in water, pond dweller/can be housed fully aquatic in aquarium or in an aquaterrarium/15°C–25°C	After a hibernation period (2°C–5°C), breeding starts with increasing temperatures	Up to 100 eggs folded between leaves of aquatic vegetation	High/mass imports from China, potential carrier of *B. salamandrivorans*
Paramesotriton chinensis/Chinese warty newt	Up to 18.5 cm/male smaller, with more pronounced cloaca and with silver-white stripe on tail during breeding season	Nocturnal, stream dweller, in captivity fully aquatic/ stream aquarium, males highly territorial/15°C–20°C	After a hibernation period (7°C–10°C), newts come in breeding condition with increasing temperature	Eggs are deposited singly between leaves of aquatic plants	Low/mass imports from China despite local protection, potential carrier of *B. salamandrivorans*
Ambystoma mexicanum/axolotl	Up to 30 cm/male with more pronounced cloaca	Nocturnal, fully aquatic, originally from canal system/aquarium/15°C–22°C	Sudden cooling the water to 10°C for a few days with subsequent gradual increase in temperature	Up to 1000 eggs deposited in small clumps among vegetation	High/paedomorphic species, most widely used urodelan species in research, near extinct in the wild but bred at large scale, several color morphs available
Ambystoma tigrinum/ tiger salamander	Up to 30 cm/male with more pronounced cloaca	Nocturnal, fossorial, terrestrial but breeds in ponds/terrarium for burrowing species, aquaterrarium or aquarium during breeding season/15°C–20°C	Depending on the origin of the animals, mostly start breeding after hibernation	Up to 800 eggs deposited in small clumps among vegetation	High, but produces large amounts of waste
Salamandra salamandra/fire salamander	Up to 28 cm/male with more pronounced cloaca	Nocturnal, terrestrial ground dweller in cool forests with streams/forest floor terrarium, males can be territorial/10°C–20°C	Courtship mostly in autumn, deposition of larvae in spring	Up to 75 larvae are deposited in streams or ponds	Intermediate
Tylototriton shanjing/ Mandarin salamander	Up to 17 cm/male with somewhat more pronounced cloaca	Nocturnal, terrestrial ground dweller in forests, breeds in ponds/forest floor terrarium/15°C–25°C	After a cooler and drier period in winter, increased temperatures and humidity induces breeding	Up to 291 eggs are deposited singly in or near water	High when captive bred/ several species of *Tylototriton* are being imported from China despite local protection, potential carrier of *B. salamandrivorans* and ranaviruses

TABLE 28.1 Key Husbandry Requirements of Frequently Kept Amphibian Species—cont'd

Scientific Name/ Common Name	Total Length/ Sexual Dimorphism	Life History/ Terrarium/ Temperature (Day/Night)	Breeding Induction	Reproduction	Suitability/Remarks
Pleurodeles waltl/ ribbed newt	Up to 30 cm/male with longer tail and nuptial pads on upper arm	Nocturnal, terrestrial salamander, aquatic during breeding season/can be kept fully aquatic in an aquarium/15°C–20°C	Often starts breeding when temperature drops in autumn	Up to 1300 eggs deposited singly or in clusters among aquatic vegetation	High
Taricha granulosa/ rough-skinned newt	Up to 22 cm/males with longer tail, smoother skin, and nuptial pads on toe tips during breeding	Terrestrial but reproduces in all types of water, flowing and standing/can be kept fully aquatic in an aquarium/18°C–20°C	Often starts breeding after hibernation at 10°C	Up to 160 eggs singly among aquatic vegetation	Intermediate/one of the most toxic newts, the skin containing tetradotoxin
Necturus maculosus/ mudpuppy	Up to 50 cm/males with papillae on the cloaca	Fully aquatic, rivers and lakes/aquarium/15°C–20°C	Winter temperature between 5°C–10°C, mates in autumn or winter, eggs deposited in spring	Up to 193 eggs laid on the roof of a nesting site and guarded by the female	Low/wild specimens still caught in large numbers and sold a.o. as fish bait or laboratory animals
Gymnophiona					
Typhlonectes compressicauda/ rubber eel	Up to 45 cm/larger white spot in the cloacal region of the male	Fully aquatic/aquarium/23°C–27°C	Appears to mate mainly in autumn	Viviparous with up to 11 young born	High

FIG 28.10 Outdoor enclosure for European anurans (midwife toads, *Alytes obstetricians*, and spadefoot toads, *Pelobates fuscus*) protected against predators by the fence and against escape of the inmates by overhanging cover stones. When properly built, such enclosures provide excellent opportunities for mass propagation of species within their geographical range. (Courtesy of Frank Pasmans.)

and completion of any required veterinary treatment, for example, against parasitic or bacterial infections. Effective treatment against enteric flagellate and/or enteric or respiratory nematode infections can make the difference between successfully establishing a captive colony or mass mortality.

Quarantine enclosures (similar enclosures can be used for amphibian patient hospitalization) for amphibians should meet all of their needs (temperature, light, humidity, proper nutrition), with an emphasis on hygiene and creating a stress-free environment. A hygienic environment that meets these demands can be created by using moist paper toweling as a substrate when possible (e.g., not for burrowing species), providing proper, easy to inspect and clean hiding places (e.g., PVC tubes), and a water bowl of appropriate size for the species. The use of paper towels facilitates inspection and collection of feces for coprologic examination. The production of feces is a good indication of the animal's appetite, with a lack suggesting anorexia. During quarantine, amphibians are preferably kept in isolation. Disturbance and handling of the animals should be kept to an absolute minimum. For nervous species, making transparent sides visible (e.g., by taping colored paper to the enclosure) avoids the development of rostral ulcerations (Fig. 28.11). The size of the container for anurans should preferably be at least the length of the frog's leap to avoid trauma. Climbing species will appreciate the presence of a variety of elevated surfaces (e.g., PVC pipes, branches, plastic plants). We prefer not to use living plants in quarantine enclosures since these cannot be properly decontaminated between uses.

Any animal that dies during quarantine should be subjected to a full necropsy examination. When possible, diagnostics should not be limited to the relatively few known amphibian pathogens but should include gross pathology and thorough histopathology including viral, bacterial, fungal, and parasitic evaluations of tissues. For all quarantined animals, testing for the most common diseases during this period (ranaviruses, *Batrachochytrium dendrobatidis*, and *B. salamandrivorans*) is mandatory. Whereas this is reliable for chytrid infections, noninvasive sampling for ranaviruses using skin swabs is less reliable, and so negative results do not invariably mean that animals are free from ranaviruses. There is no reliable method to examine the presence of many other common amphibian pathogens in clinically healthy amphibians, for example, Chlamydiales or mycobacteria. When the absence of these pathogens is a requirement (for example, in laboratory colonies or for conservation breeding programs), and where appropriate, a proportion

FIG 28.11 Snout ulceration in a frog (*Megophrys nasuta*) by leaping against the glass windows of the terrarium. (Courtesy of Frank Pasmans.)

of these animals could be euthanized and thoroughly examined. However, depending on pathogen prevalence, even such radical entry control is not guaranteed to prevent pathogen introduction. Although it is not clear to which extent most pathogens can be vertically transmitted, it is safe to assume that establishing captive colonies starting from eggs reduces the likelihood of introducing infectious diseases.

Given the risk of pathogen pollution, all materials, including water that has come into contact with captive amphibians, should be disinfected before disposal. Decontamination can be done using chemical compounds (often recommended are sodium hypochlorite or Virkon S) or by heat treatment. All materials should be thoroughly rinsed after disinfection. Disinfectants with residual activity (e.g., phenolics such as chloroxylenol-containing products) can be toxic and should not be used around amphibians. See Chapter 18 for more details.

ENVIRONMENTAL TOXINS

Zinc and copper from galvanized copper tubes are a source of possible intoxication and should be avoided. Instead, tubes should be of polyethylene, polypropylene, or nylon construction. Lead intoxication may occur as a consequence of using lead piping, or lead may be introduced in the aquarium as weights, attached to aquatic plants. Plastic softeners may release dioxinlike PCBs (polychlorinated biphenyls) in phenol and acrylic plastics or phthalate esters.[23] Only products specifically produced for aquaria or used for human food/water storage should be used. Nongloved handling of amphibians by smokers may result in acute nicotine intoxication.[24] The use of insect repellents, especially those based on DEET, is generally contraindicated when handling amphibians, although toxicity studies for amphibians are largely lacking.

TRANSPORTATION OF AMPHIBIANS

The transportation of amphibians may be subject to legal limitations for conservation or sanitary reasons (e.g., due to the emergence of *B. salamandrivorans*, the transportation of many urodelan species to and within the United States and Switzerland has been temporarily banned). International animal transportation requires fulfilling all legal and administrative obligations and following guidelines set for animal transportation. Sending amphibians by mail is illegal in most countries. When transporting amphibians, this should preferably be done in individual containers. Cohousing specimens, even from the same species, during transportation may result in mass mortality due to massive secretion of amphibian toxins when the animals are stressed. Containers should be lined with a substrate that prevents trauma when the container is rocked (e.g., foam rubber, rehydrate sphagnum), should contain ample ventilation (use caution when drilling ventilation holes as they can result in sharp edges) and provide sufficient moisture (for example, wet paper toweling or sphagnum). For short-term transportation, providing food is not advisable. Temperatures should be kept as constant as possible during transportation and at a temperature within the species' preferred thermal range. Enclosures containing animals can be put in styrofoam boxes that should comply with all relevant legislation and cushioned with newspaper or other padding. Transportation boxes should never be exposed to sunlight, because this quickly results in overheating. Aquatic species or larvae can be either transported on a wet substrate (e.g., many aquatic, nonpaedomorphic urodelans) or in plastic bags used for the transportation of live fish. These bags must be filled with water for ⅓ of the total volume. Silicon or breathable bags for fish transportation that allow gas exchange must be filled completely, which prevents the contained animals from being shaken too much. These bags even allow for the transportation of very sensitive tadpoles from stream-breeding frogs.

SUITABILITY OF SPECIES

Most species of amphibians can be kept and bred successfully in captivity. Important factors for success include acquiring healthy animals, a knowledgeable keeper, providing proper husbandry and nutrition, and use of expert veterinary care when needed. Some species have requirements that can be difficult to provide, such as some of the larger species for giant salamanders (*Andrias* sp.). Additionally, species with specific husbandry demands can be more challenging (e.g., aquatic species from cool caves or high mountain streams, species with specific dietary requirements such as ants). Overall, many species are currently being bred in sufficient numbers, and in general, acquisition of captive-bred offspring is recommended. Wild-caught animals should be avoided. The latter pose a significant risk of introducing exotic diseases not only into the captive collection but also to populations of wild indigenous species, as recently demonstrated by the emergence of *B. salamandrivorans* in Europe.[25] This fungus has likely been vectored into Europe through the pet trade in Asiatic urodelans and is currently decimating salamander populations. Introduction of wild-caught amphibians into the pet trade is stressful for the animals and often results in high mortality. Collection of wild caught amphibians often occurs when large numbers congregate, such as during breeding. Often these wild-caught animals end up in poor condition with heavy parasitic infections, secondary and often lethal bacterial skin infections, and viral or fungal diseases (Fig. 28.12).[26] Unsustainable harvesting of amphibians is one of the causes of the current global amphibian declines.[27]

STOCKING DENSITY

Generally adults of many amphibian species and most juveniles tolerate relatively high densities. However, males (primarily) of many species, especially dart frogs and urodeles, do exhibit or aggressive behavior. For these species, only a single male with one to several females should be kept in the same enclosure. Otherwise overt or cryptic aggression will result in the suppressed animal(s) becoming stressed, showing loss of appetite and behavioral anomalies, and becoming more susceptible to secondary infections. In general, only amphibians of similar size should be cohoused, because cannibalism is common. Although many amphibian larvae live in dense communities in nature, others (e.g., many species of poison dart frogs and urodeles) are highly cannibalistic

and must be raised in small groups consisting of similarly sized individuals or even in isolation.

FEEDING AND NUTRITION

Most amphibians post-metamorphosis feed on living, mostly invertebrate prey items. In captivity, many species, mainly aquatic, can be conditioned to accept substitutes like commercial pellets produced for turtles, fish, or aquatic amphibians. The advantage of feeding pellets is that these can be supplemented with minerals (calcium) and vitamins (e.g., vitamin A) that may be largely lacking when feeding live invertebrate prey. Leftovers must be removed within one hour after feeding to prevent deterioration of water quality. Other dead food items may be offered occasionally such as raw meat. However, this should not be used routinely because nutritional deficiencies, including nutritional secondary hyperparathyroidism (NSHP), can occur. Although pellets are commonly used to sustain amphibians over generations, we recommend offering a variety of food items, not only for dietary needs but also as enrichment, allowing the amphibian to display natural predatory behavior.

Amphibians not accepting pellets should be fed live prey, mostly invertebrates. For large amphibians, depending on the species, vertebrates such as fish and rodents can also be offered; however, the feeding of live vertebrates may be illegal in some areas. In principle, invertebrate prey items discussed in the section on reptile nutrition can be used. Most amphibians are not picky eaters and will consume whatever fits in their mouth. The most common commercially bred food items are crickets (Gryliidae), buffalo worms or mealworms (*Alphitobius laevigatus* or *Tenebrio molitor*), fruit flies (*Drosophila* sp.), springtails (Collembola), woodlice (Oniscidea), and annelid worms (Lumbricidae, Tubificidae, Enchytraeidae) for terrestrial amphibians. Good-quality commercial feeder animals can provide an excellent staple diet for most terrestrial amphibians. However, these invertebrates must be properly fed themselves and enriched at least with calcium and vitamin A (see below). A varied diet reduces chances of nutritional disorders (Fig. 28.13). With regard to feeding nematodes, many amphibians do not accept the commonly sold worm bait species belonging to the genera *Dendrobaena* or *Eisenia*, because these worms excrete a foul-smelling substance. Aquatic amphibians can be fed crustaceans (*Daphnia* sp.), arthropod larvae ("bloodworm," *Chironomus* larvae), nematodes (*Tubifex*, several species of terrestrial worms) or, if legally permissible, aquatic vertebrates (small fish, tadpoles). When feeding vertebrate prey to amphibians, care must be taken not to introduce parasites or infectious diseases. Hence (and also for legal and ethical aspects), these prey items should always be captive bred, and the source should be free of the most common infectious amphibian diseases (at least chytrid fungi, ranaviruses, mycobacteria). Some fish and anuran species are indeed easily bred in large numbers, for example, guppies or frogs from the genus *Discoglossus* (Pasmans et al., in press). When feeding commercial aquatic live prey like bloodworms (*Tubifex*), these should first be thoroughly rinsed to remove dead animals. Quality of these feed items often is poor and may be a source of heavy metals.[28] Use caution with quantity offered because massive die-offs of these prey items in the aquarium may quickly pollute the water. Although crustaceans like *Artemia* sp. are readily available and constitute a suitable food item, they have a short life span in fresh water, quickly die, and can pollute the water.

In general, feeding live prey items to amphibians can result in the same nutritional problems described for reptiles. Insects must be enriched with at least calcium (and vitamin D_3) and vitamin A using gut-loading of the feeder insects or dusting of the insects with a mineral- and vitamin-containing powder before feeding them to the amphibians. NSHP and hypovitaminosis A are both common nutritional disorders of amphibians. In aquatic amphibians, SNHP signs may be less obvious, given that body weight is largely supported by the water. In terrestrial amphibians, NSHP problems are often obvious, resulting in bone deformations, often of the skull and spine (Fig. 28.14). A calcium/phosphorous ratio of 1.5:1 in prey items should be attempted (combining gut-loading and dusting of feeder insects). There are no established guidelines for the recommended daily intake of vitamin A by amphibians but hypovitaminosis A (often noted as "short tongue disease") is common in captives.[29] It is likely that amphibians are not capable of processing beta-carotene in significant amounts to make vitamin A physiologically available. Thus preformed vitamin A should be provided in the diet. Excess supplementation should be avoided since hypervitaminosis A is of equal concern as it is in reptiles (see relevant chapters on nutrition, hypo-, and hypervitaminosis A). Adding vitamin D_3 to the feeder insects may likewise be beneficial, especially if diurnal amphibians do not have access to UVB radiation. As in reptiles, predation of amphibians by feeder insects occasionally occurs. This can be avoided by providing the feeder insects with food in the amphibian terrarium (e.g., a dog pellet) by not overfeeding (minimizing the number of live insects in the environment at a time) and by respecting predator–prey size relationships. Notable losses to prey can occur in amphibian larvae-fed predatory

VetBooks.ir

FIG 28.14 Nutritional secondary hyperparathyroidism in a salamander (*Salamandra infraimmaculata*), with severe spinal deformation. (Courtesy of Frank Pasmans.)

species of *Cyclops*. A final problem with live prey items is poor adaption of prey (e.g., crickets) to the cooler temperatures required for keeping many urodelans, resulting in prey death and contribution to rapid fungal growth of the substrate. Dead prey items must be removed promptly.

Aquatic amphibian larvae should receive a more species-specific diet. Urodelan larvae predate on small live prey (rule of thumb: prey items smaller than the eye). Anuran tadpoles, however, have highly divergent feeding habits. These range from herbivorous to omnivorous species, with some that scrape algae and detritus from surfaces to specialized amphibian egg feeders and predatory tadpoles. For many anuran species, feed composed of fish flakes, turtle pellets, frozen and thawed vegetables such as lettuce, and *Spirulina* cyanobacteria, enriched with yeast and a vitamin/mineral mixture provides a suitable diet. Feeding oxalate-containing plants such as spinach or kale should be avoided to prevent renal oxalosis. When feeding tadpoles, frequently feeding smaller amounts reduces deterioration of water quality. Many species exhibit direct development in ovo on land and when they hatch, can be fed small prey items. During metamorphosis, most amphibians refuse feeding.

Feeding frequency depends on the species and on the life stage. Feeding several smaller-sized prey items instead of a few large ones is recommended. For many adult amphibians, feeding once or twice weekly is sufficient. Very active amphibians with higher metabolic rates (e.g., poison dart frogs, *Mantella* sp.) and adults during the breeding period require more intensive feeding. Larval or juvenile amphibians benefit from a near-constant food supply.

A common problem when raising larvae, especially those with bright red markings, is poor color development. Although this apparently does not affect the animal's health, this can be remedied by providing carotenoid-containing prey items such as crustaceans. Carotenoids may be artificially added to the amphibian feed, for example, by feeding carotenoids to crickets. Mixed carotenoids appear to have a more beneficial effect on reddish coloration than mere beta-carotene.[30]

REPTILES AS MICROBIAL ECOSYSTEMS

Reptile patients are often approached as a collection of eukaryotic cells organized into organ systems. This is highly misleading; most of the cells in a vertebrate are prokaryotic. Bacteria are especially critical for digestion and immune function, and maintenance of healthy bacterial flora is essential. Although birds nest in the middle of the reptile family tree, making them clearly reptiles, for the purposes of this chapter, only the bacteriology of paraphyletic nonavian reptiles is emphasized.

Clinicians are also often misled by Koch's postulates; by fulfilling or not fulfilling these requirements in a controlled experiment, a microbe is often then considered dichotomously as a pathogen or not a pathogen. This is far from the case; in the real world, numerous host, pathogen, and environmental factors (including coinfections, temperature, nutrition, handling stress, crowding, and others) play significant roles in whether a pathogen manifests as disease. There are numerous documented asymptomatic Ebola virus infections in humans, and *Lactobacillus acidophilus,* which is usually thought of as a probiotic in yogurt, has caused fatal sepsis.[1,2] When infectious disease is more properly considered as ecology, it is obvious that a typical disease scenario involves several infectious agents in concert with other environmental factors. Coinfection with both *Austwickia chelonae* and ranavirus has been found in skin lesions in bearded dragons (*Pogona vitticeps*), and coinfection with *Paranannizziopsis guarroi* and *Devriesea agamarum* has been seen in skin lesions in other bearded dragons.[3,4] Like all vertebrates, reptile patients are complex ecosystems, and we are still in the early stages of learning about the complex ecological interactions between the eukaryotic components of a reptile patient and the diverse prokaryotic components. Rather than thinking of a war on bacteria, clinicians should have the goal of improving ecosystem health within a reptile patient.

Evolution is an essential concept in biology; when one considers definitions for life, perhaps the simplest and most elegant definition is that life consists of things that evolve. Clinically, this is most immediately apparent with infectious disease. Because of short generation times, evolution of bacteria occurs in a time frame impacting clinical management of a patient. To compensate, the most rapidly evolving genes in vertebrates are immune-related. A bacterium does not "want" to cause disease or not cause disease. All life on earth has been selected for billions of years to reproduce successfully, and this is all that matters from an evolutionary standpoint. If pathogenic traits provide an evolutionary advantage in a given situation, they will be selected for. If they provide a disadvantage, they will be selected against.

There are a number of important selective pressures impacting microbes in a reptile host, including nutrition, temperature, the need to transfer to a new host, competition with other microbes, and the host immune system. A reptile host is a nutrient-rich environment for bacteria. However, some nutrients may be sequestered; one example is iron, which is a limiting factor for the growth of many bacteria. Significant resources are spent by the host synthesizing transferrin, lactoferrin, and ferritin to make iron unavailable. Many bacterial virulence pathways have evolved to access this sequestered iron.[5,6] Iron storage disease or clinical administration of iron may rapidly favor bacteria with these pathways. Nutrition also plays a major and long-lasting role in the host immune response. In southern grass skinks (*Pseudemoia entrecasteauxii*), maternal carotenoid intake has been shown to have a significant effect on the immune response of offspring by providing lipopolysaccharide (LPS), which is important in developing an immunogenic bacterial cell wall component.[7]

Ectothermic hosts require bacterial flora to have the ability to survive at different temperatures. Infectious disease manifestation may be highly temperature dependent in ectotherms.[8] In reptiles, temperature manipulation is often the most significant therapeutic approach. Further investigation of the role of temperature in disease manifestation in reptiles is strongly indicated, especially with populations of many species critically declining and likely to be impacted by anthropogenic climate change.[9,10]

The need to transfer to a new host creates significant selective pressure. This often involves secretion of large amounts of bacteria via respiratory discharge or diarrhea, but other routes occur, such as use of insect vectors. There are three fundamental strategies that can be utilized to deal with limited host lifespans. First, bacteria may adapt to a balance with the host environment, creating a selective pressure to keep the host alive. Second, bacteria may survive well in the environment, decreasing selective pressure to keep the host alive. Finally, bacteria may move quickly to a new host, also decreasing selective pressure to keep the host alive; high host density favors this, and increased stocking density creates environments selecting for pathogenicity.

Microbial competition is also a major selective pressure in a reptile; many organisms want to live in such a nutrient-rich environment. The majority of antimicrobials are derived from products secreted by other microbes that help them compete for ecologic niches. Animal guts are some of the most diverse and rich ecosystems to be found anywhere. Many organisms that have evolved in such a competitive environment have resistance to many antimicrobials, with *Enterococcus* sp. being a classic example.

VetBooks.ir

There are far more bacterial cells than eukaryotic cells in a healthy reptile. Traditional approaches to examining bacterial diversity have depended on culture; this is a poor way of assaying diversity. Culture-independent methods, such as 16S PCR and cloning, or high-throughput sequencing methods, have revealed that standard culture-based methods will detect between 1% and 10% of bacterial species present in most ecologic niches. A vertebrate is a complex ecosystem.[11] This system may be very dynamic. The gut flora of Burmese pythons (*Python bivittatus*) changes significantly in response to feeding.[12] Postprandially, bacteria in the phylum Firmicutes (the "classic" gram positives, containing organisms such as *Clostridium*, *Lactobacillus*, and *Peptostreptococcus*) increase dramatically, whereas those in the phylum Bacteroidetes (primarily containing anaerobic gram negatives such as *Bacteroides* and *Prevotella*) make up a greater percentage of the fewer species present after fasting. The gut flora did not significantly share species with prey mice, with the exception of the temporary postprandial establishment of *Lactobacillus* sp.

Microbial ecologic disturbance may have significant negative impacts on many aspects of health. Damage to healthy gut flora by antibiotic use provides opportunity for invasive species; recent treatment with antibiotics markedly increases host susceptibility to *Salmonella*.[13] A 5-day course of ciprofloxacin will change human gut flora diversity and composition for several weeks, and the original composition may never reestablish.[14] In many ways, the use of broad-spectrum antibiotics for a bacterial infection in a vertebrate is analogous to starting a forest fire to get rid of coyotes. The ideal treatment for a bacterial pathogen would be as narrow-spectrum as possible, minimally disturbing the rest of the host ecosystem. Fidoxamicin, which targets only *Clostridium difficile* and a few very closely related species, and does not even significantly impact many other *Clostridium* sp., is an excellent example. Unfortunately, current market forces have resulted in pharmaceutical companies markedly cutting antibiotic development; the few antibiotics developed in recent years have as broad a spectrum as possible, and narrow spectrum antibiotics are generally not put through further development and clinical trials.

Antibiotic use without consideration of microbial ecology and evolution rapidly leads to failure. Back in the 1980s, gentamicin was promoted for eradication of *Salmonella* from turtles.[15] Over the next few years, the *Salmonella* isolates from farmed turtles acquired a high rate of aminoglycoside resistance, and therefore posed a greater risk to human health than they had previously.[16] Several studies have suggested that wild turtles may have a lower carriage rate for *Salmonella*.[17,18] The only realistic way to reduce the risk of *Salmonella* in farmed turtles over the long term is to alter the ecologic niche that it inhabits. Keeping farmed animals in high population densities increases contact rates, pathogen loads, and stress, lowering barriers to transmission. Increased ease of transmission reduces the selective pressure to keep the host alive, selecting toward virulence.[19] The stress of close confinement also has significant negative impacts on numerous health parameters.[20] The only realistic way to reduce the risk of *Salmonella* in hatchling turtles is to alter the ecology, getting rid of high-density turtle farming, as well as farming at lower densities.[21]

Other routine husbandry practices in the reptile pet trade also create strong evolutionary selective pressures toward bacterial pathogenicity. It is also common to select for color mutants. This usually involves some degree of inbreeding to select for what are often recessive traits. A major driving force for the evolution of sex is acquisition of genetic diversity for immune function. Inbreeding results in selection for greater disease.[22] Finally, reptile species from all over the world, stressed with capture, holding, and transport, are brought to large dealers and placed in the same facility. This is an ideal situation for pathogens to host jump, often resulting in dramatic disease outbreaks.[23]

To reduce significant selective pressures toward highly pathogenic bacterial diseases, major changes in the reptile industry are indicated. Genetic diversity in populations needs to be valued and monitored through appropriate use of studbooks and cooperative rather than competitive interactions with breeders. Breeding for mutations needs to be discouraged. Proper biosecurity practices must be understood and implemented. Housing needs to be revised, with larger enclosures for individual animals designed so that feeding and cleaning is accomplished without cross-contamination. Importation of wild animals for pets needs to be strongly discouraged. Facilities should focus on single species and have smaller numbers of animals at lower densities.

The routine use of antibiotics implies a low level of expertise on the part of the clinician. The use of antibiotics should be limited to cases where there are specific indications of bacterial disease. Empirical use of antibiotics should be limited to cases where a delay in therapy is likely to have a significant negative impact on the health of the patient, and diagnostic samples should be collected before starting therapy. Antibiotic therapy should always be done in conjunction with concurrent therapies and husbandry changes, addressing the patient's ability to fight infection. Antibiotic use should be based on sound pharmacokinetic data whenever possible. Allometric scaling is not reliable and should not be used for drug calculations.[24] The half life of cefovecin in dogs is 133 hours; in green iguanas, it is less than 4 hours.[25,26] If pharmacokinetic data were lacking, empirical use of cefovecin extrapolating from dog doses would result in subtherapeutic levels in iguanas. Alternate scenarios could result in toxicosis. Subtherapeutic antibiotic levels may have significant negative impacts on patient health and also have significant public health implications.[27] Subtherapeutic antibiotic use often significantly increases resistance to entirely different classes of antibiotics, due to gene linkage.[28] Development of resistance is much lower with administration of appropriate therapeutic doses.[29] Within the constraints of available knowledge, drug selection should emphasize the most narrow-spectrum, first-line antibiotic for which knowledge of therapeutic dosing is available. In keeping with numerous recommendations regarding antimicrobial stewardship, advanced cephalosporins and fluroquinolones should be reserved for resistant cases.[30]

BACTERIAL DIAGNOSTICS

In order to make a diagnosis of bacterial disease, a thorough understanding of the microbial ecology of the patient is necessary. A history and physical examination is a good starting point, with the recognition that husbandry has played a major role in almost any disease process for which a captive reptile is presented, and husbandry improvements will need to be part of the therapeutic approach. When visible lesions are present, cytology or histology is often a good next step. It is important to develop reasonable in-house cytology skills; rapid evaluation of a dif-quik, gram stain (Box 29.1), and acid-fast staining (Box 29.2) is important for further test selection; this should later be confirmed with a board-certified veterinary clinical pathologist. A complete blood count to look for evidence of infection/inflammation and a plasma biochemistry to narrow concerns to specific organ systems are often helpful. Ultrasonography, endoscopy, or other diagnostic imaging may be helpful to identify internal lesions and guide sample collection. Once the results of initial diagnostic tests are in hand, appropriate diagnostic testing for bacteria can be selected.

There are two major approaches to testing for bacterial disease. These tests are based on either the animal's acquired immune response to an agent or the presence of the agent. Acquired immune responses can be further subdivided into two categories. Tests that evaluate antibody production against specific bacteria assess the reptile's humoral immune response. The most commonly used tests for acquired immune response

VetBooks.ir

BOX 29.1 Gram Stain

Materials required:
- Clean glass slides
- Inoculating loop or sterile Q-tips or sterile microbrushes
- Bunsen burner or similar
- Distilled water
- Crystal violet (primary stain)
- Grams iodine (mordant)
- 95% Ethyl alcohol or ethanol (decolorizer)
- Safranin (secondary stain)
- Bibulous or absorbent paper
- Microscope with x1000 oil immersion

Procedure:
1. Use a flamed inoculating loop, sterile Q-tip, or microbrush to apply a thin layer of clinical material to the cleaned surface of a glass slide.
2. Air dry and heat fix.
3. Gently flood smear with crystal violet and let stand for 1 minute.
4. Tilt the slide and gently rinse with distilled water.
5. Gently flood the smear with Gram's iodine and let stand for 1 minute.
6. Tilt the slide and gently rinse with distilled water.
7. Decolorize using 95% ethyl alcohol or acetone. Tilt the slide and apply the alcohol drop by drop for 5–10 seconds until the alcohol runs almost clear. Be careful not to overdecolorize.
8. Immediately rinse with distilled water.
9. Gently flood with safranin to counterstain and let stand for 45 seconds.
10. Tilt the slide and gently rinse with distilled water.
11. Blot dry the slide with bibulous paper, or quickly air dry.
12. View the smear using a light-microscope under oil-immersion x1000.

Gram-positive bacteria appear blue, and gram-negative bacteria pink.

BOX 29.2 Acid-Fast Stain

Materials required:
- Clean glass slides
- Inoculating loop or sterile Q-tips or sterile microbrushes
- Bunsen burner or similar
- Beaker with water in tripod stand
- Tweezers
- Distilled water
- Carbol fuschin (primary stain)
- 25% sulfuric acid (decolorizer)
- Methylene blue (secondary stain)
- Bibulous or absorbent paper
- Microscope with x1000 oil immersion

Procedure:
1. Use a flamed inoculating loop, sterile Q-tip, or microbrush to apply a thin layer of clinical material to the cleaned surface of a glass slide.
2. Air dry and heat fix.
3. Cover the bacterial smear with a piece of absorbent paper cut to fit the smear and slide.
4. Place the slide over a container of boiling water.
5. Saturate the paper with carbol fuschin and steam for 5 minutes. Keep the paper moist by adding more stain as required.
6. Remove the absorbent paper using tweezers; wash the excess stain with distilled water, and allow the slide to cool.
7. Decolorize the slide with 25% sulfuric acid.
8. Rinse the slide with distilled water.
9. Counterstain the cells with methylene blue stain for 45 seconds.
10. Wash the slide with distilled water and blot dry the slide.
11. View the smear using a light-microscope under oil-immersion x1000.

Acid-fast bacteria are stained pink.

to bacteria in reptiles are western blots and ELISAs for *Mycoplasma agassizii* in *Gopherus* sp. tortoises. Tests that evaluate the presence of cellular immunity, which is centered around the T-cell receptor, are unfortunately not commonly available; assays that are used in human medicine include T-cell proliferation assays. It is important when assaying humoral immunity to consider that it is only part of the acquired immune response and generally the less important aspect for defense against intracellular pathogens.

Commonly used assays for the presence of bacteria include culture and PCR based techniques; these should be targeted as much as possible. Diverse normal flora are present on the external surfaces and in the gastrointestinal tract of reptiles; untargeted cultures of these without significant corollary data are clinically uninterpretable. If cytology indicates a morphology and gram or acid fast staining result, this should be communicated to the laboratory. An appropriate differential diagnoses list should be formulated based on the initial diagnostic findings, and it should be decided whether culture is likely to be the most practical route to diagnosis, or whether other methods such as PCR should be used.

Specimens for bacterial testing are collected before beginning antimicrobial therapy. All specimens should be transported in clean, tightly sealed, leak-proof containers according to postal regulations. Biopsies or aspirates of lesions are preferable to swabs when possible due to a lesser degree of contamination. Selection of appropriate transport media is essential for useful culture results. Hardier organisms, such as pseudomonads and enterobacteria, can be expected to survive overnight transport at room temperature on a standard collection swab in a transport medium, such as Amies with charcoal. Anaerobic samples should be placed immediately into anaerobic transport media such as thioglycollate agar; nonspore-forming obligate anaerobes rapidly die when exposed to room air, and rapid placement into media and minimizing transport time are critical. More fastidious organisms require specific transport media and should be discussed with the laboratory in advance. Molecular diagnostic testing is discussed in Chapter 36. Another important consideration when deciding on a diagnostic approach is additional testing that may be needed; sensitivity testing (diffusion disc or minimum inhibitory concentrations) is currently only economically feasible for cultured isolates.

A blood culture is indicated when an animal is suspected of being bacteremic. The spleen of reptiles is less efficient than that of mammals; bacteremia is more common in reptiles than in mammals. Blood culture can be useful for identification of organisms, especially in difficult sites to sample, such as a case of vertebral osteomyelitis.[31] However, interpretation needs to be taken in context; anaerobic spore-forming bacteria, such as *Clostridium* spp., are not uncommonly found in blood cultures of apparently healthy reptiles.[32] For blood culture, the skin at the venipuncture site should be aseptically prepared. The needle should be changed and the bottle wiped with alcohol before placing the sample in the blood culture bottle. Pediatric blood culture bottles are available and require smaller samples. Although it

TABLE 29.1 Medically Important Bacterial Phyla

Phylum	Example Genera	Morphology	Diagnostic Testing	Comments
Firmicutes	*Streptococcus* *Staphylococcus* *Enterococcus* *Erysipelothrix* *Clostridium* *Listeria*	Gram-positive rods and cocci	Grow relatively well in culture compared with other phyla, although some taxa are fastidious	The "classic" gram-positive bacteria, some taxa are spore-producing, a dominant phyla in gut flora, often obesity associated
Proteobacteria	*Salmonella* *Pseudomonas* *Providencia* *Morganella* *Helicobacter* *Neisseria* *Anaplasma*	Gram-negative rods and cocci, may be spiral shaped	Grow relatively well in culture compared with other phyla, although some taxa are fastidious	The "classic" gram-negative bacteria, often associated with increased inflammation in GI tracts
Actinobacteria	*Mycobacterium* *Nocardia* *Austwickia* *Devriesea* *Corynebacterium* *Actinomyces*	Many are gram positive or acid fast, often filamentous	Often difficult to culture, often slow growing, poorly identified by biochemical testing. PCR may be a reasonable option.	Variable antibiotic susceptibility makes profile important, often require multidrug therapy for long courses, often associated with granulomatous inflammation
Bacteroidetes	*Bacteroides* *Capnocytophaga* *Elizabethkingia* *Myroides*	Gram negative, many anaerobes	Often difficult to culture	A dominant phyla in gut flora, often associated with reduced inflammation and decreased obesity
Chlamydiae	*Chlamydia* *Parachlamydia* *Simkania*	Gram negative, obligate intracellular cocci	Very difficult to culture, PCR diagnostics	Often associated with granulomatous inflammation
Tenericutes	*Mycoplasma* *Acholeplasma*	Gram negative, cell-associated cocci	Often difficult to culture, require specialized media	Lack cell wall, will not respond to beta-lactam drugs, osmotically sensitive
Spirochaetes	*Borrelia* *Leptospira*	Spiral-shaped gram-negative rods, axial filament	Very difficult to culture, PCR diagnostics	Dark field microscopy may aid with diagnosis
Fusobacteria	*Fusobacterium* *Streptobacillus*	Gram negative, anaerobes	Often challenging to culture	Large fraction of gut microbiota in alligators
Cyanobacteria	*Microcystis* *Lyngbya*	Gram negative, often filamentous	Testing typically focuses on toxin identification	Blue-green algae, pathology is related to toxin ingestion rather than colonization of reptile

is ideal to sample the volume recommended by the manufacturer of the culture bottle, collecting such a volume may be contraindicated by the size of smaller patients, and the relatively higher loads seen in bacteremia in reptiles make it much more probable to have a colony-forming unit in a smaller volume.

Many bacteria found in reptiles grow best at lower temperatures than do those of mammals, so samples may need to be incubated at different temperatures (25°C and 37°C are commonly used, but further study is needed). Additionally, many if not all biochemical identification protocols for laboratories are developed around organisms likely to be found in mammals or birds. If an identification appears unusual, it is appropriate to question the result with a microbiologist.

AN OVERVIEW OF BACTERIAL TAXA

When working on an exotic animal, it is helpful to know what taxa you are dealing with; the clinical approach to a tortoise is different from the approach to a rodent. Unfortunately, bacteria are commonly taught as a list of genera and species, giving no higher level context. Although they may be described as gram-positive or gram-negative, these are not true clades; just as birds, bats, and dragonflies are all "animals with wings" but not closely related to each other, gram-positive or gram-negative bacteria are not necessarily groups most closely related to each other. When dealing with bacteria, the phylum level is a clinically useful starting point (Table 29.1). A useful source for the clinician to find higher-level classification of a given bacterial isolate is the National Center for Biotechnology Information's Taxonomy Browser (https://www.ncbi.nlm.nih.gov/Taxonomy/Browser/wwwtax.cgi).

FIRMICUTES

The phylum Firmicutes are the "classic" gram-positive bacteria. They comprise a large part of normal gut flora, and an increase in their proportion in gut flora is often associated with obesity and increased inflammation in humans.[33] In pythons, there is a massive postprandial shift in gut flora composition toward the Firmicutes.[12] Significant increase in oxidative damage is seen postprandially in snakes.[34] As a whole, Firmicutes are more likely to be cultivable using standard culture methods.

Streptococcus. The genus *Streptococcus,* firmicutes in the order Lactobacillales, are chain-forming gram-positive cocci. They were the

second most common cause of vertebral osteomyelitis in snakes in one study, although species were not identified.[31] *Streptococcus agalactiae* is the species most commonly associated with disease in reptiles, with reports of mortality events in green tree monitors (*Varanus prasinus*) and necrotizing fasciitis in saltwater crocodiles (*Crocodylus porosus*).[35,36] Both of these reports involved juvenile animals. Group B streptococci, containing *S. agalactae,* are typically susceptible to penicillin, making it a good empirical choice while sensitivity results are pending.

A probiotic containing a mixture of bacteria including *Streptococcus thermophilus* was associated with increased intestinal villous height and increased mucosal thickness in yellow-bellied sliders (*Trachemys scripta scripta*) and common musk turtles (*Sternotherus odoratus*), which was interpreted as a positive difference for health.[37]

Enterococcus. The genus *Enterococcus,* firmicutes in the order Lactobacillales, are chain-forming gram-positive cocci. They have a long evolutionary association with the vertebrate gastrointestinal tract, dating back approximately 500 million years ago.[38] This led to the development of a hardened cell wall, osmotic resistance, and resistance to antimicrobial compounds made by other gut flora and now appropriated by humans for use as antibiotics. These traits make clinical treatment of enterococcal infections challenging, and *Enterococcus fecalis* has emerged as a significant nosocomial pathogen in humans.

Enterococcus spp. were identified as a significant cause of infection in 17% of cold-stunned Kemp's ridley turtles (*Lepidochelys kempii*) over a 6-year period.[39] This likely represents translocation of gut flora in immunosuppressed animals. Blood, bone, joint, and respiratory tract cultures were identified as *E. fecalis* (36 cases), unidentified *Enterococcus* sp. (13 cases), and *Enterococcus faecium* (1 case), although sequence-based methods were not reported to be done. Findings of significant coevolution among *Enterococcus* spp. And their hosts suggest that species found in sea turtles may likely be divergent from those found in humans.[38]

A novel *Enterococcus* sp. most closely related to *E. faecium* has been reported in a blue-tailed skink (*Cryptoblepharus egeriae*) and several gecko species in a captive breeding facility.[40] This isolate was not successfully cultured and was identified by next-generation sequencing. These lizards had thickly encapsulated gram-positive cocci effacing many tissues including bone, lung, liver, and kidney. Unfortunately, any investigation of the presence of this organism in normal gut was not reported, and the only viral diagnostic reported was attempted viral culture of pooled tissues.

When enterococcal disease is identified in a patient, it is important to identify the cofactors that have led to the establishment of clinical disease by these normal gastrointestinal flora. Factors resulting in immunosuppression, such as thermal stress, nutritional stress, toxins, and coinfections, should be evaluated and, if possible, addressed. A history of cephalosporin use is associated with enterococcal disease, likely due to microbial ecological perturbation.[41] In humans, outcome of *E. fecalis* infection is associated with patient comorbidities and not with virulence genes.[42] Many enterococci are susceptible to an ampicillin/aminoglycoside combination, making this a reasonable empirical choice while sensitivity results are pending and predisposing conditions are being addressed.

A probiotic containing a mixture of bacteria including *Enterococcus faecium* was associated with increased intestinal villous height and increased mucosal thickness in yellow-bellied sliders (*Trachemys scripta scripta*) and common musk turtles (*Sternotherus odoratus*), which was interpreted as a positive difference for health.[37]

Staphylococcus. The genus *Staphylococcus,* firmicutes in the order Bacillales, are cluster-forming gram-positive cocci. They appear to be relatively uncommon as causes of disease in reptiles, in contrast to mammals. The emergence of multidrug resistance in this genus is of major public health concern. There are case reports of a methicillin-resistant *S. aureus* (MRSA) subspectacular abscess in a Burmese python (*Python bivittatus*) and MRSA-associated dermatitis in a turtle (species not given); these were most likely of anthropogenic origin.[43,44] Use of topical antibiotics has been shown to shift human skin flora, reducing competitors and increasing *S. aureus* loads more than 100-fold.[45]

Listeria. The genus *Listeria,* firmicutes in the order Bacillales, are small gram-positive rods. *Listeria* are common components of gut flora. There are two case reports of *Listeria monocytogenes* disease in reptiles, both in bearded dragons; one presented as meningitis and septicemia and the other as a myocardial abscess.[46,47] *Listeria* are cold-tolerant and will grow at 4°C in a refrigerator. Whereas disease often progresses so rapidly that waiting for culture results is not feasible. *Listeria* are susceptible to a wide array of antibiotics; first- or second-generation cephalosporins, penicillin, and trimethoprim-sulfamethoxazole are reasonable empirical choices.

Clostridium. The genus *Clostridium,* firmicutes in the order Clostridiales, are anaerobic spore-forming gram-positive rods. The ability to form spores makes them highly stable in the environment. *Clostridium* are commonly found in blood cultures of apparently healthy reptiles.[32] Clostridial abscesses or gangrene may arise in a variety of species when an anaerobic site is created through loss of blood supply; closing a contaminated wound with poor blood supply creates ideal conditions. Enteric clostridial disease is also commonly seen following use of antibiotics, due to ecological perturbation of the flora. Species reported from disease in reptiles include *C. perfringens, C. glycolicum,* and *C. novyi.*[48,49]

Initial diagnostics when clostridial disease is suspected include a fecal gram stain; large numbers of large spore-forming gram-positive rods are seen, often with inflammatory cells. Anaerobic cultures may be helpful, although some species, such as *C. dificile,* are more fastidious. Toxin immunoassays may support a diagnosis, although many clostridial toxins degrade rapidly, so false-negative rates may increase within hours after collection. PCR for toxin genes may also be utilized.

Many *Clostridium* spp. are susceptible to metronidazole, making it a reasonable empirical choice while predisposing conditions are being addressed; other antibiotics should be discontinued if not otherwise contraindicated. Transfaunation is perhaps the most effective therapy for enteric clostridial disease.

In pythons, there is a massive postprandial shift in gut flora composition toward *Clostridium* spp.[12] Significant increase in oxidative damage is seen postprandially in snakes.[34] A probiotic containing a mixture of bacteria that did not include *Clostridium* spp. was associated with decreased intestinal *Clostridium perfringens* counts and increased intestinal villous height in turtles, which was interpreted as a positive difference for health.[37]

Erysipelothrix. The genus *Erysipelothrix,* firmicutes in the order Erysipelotrichales, are small gram-positive rods. *E. rhusiopathiae* is the species associated with disease in a wide variety of vertebrates. It is not uncommonly found in fish, and there is greater diversity of strains found in marine environments.[50] Disease often involves rapid sepsis with thrombus formation, known in pigs and marine mammals as diamond skin disease. Disease has been seen in crocodilians.[51] *E. rhusiopathiae* represents a significant zoonotic risk to the veterinarian and direct contact with suspect infected tissues should be avoided. Very small colonies are seen on culture, which may be overgrown if a mixed infection is present. Penicillin is a reasonable empirical choice.

PROTEOBACTERIA

The phylum Proteobacteria are the "classic" gram-negative bacteria. They typically comprise a smaller part of normal gut flora than Firmicutes or Bacteroidetes, and an increase in their proportion in gut flora is often associated with increased inflammation and obesity in humans.[52] As a whole, Proteobacteria are more likely to be cultivable using standard culture methods. They are divided into several classes, of which the Alphaproteobacteria, Betaproteobacteria, Gammaproteobacteria, and Epsilonproteobacteria are most relevant in reptile medicine.

α-Proteobacteria

The class Alphaproteobacteria have many members adapted for life inside eukaryotic cells, including members involved in nitrogen fixation for plants. They tend to be more fastidious than other members of the Proteobacteria, and PCR methods are often preferable to culture for diagnostics.

Bartonella. The genus *Bartonella,* proteobacteria in the order Rhizobiales, are small gram-negative rods that are primarily intracellular. They are often vectored by arthropods. Human diseases associated with *Bartonella* sp. include cat scratch fever, trench fever, and Carrion's disease. They are difficult to culture and require specialized media. PCR-based diagnostics are more practical. PCR and sequencing of blood samples from loggerhead sea turtles (*Caretta caretta*) found that two species were present; one was *B. henselae*-like and one was *B. vinsonii*-like.[53] Unfortunately, these sequences are not available in public databases. It is very probable that *Bartonella* spp. are medically relevant for reptiles, but the diagnostic challenges have resulted in limited investigation to date.

Rickettsia. The genus *Rickettsia,* proteobacteria in the order Rickettsiales, are small gram-negative pleomorphic bacteria that are primarily intracellular. They are often vectored by arthropods. *R. honei*, *R. bellii*, *R. tamurae*, and unnamed species have been found in ticks on reptiles.[54–59] There has been little investigation of the reptiles on which these ticks were found. It is very probable that *Rickettsia* spp. are medically relevant for reptiles, but diagnostic challenges have resulted in limited investigation to date.

Ehrlichia. The genus *Ehrlichia,* proteobacteria in the order Rickettsiales, are small gram-negative pleomorphic bacteria that are primarily intracellular. They are often vectored by arthropods. *E. ruminantium,* the causative agent of heartwater in cattle, has been found in ticks on African tortoises imported into Florida.[60] A possible *Ehrlichia* sp. was reported in three *Bitis* sp. vipers that presented with neurological signs, pneumonia, and mottled kidneys.[61] When liver was cultured with viper heart cells and bovine endothelial cells, cytopathic effects were seen. PCR for *E. ruminantium* was done, but no sequencing results were reported. There were no reported diagnostics for Ferlaviruses performed, which is most consistent with the clinical findings. It is very probable that *Ehrlichia* spp. are medically relevant for reptiles, but diagnostic challenges have resulted in limited investigation to date.

Anaplasma. The genus *Anaplasma,* proteobacteria in the order Rickettsiales, are small gram-negative pleomorphic bacteria that are primarily intracellular. They are often vectored by arthropods. *A. phagocytophilum,* an agent of granulocytic anaplasmosis, was found in approximately 10% of wild squamates in a survey in northern California, but disease was not investigated.[62] An *Anaplasma* has been identified by PCR and sequencing in 13% of sand lizard (*Lacerta agilis*) skin samples from Poland.[63] Again, disease in the reptiles was not investigated. This *Anaplasma* was highly divergent and is closest to sequences found in ticks in Tunisia, Morocco, China, Korea, and California; it has been proposed that this may represent a new genus, provisionally called *Cryptoplasma californiense.*[64]

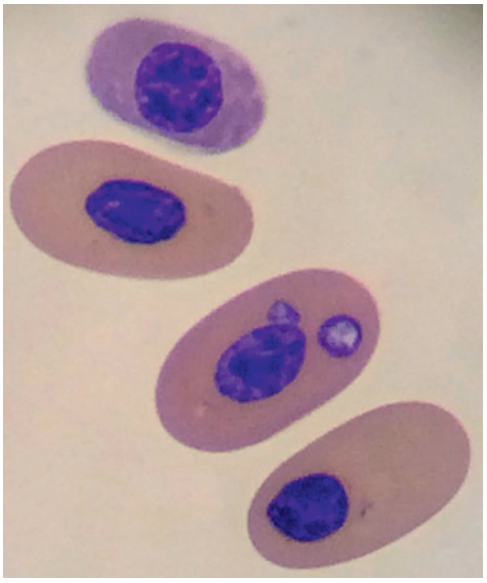

FIG 29.1 A novel *Anaplasma* in an erythrocyte of an anemic gopher tortoise (*Gopherus polyphemus*). Modified Wright's Giemsa, ×1000.

In anemic gopher tortoises (*Gopherus polyphemus*), a novel *Anaplasma* has been identified in erythrocytes (Fig. 29.1) (Wellehan et al, Proc WDA, 2016). PCR and sequencing identified it as a novel species, basal to the erythrocytic clade containing *A. marginale* and *A. ovis,* which cause anemia in ruminants. The organism was also found in gopher tortoise ticks (*Amblyomma tuberculatum*), and qPCR surveillance of tortoises found a negative correlation with packed cell volume. Treatment with doxycycline resulted in clinical resolution of anemia.

β-Proteobacteria

The class Betaproteobacteria are metabolically diverse and adapted to utilize a wide variety of nutritional substrates. They tend to be more easily cultured than average clades of bacteria.

Burkholderia. The genus *Burkholderia,* proteobacteria in the order Burkholderiales, are gram-negative rods that typically live in soil. *B. pseudomallei* is the causative agent of melioidosis. It presents significant risk of human mortality and is classified by the US government as a tier 1 select agent. Humans with diabetes are at especially high risk. It is not endemic in the United States and Europe. It has been identified in abscesses of green iguanas (*Iguana iguana*) in the United States and the Czech Republic.[65,66] Strain typing found they were consistent with strains of Central American origin. All iguanas had been in captivity with their owners for over a year. *B. pseudomallei* has also been cultured from the granulomatous liver of an elephant trunk snake (*Acrochordus javanicus*).[67] Biochemical identification of *B. pseudomallei* cultures may result in misidentification as *Chromobacterium violaceum* or *B. cepacia,* and this should be discussed with the laboratory if these are reported from abscesses. *B. pseudomallei* often has extensive resistance profiles. If the clinician encounters this organism, public health authorities should be contacted immediately.

Neisseria. The genus *Neisseria,* proteobacteria in the order Neisseriales, are gram-negative cocci typically found in oral flora. Septicemia and

abscesses have been seen in iguanas (*Cyclura cornuta* and *Iguana iguana*) associated with *N. iguanae.* It is closely related to *N. meningitidis,* the agent of meningococcal encephalitis in humans.[68,69] Bite wounds should be considered as a probable source when *Neisseria* is cultured from reptiles. Penicillin is a reasonable empirical choice.

Chromobacterium. The genus *Chromobacterium,* proteobacteria in the order Neisseriales, are gram-negative cocci that typically are found in water. Although *Chromobacterium* are not known to be clinically relevant for reptiles, biochemical identification of *Burkholderia pseudomallei* cultures may result in misidentification as *C. violaceum,* and this should be discussed with the laboratory if *C. violaceum* is reported from abscesses.

γ-Proteobacteria

The Gammaproteobacteria are the largest class of Proteobacteria. They tend to be more easily cultured than average clades of bacteria.

Pseudomonadales: *Pseudomonas aeruginosa* and *Acinetobacter baumanii.* The Pseudomonadales are an order of Gammaproteobacteria. The most relevant species for reptile medicine are *Pseudomonas aeruginosa* and *Acinetobacter baumanii.* They are gram-negative rods that are often found in water or soil. They tend to have extensive resistance profiles and are opportunists. When one of the Pseudomonadales is found in a lesion on a patient, it should provoke a search for factors causing the reptile to be compromised. The Pseudomonadales and underlying cause(s) need to be addressed. It is critical when dealing with these organisms to get a sensitivity profile. While sensitivity results are pending, aminoglycosides are reasonable empirical choices. Third-generation cephalosporins or fluoroquinolones may be required following sensitivity results.

Aeromonadales: *Aeromonas hydrophila.* The Aeromonadales are an order of Gammaproteobacteria. The most relevant species for reptile and amphibian medicine is *Aeromonas hydrophila.* They are gram-negative rods that are often found in water. They tend to have extensive resistance profiles and are opportunists. When one of the Aeromonadales is found in a lesion on a patient, it should provoke a search for factors causing the reptile to be compromised. The Aeromonadales and underlying cause(s) both need to be addressed. It is critical when dealing with these organisms to get a sensitivity profile. Standard biochemical methods may result in misidentification of *Elizabethkingia meningoseptica* as *Aeromonas salmonicida,* and this should be discussed with the laboratory if *A. salmonicida* is reported.[70] While sensitivity results are pending, aminoglycosides are reasonable empirical choices.

Xanthomonadales: *Stenotrophomonas maltophila.* The Xanthomonadales are an order of Gammaproteobacteria. The relevant species for reptile and amphibian medicine is *Stenotrophomonas maltophila.* They are gram-negative rods that are often found in soil and water. They tend to have extensive resistance profiles and are opportunists. When *S. maltophila* is found in a lesion on a patient, it should provoke a search for factors, causing the reptile to be compromised. *S. maltophila* and the underlying cause(s) both need to be addressed. It is critical when dealing with this organism to get a sensitivity profile. While sensitivity results are pending, trimethoprim-sulfamethoxazole is a reasonable empirical choice.

Enterobacteriales. The Enterobacteriales are an order of Gammaproteobacteria. They are gram-negative rods that are often found in vertebrate intestines. While often opportunists, for several taxa, such as *Salmonella, Providencia,* and *Morganella,* the opportunity can be minimal. The emergence of multidrug resistance in this order is of major public health concern. Other Enterobacteriales not discussed below that may be seen in association with disease in reptiles include *Citrobacter*, *Serratia*, *Klebsiella*, *Enterobacter*, *Escherichia*, and *Proteus.* A probiotic containing a mixture of bacteria that did not include Enterobacteriales was associated with decreased intestinal Enterobacteriacae counts and increased intestinal villous height and increased mucosal thickness in turtles, which was interpreted as a positive difference for health.[37]

Salmonella. The genus *Salmonella* represents the reptile bacteria best known by the public. *Salmonella* infection in reptiles typically begins enterically and then translocates across the gut. Hematogenous spread to other organs then occurs. Lesions often include necrotizing enteritis, granulomatous hepatitis, and proliferative osteomyelitis. *Salmonella* was the most common cause of vertebral osteomyelitis in snakes in one study, although types were not identified.[31]

Salmonella contains two species: *S. bongori* and *S. enterica. S. enterica* is subdivided into six subspecies. They are further subdivided into over 2500 serotypes, and isolates are often referred to by serotype name rather than species or subspecies name. Of the six *S. enterica* subspecies, subspecies IIIa (arizonae) and IIIb (diarizonae) are most commonly associated with both wild and captive reptiles. Human disease due to these subspecies tends to occur in young children, geriatrics, and the immunosuppressed. *S. enterica* subspecies IIIa is most strongly associated with disease in reptiles, and *S. enterica* subspecies IIIa with flagellar antigens z4 and z23 has been documented to cause loss of multiple snakes at more than one facility.[71,72] Significant disease associated with z4/z23+ strains has been reported from children with reptiles in the household.[73]

S. enterica subspecies I (enterica), especially serovars Poona, Java, Pomona, Newport, Saintpaul, and Muenchen, are also associated with captive reptiles. Studies of wild reptiles suggest that infection in wild reptiles may be less frequent, although more data are needed. *S. enterica* subspecies I is most strongly associated with disease in humans, but the serovars most pathogenic in humans, such as Typhimurium and Enteritidis, are often food-associated and are not usually reptile-associated.

Other animal sources of *Salmonella,* such as feral cat colonies, are not as appreciated by the public, with one report finding 51% of group-housed cats shedding *Salmonella,* a much higher figure than is seen in individual pet cats.[74] Nonetheless, the level of concern regarding salmonellosis in reptiles is not inappropriate. Parallel to cat colonies, the high stocking density and poor sanitation standards of animals in the pet reptile trade, especially in species housed in aquatic environments, has led to much higher carriage than what is seen in wild reptile populations (see previous section Reptiles as Microbial Ecosystems). The ban on selling aquatic turtles under 4 inches (10 cm) in length has been an enormous public health success, with a 77% reduction in frequency of turtle-associated serotypes in humans during the 6 years after passage.[75]

Owners may want their animals tested to find them *Salmonella*-free. Because no test is 100% sensitive, the possibility of a false-negative result is significant. To declare an animal *Salmonella*-free opens up a clinician to litigation, especially in the event of the death of a child. Clients should be educated on good hygiene and biosecurity techniques, and appropriate husbandry will minimize the risk.

Salmonella will grow on standard bacterial media. Since reptiles with clinical salmonellosis are often septic, blood cultures are often useful. If fecal cultures are taken, selective enrichment media should be used. Serotyping of the organism should be done to assess clinical significance, potential sources, and extent of zoonotic potential; flagellar antigen typing should be emphasized. In some countries, *Salmonella* isolation is reportable to the authorities.

VetBooks.ir

Salmonella are often present in the feces of normal animals. A positive culture of *Salmonella* from feces does not necessarily mean that it is causing disease; it needs to be correlated with other findings. Eradication from an animal through antibiotic use is not feasible. Antibiotic use in a normal animal may favor antibiotic resistance and induction of disease through disruption of normal competitive flora.[76]

In cases of clinical salmonellosis, empirical therapy using aminoglycosides is a reasonable first-line drug. However, due to antibiotic overuse, there are now strains that are resistant to aminoglycosides and may not be easily treatable.[16,77] Surgical therapy to remove granulomas may be helpful. In cases of vertebral osteomyelitis in snakes, surgical therapy is not feasible, and the prognosis is poor.

Morganella. *Morganella* is a genus in the order Enterobacteriales. *M. morganii* is the species of concern in reptiles. *Morganella* infection in reptiles typically begins enterically and then translocates across the gut. Hematogenous spread to other organs then occurs. Lesions often include necrotizing enteritis, soft tissue granulomas, and sepsis.[78–80] It is clinically similar to salmonellosis but is less commonly associated with osteomyelitis. *M. morganii* often have extensive resistance profiles that require advanced antimicrobials after sensitivity results.

Providencia. *Providencia* is a genus in the order Enterobacteriales. *P. rettgeri* is the species of concern in reptiles. Although all reptiles are affected, it is of greatest concern in crocodilians, where large epizootics with high mortality rates are seen.[81–83] Lesions often include sepsis, pneumonia, meningoencephalitis, splenitis, and hepatitis. *P. rettgeri* often have extensive resistance profiles that require advanced antimicrobials after sensitivity results, but rapid progression of disease in crocodilians may limit therapeutic response.

Coxiella burnetti. The Legionellales are an order of Gammaproteobacteria. They are gram-negative rods that are often found intracellularly in eukaryotes. They tend to be more fastidious than other members of the Proteobacteria, and PCR methods are preferable to culture for diagnostics. The known species of concern in reptiles is *Coxiella burnetti,* the agent of Q fever; it is a listed bioterrorism agent in the United States. *C. burnetti* has been isolated from Indian pythons (*Python molurus*), roofed turtles (*Batagur* or *Pangshura* spp.) and mangrove monitors (*Varanus indicus*) in India.[84] This report was before use of DNA sequence identification for bacteria identification. More diverse *Coxiella* sp. have recently been found in birds, and it is likely they are also present in reptiles.[85] Cases of splenomegaly especially merit further investigation. It is very probable that *Coxiella* spp. are medically relevant for reptiles, but diagnostic challenges have resulted in limited investigation to date. Doxycycline is the treatment of choice. If the clinician encounters *C. burnetti,* public health authorities should be contacted immediately.

Pasteurella testudinis* and *Chelonobacter oris. The Pasteurellales are an order of Gammaproteobacteria. They are gram-negative rods that are typically found in the nose and mouth of terrestrial vertebrates. They tend to be less stable in the environment than other members of the Proteobacteria, often do not survive transport well, and often require specialized media. *Pasteurella testudinis* was described from California desert tortoises (*Gopherus agassizii*) with rhinitis.[86] Later work showed a major role for *Mycoplasma agassizii* in rhinitis in this species, but *Pasteurella testudinis* may play a role as well. *Chelonobacter oris* has recently been described from Hermann's tortoises (*Testudo hermanni*) with upper respiratory disease, and the phylogenetic analysis showed that *P. testudinis* should be moved to this genus as well.[87] Again, the role of the bacterium in disease remains to be investigated. Given the significance the Pasteurellales play in disease in birds and mammals, it is likely they are significant in reptiles as well. Empirical antibiotic treatment is not recommended.

***Vibrio* spp.** The Vibrionales are an order of Gammaproteobacteria. They are gram-negative rods that are associated with marine environments. Although all reptiles may be affected, they are of greatest concern in sea turtles. In stranded sea turtles with concurrent fibropapillomatosis, *Vibrio* spp. were the most common isolate from the blood.[88] Species commonly isolated from septic sea turtles include *V. parahaemolyticus*, *V. harveyi*, and *V. alginolyticus.* Trimethoprim-sulfas, amoxycillin-clavulanic acid, and 1st generation fluoroquinolones are reasonable choices pending sensitivity testing.

ε-Proteobacteria

The class Epsilonproteobacteria are often curved or spiral-shaped gram-negative rods. Many inhabit vertebrate gastrointestinal tracts. They tend to require specialized media for culture.

Campylobacter. The genus *Campylobacter*, in the order Campylobacterales, are gram-negative curved rods that are typically found in gastrointestinal tracts. *Campylobacter iguaniorum*, most closely related to *C. fetus,* is not uncommonly found in the gastrointestinal tract of reptiles; one study found it in 10% of turtles and 3% of squamates.[89] There is genetic segregation between *C. fetus* strains of mammal origin and *C. iguaniorum* of reptile origin, but *C. iguaniorum* have been shown to cause disease in humans.[90] Most investigation has focused on risks to human health rather than on reptile health; *C. iguaniorum* has been isolated from a leopard tortoise (*Stigmochelys pardalis*) with lethargy and anorexia that responded to therapy with enrofloxacin.[91]

A second species *(Campylobacter geochelonis)* from Hermann's tortoises has also been described, but there are no data on disease or zoonotic potential.[92] *C. jejeuni,* a known human pathogen, has also been reported by qPCR identification from lizards; further strain typing may reveal whether this is actually *C. jejeuni* or a distinct reptile species.[93]

Campylobacter spp. require specific media for growth and grow under microaerophilic conditions. Samples should not be refrigerated, because *Campylobacter* is not tolerant of cooling. Antibiotic therapy is not indicated for mild cases; in a more severe case, erythromycin and potentiated sulfas are reasonable empirical choices while sensitivity results are pending.

A probiotic containing a mixture of bacteria that did not include *Campylobacter* spp. was associated with decreased intestinal *Campylobacter* counts and increased intestinal villous height and increased mucosal thickness in turtles, which was interpreted as a positive difference for health.[37]

Helicobacter. The genus *Helicobacter*, proteobacteria in the order Campylobacterales, are gram-negative spiral-shaped rods that are typically found in gastrointestinal tracts. Sepsis with a novel *Helicobacter* species was seen in a pancake tortoise (*Malacochersus tornieri*) that had concurrent cryptosporidiosis.[39] Enteritis may have led to gut translocation and sepsis. In surveillance, *Helicobacter* sp. were detected by PCR in 57% of tortoises and 29% of squamates.[94] A sequence from a Greek tortoise (*Testudo graeca*) was closely related to the pancake tortoise species. Several sequences from diverse lizards formed a separate clade. Nasal cytology from two gopher tortoises with rhinitis and weight loss, presenting 2 years apart, showed large numbers of spiral-shaped bacteria (Fig. 29.2). Neither tortoise responded to ceftazidime treatment and both died. PCR and sequencing identified the same *Helicobacter* in both tortoises, which was related to but distinct from the pancake tortoise and Greek tortoise *Helicobacter* spp. (Wellehan et al, Proc WDA, 2016). *Helicobacter* require specific media

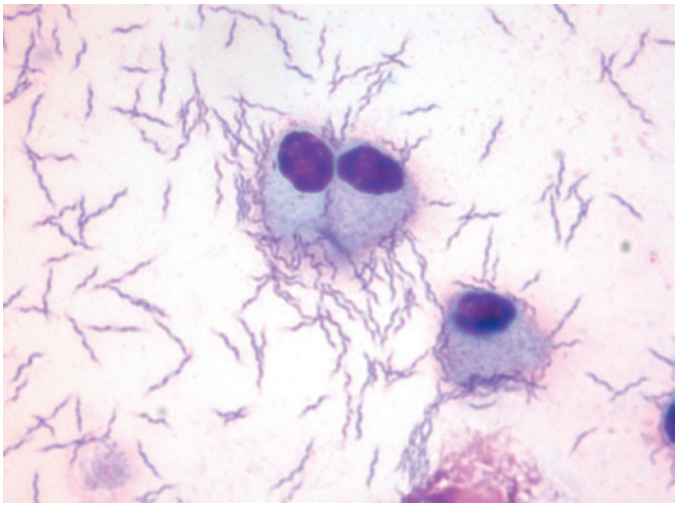

FIG 29.2 Nasal cytology from a gopher tortoise (*Gopherus polyphemus*) with rhinitis. Note the large numbers of spiral-shaped bacteria that were subsequently identified as *Helicobacter* by PCR. DiffQuik, ×1000.

for growth and grow under microaerophilic conditions. Empirical treatment is not recommended without diagnosis, but if confirmed, a clarithromycin, amoxicillin, and metronidazole combination is appropriate.[95]

ACTINOBACTERIA

The phylum Actinobacteria may stain gram-positive or may stain acid fast. Members of this phylum have thick cell walls, and many produce filaments; some can produce spores. They comprise a small part of normal gut flora and play a large role in soil ecology. They often have large immunomodulatory effects on the host. As a whole, Actinobacteria are often slow growing and poorly identified by traditional biochemical means.

Actinomyces, Arcanobacterium,* and *Trueperella. *Actinomyces*, *Arcanobacterium*, and *Trueperella* are genera of arcanobacteria in the family Actinomycetaceae. They are gram-positive rods and do not stain acid fast. *T. pyogenes* has been reported in the intestine of an unidentified gecko species and the lung of a bearded dragon.[96] These grow well on standard cultures, but standard biochemical identification has a high error rate, and DNA sequence ID may be preferable. Penicillins have been demonstrated to be effective and are reasonable empirical choices while sensitivity results are pending.

Rhodococcus. *Rhodococcus* is a genus of arcanobacteria in the family Corynebacteriales. They are gram-positive short rods that normally live in soil. *R. equi*, an important pathogen of horses, has been reported to cause sepsis in crocodilians.[97]

Corynebacterium. *Corynebacterium* is a large genus of arcanobacteria in the family Corynebacteriales. They are gram-positive, club-shaped rods that are common in soil and skin flora. Although there are reports of *Corynebacterium* infections in reptiles, they are typically considered contaminants and not clinically relevant.[98,99]

Nocardia. *Nocardia* is a genus of arcanobacteria in the family Corynebacteriales. They are weakly gram-positive bacteria that stain partially acid fast and form branching filaments. They normally live in soil. They are often slow growing and poorly identified by traditional biochemical means; molecular identification is indicated. They have primarily been reported in osteomyelitis in sea turtles.[100,101] Trimethoprim-sulfamethoxazole is a reasonable empirical choice while sensitivity results are pending.

Mycobacterium. *Mycobacterium* is a genus of arcanobacteria in the family Corynebacteriales. They do not take up gram stain and are often seen as unstained "ghost cells." They stain acid fast. Many mycobacterial species are found in biofilms in aquatic environments; they are usually found in large numbers in shower heads.[102] A large number of mycobacterial species have been identified in reptile disease, including *M. agri*, *M. avium*, *M. chelonae*, *M. confluentis*, *M. fortuitum*, *M. haemophilum*, *M. hiberniae*, *M. intracellulare*, *M. kansasii*, *M. marinum*, *M. neoaurum*, *M. nonchromogenicum*, *M. phlei*, *M. smegmatis*, *M. szulgai*, and *M. ulcerans.* There are significant differences in drug susceptibility and zoonotic risk, and any identified mycobacterial infection should be speciated. The most common lesions are granulomas; one study found that mycobacteria could be found in 14.6% of reptiles with granulomatous inflammation by acid-fast staining and 25.6% by PCR.[103] However, other lesions may also be seen less commonly, including disseminated intravascular coagulation.[104] Neurotropism has been seen with *M. haemophilum* in leatherback turtles, a close relative of *M. leprae;* leprosy is also neurotropic.[105]

Mycobacterial or actinomycete cultures are often most successful from unfixed biopsy samples. Concurrent histology with acid-fast staining is recommended if mycobacterial disease is suspected. Many granulomatous infections are paucibacterial, and it may be necessary to cut in multiple sections to see organisms. Tissue samples may be sent directly to the laboratory in a sterile sealed container. Mycobacteria are very slow growing, and culture results may take as long as several months, but culture is needed for a susceptibility profile. They are poorly identified by traditional biochemical means; molecular identification is indicated. Because culture is often slow, and knowledge of species provides important information about culture conditions, zoonotic risk, and typical susceptibility profile, submission of concurrent direct molecular diagnostic testing is recommended. Using *Mycobacterium tuberculosis* as a model, antibody response is not likely to be diagnostically useful; the World Health Organization has a position statement against the use of serological testing for *M. tuberculosis.*[106]

Before treatment is initiated, the organism should be speciated to determine zoonotic potential and probable drug susceptibility. Euthanasia should be considered for mycobacterial species of significant zoonotic concern. Any husbandry deficiencies should be addressed and corrected. Zoonotic risks need to be discussed with the owner, and the clinician needs to determine that the owner understands the risks and expense and is committed to the long-term therapy necessary. If not, euthanasia should be recommended. Antibiotic therapy will need to involve multiple drugs over a course of at least 6 months to 1 year. Single drug therapy or shorter courses are likely to result in treatment failure and antibiotic resistance. Biopsies of affected tissues should be taken and hematology repeated after 6 months to 1 year to determine whether therapy needs to be continued. Hematology should be checked every 3 months for several years to look for leukocytosis, which may be a sign of recurrence. With appropriate therapy, mycobacteriosis is a treatable disease (Wilkinson et al, Proc NAVC, 2016, pp 1302–1304).

Austwickia. *Austwickia* is a genus of arcanobacteria in the family Micrococcales. They stain gram positive, have a characteristic branching, filamentous structure, and the ability to produce motile cocci called zoospores. Formerly known as *Dermatophilus chelonae*, *Austwickia chelonae* is the sole member of the genus.[3] Histologically, although it does form filaments, they do not typically have the "train track"

VetBooks.ir

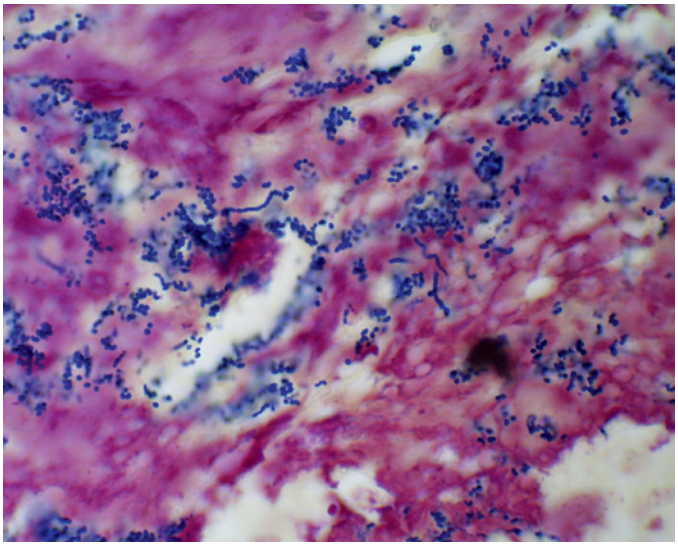

FIG 29.3 *Austwickia chelonae* (formerly known as *Dermatophilus chelonae*) form gram-positive staining rods with characteristic branching, filamentous structure. Gram stain, ×1000.

FIG 29.4 *Devriesea* cheilitis in a spiny-tailed lizards (*Uromastyx* sp.).

appearance seen with *Dermatophilus congolensis* (Fig. 29.3). *A. chelonae* is associated with granulomatous disease in reptiles. It was first isolated from turtles but has also been identified in squamates.[3,107,108] Infection typically starts in the skin and invades deeper tissues, resulting in granulomas. Coinfection with ranavirus has been documented.[3]

The clinician should communicate in advance with the microbiology laboratory when *A. chelonae* is suspected, and the microbiology laboratory should be prepared to look for actinomycete-like colonies. *A. chelonae* grows faster at 27°C than 37°C. They are poorly identified by traditional biochemical means; molecular identification is indicated. It is likely that extensive protocols comparable to mycobacterial treatment protocols may be needed. Antibiotic therapy may need to involve multiple drugs over a course of 6 months to 1 year. Single drug therapy or shorter courses seem likely to result in treatment failure.

Devriesea. *Devriesea* is a genus of arcanobacteria in the family Micrococcales. They are small, gram-positive rods. It initially presents as cheilitis and is most commonly seen in *Uromastyx* sp. (Fig. 29.4) and often leads to sepsis.[109] It has been found in association with disease in diverse agamids and iguanids, as well as a single isolate from the oral cavity of a leopard gecko without reported clinical signs.[110] It was demonstrated to cause dermatitis in inland bearded dragons by experimental infection, but this species is not usually clinically affected and is considered a carrier.[109] Despite not forming spores, it is very stable in the environment; disinfectants labeled with activity against *Mycobacterium* should be used.[111] Use of a killed vaccine on bearded dragons prevented sepsis but not dermatitis in experimental infections and elicited an antibody response; species in which disease is seen naturally were not studied.[112] Using *Mycobacterium tuberculosis* as a model, it is likely that antibody response will be less predictive of protection than cellular immunity. First-line drugs erythromycin and tetracyclines are often effective, while the third-generation cephalosporin, ceftiofur, has also demonstrated efficacy. Fluoroquinolones are often ineffective.[113]

BACTEROIDETES

The phylum Bacteroidetes stain gram negative. Many of them are anaerobic. They comprise a large part of normal gut flora, and an increase in their proportion in gut flora is often associated with decreased obesity and reduced inflammation in humans.[33] In pythons, there is a massive postprandial shift in gut flora composition away from the Bacteroidetes.[12] Significant increase in oxidative damage is seen postprandially in snakes.[34] A probiotic containing a mixture of bacteria that were mostly in the phylum Firmicutes and did not include any Bacteroidetes was associated with decreased intestinal *Bacteroides* and *Prevotella* sp. counts in turtles; this may be a negative change for health.[37]

In their usual context, most of the Bacteroidetes are commensal. In compromised patients, normal gut flora such as *Bacteroides* sp. or *Prevotella* sp. may function as opportunistic pathogens. The notable exception, in reptile medicine, is *Elizabethkingia.*

Elizabethkingia. *Elizabethkingia* is a genus of bacteroides in the family Flavobacteriales. They are small gram-negative rods that are found in aquatic environments. *E. meningoseptica* can invade intracellularly and is the species known to cause disease in reptiles. It also affects a wide variety of other vertebrates, including humans.[114,115] Former names for *E. meningoseptica* include *Chryseobacterium meningosepticum* and *Flavobacterium meningosepticum.* Little molecular identification has been done on *Elizabethkingia* in reptiles, and *E. anophelis* and *E. miricola* have also recently been recognized as human pathogens.[116] Clinical signs in reptiles typically consist of depression, anorexia, and edema shortly followed by death. Blood cultures are good antemortem samples. Standard biochemical methods may result in misidentification as *Aeromonas salmonicida*, and this should be discussed with the laboratory if *A. salmonicida* is reported.[70] *Elizabethkingia* often have extensive resistance profiles, and do not respond to many drugs commonly used for Proteobacteria, such as third-generation cephalosporins. A trimethoprim-sulfamethoxazole combination is a reasonable empirical choice, but rapid progression of disease may limit therapeutic response.[116]

CHLAMYDIAE

Chlamydia, Neochlamydia, Parachlamydia,* and *Simkania. The phylum Chlamydiae are gram-negative, obligate, intracellular bacteria that have a biphasic developmental cycle consisting of the infectious elementary body and the noninfectious replicating reticulate body. They are not known to serve commensal roles. A number of species in the phylum Chlamydiae have been identified in reptiles. The most common appears to be *Chlamydia pneumoniae*, but *C. abortus*, *C. felis*, *C. psittaci*, *C. muridarum*, unnamed *Chlamydia* sp., *Neochlamydia* sp., *Parachlamydia*

sp., and *Simkania* sp. have also been identified from reptiles.[103,117] They are very prevalent in captive reptiles; this is likely an artifact of the poor biosecurity and high stocking density standard in the reptile trade. A recent study in asymptomatic snakes found a prevalence of *Chlamydia* sp. ranging between 5% to 33% in six snake collections in Europe.[118]

Chlamydiae are challenging to culture and poorly identified by traditional biochemical means; PCR is the standard for identification. Occasionally, Chlamydiae can be seen in circulating leukocytes on a blood smear, but this is not reliable. The most common lesions in reptiles are granulomas. One study found that Chlamydiales could be found in 5.6% of reptiles with granulomatous information by immunohistochemistry, and 64.4% by PCR, underscoring both the high prevalence and the much greater sensitivity of PCR to identify the organism.[103] They are often disseminated in many tissues, although infection of a novel *Chlamydia* sp. in false gharials (*Tomistoma schlegleii*) lesions was confined to the central nervous system.[119] Nasal lavage of tortoises with nasal discharge found that 10% were PCR positive for a novel *Chlamydia*.[120]

When known granulomas are accessible at biopsy or necropsy, these are the best samples for testing. When this is not accessible, PCR of choanal and cloacal swabs has been most commonly used, but data on sensitivity, or comparison to other samples such as buffy coats, nasal lavage, or conjunctival swabs, needs to be studied.

Treatment of Chlamydiales consists of surgical removal of any known granulomas, and a 45 to 60-day course of tetracyclines or macrolides. Repeat PCR testing and hematology should be performed at 6 months and 1 year after treatment to look for evidence of treatment failure.

TENERICUTES

***Mycoplasma, Ureaplasma,* and *Acholeplasma*.** The phylum Tenericutes are gram–negative, obligate cell-associated bacteria that have lost their cell walls and many biochemical pathways, becoming highly dependent on their host cells. Medically relevant genera include *Mycoplasma*, *Ureaplasma*, and *Acholeplasma. Mycoplasma* sp. has been found in all vertebrates that have been significantly investigated, including reptiles. Infection appears to be much more common than significant disease for most *Mycoplasma* sp. in most species.

In turtles, *Mycoplasma agassizii* has been shown to be one cause of significant upper respiratory tract disease (URTD) in California desert tortoises (*Gopherus agassizii*) and Florida gopher tortoises (*Gopherus polyphemus*).[121,122] It is not uncommon to find asymptomatic tortoises; temperature is one cofactor indicated to play a role in this. There has been an association between *M. agassizii* URTD in desert tortoises and colder winters.[123] Gopher tortoises with severe URTD have been found to move longer distances over short time periods than unaffected tortoises; they also have higher body temperatures, and increased activity may be heat seeking for a behavioral fever.[124] Other factors such as reproductive status and nutrition are likely to play significant roles in manifestation of disease. Coinfection, especially with agents such as Chlamydiales, Pasteurellales, and viruses, needs further investigation.

A different species in the upper respiratory tract of California desert tortoises, *M. testudineum*, may be associated with URTD, although a causal relationship with URTD has not definitively been shown. *M. testudinis,* isolated from the cloaca of Greek tortoises (*Testudo graeca*), has not been associated with disease and is not currently considered a pathogen.

A different *Mycoplasma* sp., yet unnamed, has been found in association with URTD, first in eastern box turtles (*Terrapene carolina carolina*) and then in other North American emydid turtles.[125] This organism may cross-react serologically with *M. agassizii* and *M. testudineum,* complicating serodiagnostics.[126]

In squamates, *Mycoplasma* is not uncommonly seen in pythons, often in association with tracheitis and pneumonia.[127] This organism is closely related to but distinct from *M. agassizii* and *M. testudineum.*[128] It is commonly seen as a coinfection with python nidoviruses, and study of the interactions of these agents is indicated. *M. iguanae,* isolated from a green iguana (*Iguana iguana*), did not cause lesions in experimentally infected green iguanas.[129] *M. insons* is also likely normal flora in green iguanas.[130] An unnamed *Mycoplasma* sp. related to *M. iguanae* has been identified from the lungs of a bearded dragon with Helodermatid adenovirus 2-associated pneumonia.[130a]

In crocodilians, *M. crocodyli* is associated with polyarthritis in Nile crocodiles (*Crocodylus niloticus*).[131] *M. alligatoris* has been shown to cause pneumonia, polyserositis, and polyarthritis in American alligators (*Alligator mississippiensis*) and broad-nosed caiman (*Caiman latirostris*) but did not cause disease in Siamese crocodiles (*Crocodylus siamensis*).[132]

There is likely significant tenericute diversity in reptiles still to be determined, and a large amount of work has to be done to understand their clinical implications in different reptile species. There are no known zoonotic concerns for any of the reptile-associated mycoplasmas. Most *Mycoplasma* sp. appear to be somewhat host specific.

Tenericutes require special media for culture. Because mycoplasmas lack cell walls, they are highly susceptible to desiccation, and samples should immediately be placed into a mycoplasma culture broth such as SP4 or Frey's. If the sample is taken with a swab, chances for successful culture are greatly improved by premoistening swabs in sterile mycoplasma broth. Media typically contains a cell wall inhibitor, such as ampicillin, to inhibit the growth of other bacteria. Many mycoplasmas are slow growing, and it may take up to several weeks to obtain culture results. They are poorly identified by traditional biochemical means; PCR with sequence identification is the standard for diagnosis, whether done from cultures or directly from clinical samples.

The goal of therapy is treatment of disease. Eradication of the organism is a second goal, but *Mycoplasma* sp. are difficult to completely eradicate, and the possibility of having an asymptomatic carrier after treatment is significant. Because of the lack of a cell wall, antibiotics targeting the cell wall, such as penicillins or cephalosporins, will not be effective. Fluoroquinolones are likely to result in temporary success and relapse, and tetracyclines are recommended as a first-line choice. There is pharmacokinetic data on azithromycin in ball pythons (*Python regius*), clarithromycin in California desert tortoises (*Gopherus agassizii*), tulathromycin in desert tortoises, and oxytetracycline in American alligators (*Alligator mississippiensis*) and loggerhead sea turtles (*Caretta caretta*).[133–137] In the absence of further data, treatment should be for at least 45 to 60 days.

SPIROCHAETES

The phylum Spirochaetes are gram-negative bacteria with a double membrane and a spiral shape. They have central flagella that are between the membrane layers. Spirochaetes are difficult to grow and require special media for culture.

***Borrelia*.** *Borrelia* is a genus of spirochaetes in the family Borreliaceae. They are gram-negative spiral-shaped rods that are usually transmitted by ticks. Most investigation has focused on ticks rather than their reptile hosts; *Borrelia* sp. have been identified in ticks from diverse reptile hosts. *B. turcica* was cultured from seven of eight (88%) *Testudo* sp. tortoises being imported into Japan, and a novel *Borrelia* sp. was cultured from five of seven (71%) leopard tortoises (*Stigmocheys pardalis*).[138] These *Borrelia* were also seen in *Amblyomma* sp. ticks. When these *Borrelia* were inoculated into juvenile African spur-thighed tortoises

VetBooks.ir

(*Centrochelys sulcata*), the leopard tortoise *Borrelia* but not *B. turcica* was isolated from the African spur-thighed tortoises when the animals were sacrificed after 4 weeks. The African spur-thighed tortoises were not reported to show clinical signs, but histopathology was not performed. When *B. turcica* and the leopard tortoise *Borrelia* were inoculated into mice, no culture-positive samples were found when the mice were sacrificed after 4 weeks, suggesting that mammals may not be competent hosts.[138]

Borrelia lusitaniae, found in skin lesions of humans, was present in 19% of green lizards (*Lacerta viridis*), suggesting they may be a significant reservoir.[139] In contrast, western fence lizards (*Sceloporus occidentalis*) and southern alligator lizards (*Elgaria multicarinata*) are not competent hosts for *B. burgdorferi,* the agent of Lyme disease, and their plasma has been shown to be borreliacidal through activation of complement.[140]

Given the high prevalence in reptiles and the nebulous clinical signs and chronic nature of disease seen in mammals, it is very probable that *Borrelia* spp. are medically relevant for reptiles, but diagnostic challenges have resulted in limited investigation to date.

Skin appears to be a good sample to test, followed by blood.[138] *Borrelia* are challenging to culture; Barbour-Stoenner-Kelly (BSK) media is commonly used. PCR diagnostics may be a more practical option. A reasonable approach to treatment of *Borrelia* is a 45- to 60-day course of tetracyclines. PCR testing of a skin biopsy should be taken at 6 months and 1 year after treatment to look for evidence of treatment failure.

Leptospira. *Leptospira* is a genus of spirochaetes in the family Leptospiraceae. They are gram-negative spiral-shaped rods that are found in aquatic habitats. They are associated with renal disease in diverse species and are typically transmitted through urine. Serologic data have suggested that antibodies against *Leptospira* sp. are present in reptiles. However, validation of serologic assays has been very limited. Gastric and cloacal contents of Geoffroy's side-necked turtles (*Phrynops geoffroanus*) were found to be PCR positive for *Leptospira* sp., although sequencing identification of PCR products was not done.[141] There was no correlation of PCR results with serologic status; 5 of 25 (20%) samples from seropositive turtles were PCR positive, and 6 of 30 (20%) samples from seronegative turtles were PCR positive.

Leptospira interrogans and an unnamed *Leptospira* sp. have been identified by sequencing PCR products from the kidneys of a herald snake (*Crotaphopeltis hotamboeia*), a Jararaca viper (*Bothrops pauloensis*), and two Brazilian lancehead vipers (*Bothrops moojeni*).[142,143]

Given the presence of *Leptospira* sp. in reptiles, the challenges of leptospiral and renal diagnostics in reptiles, and the disease seen in mammals, it is very probable that *Leptospira* spp. are medically relevant for reptiles, but diagnostic challenges have resulted in limited investigation to date.

Renal samples appear to be the best tissue samples for *Leptospira* PCR.[142] Gastric washes and cloacal washes have been used as minimally invasive samples.[141] *Leptospira* are challenging to culture; specialized media is needed. PCR diagnostics may be a more practical option. Darkfield microscopy of urine to look for spirilliform bacteria may be helpful as a rapid initial test. A reasonable approach to treatment of *Leptospira* is a 45- to 60-day course of a tetracycline (e.g., doxycycline) or macrolide (e.g., erythromycin). PCR testing should be repeated after treatment to look for evidence of treatment failure.

FUSOBACTERIA

Fusobacterium necrophorum. The phylum Fusobacteria are gram-negative nonspore-forming obligate anaerobes. In most vertebrates that have been studied, they may be found in oral flora but are a very small component of gut flora (<1%). The known exception is alligators, where the flora in the colon of both wild and farmed American alligators was typically composed of more than 50% Fusobacteria.[144] The most clinically relevant species in reptiles is *Fusobacterium necrophorum,* which has been reported in clinical lesions from squamates and turtles.[145] When *F. necrophorum* is found in a lesion on a patient, it should provoke a search for factors, causing the reptile to be compromised. *F. necrophorum* needs to be addressed, but the underlying cause also needs to be addressed. Metronidazole is a reasonable empirical therapy.

CYANOBACTERIA

The phylum Cyanobacteria includes photosynthetic bacteria that are often referred to as "blue-green algae," although they are not eukaryotes. They are common in diverse habitats, especially aquatic and marine environments. They were critical in oxygenation of the early atmosphere. In reptiles, they are not typically seen as part of internal flora but are common epibiota on aquatic and marine turtles. Their clinical relevance is not from infection of animals but from toxin production.[146] In freshwater environments, *Microcystis* is one genus commonly associated with toxin production; in marine environments, *Lyngbya* is a common toxic genus. Lesions seen include vacuolar myelinopathy.[147] However, deaths without lesions may be seen. Measurement of microcystin or *Lyngbya* toxins may be helpful with diagnosis. Management includes careful monitoring of water systems and maintenance of water quality with low nitrogen and phosphate loads to avoid cyanobacterial overgrowth.[148] Antibiotic therapy is not likely to be useful.

Virology

Rachel E. Marschang

Reptile virology has undergone rapid development over the past few decades. The use of next-generation sequencing (NGS) techniques has led to a rapid increase in the number of viruses described in reptiles. Additionally, transmission studies proving the role of specific viruses in disease processes have been carried out for a number of viral infections in various reptile species. Despite many advances, the factors involved in the development of viral disease in reptiles are, in many cases, unclear. Both host and viral factors are involved. Environmental factors, particularly temperature, have long been known to influence the immune system of reptiles. Increasing evidence suggests that other factors can play an important role in the outcome of viral infections in reptiles, including various pollutants and other infectious agents. Concurrent infections with several infectious agents, including multiple viruses, may occur, and the interactions and effects of these concurrent infections are not yet understood. This makes clinical evaluation of individual test results difficult and reinforces the need to consider multiple pathogens and critically evaluate results in these individual cases. It is critical to differentiate between infection and clinical disease caused by true viral pathogens in our reptile patients.

Many different methods are available for the diagnosis of viral infections in reptiles. These include methods for the detection of viruses, viral proteins, or viral genomes and serologic methods for the detection of an immune response to viral infection (generally restricted to antibody detection). Which method should be used in a specific situation depends on many different factors. These include the host species, clinical observations, time since infection, virus species, reason for testing, and test availability. Unfortunately, some of these factors such as virus species involved or time since infection are often unknown. None of the test systems available for reptile virology are fully standardized in that repeatability and reproducibility are not consistently studied. In addition, cross-reactivity and relationships between reptile viruses are not fully understood, and the specificity of some tests may therefore be lower than expected in some cases, or may be too high, and only a subset of related viruses may be detected using some assays. It is recommended to contact your laboratory before submitting samples (Table 30.1).

The viruses in this review are presented according to taxonomic position, with double-stranded (ds) DNA viruses (adenoviruses, including atadenoviruses, siadenoviruses, and "testadenoviruses"; herpesviruses; iridoviruses, including ranaviruses, invertebrate iridoviruses, and erythrocytic viruses; papillomaviruses; poxviruses) presented first, followed by single-stranded (ss) DNA viruses (circoviruses and a "tornovirus," parvoviruses), reverse transcribing DNA and RNA viruses (hepadnaviruses, retroviruses), dsRNA viruses (reoviruses), negative sense ssRNA viruses (members of the order *Mononegavirales*, including bornaviruses, paramyxoviruses [ferlaviruses], sunviruses, rhabdoviruses; arenaviruses; bunyaviruses), and positive sense ssRNA viruses (members of the order *Nidovirales* [corona- or toroviruses], members of the genus *Picornavirales* [picornaviruses], caliciviruses, flaviviruses, togaviruses) (Table 30.2).

ADENOVIRIDAE

Adenoviruses (AdVs) are the viruses most commonly identified in many squamate species, particularly bearded dragons (*Pogona* spp.), although they have also been detected in various chelonians and crocodilians. AdVs have a relatively high resistance to inactivation and can be difficult to disinfect. Current taxonomy of the family *Adenoviridae* suggests a coevolutionary lineage of the viruses with their hosts and additional host switches. Atadenoviruses have been hypothesized to have coevolved with squamate reptiles, while a new genus ("Testadenovirus") has been proposed to have coevolved with chelonian hosts.[1] This can be important in understanding the pathogenicity of the viruses, because viruses that have coevolved with their hosts may not cause disease or may only cause disease in immune-suppressed animals or in conjunction with other infectious agents or other factors, whereas switching of hosts may lead to severe disease and death. AdVs from crocodilians have not yet been characterized.

Adenoviruses in Squamates

AdVs appear to occur worldwide in captive populations, and antibodies to AdVs have been detected in wild boa constrictors (*Boa constrictor*) from Costa Rica (Marschang et al, Proc 6th Int Cong Vet Virol, 2003, p 152) and in wild-caught rattlesnakes from the United States.[3] All of the AdVs detected in squamates so far have belonged to the genus *Atadenovirus*. Clinical signs most commonly associated with AdV infection in squamates are gastrointestinal and neurologic, including anorexia, lethargy, wasting, head tilt, opisthotonus, and circling (Fig. 30.1) In individual cases, stomatitis, dermatitis, and pneumonia have also been described.[4] AdVs have also been detected in animals with no clinical signs of disease. Koch's postulates have been fulfilled for an AdV-induced hepatic necrosis in a boa constrictor.[5] Gross pathologic examination of animals that die with AdV infection can involve only the liver, which may be enlarged and have petechiae or pale areas scattered throughout. Histologically, these animals generally have hepatic necrosis. The intestine is also frequently affected, and documented changes include dilatation of the duodenum and hyperemia of the mucosa. Basophilic intranuclear inclusions are often seen in hepatocytes and enterocytes (Fig. 30.2), as well as in myocardial endothelial cells, renal epithelial cells, endocardium, epithelial cells of the lung, and glial and endothelial cells in the brain.[4]

An important observation in many squamate AdVs is their relative species specificity: specific lizard AdVs are mostly found in a single host species, most notably Agamid AdV-1 in bearded dragons. However,

Ch1, Tortoises; *Ch2,* pond, box, and freshwater turtles; *Ch3,* sea turtles; *Ch4,* other Cryptodira; *Ch5,* side-necked turtles; *S1,* snakes; *S2,* Iguania (e.g., agamas, iguanas, chameleons); *S3,* other squamates; *?,* Some evidence of infection with these viruses in this group of reptiles.

there are a number of exceptions to this apparent rule, including the detection of a Helodermatid AdV-2-like virus in liver tissue of a western bearded dragon (*Pogona minor*) in Australia.[6] Serologic studies have also indicated that many different squamate reptiles can be infected with a variety of atadenoviruses.[3] AdV infections in squamates are also frequently found in conjunction with multiple other infections, including infections with parvo, reo, iridoviruses, coccidia, and microsporidia.

Adenoviruses in Chelonians

AdVs have only relatively recently been detected in several species of chelonians. In Travancore (Sulawesi) tortoises (*Indotestudo forstenii*), as well as in other tortoises in contact with the Travancore tortoises, infection was associated with severe systemic disease and a very high mortality rate (82%). Pathological findings in infected tortoises were multifocal hepatic necrosis, amphophilic to basophilic intranuclear inclusions and diffuse hepatic lipidosis, myeloid necrosis in bone marrow, and severe necrotizing enterocolitis. The virus detected in these tortoises differed distinctly from the AdVs characterized from squamates so far and was determined to belong in the *Siadenovirus* genus.[7] A single case of AdV infection has been reported in a leopard tortoise (*Stigmochelys pardalis*) that was also infected with a herpesvirus. This animal had biliverdinuria, wasting, and episodes of hemorrhages.[8] In Hungary, an AdV was detected in a box turtle with degeneration of liver cells, pronounced vacuolization of the cytoplasm, pyknosis of nuclei, and inclusion bodies in some hepatocytes.[9] Similar viruses have since been detected in a wider range of turtle and tortoise species in the United States and in Europe, including both healthy and diseased individuals. It has been proposed to classify these viruses in a new genus in the family *Adenoviridae*, "Testadenovirus."[1] There is some evidence that this lineage may have coevolved with chelonian hosts.

Adenoviruses in Crocodilians

Adenoviruses have been described in crocodilians, where they are mostly associated with liver disease in juvenile animals. The intestines, pancreas, and lungs are less commonly affected. Clinical signs that have been reported in infected animals have generally been limited to lethargy and anorexia. In chronically infected animals, hepatitis may lead to runting. Gross pathology may show swelling of the liver. Intestines may also be affected and show swelling. Histologically, intranuclear inclusions have been described mainly in hepatocytes and enterocytes.[10]

Identification of Adenovirus Infections

Virus Detection. A PCR targeting the DNA polymerase gene[11] has been frequently used to detect various AdVs in reptiles (Tables 30.3 and 30.4). It has been used on a wide range of samples and can detect AdVs described in squamates and chelonians. The PCR products should be sequenced, because this PCR can also detect AdVs of prey animals.[12] Recommended samples for the detection of AdVs in lizards and snakes are cloacal swabs (Fig. 30.3), liver, and intestine. Specific PCRs for the detection of reptilian AdVs have also been described. A real-time PCR has been developed for the detection of Agamid AdV-1.[13] This method will not detect other AdVs found in reptiles.

A number of AdVs from reptiles have been isolated in cell culture, which has facilitated further characterization of individual viruses. Snake AdVs have been isolated in several cases.[4] In lizards, AdVs have been isolated from helodermatid lizards,[12] and Agamid AdV-1 has been isolated on cells from bearded dragon embryos.[14]

Serology. Virus neutralization testing was first used for the detection of antibodies against a snake AdV (SAdV-1) (Marschang et al, Proc 6th Int Cong Vet Virol, 2003, p 152), demonstrating the presence of anti-AdV

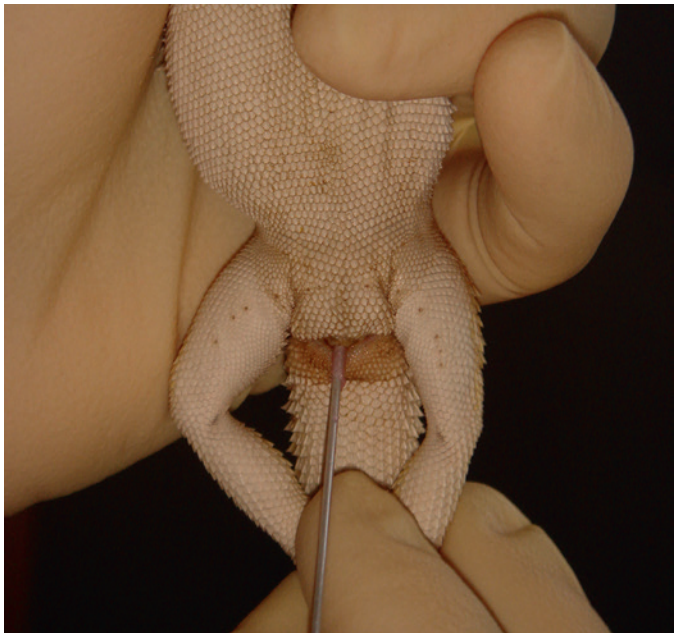

FIG 30.3 Bearded dragon (*Pogona vitticeps*). Cloacal swabs are recommended for the diagnosis of adenovirus infections in live animals.

antibodies in wild-caught snakes in Central America. In a study using Agamid AdV-1, Helodermatid AdV-1 and -2, and Snake AdV-1 and -2 in neutralization tests, antibodies against Agamid AdV-1 were most commonly found in agamid lizards, as well as in viperid and pythonid snakes, while antibodies against Helodermatid AdV-1 were most commonly found in iguanid lizards, and antibodies against Helodermatid AdV-2 were most commonly detected in helodermatid lizards.[3]

HERPESVIRIDAE

All of the reptilian HVs described so far appear to belong to the subfamily *Alphaherpesvirinae*. The genus *Scutavirus* has been created with the type species *Chelonid alphaherpesvirus 5* (chHV), also known as chelonid fibropapilloma-associated herpesvirus,[15] and herpesviruses from other chelonians have been shown to cluster with this genus.[16] It is considered probable that all vertebrates carry multiple HV species. In most cases, severe infection is only observed in very young or immunosuppressed animals or following infection of an alternative host.

Herpesviruses are relatively susceptible to disinfectants and are therefore easy to inactivate in the environment with the use of standard virucidal disinfectants. Studies on viral persistence in soil have shown that they are inactivated within about 2 weeks in the summer but may persist for longer at lower temperatures.[17] It is important to remember, though, that HV cause latent infections. Thus an HV-infected animal that survives initial infection must be considered a lifelong carrier.

In reptiles, HVs have been detected in lizards, snakes, chelonians, and crocodylians.[18] Infections are most often detected in various chelonian species, while detections in other species have been sporadic. In many, but not all, cases, infections have been associated with severe disease.

Herpesviruses in Squamates

In snakes, HVs have been detected in venom glands of various species, in some cases associated with decreased venom production,[19] and in a group of juvenile boa constrictors that died with hepatic necrosis.[20] In a disease outbreak among captive adult horned vipers (*Vipera ammodytes ammodytes*), all 71 horned vipers in the collection died within 2 weeks of developing lethargy, anorexia, and dyspnea. Common European vipers (*Vipera berus*) in the same collection were unaffected. Gross lesions in necropsied animals included petechiae and serosanguinous effusion throughout the body. Histology showed multiple foci of severe coagulative necrosis and necrosis of sinusoidal endothelial cells in the livers, myocardium, fat bodies, and spleens. Large acidophilic inclusion bodies were observed in the nuclei of endothelial cells in the liver.[21]

In lizards, a number of different HVs have been detected. HV-like particles, as well as particles resembling papova- and reoviruses, were detected by electron microscopy in papillomas of green lizards (*Lacerta viridis*).[22] Herpesviral DNA has also been detected by PCR in tissues from papillomas from green lizards.[23] A number of cases have been documented in which lizard HVs were associated with oral lesions in infected animals. Varanid HV 1 was detected in the oral mucosa and brain of emerald tree monitor lizards (*Varanus prasinus*) with proliferative stomatitis.[24] Three distinct HVs (gerrhosaurid HVs 1-3) were detected in Sudan plated lizards (*Gerrhosaurus major*) and a black-lined plated lizard (*Gerrhosaurus nigrolineatus*) with stomatitis.[25]

A few reports are available of HVs in lizards associated with lesions in the liver. Hepatitis and enteritis were diagnosed in juvenile monitor lizards that died acutely in the United States. Intranuclear inclusions were found in hepatocytes and enterocytes, and electron microscopy confirmed the presence of herpesvirus-like particles. The virus was shown to be closely related to Varanid herpesvirus 2 (GenBank accession No. AB189433), found in a monitor lizard in Japan (unpublished).[26]

Iguanid HV1 is the only lizard HV that has been isolated in cell culture from cell cultures derived from an infected green iguana (*Iguana iguana*). Transmission of the isolate to other lizards did not lead to the development of clinical signs.[27] In another case with a green iguana, HV-like particles were detected by electron microscopy in a lizard with hepatitis.[28]

Herpesviruses in Crocodilians

Several HVs have been reported in crocodilians. The first report was of the detection of HV-like particles in the skin of saltwater crocodiles (*Crocodylius porosus*) in Australia with a crust on the abdominal skin.[29] However, a direct link between the lesions and the HV detected could not be drawn, as the animals with lesions were shown to also have a poxvirus infection, as well as bacterial infections precipitated by biting. In the United States, an HV was detected in American alligators (*Alligator mississippiensis*) with lesions in the cloaca.[30] The virus was found to be very closely related to testudinid HV3, and the authors have suggested that it might have been a contaminant (GenBank accession number AY913769.1). Three different herpesviruses (Crocodyline HV1–3) were detected in saltwater and freshwater crocodiles from two large farms in Australia. The viruses were isolated in cell culture during an investigation into disease syndromes associated with conjunctivitis and pharyngitis, systemic lymphoid proliferation and encephalitis, and lymphonodular skin infiltrates in saltwater crocodiles and systemic lymphoid proliferation in freshwater crocodiles.[31]

Herpesviruses in Chelonians

Of the reptilian HVs, the chelonian HVs are most common and have been best characterized. HVs have been detected in members of the families Cheloniidae (sea turtles), Testudinidae (tortoises), Emydidae (pond turtles, box and freshwater turtles), Chelidae (Austro-American sideneck turtles), and Pelomedusidae (Afro-American sideneck turtles) so far.

In sea turtles, HV infections have been associated with skin lesions (gray patch disease); fibropapillomatosis; lung, eye, and trachea disease (LETD); loggerhead genital–respiratory HV (LGRV)-associated disease;

FIG 30.4 Green turtle (*Chelonia mydas*) with fibropapillomas.

and loggerhead orocutaneous HV (LOCV)-associated disease. Gray patch disease virus was one of the first HVs to be described in chelonians. It infects green sea turtles (*Chelonia mydas*). Aquaculture-reared, 2- to 3-month-old turtles appear to be most commonly affected. The virus was described by electron microscopy.[32]

Lung, eye, and trachea disease (LETD) has also been described in green sea turtles. Clinical signs associated with infection are gasping; harsh respiratory sounds; buoyancy abnormalities; inability to dive properly; and the presence of caseated material on the eyes, around the glottis, and within the trachea. Some of the infected turtles died after several weeks, while others became chronically ill. An HV (LETV) was isolated from diseased turtles in green sea turtle kidney cells.[33]

In sea turtles, fibropapillomatosis (Fig. 30.4) has been associated with HV infection and has been described in many different species of marine turtles, including green, loggerhead (*Caretta caretta*), Hawksbill (*Eretmochelys imbricata*), and olive ridley (*Lepidochelys olivacea*) sea turtles around the world. Infected turtles develop fibropapillomas, and individual or multiple tumors can occur externally all over the body. Internal tumors are also possible. The viral etiology has been tested by tumor transmission using cell-free tumor extracts.[34] The fibropapillomatosis HV has never been isolated in cell culture. Fibropapilloma-associated turtle HV (FPTHV) (also known as ChHV5) is considered the type species of the genus *Scutavirus*.[15] A study of geographically and genetically diverse FPTHVs indicated that these can be divided into groups, which cluster according to geographic origin, not host species.[35] Fibropapillomatosis has been treated by surgical removal of external fibropapillomas. These may recur, and the prognosis is poor in animals with extensive internal lesions or severely weakened animals.

Two HV-associated disease syndromes have been described in wild-caught loggerhead sea turtles, LGRV- and LOCV-associated disease. LGRV was associated with ulcers in the trachea, around the cloaca, and on the base of the phallus, while LOCV was associated with ulcers in the oral cavity and cutaneous plaques, which were covered with exudate and had an erythematous border, as well as with pneumonia.[36]

HV infections have been reported in many different species of tortoises. Clinical signs commonly associated with infections include rhinitis, conjunctivitis, stomatitis, and glossitis, which frequently develop into a diphtheroid-necrotizing stomatitis and glossitis (Fig. 30.5), with diphtheroid membranes covering parts of the oral cavity and extending down into the trachea and esophagus. Edema of the neck is a common sign. Affected animals are generally anorexic and lethargic. Animals that survive acute HV infection may develop central nervous system disorders, including paralysis or incoordination.[37] Hepatitis has also been described in affected animals. In a transmission study, spur-thighed tortoises inoculated with a tortoise HV either intramuscularly or intranasally developed disease signs consistent with HV infection.[38]

FIG 30.5 Russian tortoise (*Agrionemys horsfieldii*) with herpesvirus infection. Severe stomatitis with diphtheroid plaques visible throughout the oral cavity. (Courtesy of Volker Schmidt, Universität Leipzig, Leipzig, Germany.)

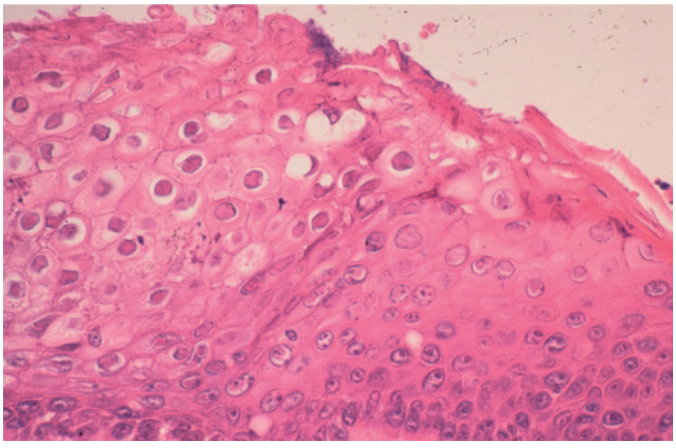

FIG 30.6 Herpesvirus infection in a tortoise (*Testudo hermanni*). Photomicrograph of the epithelium of the tongue. Ballooning degeneration is evident in numerous epithelial cells. Large intranuclear inclusions are also visible in several cells. H&E stain, ×400. (Courtesy of Horst Posthaus, Universität Bern, Berne, Switzerland.)

Development of disease and prognosis appear to depend both on the host species and on the virus involved.[37]

Histologically, HV infections in tortoises may be associated with eosinophilic or amphophilic intranuclear inclusions in infected tissues, most frequently in epithelial cells of the tongue, oral mucosa, and upper respiratory tract, as well as in the gastrointestinal tract (Fig. 30.6). Occasionally, inclusions can also be found in epithelial cells of the urinary tract, brain, liver, and spleen.[37]

There are currently four different HVs that have been shown to infect tortoises. They have been named testudinid HV1 to 4 (TeHV1 to 4).[18] TeHV1 was first detected in Russian tortoises (*Testudo horsfieldii*) and pancake tortoises (*Malacochersus tornieri*) in Japan.[39] Similar viruses have also been found in tortoises in Europe. Although they have been

VetBooks.ir

detected in several different species, many cases so far have had direct contact with Russian tortoises. TeHV1 is associated with stomatitis in infected animals but does not appear to cause high morbidity or mortality. TeHV2 was described in a California desert tortoise (*Gopherus agassizii*) in the United States. The animal exhibited anorexia, lethargy, and yellow-white caseous plaques on the tongue and palate.[40] TeHV3 has been most frequently described in Mediterranean tortoises (Hermann's [*T. hermanni*], spur-thighed [*T. graeca*] and marginated [*T. marginata*] tortoises) and Russian tortoises in Europe. It has also been detected in tortoises in the United States and in northern Africa. This virus is associated with severe disease and high morbidity and mortality, particularly in Hermann's and Russian tortoises. Spur-thighed tortoises develop disease less frequently and appear to be able to survive and carry the infection.[41] TeHV4 was detected in a clinically healthy bowsprit tortoise (*Chersina angulata*) in a zoo in the United States.[42] A similar virus has since been detected in a leopard tortoise with respiratory disease that was co-infected with a mycoplasma in Europe.[43] Studies of the genomes of several distinct TeHV3 isolates have shown genetic differences between isolates, including deletions, which appear to influence the ability of the viruses to invade the brain and may therefore influence the virulence of individual strains.[16]

A number of reports are available on HV infection in water turtles. These were first described based on histological changes in Pacific pond turtles (*Actinemys* (*Clemmys*) *marmorata*), painted turtles (*Chrysemys picta*), and map turtles (*Graptemys* spp.). Clinical signs reported in affected animals include lethargy, anorexia, and subcutaneous edema. Characteristic necropsy findings include hepatomegaly and pulmonary edema. Areas of hepatic necrosis with the presence of intranuclear inclusion bodies in hepatocytes were reported. Inclusions have also been demonstrated in the spleen, lungs, kidneys, and pancreas.[44–46] More recent descriptions have included data on the genomes of the viruses detected. In all cases the detected viruses have clustered with other chelonian alphaherpesviruses. In one case in a captive freshwater turtle (*Pseudemys concinna concinna*) the animal died with no previous clinical signs. Histologic examination showed hepatic lipidosis with intranuclear inclusion bodies in hepatocytes.[47] A similar virus was also found in a northern map turtle (*Graptemys geographica*). The turtle had shown weakness and nasal discharge prior to death. Postmortem examination showed pneumonia, as well as hepatocellular and splenic necrosis, all associated with intranuclear inclusion bodies.[48] In a study screening wild bog turtles (*Glyptemys muhlenbergii*), wood turtles (*G. insculpta*), and spotted turtles (*Clemmy guttata*) in the northeastern United States, three different HVs were detected; 51.5% of the bog turtles sampled were HV positive. None of the animals in that study were clinically ill.[49] Herpesviruses have also been described in box turtles in the United States in association with stomatitis and papillomas.[50,51]

A single report is available of an HV infection in an Australian sideneck turtle, a captive Krefft's river turtle (*Emydura macquarii krefftii*). The animal showed ulcerative lesions of the skin and shell, and histopathology showed orthokeratotic hyperkeratosis with intranuclear inclusions in keratinocytes.[52] A single report also exists of an HV infection in African sideneck turtles (West African mud turtles [*Pelusios castaneus*]. The animals were imported into Germany from a farm in West Africa. A herpesvirus was detected in oral and cloacal swabs from clinically healthy animals by PCR.[53]

Identification of Herpesvirus Infections

Virus Detection. Detection of viral DNA by PCR is the most commonly used method for detecting HVs in infected reptiles (Tables 30.3 to 30.5). A PCR using degenerate primers in a nested format targeting a highly conserved portion of the DNA polymerase gene has been used to detect HVs in chelonians, squamates, and crocodylians.[54] Results from this PCR must be confirmed (e.g., by sequencing). Other PCRs have been described targeting specific TeHVs (e.g., only TeHV1 or only TeHV3).[41] A PCR for the differentiation of TeHV3 strains has been suggested.[55] A duplex PCR has been designed for the detection of CrHVs 1, 2, and 3 in formalin-fixed tissues from infected crocodiles.[31] Real-time, quantitative PCRs have also been developed for the detection of specific viruses in specific animal species, including TeHV2 in desert tortoises[56] and Terrapene HV1 in box turtles.[57] Virus isolation in cell culture has been used to detect LETV, TeHV1, and TeHV3. Samples for HV detection in chelonians should generally include tissues with lesions. For fibropapillomatosis, viral DNA can be detected in fibropapillomas removed from live or dead animals. In tortoises, HV DNA has been detected in oral swabs from live animals. Swabs should be taken from the base of the tongue and should include cellular material (Fig. 30.7). In dead tortoises, the tongue is generally considered the best tissue for virus detection. Esophagus, stomach, intestine, trachea, liver, and brain can also be helpful in virus detection. In water turtles, HV detection has most often been reported from the liver in dead animals. In crocodylians, CrHVs have been detected in conjunctiva, skin, liver, kidney, and mixed tissues of infected animals.

FIG 30.7 Hermann's tortoise (*Testudo hermanni*). Oral swabs can be used to diagnose several different viral infections in live tortoises, particularly herpes, picorna, and ranavirus infections.

Serology. Detection of antibodies against HVs is particularly important because HVs cause latent infections, therefore, any animal found to be serologically positive for HVs must be considered a lifelong carrier, even if the animal appears healthy. Serologic tests have been described for the detection of antibodies against FPTHV and LETV in sea turtles and against TeHV1 and TeHV3 in tortoises.[58–61] High seroprevalences were found in wild green sea turtles in Florida and in loggerhead turtles with an ELISA used for the detection of antibodies against glycoprotein H of an FPTHV.[58] Seropositivity did not correlate with clinical disease. However, testing for antibodies against this virus is not widely available. An ELISA has also been described for the detection of antibodies against LETV.[59]

Virus neutralization tests and ELISAs have been described for the detection of antibodies against TeHV1 and against TeHV3.[60,61] Virus neutralization testing with both TeHV1 and TeHV3 has shown that these viruses do not cross-react serologically; thus testing for antibodies against both is recommended in Europe. Detection of antibodies against these two viruses has been shown to depend on the tortoise species involved. Hermann's tortoises, which are particularly susceptible to HV infection and disease, do not often develop neutralizing antibodies after

TABLE 30.5 Select Viruses of Crocodilians and Common Methods for Virus and Antibody Detection

Virus Family and Virus Genus	Virus Species or Strain	Host Species	Clinical Signs and/or Pathologic Changes Described in Infected Animals[1]	Diagnostic Samples in Order from Least to Most Invasive (if known, priority samples in bold)[2]	Virus Detection	Serology
Herpesviridae[31]						
	Crocodyline HV 1–3	Saltwater crocodile (*Crocodylius porosus*), freshwater crocodile (*Crocodylus johnsoni*)	Conjunctivitis, pharyngitis, systemic lymphoid proliferation, encephalitis, lymphonodular skin infiltration	Conjunctiva, pharynx, skin, fat body, liver, kidney, lung, spleen, pancreas, intestine, thymus, heart, eye, brain	PCR, virus isolation	n.d.
Poxviridae						
Unclassified[96,97]	Caiman pox virus	Common caiman (*Caiman crocodilus*)	Gray-white papular skin lesions	Skin lesions	Histology and EM	n.d.
Crocodylidpoxvirus[101]	Nile crocodilepox virus (CRV) and others	*Crocodylus* spp.	Brownish wartlike skin lesions, in some cases, deeply penetrating skin lesions	Skin lesions	Histology and EM, PCR	n.d.
Flaviviridae						
Flavivirus[196,198,203,204]	*West Nile virus*	*Alligator mississippiensis, Crocodylus niloticus*	Neurologic signs (e.g., tremors, disorientation, opisthotonus), stomatitis, lymphohistiocytic proliferative cutaneous lesions	Cloacal swabs, **blood**, serum, **liver**, lung	RT-PCR*, virus isolation	NT, ELISA

*Method most commonly commercially available.
[1]A causative relationship between infection and disease has not always been proven, and, in some cases, viruses may also have been detected in animals with no overt clinical signs of disease.
[2]In general, tissues with lesions should be included in diagnostic testing in sick animals.
ELISA, Enzyme-linked immunosorbent assay; *n.d.,* not described; *NT,* neutralization test; *PCR,* polymerase chain reaction; *RT-PCR,* reverse-transcriptase PCR.

infection. In contrast, antibodies are frequently detected in spur-thighed tortoises that have been infected. An ELISA originally developed for the detection of antibodies against TeHV3 has also been adapted to detect antibodies against TeHV2 in California desert tortoises on the basis of putative serologic cross-reactivity between TeHV2 and 3.[40,62]

IRIDOVIRIDAE

Iridoviruses belonging to two (or three) genera have been detected in reptiles—ranaviruses, invertebrate iridoviruses and a putative additional genus in the family consisting of erythrocytic viruses. Although iridoviruses are enveloped, some viruses in this family (notably the ranaviruses) do not require their envelopes to be infectious. This makes them somewhat more resistant to disinfection (especially by organic solvents) than other enveloped viruses. Studies have shown that iridoviruses may be quite resistant to inactivation in water and soil at cool temperatures and may be able to survive over winter in regions with a temperate climate.[63] There is, however, evidence that ranaviruses can be inactivated in soil in the summer (at relatively high temperatures) within several weeks.[17] Under clean conditions, iridoviruses can be disinfected using standard virucidal disinfectants.

RANAVIRUSES

Ranaviruses have been increasingly shown to be important pathogens of ectothermic animals and are one of the major causes of global amphibian declines. Both phylogenetic studies and transmission studies indicate that some ranaviruses can be transmitted between reptiles, amphibians, and fish. Analysis of whole and partial genomes from reptilian ranaviruses indicates that several different species of amphibian ranaviruses, including viruses closely related to *Frog virus 3* (FV3), the type species of the genus *Ranavirus*, as well as *Bohle iridovirus* (BIV)-like, *common midwife toad virus* (CMTV)-like, and *European catfish virus* (ECV)-like viruses can infect reptiles.[64,65] Development of disease in infected animals is dependent on the virus strain, on the host species, and on environmental factors, particularly temperature. Some animals can become inapparent carriers, while in others, infection leads to severe disease and death.

Chelonians

In chelonians, ranaviral infection has been associated with lethargy, anorexia, nasal discharge, conjunctivitis, severe subcutaneous cervical edema, ulcerative stomatitis, and "red-neck disease" (Fig. 30.8). Infection induces an inflammatory response, and detection of an acute-phase protein response has been described.[66] Histologically, infected animals have been found to have hepatitis, enteritis, and pneumonia. Basophilic intracytoplasmic inclusions have in some cases been described in epithelial cells of the gastrointestinal tract and hepatocytes of infected animals, although inclusion bodies are not always detected. In a transmission study with box turtles (*Terrapene ornata ornata*) and red-eared sliders (*Trachemys scripta elegans*), intramuscular injection of a ranavirus led to disease, including lethargy, anorexia, ocular discharge, conjunctivitis, oral plaques, and death in some animals.[67] Studies on turtles that have survived ranavirus outbreaks have suggested that some animals may become persistently infected.[68] Other transmission studies have shown that environmental temperature can affect the development of clinical disease and death in infected turtles, with a higher mortality rate documented in infected red-eared sliders kept at 22°C than at 28°C.[69]

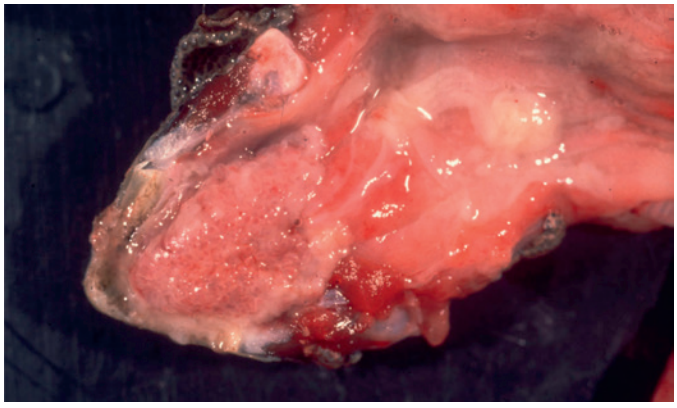

FIG 30.8 Hermann's tortoise (*Testudo hermanni*) infected with a ranavirus. Severe stomatitis. (Courtesy of Dr. Horst Posthaus, Universität Bern, Berne, Switzerland.)

Squamates

In the first description of infection in squamates, infected green tree pythons (*Morelia* [*Chondropython*] *viridis*) showed ulceration of the nasal mucosa, hepatic necrosis, and severe necrotizing inflammation of the pharyngeal submucosa.[70] In a giant leaf-tailed gecko (*Uroplatus fimbriatus*), infection was associated with granulomatous lesions in the tail and liver. In an Iberian mountain lizard (*Iberolacerta (Lacerta) monticola*), no overt disease was documented. That lizard was also infected with erythrocytic virus. In recent descriptions of ranavirus infections in various lizard species, variable skin lesions have been the most common lesion observed (Fig. 30.9). In many cases, infected lizards were from the international pet trade and had multiple other infections.[71–73]

Transmission. There is evidence that ranaviruses can be transmitted to reptiles by several different routes, including direct contact between animals, contact with contaminated water or pond sediment, and ingestion of infectious material, for example, from dead amphibians. In transmission studies, injection of virus into susceptible species has been successful,[67] but transmission via water has also been demonstrated.[74] Transmission by mosquitoes has also been proposed for FV3 in terrestrial turtles.[75]

Identification of Ranavirus Infections

Virus Detection. Molecular methods, including both conventional and real-time PCR, have been frequently used for the detection of ranaviruses in reptiles (see Tables 30.3 and 30.4). The gene most frequently targeted is the major capsid protein (MCP) gene.[76] A real-time PCR has been described for the detection of ranaviruses in eastern box turtles in the United States.[77] However, real-time PCRs can be very strain specific, and methods described so far in reptiles have generally only been able to detect FV3, not other ranavirus strains found in reptiles, thus the use of these methods could lead to false-negative results. Ranaviruses also grow well in cell culture and can be grown on a wide range of cell lines from reptiles, fish, mammals, and birds if the cells are kept at appropriate temperatures (below 32°C).

Samples for the detection of ranaviruses in chelonians should include liver and gastrointestinal tract. Spleen and kidney may also be virus positive.[67] In a transmission study viral DNA was detected in oral and cloacal swabs from intramuscularly infected red-eared sliders as early as 5 days postinoculation (p.i.) and until 26 days p.i. or until the animals died or were euthanized.[67] Oral and cloacal swabs and blood have all been used to detect ranavirus in naturally infected chelonians.[78,79]

Samples for ranavirus detection in squamates should include liver tissue and skin. A ranavirus has been detected in the blood of a live

FIG 30.9 (A) Ranavirus-infected Asian glass lizard (*Dopasia gracilis*). Skin lesions on the ventral surface of the body. An invertebrate iridovirus was also found in the skin of this animal. (B and C) Skin alterations observed in ranavirus-infected green anoles (*Anolis carolinensis*). An invertebrate iridovirus was also detected in these animals. (B) Multiple ulcera on the ventral abdominal surface. (C) Beige gray discoloration of the skin at the lateral abdomen. (D) Skin lesions in a ranavirus-infected central bearded dragon (*Pogona vitticeps*). (From Stöhr et al, 2013.)[72]

Iberian mountain lizard.[80] The optimal sample for the detection of ranaviruses in live squamates is unknown, but testing of mixed oral/cloacal swabs and blood is recommended. Skin biopsies can also be tested in cases with dermatologic signs.

Serology. An ELISA for the detection of anti-ranavirus antibodies in Burmese star tortoises, gopher tortoises (*Gopherus polyphemus*), and eastern box turtles has been developed.[81] Testing of various species with and without previous histories of ranaviral infection showed a low prevalence of anti-ranavirus antibodies in all cases.[81] This ELISA has also been adapted for the detection of anti-ranavirus antibodies in *Testudo* spp. in Europe.[78]

INVERTEBRATE IRIDOVIRUSES (IIV)

Until recently, viruses of the genus *Iridovirus* had only been described in invertebrates, in which they can cause lethal infections in a wide range of host species. These viruses have been repeatedly detected in various species of crickets sold as feed animals in the pet trade in Europe. Infected crickets show hypertrophy and bluish iridescence of the affected fat body cells.[82] In reptiles, IIVs have been isolated from the lung, liver, kidney, and intestine of two bearded dragons (*Pogona vitticeps*) and a chameleon (*Trioceros* (*Chamaeleo*) *quadricornis*) and from the skin of a frilled lizard (*Chlamydosaurus kingii*). The frilled lizard showed poxlike skin lesions, and one of the bearded dragons had pneumonia. The other lizards had died with nonspecific signs. A host-switch of this virus from prey insects to the predator lizards was postulated.[83] An IIV was isolated from several tissues of a high-casqued chameleon (*Trioceros* [*Chamaeleo*] *hoehnelii*) and successfully used to infect crickets of the species *Gryllus bimaculatus*.[84] IIV-like viruses have also been detected in multiple other lizards from various owners, as well as from crickets,[85] and in multiple lizards with skin lesions in which other viruses (e.g., ranaviruses) were detected (Fig. 30.9A–C).[71,72] The clinical significance of IIV infection in lizards is not always clear, because virus has been detected in clinically healthy animals, as well as in animals that were emaciated, had skin lesions, or died acutely.

Identification of IIV Infections

IIVs have been detected by virus isolation, conventional, and real-time PCRs (see Table 30.4). All of the methods used to detect IIVs in samples from reptiles can also be used to detect these viruses in feed insects.[85] IIVs grow on multiple cell lines from insects, reptiles, and mammals at 28°C. Because feed insects are often infected with IIVs, samples from the gastrointestinal tract, including oral and cloacal swabs in live animals,

VetBooks.ir

should not be used for IIV detection in reptiles. Skin biopsies have been used for virus detection in live animals with skin lesions, and various internal tissues including liver have been successfully used in dead animals. IIVs are often detected together with other infectious agents, particularly adenoviruses (AdVs) in agamids.

ERYTHROCYTIC VIRUSES

Viral erythrocytic infections have been described in fish and amphibians as well as lizards, snakes, and turtles. These viruses have been preliminarily classified as iridoviruses, and recent studies based on partial sequences of the DNA polymerase gene have shown that erythrocytic viruses (also called erythrocytic necrosis viruses) of reptiles and fish probably belong to a new genus in the family *Iridoviridae*.[80,86,87] They have been hypothesized to be transmitted by invertebrates. These viruses are associated with inclusions in erythrocytes of infected animals (Fig. 30.10), and inclusions were originally believed to be parasites (*Toddia* and *Pirhemocyton* sp.). Clinical signs in infected animals range from apparently healthy to severe systemic disease and death. Lethargy and weight loss associated with anemia have been reported. In a study of an outbreak in bearded dragons, infection was associated with lesions on the tongue, reduced appetite and weight loss, lethargy, and blepharospasmus in several infected animals.[88] Morphological changes in infected erythrocytes, including anisocytosis and polychromasia, as well as hepatic necrosis have been documented in reptiles with erythrocytic necrosis virus infections. A transmission study conducted with the lizards *Iberolacerta* (*Lacerta*) *monticola* and *Lacerta schreiberi* showed that infection with these agents can become systemic and may lead to death if the animals are kept at suboptimal temperatures.[89]

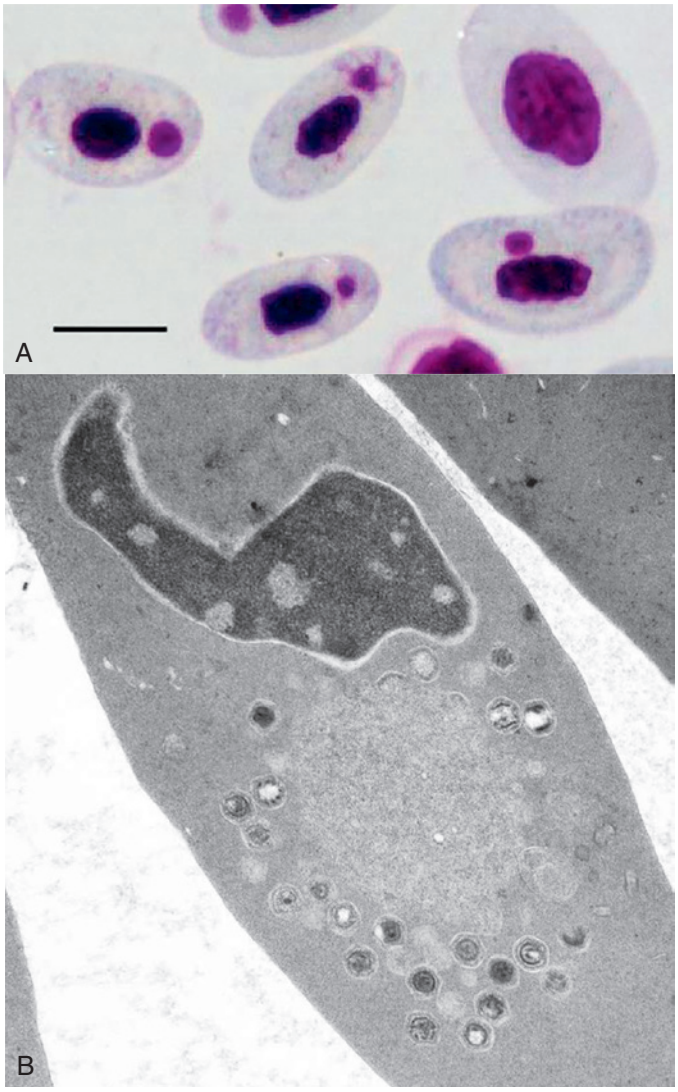

FIG 30.10 Iberian rock lizard (*Iberolacerta monticola*) erythrocytes with erythrocytic virus infection. (A) Erythrocytic necrosis virus has caused intracytoplasmic inclusions in multiple erythrocytes. H&E stain. (B) Transmission electron photomicrograph of the inclusion in an erythrocyte. The inclusions consist of viral precursors and viral particles in a crystalline array. (Courtesy of Antonio Pedro Alves de Matos, Curry Cabral Hospital, Lisbon, Portugal.)

Identification of Erythrocytic Viruses

Erythrocytic viruses have generally been diagnosed by detection of inclusions in erythrocytes in blood smears, followed by electron microscope confirmation of their etiology. Following partial characterization of the genomes of erythrocytic viruses from fish and reptiles, several PCRs have been published and may prove usefull for diagnostics.[87,88] Sampling for these viruses should always include peripheral blood as well as liver in dead animals.

PAPILLOMAVIRIDAE

Papilloma-like lesions (Fig. 30.11) have been repeatedly described in various reptiles. Their cause is not always known, and various viruses have been associated with such lesions. Papillomaviruses have only been associated with them in select cases. The papillomaviruses are highly host specific and tissue restricted. They generally cause benign tumors (warts, papillomas) in their natural host. Papillomaviruses are highly resistant to inactivation and can persist in the environment for long periods of time.

Papillomaviruses in Squamates

The first description of a papilloma-like virus (papovavirus) in reptiles was in wartlike skin lesions in a European green lizard. The virus was identified by electron microscopy based on morphologic characteristics. Herpeslike and reolike viruses were also identified in the lesions.[22] A papillomavirus has also been detected in a diamond python (*Morelia spilota spilota*) with multiple small black papillated and pedunculated skin proliferations, approximately 3 mm in diameter, as well as signs of respiratory disease.[90] The skin lesions were found to be a papilloma-like

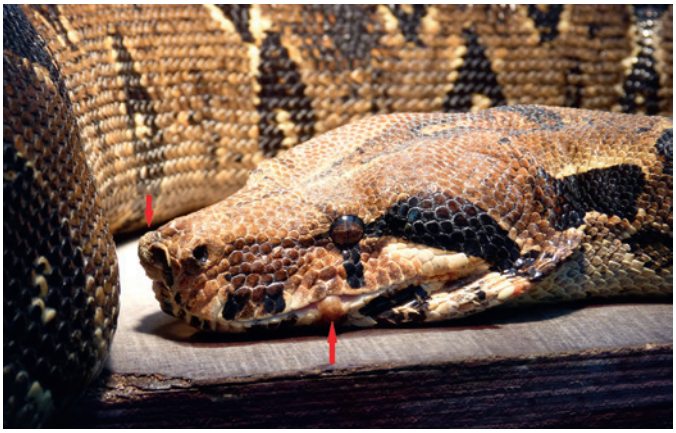

FIG 30.11 Wart-like lesions on the mouth and nares of a boa constrictor (*Boa constrictor*). This animal had inclusion body disease (IBD).

neoplasia, and inclusion bodies were found in some of the papillomas. A papillomavirus was identified in skin biopsies from this animal by PCR.[90]

Papillomaviruses in Chelonians

In chelonians, papillomaviruses have been described in Bolivian side-neck turtles (*Platemys platycephala*) with circular papular skin lesions that in some cases progressed to areas of necrosis. Viral particles were detected by electron microscopy in skin biopsies.[91] Papillomavirus-like particles were detected in a lung wash (but not in oral scrapings) by electron microscopy in a Russian tortoise with a history of stomatitis.[92] Lesions similar to those described in the Bolivian side-neck turtles were found in a loggerhead turtle and a green sea turtle.[93] The lesions resolved after several months. These two viruses (CcPV-1and CmPV-1) were shown to be distinct from one another and from previously described papillomaviruses.[93]

Identification of Papillomavirus Infections

Diagnosis of papillomavirus infections has been mostly by detection of viral particles in infected tissues via electron microscopy. The complete sequences of CcPV-1and CmPV-1 have been determined as has the complete sequence of a snake papillomavirus, so future development of diagnostic PCRs is possible.[94,95] However, these viruses are phylogenetically quite distant from one another, and nothing is known about genetic diversity of most reptilian papillomaviruses. Tissues for analysis should include affected skin.

POXVIRIDAE

Although poxviruses are enveloped, they are much more resistant to inactivation in the environment than other enveloped viruses and can remain infectious at ambient temperatures for months, especially when protected by cellular material (e.g., sloughed skin cells or blood). They are, however, inactivated by standard virucidal disinfection protocols.

The first report of poxvirus-associated disease in a reptile was in captive caimans (*Caiman crocodilus*) in the United States.[96] Similar cases have since been reported from caimans throughout the world.[97,98] Affected animals develop gray-white skin lesions on various parts of the body (Fig. 30.12).

Poxviruses have also been detected in Nile crocodiles (*Crocodylus niloticus*), as well as saltwater crocodiles (*Crocodylus porosus*) and freshwater crocodiles (*Crocodylus johnsoni*) in Australia.[99] Infected animals develop brownish wartlike skin lesions that can occur over the entire body (Fig. 30.13). Infection is associated with high morbidity but low mortality. A recent study of farmed saltwater crocodiles in Australia found that 40% to 45% of the examined animals were affected with mild cutaneous poxvirus infections.[100] An atypical form of crocodile pox has also been observed in Nile crocodiles. This virus was associated with deeply penetrating skin lesions in farmed crocodiles in Africa. A PCR was developed and used to amplify a portion of the genome of the virus associated with these lesions. Analysis of the PCR product showed that this virus was related to, but not identical with, crocodilepox virus (CRV).[101] Transmission is likely by contaminated water, possibly from infected wild animals as well as direct contact between animals. Infection by arthropod vectors as described for poxviruses of other animals may be possible.

Poxvirus infections have been detected in individual cases in other reptiles by electron microscopy. Papular skin lesions around the eyes of a Hermann's tortoise were found to contain poxlike viruses.[102] A flap-necked chameleon (*Chamaeleo dilepis*) in Tanzania was found to have two different types of intracytoplasmic inclusions in circulating monocytes. The inclusions were found to be caused by a chlamydialike organism and a poxlike virus.[103] A poxvirus infection in a tegu lizard was associated with brown papules on various parts of the body.[104]

Identification of Poxvirus Infections

Poxvirus infection in crocodilians has generally been diagnosed on the basis of the detection of intracytoplasmic inclusions in hypertrophic epithelial cells followed by electron microscopic demonstration of viral particles within these inclusions or by electron microscopic detection of viral particles in unfixed scrapings from lesions.[101,105] A PCR for the detection of CRV in scrapings from fresh lesions has also been described (see Table 30.5).[101]

CIRCOVIRIDAE AND TORNOVIRUS

Circoviruses are very resistant to inactivation in the environment and are very difficult to disinfect. A single circolike virus has been reported in macrophages of a painted turtle (*Chrysemys* sp.), with multifocal areas of necrosis in the spleen and liver. The virus was identified based on electron microscopy.[105] Studies of the genomes of snakes have shown that sequences of endogenous circoviruses can be found in these animals.[106]

A novel ssDNA virus with a circular genome (named sea turtle tornovirus 1, STTV1) was detected in two green sea turtles with fibropapillomatosis using metagenomics. Part of the genome was found

FIG 30.12 Caiman (*Caiman crocodilus*) with poxvirus infection. The skin lesions are covered with a white-gray crust. (Courtesy of Fritz W. Huchzermeyer, University of Pretoria, Onderstepoort, South Africa.)

VetBooks.ir

to be distantly related to the circovirus *Chicken anemia virus*. Both of the infected turtles were severely afflicted with fibropapillomatosis. STTV1 was detected in the fibropapillomas, as well as in external swabs from the conjunctiva, oral cavity, cloaca, unaffected skin, and numerous internal tissues. The herpesvirus FPTHV was also detected in the fibropapillomas, but not in other tissues. STTV1 was also detected in leeches collected from one of the green sea turtles. It was hypothesized that STTV1 might affect the immune system of infected sea turtles or that it might be an opportunistic pathogen.[107]

PARVOVIRIDAE

The parvoviruses are highly resistant to inactivation in the environment and are therefore difficult to disinfect. They are particularly resistant to heat. The only classified reptile parvovirus, *Squamate dependoparvovirus 1*, is a species within the genus *Dependoparvovirus*.[108] Dependoparvoviruses are generally associated with a helper virus (adeno- or herpesviruses). In reptiles, parvolike viruses were first described by electron microscopy in the duodenum of a four-lined rat snake (*Elaphe quatuorlineata*) and of an Aesculapian snake (*Zamenis* [*Elaphe*] *longissimus*), both with gastrointestinal disease. Adenolike viruses were also detected in the duodenums of both and herpes- and picornalike viruses in the duodenum of one snake.[109] Co-infections of adenovirus- and parvoviruslike viruses have been described repeatedly from both snakes and lizards, with clinical signs including gastrointestinal disease, as well as neurologic signs and pneumonia.[18] A parvovirus but no helper virus was detected in a bearded dragon with malfunctioning ovaries and aberrant yolk formation, indicating that this virus is capable of independent replication.[110] Parvoviruses isolated in cell culture from a boa constrictor and a ball python (*Python regius*) were identical and were given the name serpentine adeno-associated virus (SAAV) or *Squamate dependoparvovirus 1*. It is unclear whether SAAV can replicate without a helper virus, as both isolates were obtained together with adenoviruses.[111]

Diagnosis of parvoviruses in reptiles has been by isolation in cell culture in various reptilian cell lines and, more recently, by PCR detection of viral DNA using degenerate primers targeting a portion of the genome of dependoparvoviruses.[110] Tissues from the intestinal tract have most often been used for virus detection, although mixed samples from various internal tissues have also tested positive in some cases.

HEPADNAVIRIDAE

Hepadnaviruses are enveloped viruses that include *Hepatitis B virus* (HBV). Integration of viral DNA into the host genome is rare but possible. Hepadnaviruses generally have narrow host specificity, although studies of virus evolution indicate frequent, recent host-switching, with incongruencies between host and virus phylogenies.[106] They are hepatotropic, and infection may be transient or persistent. Endogenous hepadnavirus sequences have been detected in the genomes of avian species and in rattlesnakes (*Crotalus mitchellii*) and the king cobra (*Ophiophagus hannah*).[106] In a transmission study, HBV-positive human serum was inoculated intramuscularly into yellow pond turtles (*Mauremys* [*Clemmys*] *mutica*) and Reeves' turtles (*Mauremys* [*Geoclemys*] *reevesii*). Viral antigene and antibodies against HBV were detected in most of the inoculated animals over a period of several weeks, and viral antigen and viral DNA were detectable in cultured liver cells from the inoculated animals. No signs of acute hepatitis were noted in the animals, although edematous changes in hepatocytes and minor cellular infiltration were reported and attributed to an inflammatory response.[112] HBV DNA has also been detected in a cloacal swab from a bearded dragon. The animal was from a reptile rescue in Germany and appeared clinically healthy at the time of sampling (Ball et al, Proc 9th Int Cong Vet Virol, 2012, p 60).

RETROVIRIDAE

Historically, retrovirus nomenclature was based on electron microscopy and classified members of the genera *Alpharetrovirus* and *Gammaretrovirus* as C-type viruses (assembly of immature capsids at the plasma membrane) and members of the genus *Betaretrovirus* as A-type particles (immature capsids) in the cytoplasm. A-type particles then budded with either B- or D-type morphology.[114] Retroviruses are widely distributed among vertebrates as exogenous infectious agents. Endogenous proviruses resulting from infection of germline cells also occur widely. Various retrovirus-like particles have been described in healthy snakes and in snakes with neoplasms.[18] Retroviral sequences have been detected in the genomes of many different reptiles. Systematic searches for sequences of murine leukemia–related retroviruses have shown that related viruses can be found in a wide range of animals, including reptiles, amphibians, birds, and mammals. In reptiles these viral sequences have been detected in the genomes of a number of chelonians, squamates, and in tuatara (*Sphenodon punctatus*).[115–117] A study on endogenous retroviral sequences from crocodilians showed that the genomes of several different species from different families in the order Crocodylia contain retrovirus sequences that are related to one another but highly divergent from other members of the *Retroviridae*, some of which appear to be species specific.[118] Retroviruses have been repeatedly isolated from boid snakes with inclusion body disease (IBD),[119,120] although IBD is now believed to be caused by arenaviruses. A retrovirus was isolated from an Indian rock python (*Python molurus*) that was kept together with IBD-positive pythons. Further study indicated that this is a highly expressed endogenous virus of pythons that is not associated with IBD. A similar virus was also identified in blood pythons (*Python curtus*).[121]

REOVIRIDAE

The family *Reoviridae* consists of non-enveloped viruses that are very stable in the environment. Reoviruses of reptiles that have been characterized so far have been classified in the genus *Orthoreovirus*. Viruses in this genus infect only vertebrates and are spread by the respiratory or fecal-oral route. Many orthoreovirus infections may cause no clinical signs of disease, or only mild upper respiratory tract illness and/or enteritis, while other species have been shown to cause significant and often fatal disease in avian and mammalian hosts. Five species have been classified in the genus *Orthoreovirus*, including *Reptilian orthoreovirus*. All but the *Mammalian orthoreovirus* isolates are fusogenic in cell culture.[122] Full genome sequencing of several reptilian othoreoviruses has shown that these may have originated from a common ancestor with fusogenic mammalian reoviruses and that they likely represent different species in the genus *Orthoreovirus*.[123,124] There is also evidence that individual reptilian reovirus strains are not host species specific.[125]

Reovirus infections have been relatively frequently described in reptiles. In lizards, reoviruses have been described by electron microscopy associated with papillomas in green lizards.[22] Other viruses were also detected in those lesions. Isolation of reoviruses from lizards has been described from green iguanas that died with no specific clinical signs in Germany[126] and from a spiny-tailed lizard (*Saara* [*Uromastyx*] *hardwickii*) in the United Kingdom that died during a disease outbreak associated with pneumonia.[127] An outbreak of reovirus-associated enteropathy and hepatopathy was described in leopard geckos (*Eublepharis macularius*) in the United States (Garner et al, Proc ARAV, 2009, p 82). Serologic tests have provided evidence of reovirus infections among other lizards as well, including wild-caught lizards in Central America.[129,130]

In snakes, reoviruses have been isolated from Chinese vipers (*Azemiops feae*) with enteritis, from ball pythons, emerald tree boas, and Aesculapian snakes.[18] Virus was isolated from the brain of a prairie rattlesnake (*Crotalus viridis*) with signs of central nervous system (CNS) disease, including incoordination, loss of proprioception, and convulsions.[131] A reovirus was detected in rough green snakes (*Opheodrys aestivus*) in the United States with a necrotizing hepatitis.[132] Rough green snakes imported into Hungary from the United States were also found to be infected with an orthoreovirus (Gál et al, Proc 8th Int Cong Vet Virol, 2009, p 228). Reoviruses were isolated from Moellendorff's rat snakes (*Orthriophis* [*Elaphe*] *moellendorffi*) and beauty snakes (*Orthriophis* [*Elaphe*] *taeniuris*) with fatal respiratory disease. The virus isolated from that outbreak was inoculated intratracheally, orally, and nasally into a black rat snake (*Pantherophis* [*Elaphe*] *obsoletus*). That snake died with pneumonia 26 days p.i. A reovirus was reisolated from the lungs of the dead snake.[134] Reoviruses were isolated from three boa constrictors with IBD in Germany, and a transmission study was carried out using one of these isolates. No specific disease or pathology was observed in the infected animals, although the virus was reisolated from the infected snakes up to 18 weeks p.i.[135] A reovirus was also detected repeatedly in a collection of corn snakes with increased mortality, as well as reported dyspnea, vomitus, and cachexia. A ferlavirus and an adenovirus were also detected in the same collection.[136]

Reovirus infections have been much less frequently described in tortoises. In one case a reovirus was isolated from a captive spur-thighed tortoise in Switzerland. The tortoise was cachectic and had a necrosis of the epithelium of the tongue.[137] A disease outbreak in spur-thighed tortoises in Germany with sudden softening of the carapax in juvenile animals, as well as an increased mortality rate, was associated with nematode, picornavirus, and reovirus infections in multiple animals (Blahak et al, Proc 33 Tagung der DVG Fachgruppe AVID 2014, pp 59-60).

Identification of Reovirus Infections

Virus Detection. Reoviruses of squamates are relatively easily isolated in cell culture (VH2 and IgH2), in which they cause the formation of giant syncytia. Virus has been isolated from oral and cloacal swabs from live snakes[136] and from liver, kidney, spleen, intestine, brain, and lung of dead animals. An RT-PCR has been described and used to detect and characterize reoviruses from various reptiles[125] but appears to be less sensitive than virus isolation in cell culture (see Tables 30.3 and 30.4).[136]

Serology. Virus neutralization tests have been used to detect antibodies against reoviruses in wild-caught green iguanas, Utila iguanas (*Ctenosaura bakeri*), spiny-tailed iguanas (*C. similis*), and knob-scaled lizards (*Xenosaurus grandis*).[129,130] In a study surveying wild-caught spur-thighed tortoises in Turkey, 4.9% of the animals tested had antibodies against a tortoise reovirus.[139] A study of the serologic cross-reactivity of six different reovirus isolates from lizards showed that at least three different serogroups exist; thus results of testing for antibodies using a virus neutralization test will depend on the virus used.[126]

BORNAVIRIDAE

Bornaviruses are neurotropic and do not cause the death of infected cells. Transmission may be direct or indirect, although bornaviruses of mammals do not appear to be readily transmissible between hosts. Bornaviruses are easily disinfected. In infected animals, virus persists in the host-cell nucleus. Endogenous bornalike elements (EBL) that have been integrated into the host genome have been found in the genomes of multiple species.[140] Both exogenous and endogenous bornaviruses have been detected in various reptile species in recent years. EBLs have been detected in the genomes of snakes, including speckled rattlesnakes (*Crotalus mitchellii*) and Burmese pythons (*Python bivittatus*).[106] Bornavirus N- and X/P-like sequences have been described in the venom glands (but not the genomic DNA) of a Gaboon viper (*Bitis gabonica*),[141] indicating that this is an exogenous virus, although no information about the clinical relevance of that virus (preliminarily named reptile bornavirus) is available. The full genome of a bornavirus, named Loveridge's garter snake virus 1, was sequenced from tissues of a museum specimen of an African garter snake (*Elapsoidea loveridgei*). It is unknown if any disease was associated with infection in that animal.[142] Recently, novel bornaviruses have been detected in pythons with neurologic disease in Australia. Virus detection by PCR has been successful in live animals from oral-cloacal swabs and whole blood, and from a range of tissues from dead animals. An oral-cloacal swab appears to be the priority sample from a live animal, and the brain appears to be the priority sample from a dead animal. Further research on these viruses and their clinical significance is ongoing, but preliminary results indicate that snakes can be persistently infected, and the correlation between clinical signs, histologic findings, and the presence of virus are not strong (Hyndman T, personal communication, 2016). These findings are not inconsistent with other bornaviruses known to be pathogenic.

PARAMYXOVIRIDAE: FERLAVIRUS

Paramyxoviruses (PMVs) are easily inactivated in the environment and by standard disinfectants. Some, but not all, members of this family have hemagglutinating and neuraminidase activity. The PMVs documented in reptiles belong to the genus *Ferlavirus*, which contains PMVs detected in snakes, lizards, and chelonians. These viruses have also been referred to as ophidian PMVs or reptilian PMVs. The genus *Ferlavirus* is named after the first PMV isolated from a snake, Fer-de-Lance virus (FDLV),[143] which is considered the type species of the genus.[108] All ferlaviruses hemagglutinate chicken red blood cells and hemagglutination inhibition assays have been used for serologic comparisons between isolates, as well as for diagnostic testing. Serologic studies have, however, shown that several ferlavirus strains can be distinguished from one another.[144,145] Isolates from squamates have been divided into three different genotypes (A, B, and C). A fourth genotype ("tortoise") has been isolated from a tortoise.[136,146] These genotypes do not appear to be host-species specific, and types A and B viruses have been found in a wide range of squamate hosts, as well as in chelonian hosts in individual cases.

Ferlaviruses in Squamates

The first PMV outbreak in snakes was described in 1976 in a serpentarium in Switzerland. During that outbreak, 87% of the snakes in one room died with dyspnea, opisthotonus, and apathy, followed by abnormal activity, mydriasis, and terminal convulsions.[147] Transmission appeared to be possible via aerosol, as well as via direct contact between snakes and fomites. Since that outbreak, ferlavirus outbreaks have been documented in numerous snake collections in North and South America and Europe, and the virus has been detected in wild-caught snakes from South America. Common clinical signs described in infected snakes include abnormal posturing, regurgitation, anorexia, head tremors, abnormal respiratory sounds, and exudate in the oral cavity (Fig. 30.14). In many cases, no clinical signs may be noticed, and infected animals may be found dead in their enclosures.[147,148] Severe disease has mostly been described in viperid snakes, but ferlaviruses have also been found in snakes from the families Colubridae, Elapidae, Boidae, and Pythonidae.[149] Koch's postulates have been fulfilled for pulmonary lesions associated with ferlavirus infection in Aruba Island rattlesnakes (*Crotalus durissus*

FIG 30.14 Bush vipers (*Atheris squamigera*) infected with ferlaviruses. (A) Dyspnea and bloody secretions in the oral cavity. (B) Opisthotonus. (Courtesy of Jutta Wiechert.)

unicolor). A ferlavirus isolated from several tissues of an Aruba Island rattlesnake that died of the infection was inoculated intratracheally into four Aruba Island rattlesnakes. Several snakes developed pulmonary signs, including blood in the lungs, trachea, and oral cavity. The two animals that were not euthanized earlier died 19 and 22 days p.i.[150] In another transmission study, genotypes A, B, and C ferlaviruses were inoculated intratracheally in corn snakes. That study demonstrated clear differences in pathogenicity between the three isolates used, with the type B virus causing the greatest pathology, with the lungs most severely affected.[151]

Gross abnormalities are most consistently found in the lungs of infected snakes. Changes include congestion and hemorrhage. Histologic findings often show proliferative interstitial pulmonary disease with proliferation and vacuolation of epithelial cells lining the faveoli. In rare cases, intracytoplasmic inclusions can be seen in lining epithelial cells.[148,150]

Although ferlaviruses are most commonly described in snakes, these viruses have also been detected in several species of lizard, including a spotted false monitor (*Callopistes maculatus*), an emerald tree monitor, a flathead knob-scaled lizard (*Xenosaurus platyceps*), and a group of Caiman lizards (*Dracaena guianensis*).[149] Ferlavirus infections in lizards have been associated primarily with pneumonia, although virus infections in clinically healthy lizards have been documented. The viruses do not appear to be host specific, and transmission between different species of snakes and lizards, as well as chelonians may be possible.

Ferlaviruses in Chelonians

Descriptions of ferlavirus infections in chelonians are rare. These infections have been associated with dermatitis (Zangger et al, Proc 4th Int Coll Path Med Rept Amphib, 1991, pp 25-29) and pneumonia.[146,153] In a single case, a PMV was isolated from a Hermann's tortoise with pneumonia. That virus was further characterized and found to be related to but distinct from the described ferlaviruses from snakes and lizards so far.[146] In another case, two distinct squamate ferlaviruses were detected in a leopard tortoise with pneumonia (Fig. 30.15). The detected viruses were each most closely related to ferlaviruses from snakes. However, it was unclear whether the virus was a causative agent, because no virus was detected in the lungs of the diseased animal.[153] Antibodies against ferlaviruses have been detected in several tortoise species.[154]

FIG 30.15 Leopard tortoise (*Stigmochelys pardalis*) with severe pneumonia. A ferlavirus was detected in this animal. (From Papp T, Seybold J, Marschang RE. Paramyxovirus infection in a leopard tortoise [*Geochelone pardalis babcocki*] with respiratory disease. *J Herp Med Surg* 2010;20:64–68. With permission.)

Identification of Ferlavirus Infections

Virus Detection. Ferlaviruses were first diagnosed in snakes by isolation in cell culture.[143] Virus isolation has since been used in many cases to detect these viruses in clinical samples from snakes and lizards. A number of RT-PCRs have also been described for the detection of ferlaviruses in reptiles. An RT-PCR targeting the conserved large polymerase (L) gene has been used to detect all of the ferlavirus genotypes detected to date.[146,155] In live animals, oral and cloacal swabs, as well as transtracheal washes, can be used as diagnostic samples. Oral and cloacal shedding can be inconsistent, and tracheal washes (Fig. 30.16) were found to be the most sensitive sample for ferlavirus detection in snakes during a transmission study, although virus was inoculated intratracheally in that study.[151] In dead animals, the highest viral load is found in the lung, and this tissue is recommended for testing (see Tables 30.3 and 30.4).[145,151] In addition, virus was frequently detected in intestine, pancreas, and brain.[151] The RT-PCR is not highly specific for ferlaviruses, and

VetBooks.ir

FIG 30.16 Collection of a tracheal wash from a ball python (*Python regius*). Tracheal washes are the preferred sample for ferlavirus testing.

false-positive reactions have been shown to occur. For this reason, PCR products of the expected size (566 base pairs) should be sequenced. A direct comparison of virus isolation and virus detection by PCR showed that the PCR was more sensitive, although the highest sensitivity was achieved using a combination of both methods.[151]

Serology. Antibodies against ferlaviruses can be detected by hemagglutination inhibition (HI) assays using chicken red blood cells (see Tables 30.3 and 30.4). HI testing has been used repeatedly to detect exposure to ferlaviruses in squamates, including wild-caught snakes and lizards.[129,130,148] Serologic cross-reactivity among ferlaviruses and between ferlaviruses and other PMVs is not fully understood, and some (but not all) ferlaviruses have been shown to serologically cross-react with some avian PMVs.[145] Although serologic cross-reactivity exists between ferlaviruses, there is some indication that testing with different virus isolates will lead to different results. In a study comparing results of HI testing of plasma from eastern massasaugas *(Sistrurus catenatus catenatus)* from three different laboratories, different results were obtained from each; thus interpretation of results may be difficult.[156] Following transmission studies with three different ferlavirus genotypes (A, B, and C), clear differences were documented in the antibody titers detected against each virus, with lower or no titers detected in the group in which the highest pathogenicity was documented (infected with a genotype B virus), so that viral factors and pathogenicity may also play a role in development, titers, and persistence of antibodies.[157] Detection of anti-PMV antibodies indicates that an animal has been exposed to ferlaviruses or serologically related viruses. Persistence of ferlavirus infection in reptiles has not been recorded, but there is clinical evidence that this may occur. It is not known how long virus replication and shedding may persist after the development of HI antibodies.

SUNVIRIDAE: SUNSHINEVIRUS

A virus that is distantly related to the PMVs but differs distinctly from the ferlaviruses has been described in snakes in Australia. The virus has been named *Sunshinevirus* for the geographic location of the first isolation on the Sunshine coast of Australia. It has now been placed in a new family *Sunvirdae* in the order *Mononegavirales*. This virus was associated with neurorespiratory disease in Australian pythons and has been detected in black-headed pythons (*Aspidites melanocephalus*), woma pythons (*A. ramsayi*), spotted pythons (*Antaresia maculosa*), and carpet pythons (*Morelia spilota* spp. and *M. bredli*).[158] A single report exists of Sunshinevirus detection outside of Australia, in a ball python in Germany (Marschang et al, Proc ARAV, 2013, p 15). Clinical signs associated with infection may be similar to those reported for ferlavirus infections or be nonspecific (e.g., lethargy, inappetance). Histologically, the hindbrain white matter often exhibits spongiosis and gliosis. Neuronal necrosis has been described in severe cases. Some snakes may develop bronchointerstitial pneumonia.[160] Transmission is assumed to occur horizontally from oral and cloacal secretions, and there is evidence that the virus can also be transmitted vertically, although it may lead to the death of infected embryos.[161]

Sunshinevirus was originally detected by isolation in VH2 from diseased and contact snakes. A PCR has been described for the detection of this virus and appears to be more sensitive than isolation in cell culture. Virus detection has been carried out from oral and cloacal swabs in live animals. In dead animals, the virus is most often detected in the brain (see Table 30.4).[160]

RHABDOVIRIDAE

In reptiles, rhabdovirus infections have been documented based on both serology and virus detection. Little is known about the importance of rhabdoviruses in reptiles, but the rhabdoviruses detected in reptiles so far all appear to be arboviruses, some of which are also capable of infecting mammals. Antibodies against a vesicular stomatitis virus and Bahia Grande virus have been detected in wild-caught reptiles in Texas, while Charleville virus and Almpiwar virus have been isolated from lizards in Australia. Marco, Timbo, Chaco, and Sena Madureira viruses have been isolated from teiid lizards in South America as has another rhabdovirus from Caiman lizards.[162] Transmission studies with the rhabdovirus viral hemorrhagic septicemia virus (VHSV) and snapping turtles (*Chelydra serpentina*) and red-eared sliders have shown that aquatic turtles may be a vector for VHSV and that this virus may be able to infect turtles.[163] No clinical disease has been reported in association with these viruses in reptiles.

ARENAVIRIDAE

The family *Arenaviridae* has recently been divided into two genera, *Mammarenavirus* and *Reptarenavirus*. The genus *Reptarenavirus* was created to include arenaviruses detected in snakes and associated with IBD. These viruses have only been detected in snakes (no mammalian host), and their proteins differ from those of mammalian arenaviruses in several aspects.[164] Reptarenaviruses have been shown to be a genetically diverse group of viruses, including multiple species. It is even possible that arenaviruses of snakes may represent more than one genus.[165] Sequencing of full or partial genomes from a number of infected snakes has also shown that infection with multiple genotypes is common in captive infected snakes and that recombination and reassortment are common occurences.[166] Diversity is unequal between the genomic segments, with more L genotypes detected in infected animals than S genotypes. It has been hypothesized that human activity has led to an increased rate of viral evolution and that mixing of infected animals in captivity is a factor in virus diversity and in disease development.[165,166] The prevalence of reptarenaviruses in snakes in captivity, the existence of a possible reservoir hosts other than boid and/or pythonid snakes, and the genetic diversity of arenaviruses in the wild are not yet known.

INCLUSION BODY DISEASE (IBD)

IBD is a disease of snakes of the families Boidae and Pythonidae that has been described worldwide in captive snakes. The disease is characterized by the formation of intracytoplasmic inclusions in neurons and

VetBooks.ir

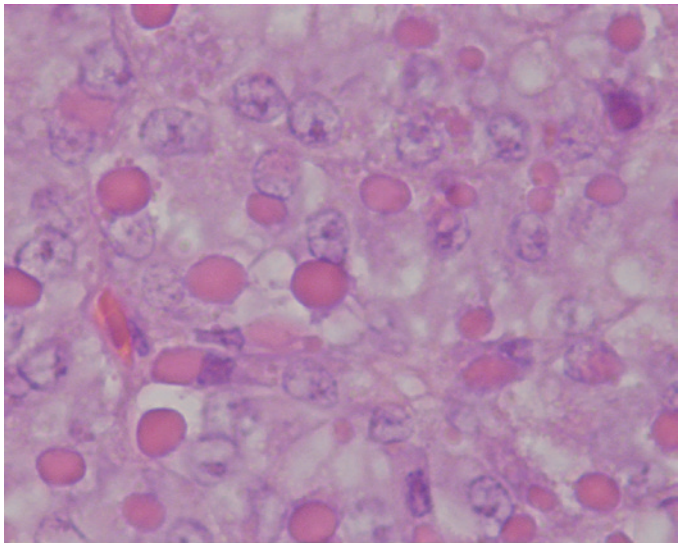

FIG 30.17 Multiple eosinophilic intracytoplasmic inclusion bodies in the pancreas of a *Boa constrictor* with IBD. H&E stain, 1000x. (Courtesy of Kim Heckers.)

in epithelial cells of various organs (Fig. 30.17). The etiology of IBD was long unknown, and various viruses have been proposed as possible causes of this disease over time.[119,120] Reptarenaviruses are now believed to be the cause of IBD.[167–169] In the first study describing the detection of these viruses, genetically variable arenaviruses were detected in 6 of 8 tested IBD-positive snakes and in none of 18 IBD-negative snakes by metagenomics and RT-PCR.[167] The inclusions are made up of a unique protein (inclusion body disease protein, IBDP), which appears to correspond to the reptarenaviral nucleoprotein.[167,168]

IBD was originally most commonly detected in Burmese pythons but is now most commonly diagnosed in boa constrictors.[105] Anecdotally, pythons tend to develop clinical diseases more quickly, while boas may remain inclusion-body positive but clinically healthy (or low morbidity, chronically diseased) for extended periods of time. The host range of IBD also includes the green anaconda (*Eunectes murinus*), yellow anaconda *(Eunectes notaeus)*, rainbow boa (*Epicrates cenchria*), Haitian boa (*Chilabothrus* [*Epicrates*] *striatus*), Madagascan boa (*Acrantophis madagascariensis*), annulated tree boa (*Corallus annulatus*), Indian rock python, reticulated python (*Malayopython* [*Python*] *reticulatus*), ball python, and carpet python.[167,170] Similar inclusions have also been reported in palm vipers (*Bothriechis marchi*) and an eastern king snake (*Lampropeltis getula*),[105,171] although it is not known if these were caused by the same virus. Clinical signs associated with IBD are variable and can range from subclinical carriers to severe neurologic disease and death. IBD is believed to cause immune suppression in affected animals, and many diverse clinical signs may result. Common signs in infected snakes include torticollis, disequilibrium, opisthotonus, inability to right itself, regurgitation, and flaccid paralysis (Fig. 30.18). Other signs that may also be observed include stomatitis and pneumonia. Skin lesions of various types have also been regularly observed in affected snakes. Lymphoproliferative disorders and round cell tumors have been described in infected snakes. Some snakes with IBD may die within weeks, but others may survive for extended periods of time. In some cases, boa constrictors have been described with inclusions but no apparent signs of clinical disease.

Studies on reptarenavirus-infected snakes with IBD have shown that infections with multiple genetically distinct viruses are very common.[165,166] As these viruses are believed to be immune suppressive, it has been hypothesized that reptarenaviruses may establish chronic infections in

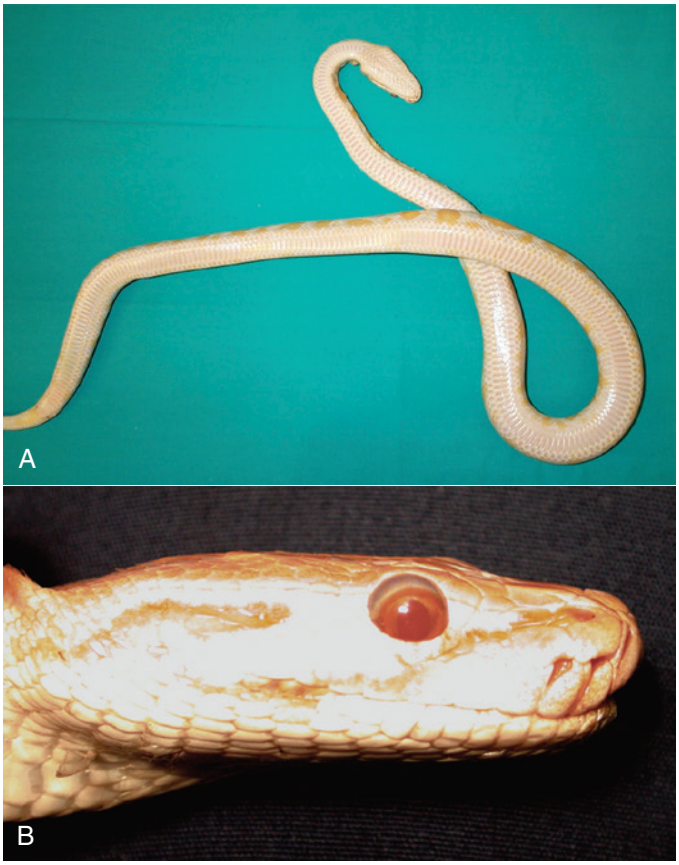

FIG 30.18 (A) Juvenile Burmese python (*Python molurus*) presented with acute onset of neurologic signs, including loss of the righting reflex and disorientation. (B) The same snake with mydriasis. (Courtesy of Jürgen Schumacher.)

snakes, possibly leading to acquired immunosuppression. Co- or superinfection of such snakes with another reptarenavirus could then result in amplified replication, with disease developing due to immunosuppression induced by the chronically infecting virus.[165]

Transmission of reptarenaviruses and development of IBD are not yet fully understood. Transmission from one animal to another appears to involve close contact over time, and cohabitation over a period of weeks or months has been demonstrated to lead to virus transmission.[166] Mites have been implicated as a possible vector,[170] and studies showing that a reptarenavirus can replicate in tick cells at 30°C support the hypothesis that these viruses may be transmitted by arthropod hosts and may even be arboviruses capable of replicating in arthropod and vertebrate hosts.[165] Transmission via biting among snakes and via aerosole have also been discussed. Vertical transmission appears to be possible, and reptarenaviruses have been detected in offspring from IBD-positive parents.[172]

Identification of IBD and Reptarenaviruses

Because IBD is defined by the presence of inclusion bodies in cells of affected snakes, cytology and histology remain important tools for IBD diagnostics. Typical eosinophilic to amphophilic intracytoplasmic inclusions in hematoxylin and eosin–stained tissue sections can be found in various tissues. The distribution of inclusions in tissues appears to depend on the host species. In pythons, inclusions are most commonly found in neurons within the central nervous system. In boa constrictors, they can also be found in glial cells, as well as in cells in the "esophageal tonsils" (Fig. 30.19), hepatocytes, pancreatic acinar cells, renal tubular

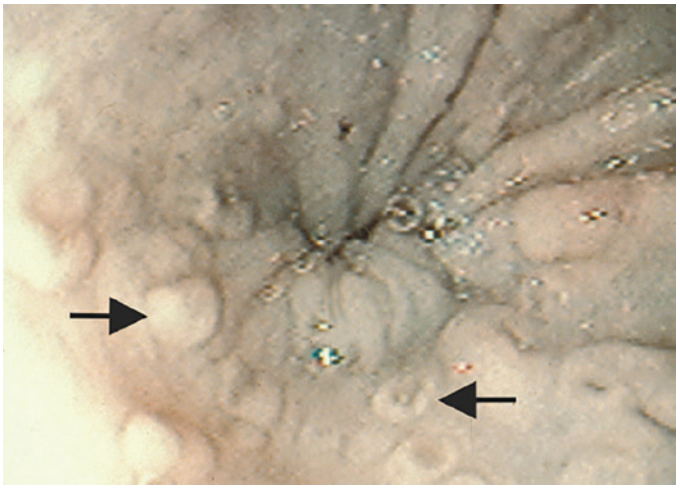

FIG 30.19 Endoscopic demonstration of prominent esophageal tonsils (arrows) in the distal esophagus of a boa constrictor (*Boa constrictor*) with inclusion body disease. (Courtesy of Jürgen Schumacher.)

epithelial cells, and epithelial cells lining the gastrointestinal and respiratory tracts.[170] In live boid snakes, inclusions can be detected in biopsies of the "esophageal tonsils," liver, and kidney. They can also be found in peripheral blood cells. Detection of inclusion bodies in live animals is much more common in boas than in pythons.

Virus detection via PCR has also become an important tool in the detection of infected animals and may be more sensitive than detection of inclusion bodies in many cases. A PCR targeting a portion of the glycoprotein gene has been described[166,167] and used for the detection of reptarenaviruses in live and dead snakes.[172] The glycoprotein gene is found on the S segment, in which less diversity has been detected than on the L segment, and this PCR has been shown to be able to detect diverse reptarenaviruses.[166] Samples used for virus detection in live snakes have included esophageal swabs/biopsies of esophageal tonsils, kidney, liver, gastric mucosa, and whole blood. In dead animals, brain is most often positive in pythons, while virus may be detectable in a wide range of tissues in boas (see Table 30.4). In some cases, animals that are arenavirus positive may not develop IBD. Persistence of virus in the brains of apparently clinically healthy animals has also been described.[172] Reptarenaviruses have also been isolated in cell culture in several cases, mostly in cell lines derived from boa constrictor kidney cells.[167,168]

BUNYAVIRIDAE

Bunyaviruses found in reptiles have all been arboviruses. A bunyavirus was isolated from the blood of a Texas soft-shelled turtle (*Apalone* [*Trionyx*] *spinifer emoryi*), which was wild-caught in Texas. The virus was isolated in suckling mice by intracerebral inoculation and caused 100% mortality in the mice. The virus was not further characterized but was found to serologically cross-react with Cache Valley and Tensaw viruses, both mosquito-borne viruses of the genus *Orthobunyavirus*.[173] Kowanyama virus, an unassigned member of the family *Bunyaviridae*, has been isolated from both mosquitoes and a skink (*Cryptoblepharus* [*Ablepharus*] *virgatus*) in Australia.[174] No disease has been described in association with bunyavirus infections in reptiles.

NIDOVIRALES: CORONAVIRIDAE

The order *Nidovirales* contains enveloped, positive-strand RNA viruses with the largest known RNA genomes. These viruses are relatively easily inactivated by chemical disinfectants. Nidoviruses have been identified in snakes, and these viruses appear to be most closely related to viruses in the family *Coronaviridae*, subfamily *Torovirinae*, and may represent a new genus in this subfamily.[175–177] Coronaviruses generally target the epithelia and are mostly associated with respiratory and gastrointestinal disease. A number of recent emerging viruses belong in this family.

In reptiles, nidoviruses have been found in snakes, particularly ball pythons in the United States and in Europe.[175,176] Nidoviruses have also been detected in Indian rock pythons, green tree pythons, a carpet python, and boa constrictors.[176,178] The most common manifestations of disease appear to be an interstitial proliferative pneumonia, but infected snakes have also been reported with a mild-to-severe tracheitis, mild-to-severe sinusitis/rhinitis, mild-to-moderate stomatitis/pharyngitis, esophagitis, mucous or caseous material in air passageways, and pulmonary hemorrhage.[175,176] Changes in other organ systems have also been detected in individual cases, including encephalitis, nephritis, nephrosis, multifocal dermatitis, salpingitis, hepatic lipidosis, conjunctivits, and pancreatic necrosis. It is unknown if changes in tissues outside the respiratory tract were related to the nidovirus infection.[175,176] Viruslike particles consisting of circular and elongated rod-shaped nucleocapsids were observed within pneumocytes of individual affected snakes by electron microscopy. Metagenomic sequencing was carried out on tissues from affected snakes, leading to detection of novel nidoviruses. No similar viruses were detected in nonaffected snakes.[175] Real-time and conventional PCRs have been used to detect nidoviruses in infected snakes. In live snakes, virus has most frequently been detected in oral swabs, although blood has also tested positive.[178] Tracheal washes may also be a sensitive sample for virus detection. Lung tissue has most often tested positive for nidoviruses, and the highest viral loads are detectable in respiratory tissues,[175] but virus has also been detected in the trachea, esophagus, liver, spleen, heart, and brain (see Table 30.4).[175,176]

PICORNAVIRIDAE

Two genetically distinct picornaviruses from reptiles have been characterized so far, both found in chelonians. They have been named torchiviruses (originally called topiviruses) and rafiviruses.[179,180] As unenveloped viruses, picornaviruses can be moderately difficult to disinfect. Studies of environmental persistence of torchiviruses show that these can persist for extended periods of time in water at cold temperatures, and inactivation at 37°C can take weeks. Inactivation in soil can take 3 weeks or more in the summer but significantly longer at lower temperatures.[17]

The first report of picornalike viruses in reptiles was based on the detection of 20- to 27-nm large viral particles in duodenal and splenic cells in a boa constrictor and in duodenal cells in an Aesculapian snake. Both snakes showed signs of gastrointestinal disease. An adenolike virus was also found in the duodenum and spleen of the boa constrictor, while parvo-, adeno-, and herpeslike viruses were detected in the duodenum of the Aesculapian snake.[109]

Picornalike viruses have been detected repeatedly by isolation in cell culture in a number of different tortoise species (Marschang et al, Proc ARAV, 2002, p 102). These viruses have been called Virus "X." They have most frequently been isolated from spur-thighed tortoises but have also been found in marginated tortoises, Hermann's tortoises, leopard tortoises, Egyptian tortoises (*Testudo kleinmanni*), and spider tortoises (*Pyxis arachnoides*). They have been associated with various signs of disease in infected animals, including softening of the carapace in young animals, diphtheroid-necrotizing stomatitis, rhinitis, conjunctivitis, and ascites (Fig. 30.20) but have also been isolated from clinically healthy animals.[137,182] There are no typical histologic lesions associated with infection. In numerous cases, tortoises infected with Virus "X"

VetBooks.ir

FIG 30.20 Spur-thighed tortoise (*Testudo graeca*) with rhinitis. This animal was infected with a picornavirus (topivirus, "virus X"), as well as with a herpesvirus and *Mycoplasma*.

have also been shown to be infected with other pathogens, especially herpesviruses and *Mycoplasma* spp.[18] Sequencing of a large part of the genomes of isolates obtained from tortoises in Germany and Hungary over several years showed that all isolates were related to one another and belonged to the family *Picornaviridae*. They clearly form a new genus that has now been named "Torchivirus."[179] A transmission study in which juvenile spur-thighed and Hermann's tortoises were inoculated with a torchivirus isolate led to a decrease in bone density and tubular vacuolization in the kidneys (Paries et al, Proc iCARE 2015, p 351).

A genetically distinct picornavirus was detected in the spleen of a Travancore (Sulawesi) tortoise. The animal was from a group that died during a severe disease outbreak in which an adenovirus (Sulawesi tortoise adenovirus 1) was considered the causative agent.[7] The genus name "Rafivirus" was proposed for this new virus. The role of the detected picornavirus in the disease outbreak was unknown.[180]

Identification of Picornavirus Infections in Tortoises

Virus Detection. The detection of torchiviruses in tortoises has most often been described via isolation in cell culture. Virus can be isolated on TH-1 (*Terrapene* heart cells, ATCC CCL-50). An RT-PCR for the detection of viral RNA has also been developed.[184] The best samples for virus detection in live animals are oral swabs. In dead animals, samples from the entire gastrointestinal tract (tongue to cloaca) can all be used for virus detection. Virus is frequently also found in other tissues (including liver, kidney, heart, brain, and lung) (see Table 30.3).

Rafiviruses have not been isolated in cell culture. A PCR for their detection in tissues from affected animals has been described.[180] It has been successfully used to detect virus in liver and kidney samples from animals in the original disease outbreak.

Serology. Serological detection of antibodies against torchiviruses can be carried out using virus neutralization methods. Antibodies against this virus are frequently found in tortoises in Europe, and low titers have also been detected in wild-caught tortoises in Turkey.[139] It is unknown how closely related all torchivirus isolates are to one another, so cross-reactivity among these viruses and between these viruses and other picornaviruses is not yet understood.

CALICIVIRIDAE

Caliciviruses (CVs) infect a broad range of animals, and most individual CV species exhibit a natural host restriction. However, the vesicular exanthema of swine virus (VESV) is an exception, with a broad host range. Transmission is generally via contaminated food, water, fomites, and sometimes via aerosolization.[185] Caliciviruses can be inactivated using standard virucidal disinfectants (e.g., bleach and acid-based disinfectants) very quickly and are generally inactivated by alcohol formulations used for hand disinfection.

In reptiles, CVs closely related to the San Miguel sea lion CV have been isolated from four different snake species—Aruba island rattlesnakes, a rock rattlesnake (*Crotalus lepidus*), and an eyelash viper (*Bothriechis* [*Bothrops*] *schlegeli*)—as well as from Bell's horned frogs (*Ceratophrys ornata*) in a single collection in the United States.[186] Some, but not all, of the animals from which virus was isolated had enteritis and hepatitis. A transmission study with prairie rattlesnakes showed that these animals could be infected and the virus could be reisolated (in one out of two snakes inoculated), but no pathognomonic disease was observed in the infected snake. Transmission of the virus to pigs led to seroconversion but not disease.[186] A PCR for the detection of reptile calicivirus, as well as other vesiviruses, has been described,[187] but no information is available on the prevalence of this virus in reptiles.

FLAVIVIRIDAE

All of the flaviviruses described in reptiles belong to the genus *Flavivirus*, which contains viruses that are transmitted by hematophagous arthropods (arboviruses). Some flaviviruses are able to infect and replicate in a wide variety of vertebrate hosts (including mammals, birds, and reptiles). The focus of much interest in flaviviruses of reptiles has been the role of these animals as reservoirs for human disease.

Antibodies against various flaviviruses, including St. Louis encephalitis virus, Powassan virus, Japanese encephalitis virus, and West Nile virus (WNV), have been found in chelonians, snakes, and crocodilians in various parts of the world.[18,188] Japanese encephalitis virus has been isolated from Chinese rat snakes in Korea.[189] Transmission studies with Japanese encephalitis virus have shown that lizards can be infected with this virus both by parenteral inoculation and, in some species, by feeding on infected mosquitoes. Infected animals develop viremia, and the development of viremia is temperature dependent.[190] No clinical signs of disease were reported in the lizards. A flaviviruslike virus was isolated from a leopard tortoise with epistaxis, cloacal hemorrhage, biliverdinuria, and anemia. Herpes and adenoviruses were isolated from other animals in the same collection, and intraerythrocytic inclusions of unknown etiology were also described in these tortoises.[8,191] The most commonly described flavivirus in reptiles is West Nile virus.

WEST NILE VIRUS (WNV)

WNV is a flavivirus that primarily cycles between mosquitoes and birds. It is zoonotic, and care should be taken when dealing with suspected cases (especially in crocodilians). A number of transmission studies have been carried out with WNV and various reptile species. In one transmission study iguanas, snakes, and frogs became infected, and the iguanas and frogs both developed low-level viremias. No disease was reported in any of the infected animals.[192] Viremia was induced by subcutaneous inoculation into common garter snakes (*Thamnophis sirtalis*).[193] Another transmission study was able to induce a moderate viremia in four western fence lizards following inoculation with WNV.[194]

WNV has been shown to be pathogenic for crocodilians and causes high-titer viremias in these animals. Antibodies against WNV have been

VetBooks.ir

detected in crocodilians in many different countries, including crocodiles at a commercial farm in Israel,[195] wild alligators in Florida,[196] and farmed and wild crocodiles in Mexico.[188,197] In the United States, WNV has been detected in disease outbreaks in American alligators in a number of different states, including Georgia,[198] Florida,[196] and Louisiana.[199] Infection of crocodilians can occur by bite from infected mosquitoes, orally by consumption of contaminated meat (e.g., infected horses), and by contact with viremic tankmates.[198,200] The development and duration of viremia are dependent on ambient temperature.[200] The highest mortalities have been found in young animals. Neurologic signs have included anorexia, tremors, swimming on their sides, spinning in the water, and opisthotonus. Oral lesions (stomatitis) have also been noted. Death may occur 24 to 48 hours after the appearance of clinical signs. The highest viral loads were detected in the livers of affected animals.[196,198] WNV has also been associated with lymphohistiocytic proliferative cutaneous lesions in American alligators. Round to ovoid lesions were described in the superficial dermis of infected alligators. No virus was detectable in the lesions, but animals with lesions consistently tested positive for antibodies against WNV and 97.5% tested positive for WNV RNA in pooled skin and liver-brain samples.[201] In a transmission study with alligators, viremia developed in all alligators infected by subcutaneous injection, with the time to development and duration of viremia dependent on temperature (32°C or 27°C), with longer duration of viremia at 27°C, while only tankmates of infected alligators kept at 32°C became infected. Viremia also developed after oral infection and also led to the infection of tankmates. Viral titers in serum of infected animals were sufficiently high to infect mosquitoes (*Culex quinquefasciatus*), and high virus loads were also documented in the cloaca.[200] WNV has been detected in mosquitoes associated with alligator farms.[202]

Identification of WNV Infections

Detection of WNV can be performed with the use of serum or whole blood in infected crocodilians. Viremic alligators have also been shown to shed virus via the cloaca.[200] In dead animals, virus can be detected in a number of tissues, including liver, lung, and blood. Liver has been shown to have the highest titers and yield the most positive results in American alligators (see Table 30.5).[196,198] Virus detection has been carried out by isolation in cell culture (e.g., Vero cells) or by detection of viral RNA using RT-PCR. A number of RT-PCR protocols have been described for the detection of WNV RNA in various animals. WNV is currently grouped into five different lineages, and the choice of RT-PCR will affect which lineages can be detected. Lineage 1 is found in North America, southern Europe, Asia, and Africa, whereas lineage 2 is found in southern Africa and has recently also been found in Europe. Real-time quantitative PCRs have been described for the combined detection of both lineages but have not been tested with crocodilian samples.[203]

Antibodies against WNV can be detected in tthe serum of infected crocodilians. In a transmission study with American alligators, antibodies were detected within 25 days of virus detection in infected animals. Methods used for the detection of anti-WNV antibodies have included a plaque reduction assay for the detection of neutralizing antibodies and an ELISA. The plaque reduction assay requires live virus and must therefore be carried out in a biosafety level 3 laboratory. An ELISA has been developed for the specific detection of antibodies against WNV in alligators.[204] Antibodies against WNV can cross-react with antibodies against other related flaviviruses.

TOGAVIRIDAE

The togaviruses detected in reptiles to date have all belonged to the genus *Alphavirus*, which contains viruses that have the ability to replicate in and be transmitted horizontally by mosquitoes. Most alphaviruses can infect a wide range of vertebrates, mostly birds and mammals, but several have also been reported in reptiles. Studies on alphaviruses in reptiles have mostly focused on the possible role of these animals for the transmission of alphaviruses to humans and livestock. This has led to a focus on persistence of alphaviruses in reptiles, particularly viral persistence over winter in temperate regions in the absence of mosquito activity.[205] Detection of alphavirus infection in reptiles has been carried out by detection of virus in blood or detection of antibodies. Eastern equine encephalitis virus (EEEV), Western equine encephalitis virus (WEEV), and antibodies against these viruses have been found in various chelonians, lizards, and snakes, including a number of wild-caught reptiles in the United States.[105] Antibodies against Venezuelan equine encephalitis virus (VEEV) have been found in free-ranging caimans in Brazil.[206] In a serosurvey of various frogs, turtles, lizards, and snakes in Alabama for antibodies against EEEV, seropositivity was detected most often in various snake species,[207] and repeated cycles of viremia were documented in garter snakes. EEEV RNA was detected in serum of wild-caught copperheads (*Agkistrodon contortrix*) and cottonmouths (*Agkistrodon piscivorus*) in Alabama.[208] Experimental transmission of WEEV and EEEV to garter snakes has shown that these animals can develop sufficiently high viremias to infect mosquitoes following hibernation.[18,209] Transmission studies with EEEV and WEEV in spotted turtles (*Clemmys guttata*) and Texas tortoises (*Gopherus berlandieri*) both led to viremia in injected animals.[210,211] Viremia was longer at lower temperatures than at high environmental temperatures. None of the transmission studies described any signs of clinical disease in infected reptiles.

Mycology

James F.X. Wellehan and Stephen J. Divers

REPTILE-FUNGAL ECOLOGY

Reptile patients are often approached as a collection of vertebrate cells organized into organ systems. This is highly misleading; most of the cells in a vertebrate are microbial. Microbes are especially critical for digestion and immune function, and maintenance of healthy flora is essential to the health of a reptile patient.

Clinicians are also often misled by Koch's postulates; by fulfilling or not fulfilling these requirements in a controlled experiment, a microbe is then considered dichotomously as a pathogen or not a pathogen. This is far from the case; in the real world, numerous host, pathogen, and environmental factors (including coinfections, temperature, nutrition, handling stress, crowding, and others) play significant roles in whether a pathogen manifests as disease. When infectious disease is properly considered as ecology, it becomes obvious that a typical disease scenario involves several infectious agents in concert with other environmental factors. Coinfection with both *Nannizziopsis guarroi* and *Devriesea agamarum* has been seen in skin lesions in inland bearded dragons (*Pogona vitticeps*),[1] and coinfection with *Encephalitozoon pogonae,* coccidia, and Agamid adenovirus 1 has been reported in other bearded dragons.[2] Like all vertebrates, reptile patients are complex ecosystems, and we are still in the early stages of learning about the complex ecological interactions between the microbial components of a reptile patient. Rather than thinking of a war on fungi, clinicians should have the goal of improving ecosystem health within a reptile patient.

Evolution is an essential concept in biology; when one considers definitions for life, perhaps the simplest and most elegant definition is that life consists of things that evolve. Clinically, this is most immediately apparent with infectious disease. Because of short generation times, evolution of microbes occurs in a time frame impacting clinical management of a patient. To compensate, the most rapidly evolving genes in vertebrates are immune related. A fungus does not "want" to cause disease or not cause disease. All life on earth has been selected for billions of years to reproduce successfully, and this is all that matters from an evolutionary standpoint. If pathogenic traits provide an evolutionary advantage in a given situation, they will be selected for. If they provide a disadvantage, they will be selected against.

There are a number of important selective pressures impacting microbes in a reptile host, including nutrition, temperature, the need to transfer to a new host, competition with other microbes, and the host immune system. A reptile host is a nutrient-rich environment for fungi. However, some nutrients may be sequestered; one example is iron, which is a limiting factor for the growth of many fungi. Significant resources are spent by the host synthesizing transferrin, lactoferrin, and ferritin to make iron unavailable. Many fungal virulence pathways have evolved to access this sequestered iron.[3] Iron storage disease or clinical administration of iron may rapidly favor fungi with these pathways.

Ectothermic hosts require microbial gut flora to have the ability to survive at different temperatures. Infectious disease manifestation may be highly temperature dependent in ectotherms.[4] In reptiles, temperature manipulation is often a significant therapeutic approach. Further investigation of the role of temperature in disease manifestation in reptiles is strongly indicated, especially with populations of many species critically declining and likely to be impacted by anthropogenic climate change.[5,6]

The need to transfer to a new host creates significant selective pressure. Most fungi may survive well in the environment, decreasing selective pressure to keep the host alive. High host density also favors virulence, and increased stocking density creates environments selecting for pathogenicity.

Microbial competition is also a major selective pressure in a reptile; many organisms want to live in such a nutrient-rich environment. The majority of antimicrobials are derived from products secreted by other microbes that help them compete for ecologic niches. Animal guts are some of the most diverse and rich ecosystems to be found anywhere. Microbial ecologic disturbance may have significant negative impacts on many aspects of health. Damage to healthy flora by antimicrobial use provides opportunity for invasive species; recent treatment with antibiotics markedly increases host susceptibility to *Candida*,[7] and previous treatment with itraconazole makes frogs more susceptible to *Batrachochytrium.*[8] A 5-day course of ciprofloxacin will change human gut flora diversity and composition for several weeks, and the original composition may never reestablish.[9] Reduction in antibiotic use should result in reduction in fungal disease.

Other routine husbandry practices in the reptile pet trade also create strong evolutionary selective pressures toward fungal pathogenicity. It is common in the pet reptile trade to select for color mutants. This usually involves some degree of inbreeding to select for what are often recessive traits. A major driving force for the evolution of sex is acquisition of genetic diversity for immune function. Inbreeding results in selection for greater disease.[10]

ISSUES IN MYCOLOGY

Mycology is a field with serious flaws. Bacteriology and virology long ago abandoned morphology as a definitive method for identification; it is still commonly used in mycology. Because microbes have relatively few morphologic characteristics on which to base identification, it is not unexpected to find a high error rate. This has led to serious errors, such as the misidentification of multiple significant reptile pathogens as "*Chrysosporium* anamorph of *Nanniziopsis vriesii*." Information on morphologic ID of fungi is interspersed throughout the literature, and it has become an arcane field. A paper on a snake fungal infection indicated "The identification of the fungus can cause some difficulties to the nonskilled mycologist…. The final diagnosis can be performed

VetBooks.ir

only by a skilled specialist."[11] Ironically, this was later shown by molecular methods to be a different species.[12] A good mycologist should not have complete confidence in morphologic identification.

Mycologists have also used a nomenclature inconsistent with the rest of biology. With other clades of organisms, such as coccidia, cestodes, or cnidaria, life stages with very different morphology had not been recognized as the same species and had been named as separate organisms. However, as soon as they were recognized as the same organism, they were merged under one name. In mycology, separate taxonomic systems for asexual anamorph stages and sexual teleomorph stages of the same organism were deliberately kept, resulting in multiple species names and paraphyletic taxa. The anamorph species *Blastomyces dermatitidis* and *Histoplasma capsulatum* are in different genera, but their teleomorphs *Ajellomyces dermatitidis* and *Ajellomyces capsulatus* are congeneric. The availability of sexual structures meant that teleomorph classification was somewhat more accurate. In 2011 it was decided by the Nomenclature Section meeting of the International Botanical Congress that teleomorph names should be used.[13] This is very problematic for clinicians, because nearly all names of systemic fungi routinely used in medicine are anamorph names (e.g., *Cryptococcus*, *Blastomyces*, *Histoplasma*, etc.).

There is a significant need for major revision of fungal nomenclature.

FUNGAL DIAGNOSTICS

Diagnosis of fungal disease needs to be done with an understanding of the microbial ecology of the patient. A history and physical examination is a good starting point, with the recognition that husbandry has played a major role in almost any disease process for which a captive reptile is presented to a veterinarian, and husbandry improvements will need to be part of the therapeutic approach. When visible lesions are present, cytology or histology is often a good next step. A complete blood count to look for evidence of infection/inflammation and a plasma biochemistry to narrow concerns to organ systems are often helpful. Ultrasonography, endoscopy, or other diagnostic imaging may be helpful to identify internal lesions and guide sample collection. Once the results of initial diagnostic tests are in hand, appropriate diagnostic testing for fungi can be selected.

There are two major approaches to testing for infectious diseases. These tests are based on either the animal's acquired immune response to an agent or the presence of the agent. There is a lack of availability of validated immunological testing for fungi in reptiles, and currently available testing for fungal disease looks directly for the fungus.

Commonly used assays for the presence of fungi include culture and polymerase chain reaction (PCR)–based techniques; these should be targeted as much as possible. Diverse normal flora are present on the external surfaces and in the gastrointestinal tract of reptiles; untargeted cultures of these without significant corollary data are clinically uninterpretable. If cytology or histology indicates the presence of and morphologic information on fungi, this should be communicated to the laboratory. An appropriate differential diagnoses list should be formulated based on the initial diagnostic findings, and it should be decided whether culture is likely to be the most practical route to diagnosis or other methods such as PCR should be used.

Whenever possible, specimens for fungal testing are collected before antifungal therapy is begun. All specimens should be transported in clean, tightly sealed, leak-proof containers. Biopsies of lesions are preferable to swabs whenever possible. Once a laboratory has cultured and isolated a fungus, the most common method of identification is morphologic identification. As might be expected for a microbe, the error rate for morphologic identification is high, and it is strongly recommended that molecular diagnostic testing be considered for any serious fungal disease. Molecular diagnostic testing is discussed in Chapter 36. If corollary diagnostics suggest fungal infection and there does not appear to be multiple species present, it may be possible and more rapid to proceed directly to molecular diagnostic testing on uncultured samples. However, an important consideration when deciding on diagnostic approach is additional testing that may be needed; sensitivity testing is currently only economically feasible for cultured isolates. If an identification appears unusual, it is appropriate to question the result with a microbiologist.

PHARMACOLOGIC ANTIFUNGAL THERAPY

As members of the eukaryote clade Opisthokonta, the fungi are among the closest relatives of metazoan animals.[14] A lizard and a mushroom are more closely related to each other than either one is to an oak tree or a coccidian. Antimicrobial drug therapy targets differences between microbe and host; there are significantly fewer differences between animals and fungi than there are between animals and bacteria. Although we have a number of different targets for antibacterial drug therapy, antifungal drugs have comparatively few targets, with most targeting ergosterol. Antifungal drugs also tend to have more toxic side effects. Treatment of fungal disease often needs drug courses of months or years. Intermittent therapy may be more likely to lead to drug resistance and is not advised.

Polyene drugs bind to ergosterol in the fungal cell membrane. Commonly used polyenes include nystatin, natamycin, and amphotericin B. They are generally not well-absorbed enterically and require parenteral administration for systemic use. Nystatin is commonly given orally to achieve high levels in the gastrointestinal tract without significant systemic levels.

Azole drugs inhibit ergosterol synthesis via lanosterol 14α-demethylase. They are generally well-absorbed enterically. Fluconazole and ketoconazole have fairly limited spectra, significantly limiting their utility. Ketoconazole also disrupts host steroid synthesis more significantly, causing greater toxicosis. Itraconazole tends to have a broader spectrum than fluconazole and ketoconazole, and although expensive, is significantly less costly than voriconazole, posaconazole, or ravuconazole. However, there are fungal taxa that tend to be itraconazole resistant, with the most problematic for reptile clinicians being *Nannizziopsis guarroi*. Voriconazole, posaconazole, and ravuconazole all have significantly broader spectra but are very expensive.

Allylamines inhibit ergosterol synthesis via squalene epoxidase. The most commonly used allylamine is terbinafine. It is generally well-absorbed enterically. It is often synergistic with azoles and is relatively nontoxic and inexpensive. Combination therapy with terbinafine and an azole is often a reasonable empirical choice.

Echinocandins inhibit glucan synthesis in fungal cell walls via β-1-3-glucan synthase. They were primarily developed for use against non–*albicans Candida*, which tend to be highly resistant to other drug classes. Commonly used echinocandins include caspofungin, anidulafungin, and mycofungin. They are generally not well absorbed enterically and require parenteral administration for systemic use. They are expensive, and data on their use in reptiles is lacking.

AN OVERVIEW OF FUNGAL TAXA

When working on an exotic animal, it is helpful to know what taxa you are dealing with; the clinical approach to a tortoise is different from the approach to a rodent. Unfortunately, fungi are commonly taught as a list of genera and species, giving no higher-level context. When dealing with fungi, the phylum level is a clinically useful starting point (Table 31.1). A useful source for the clinician to find higher-level classification of a given fungal isolate is the National Center for Biotechnology

VetBooks.ir

TABLE 31.1 Medically Important Fungal Taxa

Taxonomy (SK, P, O, F, G)	Morphology	Diagnostic Testing	Typical Lesions	Comments
Microsporidia (P) *Encephalitozoon* (G) *Enterocytozoon* (G) *Heterosporis* (G)	Oval or pyriform spores	Histology/cytology, PCR/sequencing	Disseminated	Periodic acid–Schiff positive, gram positive, acid-fast positive spores
Chytridiomycota (P) *Batrachochytrium* (G)	Flask-shaped sporangia in epithelium	Histology/cytology, PCR/sequencing, probe hybridization qPCR, skin cytology	Keratinized skin, electrolyte imbalance	Major amphibian pathogens, not reptile pathogens
Zoopagomycota (P) *Schizangiella* (G)	Primarily seen in vivo as yeast	Histology/cytology, culture, PCR/sequencing for definitive diagnosis	Fungal granulomas	Some previous reports of *Basidiobolus* in amphibian deaths may have been chytrids
Mucormycota (P) *Mucor* (G)	Hyphae	Histology/cytology, cultures well, PCR/sequencing for definitive diagnosis	Dermatitis	Opportunists, extensive drug resistance
Dikarya (SK)	Life stage with two nuclei			Largest extant fungal clade
Basidiomycota (P) Tremellales (O) *Cryptococcus* (G)	Yeast with thick capsule	Histology/cytology, cultures infectious, PCR/sequencing or probe hybridization qPCR	Pulmonary granulomas	Significant human pathogen, contagious if cultured; notify diagnostic laboratory if suspected.
Trichosporonales (O) *Cutaneotrichosporon* (G)	Yeast	Histology/cytology, culture, PCR/sequencing for definitive diagnosis	Dermatitis	
Ascomycota (P) Onygenales (O) Onygenaceae (F) *Ophidiomyces* (G) *Coccidioides* (G) *Aphanoascella* (G)	*Ophidiomyces* form hyphae in tissues, *Coccidioides* form characteristic spherules	Histology/cytology, culture, PCR/sequencing of ITS2 for definitive diagnosis, qPCR available for *Coccidoides, Ophidiomyces*	*Coccidioides:* pneumonia *Ophidiomyces, Aphanaoascella:* dermatitis	*Coccidioides* is a significant human pathogen, contagious if cultured; notify diagnostic laboratory if suspected; *Ophidiomyces* having population-level effects
Nanizziopsiacae (F) *Nannizziopsis* (G) *Paranannizziopsis* (G)	Hyphae in tissues		Dermatitis	Significant diversity with differing temperature tolerance; major reptile pathogens
Chaetothyriales (O) *Exophiala* (G) *Veronaea* (G)	Pigmented yeast		Disseminated fungal granulomas	*Exophila equina* in Galapagos tortoises
Hypocreales (O) Ophiocordycipitaceae (F) *Purpureocillium* (G)	Hyphae in tissues		Pneumonia, dermatitis	Extensive drug resistance
Cordycipitaceae (F) *Beauveria* (G) *Lecanicillium* (G)			*Beauveria:* pneumonia *Lecanicillium:* dermatitis, disseminated granulomas	Used as insect biocontrol agents
Clavicipitaceae (F) *Metarhizium* (G)			Pneumonia, dermatitis, glossitis, disseminated granulomas	Used as insect biocontrol agents, some species have extensive drug resistance
Nectriaceae (F) *Fusarium* (G)		Histology/cytology, culture, PCR/sequencing of EF-1α for definitive diagnosis, ITS2 not definitive	Pneumonia, dermatitis, glossitis, disseminated granulomas	Opportunists, extensive drug resistance
Saccharomycetales (O) *Candida* (G)	Yeast	Histology/cytology, culture, PCR/sequencing for definitive diagnosis	Enteritis, pneumonia, disseminated granulomas	Clinical disease typically secondary to antibiotic use; non-*albicans* species have extensive drug resistance

SK, Sub kingdom; *P,* phylum; *O,* order; *F,* family; *G,* genera.

Information's Taxonomy Browser (https://www.ncbi.nlm.nih.gov/Taxonomy/Browser/wwwtax.cgi). The earliest divisions within the fungi, the microsporidia and chytrids, have atypical morphology.[15] The remaining taxa generally have a hyphal morphology, making them more recognizable as fungi. There are several primitive groups of fungi that branch off next. Formerly known as zygomycetes, these primitive hyphal fungi are not more closely related to each other than to the Dikarya and should be considered as several independent clades rather than a single group. The most speciose group of fungi is the subkingdom Dikarya, which are further divided into the phyla Basidiomycetes and Ascomycetes.[16]

Microsporidia

Members of the phylum Microsporidia do not have typical fungal morphology. They are obligate animal parasites and lack mitochondria. They have two life stages, spore and meront. Spore morphology is typically oval or pyriform and includes a chitin coat and a polar filament. The polar filament is attached to one end of the spore, coils around the spore contents, and ends near the posterior vacuole at the other end of the spore. It has morphologic similarity to stinging cells of jellyfish. The spore injects the sporoplasm into the host cell via the polar filament, and development of the meront occurs inside the host cell.

In reptile hosts, microsporidiosis was first reported in lizards and tuatara *(Sphenodon punctatus)*, and most reports are from squamates.[17,18] The first molecular characterization of a microsporidian in a reptile host was *Encephalitozoon pogonae* in inland bearded dragons.[19] Closely related to *E. cuniculi* from rabbits *(Oryctolagus cuniculus)*, *E. pogonae* is most commonly associated with nonspecific signs in bearded dragons such as lethargy, anorexia, weight loss, and polydipsia. It develops within macrophages in granulomas in multiple tissues, especially kidneys, but also including intestine, liver, ovary, spleen, lungs, vascular endothelium, and ventricular ependymal cells in the brain. Prevalence appears to be fairly high in captive inland bearded dragons outside Australia. Fecal shedding occurs, and it is likely that fecal-oral is the primary route of transmission. Coinfection with Agamid adenovirus 1 and coccidia has been reported, and it is probable that coinfection exacerbates disease.[2] Also seen in squamates is *Heterosporis anguillarum,* described by DNA sequence identification from eels (Anguilliformes) before it was found in a garter snake *(Thamnophis)* and sea snakes (Hydrophiinae).[20,21] Granulomas are seen in the muscle of the body wall.

Enterocytozoon bieneusi has also been identified by DNA sequence from the feces of two snake species, Indian cobra (*Naja naja*) and Oriental rat snakes (*Ptyas mucosus*).[22] *Enterocytozoon bieneusi* is known to use diverse amniotes as hosts and is of zoonotic concern. Although lesions were not investigated in the snakes, in other hosts, *E. bieneusi* causes enteritis.

Encephalitozoon hellem has been identified by DNA sequence from a juvenile freshwater crocodile (*Crocodylus johnstoni*) in Australia.[23] The animal was found dead with no previously identified signs of illness. Kupffer cells in the liver contained large numbers of *E. hellem,* and it was attributed as the primary cause of death.

Microsporidia have been described morphologically in four Hermann's tortoises (*Testudo hermanni*) from Germany.[24] The primary lesion seen histologically was granulomatous hepatitis, with organisms also seen in lung, heart, intestine, and kidney. The microsporidian was not identified.

Diagnosis. Specific diagnosis of microsporidiosis is best accomplished by histopathology in combination with PCR and sequencing of affected tissue. *Encephalitozoon* and *Enterocytozoon* are often shed per cloaca and may be an acceptable sample for testing, although data on sensitivity in reptiles are lacking.

Treatment. Treatment of microsporidiosis is challenging; they do not respond to traditional antifungal drugs.[25] Benzimidazoles such as oxfendazole, fenbendazole, and albendazole have some activity against microsporidia in vitro. However, the effects on the host can be significant, with bone marrow suppression and enterocyte necrosis seen particularly with fenbendazole.[26] It remains to be determined whether benzimidazole therapy of microsporidia in reptiles is beneficial or deleterious. Fumagillin is efficacious against microsporidia but bone marrow suppression is a significant potential side effect,[27] and data in reptiles is lacking.

Chytridiomycota

Members of the phylum Chytridiomycota do not have typical fungal morphology. Most are parasites of plants, algae, or oomycetes. Only two species are known vertebrate pathogens; *Batrachochytrium dendrobatidis* and *B. salamandrivorans,* both causing significant disease in amphibians. Neither appears to be a reptile pathogen. *Batrachochytrium dendrobatidis* has been associated with significant population declines in amphibians worldwide; to date, *B. salamandrivorans* has only been found in salamanders in Europe and Asia. They have two life stages; flask-shaped zoosporangia and uniflagellated motile zoospores. Zoosporangia are found in squamous epithelium of amphibians and also in gastrointestinal tracts of crayfish.[28] Amphibian skin is crucial for respiration and osmoregulation, and chytridiomycosis causes fatal electrolyte imbalances.[29] Maintenance of healthy skin flora is important for disease resistance; normal bacterial skin flora significantly inhibit *Batrachochytrium* spp.[30] Fungal skin flora are likely also important; previous treatment with itraconazole makes frogs more susceptible to *Batrachochytrium.*[8]

Diagnosis. Skin of the ventrum, especially the thighs and caudal abdomen, is generally the best diagnostic sample. Infected frogs often show a higher shed rate. Thalli containing zoosporangia may be seen in epithelium on cytologic examination of skin (Fig. 31.1), although the orientation of the thalli is usually such that the narrower "flask-shaped" portion is not visible, as is often seen histologically. Definitive disease diagnosis may be made through use of histopathology/cytology and PCR and sequencing or validated probe hybridization quantitative PCR (qPCR) (see Chapter 36).

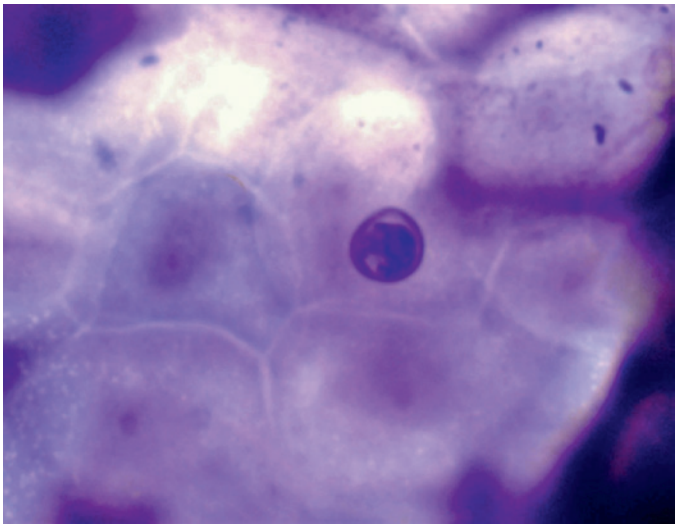

FIG 31.1 Cytological appearance of *Batrachochytrium dendrobatidis* in a White's tree frog (*Litoria caerulea*). (Courtesy of Jennifer L. Owen.)

VetBooks.ir

Treatment. For amphibian species tolerant of higher temperatures, temperature manipulation may be the best therapeutic approach. Housing frogs at 37°C for 16 hours was found to clear frogs of *B. dendrobatidis.*[31] Housing frogs at 30°C for 10 days has also been found to clear frogs of *B. dendrobatidis.*[32] This may be at least partially due to alteration of bacterial skin flora.[33]

Pharmacologic therapy of *Batrachochytrium* is also possible. Itraconazole treatment in 0.01% baths has been shown to be effective in reducing *B. dendrobatidis* beyond detectable levels, but follow-up testing often found that infection was still present several months later.[34] Itraconazole also has significant toxic effects with negative effects on growth and weight gain, with fatal side effects seen, and some trials have found that a lower dose of 0.0025% itraconazole for 5 minutes/day for 6 days may be more efficacious.[35] Terbinafine, amphotericin B, voriconazole, and chloramphenicol all have activity against *B. dendrobatidis,* and further study is indicated.[36] Study of terbinafine/azole combinations is especially merited.

Batrachochytrium salamandrivorans tends to be more drug resistant than *B. dendrobatidis.* Combinations of voriconazole, polymyxin E, and temperature therapy were found to clear infection in infected fire salamanders (*Salamandra salamandra*), although follow-up testing was only done for 3 weeks.[37]

Zoopagomycota

The fungi formerly grouped as the now-defunct zygomycetes have been shown to be paraphyletic, with Zoopagomycota a more basal branch than Mucoromycota.[38] Zoopagomycota have more recognizable hyphal fungal morphology than microsporidians or chytrids. Most are pathogens or commensals of invertebrates, other fungi, or amoeba. The Zoopagomycota that are known potential vertebrate pathogens are in the subphylum Entomophthoromycotina, which are primarily known as arthropod pathogens.

Basidiobolus ranarum. *Basidiobolus ranarum,* in the class Basidiobolomycetes, order Basidiobolaceae, is commonly found as commensal intestinal flora in reptiles and amphibians. While it has been reported as a cause of fatal skin disease in anurans, these reports all date before the discovery of *Batrachochytrium dendrobatidis.* Histologic images from at least one report of *Basidiobolus ranarum* infection in anurans show what appear to be *Batrachochytrium dendrobatidis* thalli.[39] *Basidiobolus ranarum* is much more easily cultured than *Batrachochytrium dendrobatidis,* and, in hindsight, many reports of basidioboliasis in anurans may have been misattributed chytridiomycosis cases.

Schizangiella serpentis. *Schizangiella serpentis,* also in the class Basidiobolomycetes, order Basidiobolaceae, has been reported from an esophageal granuloma in an eastern rat snake (*Pantherophis alleghaniensis*).[40] Growth is yeastlike. Definitive diagnosis may be made through use of PCR and sequencing; susceptibility and treatment response has not been reported.

Mucormycota

The fungi formerly grouped as the now-defunct zygomycetes have been shown to be paraphyletic, with Mucoromycota being more closely related to Dikarya than Zoopagomycota.[15,38] Mucoromycota have more recognizable hyphal fungal morphology than microsporidians or chytrids. Most are associated with plants as commensals or decomposers.

Mucor. *Mucor* spp. have been reported from skin lesions in Florida softshell turtles (*Apalone ferox*).[41] Five of 30 recently captured wild Marlborough green geckos (*Naultinus manukanus*) developed skin lesions, from two of which *Mucor ramosissimus* was cultured, and both died.[42] It is probable that capture stress and husbandry played significant roles in disease. *Mucor* are relatively easy to culture and are not uncommon in the environment. Colonies are fluffy and white to gray, with wide hyphae and terminal round, spore-filled sporangia. Once infection is established, pharmacologic therapy is difficult. *Mucor* are often susceptible to amphotericin B and posaconazole, with limited susceptibility to other azoles and resistance to echinocandins.[43] Terbinafine is usually synergistic in combination.[44]

Dikarya

Dikarya is a subkingdom containing the largest extant clade of fungi. They do not have any flagellated life stages. Their name comes from dikaryons, a life stage containing two genetically distinct nuclei. They are divided into two phyla, Basidiomycota and Ascomycota.

Basidiomycota. Basidiomycota is a phylum in the Dikarya. Members of the phylum Basidiomycota have typical fungal morphology, with diploid zygotes called basidiospores. They often have large fruiting bodies; mushrooms are basidiomycetes. Most are associated with plants as decomposers or pathogens. Typically, animals eat mushrooms and mushrooms do not eat animals; the most major exception is *Cryptococcus/Filobasidiella.*

Cryptococcus/Filobasidiella. Although best known by the anamorph name *Cryptococcus,* the medically relevant members of the genus are technically more correctly called by the teleomorph name *Filobasidiella.*[13] It remains to be seen whether this will ever be generally accepted by the medical field. There are other members of the anamorph genus associated with several other teleomorph genera, but only two species, *C. neoformans* and *C. gattii,* are significant pathogens, and both are *Filobasidiella. Cryptococcus/Filobasidiella* is in the subphylum Agaricomycotina, class Tremellomycetes, order Tremellales. They cause pneumonia and encephalitis in a variety of animals, including humans. In animals, it is seen as a yeast with a distinctive thick capsule. This capsule helps avoid phagocytosis. The yeast form that grows in the animal is not the infective stage, and direct contact with a *Cryptococcus*-infected animal does not present undue zoonotic risk. The infective stage is environmental and has strong geographical and plant associations. It is strongly associated with trees, especially Douglas firs *(Pseudotsuga menziesii)* in Pacific northwestern North America, *Eucalyptus* trees in Australia, and carob *(Ceratonia siliqua)* and olive trees *(Olea europaea)* in the Mediterranean.

In reptiles, *Cryptococcus* has been reported in a captive green anaconda (*Eunectes murinus*) with ataxia, weight loss, and lethargy.[45] Interestingly, it had been raised in captivity in a region of the United States where *Cryptococcus/Filobasidiella* is not endemic. Granulomatous pneumonia and meningoencephalitis with intralesional yeast were seen histologically. It was identified by immunohistochemistry as *C. neoformans,* although this was before the recognition of *C. neoformans* and *C. gattii* as separate species. Cryptococcosis has also been reported in a captive eastern water skink (*Eulamprus quoyii*) in Australia.[46]

Diagnosis. Although standard radiography is insensitive for diagnosis of pneumonia in reptiles, computed tomography or endoscopy may be of more use. Histology or cytology may reveal the presence of yeast with thick capsules. If there is strong suspicion of *Cryptococcus,* culture should only be done by a referral laboratory; cultures will have the infective stage and are a biosafety level 3 risk to laboratory personnel. Direct testing of infected tissue without culture may be preferable. Definitive identification may be made through use of PCR and sequencing or validated probe hybridization qPCR (see Chapter 36).

Treatment. Whenever feasible, infected tissue should be excised surgically. An azole/terbinafine combination is a reasonable therapeutic approach.

Cutaneotrichosporon. *Cutaneotrichosporon* are Basidiomycetes in the class Tremellomycetes, order Trichosporonales. *Cutaneotrichosporon* were formerly known as *Trichosporon.*[47] They are yeasts, and sexual reproduction is not known. *Cutaneotrichosporon jiroveci* has been reported from

ulcerative skin lesions on a Hermann's tortoise.[48] The author is aware of additional cases in emydid turtles and snakes. Although *C. mucoides* is a human pathogen that may have systemic effects, *C. jiroveci* does not grow above 36°C and is not considered a significant zoonotic risk.[49]

Diagnosis. Skin biopsies are indicated to diagnose cutaneotrichosporonosis. Histologically, 14- to 16-µm round yeasts and pseudohyphae are seen. On culture, colonies are white and waxy and frequently have a wrinkled appearance. Biochemical methods of identification frequently result in errors.[50] Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

Treatment. The Hermann's tortoise reported with cutaneotrichosporonosis responded to surgical debridement and topical iodine therapy.[48] Pharmacologic antifungal therapy may not be needed. If indicated, clinical *C. jiroveci* isolates from humans are resistant to amphotericin B and susceptible to itraconazole and voriconazole.[50]

Ascomycota

Ascomycota is a phylum in the Dikarya. Members of the phylum Ascomycota have typical fungal morphology, with diploid zygotes called ascospores. They are often called sac fungi. They are the largest extant fungal phylum.

Pezizomycotina—Eurotiomycetes: Onygenales. Within the ascomycete order Onygenales (subphylum Pezizomycotina, class Eurotiomycetes), the majority of the fungal pathogens most significant for immunocompetent vertebrates are found, including *Blastomyces*, *Histoplasma*, *Coccidioides*, *Microsporum*, *Trichophyton*, *Lacazia*, *Paracoccidioides*, *Nannizziopsis*, *Paranannizziopsis*, and *Ophidiomyces.* The Onygenales have been shown to have reduced numbers of plant cell wall–degrading enzymes and tend to have increased numbers of proteases, especially keratinases, which may be adaptations for living on animal hosts.[51]

The anamorph name *Chrysosporium* is used widely for diverse anamorphs found widely across the order Onygenales and contains organisms in diverse teleomorph genera, including *Amaurascopsis*, *Amauroascus*, *Aphanoascus*, *Arthroderma*, *Bettsia, Ctenomyces*, *Neogymnomyces*, *Pectinotrichum*, *Renispora*, *Uncinocarpus*, *Ophidiomyces*, and *Nannizziopsis.*[52] There are significant differences in appropriate clinical approaches to king cobras *(Ophiophagus hannah)*, Oustalet's chameleons *(Furcifer oustaleti)*, and Mexican blind lizards *(Anelytropsis papillosus)*, all in the order Squamata. Similarly, the wide distribution of the genus *Chrysosporium* across an entire diverse order renders it a relatively clinically useless name, and teleomorph names should be used.[13] Older reports may have misidentified members of the Onygenales as *Geotrichum*, *Trichophyton*, or *Microsporum.*

Ophidiomyces. *Ophidomyces ophiodiicola,* in the order Onygenales, family Onygenaceae, has recently been recognized as a major concern in North American snakes. The clinical presentation of the organism is commonly uncreatively called "snake fungal disease," although ophidiomycosis is a better term. Initially misidentified in reports as "*Chrysosporium* anamorph of *Nannizziopsis vriesii*,"[53] *O. ophiodiicola* is more closely related to *Coccidioides immitis* than it is to *Nannizziopsis* spp.[12,54] It was first characterized in 2009 from a black rat snake (*Pantherophis obsoletus*).[55] Reports of cases consistent with ophidiomycosis date to significantly earlier.[56,57] Snakes present with crusting dermatitis, often distributed around the head (Fig. 31.2). Invasion of deeper tissues is possible. It is capable of causing population-level impacts; it appears to be the primary cause for the near-extinction of the timber rattlesnake *(Crotalus horridus)* in New Hampshire.[58] Most reports have involved snakes in eastern North America, where most investigations have focused, but distinct strains of the organism have been reported in Europe.[59] Taxa most commonly affected are viperids and colubrids. Normal cutaneous flora inhibit the growth of *O. ophiodiicola,* so antibiotic use may predispose animals to ophidiomycosis.[60]

FIG 31.2 *Ophidiomyces ophiodiicola* dermatitis in an eastern king snake (*Lampropeltis getula*). (Courtesy of Rob Ossiboff.)

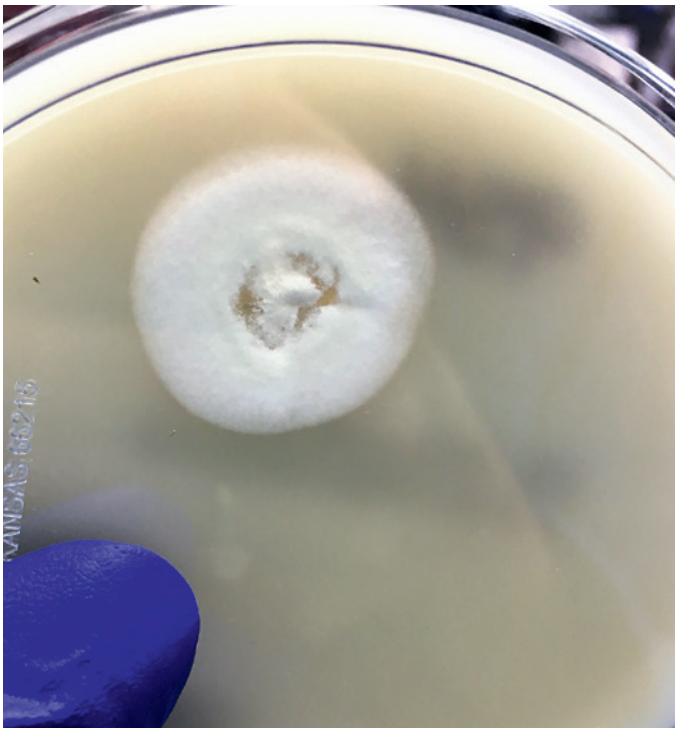

FIG 31.3 *Ophidiomyces ophiodiicola* colony. (Courtesy of Rebecca Richardson.)

Diagnosis. Histological examination of affected skin reveals 2 to 6 µm wide, parallel-walled, septate, rarely branching hyphae. Arthroconidia may be seen. Culture of *Ophidiomyces* cases commonly results in growth mixed with other more rapidly growing fungi, such as *Cladosporium* sp., and overgrowth by nontarget fungi can delay diagnosis. *Ophidiomyces* colonies are white and powdery on potato dextrose agar (Fig. 31.3). Narrow, cylindrical-to-slightly clavate conidia are seen. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used. There are also validated probe hybridization quantitative PCR assays for diagnosis of *O. ophiodiicola.*[61,62]

Treatment. Initial data on susceptibility of *O. ophiodiicola* suggests it is relatively drug resistant. The minimal inhibitory concentration (MIC) of itraconazole for two *O. ophiodiicola* isolates was 0.5 to 1 µg/mL.[63] Another member of the Onygenales, *Blastomyces dermatitidis,* has an itraconazole MIC <0.016 µg/mL, and the EUCAST breakpoint for *Aspergillus fumigatus* susceptibility is ≤1 µg/mL,[64,65] suggesting that

VetBooks.ir

a small shift in susceptibility would result in resistance. Administration of itraconazole at 10 mg/kg per cloaca also did not result in expected therapeutic levels.[63]

The MIC of voriconazole for two *O. ophiodiicola* isolates was 0.25 µg/mL (*B. dermatitidis* MIC 0.063 µg/mL, EUCAST *A. fumigatus* breakpoint ≤1 µg/mL), and the MIC of posaconazole for two *O. ophiodiicola* isolates was 0.5 µg/mL (*B. dermatitidis* MIC 0.016 µg/mL, EUCAST *A. fumigatus* breakpoint ≤0.125 µg/mL), suggesting voriconazole may be effective, and posaconazole is unlikely to be effective.[63–65] Voriconazole and itraconazole have been found to kill *O. ophiodiicola* in vitro.[63] There are significant concerns with safety; injection of voriconazole at 5 mg/kg subcutaneously resulted in the death of 3 of 6 cottonmouths (*Agkistrodon piscivorus*) within 12 hours.[63] Use of implantable osmotic pumps for voriconazole did not result in consistent therapeutic levels.[63] Clinical ophidiomycosis lesions on timber rattlesnakes resolved when given 10 mg/kg voriconazole per cloaca 3 times per week for 4 weeks, with no adverse effects detected.[54] However, levels of voriconazole in the snakes were not measured. The MIC of clotrimazole for two *O. ophiodiicola* isolates was <0.03 µg/mL, and the MIC of miconazole was 0.06 µg/mL.[63] These are low values, suggesting likely efficacy; further study of these drugs for *O. ophiodiicola* treatment is indicated.

The MIC of terbinafine for two *O. ophiodiicola* isolates was 0.015 µg/mL, suggesting this drug is likely to be effective.[63] Terbinafine administered by nebulization or subcutaneous implant resulted in levels expected to be therapeutic.[66] Terbinafine is often synergistic with azoles, and study of combination therapy is merited; clotrimazole/terbinafine nebulization may be effective. Bleach and 70% ethanol are effective for environmental disinfection of *O. ophiodiicola* on cleaned nonporous surfaces.[67]

Coccidioides. *Coccidioides,* in the order Onygenales, family Onygenaceae, contains the species *C. immitis* and *C. posadasii,* which are both significant pathogens in a variety of vertebrates. These two species are not morphologically distinguishable and were only recognized as separate species in 2002. Both species like arid environments with alkaline soil, with *C. immitis* endemic in California and *C. posadasii* endemic in the rest of the southwestern United States and northern Mexico, Guatemala and Honduras, eastern Brazil, and eastern Bolivia/Paraguay to central Argentina. There is no corresponding teleomorph name. Disease in humans is primarily pulmonary and is known as valley fever. In reptiles, natural coccidioidomycosis has been documented in snakes, and experimental infection in other toxicoferan squamates.[68–70] Of these, only one report has attempted molecular identification; in this case, although DNA from other fungi were amplified and sequenced from formalin-fixed paraffin-embedded tissues, *Coccidioides* spp. could not be detected by PCR.[70] A report of histological identification of coccidioidomycosis in a reticulated python (*Malayopython reticulatus*) from Dhaka Zoo in Bangladesh is surprising; neither the location of the zoo nor the endemic range of reticulated pythons are within known range of *Coccidioides* sp.[69] Soil in this area is also acidic. There are sporadic reports of human coccidioidomycosis in nonendemic areas, and further investigation is indicated.[71]

Diagnosis. Although standard radiography is insensitive for diagnosis of pneumonia in reptiles, computed tomography and/or endoscopy can be more useful. Pulmonary lavage or endoscopic biopsy are viable sampling techniques in snakes with potential coccidoidomydosis. Histological examination of affected tissue reveals 10 to 100 µm diameter spherules containing 2 to 5 µm endospores.[72] There is significant cross-reactivity of *Coccidioides* enzyme immunoassays with other endemic mycoses.[72] Although not considered directly infectious from contact with an infected animal, cultures of *C. immitis* or *C. posadasii* are biosafety level 3 (BSL3) agents in the United States, presenting significant risk to laboratory personnel. If a patient is suspected to have coccidioidomycosis, the laboratory should be informed of this when diagnostic samples are submitted. *Coccidioides* colonies produce white cottony mycelia on potato dextrose agar. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used; specific probe hybridization qPCR is also available.[73]

Treatment. In humans, pharmacological treatment of coccidioidomycosis is only recommended in symptomatic patients.[72] *C. immitis* and *C. posadasii* are not highly antifungal resistant; only 1% of isolates are resistant to itraconazole.[73a] Surgical debridement may be an important component of therapy when possible.[72]

Aphanoascella. *Aphanoascella galapagosensis,* in the order Onygenales, family Onygenaceae, has been isolated from carapacial keratitis lesions on a Galapagos tortoise (*Chelonoidis nigra*).[74] Data on susceptibility and treatment of this organism is lacking. *Aphanoascella* colonies are white and cottony. Arthroconidia are cylindrical to slightly barrel-shaped. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is appropriate.

Nannizziopsis. *Nannizziopsis* spp., in the order Onygenales, family Nannizziopsiaceae, have been recognized as a major concern in squamates. They are commonly known by reptile hobbyists as "yellow fungus disease," although nannizziomycosis is a better term. Patients initially present with crusting dermatitis, but invasion of deeper tissues is common and fatality rates are high. Initially misidentified in reports as "*Chrysosporium* anamorph of *Nannizziopsis vriesii* (CANV)," much of the literature unfortunately is incorrect on which fungal species is actually found, resulting in significant confusion. The term CANV should not be used.

Nannizziopsis dermatitidis was first reported in 1999 from chameleons.[12,75] *N. dermatitidis* has also been reported from leopard geckos *(Eublepharis macularius)* and day geckos *(Phelsuma)*.[12] The name *N. arthrosporioides* may have also been used with an isolate of this organism from a water dragon (*Physignathus* sp.), and this characterization involved a more robust gene set.[76] It remains to be determined which name will be accepted. It is the *Nannizziopsis* species most closely related to *N. vriesii.* It does not typically grow at temperatures greater than 30°C, and temperature manipulation may be therapeutically useful.

The best-studied and most clinically common species is *Nannizziopsis guarroi.* It was first characterized in 2010.[77] The genetic distance between *N. guarroi* and *N. vriesii* is similar to that between *Blastomyces dematitidis* and *Histoplasma capsulatum,* implying that similar differences in clinical management are probable.[54] *N. guarroi* is widespread in captive inland bearded dragons and green iguanas (*Iguana iguana*) in North America and Europe and has been reported in green iguanas in South Korea.[78] Growth is more rapid at 35°C than at 30°C, and temperature manipulation is unlikely to be therapeutically useful for most patients.

Nannizziopsis chlamydospora was identified in inland bearded dragons from the United States.[76] It is most closely related to *N. guarroi* and *N. draconii.* Unlike *N. guarroi* and *N. draconii,* it will grow on Sabouraud's dextrose agar with 3% NaCl.[76] It grows at temperatures up to 40°C, even higher than *N. guarroi,* and temperature manipulation is unlikely to be therapeutically useful.

Nannizziopsis draconii was identified in an inland bearded dragon from Spain.[76] It is most closely related to *N. guarroi* and *N. chlamydospora.* It grows at 25°C but not at 40°C, and further study is needed to determine whether temperature manipulation is likely to be therapeutically useful.

Nannizziopsis pluriseptata was identified in a five-lined skink (*Plestiodon inexpectatus*) from the United States.[76] It is divergent from other known *Nannizziopsis* species, making extrapolation from other species more tenuous. It grows at temperatures up to 40°C, even higher than *N. guarroi,* and temperature manipulation is unlikely to be therapeutically useful.

Nannizziopsis barbata was identified in captive and wild coastal bearded dragons (*Pogona barbata*) in southwest Australia.[79] It has not yet been reported outside of Australia. It is most closely related to *N. crocodili,* from Australian crocodiles.[12] It does not grow at temperatures greater than 30°C, and temperature manipulation may be therapeutically useful.

Nannizziopsis crocodili has been associated with fatalities in farmed saltwater crocodiles *(Crocodylus porosus)* in Australia and is the first species identified from lesions in nonsquamate reptiles.[80] It is most closely related to *N. barbata,* possibly representing an Australian clade.[12] Forty-eight hatchlings died in two outbreaks, suggesting a possible age predisposition. It grows at 25°C, more slowly at 35°C, and not at 37°C, so temperature manipulation may be therapeutically useful.

Nannizziopsis infrequens, *N. obscura*, and *N. hominis* have only been identified in human patients. They are all very close relatives of *N. guarroi,* raising concerns of zoonosis by the more thermophilic *Nannizziopsis* spp.[12] There is debate as to whether an isolate termed UTHSC R-4317 from a human represents *N. guarroi* or *N. hominis.*[12,76]

Diagnosis. Histologic examination of affected skin reveals 2 to 12 µm wide, parallel-walled, septate, occasionally branching hyphae.[81] Arthroconidia may be seen. *Nannizziopsis* colonies are white and powdery on potato dextrose agar and grossly resemble *Ophidiomyces.* Morphologic identification is not reliable, and confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

Treatment. There is a significant lack of antifungal susceptibility data for *Nannizziopsis* spp.; it consists largely of uncontrolled case reports of treatment. This is confounded by lack of proper identification; most reports lack proper fungal species identification. A report of susceptibility of "CANV" isolates from inland bearded dragons in Belgium says that sequence data matched *Nannizziopsis vriesii* 100%, but the GenBank accession number given was for *Aphanoascus fulvescens* (*Chrysosporium keratinophilum*).[82] There are significant differences in antifungal susceptibility profiles between different species in the same genus for other fungi, and it is probable that this will be found in *Nannizziopsis* sp.[65]

There is only a single report of *N. dermatitidis/arthrosporioides* therapy. In one of two infected chameleons treated with itraconazole therapy, clinical resolution was seen.[75] There are more reports of *N. guarroi* treatment. In one report, one of three infected inland bearded dragons responded to itraconazole therapy; the other two died.[83] Combination therapy with terbinafine and ketoconazole resulted in clinical resolution in two green iguanas.[84] Treatment of an infected inland bearded dragon with oral voriconazole for 14 days resulted in initial improvement, but the animal recrudesced and was euthanized.[85]

Treatment of inland bearded dragons infected with *N. chlamydospora* has been attempted with either oral voriconazole or oral itraconazole; disease recrudesced in all animals and the animals were euthanized.[85] Treatment of *N. barbata* has been attempted with oral itraconazole, topical nystatin, and topical iodine.[79] All attempted treatments were unsuccessful, resulting in progression of disease and euthanasia.

In summary, there are currently no consistently effective therapy recommendations for any *Nannizziopsis* sp., and the available data are concerning. Clinically it is crucial to determine which species is present in a patient. For some species, environmental temperature manipulation may be an important part of therapy. Surgical debridement may be an important component of therapy when possible. Susceptibility to antifungal drugs should be determined when possible. While susceptibility panels are waiting, a combination of terbinafine and voriconazole is a reasonable empirical therapy, and it is expected that therapy will need to be continued for at least several months. There are concerns about possible itraconazole toxicosis in bearded dragons; in one case series, 5 of 7 inland bearded dragons died when given 5 mg/kg PO q24h for 4 weeks.[82] The cost of long-term voriconazole justifies the cost of drug susceptibility testing.

Paranannizziopsis. *Paranannizziopsis* spp., in the order Onygenales, family Nannizziopsiaceae, have been recognized as a significant clinical concern in squamates and tuatara. Patients initially present with crusting dermatitis, but invasion of deeper tissues is common and fatality rates may be high. Initially misidentified in reports as "*Chrysosporium* anamorph of *Nannizziopsis vriesii* (CANV)," much of the literature unfortunately is incorrect on which fungal species is actually found, resulting in significant confusion. The term CANV should not be used.

Paranannizziopsis crustacea has been identified in an unidentified skink with multifocal dermatitis and in tentacled snakes (*Erpeton tentaculum*).[12,76] The name *Chrysosporium longisporum* has also been used with this organism.[76]

Paranannizziopsis australasiensis has been identified in file snakes (*Acrocordus* sp.), a coastal bearded dragon, and tuatara.[12,86] There appear to be significant differences in susceptibility between species; all cases in tuatara resolved with or without therapy, whereas the coastal bearded dragon was euthanized due to disease progression despite itraconazole treatment.[86] Rapid fatal disease was also seen in file snakes.[12] It is possible that the lower normal temperatures of tuatara may have played a role in case outcomes, and there may be host differences in immune response.

P. californiensis, reported from a tentacled snake isolate, is a very close relative of *P. australasiensis.*[12] Several snakes died in the outbreak.

Diagnosis. Histologic examination of affected skin reveals 2 to 3 µm wide, parallel-walled, septate, branching hyphae.[86] Arthroconidia may be seen. *Paranannizziopsis* colonies are white and powdery on potato dextrose agar and grossly resemble *Nannizziopsis* or *Ophidiomyces.* Morphologic identification is not reliable, and confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.[87]

Treatment. There is a significant lack of antifungal susceptibility data for *Paranannizziopsis* spp. Treatment of a coastal bearded dragon with itraconazole for *P. australasiensis* was ineffective.[86] For some species, environmental temperature manipulation may be an important part of therapy. Surgical debridement may be an important component of therapy when possible. Susceptibility to antifungal drugs should be determined when possible.

Pezizomycotina—Eurotiomycetes: Chaetothyriales. Within the ascomycete order Chaetothyriales (subphylum Pezizomycotina, class Eurotiomycetes), a variety of darkly pigmented fungi may be found, which may cause chromomycosis or phaeohyphomycosis.

Exophiala and Veronaea. The genera *Exophiala* and *Veronaea,* in the order Chaetothyriales, family Herpotrichiellaceae, are significant reptile pathogens. *Exophiala* is a large, paraphyletic genus, and *Veronaea* nests within it.[52] Teleomorphs of *Exophiala* sp have been named *Capronia* sp., but this name is not used significantly in the medical literature. These organisms appear to be most significant in chelonians. *Exophiala equina* was first reported from a Galapagos tortoise.[88] This organism seems to be a specific problem for Galapagos tortoises, and the author is aware of at least three additional cases of *E. equina* in this species. Lesions may be disseminated, and common sites include lungs and bone (Fig. 31.4). Carapacial phaeohyphomycosis due to *E. oligosperma* has been reported in an Aldabra tortoise (*Aldabrachelys gigantica*).[89] An *Exophiala* sp. was reported from a wild eastern box turtle (*Terrapene carolina*) with an extensive granulomatous lesion of the right hind leg.[90] Although the organism was thought to be *E. jeanselmei* based on morphology, there was no molecular characterization done, and organisms with *E. jeanselmei*-like morphology have been shown to be

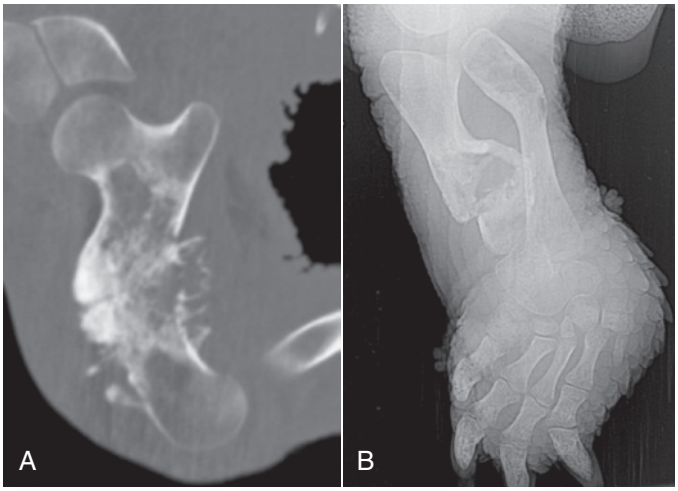

FIG 31.4 (A) Computed tomography of *Exophiala equina* osteomyelitis in the femur of a Galapagos tortoise (*Chelonoidis nigra*). (B) Radiograph of *Exophiala equina* osteomyelitis in the tibia of a Galapagos tortoise. (Courtesy of James F.X. Wellehan.)

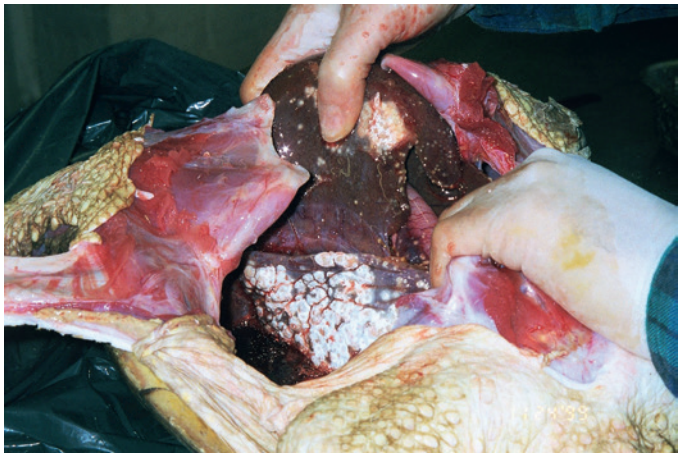

FIG 31.5 Disseminated *Beauveria bassiana* in a common snapping turtle (*Chelydra serpentina*). (Courtesy of James F.X. Wellehan.)

phylogenetically diverse.[91] Obstructive tracheitis due to *Veronaea botryosa* has been reported in green turtles (*Chelonia mydas*).[92]

Diagnosis. Infection with *Exophiala* or *Veronaea* typically causes destructive granulomatous lesions. If present in bone, they may be seen radiographically. Whereas standard radiography is insensitive for diagnosis of respiratory disease in reptiles, computed tomography and/or endoscopy may be more useful (see Fig. 31.4). When tissues are examined histologically, pigmented fungi in granulomatous lesions may be seen. In culture, colonies are dark on potato dextrose agar. Early growth shows yeast; older colonies may show hyphae with clusters of oval conidia. Morphological identification is not reliable, and confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

Treatment. *E. equina* isolates are susceptible to itraconazole and posaconazole but resistant to fluconazole and voriconazole.[93] *E. oligosperma* is also most susceptible to itraconazole and posaconazole, as well as amphotericin B.[94] Terbinafine also shows activity against many *Exophiala* isolates and may be synergistic in combination with azoles.[94] Susceptibility to antifungal drugs should be determined when possible. Surgical debridement may be an important component of therapy when possible.

Pezizomycotina—Sordariomycetes: Hypocreales. The ascomycete order Hypocreales (subphylum Pezizomycotina, class Sordariomycetes) contains a number of significant reptile pathogens. This order contains many significant arthropod pathogens, and some members are used for biological control of arthropod pests.

Purpureocillium. *Purpureocillium lilacinum,* in the order Hypocreales, family Ophiocordycipitaceae, was originally classified in the genus *Penicillium,* then *Paecilomyces*, before being classified as *Purpureocillium.* Clinical disease typically presents as pneumonia, although disseminated infection may be seen.[95–97] Turtles in the Trionychia are also prone to skin lesions.[98–99]

Diagnosis. Whereas standard radiography is insensitive for diagnosis of pneumonia in reptiles, computed tomography or endoscopy may be more useful. Pulmonary lavage or endoscopic biopsy are viable sampling techniques in reptiles with potential *Purpureocillium* infection. Histologically, fungal granulomas with hyphae are seen. Colonies are initially white but take on a reddish-purple color. Morphology is similar to *Penicillium,* with bowling pin–shaped phialides supporting chains of oval conidia. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

Treatment. *Purpureocillium lilacinum* isolates tend to be resistant to amphotericin B and itraconazole but susceptible to voriconazole, posaconazole, and terbinafine. A combination of posaconazole and terbinafine is the best empirical choice for treating *P. lilacinum* infection.[100] Topical malachite green has also been used for cutaneous lesions.[98] Susceptibility to antifungal drugs should be determined when possible. Surgical debridement may be an important component of therapy when possible.

Beauveria and Lecanicillium. *Beauveria bassiana,* in the order Hypocreales, family Cordycipitaceae, is best known as an insect pathogen. It is also a significant reptile pathogen. The teleomorph name has been *Cordyceps bassiana.* Commercial use of *B. bassiana* as an insect biocontrol agent is widespread and has implications for wild reptile populations. Whereas there has been significant study of virulence mechanisms in insect hosts, these studies have primarily been focused on how to increase virulence.[101] Lesions in reptiles are typically pulmonary and have been reported in alligators, tortoises, and emydid turtles (Fig. 31.5).[102–104]

Lecanicillium, like *Beauveria,* are in the order Hypocreales, family Cordycipitaceae. They are also known as arthopod pathogens and are used commercially for insect control, which may have implications for wild reptiles. Members of the genus were formerly known as *Verticillium* before being moved to *Lecanicillium.* A *Lecanicillium* most closely related to *L. attenuatum* and *L. muscarium* caused systemic mycosis in captive Guthega skinks (*Liopholis guthega*).[105] Lesions were first seen as necrotic dermatitis which progressed to myositis, hepatitis, and pneumonia.

Diagnosis. Whereas standard radiography is insensitive for diagnosis of pneumonia in reptiles, computed tomography and/or endoscopy may be more useful. Pulmonary lavage or endoscopic biopsy are viable sampling techniques in reptiles with potential *B. bassiana* infection. Histologically, fungal granulomas with hyphae are seen. Birefringent calcium oxalate crystals may be seen.[103] *B. bassiana* and *Lecanicillium* spp. colonies are typically white to yellow in color. *Beauveria* have flask-shaped structures supporting small numbers of small oval conidia. *Lecanicillium* have elongate pointed phialides with single conidia. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

VetBooks.ir

Treatment. *B. bassiana* isolates tend to be comparatively susceptible to itraconazole, less so to voriconazole, and resistant to fluconazole.[106,107] Data on *Lecanicillium* spp. susceptibility is not yet published, but skinks treated with a regime including oral voriconazole showed clinical resolution.[105] Susceptibility to antifungal drugs should be determined when possible.

Metarhizium. *Metarhizium* spp., in the order Hypocreales, family Clavicipitaceae, are best known as insect pathogens. Characterized teleomorph names are in the genus *Metacordyceps. M. anisopliae* is used commercially for insect control, which has implications for wild reptiles. In experimental challenges, fringe-toed lizards (*Acanthodactylus dumerili*) exposed to *M. anisopliae* either by ingestion or inhalation showed decreased activity compared with controls, with mycotic pneumonia seen at necropsy in some animals.[108] Pneumonia caused by *M. anisopliae* has also been reported in alligators.[109]

Metarhizium granulomatis, previously described as *Chamaeleomyces granulomatis* and *Paecilomyces viridis*, has been associated with dermatitis, glossitis, and disseminated granulomatous mycosis. Veiled chameleons (*Chamaeleo calyptratus*) are the most commonly affected species, with disease in an inland bearded dragon and a panther chameleon (*Furcifer pardalis*) also reported.[110] There are distinct genotypes of *M. granulomatis,* with genotype A more associated with dermatitis, and genotypes B to E more associated with glossitis.[110] *M. granulomatis* has been found in environmental soil samples, and it is probable that this is its usual habitat.

Metarhizium viride, previously described as *Chamaeleomyces viridis* and *Paecilomyces viridis,* has been associated with dermatitis, pharyngitis, glossitis, and disseminated granulomatous mycosis.[111] *M. viride* appears to have a broader host range than *M. granulomatis;* there is a distribution of reported hosts, including veiled chameleons, inland bearded dragons, panther chameleons, and carpet chameleons (*Furcifer lateralis*); the bias toward veiled chameleons seen with *M. granulomatis* is not seen with *M. viride.*

Diagnosis. Glossitis or dermatitis lesions due to *M. granulomatis* or *M. viride* are fairly easily accessible. Whereas standard radiography is insensitive for diagnosis of *M. anisopliae* pneumonia in reptiles, computed tomography and endoscopy may be more useful.[109] Pulmonary lavage or endoscopic biopsy are viable sampling techniques in reptiles with potential *M. anisopliae* infection. Histologically, fungal granulomas with hyphae are seen. Birefringent calcium oxalate crystals may be seen.[109] *Metarhizium* colonies are typically olive green in color. They have cylindrical conidia produced in long chains from branched, subcylindrical phialides. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

Treatment. *M. anisopliae* isolates tend to be susceptible to itraconazole and voriconazole but highly resistant to fluconazole and amphotericin B.[112] *M. granulomatis* isolates were found to be resistant to all doses of itraconazole and ketoconazole tested, and inhibitory concentrations of terbinafine, clotrimazole, voriconazole, posaconazole, and amphotericin B were high enough that clinical therapy with these drugs as a single therapy is unlikely to be susceptible.[110] Treatment of chameleons with *M. granulomatis* using terbinafine and nystatin resulted in continued disease progression and death.[110] Further studies on synergy of posaconazole and terbinafine against *M. granulomatis* are indicated. *M. viride* showed high resistance to voriconazole, fluconazole, clotrimazole, nystatin, posaconazole, nystatin, and amphotericin B, and treatment appears problematic.[111] Whenever feasible, infected tissue should be excised surgically.

Fusarium. *Fusarium* spp. are in the order Hypocreales, family Nectriaceae. It is a large genus with at least 200 species divided into 20 complexes, and many members are common in soil in association with plants and in marine environments. A number of them are plant pathogens. Although *Fusarium* infections are typically not primary pathogens, once they have become established as secondary infections, they are typically very drug resistant and difficult to treat. Cutaneous and respiratory infections are most common in reptiles.

Most infections in reptiles are from members of the *F. solani* complex, which contains at least 18 species associated with disease in animals.[113] Juvenile sea turtles and eggs are commonly affected; loggerhead turtle (*Caretta caretta*) eggs exposed to *F. solani* complex had an 83.3% mortality rate in comparison to 8.3% mortality in control eggs.[114]

Fusarium incarnatum, formerly known as *F. semitectum,* is a member of the *F. incarnatum-equiseti* species complex. It has been associated with scute lesions in Texas tortoises (*Gopherus berlandieri*).[115] *Fusarium proliferatum,* a member of the *F. fujikuroi* species complex, has been associated with dermatitis in 9 of 40 (22.5%) wild fringe-toed lizards (*Acanthodactylus nilsoni*).[116] Lesions were distributed on the front digits and the back of the neck, which may be consistent with combat and mating bite wounds providing a route for infection. The *F. fujikuroi* species complex has also been associated with pneumonia in an alligator.[117] A member of the *F. oxysporum* complex caused disseminated granulomatous infection in a red-bellied black snake (*Pseudechis porphyriacus*).[118] Treatment with itraconazole was unsuccessful.

Diagnosis. Dermatitis lesions due to *Fusarium* spp. are easily accessible. Whereas standard radiography is insensitive for diagnosis of *Fusarium* pneumonia in reptiles, computed tomography and/or endoscopy may be more useful. Pulmonary lavage or endoscopic biopsy are viable sampling techniques. Histologically, fungal granulomas with hyphae are seen. *Fusarium* colonies are white to cream initially but may develop purple to peach coloration as they mature. They have both larger canoe-shaped septate conidiophores and smaller single oval conidiophores. Confirmation of identity should be based on molecular identification. The ITS2 region of the ribosomal RNA genes, commonly used in other fungal taxa, is not sufficient for species identification in *Fusarium* spp. Sequencing of the *ef-1α* and *rbp2* genes is indicated.[119]

Treatment. Treatment of fusariomycosis is very challenging. They are usually multidrug (including itraconazole) resistant. Empirically, a combination of terbinafine with either posaconazole or voriconazole may be used while identification, speciation, and sensitivity results are pending. Whenever feasible, infected tissue should be excised surgically.[120]

Pezizomycotina—Eurotiomycetes: Eurotiales

Aspergillus. *Aspergillus* spp. are in the order Eurotiales, family Aspergillaceae. They are widespread and extremely common in decaying plant matter. Although common pathogens of birds and mammals, they are surprisingly uncommon as pathogens in reptiles. There is only one report of aspergillosis in reptiles with molecular sequence identification; a case of granulomatous pneumonia and hepatitis in a Siamese crocodile (*Crocodylus siamensis*) due to *A. fumigatus.*[121] Unfortunately, details on PCR or sequencing were not given, and sequence data were not placed in a public database.

Saccharomycotina—Saccharomycetes: Saccharomycetales

Candida. *Candida* is a genus in the order Saccharomycetales, which are ascomycete yeasts. They are common in vertebrate gastrointestinal tracts, including reptiles.[122] They are typically benign and form a normal part of gut flora. A major risk factor for development of clinical disease due to *Candida* spp. is the use of antibiotics, disrupting normal bacterial flora.[7] Cephalosporin use, β-lactam–β-lactamase inhibitor combination use, and fluoroquinolone use are especially inked with candidiasis.[7,123] Clinical candidiasis is more common in chelonians than in other reptiles.

VetBooks.ir

Candida albicans has been reported to cause disseminated disease in an elongated tortoise (*Indotestudo elongata*).[124] The animal had recently been treated with enrofloxacin for a wound and subsequently developed fatal candidiasis. *C. albicans* pneumonia has been reported in a Greek tortoise (*Testudo graeca*).[125]

Several reports of clinical candidiasis in reptiles lack identification of which species of *Candida* was present. From healthy tortoises, *C. tropicalis*, *C. famata*, *C. albicans*, *C. guillermondi*, *C. intermedia*, and *C. parapsilosis* were identified in oral and cloacal swabs from *Testudo* and *Chelonoidis* tortoises.[126,127] In healthy sea turtles, *C. parapsilosis*, *C. guillermondi*, *C. tropicalis*, *C. albicans*, and *C. intermedia* were identified.[127] Prevalence is high in healthy chelonians, with 67% of healthy *Chelonoidis* tortoises colonized.[127]

Diagnosis. A history of recent broad-spectrum antibiotic use in chelonians increases the concern for candidiasis. Light-colored plaques are often present with severe overgrowth, and cytology of affected mucosa will reveal large numbers of yeast. Histologically, 2- to 12-µm round yeasts and pseudohyphae are seen. *C. albicans* tends to be at the larger end of the range, whereas other species tend to be smaller. In disseminated cases, blood culture may be useful. On culture, colonies are cream colored and waxy. Confirmation of identity should be based on molecular identification. Sequencing of the ITS2 region of the ribosomal RNA genes is commonly used.

Treatment. Although *C. albicans* are frequently susceptible to azoles, non–*albicans Candida* spp. are frequently significantly more drug resistant. Susceptibility to antifungal drugs should be determined when possible. When mucosal surfaces are affected, nystatin may be effective. Pneumonia due to *C. albicans* in a Greek tortoise (*Testudo graeca*) was successfully treated with intrapulmonary amphotericin B delivered via a transcarapacial pulmonary catheter.[125]

Parasitology (Including Hemoparasites)

James F.X. Wellehan and Heather D.S. Walden

REPTILE-PARASITE ECOLOGY

Parasites are organisms that live in or on other host organisms and benefit by deriving nutrients at the host's expense. In common medical jargon, and for the purposes of this chapter, only nonfungal eukaryotic parasites will be considered. Reptile patients are often approached as a collection of vertebrate cells organized into organ systems. This is highly misleading; most of the cells in a vertebrate are microbial. Microbes are especially critical for digestion and immune function, and maintenance of healthy flora is essential to the health of a reptile patient.

Clinicians are also often misled by Koch's postulates; by fulfilling or not fulfilling these requirements in a controlled experiment, an organism is often considered dichotomously as a pathogen or not a pathogen. This is far from the case; in the real world, numerous host, pathogen, and environmental factors (including coinfections, temperature, nutrition, handling stress, crowding, and others) play significant roles in whether a pathogen manifests as disease. When infectious disease is more properly considered as ecology, it is obvious that a typical disease scenario involves several infectious agents in concert with environmental factors. It is critical to determine whether an organism is acting as a parasite in a given context. Bullfrog tadpoles (*Rana catesbeiana*) that have the pinworm *Gyrinicola batrachiensis* develop more quickly and have better gut fermentation than controls without pinworms, indicating a mutualistic rather than parasitic relationship.[1] Vertebrates have more than likely had gut helminths over most of their evolution.[2] The vertebrate immune system has adapted to living with gut helminths; eradication of gut helminths is associated with a significant increase in autoimmune and allergic disease.[3] Rather than thinking of a war on parasites, clinicians should have the goal of improving ecosystem health within a reptile patient.

Evolution is an essential concept in biology; when one considers definitions for life, perhaps the simplest and most elegant definition is that life consists of things that evolve. Clinically, this is most immediately apparent with infectious disease. Because of short generation times, evolution of parasites occurs in a time frame impacting clinical management of a patient. To compensate, the most rapidly evolving genes in vertebrates are immune related. A parasite does not "want" to cause disease or not cause disease. All life on earth has been selected for billions of years to reproduce successfully, and this is all that matters from an evolutionary standpoint. If pathogenic traits provide an evolutionary advantage in a given situation, they will be selected for. If they provide a disadvantage, they will be selected against.

The need to transfer to a new host creates significant selective pressure. Some parasites, such as *Rhabdias* spp., with both homogonic and heterogonic life cycles, may survive and reproduce well without their hosts, decreasing selective pressure to keep the host alive. High host density also favors virulence by increasing access to new hosts, and increased stocking density creates environments selecting for pathogenicity.

Other routine husbandry practices in the reptile pet trade also create strong evolutionary selective pressures toward pathogenicity. It is common in the pet reptile trade to select for color mutants. This usually involves some degree of inbreeding to select for what are often recessive traits. A major driving force for the evolution of sex is acquisition of genetic diversity for immune function. Inbreeding results in selection for greater disease.[4]

Understanding life cycles is crucial for parasite control. Parasites with direct life cycles complete their life cycles using one host. Keeping that host alive maintains their habitat and is advantageous for the parasite. Parasites with indirect life cycles utilize more than one host and include intermediate hosts. It is often advantageous for the parasite to cause disease in intermediate hosts that will result in death or illness of that host and allow completion of the life cycle. If a rodent with *Baylisascaris procyonis* is mentally impaired by neural larval migrans, that rodent is more likely to be predated upon by a raccoon, completing the life cycle. Clinical parasitic disease is typically much more significant for intermediate hosts than definitive hosts.

DIAGNOSTIC CONFIRMATION

Diagnosis of parasitic disease needs to be done with an understanding of the ecology of the patient and parasite. A history and physical examination is a good starting point, with the recognition that husbandry has played a major role in almost any disease process for which a captive reptile is presented to a veterinarian, and husbandry improvements will need to be part of the therapeutic approach. Wild-caught animals are more likely to have parasitic disease than captive-bred animals, and parasites with direct life cycles are much more likely to persist in captive populations than those with indirect life cycles.

Diagnosis of parasites in their definitive hosts, where ova, oocysts, cysts, or larvae are produced, is much easier than diagnosis of parasites in intermediate hosts. Many of these parasite diagnostic stages are shed in feces. Fecal flotation is very useful for diagnosis of enteric coccidia, as well as many nematodes, cestodes (if eggs have been released from proglottids), and sometimes pentastomids. Different flotation media are used; some are concentrated salts, and others are sugars. Some parasites are best identified using specific solutions. The specific gravities of these solutions are important, as are the specific gravities of the diagnostic stages of the parasites in question. Using a centrifuge for fecal flotations, in addition to a solution with higher specific gravity, increases the ability to detect these diagnostic stages, especially when sample sizes are small, as many reptile samples are, and when there are few ova, oocysts, cysts, or larvae present in the samples. Some enteric parasite diagnostic stages have a high specific gravity, including ova of trematodes, acanthocephalans, and some nematodes and pentastomids, and fecal sedimentation is preferred. The salt or sugar flotation solutions can sometimes distort the morphologic characteristics of larvae recovered in feces, so a sedimentation can also be used to preserve these

VetBooks.ir

characteristics and allow identification. Quantification of parasite egg counts using modified McMaster techniques or larval counts using modified Baermann techniques can also provide valuable information on parasite burden and response to therapy. This can be especially important when formulating strategic anthelmintic strategies for reptiles kept outside.

Direct microscopic examination of feces by direct fecal smear in saline is the best way to detect motile enteric protozoa. Feces need to be fresh and at room temperature to observe motility of trophozoites, including flagellates, ciliates, and amoeba, because these organisms are susceptible to desiccation and cold or hot temperatures. Fresh feces can also be fixed in zinc polyvinyl alcohol (Zinc-PVA) and stained with a trichrome or iron hematoxylin stain to show the internal characteristics of the protozoans. The trichrome stain method is preferred for identification of amoeboid cysts and trophozoites. Hemoparasites can be detected with blood smears stained with Wright's or Giemsa stain or a combination. Some blood parasites are intracellular, and some are extracellular. Additional blood samples should be stored frozen for molecular identification.

Pseudoparasites are parasites found during patient or fecal examinations of a reptile, but the parasite is actually from another host. For example, if reptiles are fed mice, four helminth eggs might appear in fecal examinations that are parasites of the mice (prey) and not the reptile (Figs. 32.1 through 32.4). Pseudoparasites are common and can be easily confused with true parasites, an important distinction because the former do not require treatment.

For the diagnosis of gastric *Cryptosporidium*, gastric biopsies are the gold standard. For intestinal species, the biopsy should be from the intestines. If animals in a collection are dying, necropsy and histopathologic examination of gastric and intestinal tissue are helpful in determination of the cause.

Reptiles fed mice may have false-positive fecal examination results because mice harbor their own *Cryptosporidium* species, and these cause problems for diagnosis based on lack of morphologic differences from those that are parasites of reptiles (Fig. 32.5).

Diagnosis of parasites in intermediate hosts, where parasites are more typically encysted in tissues, waiting to be ingested by the definitive host, is more challenging. Physical examination or imaging may identify potential sites of encysted parasites, and excisional biopsy may be needed to acquire samples. Samples of parasites are best kept in 70% ethanol or at −80°C; formalin fixation damages DNA, preventing molecular diagnostics, and can hinder gross identification. Further detail on parasite preservation may be found in Sepulveda and Kinsella.[5]

SINGLE-CELLED PARASITES

Identification of single-celled parasites is more challenging. They generally are not visible without magnification and lack sufficient morphologic

features to make morphologic identification reliable. There is also significantly more diversity present. Multicellular parasites are found in one clade, the Metazoa, or animals; unicellular parasites are found across the Eukaryota. Morphologic groupings, such as flagellates or amoeba, are widespread across diverse taxa and do not imply relatedness. There is a life stage of humans and reptiles that is a flagellate, and phagocytic immune cells are amoeboid. Molecular sequence may be necessary for accurate identification, and, for PCR-based methods, it is necessary to have primers that amplify primer but not host. Because flagellates are widespread across eukaryotes, primers that would amplify DNA from all eukaryotes would also amplify DNA from animal hosts. It is therefore necessary to target PCR assays more narrowly toward specific clades. Techniques such as next-generation sequencing (NGS), which involve obtaining large numbers of nontargeted nucleic acid sequences from a given sample and then identifying the resultant sequences, may hold promise for the future. However, although costs have dropped dramatically, NGS is still too expensive for routine diagnostic use, and the lack of reference sequence, especially in nondomestic animals and their parasites, is a major impediment to interpretation of data.

Alveolata

The Alveolata are a clade of eukaryotes that have cortical alveoli, which are vesicles underlying the cell membrane. There are a number of phyla within the alveolates, of which the Ciliophora and Apicomplexa are the most relevant for reptile parasitology.

Ciliophora (*Balantidium, Nyctotherus*). Ciliophora is a phylum of aveolates that have short hairlike cilia that move in an undulating pattern (Fig. 32.6). Although common in gastrointestinal tracts of vertebrates, there is limited data on their pathogenicity. There is a single case report of ciliate-associated enteritis in a puff adder (*Bitis arietans*) kept at inappropriate temperatures.[6] A collection of snakes with enteritis had ciliates morphologically consistent with *Balantidium* sp. present, as well as bacteria morphologically consistent with *Clostridium,* and improved after treatment with metronidazole.[7] Overall, ciliates do not appear to be highly pathogenic in reptiles, and high numbers are more indicative of gut dysbiosis. Cysts of the genus *Nyctotherus* strongly resemble trematode ova; one way to differentiate them is that *Nyctotherus* cysts will be commonly found on a fecal flotation, whereas trematode ova usually will not (Fig. 32.7). However, there are occasions where trematode ova are detectable on a fecal flotation, so this should not be used as a sole method of differentiation.

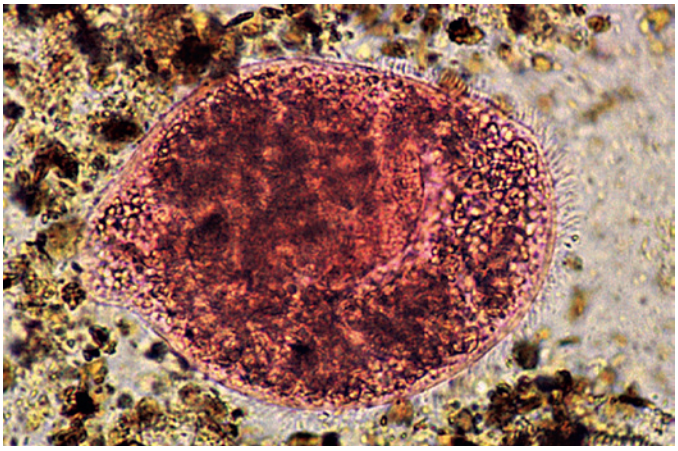

FIG 32.7 *Nyctotherus* (merthiolate stain). (Courtesy of F.L. Frye.)

Apicomplexa. Apicomplexa is a phylum of alveolates that have apicoplasts, unique organelles that have their own genomes and are involved in important cellular functions, much like mitochondria or chloroplasts. They typically do not have cilia, flagella, or pseudopods, and they move using gliding motility. This phylum contains many of the most clinically significant reptile parasites. They are divided into the classes Aconoidasida, containing the orders Haemosporidia and Piroplasmida, and Conoidasida, containing the subclasses Coccidia and Gregarinasina.

Haemosporidia (*Plasmodium, Haemoproteus, Haemocystidium*). The order Haemosporidia are intraerythrocytic parasites in the class Aconoidasida with indirect life cycles, typically transmitted by invertebrates. Important genera infecting reptiles in this group include *Plasmodium*, *Haemoproteus*, and *Haemocystidium.* All are insect vectored and target erythrocytes. Molecular sequence data have shown that the *Plasmodium* of reptiles are paraphyletic.[8] Although haemosporidians are generally considered to have high host fidelity, *Haemoproteus anatolicum* has been found to infect both Horsfield's tortoises (*Agrionemys horsfieldii*) and Greek tortoises (*Testudo graeca*).[9] Much work needs to be done to determine the diversity of haemosporidians using nonavian reptile hosts and their clinical significance. *Plasmodium falciparum* caused 212 million cases of malaria in humans, resulting in 429,000

VetBooks.ir

deaths from the infection in 2015.[10] The significance of malarial parasites in mammals suggests that they are likely significant in reptiles as well. Their indirect life cycles tend to make them less significant in captivity, where life cycles may be interrupted by separation from vectors. Drugs used for treatment of human malaria include mefloquine, primaquine, chloroquine, doxycycline, and atovaquone; data on these drugs in reptiles are lacking.

Coccidia. The subclass Coccidia are intracellular parasites in the class Conoidasida, phylum Aveolata. The order Eucoccidiorida contains the vertebrate parasites and is divided into the suborders Adeleorina and Eimeriorina.

Adeleorina (*Hepatozoon, Hemolivia, Haemogregarina, Karyolysus*). The suborder Adelorina are intracellular coccidian parasites. They have indirect life cycles and may be transmitted by hematophagous insects, ticks, or leeches. They are most commonly found in aquatic reptiles. Disease appears to be most strongly associated with aberrant hosts.[11] Diagnosis is commonly made through examination of blood smears or through histopathology. Specific identification of organisms may be done though nucleic acid sequencing. There is a lack of data on safety or efficacy of pharmacologic treatment of adelorine parasites in reptiles; in dogs, *Hepatozoon americanum* is most commonly treated with decoquinate or ponazuril.[12] Limited data found a decrease in hemogregarine loads in lizards treated with atovaquone.[13]

Eimeriorina (*Cryptosporidium, Isospora, Sarcocystis, Eimeria, Caryospora, Schellackia, Choleoeimeria*, Intranuclear Coccidium of Tortoises). The suborder Eimeriorina are intracellular coccidian parasites. There are three families that are relevant for reptile medicine: Cryptosporidiidae, Eimeriidae, and Sarcocystidae. Sexual reproduction is typically in the intestine of the definitive host, followed by fecal shedding. In many cases in which coccidian oocysts are seen in the feces, whether disease or simply infection exists is unknown, and additional clinical data such as histopathology are needed. Cryptosporidiidae and Eimeriidae typically have direct life cycles, utilizing a single host, with oocysts passed in the feces. Sarcocystidae typically have obligate two-host cycles, although exceptions exist, and oocysts are passed in the feces of the definitive host (Figs. 32.8 to 32.11). To date, vertical transmission of coccidia has not been shown in reptiles.

Coccidian oocysts generally need time to sporulate after they are shed before they are infective; *Cryptosporidium* and some species of *Sarcocystis* are exceptions. In general, once the sporulated oocyst is ingested, the sporozoites leave the oocyst and penetrate epithelial cells that line gastrointestinal mucosa. Development is intracellular, and with each phase of the cycle, more host cells are killed as the parasites exit the host cells in which they were produced and enter other cells.

Set numbers of asexual generations exist within one life cycle, and then the sexual phase ensues and produces gametes and zygotes. A wall is produced by the parasite around the zygote that is now an oocyst. It is expelled from the host cell and passes in the feces.

Whether disease is caused by the developing coccidian depends on the number of oocysts initially ingested, the ability of the host to replace the cells killed quickly enough to preclude clinical disease, the genetics of the parasite itself, and the host immune status. Coccidia that infect cells beyond the gastrointestinal tract are often associated with more significant pathology. Enteric coccidiosis is most commonly a disease of young animals, where stunting or slowing of growth and maturation may be evident. See Table 32.1 for generic oocyst morphology.

Cryptosporidiidae. Cryptosporidiidae contains a single genus, *Cryptosporidium*. Cryptosporidian parasites are epicytoplasmic in host cells rather than intracytoplasmic, unlike most other coccidia. All *Cryptosporidium* species have direct life cycles. Oocysts are less than 8 µm in diameter and stain acid-fast (see Fig. 32.5). It should be noted that *Cryptosporidium* only stains acid-fast on fresh smears and not in

TABLE 32.1 Generic Oocyst Morphology

	Sporocyst No.	Sporozoites/Sporocyst No.
Cryptosporidium	0	4/oocyst
Caryospora	1	8
Isospora	2	4
Sarcocystis	2	4[a]
Eimeria	4	2

[a]Oocysts of Sarcocystis rupture while passing through the gut; thus, one typically sees sporulated sporocyst.

formalin-fixed tissues. Oocysts are sporulated and infective when feces is passed. Morphologic species identification is not reliable, and sequence-based techniques are needed to differentiate species.[14] Differentiation of species is especially important because prey items may have *Cryptosporidium* sp. that do not infect reptiles but may pass intact through the gastrointestinal tract and be seen in feces; *C. muris* is commonly seen in rodent-eating reptiles and has no clinical significance for reptiles. Some studies have found *C. muris* to have a higher prevalence in snakes than *C. serpentis.*[15] *Cryptosporidium* sp. vary significantly in their host specificity; some are highly tropic for one host taxon, whereas others have a broad host range.

There are two major clades of *Cryptosporidium;* one is tropic for the stomach and the other is tropic for the intestines. In squamates, the most common gastric species is *C. serpentis.* In chelonians, the most common gastric species is *C. testudinis.*[16] *Cryptosporidium testudinis* has also been reported in ball python (*Python regius*) feces, indicating that squamates may also be susceptible.[16] Neither is known to be zoonotic, although *C. serpentis* has been found in cattle.[17] Gastric cryptosporidiosis often presents with regurgitation. In snakes, gastric thickening may be externally visible.

In squamates, the most common intestinal species is *C. varanii.* This species has also been incorrectly reported in the literature as *C. saurophilum.*[18] In chelonians, the most common intestinal species is *C. ducismarci.*[16] There is comparatively more diversity among intestinal *Cryptosporidium,* with several additional species possibly present.[19] Intestinal cryptosporidiosis often presents as poor growth or weight loss.

An uncharacterized *Cryptosporidium* has been seen in the ears of green iguanas (*Iguana iguana*), and *Cryptosporidium* avian genotype V has been seen in urinary bladders of the same species.[20,21]

Advanced cryptosporidiosis is typically fatal in reptiles, although subclinical infections may persist without clinical signs. Coinfections with agents such as adenoviruses appear to increase the likelihood of disease manifestation.

Diagnostic samples vary depending on site of infection. For gastric species, gastric biopsies or washes are better samples than feces. For intestinal species, biopsy or feces are preferred. Histopathologic evidence of disease is ideal, and endoscopic biopsies are a good way of obtaining antemortem samples. Organisms may be seen on the apical surface of enterocytes. There are significant gaps in knowledge of antigen cross-reactivity with antibody-based assays, making them unreliable. PCR with sequencing is the current best approach for identification of the etiologic agent.

There are no known effective treatments for cryptosporidiosis in reptiles. Drugs such as paromomycin or nitazoxanide have been used and do not consistently clear infection. Maintenance of a closed group, testing of populations, strict quarantine, and stringent biosecurity practices are the most effective means of prevention. *Cryptosporidium* oocysts are exceptionally stable in the environment; they are not susceptible to ultraviolet disinfection, and even 6% bleach with a 2-hour contact time only resulted in 92.7% reduction. Chloro-m-cresol was more effective.[22]

Eimeriidae. Eimeriidae are intracellular coccidian parasites. They tend to have direct life cycles and are typically transmitted by fecal-oral routes. Important members of this group include *Isospora*, *Eimeria*, *Caryospora*, *Schellackia*, *Choleoeimeria*, and the intranuclear coccidium of tortoises. Eimeriidae with extraintestinal life stages tend to be associated with more significant disease. Although initial morphologic identification was based on sporulation patterns, use of this has led to errors. Molecular sequence data has shown conclusively that what was formerly considered to be *Isospora,* based on sporulation patterns, consisted of two evolutionarily distinct groups. The presence or absence of Stieda bodies, the use of paratenic hosts, and reptilian or mammalian host specificity, are more phylogenetically informative than number of sporocysts or sporozoites for these genera.[23] The use of sporulation patterns has resulted in paraphyletic definitions of *Caryospora* and *Eimeria* that are widespread across the Eimeriidae.[24]

Caryospora are an eimeriid genus with both direct and indirect life cycles, containing more than 25 species. Oocysts have a single sporocyst with eight sporozoites. Carnivorous birds and other carnivorous reptiles serve as definitive hosts, where *Caryospora* sp. replicate in the intestines. Known intermediate hosts are typically prey mammals, where

VetBooks.ir

extraintestinal tissue cysts may be in the skin. Clinical signs in carnivorous reptiles center around enteritis, weight loss, and diarrhea. Management centers around excluding *Caryospora* sp. from collections through quarantine surveillance, disinfection of contaminated areas, and breaking the life cycle by obtaining food animals that are free of *Caryospora. Caryospora* have recently been recognized as significant pathogens associated with mortality events in sea turtles.[24]

Eimeria is a diverse eimeriid genus with direct life cycles. Oocysts have four sporocysts, which each contain two sporozoites. Most species replicate in intestinal epithelium. Management centers around excluding *Eimeria* sp. from collections through quarantine surveillance and disinfection of contaminated areas. *Eimeria* tend to be very host specific, and host-jumping between distantly related reptile taxa is rare. However, there are potential concerns for transmission between more closely related taxa. Coinfections with agents such as adenoviruses may play significant roles in disease manifestation. Infections in otherwise healthy adult animals are often subclinical.

Isospora is a diverse eimeriid genus with direct life cycles. Oocysts have two sporocysts, which each contain four sporozoites. However, molecular sequence data have shown conclusively that what was formerly considered to be *Isospora*, based on sporulation patterns, consisted of two evolutionarily distinct groups. All former *Isospora* of mammals are members of the Sarcocystinae, and not the Eimeriidae, and were moved into the new genus *Cystoisospora.* All true *Isospora* utilize reptilian hosts, including the Dinosauria (birds). *Isospora amphibolouri* (see Fig. 32.8) is the most common coccidian found in bearded dragons (*Pogona vitticeps*); it is not known to have extraintestinal stages but can cause significant enteritis in young animals.

Schellackia are a group of eimeriid coccidia that have indirect life cycles and infect squamates. Oocysts contain eight naked sporozoites. After undergoing sexual reproduction in the intestine, sporozoites are released into the bloodstream rather than the intestinal lumen, where they infect erythrocytes or lymphocytes. They are then transmitted by hematophagous invertebrates. Because they are not shed in feces, they will not be seen on fecal examination and may be found on blood smears. Because of their indirect life cycle, they are uncommon in captive-bred animals. They are closely related to the sea turtle *Caryospora* and to *Eimeria gruis,* an extraintestinal coccidian of cranes.[24]

Choleoeimeria are eimeriid coccidia that are similar to *Eimeria,* but endogenous development occurs in biliary epithelium rather than intestinal epithelium. *Choleoeimeria hirbayah* is a significant pathogen of veiled chameleons (*Chamaeleo calyptratus*).[25]

The still-unnamed intranuclear coccidium of tortoises (TINC) is a major tortoise pathogen, especially in Old World tortoises such as radiated tortoises (*Astrochelys radiata*) and leopard tortoises (*Stigmochelys pardalis*), although red-footed tortoises (*Chelonoidis carbonaria*) have also been infected.[26] Detections thus far have been restricted to hosts in the superfamily Testudinoidea, with most reports in the family Testudinidae (tortoises). TINC has also been identified in the members of the families Emydidae (Eastern box turtle [*Terrapene carolina*]) and Geoemydidae (Arakan forest turtle [*Heosemys depressa*]).[27]

TINC is often multisystemic, infecting epithelial cells, and can be associated with lymphoplasmacytic, or mixed inflammation, and variable necrosis and epithelial hyperplasia. Clinical findings in TINC-infected tortoises are nonspecific and may include anorexia, lethargy, weight loss, emaciation, weakness, diarrhea, ocular and nasal discharge, ulcers of the oral or gastrointestinal mucosa, respiratory distress, swollen erythematous vent, and ascites. The course of disease is often very rapid, and mortality rates are high.

The life cycle of TINC is not fully understood. Oocysts have yet to be identified. The organism may be shed cloacally in large amounts in Old World tortoises, but this was not seen in red-footed tortoises.[26]

Surprisingly, the organism was found by qPCR in the blood of affected red-footed tortoises but was not found in cloacal swabs, which is the opposite of what is seen in Old World tortoises.

Antemortem diagnosis of TINC was first achieved through PCR of nasal lavages from Sulawesi tortoises (*Indotestudo forstenii*) with rhinosinusitis.[28] A quantitative polymerase chain reaction assay (qPCR) targeting a unique region from the TINC 18S rRNA gene was developed to be specific for TINC and can detect as few as 10 copies of target DNA.[27]

Treatment of intranuclear coccidiosis with ponazuril is possible. The clinical signs of treated animals often improve with ponazuril, but follow-up testing often reveals shedding of the organism. This may be because ponazuril is more active against actively dividing parasites and may not affect encysted latent organisms. Pharmacokinetic data show low oral bioavailability but a very long half-life of ponazuril in red-footed tortoises.[29]

Two additional unnamed coccidia in the Eimeriidae have been found in the adrenal glands of leatherback sea turtles (*Dermochelys coriacea*) in the Atlantic.[30] They were associated with lesions in the adrenal glands of 100% of 17 adult and subadult turtles, although none of the four juvenile turtles had lesions or parasites detected.

Sarcocystidae. Sarcocystidae contains several different genera, not all of which have proven to be valid when further examined. The clinically relevant genera in reptile hosts include *Sarcocystis*, *Besnoitia*, and *Toxoplasma.* Sarcocystidae typically have obligate indirect life cycles, although some species may be facultatively direct in their definitive hosts. Reptiles may be intermediate, definitive, or both hosts, depending on the parasite. Host fidelity is typically higher, and pathology is less significant in definitive hosts.

Sarcocystis are a sarcocystid genus containing more than 120 known species. Oocysts have two sporocysts with four sporozoites (see Fig. 32.9A), similar to *Isospora* in the Eimeriidae. Carnivorous or omnivorous vertebrates serve as definitive hosts, where *Sarcocystis* sp. replicate in the intestines. Clinical disease in definitive hosts centers around enteritis, with weight loss and diarrhea the most common signs. Definitive host ranges tend to be more limited than intermediate host ranges. Intermediate hosts are prey animals, where initial stages replicate in blood vessels, followed by development of sarcocysts in tissues, commonly muscle (see Fig. 32.9B). Sarcocysts are often grossly visible and may appear as white streaks in muscle. The most significant disease is seen in intermediate hosts, where signs may include depression and sudden death. Induction of disease in intermediate hosts may make predation more likely, completing the parasite's life cycle. There is zoonotic potential for humans to serve as intermediate hosts for *Sarcocystis* sp., with snakes as definitive hosts.[31] Management centers around excluding *Sarcocystis* sp. from collections through separation of definitive hosts and their feces from intermediate hosts and, for carnivorous/omnivorous reptiles, exclusion of potential other intermediate hosts that may be ingested.

Besnoitia is a sarcocystid genus with a facultatively indirect life cycle. In intermediate hosts, meronts develop in mesenchymal cells forming cysts. Various squamate species have been reported to serve as intermediate hosts, although further characterization to species has not been done.[32]

Toxoplasma is a sarcocystid genus with a facultatively indirect life cycle, containing one species, *T. gondii.* Cats are the definitive hosts. *Toxoplasma gondii* has very little specificity for intermediate hosts and is a zoonotic disease. All amniote species should be considered susceptible intermediate hosts; those that ingest other intermediate hosts or cat feces are at greater risk, and infection has been best characterized in vipers and cobras from areas with higher temperatures.[33] Management centers around excluding *T. gondii* from collections through exclusion of cats and cat feces and, for carnivorous/omnivorous

VetBooks.ir

reptiles, exclusion of potential other intermediate hosts that may be ingested.

Excavata

The Excavata are a clade of eukaryotes that are often flagellated, may lack mitochondria, and often have a ventral feeding groove. Within the Excavata, the superclass Fornicata, superclass Parabasalea, and phylum Euglenozoa contain the most relevant reptile parasites.

Fornicata (*Giardia, Hexamita*). The excavate superclass Fornicata contains the Diplomonadida, which contains the family Hexamitinae. The Hexamitinae are flagellates that have two nuclei and lack true mitochondria, although they may have homologous mitosomes that do not synthesize ATP. The most clinically relevant organisms within the Hexamitinae are the genera *Giardia*, *Spironucleus*, and *Hexamita.*

All parasites in this group have direct life cycles. Although *Giardia* are significant enteric pathogens in mammals, their pathological role in reptiles, including the birds, is not as well established. The mammal pathogen *G. duodenalis* was found in 16% of wild lizards in Europe; although disease associated with this organism has not been reported in lizards, it is of significant zoonotic concern.[34] *Giardia* is a graceful swimmer, and on a direct smear as it rolls over, one can see the concave sucking disc (Fig. 32.12).

The genus *Hexamita* contains significant but poorly understood reptile pathogens. Reported clinical disease caused by *Hexamita* sp. is typically tubulointerstitial nephritis, leading to renal failure and death.[35] Disease is most commonly seen in chelonians but also occurs in squamates. They are thought to have direct life cycles, and renal infection is thought to ascend from the cloaca.

Diagnosis of hexamitiasis is challenging; there is a lack of clinically applicable molecular diagnostic assays for these agents. *Hexamita* is smaller than other flagellates, usually less than 8 microns in length, and quickly swims directly out of the field of view at high magnifications (Fig. 32.13). Current disease reports have been based on morphological diagnosis of binucleate flagellates lacking the disc structure seen with *Giardia* or *Spironucleus.* Controlled studies on treatment of hexamitiasis in reptiles are lacking; metronidazole has been found to be effective for treatment of *H. salmonis* in rainbow trout.[36]

Parabasalea (*Monocercomonas*). The excavate superclass Parabasalea are flagellates, often associated with animal gut flora. They have single nuclei, are anaerobic, and lack mitochondria and a feeding groove. The best studied reptile pathogen in this clade is *Monocercomonas colubrorum,* in the order Tritrichomonadida. However, it is probable that there is significant diversity still to be identified.

Monocercomonas has a stiff axostyle running its length, three anterior flagella, and a single trailing flagellum. *Monocercomonas colubrorum* is a significant disease in squamates, where it causes enteritis.[37] Large numbers of flagellates are seen on a fresh fecal wet mount in saline. Morphological identification led to significant misclassification of the Parabasalea, especially the family Monocercomonadidae, and sequence data is more reliable.[38] An in situ hybridization (ISH) assay has been developed for diagnosis of *M. colubrorum,* and it was found in 34 of 182 (19%) snakes with enteritis, a greater proportion than was found for *Cryptosporidium* (4%) or *Entamoeba* (7%).[39]

Controlled data on treatment of *M. colubrorum* is lacking, but Tritrichomonadida tend to be responsive to metronidazole.[40] Pharmacokinetic data is available in squamates.[41]

Euglenozoa (*Trypanosoma, Leishmania*). The excavate superclass Euglenozoa are flagellates. The medically significant members are in the order Kinetoplastida. Kinetoplastida have a kinetoplast, a large mitochondrion near the flagellar basal body. Within the Kinetoplastida, the family Trypanosomatidae contains the genera *Trypanosoma* and *Leishmania*, which both contain significant human hemoparasitic pathogens that are primarily insect-vectored.

The genus *Trypanosoma* have a single flagellum. They cause significant human diseases, including African sleeping sickness and Chagas disease. They typically have an indirect life cycle, utilizing insects as intermediate hosts, although some *Trypanosoma* sp. found in aquatic reptiles are vectored.[42] However, *T. equiperdum,* the agent of dourine in horses, is primarily transmitted through direct contact, usually sexual.

Trypanosoma brucei, the causative agent of African sleeping sickness and a close relative of *T. equiperdum*,[43] has been found to successfully infect Nile monitors (*Varanus niloticus*), and there is serologic evidence wild monitors may be infected.[44] The vectors for *T. brucei* are tsetse flies (*Glossina* sp.), and *G. fuscipes* was found in one study to take up to 27% of its blood meals from Nile monitors.[45] The import of wild-caught Nile monitors is still common, and the potential for zoonotic disease should be considered. Although tsetse flies are not yet endemic outside of Africa, veterinarians may be at higher risk for contact with blood.

There are very limited data on pathology of *Trypanosoma* sp. in reptiles. *T. therezieni,* found in short-horned chameleons (*Calumma brevicorne*), was experimentally inoculated into carpet chameleons (*Furcifer lateralis*). Infected carpet chameleons died within 11 to 18 days with high levels of parasitemia.[46] It is probable that trypansomes

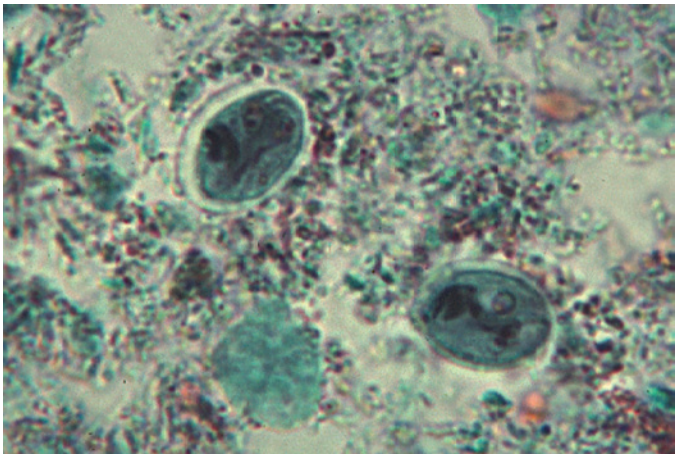

FIG 32.12 *Giardia lamblia.* (Courtesy of F.L. Frye.)

FIG 32.13 *Hexamita* from *Clemmys marmorata.* (Courtesy of F.L. Frye.)

VetBooks.ir

will be most pathogenic in nonendemic hosts that are closely enough related to their adapted endemic hosts for trypanosomes to infect but have not yet had selection on their populations by the given parasite. Diagnosis of trypanosomiasis in reptiles is currently based on visualization of trypomastigotes in stained blood smears. Molecular identification by PCR and sequencing is needed for species identification.

Data on treatment of trypanosomiasis in reptiles are lacking. Antitrypanosomal drugs tend to be toxic, and different drugs are used in humans for African sleeping sickness and Chagas disease. In one author's experience, use of eflornithine in an African side-necked turtle (*Pelusios* sp.) was rapidly followed by death, consistent with toxicosis.

Leishmania is a genus in the family Trypanosomatidae with indirect life cycles that are transmitted by sandflies. The motile promastigote stage develops in the sandfly vector, and amastigotes, lacking flagella, reproduce in the vertebrate host. In reptiles, reproduction typically occurs in erythrocytes. Although organisms from reptile hosts were formerly considered as a separate genus, *Sauroleishmania,* sequence data has shown this to be incorrect. A *Leishmania* isolated from a plated lizard has been shown to cause cutaneous leishmaniasis in mice.[47] There has been a long relationship between *Leishmania* and reptiles; nucleated red cells in the gut of sandflies in early Cretaceous amber contain organisms morphologically consistent with *Leishmania.*[48] Despite the fact that leishmaniasis causes 20,000 to 40,000 human deaths per year,[49] there has been no published investigation of disease in reptiles.

Amoebozoa (*Entamoeba*)

The Amoebozoa are a clade of eukaryotes with trophozoites that primarily move by extension of pseudopods and whose primary mode of nutrition is phagocytosis. They are not the only clade with these characteristics (e.g., *Naegleria* is not in the Amoebozoa), and some members do have flagellar motion. They appear to be the closest relatives of the Opisthokonta, the clade containing fungi and animals. Diverse members of the Amoebozoa are found in association with reptile gastro-intestinal tracts, including *Rhizomastix*, *Hartmannella*, *Echinamoeba*, and *Acanthamoeba.*

Entamoeba Invadens. The taxon most strongly associated with disease in reptiles is *Entamoeba,* and *E. invadens* is the best-characterized reptile pathogen in the genus. This organism has a direct life cycle, and transmission is through fecal-oral route. Disease due to *E. invadens* presents as necrotic enteritis and hepatitis. Signs include lethargy, depression, hematochezia, and death. The life cycle of *E. invadens* consists of a motile trophozoite and a more environmentally stable cyst (Fig. 32.14).

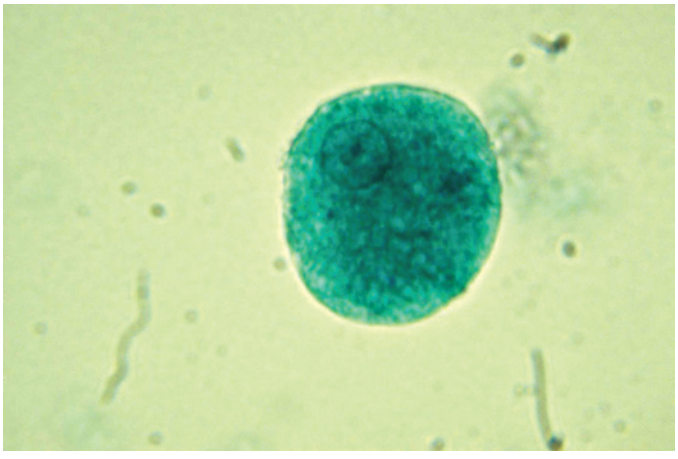

FIG 32.14 Amoeba, *Entamoeba invadens* trophozoite. Photomicrograph magnification, 1000×.

Although disease often presents more dramatically in squamates than in chelonians or crocodilians, chelonians are certainly susceptible to disease, and all nonavian reptiles should be considered at risk.

Diagnosis is often made based on trichrome staining and morphologic characterization; however, many species can potentially be present and, combined with poor sample quality, may hinder identification. Molecular sequencing has also found *E. terrapinae*, *E. insolita*, *E. barreti*, *E. testudinis*, and *E. ranarum* in reptiles.[50] Unfortunately, the sensitivity of currently described PCR techniques is rather poor, and improved methods are needed. Amplification of nonspecific products is common with available methods, and all PCR products should be identified by sequencing.

The most important component of therapy for *E. invadens* is temperature manipulation. In experimentally inoculated snakes, snakes that were maintained at 13°C, 33°C, and 35°C did not develop clinical disease. However, snakes kept at 25°C consistently died with clinical disease.[51,52] Metronidazole is also commonly used for treatment of *E. invadens.*[41] For species with appropriate thermal tolerances, the author treats *E. invadens* by raising enclosure temperatures to a minimum of 33°C for 60 days and administering metronidazole at 20 mg/kg PO daily.

METAZOAN PARASITES

The Metazoa are multicellular animals. They cluster with fungi in the clade Opisthokonta. Reptile parasites are largely found in the Bilateria, animals with bilateral symmetry. Within the Bilateria, reptiles and other vertebrates fall within the Deuterostomia, and metazoan parasites of reptiles fall within the Protostomia. In the Protostomia, the important reptile parasites are found within the Platythelminthes, Annelida, Lophotrochozoa, and Ecdysozoa.

Platyhelminthes

The Platyhelminthes are acoelomate flatworms, with no specialized circulatory or respiratory organs and a single opening into the digestive cavity. Platyhelminth parasites of reptiles are found in the Trematoda, Cestoda, and Monogenea.

Trematoda (Flukes). The Trematoda are composed of the Digenea and the Aspidogastrea. Trematodes have obligate indirect life cycles, although aspidogastreans do not asexually reproduce as larvae in intermediate hosts.

Aspidogastrean trematodes have the ventral surface subdivided as a holdfast organ. Most of these are parasites of molluscs, but a few species are gastrointestinal parasites of turtles. They are not usually associated with significant pathology.

Digeneans are commonly found in all groups of reptiles, and some are extremely pathogenic. They are the most diverse group of trematodes (Figs. 32.15 through 32.21). All digeneans require at least one intermediate host to complete their cycles, and some require two or more. These live in nearly every soft tissue organ in the body of their reptilian hosts, although most reside in the gastrointestinal tract. They all have the potential to alternate between generations of sexual and asexual reproduction. The former occurs in the definitive host, and the latter occurs in the first intermediate host, which is normally a mollusc. Some use terrestrial gastropods for their intermediate hosts and are therefore not tied to an aquatic habitat.

Other digenetic trematodes need aquatic snails for their first intermediate host, and thus flukes have different potentials to be found in captive reptilian collections kept in natural settings. Many digenetic trematodes are associated with little or no pathology in definitive hosts. The presence of trematodes attached to the oral mucosa and esophagus may be more of an esthetic concern than a medical problem. These

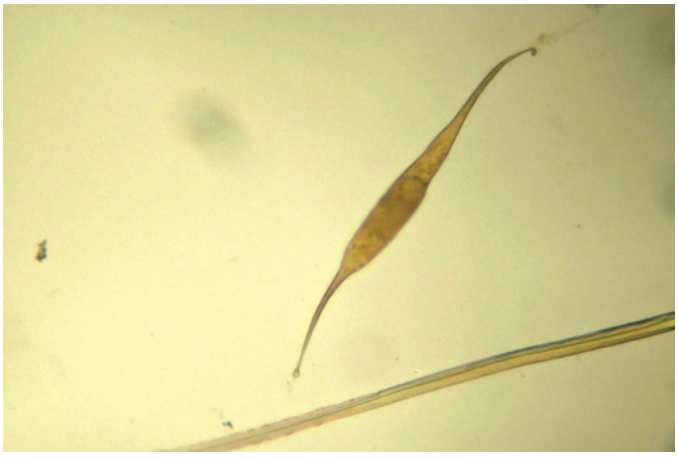

FIG 32.20 *Hapalotrema loossi* from a loggerhead sea turtle (*Caretta caretta*). Photomicrograph magnification, 400×.

flukes include *Haplometroides*, *Ochetosoma*, *Pneumatophilus*, *Stomatrema*, and *Zeugorchis*. They are acquired by eating a vertebrate second intermediate host containing encysted metacercariae.

Spirorchiidae, a family of flukes whose adults live in blood vessels and the heart, are pathogenic. To disseminate eggs from the blood, the eggs are trapped in capillary beds and then worked passively through the host tissue into the gut, where they are then shed in the feces. Adults or eggs may be numerous enough to block smaller vessels (capillaries), causing ischemia and tissue damage. Eggs that leave the gut may also be trapped by the host and form granulomas. These can be found in most soft tissues of the body, and the more of these that develop in an organ, the less functional that organ becomes.[53] Marine turtles are most

VetBooks.ir

FIG 32.21 *Learedius learedi* from a green sea turtle (*Chelonia mydas*). Photomicrograph magnification, 400×.

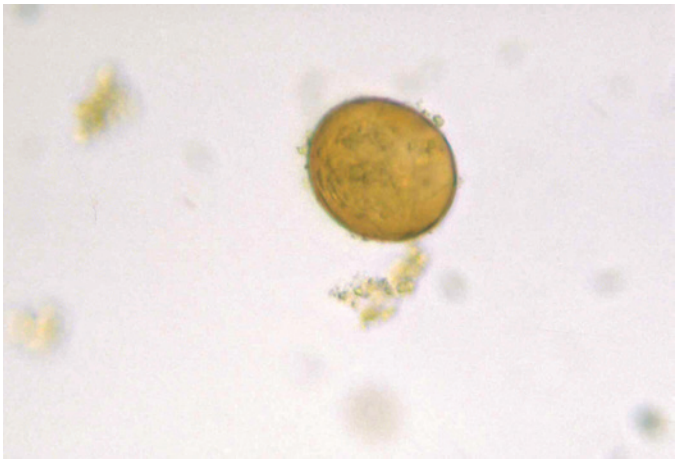

FIG 32.22 *Neospirorchis* sp. from a loggerhead sea turtle (*Caretta caretta*). Photomicrograph magnification, 400×.

commonly affected by these flukes (Fig. 32.22), although freshwater turtles may also be affected.[54]

Other flukes, such as *Styphlodora* spp., live in the urinary tract. This is a common parasite in free-ranging snakes, with up to 66% of some snake populations infected. A captive boa died after about 6 months of anorexia, and the adults of *Styphlodora horrida* were recovered from the preserved kidneys.[55] The flukes were believed to be the cause of death.

Management centers around excluding trematodes from collections through separation of definitive hosts and their feces from intermediate hosts and, for carnivorous/omnivorous reptiles, exclusion of potential other intermediate hosts that may be ingested. Although pharmacologic therapy with praziquantel is possible, especially with trematodes in viscera such as with spirorchids, the inflammatory response to large numbers of dead trematodes in tissues has the potential to be fatal.

Cestoda (Tapeworms). Cestodes are platyhelminths with obligate indirect life cycles. They have a scolex (holdfast organ) and a chain of proglottids (repetitive reproductive sections). Each proglottid increases in maturity as they move farther from the scolex with budding of new sections. The adults reside in the small intestine of their definitive host (Fig. 32.23). Tapeworms parasitize all groups of reptiles.

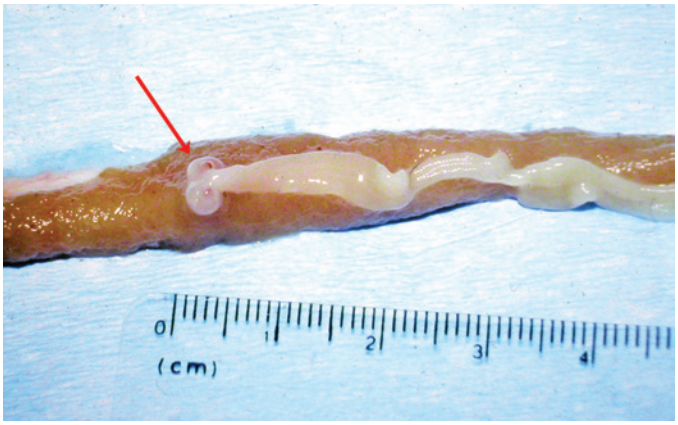

FIG 32.23 *Bothridium* sp. tapeworm in the intestine of a ball python (*Python regius*). Note the scolex on the left side of the photograph (arrow). (Courtesy of Stephen Barten.)

Cestodes are not usually considered to be significant pathogens in their definitive hosts, although they can outcompete the host for basic nutrients, and heavy loads may cause intestinal obstruction. In intermediate reptile hosts, larval cestodes are often subcutaneous, causing bumps or ridges in the skin, and make a reptile less attractive for display purposes.

Many of the adult tapeworms of reptiles are in the families Anoplocephalidae, Diphyllobothriidae, and Proteocephalidae. Anoplocephalidae typically use a mite or an insect as the intermediate host. The life cycle of Diphyllobothriidae uses two intermediate hosts, typically an aquatic crustacean as the first and a vertebrate as the second.

The eggs of Proteocephalidae are eaten by copepods, where the procercoid larva develops, and these are infective to the definitive host, where they develop into plerocercoids. These develop in the solid organs, such as the liver. The parasite then wanders through the host, and if it reaches the lumen of the intestine, it attaches and matures. Adult tapeworms may be diagnosed with fecal flotation if the eggs are released from the proglottids or with visualization of free proglottids in the feces and a search for eggs in normal saline solution. All tapeworm eggs (except species of the Diphyllobothriidae) from reptile feces should contain a fully formed oncosphere with six hooks (Figs. 32.24 through 32.30).

Larval tapeworms of *Spirometra* (spargana) may be found in the viscera or subcutaneously in snakes and lizards, and the same is true for the tetrathyridia of *Mesocestoides.* The latter should contain an inverted scolex with four suckers, but this is not always obvious.

Management centers around excluding cestodes from collections through separation of definitive hosts and their feces from intermediate hosts and, for carnivorous/omnivorous reptiles, exclusion of potential other intermediate hosts that may be ingested. Although pharmacologic therapy with praziquantel is possible, especially with larval cestodes in intermediate hosts, the inflammatory response to large numbers of dead cestodes in tissues has the potential to be fatal, and surgical removal may be preferred.

Monogenea. Formerly classified in the Trematoda, the Monogenea are now recognized as phylogenetically distinct platyhelminths. They have direct life cycles and can build to high levels in captivity. Although most are parasites of fish, the family Polystomatidae often utilize aquatic turtles as hosts. Host fidelity is not particularly high, and host-switching from red-eared sliders (*Trachemys scripta*) to Mediterranean pond turtles (*Mauremys leprosa*) has been documented.[56] Adult parasites may be found in the urinary bladder, cloaca, pharynx, and conjunctival sacs of

fresh-water turtles. Treatment by manual removal is often possible, and use of praziquantel may also be effective. Environmental decontamination is essential, because free swimming oncomiracidia can build to high levels.

Lophotrochozoa

The Lophotrochozoa are a clade in the Protostomia containing molluscs, annelids, rotifers, and acanthocephalans. They are a sister group to the platyhelminths.

Annelida (Leeches). Annelids are a phylum in the Lophotrochozoa and are commonly known as segmented worms. Most annelids are free-living organisms, but the subclass Hirudinea, the leeches, has a number of parasitic members. These hematophagous annelids are found on aquatic reptiles such as turtles and crocodilians. The leeches on American alligators (*A. mississippiensis*) are *Placobdella multilineata* and *P. papillifera.*[57,58] They are able to transmit hemogregarines, such as *Haemogregarina crocodilinorum.*[59] Infestations of large numbers of leeches have been reported to cause anemia in young crocodilians.

When leeches feed on aquatic animals, the resultant lesion may allow secondary bacteria to invade and establish infections. Marine leeches (*Ozobranchus margoi*) can be found in massive numbers on green sea turtles (*Chelonia mydas*), Atlantic hawksbill (*Eretomochelys imbricata*), loggerhead sea turtles (*Caretta caretta*), and Atlantic ridleys (*Lepidochelys kempi*). High populations of this leech usually are seen on severely emaciated turtles. Treatment by manual removal is typically the best way to deal with leech infestations.

Acanthocephala (Thorny-Headed Worms). Acanthocephala is a phylum in the Lophotrochozoa. They are most closely related to the rotifers. Adults live within the small intestines. They have a retractable proboscis armed with spines that is inserted into the mucosa as a holdfast. They have separate sexes and lack a digestive system. Acanthocephalans have indirect life cycles. The eggs of acanthocephalans are usually complex, with multiple layers enclosing the acanthor larva (Fig. 32.31). The first intermediate host is usually an arthropod, and within this intermediate host it matures to a cystacanth. There may be additional paratenic hosts, and cystacanth larvae may be encysted in the abdominal cavity until eaten by a definitive host, when it matures and embeds in the gut wall.

Eggs of some acanthocephalan species may rise on fecal flotation, but most must be detected with a sedimentation procedure. *Neoechinorhynchus* sp. are seen in emydid turtles; *Bolbosoma* sp. and *Rhadinorhynchus* sp. have been reported in sea turtles; and *Acanthocephalus* sp., *Centrorhynchus* sp., *Corynosoma* sp., *Oligacanthorhynchus* sp., *Oncicola* sp., *Pseudoacanthocephalus* sp., and *Sphaerirostris* sp. have been reported in squamates. The proboscis often embeds deeply into the gut wall, causing significant pathology.

Management centers around excluding acanthocephalans from collections through separation of definitive hosts and their feces from intermediate hosts and, for carnivorous/omnivorous reptiles, exclusion of potential other intermediate hosts that may be ingested. Acanthocephalans do not typically respond well to most anthelminthic drugs. Loperamide, normally thought of as an antidiarrheal drug, has shown activity at high doses against acanthocephalans in pigs and ray-finned fish and may have application for treatment of acanthocephalans in reptiles.[60,61] Surgical removal is also an option.

Ecdysozoa

The Ecdysozoa are a clade of Protostomes whose members all grow by ecdysis, shedding their exoskeletons. Important reptile parasite groups in the Ecdysozoa include nematodes, arthropods, and pentastomids.

Nematoda. The phylum Nematoda has more than 25,000 described species, with much more undescribed diversity likely present. They are commonly called roundworms. More than half of known species are parasitic, and hosts include all orders of reptiles. They may have either direct or indirect life cycles. They have separate sexes and complete digestive systems. The two classes within the phylum are the Chromadorea and the Enoplea.

The effects of most nematodes are unknown, and many could be neutral or even beneficial in their influence on their hosts, depending on context. Nematodes are the most diverse group of helminths that infect reptiles. Some produce eggs, some release first stage (L1) larvae, and some produce microfilariae that are motile embryos. Those that produce eggs shed in feces are diagnosed with fecal flotation, and those that release larvae into the gastrointestinal tract are easily diagnosed with a Baermann funnel or fecal sedimentation. These larvae do float but may be greatly distorted by the flotation medium. Nematodes that produce microfilariae can be seen in the blood by direct smear or Modified Knott's.

Pharmacologic treatment of nematodes typically uses four classes of drugs: avermectins, benzimidazoles, pyrantel, or octadepsipeptides. Avermectins, such as ivermectin or selamectin, kill the worm by binding

VetBooks.ir

to glutamate receptors; the drugs are normally excluded from receptors in the brain by the blood-brain barrier. However, in turtles and crocodilians, the blood-brain barrier is less effective at excluding avermectins, and there is a greater risk of toxicity. Benzimidazoles work by binding to tubulin, interfering with cytoskeletal structure. For the host, this has greatest implications for rapidly dividing cells, and some benzimidazoles may have significant effects on bone marrow and gut epithelium; heterophil numbers drop quickly after high doses.[62] Pyrantel and octodepsipeptides hold promise, but controlled studies in reptiles are lacking.

Strongyloidoidea. The family Rhabdiasidae is in the order Strongyloidoidea, class Chromadorea, and includes the genera *Rhabdias*, *Serpentirhabdias*, *Pneumonema*, and *Entomelas* (Fig. 32.32).[63] Larvae typically hatch in feces and are seen on fecal examination rather than eggs. Molecular sequence data are usually needed to differentiate species within these genera. All of these genera alternate generationally between the host and a free-living phase, known as heterogony. The genus *Serpentirhabdias* may also have multiple generations of parthenogenetic females in the host, known as homogony.[63] The ability to survive as free-living worms without a host reduces the selective pressure to keep the host alive. Environmental removal is an essential part of addressing *Rhabdias* in a patient. Infective stages can penetrate intact skin and usually move to the lungs, although *Entomelas* may move to the esophagus. Clinical signs often include great quantities of mucus production, pneumonia, and gasping for air. The eggs are larvated when shed by the females, and these may hatch as they exit the host.

The family Strongylidae is in the order Strongyloidoidea, class Chromadorea, and includes the genus *Strongyloides* (Fig. 32.33). These should not be confused with the similarly named hookworm suborder Strongylida, which is not closely related. *Strongyloides* alternate generationally between the host and a free-living phase. The ability to survive as free-living worms without a host reduces the selective pressure to keep the host alive. Environmental removal is an essential part of addressing *Strongyloides* in a patient. Infective stages can penetrate intact skin and usually move to the intestine, where they embed in the mucosa. Either larvae or larvated eggs may be seen on fecal examination. Significant enteritis was seen in colubrid snakes (*Liophis miliaris*) experimentally infected with *S. ophidiae,* with resultant mortalities.[64] Four of five experimentally infected snakes died. Interestingly, three of three snakes treated with ivermectin died, whereas only one of two untreated snakes died. Further studies are needed, but it is possible that the inflammatory response to a large burden of dead worms contributed to mortality.

Rhabditida. The suborder Strongylida is in the order Rhabditida, class Chromadorea. The Rhabditida should not be confused with the similarly named family Rhabdiasidae, which is not closely related. Similarly, Strongylida should not be confused with the order Strongyloidoidea, another confusingly similar unrelated group. Life cycles have not been elucidated for most species, but in general, they are direct, with hosts ingesting infective larvae. *Kalicephalus,* found in snakes, can cause significant pathology (Fig. 32.34). They normally reside in the small intestine but have been reported from the mouth and esophagus of snakes (Fig. 32.35). The oral cavity is distinctive (Fig. 32.36), and the males have a prominent copulatory bursa (Fig. 32.37). *Oswaldocruzia* and *Bakeria* are other significant genera in squamates. *Chapiniella* is a genus of strongylids found in New World tortoises (Fig. 32.38).[65] Management of strongylids involves removal of organic substrates that may sustain infective larvae, as well as pharmacologic therapy.

Spirurida. The order Spirurida are in the class Chromadorea. They have indirect life cycles, typically utilizing arthropod intermediate hosts, sometimes with additional vertebrate intermediate hosts. Reptiles may be either definitive or intermediate hosts. Ova, when present, are larvated.

FIG 32.39 Distinctive mouth parts of *Spiroxis* sp. from a freshwater turtle. Photomicrograph magnification, 400×.

The genus *Abbreviata* in the family Physalopteridae and the genus *Tanqua* in the family Gnathostomatidae are commonly found in monitor lizards (*Varanus* sp.), where gastric lesions are seen in definitive hosts.[66,67] It is also common to see encysted larvae in squamates acting as paratenic hosts. *Spiroxys,* in the family Gnathostomatidae, lives in the stomachs of freshwater turtles, where it may cause severe granulomatous lesions (Fig. 32.39).[68] *Serpinema*, in the family Camallanidae, is also common in freshwater turtles and has been associated with pancreatitis due to migrating worms (Fig. 32.40).[69] Management of nonfilarial spirurids centers around excluding them from collections through separation of definitive hosts and their feces from intermediate hosts, and exclusion of arthropod intermediate hosts that may be ingested. Due to their indirect life cycle, they are more typically a problem of wild-caught animals. Although spirurids may be significant pathogens, the presence of potentially large numbers of worms in tissues complicates treatment of intermediate hosts; use of anthelminthics may result in a massive inflammatory response to dead worms. When possible, coelioscopic inspection and removal is advisable before pharmaceutical therapy.

Within the order Spirurida, the superfamily Filarioidea are distinct in that they have larvae that circulate in blood and are vectored by hematophagous arthropods. Adult worms may be in blood vessels, connective tissue, or subcutaneous, and larvae are found circulating in blood. Microfilariae will precipitate to the level of the buffy coat when a microhematocrit tube is spun, and their motion can be seen when

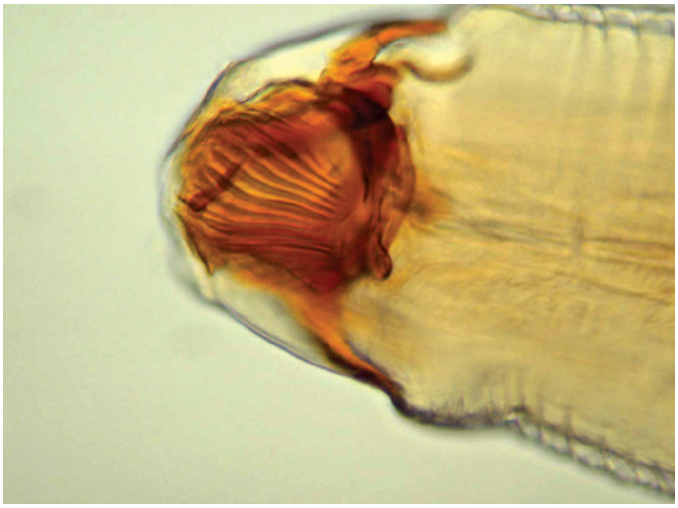

FIG 32.40 *Serpinema* sp. common spirurid from a freshwater turtle. Note the distinctive buccal capsule. Photomicrograph magnification, 160×.

FIG 32.43 *Dujardinascaris* sp. from an American alligator (*Alligator mississippiensis*). Photomicrograph magnification, 400×.

the tube is examined under a microscope. Some genera that use reptile hosts include *Foleyella*, *Macdonaldius*, *Madathamugadia*, and *Oswaldofilaria*. Studies in frilled lizards (*Chlamydosaurus kingii*) found that the presence of *Oswaldofilaria chlamydosauri* was not associated with changes in hematocrit, body condition, or oxygen consumption.[70] A necrotic muscle lesion was attributed to occluded arteries caused by *Macdonaldius*.[71] *Foleyella* adults are often subcutaneous, and surgical removal may be a reasonable option.[72] A chameleon treated with ivermectin for *Foleyella* died, and lesions seen were consistent with an inflammatory response to dead worms.[73] Management of filarial spirurids centers around excluding them from collections through exclusion of hematophagous arthropod intermediate hosts. Due to their indirect life cycle, they are more typically a problem of wild-caught animals. The presence of potentially large numbers of worms in tissues complicates treatment of intermediate hosts; use of anthelminthics may result in a massive inflammatory response to dead worms. When possible, coelioscopic inspection and removal is advisable before pharmaceutical therapy.

Ascaridida. The order Ascaridida in the class Chromadorea contains very large worms that have three prominent lips (Fig. 32.41) and have indirect life cycles. The eggs are large and have pitted or roughened shells. Typically, they may initially utilize a wide range of invertebrate or vertebrate hosts, then are eaten by vertebrates, where they mature in the coelom. If in their definitive host, they then migrate to the gastrointestinal tract.[74] There are exceptions to this; *Cyrtosomum penneri*, in the family Atractidae, is transmitted between lizards venereally.[75] Primates have experimentally been found to be suitable intermediate hosts for *Hexametra*, raising zoonotic concerns.[76] Ascarids may cause significant enteritis in their definitive reptile hosts.[77] The genera *Hexametra*, *Amplicaecum*, *Ophidascaris*, and *Polydelphis* utilize squamates as definitive hosts (Fig. 32.42) and lack sequence data for appropriate phylogenetic classification. *Dujardinascaris* and *Ortleppascaris* in the family Heterocheilidae utilize crocodilians as definitive hosts (Fig. 32.43).[78,79] *Ortleppascaris* can cause significant gastric pathology.[80]

Krefftascaris, also in the Heterocheilidae, utilizes side-necked turtles as definitive hosts.[81] *Sulcascaris sulcata*, in the family Anisakidae, utilizes loggerhead sea turtles as definitive hosts and oysters as intermediate hosts (Figs. 32.44 and 32.45). Loggerhead sea turtles have also been found to be intermediate hosts for *Anisakis* spp.[82] *Angusticaecum* spp. utilize tortoises as definitive hosts, where they are associated with disease.[83]

Management centers around excluding ascarids from collections through separation of definitive hosts and their feces from intermediate

FIG 32.44 *Sulcascaris sulcata* from a loggerhead sea turtle (*Caretta caretta*). Photomicrograph magnification, 400×.

FIG 32.46 *Ozolaimus* sp. from a green iguana (*Iguana iguana*). Photomicrograph magnification, 400×.

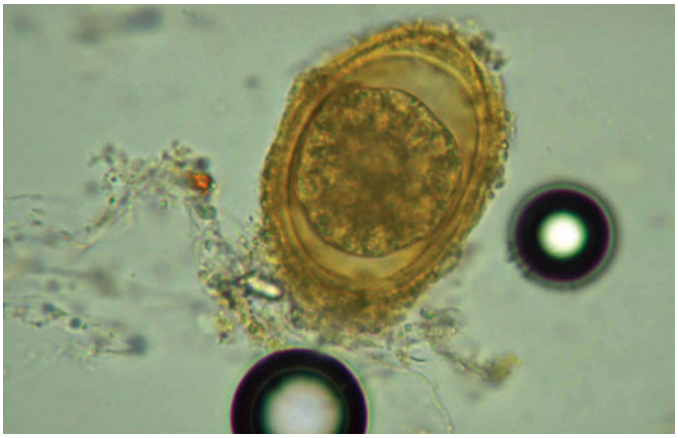

FIG 32.45 *Sulcascaris sulcata* from a loggerhead sea turtle (*Caretta caretta*). Photomicrograph magnification, 400×.

FIG 32.47 Unknown pinworm from a spur-thighed (Greek) tortoise (*Testudo graeca*). Photomicrograph magnification, 400×.

hosts and, for carnivorous/omnivorous reptiles, exclusion of potential intermediate hosts that may be ingested. Due to their indirect life cycle, they are more typically a problem of wild-caught animals. Although ascarids are significant pathogens, the presence of potentially large numbers of worms in the coelomic cavity complicates treatment; use of anthelminthics may result in a massive inflammatory response to dead worms. When possible, coelioscopic inspection and removal is advisable before pharmaceutical therapy.

Oxyurida. The order Oxyurida, in the class Chromadorea, contains pinworms. They have direct life cycles and, because of this, are the most common helminths seen in captive-breeding facilities. There are many genera that infect reptiles, and they tend to be host-specific. Eggs are smooth and elongate, with a straight side and a lens-shaped plug at one end (Figs. 32.46 to 32.48). It is important to differentiate oxyurid ova from strongyle ova, as the clinical approach to these two groups is markedly different. Pinworms have an esophageal bulb, and the females have a long tapering tail that gives them their name. Tortoises often have a community of multiple species of these short worms (Fig. 32.49). The male posterior ends are all-important in identification, and two such tails are illustrated: *Ozolaimus* lateral view (Fig. 32.50) and *Aleuris* sp. ventral view (Fig. 32.51). They live in the lumen of the large intestine (Fig. 32.52). Normally these worms pose little pathologic significance, and may even potentially be beneficial, and could therefore be commensals and not parasites. Bullfrog tadpoles (*Rana catesbeiana*) that

FIG 32.48 Unknown pinworm from a spur-thighed (Greek) tortoise (*Testudo graeca*). Photomicrograph magnification, 400×.

have the pinworm *Gyrinicola batrachiensis* develop more quickly and have better gut fermentation than controls without pinworms, indicating a mutualistic rather than parasitic relationship.[84] Unlike ascarids, oxyurids are not associated with disease in tortoises.[83] Under extremely poor husbandry, very high worm burdens may accumulate; captive reptiles

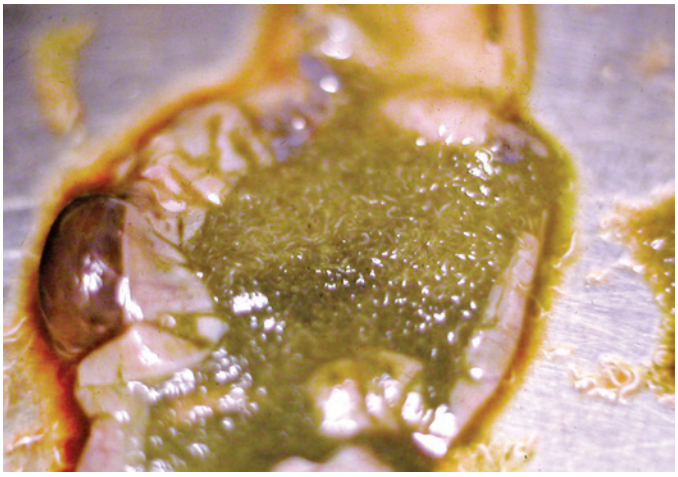

FIG 32.49 Large colon from a desert tortoise (*Gopherus agassizii*) impacted with oxyurid larva. (Courtesy of Douglas R. Mader.)

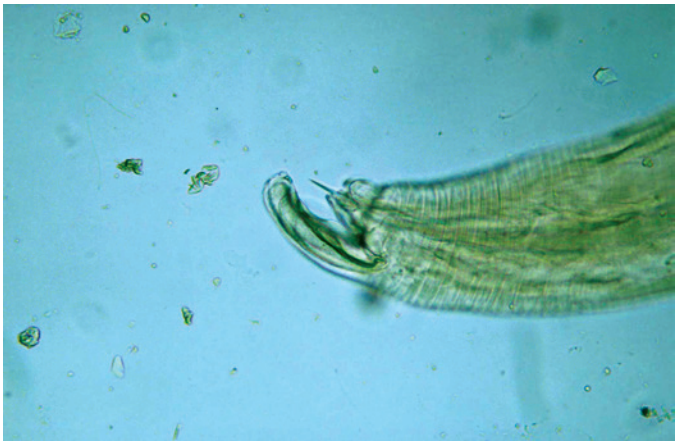

FIG 32.50 Posterior end of male *Ozolaimus* sp., lateral view. This is an important distinction for identification of different species of pinworms.

FIG 32.51 Posterior end of a male *Aleuris* sp., ventral view.

can always benefit from husbandry improvements. The risk/benefit ratio of pharmacologic therapy is poor, and it is not indicated.

Trichinellida. The order Trichinellida is in the class Enoplea. This class difference is most significant during treatment; they tend not to respond as well to most anthelminthics as the Chromeadorea do.

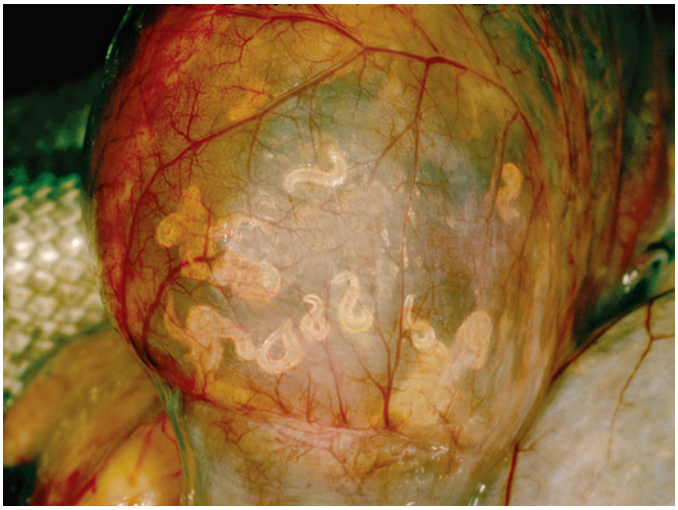

FIG 32.52 Oxyurids in the distended colon of a green iguana (*Iguana iguana*). (Courtesy of Stephen Barten).

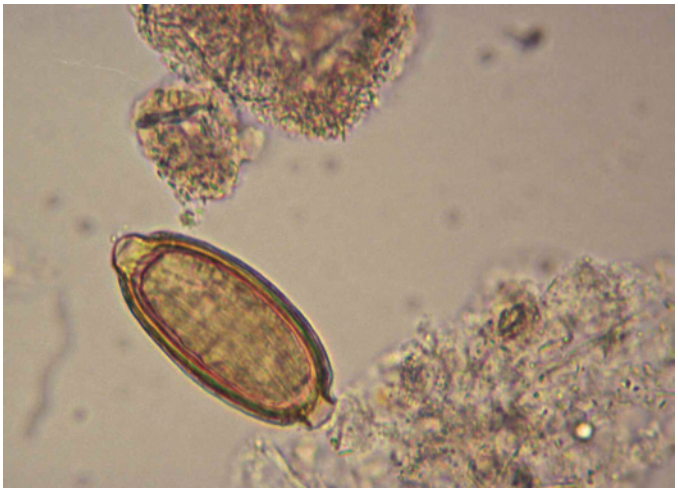

FIG 32.53 *Capillaria* sp. egg from a green tree python (*Morelia viridis*). Photomicrograph magnification, 400×.

Capillaria spp., in the family Capillariidae, are primarily found in the GI tract and have bipolar eggs like whipworms (*Trichuris* spp.) (Figs. 32.53 through 32.56).[85] Life cycles are thought to be direct. *Paratrichosoma* spp., in the family Trichosomoididae, live under the skin of crocodilians and leave dark tracks in the skin as they migrate, damaging leather quality.[86] Low rainfall is associated with higher *Paratrichosoma* worm burdens.[86]

Dioctophymatida. The order Dioctophymatida is in the class Enoplea. This class difference is most significant during treatment; they tend not to respond as well to most anthelminthics as the Chromeadorea do. *Eustrongylides* sp., in the family Dioctophymatidae, have indirect life cycles involving at least two intermediate hosts. Reptiles are usually intermediate hosts, but crocodiles have rarely been found to be definitive hosts.[87] Severe granulomatous lesions may be seen in reptiles acting as intermediate hosts.[88]

Management centers around excluding *Eustrongylides* from collections through separation of definitive hosts and their feces from intermediate hosts and, for carnivorous/omnivorous reptiles, exclusion of potential intermediate hosts that may be ingested. Due to their indirect life cycle, they are more typically a problem of wild-caught animals. Although

VetBooks.ir

FIG 32.56 *Capillaria* sp. egg from a boa (same egg as in Fig. 32.55—focus is on the shell surface). Photomicrograph magnification, 400×.

Eustrongylides are significant pathogens, the presence of potentially large numbers of worms in the coelomic cavity complicates treatment; use of anthelminthics may result in a massive inflammatory response to dead worms. When possible, coelioscopic inspection and removal is advisable before pharmaceutical therapy.

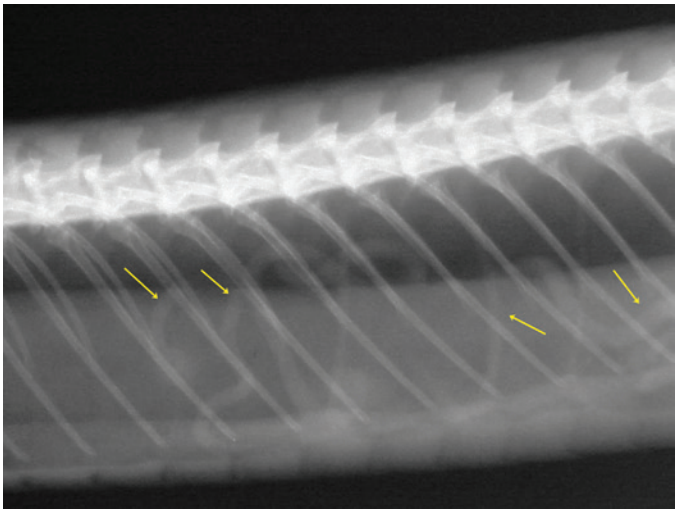

FIG 32.57 Radiograph of a wild indigo snake (*Drymarchon couperi*). Note the radiodense serpiginous pattern within the lungs (*yellow arrows*). These are internal pentastomid parasites. (Courtesy of Douglas R. Mader.)

Arthropoda. The phylum Arthropoda have chitinous exoskeletons with jointed appendages. The most clinically relevant taxa that parasitize reptiles are the subclass Pentastomida, the class Arachnida, and the class Insecta.

Pentastomida. The subclass Pentastomida is a member of the subphylum Crustacea in the ecdysozoan phylum Arthropoda. Their closest known relatives are branchiuran fish lice, such as *Argulus.*[89] They have indirect life cycles, typically utilizing vertebrate hosts. Many species use reptiles as definitive hosts, and adults are typically found in the lungs. Eggs are then coughed up, swallowed, and excreted in feces. Especially in squamates, where the lumen of the lung is large and the diameter of the trachea may be smaller than the pentastomid, there is a risk of respiratory obstruction by adult pentastomes, but the greatest pathology is seen in intermediate hosts, where they may be embedded in diverse tissues. There are two orders, the Cephalobaenida and the Porocephalida. The Porocephalida present a greater zoonotic risk. The porocephalan *Armillifer armillatus,* which typically utilizes *Bitis* spp. vipers as definitive hosts, is not uncommonly found in humans in endemic regions and may cause fatal lesions in the brain.[90] Feces from wild-caught *Bitis* sp. should be handled with appropriate protection. The porocephalan *Porocephalus crotali* utilizes North American vipers as definitive hosts and has caused fatal infection in dogs.[91] The porocephalan *Kiricephalus coarctatus* is common in North American colubrids; due to its close relationship to *Porocephlalus* and *Armillifer,* feces from positive snakes should be handled with caution. The porocephalan genus *Sebekia,* in the family Sebekidae, utilizes crocodilians as definitive hosts. Greater inflammatory response was seen in experimentally infected rodent paratenic hosts than in turtles.[92] *Alofia* sp., also in the Sebekidae, utilize chelonian definitive hosts. The genus in the Cephalobaenida most commonly seen by practitioners is *Raillietiella,* which utilizes squamate hosts and is not uncommon in wild-caught geckos.

Evidence of the adult worms living in the lungs on survey radiographs is not uncommon (Fig. 32.57). Eggs may be seen on fecal flotation. A pulmonary wash is an even better sample. Eggs contain larvae and have four leg-like appendages; it is not uncommon to see hatched larva and empty eggshells (Figs. 32.58 through 32.61). Specific diagnosis may be done via morphologic characterization of adults or DNA sequencing.[93]

VetBooks.ir

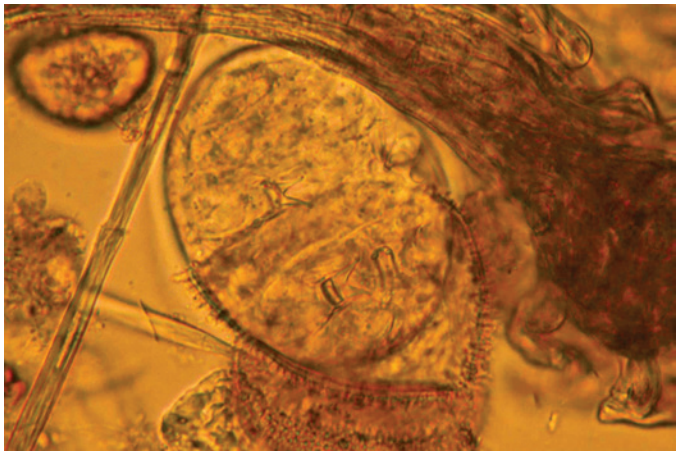

FIG 32.58 Pentastome eggs are characteristically thin walled and can measure up to 130 μm in diameter. Larvae with four hooklets are typically seen within eggs. This is an unidentified pentastome from a water monitor (*Varanus* sp.).

FIG 32.61 Unknown pentastome from a narrow-head softshell turtle (*Chitra indica*). Photomicrograph magnification, 400×.

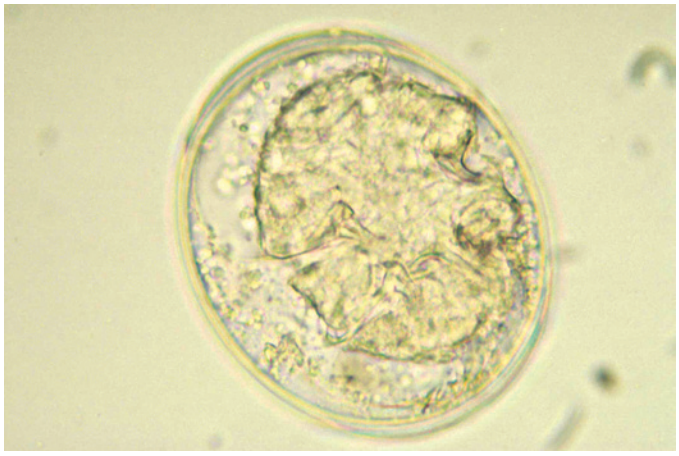

FIG 32.59 *Railietiella frenatus* from a Tokay gecko (*Gekko gecko*). Photomicrograph magnification, 400×.

FIG 32.62 Extracted adult pentastomid from the lung of an indigo snake (*Drymarchon couperi*). Endoscopy allows simple, safe extraction of the typically low worm burden. (Courtesy of Douglas R. Mader.)

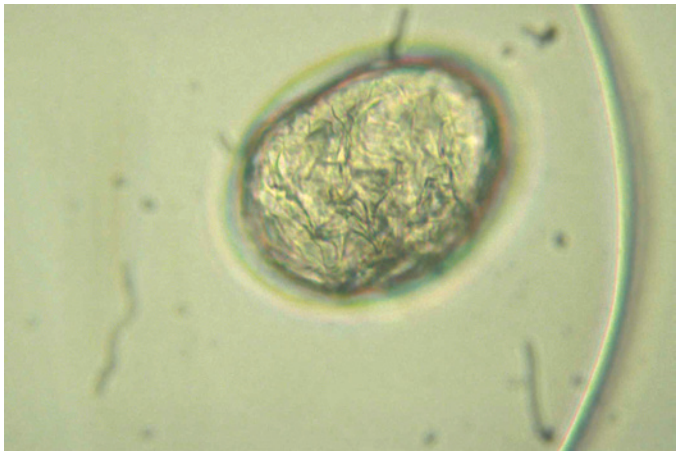

FIG 32.60 *Sebekia* sp. from a softshell turtle (*Apalone* sp.). Photomicrograph magnification, 400×.

Management centers around excluding pentastomids from collections through separation of definitive hosts and their feces from intermediate hosts and, for carnivorous/omnivorous reptiles, exclusion of potential intermediate hosts that may be ingested. Due to their indirect life cycle, they are more typically a problem of wild-caught animals. There are no effective anthelminthics for treatment of pentastomids, although there are reports of high doses of ivermectin arresting ova shedding. Pulmonoscopy and removal of adult pentastomes is the best therapeutic approach (Fig. 32.62).[93]

Arachnida. The class Arachnida is a member of the subphylum Chelicerata in the ecdysozoan phylum Arthropoda. They have eight legs as adults. The subclass Acari contains mites and ticks, which are both significant ectoparasites of reptiles.

The order Ixodida contains ticks, hematophagous arthropods. The two major groups of ticks are the hard ticks (Ixodidae) and the soft ticks (Argasidae). Most ticks seen on reptiles are ixodids. Some of the tick genera that feed on reptiles include *Amblyomma*, *Aponomma*, *Haemophysalis*, *Hyalomma*, and *Ixodes*. *Aponomma* is the genus most commonly seen on squamates. *Amblyomma* is the most common genus

VetBooks.ir

seen on tortoises and are known vectors for *Ehrlichia ruminantium,* the agent causing heartwater in ruminants. Although *E. ruminantium* has not been found to infect tortoises, it has been found in *Amblyomma* sp. on tortoises, and imports of tortoises from heartwater-endemic regions represent an agricultural risk. *Amblyomma tuberculatum,* the gopher tortoise tick, also carries an *Anaplasma* sp. that causes anemia in tortoises. The best therapeutic approach to ticks is manual removal. See Chapter 120 for more therapeutic options.

The order Mesostigmata are parasitic mites. The mite most commonly seen causing concerns in captive reptiles is *Ophionyssus natricis,* found on squamates (Fig. 32.63). The life cycle of *O. natricis* is egg > larva > protonymph > deutonymph >adult. Only the protonymph and adult feed on the blood of the squamate host; other stages are off the host and in the environment. Although it has been proposed as a potential vector of reptarenaviruses, this remains to be proven. It is a small black mite that may often be found in the gular fold, at the margins of the spectacles, or in water bowls. Diagnosis is by identification of adult mites. Environmental cleanup is an essential part of management. Pyrethrins are commonly used to treat infested squamates. Predatory mites have also been used to control *O. natricis.*[94] Maintenance of environments at temperatures over 42°C together with removal of water sources for several days will eliminate stages off the reptiles, provided they do not have access to cooler areas. See Chapter 120 for additional therapeutic options.

The order Trombidiiformes are a diverse order of mites. The family Cloacaridae contains the genera *Cloacarus* and *Caminacarus,* which live in the cloaca of turtles.[95] The impacts of Cloacaridae on reptile health has not yet been studied.

Insecta. The class Insecta is a member of the subphylum Hexapoda in the ecdysozoan phylum Arthropoda. They have six legs as adults. The order Diptera contains flies, which can be significant ectoparasites of reptiles. Hematophagous flies may be important disease vectors. The most significant dipteran parasite of North American reptiles is *Cistudinomyia cistudinis.*[96] This fly will lay eggs on box turtles (*Terrapene* sp.), most commonly beneath the carapace dorsal to the head. Larva will burrow in and eat underlying tissue, causing large defects. Surgical removal of the larva is the most effective treatment.

Hematology

J. Jill Heatley and Karen E. Russell

This chapter strives to provide a clinically useful guide for veterinarians and other biologists on sample collection, sample handling and clinical interpretation of hematology results from reptile and amphibian species. This detailed summary will focus on hematologic principles and knowledge specific to reptiles and amphibians commonly presented in clinical practice. Although most information in this chapter will be based on more commonly seen species, other esoteric species may have been studied in more detail and may be included when necessary to illustrate general and expected findings (venomous species, tuatara crocodilians, etc). Should the reader require more specifics for zoo or wildlife species beyond this chapter, a review of primary literature is highly recommended.

Indications for hematologic assessment in reptiles and amphibians are numerous and are similar to those of companion mammals (Table 33.1). However, based on numerous factors including lack of baseline clinicopathologic data and normal physiology of ectotherms, results may be less accurate or specific for diagnosis than in traditional species. Most hematology information available for amphibians and reptiles, although valuable and peer reviewed, does not conform to the current ASVCP guidelines for reference range creation.[1] Finally, initial hematologic assessment generally provides nonspecific results to support (or refute) the clinician's working diagnosis based on historical and physical examination findings.[1] Additionally, more specific diagnostic testing (serology, PCR, histopathology, culture, etc) may be necessary to arrive at a definitive diagnosis. Though expensive and sometimes challenging to obtain in clinical practice, these additional steps maybe particularly necessary in the case of herpetological patients wherein few standard clinicopathologic tests have been rigorously investigated or validated. This chapter has three major sections: (1) sample collection, handling, and storage, (2) brief review of selected analyte methodologies as it pertains to analyte choice, and (3) analyte choice and evaluation, which have been carefully edited to provide information deemed essential for the clinician. For more in depth information regarding analyte or sample collection methodology, review of the primary literature and basic clinical pathology texts is recommended.

SAMPLE COLLECTION AND PRESERVATION

Choice of materials for blood collection from reptiles and amphibians is dependent on a number of factors, including species, patient size, anatomy, temperament, sample desired, sample collection conditions, equipment availability, and practitioner skill. A sample collection plan should be determined and materials prepared before sample collection for best results.

Restraint and Site Preparation

Sedation or anesthesia for routine diagnostic sampling is seldom necessary in reptile species commonly maintained as exotic pets but may be necessary for larger or potentially dangerous species. Excellent resources for reptile and amphibian sedation anesthesia and immobilization are available (see Chapters 48 and 49).[2] For amphibians, submersion or gas anesthesia may be necessary for best results. Should topical local anesthetics (lidocaine or benzocaine creams or gels) be used to facilitate amphibian venipuncture, avoid overzealous application, as overdose may results in anesthesia or death.[3] Cleaning and disinfecting the venipuncture site is highly recommended in reptiles, and small synthetic bristle (tooth, nail or scrub) brushes may be required for adequate surface cleaning of the heavily scaled skin of some species. However, application of alcohol alone is seldom advantageous in reptiles with thick, scaled, and opaque skin. Conversely in amphibians, topical antiseptic use is not advised.[4]

Venipuncture Equipment

For most reptiles and amphibians 27- to 22-gauge needle ranges and 0.3- to 3-mL syringes are sufficient. However, sampling of large lizards, snakes, or tortoises may require longer (1.5- to 2-inch) needles. The low blood pressure, slow heart rate, and large but relatively sturdy osmotic nature of blood cells in some reptile and amphibian species supports the preference of a larger-gauge needle but smaller-size syringe than one might choose in similarly sized birds or mammals (Table 33.2).[5,6] These syringe-needle combinations allows blood to flow slowly into the smaller syringe while minimizing aspiration pressure to preserve cell integrity and lessening the concern of thrombocyte activation and microclot formation. Furthermore, in amphibians, use of smaller than 25-gauge needles in species with relatively large RBCs may result in hemolysis.[3] Butterfly administration sets may also be useful when the sample size is sufficient to lose the 0.05 mL, which may coat the tubing. Use of syringes or needles precoated with heparin or other anticoagulant is unnecessary, and avoidance precludes dilutional and cellular staining artifact.[7–9] However, in amphibians relatively decreased clotting times may necessitate use of syringes or needles precoated or flushed with heparin.[3]

Anticoagulant

Whole anticoagulated blood, without lymphatic or cerebrospinal fluid dilution, is the preferred sample for routine hematology. Choice of anticoagulant and blood collection equipment is based on similar factors as detailed under equipment, but species, sample collection conditions, availability, and postcollection sample use are also primary concerns. All anticoagulants can affect cell morphology and staining characteristics (Figs. 33.1 and 33.2). Although lithium heparin is commonly used, EDTA has been shown to be superior for assessment of leukocyte count and morphology and other parameters in lizards and snakes but can cause hemolysis in chelonians.[8,10] However, lithium heparin provides the added possible benefit of obtaining both whole blood for hematology (complete blood count [CBC], packed cell volume [PCV], total solids)

VetBooks.ir

and plasma for biochemical analyte determination from the same sample. Sodium citrate has received minimum study in reptiles but resulted in hemolysis of samples from Burmese pythons (*Python bivittatus*).[11] An overview of current knowledge regarding anticoagulant choice for hematology is provided in Table 33.3**.** Lithium or ammonium heparin is the preferred anticoagulant for amphibian blood, unless the blood is intended for bacterial culture.[3]

Acceptable blood collection tubes include microtainer, pediatric, or larger sizes based on sample requirements. Microtainer plastic tubes coated with freeze-dried anticoagulant are preferred for blood storage before diagnostic testing to avoid sample dilution and allow small sample collection. Heparinized microhematocrit tubes (75 mm) may be used for blood collection from very small species, but sample recovery compared with microtainer tubes appears somewhat less and is challenging without specialized sample expulsion bulbs.[3] Furthermore, diagnostic assays available from this method are limited based on the relatively small sample size collected.

Two to three smears of blood not exposed to anticoagulant should be created for each blood sample collected.[4] Blood smears may be made on cover slips or slides. The best blood smear technique is one that provides for the best creation of a monolayer of cells and the fewest damaged cells. Technique options include cover slip to slide, slide to slide (wedge), and cover slip to cover slip. A single study that evaluated these methods for use in reptiles found the slide-to-slide method preferred for use in green iguanas (*Iguana iguana*).[9] The small fragile nature of cover slips is generally prohibited from use as the primary mode for assessing reptile and hematology based on their small fragile nature, which makes shipping, review, and storage challenging. In addition, cover slips are generally incompatible with automated slide stainers. Blood smears should be actively and quickly air dried to reduce drying artifact. Blood films are best fixed in methanol within 1 to 4 hours of preparation.[12] Based on current methodologies available in veterinary diagnostic laboratories, assessment of CBC is highly dependent on the quality of the blood smear provided. Samples for hematology and cytology should never be shipped in the same container as those containing biopsied tissues in formalin; formalin fumes will markedly

TABLE 33.1 Indications for Clinicopathologic Assessment of Reptiles

Health assessment	Entry or exit of collection, baseline determination, presurgical assessment, pre- or posthibernation assessment
Diagnosis	Clinical suspicion of inflammation or organ dysfunction
Therapeutic assessment	Assessment of treatment plan as for renal or liver dysfunction, sepsis, chemotherapy, other chronic diseases
Prognosis	Assessment of seriousness of infection, inflammation, blood loss, etc

TABLE 33.2 Comparative Osmotic Fragility of Select Reptilian and Mammalian Erythrocytes[5]

Common Name	Scientific Name	Solution %*
Green iguana	*Iguana iguana*	15–70
Bengal monitor, common Indian monitor	*Varanus bengalensis*	15–55
Gold or golden tegu, common tegu, black tegu, Colombian tegu, tiger lizard	*Tupinambis teguixin*	20–60
Broad-snouted caiman, Yacare caiman	*Caiman latirostris, Caiman jacare*	20–40
Nile crocodile	*Crocodylus nilotocus*	20–70
Common agama, red-headed rock agama, rainbow agama	*Agama agama*	10–60
Camel	*Camelus* spp.	21–30
Rabbit	*Oryctolagus* spp.	30–50
Human	*Homo sapiens*	35–50

TABLE 33.3 Impactful Studies for Anticoagulant Choice in Reptiles: Exceptions to and Support for the Rule of Green

Anticoagulant(s)	Species	Parameter Changes
CPDA-1, ACD	American alligator *(Alligator mississippiensis)*	Comparable; blood may be stored up to 35 days based on PCV, methemoglobin, osmotic fragility, and morphologic evaluation[67]
K_2- or Na_2-EDTA, Heparin	Puff adder (Bitis arientans)	All PCV similar[65]
EDTA Lithium heparin	Burmese python *(Python bivitattus)*	No hematologic differences[11]
K_3-EDTA **Lithium heparin**	**Hermann's tortoises (Testudo hermanni)**	**Lysis in EDTA at 6 hours; no lysis in lithium heparin**[64]
EDTA **Lithium heparin**	**Spiny softshell turtle *(Apalone spinifera)***	**All EDTA samples hemolyzed**[10]
EDTA	*American alligator (Alligator mississippiensis)*	*Used for hematologic parameter determination without apparent problems*[68]
EDTA	*Green iguana (Iguana iguana)*	*Thrombocytes, WBC, heterophils, and monocytes of EDTA sample had best agreement with differential of fresh blood smear*[9]
EDTA *Lithium heparin*	*Yellow-blotched map turtle (Graptemys flavimaculata)*	*EDTA preferred*[66]
EDTA	*Yellow rat snake (Pantherophis obsoleta quadrivittatta)*	*Acceptable results with EDTA for cellular morphology*[56]
Ca-EDTA *Lithium heparin*	*Chinese water dragon (Physignathus cocincinus)*	*Morphologic features of distortion and leukergy (WBC clumping) in LiHep samples; EDTA preferred*[69]

Studies in which heparin was a preferred anticoagulant are boldface, while those in which EDTA was preferred are italic. Equivocal studies or those with different anticoagulants are neither.
When confronted with a reptile or amphibian for which anticoagulants have not been studied, generally one should choose lithium heparin as the anticoagulant of choice.
ACD, acid-citrate-dextrose; *CPDA-1*, citrate-phosphate-dextrose-adenine; *EDTA*, Ethylenediaminetetraacetic acid; *PCV*, packed cell volume; *WBC*, white blood cells.

TABLE 33.4 Effects of Venipuncture Site and Lymphatic* Contamination Upon Reptile Cellular Components and Total Solids

Species	Sampling Sites	Differences Found in Samples with Lymphatic Contamination (LC)* or Associated With Venipuncture Site (VS)
Desert tortoise *(Gopherus agasizzi)*	Jugular vein Occipital plexus	VS: PCV, RBC count, WBC count, and hemoglobin were lower in samples from the occipital sinus;[70] VS: PCV, RBC count, WBC count, and hemoglobin were lower in samples from the occipital sinus[70]
Marginated tortoise *(Testudo marginata)*	Coccygeal vein Brachial vein	VS: RBC, Hct, and Hb were greater in brachial vein samples compared with coccygeal vein samples;[71] VS: RBC, Hct, and Hb were greater in brachial vein samples compared with coccygeal vein samples[71]
Northern map turtle *(Graptemys geographica)*	Coccygeal vein Subcarapacial vein	LC: Visual hemodilution noted in 16% of coccygeal samples but 75% of subcarapacial samples;[72] LC: Visual hemodilution noted in 16% of coccygeal samples but 75% of subcarapacial samples[72]
Red-eared slider *(Trachemys scripta elegans)*	Coccygeal vein Occipital vein	VS: Total WBC count, total plasma protein lower in samples from the dorsal coccygeal vein;[73] VS: Total WBC count, total plasma protein lower in samples from the dorsal coccygeal vein[73]
Leatherback sea turtle *(Dermochelys coriacea)*	Occipital vein Interdigital vein	VS: PCV, total solids, WBC count, heterophils, lymphocyte, monocyte, eosinophil, basophil from each site were comparable;[74] VS: PCV, total solids, WBC count, heterophils, lymphocyte, monocyte, eosinophil, basophil from each site were comparable[74]
African spurred tortoise *(Centrochelys sulcata)*	Coccygeal vein Subcarapacial vein	VS: Total solids had increased concentrations in samples from the tail versus the subcarapacial sampling site[18]
Common chameleon *(Chameleo chameleon)*	Jugular vein Tail vein	VS: No difference in WBC, RBC. Jugular venipuncture preferred based on likelihood of obtaining sample and darkening of the tail;[75] VS: No difference in WBC, RBC. Jugular venipuncture preferred based on likelihood of obtaining sample and darkening of the tail[75]
Hydrophiine sea snakes (*Hydrophis* spp.)	Tail vein	LC: Samples with observed lymphatic contamination had increased azurophils, total WBC count, and decreased PCV and total solids;[76] LC: Samples with observed lymphatic contamination had increased azurophils, total WBC count, and decreased PCV and total solids[76]

*Although previously identified as lymphatic contamination, venipuncture sites close to the cervical or coccygeal spine may be contaminated with cerebrospinal fluid.
Hb, Hemoglobin; *Hct*, hematocrit; *PCV*, packed cell volume; *RBC*, red blood cells; *WBC*, white blood cells.

affect cellular staining properties and render the sample unacceptable for microscopic evaluation (formalin fog)[12] (see Figs. 33.1 and 33.2).

Lymphatic dilution may occur from any venipuncture site in reptiles but is least likely to occur when samples are obtained from the jugular vein or heart.[13] Contamination of samples with CSF may be more likely to occur from venipuncture sites near the vertebral column (subcarapacial, supravertebral, coccygeal veins) (Divers S, personal observations). Thus the venipuncture site may affect multiple hematologic analytes based on lymphatic or CSF dilution or other factors. Lymphatic or CSF dilution should be suspected based on the rapid filling of the syringe with clear to light transparent light yellow fluid, which may be followed by blood. With cardiocentesis, clear fluid obtained should be differentiated from pericardial fluid. In humans, expected cell count, glucose and protein concentrations, and LDH activities of pericardial fluid are known; for reptiles these values have yet to be investigated. In mammals, most pericardial fluid samples are blood tinged and may have mesothelial cells not present in peripheral blood. Rather than discarding lymphatic samples, the authors recommend they be used for assessment of serology, PCR, or select plasma chemistries. Expected hematologic differences associated with lymph/CSF contamination of the blood sample include decreased PCV and RBC. In addition, increased lymphocytes may be seen with lymph-contaminated samples. When lymph is obtained during venipuncture we recommend drawing a reasonable sample for serology and/or plasma chemistries, or until a slight tinge of blood is seen, which may signal the collapse of local lymphatics. Use of a new needle and syringe in an approach along the same route will often provide a blood sample without lymphatic contamination. Both venipuncture site and lymph/CSF contamination may affect analyte results in reptiles.[14] Unfortunately, the effects of such contamination, venipuncture site, and associated changes in hematological analytes have been studied in relatively few species (Table 33.4).

Venipuncture Sites

Choice of the best sample site depends on many factors, including vascular anatomy, patient temperament, and practitioner skill. Consultation of taxa-specific reviews are recommended should training via a skilled and experienced veterinarian not be available (see also Chapter 43).[3,15–17] An overview of multiple options for vascular access based on reptile class and common site usage are provided in Table 33.5; however, other sites may be appropriate and preferred based on practitioner experience and knowledge. Sample site alone or in conjunction with lymph/CSF dilution may affect multiple hematologic parameters (see Table 33.4).[14] Clinically and for experimental purposes one should always document the venipuncture site used for each sample obtained. Further, for serial sampling, when possible, the same sample site should be used to facilitate direct comparisons. Samples obtained from more craniad sites may be more valid for interpretation of health or experimental outcomes in some reptiles.[14,18]

Sample Storage and Expected Analyte Changes

Few studies have focused on best or acceptable storage methodologies for reptilian blood samples bound for hematological analysis. The effect of delay upon hematology values has been studied in relatively few reptilian and amphibian species. Thus testing within 24 hours of sample collection is recommended for most hematologic analytes, and the sooner a sample can be analyzed, the better. However, amphibian blood samples diluted with Natt and Herrick's solution shortly after collection and refrigerated can maintain integrity for up to 2 years, and cell counts

TABLE 33.5 Venipuncture Site Options in Reptiles and Amphibians

Reptile Class	Preferred	Other Options
Snakes	Caudal (ventral coccygeal) vein, cardiocentesis	Jugular vein
Lizards	Caudal (ventral coccygeal) vein, jugular vein	Ventral abdominal vein, casque vein
Chelonians	Jugular vein	Brachial vein, subcarapacial sinus, caudal (dorsal and ventral coccygeal) veins, postoccipital venous sinus
Crocodilians	Supraoccipital sinus, tail vein	Ventral abdominal vein
Amphibians	Caudal (ventral coccygeal) vein, ventral abdominal vein, maxillary (facial) vein	Lingual vein, femoral vein

TABLE 33.6 Common Analytes Provided in the Reptile and Amphibian Complete Blood Count

Analyte	Measurement, Abbreviation, Units	Methodology Gold Standard	Other Methods	
Erythrocytes	PCV, %	Packed cell volume, centrifugation	Hematocrit calculation from hemoglobin and cell dimension often invalid/ inappropriate	Derivation from impedance (iSTAT) requires validation/ correction factor for the species
Leukocytes	WBC, 10^9/L or 10^3/mm^3 or /µL	Natt and Herrick's stain, cell counting chamber	Phloxine stain, cell-counting chamber	Slide estimate
		Total WBC count, manual, direct	Total WBC count, manual, indirect	Total WBC count, slide estimate
Heterophil	Absolute 10^9/L or 10^3/mm^3 or /µL,%	Differential leukocyte counts based upon % from blood smear × TWBC	Direct count of phloxine-stained eosinophils + heterophils	Estimate, %
Lymphocyte	Absolute 10^9/L or 10^3/mm^3 or /µL,%		Indirect calculation	Estimate, %
Monocyte	Absolute 10^9/L or 10^3/mm^3 or /µL,%		Indirect calculation	Estimate, %
Azurophil*	Absolute 10^9/L or 10^3/mm^3 or /µL,%		Indirect calculation	Estimate, %
Basophil	Absolute 10^9/L or 10^3/mm^3 or /µL,%		Indirect calculation	Estimate, %
Eosinophil	Absolute 10^9/L or 10^3/mm^3 or /µL,%		Direct count of phloxine stained eosinophils + heterophils	Estimate, %
Thrombocytes	Cells/µL		Slide estimation (low, adequate, high)	Estimate, %
Plasma Protein	Total solids (TS) or total protein (TP) g/dL or g/L**	Protein electrophoresis (EPH)	Refractometry	BCG binding, Biuret

*Many laboratories may include azurophils as or within monocytes for the count of percentage. Consultation with your laboratory and clinical pathologist is recommended to determine your lab's methodology

**Total solids may or may not be equivalent to total protein; for more information, see Chapter 34.

may be performed days to weeks after collection without compromise of result quality.[3] Older amphibian blood samples stored in this way suffer from loss of differential staining properties, thrombocyte-lymphocyte confusion, and leukocyte aggregation or clumping (Leukergy) resulting in decreased WBC counts.[3] In heparinized blood samples of loggerhead sea turtles (*Caretta caretta*) in which cells remained in contact with plasma and were refrigerated for up to 96 hours, minimal hemolysis occurred by 24 hours but moderate hemolysis occurred at 48 and 96 hours. Samples from Burmese pythons collected into heparin-coated syringes and transferred to containers with multiple anticoagulants and bovine serum albumin were evaluated for cellular changes over time.[11] Python blood samples anticoagulated with lithium heparin or K3-EDTA and refrigerated at 4°C for up to 24 hours had similar hematologic results to those immediately processed and were therefore preferred, whereas the addition of bovine serum albumin failed to provide any advantage for the analytes assessed.[19]

THE HEMATOLOGY REPORT

Complete Blood Count (CBC)

The parameters provided in a hematology report (often referred to as a complete blood count or CBC for other species) from commercial and university reference laboratories are more limited compared with those provided for mammals. These differences are based on a lack of automation for cell counts and the necessity of performing many tests manually, which increases the cost and time needed. Common evaluated parameters provided for the herpetological hematology report (complete blood count [CBC]) include PCV and total solid concentration (also referred to as plasma protein or total protein), thrombocyte estimate (low, adequate, high, clumped), leukocyte count and differential, evaluation of leukocyte and erythrocyte morphology, and examination for cell inclusions and hemoparasites (Table 33.6). Reptile and amphibian veterinarians are urged to choose a laboratory that provides a cell

VetBooks.ir

count based on hemocytometer rather than slide estimation for more accurate and precise results. No peer-reviewed, database publication in reptile or amphibian medicine has suggested that a WBC (slide) estimate provides results comparable to that of a hemocytometer-based WBC count. However, in both cases results are highly dependent on the quality of the blood smear, which is best made at the time of sampling. Although determination of the leukocyte count and differential may be beyond the time constrains of a practitioner, it is highly recommended that at least a PCV, total solids concentration (refractometric), and a slide review be performed in house to obtain actionable clinicopathologic data until results from the reference laboratory are available. This method, along with slide storage, provides an insurance policy against shipment loss, slide breakage, and cellular change/artifact that may occur based on storage, transport, and shipping to a reference laboratory.

Multiple methodologies may be used to determine the CBC, which may lead to confusion regarding clinical interpretation. Commonly used methods are not interchangeable and rarely agree. Manual leukocyte counts remain the preferred method for amphibian and reptilian blood samples but have an inherent error of approximately 20% despite use of experienced personnel.[3,20] Methodologies commonly used to determine the total and differential WBC count and differential include slide estimates (estimated WBC) and hemocytometer counts using Phloxine staining (indirect total WBC; e.g., Leukopet, Vetlab Supply, Palmetto Bay, FL) or Natt and Herrick's staining (direct total WBC; e.g., Natt and Herrick's stain, Vetlab Supply); these methods are listed in order of increasing accuracy, cost, time, and training necessary for correct performance. As most reptiles are predominantly lymphocytic, Phloxine techniques, which are based on granulocyte counts, may easily underestimate lymphocytes. Staining choices for determination of cell counts may also influence results. In general, eosin stains are recommended to provide more accurate counts from species that have leukograms predominated by heterophils and eosinophils, whereas Natt & Herrick's solution may be more appropriate for cell counts of lymphocytic reptile and amphibian species. Further, the preferred method of leukocyte counting (Natt and Herrick's staining, hemocytometry of all cells) is often not what is most commonly provided for reptiles and amphibians in commercial reference laboratories (likely based on cost, time, and technical difficulty prohibitions). Estimating the total WBC count based upon blood smear evaluation is seldom accurate except to subjectively judge whether leukocyte numbers appear low, adequate, or high. However, the differential percentages are generated from the blood smear in all cases; therefore, the quality of the slide and smear can greatly affect the differential and the relative WBC counts derived therefrom. Commonly provided hematologic parameters and methodologies are provided in Table 33.6, and examples are provided in Figs. 33.3 through 33.5. See Box 33.1 for specific instructions and methodologies used for determination of the total and differential WBC counts in reptiles and amphibians.

For the clinician, review and banking of the fixed blood smear is just as important as the receipt and interpretation of CBC results. Observing the blood smear in house, one may make several important clinical conclusions that may benefit the patient without a 24- to 48-hour

Approximately 2% of the herterophils have a large nucleus with increased N:C ratios, increased basophilia of the cytoplasm, decreased granularity, and the presence of dark purple granules. These findings are consistent with immature heterophils and therefore a left shift.

Addendum: Occasionally, monocytes contain blue to green to yellow to rarely black, refractile, granular to globular material. Monocytes in the peripheral blood of reptiles often exhibit phagocytic activity and erythrophagia and leukocytophagia in the peripheral blood of reptiles can be associated with anemia and infectious diseases. Additionally, the cells with black material may represent melanophages, a type of macrophage common in lower vertebrates, which can be found in blood smears of reptiles with inflammatory diseases. Overall, this finding is most likely associated with a systemic inflammatory process given the inflammatory leukogram, and no overt cause for the inflammation is noted within the blood smear. Continued monitoring of CBCs to assess the inflammatory process as well as the presence of these cells is recommended if clinically warranted.

FIG 33.4 Adult female leopard tortoise (*Stigmochelys pardalis*) presented moribund despite previous treatment with systemic parenteral antibiotics and fluids. The WBC count was provided by hemocytometry, and the packed cell volume was provided by centrifuge rather than by calculation (Hct). Note the profound leukocytosis, heterophilia with left shift and toxic changes, and monocytosis suggestive of chronic, severe inflammation/infection. (Courtesy of J. Jill Heatley and Karen E. Russell.)

delay. Major tasks for review of the blood smear include differentiation of cell types, assessment of cell morphology and observation of morphological cell abnormalities, and observation of cellular inclusions or extracellular abnormalities such as hemoparasites. Cellular morphology based on systemic inflammation, infection, etc., has been minimally investigated in reptiles. However, toxic change associated with whole body toxins affecting the bone marrow and left shift associated with acute severe inflammation have been anecdotally reported (Figs. 33.9 through 33.11). Increased glucocorticoid levels are associated with degranulation of the granulocytes (heterophils and eosinophils) in some species.[21] Detection of these cellular morphologic changes may be vitally important for practitioners to detect life-threatening conditions in patients that show minimal signs of ill health yet may lack a leukocytosis or overt leukopenia.

Leukogram (White Blood Cell Count and Differential)

Most reptiles and amphibians are lymphocytic. Table 33.7 provides examples of species, which in contrast to most other reptiles, have a leukogram predominated by a cell type other than lymphocytes in the apparently healthy state.

Clinical interpretation of the leukogram is made challenging by numerous factors. First, rigorous reference ranges, including total WBC and expected cell percentages, are seldom available for healthy reptiles. Additionally, species' cellular percentages and total count ranges vary widely even within healthy members of each class of reptile. Second, as primarily ectothermic species, numerous normal physiological factors may greatly affect the leukogram such as season, temperature, sex and reproductive status, and age, among others. Third, the expected leukocyte effects of specific conditions such as fungal, bacterial, viral, or parasitical infection or stress have been minimally investigated in these species. Few studies have attempted to induce increased or decreased numbers of specific cell types within the WBC differential. Additionally, many classical cellular changes associated with stress, toxic change, parasitism, and more, have only been anecdotally reported as supportive of an existing condition rather than prospectively induced by said condition. Therefore we are left with anecdotal reports of cellular numbers and morphologic changes observed in association with diseases or conditions. In the future, meta-analysis of the literature might be worthwhile to further investigate leukogram values and their association with inflammatory disease. Currently, clinicians must coordinate case clinical pathology

FIG 33.5 Hematology report of a juvenile sulcata tortoise (*Centrochelys sulcata*) with a cloacolith blockage. WBC count is provided by slide estimate and leukocytosis was determined. However, based on the likely minimum 20% expected variability of the estimated count, and the few reference ranges available for this species, this conclusion is debatable. Anemia is also identified and would be more acceptable if the jugular vein was used for venipuncture (avoiding lymphatic contamination), and this was not a 100-g (juvenile) animal. Heterophilia is present (4:1 ratio), but the young age of this animal may be contributory. Toxic changes may or may not be present. (Courtesy of J. Jill Heatley and Karen E. Russell.)

results with pathology and microbiology results retrospectively. Reporting this information remains critical for the advancement of herpetologic clinical pathology and health care.

Stress may account for increased WBC and differential derangements, but the extent of these changes has not been extensively investigated in reptiles. Increased glucocorticoid levels are associated with heterophilia, lymphopenia, and degranulation of the granulocytes (heterophils and eosinophils) in some species.[21] Free living box turtles affected by clear-cutting of their home range suffered increased total WBC counts.[22] In *Uromastyx aegyptius*, heat stress is associated with increased WBC counts.[23] With few exceptions, we lack fundamental knowledge regarding the timing of inflammation and the associated cellular responses in reptiles. Based on the author's experience, in many species, inflammation, as caused by infection, trauma, neoplasia, and so on, may be more likely to cause a shift in leukocyte percentages rather than an increased total leukocyte count. Thus leukocytosis, although reported in reptiles, may occur less commonly in reptiles than in birds or mammals. Consequently, leukopenia in reptiles, possibly even more so than in birds and mammals, may be cause for clinical concern and a guarded prognosis. However, many natural reptile processes may be associated with a relative decrease in WBC count.

Red Blood Cells

Erythrocytes of reptiles and amphibians are nucleated ellipsoidal disks. Comparative erythrocyte size and volume generally proceeds from the smallest in some lizards, to snakes, crocodilians, chelonians, and the largest in amphibians. This spectrum of increasing red cell size is accompanied by decreasing red cell number, resulting in similar PCVs among these groups.[24] However, multiple species diverge from this generality (Table 33.8). In general, despite great variability in the total number of red blood cells (RBC), the mean cell volume (MCV) and mean cell hemoglobin (MCH), the hemoglobin level (Hb), PCV, and mean cell hemoglobin concentration (MCHC) are relatively constant but lower in reptiles compared with birds and mammals.[25] Thus oxygen carrying capacity also tends to be relatively lower in exothermic species.[25]

RBC, MCV, MCHC, MCH, Hb, and the attendant calculations are rarely determined for reptiles based on current analyzer methodologic limitations and incompatibility with the analysis of nucleated nonround cells. Some methods require sophisticated cell analysis techniques or lysis of cells to remove the nuclei.[26] However, these values have been determined for some species experimentally.[24,27,28] Beware of calculated

BOX 33.1 Methods for Determining Total and Differential White Blood Cell Counts in Reptiles and Amphibians

1. Slide estimate
   a. Materials needed: Slides with well-executed blood smears, cellular differentiating stain, microscope with at least ×400 magnification, ×1000 magnification preferred. Microscopist trained in differentiation of reptile or amphibian leukocytes.
   b. Time investment
      i. Differential 20 minutes
      ii. WBC estimate 10 minutes
   c. Technique
      i. 100 WBCs are counted and differentiated to create a percentage of cells = differential
      ii. At 400 magnification (high-dry, 40×), WBCs are counted in 10 separate fields in the monolayer, in which RBC are just barely touching. Sources vary as to the multiplier best used to provide an estimate of the total white blood count, which is generally from 1500 to 2500.
   d. Advantages: Minimum expense, small volume requirement (1 drop)
   e. Disadvantages: Time consuming for clinical practice, requires a well-trained eye, results likely very inaccurate, it is an estimate
2. Indirect phloxine stain technique (indirect method)
   a. Description: In the indirect method, acidophilic granulocytes (heterophils and eosinophils) are stained with phloxine solution and counted in a hemacytometer. Additionally, a differential cell count is performed on a blood film stained with Romanowsky-type stains (e.g., Wright-Giemsa).
   b. Materials needed: Slides with well-executed blood smears; cellular differentiating stain; aliquoted eosinophil stain; pipettor; anticoagulated blood; Neubauer improved hemocytometer; microscope with ×10, ×20, ×40, and ×100 objectives preferred. Microscopist trained in differentiation of reptile/amphibian leukocytes on blood smears and able to count granulocytes within the hemocytometer.
   c. Time investment
      i. Differential 20 minutes
      ii. Granulocyte count 30 minutes
      iii. Calculations 10 minutes
   d. Technique
      i. Mix 25 µL blood with 0.775 µL mL phloxine stain. Mix and stand for 10-15 mins.
      ii. Charge both sides of the Neubauer improved hemocytometer (Fig. 33.6, 33.7)
      iii. Place in humidity chamber for 10 minutes to allow cell settling
      iv. Count all granulocytes (pink dots) in large corner squares from one side = X
         1. Should any quaker be less than 50% of another square, cells were not distributed evenly; start count on other side of hemocytometer or return to (ii) with new hemocytometer.
      v. The total WBC ($\times 10^9$/L) = (average number of stained heterophils + eosinophils in 9 squares of hematocytometer × 1.1 × 16 × 0.1), divided by the percentage of heterophils + eosinophils in the differential. Multiply by 1000 for TWBC/µL.
   e. Advantages: Faster than Natt and Herrick's, more accurate than an estimate
   f. Disadvantages: Requires specialized equipment and reagents. Indirect method may underestimate total cell count in species that have nongranulocytic cells as the predominant inflammatory cell. This technique is heavily reliant on a quality blood smear to produce an accurate differential; a damaged or poorly fixed blood smear will cause erroneous results. When heteropenia exists the total leukocyte count may be falsely elevated.
3. Direct Natt and Herrick's stain technique
   a. Materials needed: Slides with well-executed blood smears; cellular differentiating stain; aliquoted Natt and Herrick's stain; pipetter; anticoagulated blood; Neubauer improved hemocytometer; microscope with ×10, ×20, ×40, and ×100 objectives preferred. Microscopist trained in differentiation of reptile/amphibian leukocytes in both Natt and Herrick's stain and within blood smears.
   b. Time investment
      i. Differential 20 minutes (not necessary for numbers, but slide review of morphology and platelet estimate should be performed)
      ii. Cellular counts 60 to 90 minutes
      iii. Calculation 5 minutes
   c. Technique: Dilute whole anticoagulated blood 1 : 200 with Natt and Herrick's solution. Allow the diluted blood to mix for a minute or two before discharging into the hemocytometer counting chamber. Allow the hemocytometer contents to settle for approximately 3 minutes.
      i. Performing the total erythrocyte count using the high dry (40×) objective of the microscope; count the total number of RBCs (easily recognizable by their nuclei) in the four corners and central squares of the central large square of the counting chamber. Count all cells that overlap the top and left border. Do not count any cells that overlap the bottom or right borders. Multiply the total number of cells counted by 0.01 to obtain TRBC $\times 10^{12}$/L. Multiply total number of counted cells by 10,000 to obtain TRBC/µL.
      ii. WBCs tend to stain dark blue to purple and may exhibit some granularity. The total leukocyte count is obtained by counting all leukocytes present in the nine large ruled squares of both sides of the hemacytometer, and calculating the average of the two. Count all cells that overlap the top and left border. Do not count any cells that overlap the bottom or right borders (Fig. 33.8). The computation for total leukocyte count is: Total WBC × 10^9/L = total leukocytes counted in 9 squares (average of both sides) × 1.1 × 0.2. For total WBC/µL ×1000.
   d. Advantages allow for direct counting of both erythrocytes and leukocytes in amphibian and reptilian species. As the same dilution is used for both red and white cells, a total leukocyte and a total erythrocyte count can be obtained simultaneously from the same charged hemacytometer.
   e. Disadvantages: Because many more cells are there for the counting, this method can be very time consuming. Differentiating WBC from thrombocytes may be difficult; thrombocytosis could result in an erroneously high WBC.

hematocrits in reptiles, which, based on cellular size and shape, may or may not be reflective of a centrifuge-determined PCV (the gold standard). Similarly, RBC count by automated cell counters may be suspect when species-specific standards are not provided. Calculated or other methodologies for determination of HCT are seldom validated for use in reptiles. Manual methods for manual determination of RBC necessitate use of dilution pipettes, hemocytometers, and Natt and Herrick's or other specialized cell stains, as well as a trained and proficient hematology technician.[24]

Packed Cell Volume

Clinical evaluation of the reptilian and amphibian RBC parameters is often best provided by PCV determination (Tables 33.8 and 33.9). Causes for relatively increased or decreased PCV of reptiles are numerous and

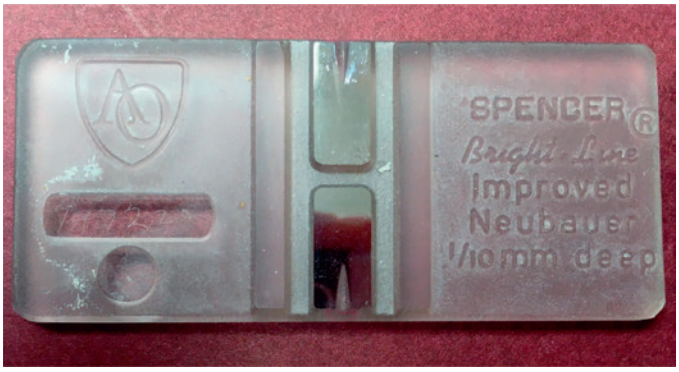

FIG 33.6 Glass Neubauer cell counter, which can be used for hemocytometry. These antiques may be used for prolonged periods, but as glass they are fragile, must be carefully cleaned and dried between counts, and require a new cover slip for each count. For more detail, see Fig. 33.8. (Courtesy of J. Jill Heatley and Karen E. Russell.)

include both normal physiological and disease-based origins. Causes for increased or decreased PCV in ill or injured reptiles parallel those of companion mammals. For example, chronic lower gastrointestinal tract strictures of green sea turtles *Chelonia mydas* have been associated with a persistent anemia.[29] Table 33.10 provides etiologies of PCV change in reptiles.

Causes for physiological change in RBC parameters for reptiles are numerous. As reptiles age, MCV, MCHC, MCH, RBC, PCV, and Hb tend to increase.[30–32] In general, one might expect increased RBC and PCV posthibernation compared with prehibernation, as well as during active periods compared with hibernation or less active periods.[33] Similarly, posthibernation reptiles can have a marked regenerative erythroid response accompanied by basophilic stippling.[26] However, many exceptions exist; for example, the captive South American rattlesnake (*Crotalus durissus terrificus*) had significantly higher RBC, PCV, Hb, MCV, MCH, and MCHC in winter than in summer.[31] Relatively increased Hb, PCV, and/or RBC mass occur in some male chelonia compared with females, but many reptile species do not adhere to this expectation.[34] For example, captive female green iguanas had higher PCV and MCHC values than males.[33]

Pathologic changes in PCV or other RBC parameters can be characterized as anemia or polycythemia. True polycythemia has not been reported in reptiles; however, hyperviscosity syndrome may occur in association with rapid temperature change or envenomation.[13] Increased PCV and RBC count have been reported in terrapins subjected to hyperosmotic stress.[21] Polycythemia may be considered when PCV exceeds 40% but is rare and more commonly caused by dehydration.[13]

Anemia, a decreased PCV and/or RBC count, may be classified as regenerative or nonregenerative. Clinicopathologic markers of regenerative anemia of reptiles include cytoplasmic basophilic stippling, polychromasia, binucleation, increased anisocytosis and anisokaryosis, and an increased number of mitotic figures and/or early erythroid precursors.[33] A regenerative response in reptiles is also typically associated with a decrease in MCV and MCHC.[33] As in other vertebrates common differentials for regenerative anemia include acute blood loss from trauma or parasitism, hemolytic diseases (including oxidative damage from zinc toxicosis), hemoparasites or other infectious disease, microangiopathic disease, and marked hypophosphatemia. Hemoparasitism or heavy metal toxicity may result in hemolytic anemia.[26] However, hemoparasitism does not dictate hemolytic anemia, and this sign likely depends on a number of factors including the species of hemoparasite, host adaptation, and the primarily affected cell type. In the teiid lizard

FIG 33.7 (A–C) Disposable hemocytometer examples. These hemocytometers are plastic and relatively inexpensive but must be bought in batches of 50 from standard laboratory supply companies. Four- rather than two-chamber disposable counters are also available (C, four-chip Neubauer improved plastic cell counting chamber, bulldog-bio.com). (Courtesy of J. Jill Heatley and Karen E. Russell.)

(*Ameiva ameiva*), hematozoon parasitism causes a monocytosis and ultrastructural changes in infected monocytes but does not affect erythrocyte parameters.[35]

Nonregenerative anemias are characterized by a lack of cytologically appreciable response; however, normal reptile regenerative response times have not been characterized and are likely slower than mammals, based on their expected RBC lifespan of 600 to 800 days.[36] Reptiles with iron-deficiency anemia may have hypochromic erythrocyte with decreased MCH and MCHC. Causes for iron deficiency in reptiles are similar to other vertebrates and include chronic inflammatory disease, iron-deficient diets, and malabsorption due to gastrointestinal disease. Anemia of chronic disease is likely the most common cause of nonregenerative anemia in reptiles and includes a multitude of etiologies:[33]

TABLE 33.10 Etiologies of Packed Cell Volume (PCV) Changes in Reptiles[22,24,26]

	Factor	Comments
Increased PCV		
Physiological	**Male**	Reproductive activity and hydration status
	Pre-hibernation [brumation]	Activity increased need for blood cells
	Favorable environmental conditions	Summer, increased temperature, geographic variation
Disease	Dehydration	Husbandry, renal disease, gastrointestinal disease
Decreased PCV		
Physiological	**Female**	Reproductive activity and hydration status
	Juvenile	Hatchling to year one
	Posthibernation [brumation]	Inactivity reduced need for blood cells
	Unfavorable environmental conditions	Winter, decreased temperature, other unfavorable climatic conditions, lack of food, clear cutting, poor husbandry
Disease	**Systemic chronic inflammation or degenerative disease**	Coagulation disorders, thrombocytopenia*
		Neoplasia, infection
	Blood loss	Trauma to include surgery, gastrointestinal tract ulcers, hemoparasitism, hematophagous ectoparasitism
	Pollution	Lead, zinc, other environmental toxins
Artifactual	**Collection technique**	Lymphatic or cerebrospinal fluid contamination
		Hemolysis from inappropriate choice of handling, storage, venipuncture technique, anticoagulant

Italic factors are commonly regenerative. Boldface factors are commonly nonregenerative.
*May be regenerative in early stages until iron stores are depleted. Reptilian regenerative and nonregenerative anemias have not been well characterized and are assumed to follow the same general trends as mammals. However, time until visualization of regenerative cytological signs may be relatively prolonged in these ectothermic species.

- Systemic infectious disease
- Chronic degenerative or inflammatory diseases of the liver, kidney, spleen, or lungs
- Gastrointestinal disease
- Inappropriate husbandry/starvation
- Hematopoietic neoplasia
- Multifactorial from above

Assessment of anemia relies heavily upon evaluation of cellular morphology to identify a regenerative response. Polychromatophilic cells are often assessed as synonymous with reticulocytes, which are generally <1% to 2.5% in healthy reptiles. Increased polychromasia may have also been associated with ecdysis and young age (Fig. 33.12). Similarly, anisocytosis, variation in cell size, is mild to minimal in healthy reptiles and amphibians. A highly regenerative response is associated with polychromasia as well as binucleated erythrocytes, a few mitotic figures, and even younger erythroid precursors such as rubricytes and prorubricytes. However, similar regenerative responses (binucleated RBC, anisokaryosis, mitosis) have, in reptiles, been associated with hibernation emergence, severe inflammation, malnutrition, starvation, and in amphibians with increased lactate or changes in oxygen and carbon dioxide tension of polluted water.[37] Basophilic stippling of reptilian erythrocytes is rare but associated with lead toxicity, iron deficiency, or regenerative responses.[26] An increased number of fusiform or teardrop-shaped erythrocytes has been associated with septicemia or chronic infectious disease; however, these cell shapes are commonly found in the circulation of healthy amphibians.[3,33]

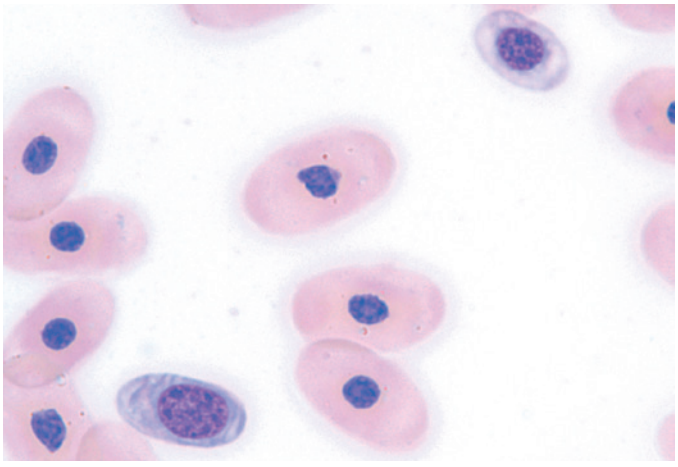

FIG 33.12 Blood smear from a red-eared slider (*Trachemys scripta elegans*), 1000× magnification, Modified Wright Giemsa stain. Polychromatophils (immature bluish RBCs, upper right, lower left) starkly contrast the adult erythrocytes and support a regenerative response to anemia in this patient, which was infected by hemogregarines. (Courtesy of J. Jill Heatley and Karen E. Russell.)

LEUKOCYTE MORPHOLOGY, FUNCTION, AND INTERPRETATION

Leukocytes of amphibians and reptiles are thought to have similar function as those of other vertebrates, but few functional studies have been performed.[3] As reptiles age, WBC counts tend to decrease.[30,31] The agranulocytes consist of lymphocytes, monocytes, and azurophils. The granulocytes include the heterophil, eosinophil, and basophil. Cell differentiation may be complicated by species variety.

Lymphocyte

Reptilian and amphibian lymphocytes and monocytes have similar morphology and likely similar function to those of mammals.

VetBooks.ir

TABLE 33.11 Clinical Differentiation of Reptile and Amphibian Mononuclear Cells With Immune Function

Factors	Monocyte	Lymphocyte	Thrombocyte
Shape	Round-oval	Round	Inactivated: Elongate oval similar to erythrocyte Activated: Round sometimes with small pseudopodia
Cytoplasm	Abundant pale blue-gray, vacuoles variably present Vacuoles may contain: melanin, nucleoproteinaceous debris, lipid, erythrocytes, hemosiderin	No granules, thin, blue	Clear to very light purple or blue, small pink granules
Nucleus	Round, oval, reniform, or multilobed Smooth to slightly clumped chromatin	Eccentric, round dark blue-purple, chromatin clumping, or nucleoli may be seen	Centric, very dark purple, often indented, no internal structures visible
N:C	1:3	4:1	1:1
Activity	Clumping uncommon	Clumping uncommon but may be induced by some anticoagulants	Rafting (clumps) common
Size (μm)	8–25	5–15	8–16 × 5–9

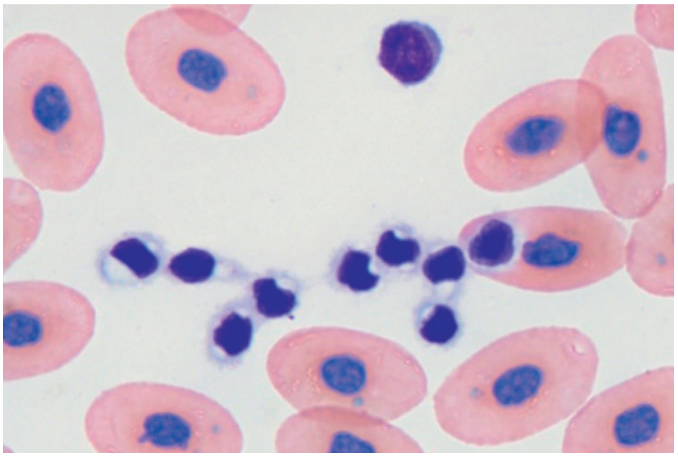

FIG 33.13 Blood smear from a box turtle (*Terrapene carolina*), 1000× magnification, Modified Wright Giemsa stain. Thrombocytes (central) and lymphocyte (upper). (Courtesy of J. Jill Heatley and Karen E. Russell.)

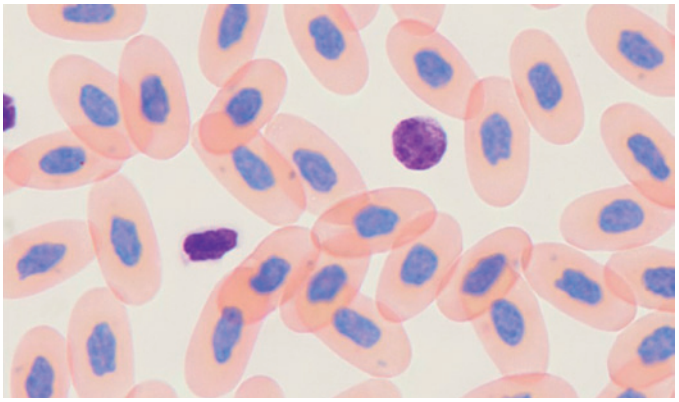

FIG 33.14 Blood smear from a red tegu (*Tupinambus rufescens*), 1000× magnification, Modified Wright Giemsa stain. Thrombocyte (left) and lymphocyte (right). (Courtesy of J. Jill Heatley and Karen E. Russell.)

Lymphocytes are the most common leukocyte, accounting for up to 80% of the differential of most healthy reptiles, although exceptions to this general rule exist (see Table 33.7).[33] The thrombocyte may be challenging to differentiate from small lymphocytes, resulting in erroneously high lymphocyte counts within differentials (see Table 33.11 and Figs. 33.13 and 33.14). Immune stimulation based on inflammatory or infectious disease has been associated with the peripheral circulation of large lymphocytes, reactive lymphocytes, lymphoblasts, plasmacytoid lymphocytes, granular lymphocytes, and rarely, plasma cells.[33] Plasma cells are larger than the normal lymphocyte with a deep blue cytoplasm, a round eccentric nucleus with chromatin clumping, and a perinuclear halo created by the golgi apparatus. Etiologies of lymphocytosis include subacute causes of inflammation associated with infection, wound healing, parasitism, and viral disease.[33] Clinicopathologic etiologies of lymphopenia should include exogenous testosterone administration, endogenous or exogenous steroid exposure, acute bacterial infection, and other causes of immunosuppression (including poor husbandry and malnutrition).[38] Reptile B lymphocyte and T lymphocyte functions include immunoglobulin production and cell-mediated immune responses.[33]

Monocyte

Reptilian and amphibian monocytes have similar morphology and likely similar functions to those of mammals (Figs. 33.15 through 33.17). Monocytes may comprise up to 10% of the leukocytes in a healthy reptile.[33] Physiological causes of relative monocytosis include (pre)hibernation in free-ranging gopher and desert tortoises; however, similar findings were not apparent in pre- and posthibernation captive vipers.[39–41] Otherwise, and in comparison to other leukocytes of reptiles, monocyte counts change minimally between seasons. Absolute monocytosis may occur due to chronic antigenic stimulation or chronic inflammation associated with bacterial and parasitical diseases, dystocia, and leukemic neoplasia.[33,42] Circulating monocytes may phagocytose erythrocytes, hemosiderin, melanin, and other cellular components. Differential etiologies of these cells in circulation include postsurgical or other trauma, wound healing, sepsis, infectious disease, delayed sample processing, and immune-mediated disease.[33,43–45] Differentiation between large lymphocytes and monocytes may also be challenging during the cell counting process if Natt and Herrick's solution is used. In the teiid lizard *Ameiva ameiva,* hematozoon parasitism causes ultrastructural changes in infected monocytes, monocytosis and leukocytosis.[35]

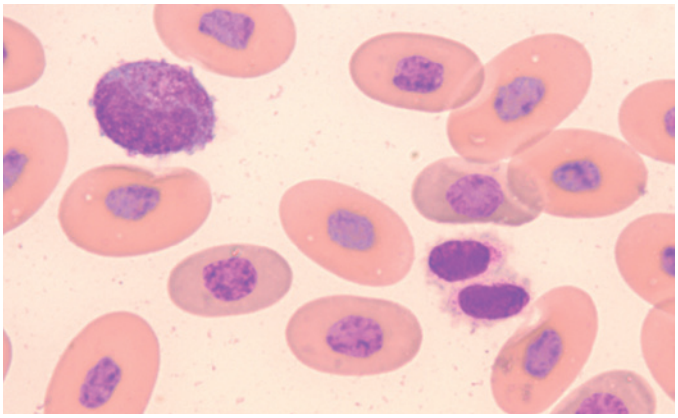

FIG 33.15 Blood smear from a Panther chameleon (*Furcifer pardalis*), 1000× magnification, Modified Wright Giemsa stain. An azurophilic monocyte (upper left) and two activated thrombocytes (lower right) are shown. (Courtesy of J. Jill Heatley and Karen E. Russell.)

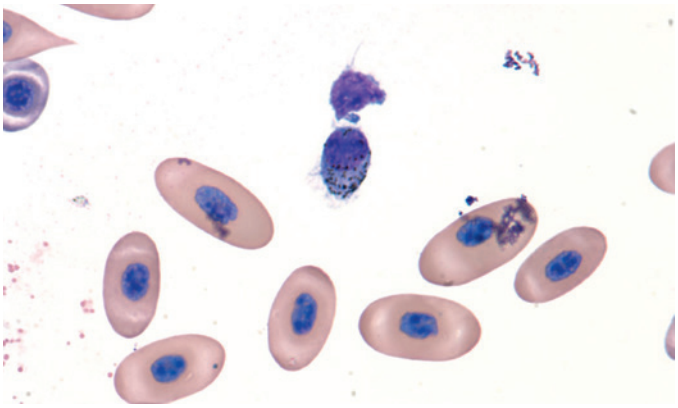

FIG 33.16 Blood smear from a long-nosed horned frog (*Megaphrys nasuta*), 1000× magnification, Modified Wright Giemsa stain, melanomacrophage.

Azurophil

The azurophil is a relatively large mononuclear cell that appears unique to the monocyte line of reptiles and amphibians. This cell is similar in size to the monocyte but has a fine dusting of small azurophilic granules that may impart a darker blue (azure) appearance. These cells occur commonly in snakes and may account for up to 35% of the WBC differential in healthy specimens.[33] These cells also occur on lizards, crocodilians, and least commonly chelonians[33] (see Fig. 33.15). The azurophil may function differently based on the species. Cytochemical staining of snake azurophils indicates a function similar to mammalian neutrophils, whereas those of lizards may function more like mammalian monocytes.[33] Thus in snakes, azurophilia has been associated with acute stages of inflammation and infectious disease, whereas in other reptiles increased number of azurophils may more likely signal chronic inflammation.[33,46,47] Although the exact function of the azurophil remains unknown, functions likely include those similar to the monocyte including phagocytosis. Azurophils have been tentatively identified in amphibians.[48,49] Based on the variable presence and likely function of this cell in reptiles and amphibians, the clinician must be familiar with the cell-counting procedures of their reference laboratory because azurophils may or may not be counted separately from monocytes. The resultant differential, especially in snakes, could vary markedly depending on the laboratory classification of these cells.

Heterophil

Heterophils are commonly the most numerous granulocytes followed by eosinophils and basophils (Table 33.12). Heterophils are a granular leukocyte characterized by granules that have variable sizes and staining characteristics. As such, the term heterophil is most often used to describe the granulocyte (and second-most common leukocyte) with rod or variably shaped granules that may fail to uptake stain (appear clear) or appear pale pink, bright orange, or even green-blue (see Figs. 33.9 through 33.11). In some crocodilians and chelonians, heterophils may account for greater than 50% of the differential in the healthy animal.[33] Heterophils are believed to function similarly to that of mammalian neutrophils; they can phagocytize bacteria and other foreign materials. As primary responders for the innate immune system, increased heterophils in the peripheral blood may occur based on a variety of inflammatory stimuli. The term heterophil has been used for the primary amphibian granulocyte, but based on cytochemical staining and enzyme contents, neutrophil is now preferred.[3]

Heterophil number changes have been reported based on numerous physiological factors. In general, relative increases are often associated with adult males, juveniles, summer season (compared with hibernation), and free-living states (compared with captivity). [33] Etiologies of pathologic heterophilia are presumed similar to those of other vertebrates, including acute, active inflammatory conditions, such as infectious diseases (bacterial, parasitical), tissue injury, necrosis, gravidity, exogenous or endogenous glucocorticoids, and neoplasia, including granulocytic leukemia.[33] Severe, acute inflammation may result in heteropenia with a left shift or toxic changes.[47] Heteropenia may occur due to acute toxicity (e.g., fenbendazole administration) or severe, acute inflammatory disease, such as overwhelming sepsis (which may also be accompanied by left shift and/or toxic changes).[68]

Eosinophils

Eosinophil morphology of reptiles and amphibians is similar to that of mammals (see Table 33.12 and Figs. 33.18 and 33.19). An important exception to this rule is the "green" eosinophil of some iguanid, teiid, and agamid lizards, so named based on their pale blue-green granules (Fig. 33.20). Eosinophils are rare to absent in most snakes but have been documented in the king cobra (*Ophiophagus hannah*), Burmese

VetBooks.ir

TABLE 33.12 Differential Morphology of Reptile Granulocytes Based on Modified Wright Stain

Cell	Cytoplasm	Granules	Nucleus	Size (μm)
Heterophil	Clear	Distinct fusiform (crocodilians, chelonians) Angular pleomorphic, densely packed (squamates) Orange-pink	Round to oval (snakes, chelonians, crocodilians) Bilobed or multilobed (lizards) Eccentric	10–23 (Figs. 33.5 and 33.6)
Eosinophil	Clear	Round and pink Exceptions: blue-green in iguanas, tegu, rainbow lizard	Eccentric, round to oval elongated or bilobed	9–20 (Figs. 33.9, 33.15, and 33.17)
Basophil	Pale purple	Numerous, small round, deep purple (metachromic)	Round eccentric, often obscured by granules	7–12 (Figs. 33.7 and 33.9)

Cells are listed in decreasing order of appearance in most reptilian species.[47,52]

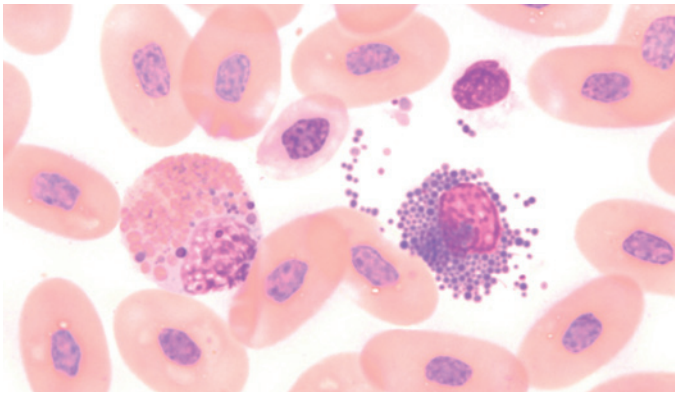

FIG 33.18 Blood smear from a savannah monitor (*Varanus exanthematicus*), 1000× magnification, Modified Wright Giemsa stain. Two granulocytes are present: An eosinophil is shown on the left and a fractured basophil with free granules is on the right. (Courtesy of J. Jill Heatley and Karen E. Russell.)

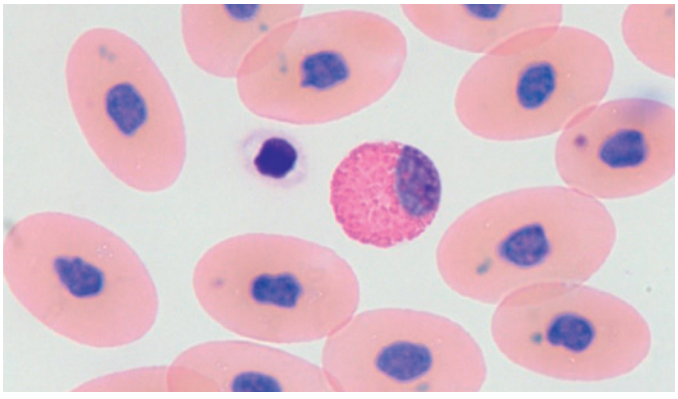

FIG 33.19 Blood smear from a box turtle (*Terrapene carolina*), 1000× magnification, Modified Wright Giemsa stain. Eosinophil (center) and a thrombocyte to the left. (Courtesy of J. Jill Heatley and Karen E. Russell.)

python, reticulated python (*Malayopython reticulatus*), African rock python (*Python sebae*), green tree python (*Morelia viridis*), and boa constrictor (*Boa constrictor*).[50,51,52,53] Eosinophils may represent a second heterophil type in snakes.[54,52,55,56] In healthy reptiles, eosinophils range from 7% to 20% of the WBC differential, with relatively fewer cells in lizards and increased numbers in chelonia. The functions of reptile and amphibian eosinophils remain minimally studied, but increased numbers have been associated with parasitic disease.[33,57] Reptile eosinophils can phagocytose immune complexes and bacteria and have microbicidal properties.[33]

Basophils

Basophils, the small "cluster of grapes" cell, are usually easily differentiated from other reptile and amphibian granulocytes (Table 33.11 and Figs. 33.18 and 33.21). However, basophils may degranulate to expose their eccentric nucleus, pale purple cytoplasm, and the remaining clear distinct cytoplasmic vacuoles. Occasionally, nearby granules may be observed or, even more rarely, the act of granule expulsion may be evident.[48] Basophil degranulation may occur because of a number of external factors including methanol quick-based stains (e.g., DiffQuik) and inappropriate sample collection, handling, slide preparation, or delayed processing.[33,48] Lack of metachromatic staining of basophil granules may also occur with use of aqueous-based stains.[58] Despite documented possession and release of histamine and expression of immunoglobulin, the function of the reptile basophil remains poorly understood.[59,60]

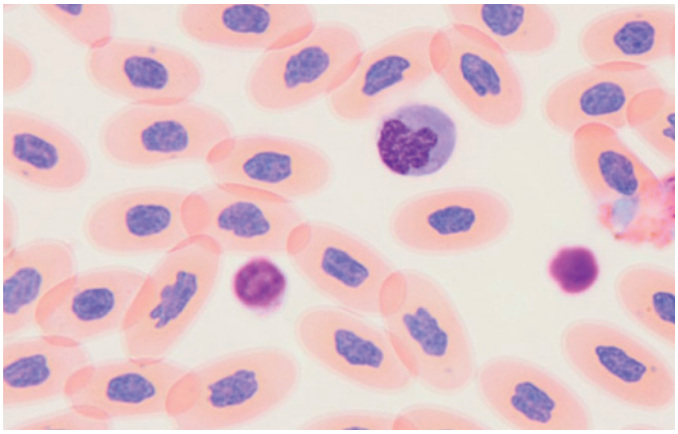

FIG 33.20 Blood smear from a red tegu (*Tupinambus rufescens*), 1000× magnification, Modified Wright Giemsa stain. "Green" eosinophil. (Courtesy of J. Jill Heatley and Karen E. Russell.)

Basophils appear more commonly in chelonians with up to 40% to 65% reported in some healthy species.[59,61] In some amphibians, basophils can be the predominant leukocyte (see Table 33.7).[3] Likely based on the predominance of basophils in some chelonia, reports of relatively increased numbers of these cells based on physiological factors so far appear limited to these species. In chelonia, one might expect increased

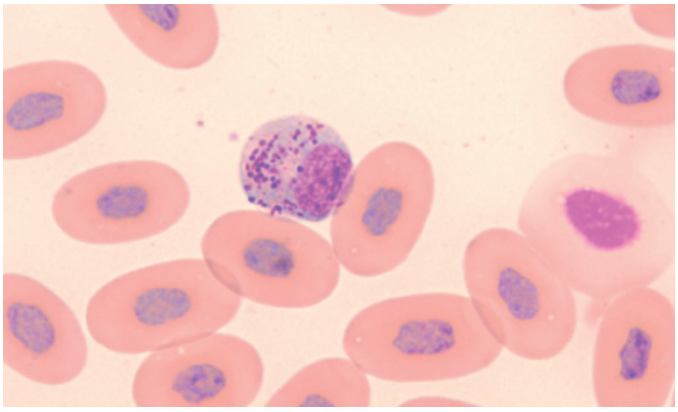

FIG 33.21 Blood smear from a Panther chameleon (*Furcifer pardalis*), 1000× magnification, Modified Wright Giemsa stain. Minimal granulation in a basophil, which allows the eccentric nonlobulated nucleus to be observed. (Courtesy of J. Jill Heatley and Karen E. Russell.)

basophil numbers in spring versus summer or during active periods versus hibernation.[33] Pathologically increased numbers of basophils have been associated with hemic infections, including hemoparasites and iridovirus.[33]

Thrombocytes

Thrombocytes are ovoid cells with pale cytoplasma but transform to round cells when activated (see Figs. 33.13, 33.14, and 33.19). Fig. 33.2A depicts multiple small lymphocytes as well as multiple inactivated thrombocytes. The thrombocyte may be challenging to differentiate from the small lymphocyte, resulting in erroneously high lymphocyte counts within differentials. Table 33.11 provides figures and explanations to differentiate these cells. Best methods for accurate determination of thrombocyte counts remain to be demonstrated in reptiles.[62] Comparison among the many differing methodologies makes meaningful clinical interpretation of the extant literature challenging. Platelet estimation from the blood smear is most commonly reported as reduced, adequate, increased or clumped. Direct thrombocyte counting techniques are hampered by numerous, similarly stained, shaped, and sized mononucleated cells, most notably small lymphocytes. Despite these challenges, the reptile thrombocyte is an important part of the clotting response and is also thought to have phagocytic properties. Currently, use of thrombocyte counts as a significant prognostic or diagnostic tool is unreliable.[62] The hematology report should include thrombocyte numbers if direct (Natt and Herrick's) hemocytometry methods were used. Otherwise, these cells could have been mistaken for lymphocytes, resulting in an erroneously high lymphocyte count.[3] As reptiles age, thrombocyte counts tend to decrease.[32,30,31]

Hemoparasites and Cellular Inclusions

Hemoparasites are not uncommonly encountered in the blood smears of wild-caught or free-living reptiles. Specific treatment is seldom pursued unless clinical disease is evident; supportive care and removal of intermediate hosts from the environment are generally sufficient. Hemoparasites include: *Hemogregarina* spp. (Fig. 33.22), *Karyolysus* spp., *Trypansoma* spp., and microfilaria of *Filarid* spp. (Fig. 33.23). For a more detailed description of the numerous species and host interactions and morphology of hemoparasites of reptiles a complete text is available.[63] Cellular inclusions of multiple types are not uncommon in reptiles and may signal a variety of conditions, ranging from benign to life threatening. Differentials include reptarenavirus (Fig. 33.24) iridovirus, poxvirus, *Chlamydia*, degenerate organelles (see Figs. 33.23

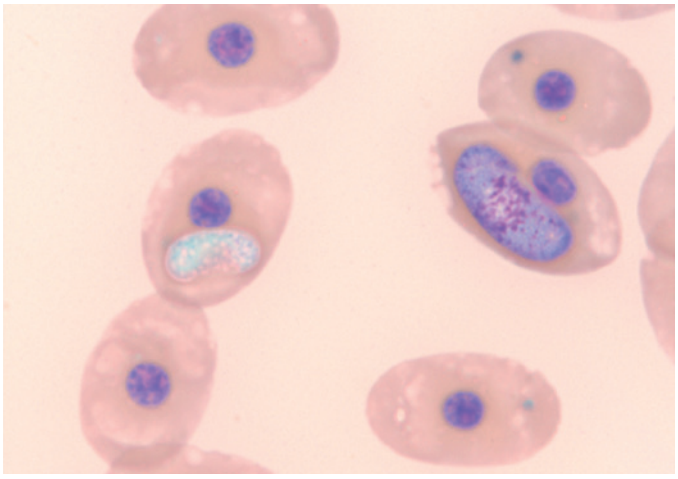

FIG 33.22 Blood smear from a common snapping turtle (*Chelydra serpentine*), 1000× magnification, Modified Wright Giemsa stain. Two forms of the hemogregarine parasite are observed within erythrocytes. Also note multiple clear areas within several RBCs that likely represent drying artifact. (Courtesy of J. Jill Heatley and Karen E. Russell.)

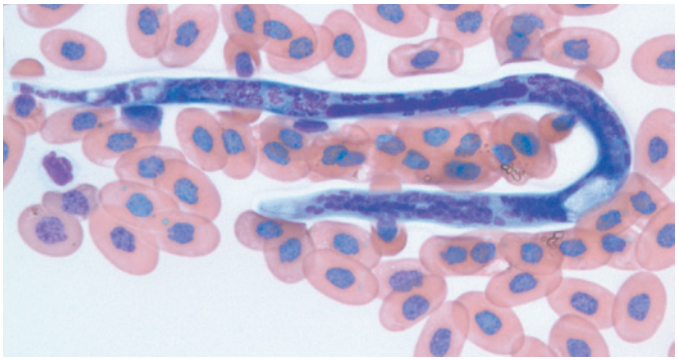

FIG 33.23 Blood smear from an adult male box turtle (*Terrapene carolina*), 600× magnification, Modified Wright Giemsa stain, Microfilariasis (spp. unknown). Punctate blue inclusions in multiple erythrocytes are considered degenerate organelles but lack clinical importance. (Courtesy of J. Jill Heatley and Karen E. Russell.)

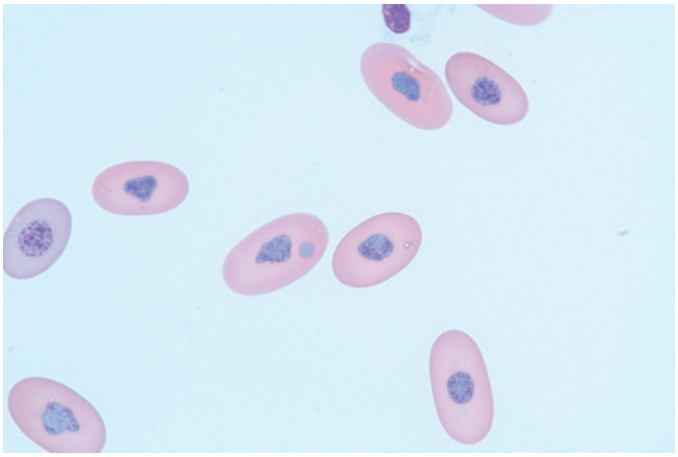

FIG 33.24 Blood smear from a reticulated python (*Malayopython reticulatus*) suffering regurgitation and dehydration, 1000× magnification, Modified Wright Giemsa stain. Note the blue-tinged cytoplasmic inclusion body in the central erythrocyte. This animal had classical histopathologic lesions of inclusion body disease and was PCR positive for Reptarenavirus. (Courtesy of J. Jill Heatley and Karen E. Russell.)

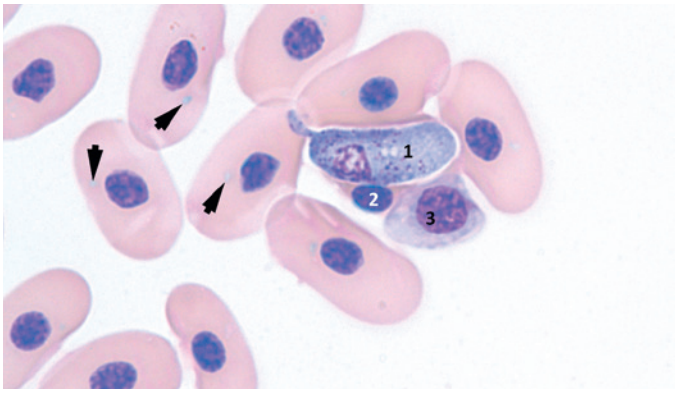

FIG 33.25 Blood smear from a red-eared slider (*Trachemys scripta elegans*), 1000× magnification, Modified Wright Giemsa stain. The hemogregarine (1) that displaces the nucleus and deforms the host erythrocyte (2) is seen above the erythroblast (3). The small, intracytoplasmic, light green-blue structures (arrows) are artifacts commonly observed in reptile blood smears that likely represent degenerate organelles. (Courtesy of J. Jill Heatley and Karen E. Russell.)

and 33.25), and drying artifacts. Therefore it behooves the practitioner to be familiar with common artifacts and inclusions, which may be found on the reptile blood smear (see Figs. 33.1, 33.3, and 33.4). In teiid lizards, hematozoon parasitism causes ultrastructural changes in infected monocytes.[35]

Clinical Chemistry

J. Jill Heatley and Karen E. Russell

This chapter strives to provide a clinically useful guide for veterinarians and biologists of indications and methodologies for collection, handling, storage, and clinical interpretation of bodily fluid samples (plasma, serum, coelomic effusions, and cerebrospinal fluids). Although most information in this chapter will be based on more commonly seen species, other esoteric species may have been studied in more detail and may be included when necessary to illustrate general and expected findings. Should the reader require more specifics, a review of primary literature is recommended. Indications for clinical chemistry assessment in reptiles and amphibians are numerous and are similar to those of companion mammals (Table 34.1). However, based on numerous factors, including lack of baseline data, clinical chemistry data, and variable physiology of ectotherms, results may be less accurate and/or specific for diagnostic purposes compared with more domesticated species. Additionally, more specific diagnostic testing (serology, PCR, histopathology, culture, etc.) may be necessary to arrive at a definitive diagnosis. This chapter has two major sections: (1) sample collection, handling, and preservation and (2) laboratory tests/techniques and clinical interpretation. For more in-depth information on this material, a review of the primary literature and veterinary clinical pathology texts is recommended.[1]

VENIPUNCTURE

Choice of materials for blood collection from reptiles and amphibians is dependent on a number of factors, including species, patient size/weight, anatomy, temperament, sample desired, sample collection conditions, equipment availability, and practitioner skill. A sample collection plan should be determined and materials prepared beforehand. Sedation or anesthesia for routine diagnostic sampling is seldom necessary in companion reptile species but may be necessary for larger or potentially dangerous species. Operant conditioning for voluntary blood draws has been performed in reptiles.[2] Cleaning and disinfecting of the venipuncture site is recommended, and small brushes (such as a toothbrush or surgical scrub brush) may be required in cases of thick or heavily keeled scalation. Application of alcohol alone to the intended sampling site often provides little benefit, as contact time necessary for disinfection is seldom achieved, and the keratinized skin of reptiles does not usually allow better visualization of vessels. Alcohol is contraindicated for use in amphibians. An overview of sample site options preferred to provide the volume and sample integrity necessary for biochemical and hematological analysis is provided in Chapter 33. However, additional sites may prove acceptable for sampling volumes for genetic and other analyses as sample requirements become smaller, and less reliant on cellular integrity.[3] The clinician and biologist are advised to choose the least invasive sample and sample collection techniques that still provide adequately viable results.

For most animals, 21- to 26-gauge needles and 1 to 3 mL syringes are sufficient. However, sampling of large reptiles may require longer or larger-gauge (3–6 cm, 1.5–2 inch) needles. Butterfly administration sets may also be useful when the sample size is sufficient to lose the 0.05 mL that may coat the tubing. Use of syringes or needles precoated with heparin or other anticoagulant is unnecessary and avoidance precludes dilutional and cellular staining artifacts. Acceptable blood collection tubes include microtainer, pediatric, or larger sizes based on desired sample volume. The low blood pressure, slow heart rate, and large but relatively osmotically robust nature of the herpetological erythrocyte supports the preference of a larger-gauge needle and smaller syringe than one might choose for similarly sized birds or mammals.[4–6] This syringe–needle combination allows blood to flow slowly into the smaller syringe while minimizing aspiration pressure to preserve cell integrity.

GROSS PLASMA EVALUATION

Plasma is generally the sample of choice for determination of biochemistry profiles. Factors for this choice include the lower harvest expected from serum and the (variable and prolonged) time for complete clot formation, which may result in serum analyte changes, associated with increased clot contact time.[7,8] However, in some cases lymph may be an acceptable sample for select biochemistries and may be particularly suitable for serological or PCR-based assays (Table 34.2). Gross color, opacity/ transparency, and turbidity should be subjectively evaluated and recorded for plasma samples to facilitate quality control and as a diagnostic assessment. Amphibian plasma may be clear to yellow or even blue, as in the case of the Japanese giant salamander (*Andrias japonicas*) and the white-lipped tree frog (*Litoria infrafrenata*).[1] Common abnormalities of plasma that deserve attention consideration include lipemia, biliverdinemia, lymphatic or cerebrospinal fluid dilution, and hemolysis. Green plasma in reptiles and amphibians has been associated with biliverdinemia, which may be associated with active hemic or hepatic disease. However, in some lizard species, biliverdinemia is physiologically normal (Figure 34.1).[8a] Interference and other effects of many of these gross abnormalities upon analytes are often inferred from other species and have yet to be adequately investigated for many reptiles and amphibians. The effect of biliverdinemia upon analytes in reptilian and amphibian blood remains uninvestigated.

Lipemia

The expected gross plasma findings for lipemia are a white opaque milky layer that may float to the top of the sample (Figs. 34.2 and 34.3). The most common physiologic causes of lipemic plasma in reptiles are lack of adequate fasting before sample collection or reproductive activity.[9] In other species, measurements of many metabolite activities (including alanine aminotransferase [ALT], aspartate aminotransferase [AST], and glucose) and most electrolyte concentrations are known to be falsely decreased by lipemia.[10] Analyte differences caused by lipemia may also

VetBooks.ir

vary based on the analyzer.[10] In most cases, lipemia can be removed and measurement can be done from a "cleared" sample without interferences based on ultracentrifugation at the reference laboratory or extraction with nonpolar solvents or polymer binding for precipitation. However, polymer-binding treatment (Lipoclear) may also result in low recovery of cardiac troponins, gamma-glutamyl transferase (GGT), and some isoforms of creatine kinase (CK).[10]

Lymphatic and Cerebrospinal Fluid Dilution

Lymphatic dilution may occur from any venipuncture site in reptiles, whereas cerebrospinal fluid (CSF) contamination is more likely from blood collection sites close to the vertebral column (e.g., subcarapacial, supravertebral, coccygeal), and pericardial fluid may contaminate cardiocentesis samples. Blood dilution seems least likely when sampling from the jugular vein, followed by the heart.[11] Lymphatic or CSF dilution is recognized by a rapid filling of the syringe with clear to lightly transparent yellow-colored fluid, often followed by blood. The appearance of lymphatic dilution in plasma may be difficult to detect grossly, but a lighter color than that encountered in pure plasma would be expected. In the case of cardiocentesis, clear fluid obtained should be differentiated from pericardial fluid. In humans, expected cell count, glucose and protein concentrations, and LDH activities of pericardial fluid are known. However, for amphibians and reptiles, these values have yet to be

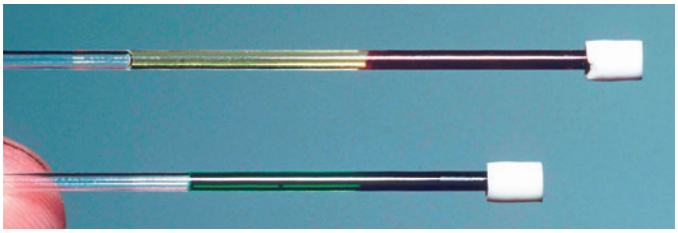

FIG 34.1 Green plasma from a skink (*Prasinohaema*). Biliverdinemia is normal for this species. (Courtesy of Christopher C. Austin.)

FIG 34.2 Lipemic plasma from a leatherback sea turtle (*Dermochelys coriacea*). Note the use of the green top lithium heparin tube (Becton, Dickinson and Company, Franklin Lakes, NJ) as the most appropriate anticoagulant for this species. (Courtesy of Charles J. Innis.)

TABLE 34.1 Indications for Clinicopathologic Assessment of Reptiles

General health assessment	Entry or exit from collection, baseline determination, presurgical assessment, pre- or posthibernation assessment
Diagnosis	Clinical suspicion of organ dysfunction or abnormal fluid accumulation
Therapeutic assessment	Assessment of treatment plan for renal, liver, or other organ dysfunction, chemotherapy, other chronic diseases, response to treatment
Prognosis	Assessment of seriousness or etiology of organ dysfunction or fluid accumulation

TABLE 34.2 Impactful Studies for Anticoagulant Choice in Reptiles Based on Biochemical Changes

Anticoagulant	Species	Parameter Changes
EDTA Lithium heparin	Burmese python (*Python bivitattus*)	Glucose concentration decreased; potassium concentration increased over time in heparinized blood samples[34]
Citrate- phosphate-dextrose-adenine (CPDA-1), acid-citrate-dextrose (ACD)	American alligator (*Alligator mississippiensis*)	Comparable, blood may be stored up to 35 days based on blood culture, blood gas analysis, methemoglobin, osmotic fragility[154]
Lithium heparin	Hermann's tortoises (*Testudo hermanni*), spur-thighed tortoises (*Testudo graeca*), and Horsfield tortoises (*Agrionemys horsfieldii*)	Ionized Ca: no significant differences between heparinized plasma samples stored for 48 hr at 5°C (23°F) and fresh heparinized whole blood. Sodium and potassium: significantly lower sodium and higher potassium in the stored heparinized whole blood compared to the fresh heparinized whole blood.[139]
Sodium heparin, sodium citrate, and citrate-phosphate-dextrose-adenine (CPDA-1).	Loggerhead sea turtle (*Caretta caretta*)	No change in total solids (TS) over 24 hours Electrolytes, glucose, and venous blood gas analytes all change over time[31]

VetBooks.ir

FIG 34.3 Lipemic plasma from a bearded dragon (*Pogona vitticeps*). Note the use of the lithium heparin tube, which is orange in the EU (Sarstedt AG & Co. KG, Nümbrecht, Germany) (Courtesy of Lionel Schilliger.)

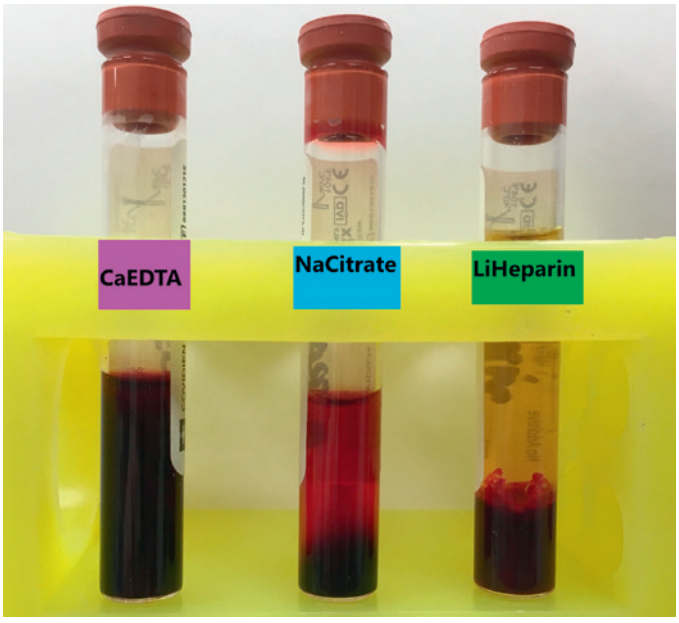

FIG 34.4 Plasma and packed cells from placement of chelonian blood (*Gopherus berlandieri*) in EDTA (hemolyzed), lithium heparin, and sodium citrate.

investigated. Both venipuncture site and lymphatic/CSF contamination may affect analytes results in reptiles.[12] Unfortunately the effects of lymphatic/CSF contamination, venipuncture site comparisons, and their associated effects on biochemistry analytes have been studied in only a few reptilian species. Rather than discarding lymphatic samples the authors recommend they be considered for serology or PCR. Select analytes of lymph that are similar to plasma chemistries obtained from blood are presented in Table 34.3.

Hemolysis

Hemolysis may impart an orange, red, or pink hue to plasma. The specific effects of hemolysis upon biochemical constituents of reptilian and amphibian blood remain minimally investigated. Because the internal biochemical constituents of the erythrocytes of many of these species are also unknown, expected effects of hemolysis also remain obscure. In samples from iguanas (*Iguana iguana*) and red-eared sliders (*Trachemys scripta* elegans), the samples with hemolysis had altered protein electrophoretic profiles, which may reflect species differences in hemoglobin structure.[13] In the green iguana, hemolysis did not affect concentrations of sodium, calcium, uric acid, or CK but did increase potassium, phosphorus, total protein, albumin, and aspartate aminotransferase.[14]

ANTICOAGULANTS, PRESERVATION, AND VENIPUNCTURE SITES

Anticoagulants

Choice of anticoagulant and blood collection equipment is based on similar factors as detailed in Chapter 33 and above under venipuncture, but species, sample collection conditions, availability, and sample use are also primary concerns. All anticoagulants can damage cell architecture and affect biochemical parameters. An overview of current knowledge regarding anticoagulant choice for biochemistry in reptiles is provided in Table 34.2. Microtainer, plastic tubes coated with freeze-dried anticoagulant, are preferred to avoid sample dilution and allow small volume collection. Hematocrit tubes may be used for blood collection from very small species, but the authors find that sample recovery (when compared with microtainer tubes) is less effective as well as challenging without specialized sample expulsion bulbs. Appropriate anticoagulants for use with cerebrospinal, joint, or coelomic fluids have not been investigated for amphibians or reptiles. However, based on extant literature review, anticoagulation may be unnecessary for these fluids and red-top tubes, without additive, may be suitable.[15–24] For biochemical determinations, plasma, rather than serum, remains the sample of choice based on prolonged or unpredictable clotting times.

Lithium heparin is the most commonly used anticoagulant, may be accompanied by plasma separator gel, and appears less likely to cause hemolysis of reptile blood, particularly in chelonians (Figure 34.4). However, investigation of other anticoagulants with reptile blood remains minimally studied.[25–28] Blood collection into heparin also yields more heparinized plasma than the volume of serum from clotting of whole blood.[29]

Heparin-gel separator tubes are convenient and facilitate plasma separation from cells. However, gel may only prevent migration of some analytes (notably potassium, phosphate, and glucose) between plasma and cells for only a few hours.[30] Further, inadequate centrifugation may result in a cell layer remaining on top of the gel, which could cause further change in the resultant concentration of some plasma analytes with this method of storage.[30] Lastly, many instrument companies discourage use of tubes with separator gels because the gel can affect tubing and other instrument parts, causing malfunction.

A recent comparison of total solids (TS), electrolytes, glucose, and venous blood gas analytes over a 24 hr storage from 8 loggerhead sea turtles (*Caretta caretta*) was performed for the anticoagulants sodium heparin, sodium citrate, and citrate-phosphate-dextrose-adenine (CPDA-1) with whole blood.[31] Blood was stored at 4°C to 8°C (39°F–46°F) for up to 24 hours before analysis. Total solids, evaluated at 0, 3, 6, 12, and 24 hours, did not change significantly, independent of the anticoagulant chosen. However, pink plasma was observed in 62.5%

TABLE 34.3 Effects of Venipuncture Site (VS) and Lymphatic Contamination (LC)* Upon Reptile Biochemical Analytes[12]

Species	Sampling Sites	Differences Found in Samples with Lymphatic Contamination (LC) or Site Based (VS)
Gopherus agasizzi[155]	Jugular, occipital plexus	For samples obtained from the occipital sinus, most values were relatively lower: Glu, K, UA, Ca, P, TP, Alb, Glob, ALP, AST, ALT, and total Chol. Cl was relatively increased
Chelonia mydas[156]	Jugular, coccycgeal, subcarapacial	Analytes of clear fluid obtained from the jugular vein area were similar to values of blood plasma for the same species based on biochemical analysis
Testudo marginata[157]	Coccygeal, brachial	TP, UA, AST, ALT, LDH, ALKP, Ca, and P greater in brachial vein samples than from coccygeal vein samples
Graptemys geographica[158]	Coccygeal, subcarapacial	Visual hemodilution noted in 16% of coccygeal samples and 75% of subcarapacial samples
Apalone spinifera[159]	Coccygeal, subcarapacial	Glu and K concentrations increased in samples from the subcarapacial vein
Trachemys scripta[160]	Coccygeal, occipital	Total protein lower in samples from the dorsal coccygeal vein
Dermochelys coriacea[161]	Occipital, interdigital	Values for Alb, Ca, Glob, Glu, P, K, Na, TP, TS, and UA from each site comparable; AST and CK activities higher in samples obtained from cervical sinus
Centrochelys sulcata[37]	Coccygeal, subcarapacial	Total solids, TP, P, and Glob had increased concentrations in samples from the coccygeal versus the subcarapacial
Chameleo chameleon[162]	Jugular, tail	No difference in TP, UA; jugular venipuncture preferred based on likelihood of obtaining sample and darkening of the tail
Hydrophis spp.[36]	Tail	Observed lymph contamination; increased Na, decreased TS, Alb, ALP, Ca, Chol, Glob, and protein
Mauremys leprosa[12]	Jugular, subcarapacial, coccygeal	Subcarapacial samples had lower Alb, TP, Glu, Chol, Trig, UA, BUN, Ca, P, iron, and ALP than those of jugular blood; corticosterone, Alb, TP, Glu, Chol, Trig, UA, Ca, P, ALP higher in samples from more cranial sites than those from caudal sites
Trachemys scripta elegans[163] N = 36	Multiple	Blood-lymph mixtures had lower concentrations of TP and K but values for Glu, BUN, Ca, P, ALP, CK, LDH, AST, and Na were comparable; although not significantly different, chloride concentrations of blood-lymph samples were lower than in pure plasma
Centrochelys sulcata[37] N = 60	Dorsal coccygeal (tail), subcarapacial v.p., based on body size	TS, TP, P, Glob were higher values in samples from the tail versus the subcarapacial sampling site; reading of Glob failed in over 50% of samples from the subcarapacial site

*When sampling close to the spinal cord (e.g., subcarapacial, coccygeal), cerebrospinal fluid contamination is likely and may be confused with lymphatic contamination.

Alb, Albumin; *ALT,* alanine transaminase; *ALP,* alkaline phosphatase; *AMS,* amylase; *AST,* aspartate transaminase; *BA,* bile acids; *BUN,* blood urea nitrogen; *Ca,* calcium/total calcium; *Chol,* cholesterol; *CK,* creatine kinase; *Cl,* chloride; *Cort,* corticosterone; *Fib,* fibrinogen; *GGT,* glutamyltransferase; *Glob,* globulin; *Glu,* glucose; *GMD,* glutamate dehydrogenase; *HDL,* high-density lipoproteins; *iCa,* ionized calcium; *K,* potassium; *Lact,* lactate; *LDH,* lactate dehydrogenase; *LDL,* low-density lipoproteins; *Lip,* lipase; *Mg,* magnesium; *Na,* sodium; NH_3, ammonia; *OSM,* osmolality; *P,* phosphorus; *SDH,* sorbitol dehydrogenase; *Trig,* triglycerides; *TP,* total protein; *TS,* total solids; *UA,* uric acid; *VLDL,* very low–density lipoproteins;

(5/8) of CPDA-1 and 12.5% (1/8) of citrate specimens at 24 hours. Specimens in CPDA-1 and citrate had increased potassium concentrations at 24 hours. Specimens stored in heparin and citrate had relatively decreased pH and increased P_{CO_2} at 24 hours postcollection. Sodium values decreased over time in citrate and CPDA-1 specimens. Thus in these sea turtles as in many other chelonian species, based on the assay of multiple biochemical constituents and short-term storage, heparin remains the preferred anticoagulant.

Sample Preservation

Few studies have focused on acceptable storage methodologies for reptilian blood or bodily fluid samples. Thus testing within 24 hours of sample collection is recommended for most analytes, and the sooner a sample can be analyzed, the better. Plasma should be separated immediately after centrifugation and kept refrigerated or frozen until processed or shipped to a diagnostic laboratory. [1] Proteins, enzymes and electrolytes are the most sensitive biochemical analytes, and the most likely to be affected by storage.[32]

For chelonia, studies of the effect of time on plasma analytes are limited to those of tortoises and sea turtles. In heparinized blood samples from loggerhead sea turtles (*Caretta caretta*), plasma in contact with cells and refrigerated for up to 96 hours had relatively few biochemical changes. Minimal hemolysis occurred by 24 hours, but moderate hemolysis was present at 48 and 96 hours. Of the 17 analytes measured (alkaline phosphatase [ALP], AST, GGT, CK, sodium, chloride, potassium, magnesium, calcium, phosphorus, cholesterol, glucose, blood urea nitrogen [BUN], uric acid, total protein, albumin, and calculated globulin) no significant changes (compared with time 0) were detected at 4 hours postcollection for any analyte. At 24 hours postcollection, only GGT had a significant difference in mean activity compared with activity at 0 hours. This decrease persisted throughout the time period of the study. At 24 to 96 hours of storage, glucose concentrations and GGT activities were decreased compared with fresh samples. At 96 hours, AST increased by 2%, GGT decreased by 25%, glucose increased by 7%, and uric acid increased by 25%. Storage also affected phosphorous and cholesterol.[32] In Aldabra tortoises (*Aldabrachelys gigantea*) storage time and temperature (4°C and 25°C) did not affect potassium concentrations, but decreases in sodium concentration occurred over time regardless of storage temperature.[8] In Burmese mountain tortoises (*Manouria emys*) potassium concentrations increased over time, although increases were less at 4°C than at 25°C and sodium concentrations decreased over time at both temperatures.[8]

VetBooks.ir

For squamates, studies on the effect of time upon plasma biochemical analytes is limited to a single lizard and large constricting snake species. In the green iguana, hemolysis did not affect concentrations of sodium, calcium, uric acid, or CK but did increase potassium, phosphorus, total protein, albumin, and aspartate aminotransferase.[14] Blood samples of free-living anacondas (*Eunectes murinus*) processed after cold storage for 1 to 2 days had relatively decreased concentrations of glucose, total CO_2, total bilirubin, and iron, and increased concentrations of lactate and lactate dehydrogenase activities compared with samples processed within 12 hrs of collection.[33] Blood samples from Burmese pythons (*Python bivittatus*) were collected into heparin-coated syringes and transferred to containers with the anticoagulants lithium heparin, K3-EDTA, or sodium citrate and/ or bovine serum albumin. These samples were evaluated for biochemical and cellular changes based on time and anticoagulant.[46] Samples anticoagulated with lithium heparin and refrigerated at 4°C for up to 24 hours had potassium concentrations that increased and glucose concentrations that decreased over time compared with those anticoagulated with K3-EDTA.[34]

Protein analytes may also be affected by sample storage. Protein electrophoresis of samples from loggerhead sea turtles showed that storage temperature and duration affected albumin, β-globulin, and A/G ratio but not total protein concentrations. Albumin percentage was decreased with 2 and 7 days of storage +4°C or −20°C whereas β-globulins were increased after 2 days at −20°C and after 7 days at both storage temperatures, which resulted in a reduced AG ratio. Thus for plasma protein determination, plasma should not be refrigerated for >48 hrs before analysis.[35] Comparison of samples obtained from healthy sea snakes (*Hydrophis* spp.) for protein with standard methods versus reconstitution from freeze-dried samples resulted in lower values (~10 g/L or 1.0 g/dL less) for frozen samples, suggesting this method of storage is unsatisfactory.[36]

Venipuncture Sites

Choice of the best sample site depends on many factors, including vascular anatomy, patient temperament, and practitioner skill. An overview of multiple options for vascular access based on taxa is provided in Table 33.5. However, other sites may be appropriate and preferred based on practitioner experience and knowledge. Sample site alone or in conjunction with lymphatic or CSF dilution may affect multiple hematologic, biochemical, metabolite, and enzyme parameters (see Tables 33.2 and 34.3).[12] Clinically and for experimental purposes one should always document the venipuncture site used for each sample obtained. Further, for serial sampling, when possible, the same sample site should be used to facilitate analyte comparison and health evaluation. Samples obtained from more craniad sites may be more valid for interpretation of health or experimental outcomes in some reptiles.[12,37]

BLOOD CHEMISTRY

Review of commonly available plasma biochemical panels available to private practitioners reveals a diversity of analytes, some of which may or may not be appropriate for diagnostic use (Table 34.4). The lack of other apparently useful analytes, based upon literature review, is also notable. Significant interspecies variation in many analytes occurs. Blood biochemistry can be affected by seasonal variation and by disease. In a comprehensive study of the Hermann's tortoise (*Testudo hermanni*) no less than 13 parameters showed distinct seasonal variation.[38] For amphibians, a recent review of amphibian clinical pathology perfectly summarized our current understanding and interpretation of enzymes for use in these species: "Almost nothing is known of the diagnostic significance of hepatic, pancreatic, muscular, or cardiac enzymes in amphibian blood."[1]

As we progress in the age of data, we will likely continue to discover appropriate enzymes and biochemical combinations to allow better discrimination of health (including life stage and seasonal changes) and disease (Table 34.5). For example, a recent study of captive Balkan whip snakes (*Hierophis gemonensis*) reviewed biochemical parameters during different periods of the biological cycle, including pre- and posthibernation, hibernation, sexual activity, and normal activity. Use of values for urea, glucose, and LDH simultaneously could discriminate between the various physiological conditions during the biological cycle for this species. Thus these parameters may also be useful in clinical assessment of snakes.

Enzyme Activities

Choice and clinical interpretation of enzyme activities remains minimally studied in reptiles, in comparison to companion mammals such as dogs and cats. Most commonly used or recommended analytes were designed for humans, with assays run at 37°C. Studies of analytes determined by in-house analyzers with those of reference labs show that values obtained are seldom directly comparable.[39] Most of these assays have not been validated for reptiles or amphibians. Practitioners are encouraged to compare clinicopathologic results with anatomical pathology and report their findings to improve our knowledge base. Foundational studies of tissue enzyme activities in reptiles are summarized in Table 34.6. To our knowledge, half-lives of commonly used enzymes for reptiles have not been determined. The assumption that half-lives of reptile enzymes are similar or even relative to those of mammals or humans should be viewed with circumspection.

Creatine kinase or phosphokinase (CK or CPK) and AST are commonly evaluated and generally attributed to muscle injury (skeletal myocytes, cardiac myocytes, smooth muscle myocytes), but significant CK activity also occurs in the brain (~10% that of skeletal muscle).[40–47]

TABLE 34.4 Commercially Available Plasma Biochemical Panels for Use in Reptile Species

Laboratory	Specific Panel or Rotor	Analytes Available
Abaxis VS2 (in house)	Rotor: Avian /Reptilian Profile Plus	Alb, AST, BA, Ca, CK, Glob, K, Na, P, TP, UA
Comparative Path Laboratory Miami	Advanced Reptile Chemistry Panel	ALP, AMS, anion gap, AST, BUN, CK, Ca, Chol, Cl, CO_2, GGT, Glu, K, Lip, Mg, Na, osmolality, P, TP, Trig, UA
IDEXX Reference laboratories	Reptile Profile 5	Alb, AST, BUN, Ca, Cl, Chol, CK, Glu, P, K, Na, Trig, TP, UA
IDEXX Reference laboratories	Reptile Profile 2 with Bile Acids	Alb, AST, BUN, Ca, CK, Glu, LDH, P, TP, BUN, UA, BA
Avian & Exotic Clin Path Lab	Complete reptile	TP, AST, total bilirubin, UA, glucose, CK, Ca, P

TABLE 34.5 Recommended Biochemical Analytes for Health Assessment of Major Groups of Reptiles and Amphibians*

Class	Enzymes	Ions, Glucose, Blood Gases	Proteins, Lipids	Other
Squamates *Lizard*	CK, AMS, LDH, AST, SDH, LDH	Glu, Na, K, Cl, Ca, iCa, P, OSM	Chol (HDL, LDL, VLDL) Trig, Alb,* Glob, TP	BA, UA
Squamates *Snake*	LDH, AST, ALT, CK	Glu, Na, K, Cl, Ca, iCa, P, OSM	Alb,* Glob, TP	UA
Terrestrial chelonian *Tortoises*	AST, CK, ALT, ALP	Glu, Na, K, Cl, Ca, iCa, P, OSM	Alb,* Glob, TP Fib	BA, BUN, UA
Aquatic chelonian *Sea turtle*	AST, CK, LDH, AMS, Lip, ALP, ALT, ALP, GGT	pH, Po_2, Pco_2, Lact, Glu, Na, K, Cl, Ca, iCa, P, OSM	Alb,* Glob, TP, Fib	BA, BUN, UA, NH_3 (creatinine)
Crocodilian	CK, LDH, ALT, AST	Na, K, Ca, iCa, P, Mg, Cl, OSM	Chol (HDL, LDL, VLDL) Trig, Alb,* Glob, TP, Fib	UA, NH_3
Amphibian	CK, LDH, ALT, AST, GGT, ALP, Lip	Glu, glycerol Na, K, Cl, pH, iCa, Ca, P, OSM	Chol (HDL, LDL, VLDL) Trig, Alb,* Glob, TP, Fib	Aquatic, NH_3; adult terrestrial, BUN; some tree frogs, UA

*Albumin measurements are often inaccurate by bromocresol green methods; protein electrophoresis is preferred.
For a full list of abbreviations, see Table 34.3.

TABLE 34.6 Foundational Studies of Reptile and Amphibian Tissue and Plasma Enzymes[42-47]

Species	Tissues Examined	Enzymes Examined	Useful Enzyme Activities	Useless Enzymes
Green iguana (*Iguana iguana*)	Liver, kidney, epaxial muscle, heart, lung, spleen, small intestine, pancreas from 6 juveniles	ALP, LDH, AST, ALT, GGT, CK, GMD, AMS	High CK confined to epaxial muscle, heart. AMS activity confined to pancreas. Moderate LDH and AST activities in all tissues. Low ALT and ALP activities in many tissues.	Plasma, tissue activities of GGT, GMD low to undetected.
Loggerhead sea turtle (*Caretta caretta*)	30 tissues of 5 stranded turtles	AMS, Lip, CK, GGT, ALP, LDH, AST, ALT	High CK activity confined to epaxial and heart muscle. AMS activity confined to pancreas. Moderate LDH and AST activities in all tissues. Low ALT and ALP activities in many tissues.	Plasma, tissue activities of GGT, GMD low to undetected
Yellow rat snake (*Pantherophis obsoleta quadrivitatta*)	Liver, kidney, skeletal muscle, heart, intestine, lung, pancreas, free-living snakes	ALP, LD, AST, ALT, GGT, CK	Major enzyme activities of liver were LD and AST. Kidney had moderate activities of LDH, AST, ALT, and CK. Skeletal muscle and heart had high CK activity. Intestine, lung, and pancreas had low activities for most enzymes. Serum enzyme activities of CK were increased in rat snakes compared with other reptiles.	Little to no GGT in serum or tissues
Kemp's ridley turtles (*Lepidochelys kempii*)	Liver, kidney, skeletal muscle, cardiac muscle, pancreas, lung, small intestine, and spleen from 13 juvenile strandings	ALT, ALP, AST, CK, GGT, LDH, lipase	AST, CK, and LDH highest in cardiac and skeletal muscle but found in all other tissues. AMS and Lip highest in the pancreas, low in other tissues. ALP highest in lung. ALT highest in liver, kidney, and cardiac muscle. GGT highest in kidney.	ALT, GGT low in all tissues
Cuban tree frogs (*Osteopilus septentrionalis*)	Liver, cardiac muscle, lung, kidney, skeletal muscle, gonad, and pancreas	Amylase, lipase, ALP, ALT, AST, LDH, CK, GGT	CK, LDH mainly from skeletal and cardiac muscles; ALT mainly from kidney and liver; AST mainly from liver, kidney, and skeletal and cardiac muscles; GGT mainly from kidney; ALP mainly from kidney and cardiac muscle; Lip mainly from liver.	AMS highest in the plasma, lacked other tissue specificity
American alligator (*Alligator mississippiensis*)	Liver, cardiac muscle, lung, kidney, skeletal muscle, and mid–small intestine	ALP, ALT, AST, LDH, CK, GGT	CK and LDH mainly in skeletal and cardiac muscle; ALT mainly in kidney and skeletal muscle tissue; AST mainly in liver and skeletal muscle.	GGT, ALP of little diagnostic value in sampled tissues

For a full list of abbreviations, see Table 34.3.

VetBooks.ir

In comparison, increased AST may derive in large quantities from muscle, liver, or other tissues. Although plasma CK activities may increase based on capture stress of reptiles,[48] intramuscular injections have yet to be documented to increase CK activities in reptiles and amphibians. Increased AST in the absence of increased CK is often considered indicative of liver damage but could be based on other tissue damage as well (as this enzyme is fairly widespread in body tissues, despite relatively high concentrations occurring in the liver). Loggerhead sea turtles suffering illness may have relatively increased AST and decreased ALT (alanine aminotransferase) plasma activities. However, in another study of the same species, AST activity was lower in turtles with serious illness compared with those in good health.[49] This finding may serve as an example of end-stage disease wherein a lack of hepatocytes result in relatively "normal" liver enzyme activities. Rat snakes (*Patherophis obsoleta*) appear to have relatively high CK plasma activities whereas the yellow-marginated box turtle (*Cuora flavomarginata*) has lower ALT activities compared with other chelonians.[41,50] Additionally, in juvenile alligators (*Alligator mississippiensis*) body condition index, AST, and CK were correlated.[51] Of interest, a study of 43 wild-caught southwest carpet pythons (*Morelia spilota imbricate*) failed to reveal any effects of intrinsic or extrinsic factors (season, locale, sex, presence of hemoparasites, surgical transmitter replacement, or anesthetic state) upon CK or AST plasma activities.[52] These findings suggest that although CK and AST may be more specific to serious disease processes than physiological changes, they may also be less sensitive for detection of organ disease in this species. Based on a few extant studies in reptiles, GGT and glutamate dehydrogenase (GLDH, GDH) are less useful diagnostically based on their pan organ distribution, low analyte activities, and/or lack of detection in the tissues assayed.[42,43,45–47]

Enzyme activity interpretation for health assessment of reptiles may be further complicated by changes based on season, sex, age class, and species, as well as inadequate reference ranges. In alligators, LDH activities of muscle were greater in winter compared with summer, and although mitochondrial enzyme activity was relatively increased in males, LDH activity did not differ between sexes.[53,54] In plasma of male Herman's tortoises, ALT, bile acids, LDH and GLDH, and in both sexes ALP were relatively increased by midsummer. Similar seasonal variations occur in both captive and free-living reptile species.[55–57] In apparently healthy adult hawksbill turtles (*Eretmochelys imbricate*), ALP, AST, bilirubin, LDH, CK, and amylase were increased and ALT was decreased during nesting compared with the foraging season, which the authors attributed to reproductive output.[58] In male radiated tortoises (*Astrochelys radiata*), LDH activity was decreased during winter; LDH and CK activities similarly increased in summer, compared with females.[59] Feeding and activity may also affect multiple analytes. In 2-hour postprandial green sea turtles (*Chelonia mydas*), but not Kemp's ridley turtles (*Lepidochelys kempii*), plasma activities of ALP, AST, ALT, and amylase were significantly increased.[9] In captive mugger crocodiles (*Crocodylus palustris*), the effect of age was studied. Subadults had lower mean ALP activities than juveniles, but adults had the lowest AST and ALT activities. Subadult LDH activities were lower than for juveniles and adults.[60] In the yellow-marginated box turtle, marked seasonal variations of ALP, AST, and CK were attributed to the gender, reproduction, and seasonal temperature changes.[50] Additionally, in summer, captive female panther chameleons (*Furcifer pardalis*) have increased ALT and AST compared with winter.[61] In summer, gravid females had increased ALT activity whereas males had higher CK activities in winter.[61] Experimentally induced toxic hepatopathy in green iguanas has demonstrated ×40 increases in AST, ×4 increases in ALT, ×15 increases in sobital dehydrogenase (SDH), and 100× increases in LDH (Schnellbacher et al, Proc ARAV, 2014, pp 127–128).

Biliverdin and Bilirubin

Heme pigment metabolism in reptiles and amphibians remains poorly understood. In some species (green lizard, *Lacerta viridis*, and common frog, *Rana temporaria*) bilirubin is not produced in appreciable amounts due to the lack of the biliverdin reductase and bilirubin conjugation enzyme (uridyl diphosphate glucuronyltransferase, UDPG).[62] Therefore unconjugated biliverdin is the main product excreted in the bile of these species. Bilirubin does occur in the bile of alligators (*Alligator mississipiensis*) but not in eastern racers (*Coluber constrictor*).[63] Some reptiles, such as the indigo snake (*Drymarchon corais*), anaconda (*Eunectes*), and green iguana (and likely other squamates), have significant plasma bilirubin and may therefore develop hyperbilirubinemia (jaundice or icterus).[33,64] Activity of UDPG is less in some snakes than in mammals. The indigo snake serves as a model of hyperbilirubinemia, having 10 times more unconjugated plasma bilirubin than other snake species.[65] Therefore we know that for this species, hepatic uptake of injected bilirubin is relatively slow (compared with mammals) and that plasma clearance of bilirubin and sulfobromophthalien in indigo snakes is slower than in rat snakes. In the anaconda, blood samples processed within 12 hours of collection had higher total bilirubin levels than samples processed after cold storage (on ice in a cooler or refrigerated) for 1 to 2 days, suggesting that this analyte is best measured in snakes within <12 hours of sampling.[33] In amphibians, bilirubin may be present in appreciable quantities, but this analyte's diagnostic value remains unproven.

Biliverdin is present in the green plasma of skinks (*Prasinohaema*), some arboreal snakes, monitor lizards (*Varanus*), and the Cambodian frog (*Chiromantis samkosensis*).[66] Biliverdinemia may represent an ecological or physiological adaptation. Green blood that imparts a green body color occurs nearly exclusively in species inhabiting green vegetation, and accumulation of biliverdin might also deter *Plasmodium* spp. hemoparasitism.[67,68] Despite the short half-life of biliverdin, as the end product of heme synthesis in reptiles and other lower vertebrates, the lack of a commercially available biliverdin assay continues to confound diagnosis of liver disease in these species. Interestingly, an assay of total bile pigments (to include biliverdin) was reported in 1966, and multiple assays for biliverdin have been developed, including a more recent high throughput assay via infrared fluorescence.[66,69,70]

Bile Acids

Bile acids (3α-hydroxy bile acids) have been scientifically evaluated for clinical use in relatively few reptile species (see Table 67.1).[71] Nonetheless they are commonly assayed and used as an indicator of hepatic dysfunction when fasted values are >60 µmol/L (>24.5 µg/mL) (see Chapter 67). Bile acids assess function whereas liver enzyme activities are associated with hepatocellular damage. As in other species, postprandial effects have been demonstrated and so obtaining both fasted and postprandial samples for bile acids are more diagnostically valuable. Bile acid stimulation procedures for use in reptiles are provided in Box 67.1. Bile acids of the Hermann's tortoise were increased midsummer.[38] Mean plasma bile acid concentration in plasma samples from healthy 24-hr fasted green iguanas was 15.89 ± 15.61 µmol/L (6.49 ± 6.38 µg/mL) and 48-hr fasted was 9.56 ± 8.52 µmol/L (3.91 ± 3.48 µg/mL). Bile acids increase in plasma of green iguanas with chronic liver diseases with the highest concentrations (>70 µmol/L; >28.6 µg/mL) present in patients suffering from liver cirrhosis, liver lipidosis, and liver neoplasms.[72–74] Plasma appears to be the preferred sample for determination of bile acids based on increased values obtained from serum samples.[7] The validity, sensitivity, and specificity of bile acids as a diagnostic for liver disease in some reptiles remains suspect as demonstrated by a recent case report of suspected hepatic encephalopathy in a boa (*Boa constrictor*) with a plasma bile acid concentration of less than 35 µmol/L (<14.3 µg/mL).[75]

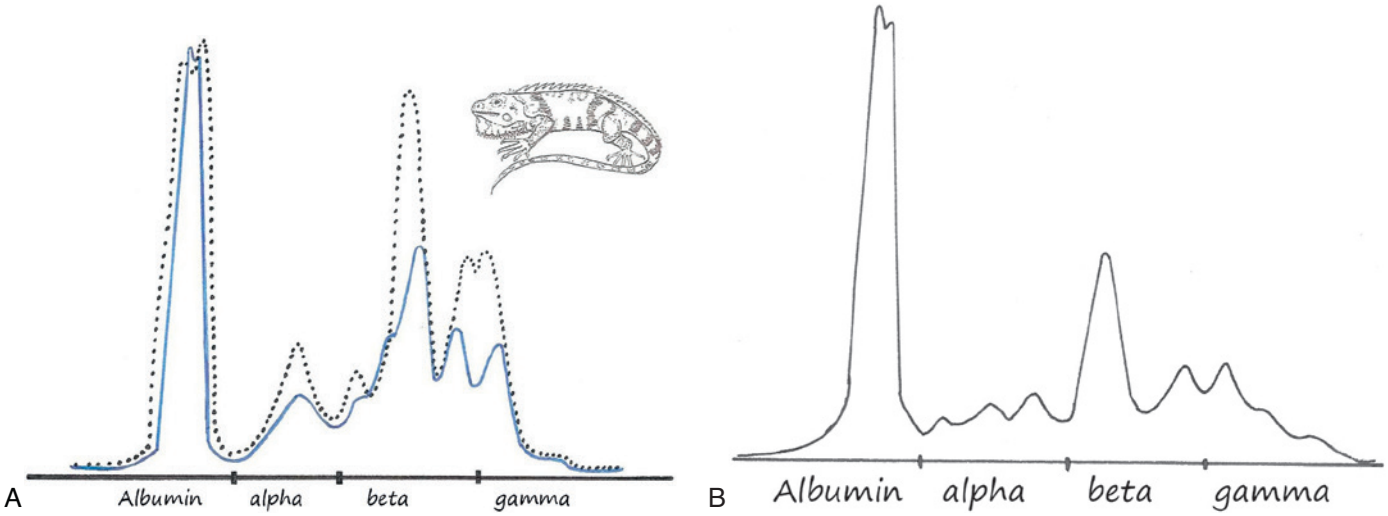

FIG 34.5 Diagrammatic representations of reptile electrophoretograms. Albumin, alpha-globulins (alpha), beta-globulins (beta), and gamma-globulins (gamma) are demarcated horizontally along the x axis. Overall, species, seasonal and protein charge, and size variation from that of mammals make accurate diagnostic interpretation of results from this assay challenging. (A) Agar gel electrophoretogram (AGE) of different iguanas *(Iguana iguana)*. Overlying diagrams show the wide acceptability of variation within healthy animals and bisalbuminemia (dotted line), which occurs in approximately 40% of healthy iguanas.[13,86] (B) Cellulose acetate electrophoretogram (CAE) of the same iguana in (A) (blue solid line), which demonstrates the lack of interchangeability of the two techniques.[13] (Redrawn from cited source by Sylvia Hester.)

Proteins and Acute Phase Reactants

Plasma and serum proteins are commonly evaluated in reptiles based on the myriad of systems in which they may reflect health and disease. Common causes of relatively increased total protein include dehydration and active reproductive processes (vitellogenesis) in females.[58,76] Plasma and serum proteins may change due to inflammation, hydration status, liver, kidney, and gastrointestinal function.

Proteins may also be affected by a variety of factors that are more specific to reptiles, including venipuncture site, gender and reproductive status, season, age, fasting or feeding status, sample type, and assay used (Figures 34.5 through 34.10).[55,77] Two distinct albumins occur in red-eared slider plasma and may also occur in other reptiles.[78] In healthy loggerhead sea turtles, albumin concentrations in juvenile and subadult turtles are lower compared with adults, and total protein concentrations are lower in subadults compared with adults.[49] Gravid females tend to have greater concentrations of albumin and therefore total protein.[50,61] Seasonal variation also occurs with increased total protein and albumin expected in the summer for some species.[50,61] In green sea turtles, albumin and consequently total protein were increased 2 hrs after feeding compared with a preprandial samples.[9]

The methods commonly used to determine plasma protein in reptiles, in order of increasing specificity/accuracy but also cost, include refractometry, dry or wet analyzers (dye binding/biuret), and electrophoresis.[79] Although protein electrophoresis is the gold standard for protein determination in reptiles, few studies have compared techniques, and comparison to other protein determination techniques have shown mixed results.[13,80–82] Comparisons between protein electrophoresis (EPH) and bromocresol green dye-binding (BCG) methods for determination of proteins indicated poor agreement between healthy and especially ill turtles of multiple species. Recent work at the University of Georgia has also demonstrated inaccuracies between albumin measurements by bromocresol green when compared with electrophoresis in the bearded dragon (*Pogona vitticeps*) (Comolli et al, Proc ICARE, 2017, pp 575–576).

Plasma EPH may also be the most appropriate assay to measure albumin and globulins in amphibians.[83] However, EPH of plasma rather than serum may yield heparin and/or fibrinogen bands or spikes. The validity of changes in amphibian proteins determined by EPH, such as acute phase proteins, reduced or increased albumin:globulin ratios, or monoclonal gammopathies, remains unknown.

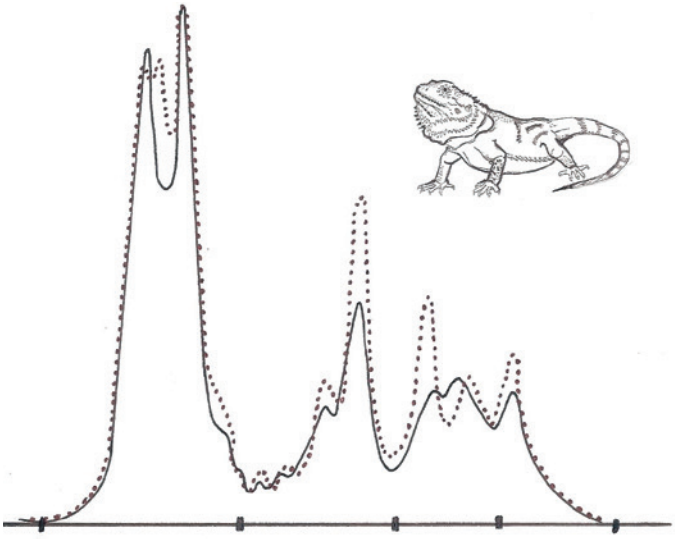

FIG 34.6 Diagrammatic representation of plasma electrophoretogram of two apparently healthy bearded dragons (*Pogona vitticeps*) that illustrates the inherent variability of this diagnostic assay, which may result in difficulty of interpretation or diagnosis of health or disease in reptiles.[168] (Redrawn from cited source by Sylvia Hester.)

Studies conflict regarding agreement of BCG and EPH methods in reptiles. For diseased Hermann's tortoises, protein values for BCG were increased compared with EPH.[79,84,85] Evaluation of protein electrophoretic profiles is further confounded because of inherent differences within commonly available EPH assays and the lack of comparability of results.[13] Electrophoretic protein patterns must be interpreted based on the method

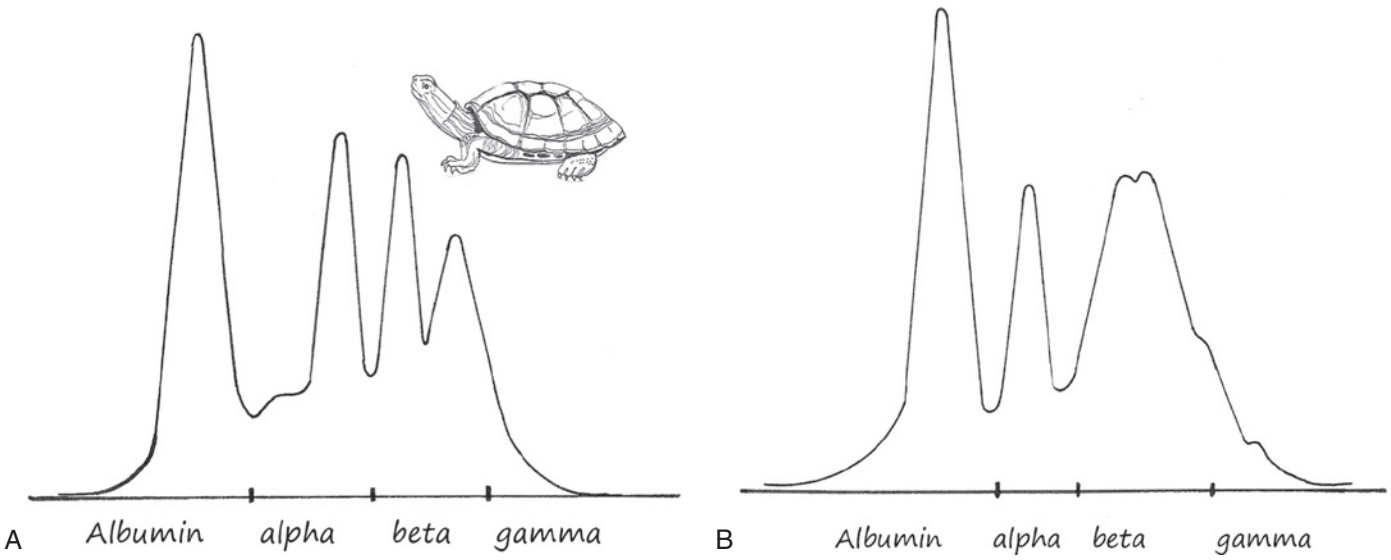

FIG 34.7 Diagrammatic representation of plasma electrophoretogram of a red-eared slider (*Trachemys scripta elegans*). The variability between the two methods: (A) Agarose gel (AGE) and (B) cellulose acetate (CAE) is illustrated.[13] (Redrawn from cited source by Sylvia Hester.)

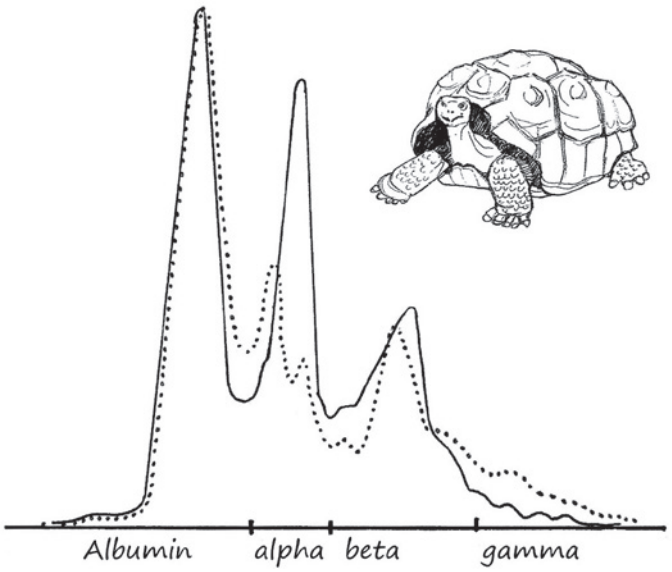

FIG 34.8 Diagrammatic representation of comparative seasonal plasma protein electrophoretogram of the Hermann's tortoise (*Testudo hermanni*) based on the agarose gel method. Summer (July) is denoted by the black line whereas fall (September) is shown via the dotted line.[84] (Redrawn from cited source by Sylvia Hester.)

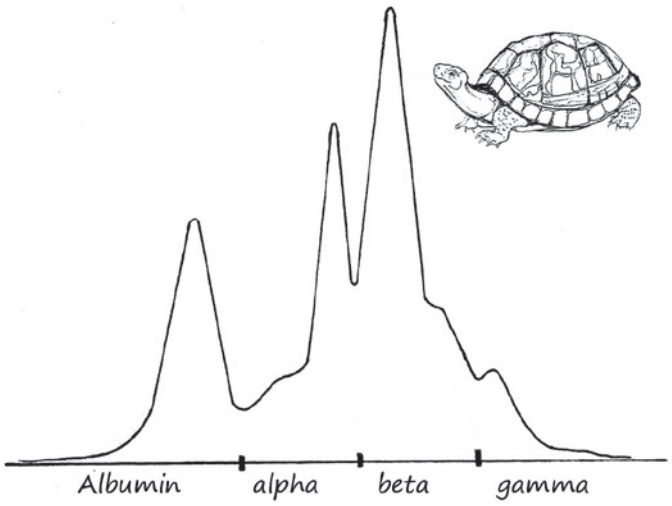

FIG 34.9 Diagrammatic representation of plasma electrophoretogram of an apparently healthy Eastern box turtle (*Terrapene carolina*).[82] (Redrawn from cited source by Sylvia Hester.)

used, the species analyzed, the sex and season, and the quality of the plasma sample, as each of these factors may affect the resultant pattern (see Figs. 34.5 through 34.9).[13,55,84,86] In box turtles (*Terrapene carolina*), EPH fractions were affected by variables such as age, sex, season, and location.[82] Total protein concentrations were similar in male and female radiated tortoises (*Astrochelys radiata*); however, female tortoises had higher concentrations of alpha1- and beta-globulins compared with males.[59] In wild-caught carpet pythons (*Morelia spilota imbricate*), no intrinsic or extrinsic factors appeared to influence total protein, but albumin and therefore albumin:globulin ratios were increased in summer.[52] In captive panther chameleons, albumin and therefore total protein plasma concentrations were lower in the summer compared with winter for both sexes, and males tended to have higher values than females, independent of season.[61]

Determination of total serum solids via refractometry in the Arrau turtle (*Podocnemis expansa*) and Geoffroy's toadhead side-necked turtle (*Phrynops geoffroanus*) agreed with the biuret method of protein determination. This finding suggests that for clinical application in some reptiles, refractometry may be an acceptable substitute for determination of total solids.[87] In juvenile green sea turtles, the formula for conversion of refractive index (Y, total solids) to total plasma proteins (X, biuret method for total protein) was $Y = 1.34 + 0.00217(X)$.[88] The albumin to globulin ratio (A:G) in most reptiles is inverted (compared with mammals), with higher globulins than albumins often encountered in apparently healthy reptiles.[82,88] Healthy gravid female iguanas have lower A:G than males or nongravid females.[76]

Potential etiologies for decreased total protein or albumin include kidney, liver or gut dysfunction, secondary protein loss (e.g., severe

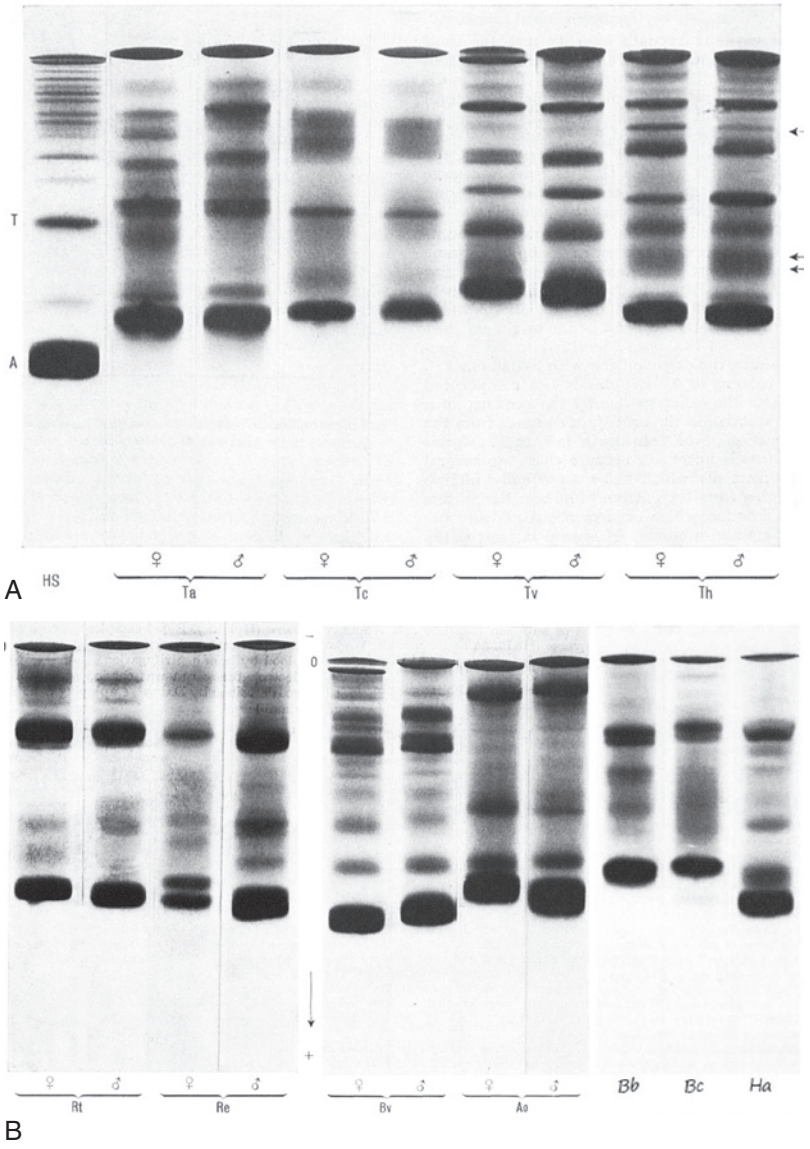

FIG 34.10 Comparative polyacrylamide gels of serum proteins of multiple amphibians, illustrating normal species and class diversity of proteins. All samples were collected during the breeding season.[169] (A) Electrophoretic separation of human serum (HS) and serum proteins of *Triturus alpestris* (Ta), *T. cristayus* (Tc), *T. vulgaris* (Tv), and *T. helveticus* (Th) in polyacrylamide gels. *A*, Albumin; *T*, transferrin. (B) Electrophoretic patterns of serum proteins of multiple anurans illustrative of natural species diversity among proteins: *Rana temporaria* (Rt) and *R. esculenta* (Re); *Bombina variegata* (Bv) and *Alytes obstetricans* (Ao); *Bufo bufo* (Bb), *B. calamita*, (Bc) and *Hyla arbores* (Ha) (all males). The largest band on the bottom is presumed albumin; the male Re shows bisalbuminemia.

burns), or extreme and prolonged inanition leading to catabolism and loss of total body protein stores. Lower gastrointestinal tract strictures of green sea turtles have been associated with a persistent hypoproteinemia and hypoalbuminemia.[89] Ill loggerhead sea turtles had lower total protein and albumin concentrations than subjects in good health.[49] Upper gastrointestinal obstruction and vomiting in a red-footed tortoise (*Chelonoidis carbonaria*) was associated with hyperproteinemia attributable to dehydration.[77]

Acute Phase Proteins

Acute phase reactants (APR) or acute phase proteins (APP) have been studied in a few reptiles, mainly chelonia.[90,91] These nonspecific components of the innate immune system provide restoration of homeostasis in response to inflammation and infection. Thus APR may be more sensitive to detect early and/or continuing acute inflammation than assessment of cellular counts or protein ratios. However, APR increases are nonspecific and may be caused by infection, surgery, trauma, autoimmune responses, toxin exposure, neoplasia, and stress (including transport) and affected by dehydration. Preliminary investigations suggest that fibrinogen, serum amyloid (SAA), complement (C3), and cathepsin-L may serve as positive acute phase reactants in reptiles, and albumin may serve as a negative acute phase protein.[92] However, expression of these molecules were only assessed via PCR of liver; plasma concentrations were not determined. Fibrinogen has received more attention, but preliminary results are not readily comparable based on the variety of methodologies and anticoagulants used. Fibrinogen's clinical usefulness

VetBooks.ir

TABLE 34.7 Acute Phase Reactant Data for Apparently Healthy Reptiles

Species	Units	Method	Data	Acute Phase Reactant	Data Format
Box turtle[91] (*Terrapene carolina*)	mg/dL	Modified clauss	97.9–117	Fibrinogen	95% CI
Box turtle[82] (*Terrapene carolina*)	mg/mL	Haptoglobin	0.27–0.38	hemoglobin binding protein ([HBP], haptoglobin)	95% CI
Spiny-tailed lizard[90] (*Uromastyx* spp.)	g/L	Heat precipitation	1.80 ± 0.13 (0.0–6.0)	Fibrinogen	Mean ± SEM (min-max)
Red-eared slider[93] (*Trachemys scripta elegans)*	mg/mL	Jacobsson	1.68–6.71	Fibrinogen	RI
Brown tree snakes[164] (*Boiga irregularis*)	mg/dL	Heat precipitation	150 ± 92.7 [0–500]	Fibrinogen	Mean ± SD [min-max]

is further hindered by gender and reproduction (e.g., female red-eared sliders have higher concentrations than males).[93] Alligator serum contains a protein antigenically similar and with nearly identical molecular weights as human complement protein C3.[94,95] A complement-facilitated humoral immune response analogous to that of mammals is present in alligator serum, partially based on the presence of this protein.[94,95] Reference data for circulating APR in apparently healthy and unhealthy reptiles is provided in Table 34.7.

Reptile Glucose

In reptiles, blood glucose concentrations tend to be lower than that of mammals and birds. Blood glucose may vary with metabolic rate, environmental adaptations or influence, and physiological changes. Thus season, gender, health, temperature, and many other factors may affect blood glucose concentrations. Examples of expected physiological changes include increased glucose with increased body length in Galapagos marine iguanas (*Amblyrhynchus cristatus*) and maturity in mugger crocodiles.[60,96] Increased glucose concentrations are evident in nesting versus foraging hawksbill turtles.[58] A relative increase in glucose in warmer or summer months have been documented in the Hermann's and yellow-marginated box turtle.[38,50] In captive panther chameleons, blood glucose concentrations varied based on gender and season.[61] Males tended toward higher glucose concentrations than females, independent of season, and both sexes tended toward lower blood sugar concentrations in summer.[53,54,61]

Hypoglycemia. Normal low blood glucose states (prolonged physiological hypoglycemia) may occur during hibernation or brumation in some species. For example, hibernation is associated with an approximately 60% decrease in mean blood glucose in the desert monitor (*Varanus griseus*).[97,98] However, in the common water snake (*Nerodia sipedon*), experimental fasting for 15 days had no effect on blood glucose.[99] Serious, profound, and/or prolonged hypoglycemia has been associated with a number of serious abnormalities in reptiles. Profound hypoglycemia is commonly associated with sea turtle strandings and may be more severe or prolonged based on the degree of debilitation (52.80 ± 43.01 mg/dL; 2.93 ± 2.39 mmol/L) or disease processes such as intestinal and cloacal strictures, enterococcal infection, or phaeohyphomycosal obstructive tracheitis (18 mg/dL; 1 mmol/L).[89,100–102] In other species, hypoglycemia associated with specific disease processes has rarely been documented. Mycobacterial cholecystitis of a Pacific gopher snake (*Pituophis catenifer*) was associated with a blood glucose of 28 mg/dL (1.55 mmol/L).[103] Experimental application of the organochlorine endosulfan to the garden lizard (*Calotes versicolor*) resulted in a decrease of blood glucose from ~114 mg/dL (6.33 mmol/L) in controls to ~75 mg/dL (4.16 mmol/L) 120 hrs postadministration.[104] Hypoglycemia associated with the neurological signs of mydriasis, altered mentation, and/or opisthotonus has been described in crocodilians.[15]

Hyperglycemia. Hyperglycemia in reptiles is rarely confirmed as a consistent or specific indicator of any disease, including diabetes mellitus.[105] Stress-associated hyperglycemia has been reported in a number of species, including freshwater and sea turtles, crocodilians, and snakes. Upper ranges for blood glucose levels due to stress often vary between species from 100 to 175 mg/dL (5.56–9.71 mmol/L).[48,105–111] Physiologically increased blood glucose has also been noted postprandially (particularly following starvation), seasonally during emergence from hibernation, as a cryoprotective mechanism, during the breeding season of temperate reptiles, and upon diving or forced submergence in turtles.[105,112,113] Vomiting and gastrointestinal obstruction in reptiles may be accompanied by hyperglycemia and hypochloremic metabolic alkalosis.[77,114] Experimental hyperglycemia has been induced in multiple species after injections of glucose or epinephrine (lizards, snakes, tortoises, caiman) and pancreatectomy (tegus, snakes).[115–118]

For the more than 20 cases of reptile hyperglycemia reported, affected taxa appears limited to snakes, lizards, turtles, and tortoises.[73,105,119,120] Pancreatic disease, liver disease (often hepatic lipidosis), or renal disease often occur in association with changes in blood glucose.[105] Neoplasia, of a variety of types, deriving from the liver, pancreas, gastrointestinal tract, or undifferentiated tissues, is often reported in these cases.[105] Gastric neuroendocrine carcinoma appears to be the most common cause of hyperglycemia in bearded dragons (*Pogona vitticeps*).[119,121] In a single free-living timber rattlesnake (*Crotalus horridus*) affected by *Ophidiomyces ophiodiicola* dermatitis that died during biopsy, hyperglycemia (220 mg/dL, 12.21 mmol/L) could not be attributed to any histopathologic lesions.[122] Mild hyperglycemia (257 mg/dL; 14.26 mg/dL) has been documented in a single case of atherosclerosis and pericardial effusion in a male bearded dragon.[123] Intracoelomic administration of 5% dextrose + 0.9% Na Cl solutions 1:1 to rehabilitating sea turtles resulted in approximately 100 mg/dL (5.55 mmol/L) higher concentrations of blood glucose compared with other fluid combinations.[100]

Amphibian Glucose

Freeze-tolerant overwintering amphibians such as wood frogs (*Lithobates sylvaticus*), spring peepers (*Pseudacris crucifer*), and western chorus frogs (*Pseudacris triseriata*) accumulate glucose or glycerol in tissues (including blood) for cryoprotection.[124] Thus a physiological hyperglycemia is present if animals are sampled soon after hibernation or during hibernation. Blood glucose concentrations of wood frogs 1 hour post hibernation can reach > 400 mmol/L (>7000 mg/dL), while blood glucose of those that have not withstood freezing temperatures is ~1.5 mmol/L (27 mg/dL). In the gray tree frog (*Hyla versicolor*), this cryoprotective response is dependent on age. Glucose concentrations of adults remain unchanged during freezing, while glycerol concentrations increase from 6.8 to 423 mmol/L (122.5–7621.6 mg/dL). However, immature gray tree frogs have a mild increase in both glycerol (0.1–16.3 mmol/L; 0.09–150.1 mg/dL) and glucose (1.46– 25.9 mmol/L; 26.3–25.9 mg/dL).

VetBooks.ir

Lipids and Lipoproteins

Hypercholesterolemia can be associated with excessive production or decreased excretion (e.g., extrahepatic biliary obstruction). Normal female reptiles undergoing vitellogenesis often exhibit increases in cholesterol and triglycerides; however, sustained elevations or elevations in males may be associated with hepatic lipidosis. In addition to cholesterol and triglycerides, some commercial laboratories offer lipoprotein profiles. Plasma triglyceride concentrations are reasonable indicators of long term feed intake but may be slow to rise due to slow rates of digestion. For example, at 2 hours post feeding of green sea turtles, plasma cholesterol increased significantly.[9] In Hermann's tortoises, plasma triglycerides and cholesterol were significantly higher in females.[38] As postprandial effects on triglyceride and cholesterol concentrations remain minimally studied, fasting before sampling is recommended.

Extrinsic factors that may affect lipids and lipoproteins in reptiles include age and season. Decreased cholesterol occurs with increased age in the male iguanid, *Tropidurus torquatos,* possibly based on the change from omnivory to herbivory as the animal matures.[36] Similarly, differences in cholesterol and fatty acids have been documented between captive and free-living tuatara (*Sphenodon*).[125,126] In the captive mugger crocodile, cholesterol and triglycerides vary based on age class.[60] Cholesterol concentrations were relatively increased for subadults and juveniles compared with adults, while triglyceride concentrations were relatively decreased for subadults and highest for juveniles. Cholesterol concentrations were also relatively increased in juvenile males compared with juvenile females. Free-ranging Moreletti's crocodiles (*Crocodylus moreletii*) had decreased plasma cholesterol concentrations compared to those of the captive animals. [127] Marked seasonal variation in triglycerides has been documented in the yellow-marginated box turtle.[50]

Concentrations of cholesterol and triglycerides tend to decrease due to stress.[48] In the Indian spiny-tailed lizard (*Uromastix hardwickii*), plasma cholesterol concentrations and HDL:LDL ratios are affected by emergence from hibernation, activity periods, prehibernation preparation, and hibernation states (Table 34.8).[98,128] Similar changes are expected during vittelogenesis. Female radiated tortoises had higher triglyceride concentrations in winter (presumably during early vitellogenesis), and lower cholesterol and triglyceride concentrations in summer (presumable after laying), compared with males.[59] Hypercholesterolemia (cholesterol 937 mg/dL; 24.27 mmol/L) has been documented in a single case of atherosclerosis and pericardial effusion in a male bearded dragon.[123] Xanthomatosis in lizards has been associated with mild (20.1 and 22.4 mmol/L; 776–865 mg/dL) to marked increases (35.46 mmol/L, 1369 mg/dL) in plasma cholesterol. [129,130]

Captive anurans (especially tree frogs) are prone to obesity and other lipid disorders such as xanthomatosis and corneal lipidosis.[131] These diseases are associated with an increased plasma cholesterol of captive specimens (27.5 mmol/L, 1062 mg/dL) compared with their free-living counterparts, unaffected by lipidosis (3.86 (0–8.26, 95% CI) mmol/L or 149 (0–319, 95% CI) mg/dL). However, despite multiple publications, the overall number of amphibians investigated for these diseases based on plasma assessment of blood lipids and lipoproteins remains low at less than 75 individuals.[131]

TABLE 34.8 Cholesterol Values for a Seasonally Active Reptile *Uromastix hardwickii* [28]

Activity State	Cholesterol (mg/dL, mmol/L)	Mean HDL:LDL
Hibernation	250 ± 110, 6.47 ± 2.85	70.9: 29.1
Arousal	226 ± 104, 5.85 ± 2.69	73.5: 26.5
Activity	348 ± 117, 9.01 ± 3.03	72.3: 27.7 (Max in May: 85.7:14.3)
Prehibernation	457 ± 134, 11.84 ± 3.47	57.1: 42.9

Calcium, Phosphorus, and Magnesium

Calcium and phosphorous remain important analytes in the reptile and amphibian biochemical panel. Seasonal plasma increases of total calcium and phosphorous in free-living and captive females during vitellogenesis occurs in all major reptile taxa.[38,59,61,132 52] A similar trend of relatively increased serum or plasma calcium in females, compared with males, has been reported for eastern hellbenders (*Cryptobranchus alleganiensis*), African clawed frogs (*Xenopus laevis*), and American bull frogs (*Lithobates catesbeianus*).[1] In some amphibians, calcium metabolism changes with season and life stage.[1] Amphibian plasma calcium increases in spring and summer as larvae approach metamorphosis, but decreases in winter.[133] In nesting loggerhead sea turtles, a positive correlation between plasma phosphorous and successful hatching was observed, however nesting turtles were more likely to have lower plasma calcium concentrations than those that false crawled.[134] Differentiation of seasonal changes and reproduction from disease is not straightforward. Seasonal changes of calcium and phosphorous in the apparent absence of reproductive activity also occurs in reptiles.[50,61] In captive panther chameleons, winter values of Ca and P for both sexes were significantly higher than in summer. But within summer, gravid females had significantly higher Ca and P than nonreproductive females Ca (5.3 ± 3.5 vs. 2.9 ± 2.9 mmol/L), P (2.6 ± 1.1 vs. 1.9 ± 0.6 mmol/L).[61] Finally, species differences in total calcium and phosphorous values may be dramatic. Normal physiological hypercalcemia and hyperphosphatemia and relative hypervitaminosis D of indigo snakes has been documented and could be based on their specific diet, UVB exposure, or possibly PTH levels.[135]

To avoid seasonal, gender, and species related complexities of calcium analyte interpretation, the practitioner is encouraged to assess ionized (or free) calcium concentrations (iCa) as well as the total calcium provided by standard biochemical panels. As the biologically active form of calcium, iCa concentrations are relatively conserved across reptile taxa with expected values from healthy reptiles and amphibians being approximately 1.4-1.9 mmol/L.[136-139] Pathological derangements in calcium or phosphorous include nutritional/renal secondary hyperparathyroidism, primary hyperparathyroidism, osteolytic bone disease and pseudohyperparathyroidism.[138] Muscle tremors, fasiculations, and seizures may be caused by hypocalcemia, which most commonly occurs in herbivorous or omnivorous reptiles.[15] Lower gastrointestinal tract strictures of green sea turtles have been associated with persistent hypocalcemia.[89]

If magnesium is the forgotten analyte in mammals, then it remains doubly so in reptiles and amphibians. While one study of reproductive female alligators associated an increase in plasma magnesium with vitellogenesis, a similar study of cobras failed to provide similar results.[132,140] Magnesium toxicosis in leopard geckos (*Eublepharis macularius*) based on ingestion of vermiculite has been reported; however, blood concentrations of the offending ion were not confirmed.[141]

Osmolality, Sodium, Potassium, Chloride, and Bicarbonate

The evaluation of electrolytes from reptiles is made challenging because of widely differing physiology. As an example, Galápagos marine iguanas exhibit some of the highest known blood sodium concentrations, (~ 178 mEq/L = mmol/L), among reptiles.[96] Similarly, increased plasma sodium, chloride, and potassium concentrations have been reported

VetBooks.ir

in sliders subjected to hyperosmotic stress.[142] In aquatic Chinese soft shelled turtles (*Pelodiscus sinensis*), exposed to 15% salt water, plasma osmolality and concentrations of Na, Cl and BUN increased.[143] Similarly, sea turtles tend to have relatively increased reference intervals for plasma electrolytes compared with other land or freshwater reptiles.[48] Many reptiles have the ability to modulate electrolyte balance using multiple organs: salt gland, kidney, adrenal gland, and the gastrointestinal tract. Dysfunction in these organs may be assumed, but is seldom proven, to have the same effects that one would classically encounter in a mammal. Vomiting and gastrointestinal obstruction may result in hyperglycemia, hypochloremia, and metabolic alkalosis.[77,114] Low potassium has occurred in sea turtles in association with debilitation, nesting, diarrhea, and inanition. In nesting loggerhead sea turtles, those that actually nested had lower potassium concentrations than those that false crawled.[134]

Relative electrolyte concentrations may also be affected by species or size. For example, in postprandial green sea turtles (but not Kemps' ridleys), plasma chloride was relatively decreased.[9] In the Galápagos marine iguana, body length positively correlated with increased HCO_3 and glucose. Electrolyte values may also be affected by season, activity, and sex.[132] For example, male radiated tortoises had increased sodium concentrations during winter compared with females.[59] In captive mugger crocodiles, potassium concentrations were significantly greater in juvenile males than in juvenile females, and subadult animals also had a comparatively lower potassium concentration than other age classes.[60] Prolonged storage of heparinized whole blood may result in relatively increased potassium and decreased sodium concentrations of plasma. The clinician should separate plasma from the cellular components of blood before overnight shipment for analysis.[34,139]

Plasma osmolality, an indicator of hydration state and electrolyte status, has been determined for a number of reptiles. As the concentration of active particles in an aqueous solution, osmolality is best measured directly by an analyzer. Freezing point depression osmometers are more common and more accurate than vapor pressure depression osmometers.[40] However, in the absence of measured osmolality, for some species, calculations may allow the practitioner to calculate an estimate of osmolality. Measured osmolality ranges for select reptiles and amphibians as well as associated recommended osmolality estimate calculations are provided in Table 34.9. Amphibians and reptiles appear tolerant of relatively wide ranges of osmolality, which are likely affected by environmental and physiological conditions.[1] Overwintering frogs and salamanders purposefully dehydrate; thus a healthy hibernating or near-hibernating amphibian should have relatively increased plasma osmolalities,[1] whereas plasma osmolality of active toads from arid areas remain similar throughout the year.[144] Chytridiomycosis, infection with *Batrachochytrid dendobatidis*, is associated with reduced plasma osmolality and decreased sodium, potassium, magnesium, and chloride in affected frogs (green [White's] tree frogs, mountain yellow-legged frogs [*Rana muscosa*]).[1]

Blood Gases and Acid-Base Balance

Few clinically relevant studies of acid–base status and blood gas values have been performed in reptiles or amphibians. However, electrolyte and acid–base status as well as venous blood gas values hold promise as indicators of function and integrity in organs such as kidney, lung, and gastrointestinal tract. For these organs many standard mammalian biomarkers remain inapplicable, poorly sensitive, nonspecific, or irrelevant. However, reptile and amphibian physiology may also allow a relatively wide variation in many acid–base, electrolyte, and blood gas values compared with mammals. Thus, values that would be considered diagnostic of disease in mammals may be within normal physiologic ranges for highly adapted and evolved reptiles or amphibians.[96,145] At present, evaluation of these analytes is mainly relegated to research purposes wherein arterial samples may be obtained. Within the genre of sea turtle stranding, however, determination of values from venous blood has proven useful for determination of prognosis and continued case management.[100,146,147] In anurans, an overly acidic habitat substrate (pH ≤ 4–5) may interfere with the integumental sodium–potassium pump, resulting in hyponatremia, often accompanied by subcutaneous edema.[1] Wild-caught mountain yellow-legged frogs infected with *B. dendrobatidis* retained apparently normal acid–base balance and blood gas values despite electrolyte imbalance.[148]

Uric Acid, Urea, and Ammonia

Evaluation of renal disease in reptiles and amphibians based on plasma markers remains challenging based on a number of factors including the diversity of species and physiological adaptations for nitrogenous waste excretion. For a review of urinalysis in reptiles, please see Chapter 66. Nitrogenous end-products vary in reptiles (see Table 66.2) and amphibians. Quantification of blood urea nitrogen (BUN) and ammonia is recommended for chelonians and crocodilians (see Table 66.2.) but is expected to change due to hydration, postprandial effects, hepatobiliary function, and renal impairment. Uric acid (UA) is most commonly assessed in lizards and snakes but is neither sensitive nor specific for renal disease and may increase in association with profound dehydration, a recent carnivorous meal, or decreased temperature. UA may decrease due to anorexia, fasting, or possibly severe hepatopathy.[9,149] Analysis of blood samples from 43 wild-caught southwest carpet pythons failed to reveal intrinsic or extrinsic factors that influenced UA in apparently healthy snakes.[52] Published cases in which hyperuricemia is linked to primary renal disease are actually relatively few. Hyperuricemia has been reported in a green iguana with small intestinal obstruction and volvulus, which was suspected to be secondary to vomiting and dehydration.[114] In tortoises, increased BUN may indicate renal disease or dehydration. However, ammonia is a major nitrogenous waste product excreted by crocodilians and some aquatic chelonians. Increased plasma or serum BUN concentrations may be associated with normal physiological processes in some desert species or following emergence from hibernation.[150] Multiple changes in plasma analytes are often seen in conjunction with azotemia and hyperosmolality, including hypercholesterolemia, hypophosphatemia, increased AST, and to a lesser extent, hyperchloremia, hypocalcemia, and anemia.[150–152] Thus renal assessment via plasma is best performed in the fasted, normothermic reptile, before and after fluid therapy.

TABLE 34.9 Plasma Osmolalities of Select Reptiles and Amphibians

Species	n	Osmolality (mOsm/Kg)	Data Format	Recommended Calculation
Corn snakes, *Pantherophis guttatus guttatus*[165]	12	344.5 (304.5–373.0)	Mean (Range)	$2 \times [Na^+ + K^+]) + ([Glu \text{ in mg/dL}]/18)$
Bearded dragons, *Pogona vitticeps*[166]	11	295.4 ± 9.35	Mean ± SD	$1.85 (Na^+ + K^+)$
American alligators, *Alligator mississippiensis*[167]	46	267.7–270.9; 269.3 ± 10.8	95% CI; Mean ± SD	$1.79 \times Na^+ + 0.05 \times [Glu \text{ in mg/dL}]$
European green toad, *Bufo viridis*[144]	47	377 ± 5	Mean ± SEM	Not determined

UA and other renal biomarkers may be affected by a number of extrinsic factors. In captive mugger crocodiles, multiple analytes associated with renal function were affected by age and gender. BUN was lower for subadults than for adults or juveniles, whereas UA concentrations were higher in juvenile (than for subadult and adult) females (compared with males). In healthy loggerhead sea turtles, lower plasma creatinine and BUN concentrations occurred in juvenile and subadult turtles, compared with adults.[49] Free-ranging Morelet's crocodiles had greater UA values than captive crocodiles.[127]

Season may also affect renal markers in apparently healthy reptiles, whether free-living or captive. In plasma of the yellow-marginated box turtles, marked seasonal variations occur with BUN, UA, and creatinine.[50] In captive panther chameleons, summer and winter UA values differed based on gender, with relatively increased plasma uric acid concentrations in gravid females.[61] Seasonal effects have also been reported in Hermann's tortoise with UA increased during midsummer.[38] In captive radiated tortoises, UA, BUN, and chloride values were higher in summer than in winter and were higher in males than in females. These changes were attributed to increased activity and seasonal dehydration, which may be normal in males of this arid species.[59]

Evaluation of renal disease in amphibians based on biochemical constituents of plasma is challenging due to the variety of nitrogenous end products and variable, environmentally adapted physiology. Many amphibians have a tolerance for relatively high plasma BUN concentrations to facilitate water uptake via the skin.[1] The appropriate nitrogenous end product to measure varies with species. In the ammonotelic aquatic adults and larvae (*Xenopus* spp., tadpoles) ammonia is the most appropriate analyte to determine. Examples of obligatory ammonotelics are Kuhl's creek frog (*Limnonectes kuhlii*), the fork-tongued frogs (Dicroglossidae), the striped stream, spotted stream, or Matang frog (*Pulchrana signata*), as well as Schlegel's, the brown stream, copper-cheeked, or white-lipped frog (*H. chalconota*).[153] Adult terrestrial amphibians, like most toads, are ureotelic and BUN should be measured. Some tree frogs (waxy tree frogs, *Phyllomedusa* spp.; painted-belly monkey frogs, *Phyllomedusa sauvagii*; leaf frogs, *Phyllomedusa tarsius;* and some species of foam-nesting tree frogs, *Chiromantis* spp.) are uricotelic. These frogs produce UA even when ample water is available and are prone to urate cystic calculi.[153] Thus UA would be the most appropriate nitrogenous end-product analyte to evaluate for these species.[1] In anurans, edema and renal disease are associated with hypoproteinemia (due to renal losses) and hyponatremia (due to lack of tubular resorption).[1]
