Gastroenterology—Oral Cavity, Esophagus, and Stomach

Ryan De Voe

Just about every imaginable feeding strategy is employed by members of the class Reptilia, with carnivores, herbivores, omnivores, and a variety of specialized feeders represented (Fig. 73.1). As expected, there is tremendous variation in gastrointestinal anatomy and physiology. Lack of knowledge of these differences and how they affect husbandry, captive nutrition, and medical management can significantly limit a clinician's ability to provide effective care. It is impossible for even the most knowledgeable reptile veterinarian to be familiar with all possible variations of anatomy and physiology. Therefore the interested clinician should become intimately familiar with the anatomy and feeding strategies of commonly seen species. When unfamiliar species are presented, the clinician should recognize the need to research specific information regarding gastrointestinal anatomy and function or at the very least extrapolate from what is known about a similar species.

ANATOMY AND PHYSIOLOGY

One of the most important features of reptilian gastrointestinal physiology is the effect of ectothermy. Many of the unique adaptations revolve around the ectotherm's ability to efficiently process calories. Similarly sized reptiles, birds, or mammals have extremely different caloric and nutrient requirements to function and grow. Though variation occurs between taxa, in general, reptiles use approximately 10% the energy of mammals and birds with comparable feeding strategies and niches.[1,2] Some species of reptiles eat infrequently in nature; others will forage/graze and eat frequently but can often survive extended periods of anorexia without suffering the acute consequences that would be encountered in most mammals or birds. Understanding the feeding ecology of a species in the wild is paramount for maintaining them in captivity.

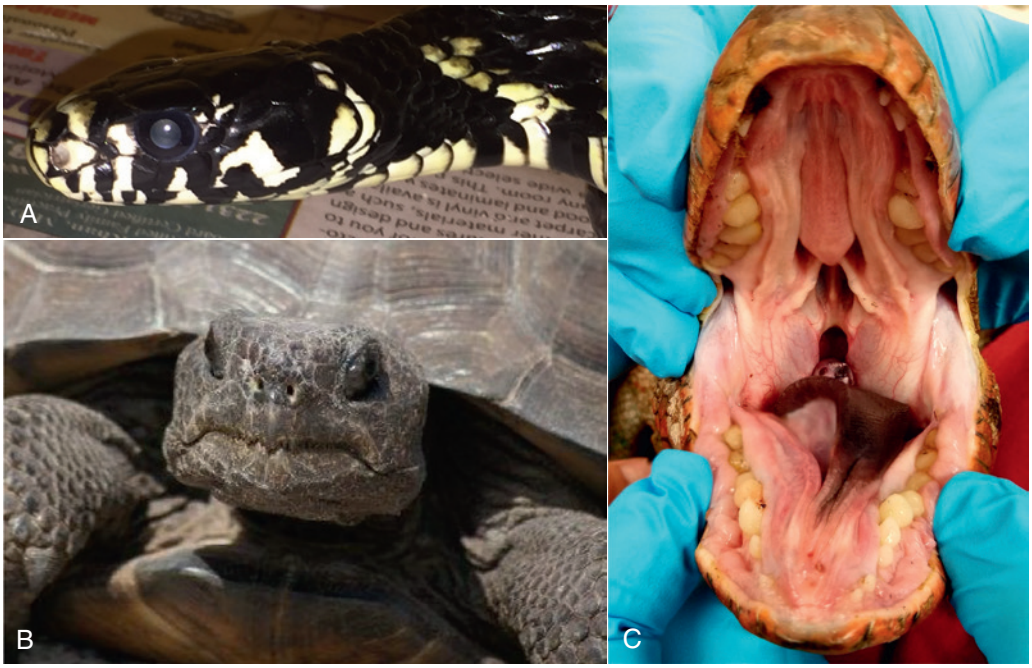

FIG 73.1 Many different feeding strategies are represented in the class Reptilia. As examples, snakes are exclusively carnivorous, some tortoises are grazing herbivores, and caimen lizards are specialized mollusk feeders: (A) tiger rat snake (*Spilotes pullatus*), (B) gopher tortoise (*Gopherus polyphemus*), and (C) caimen lizard (*Dracaena guinanensis*). Diseases of the gastrointestinal tract are relatively common in reptiles. Both primary gastrointestinal disease and dysfunction secondary to other disease processes and husbandry deficiencies are encountered.

Oral Cavity

The anatomy of the reptilian oral cavity varies dramatically according to taxa. Squamates have lips that protect the gingiva and teeth. Lizards typically possess two maxillary and two mandibular dental arcades, whereas snakes have two additional palatal arcades for a total of six arcades (Fig. 73.2). The vomeronasal organ is located in the rostral maxilla. In the roof of the mouth, snakes and lizards have a choana in which the tubular larynx sits when the mouth is closed. The lingual structure varies drastically in different species of lizards. Some lizards, such as chameleons, have specialized tongues and hyoid apparatus for capture of prey from a distance, whereas others have fleshy tongues in a form similar to that of mammals. Varanid lizards and snakes have specialized telescoping, forked tongues with keratinized epithelium that are used for collection and delivery of scent particles to the vomeronasal organ. The forked tongue facilitates tracking of prey scent trails.[3]

The dentition of squamate reptiles also shows great anatomical diversity. Lizards possess either acrodont or pleurodont dentition. With acrodont dentition, the teeth are fused to the maxillary and mandibular ridges. With advanced age, the teeth of some lizards with acrodont dentition may become worn down to the point where only the bony ridges of the mandibles and maxillae remain. Agamid lizards, such as bearded dragons (*Pogona vitticeps*), and chameleons possess acrodont dentition. With pleurodont dentition, the replaceable teeth are seated in grooves on the medial aspect of the maxilla and mandibles. Iguanid lizards have pleurodont dentition (Fig. 73.3). Snakes are considered to have modified pleurodont dentition, and teeth are constantly shed and replaced throughout life. Snake dentition is further defined according to the presence of fangs and, when present, venom delivery systems. Aglyphous snakes do not have specialized fangs for venom delivery and represent many of the nonvenomous species frequently kept in captivity. Solenoglyphous snakes are the viperids, which have hollow fangs. These fangs are mobile and lie folded against the roof of the mouth when not in use. Proteroglyphous snakes are the elapids; the fangs are fixed in an erect position. Opisthoglyphous snakes are rear-fanged venomous snakes, where the fixed erect fangs are typically found at, or caudal to, the level of the eye.[3]

Lizards have numerous mucous glands as well as labial, lingual, sublingual, palatine, and dental salivary glands. Snakes are similar but do not possess dental salivary glands.[4] Lizards and snakes are capable of producing copious amounts of saliva and mucous in the oral cavity, which lubricates food items for swallowing.[5] There are specialized oral glands in the various venomous species, including the labial venom glands of helodermatid and varanid lizards[6] and the venom glands of some snakes, which are associated with the maxillae.[4,7]

Chelonians possess keratinized beaks instead of lips and teeth. Most chelonians have broad, fleshy, relatively mobile tongues. Some aquatic turtles, such as alligator snapping turtles (*Macrochelys temminckii*), have lingual appendages that mimic worms that they use to bait prey. Other chelonians that specialize in eating crustaceans and mollusks have keratinized palatal plates that are used for crushing the shells of the prey. Chelonians also have a tubular glottis and palatal structure similar to that of avian species.[3]

Crocodilians have no lips and the teeth are exposed when the mouth is closed (Fig. 73.4). The tongue in crocodilians fills the entire intermandibular space and is immobile, being firmly attached ventrally. A palatal fold arises from the base of the tongue and can effectively seal the pharyngeal region so the crocodilian can open its mouth and prehend food without introducing water to the pharynx. The laryngeal opening is found just caudal to the palatal fold and is similar in appearance to that of mammals, albeit with a much reduced epiglottis. Crocodilians possess thecodont dentition, in which the teeth are seated in sockets in the maxilla and mandibles similar to what is seen in mammals. Thecodont teeth are replaced throughout the life of the animal.[8]

Esophagus

The structure of the reptilian esophagus varies across taxa but is generally similar to that of mammals. The esophagus is variably distensible and typically has longitudinal folds extending the entire length. The esophagus of snakes is quite distensible and relatively longer than that of other taxa. In snakes, the stomach may be too small to completely accommodate a large prey item or items, therefore the esophagus may assist in food storage. Reflux of digestive enzymes may allow digestion

to begin in the esophagus.[9] The esophagus of sea turtles is uniquely lined by conical, keratinized, caudally directed papillae. These papillae are thought to facilitate the movement of slippery food items aborad and facilitate mechanical digestion in the esophagus.[9] There are submucosal lymphoid aggregates throughout the esophagus of reptiles, which may be organized into esophageal tonsils in some species. Endoscopic biopsies of the esophageal tonsils of boid snakes[10] are often collected for histopathology and/or molecular diagnostics in screening for arenavirus infections.[11] The tunica muscularis is variably developed in different taxa. In some it is quite robust, allowing for some degree of mechanical digestion in the esophagus of some chelonians, whereas in others it is relatively thin and fragile and can easily be damaged if care is not utilized when administering medications, gavage, or assist-feeding.[9]

Stomach

The reptilian stomach is divided into cardiac, fundic, and pyloric regions, which are variably developed according to taxa. The snake stomach represents one end of the spectrum, as it can be difficult to differentiate from the esophagus and duodenum. The stomachs of "sit and wait" predators are extremely distensible in order to accommodate large, intermittent meals. The gastric mucosa has mucosal folds or rugae to varying degrees. The fundic portion of the crocodilian stomach is quite muscular with keratinized mucosa similar to the avian ventriculus. Gastroliths are commonly encountered in crocodilians.[8,9] The stomach functions to store and begin digestion of ingesta via both mechanical and chemical means. The mucosal glands produce hydrochloric acid and pepsinogen, which is cleaved to the active product pepsin. The pH of the stomach can drop dramatically in response to ingestion of a meal, especially in animals that have not eaten recently (from 7–2 in Burmese pythons, *Python bivittatus*). The typical pH of the reptilian stomach during digestion appears to be between 2 and 2.5. The presence of secretory glands in the gastric mucosa tends to be regionally variable; in some snakes the largest number of glands are present in the middle portion of the stomach with relatively nonglandular regions in the cranial gastric mucosa.[9,12]

Reptilian gastric conformation can also depend on recent feeding history. The stomach of reptiles has adapted to consume occasional large meals and will vary in mass and structure depending on the stage of digestion. Sit-and-wait predators such as Burmese pythons best represent this digestive strategy. The digestive function of Burmese pythons has been extensively studied, revealing that in between meals the stomach is maintained in an atrophied, quiescent state. No acid or enzymes are secreted and the actual mass of the stomach is significantly reduced.[13] Species that forage or graze and feed daily represent the other end of the reptile extreme. In these species, gastric anatomy and function is maintained and relatively static in health.

Digestive function in the stomach and other organs is dependent on access to temperatures capable of supporting these processes. If the reptile is not allowed to thermoregulate effectively, gastric activity can be inhibited, resulting in maldigestion.

CLINICAL INVESTIGATION

History and Physical Examination

History is paramount in the evaluation of reptile patients. Even seemingly minor deficiencies in husbandry and nutrition can dramatically impact a reptile's health. Thus specific information should be collected regarding environmental parameters and stressors, dietary composition, and consumption. Evaluation of appetite and fecal output can be especially difficult based on the intermittent feeding and defecation behaviors of some species. Differentiation between a physiological fast (seasonal, reproduction-related) and anorexia due to illness is often challenging.

Lizards with acrodont dentition appear uniquely predisposed to the development of periodontal disease due to the relatively thin and fragile gingival tissue found along the lateral surfaces of the maxillary and mandibular bones. When the gingival tissue is disrupted due to trauma or dessication, secondary infection may occur, leading to periodontitis/stomatitis and occasionally osteomyelitis.[14]

Many cases of stomatitis can ultimately be attributed to husbandry issues. Identification and correction of the inciting cause is critical for successful management of the condition. Trauma to the tissues of the rostrum and oral cavity due to interactions with the environment can lead to trauma and stomatitis. Abrasive or sharp surfaces within the animal's environment, especially those associated with potential escape routes (screen tops on aquaria), are important risk factors. Factors that result in efforts by the animal to escape from its enclosure can lead to incessant nose-pressing and pacing along and crashing into barriers, resulting in trauma even in the absence of inappropriate surfaces. Causes of continued escape efforts can include, but are not limited to, enclosure size and configuration, inappropriate thermal and light gradients, the presence of cagemates or conspecifics housed in close proximity (especially during breeding seasons), and lack of hide areas. Some species, such as basilisks (*Basiliscus basiliscus*) and water dragons (*Physignathus cocincinus*), can be nervous in captivity and have long flight distances, predisposing them to crashing into enclosure walls in response to environmental disturbances. Nervous snakes will sometimes strike repeatedly against glass barriers when disturbed. Environmental humidity and water availability can also be important factors in the development of stomatitis. Dehydration and dessication of the oral mucous membranes as well as dysecdysis with retention of exuviae along the lip margins can predispose to stomatitis.

Short of dysphagia, regurgitation (from the esophagus), and vomiting (from the stomach), the clinical signs associated with disease of the upper gastrointestinal tract are often vague. Lethargy, anorexia, and weight loss are frequently encountered and are nonspecific signs. A thorough oral examination is always indicated. Oral examination is

VetBooks.ir

often daunting due to dangers working around the mouth in large or venomous species, or simply the inability to access and open the mouth of many chelonians. The diminutive size and fragile nature of the oral structures of some species can also create challenges. At the very least, competent and firm handling should be utilized; however, sedation or anesthesia may be necessary. Struggling with a reptile to open the mouth can potentially result in injury to both animal and handler, not to mention that a thorough examination is often impossible with an uncooperative patient. Many reptiles will gape when handled, which may allow at least a visual examination. Decisions regarding measures to facilitate oral examination should be made on a case-by-case basis.

Thorough palpation of the neck and coelom can occasionally yield useful information about abnormalities of the esophagus and stomach. Snakes and some lizards have anatomy that allows for meaningful palpation with adequate knowledge of anatomy. Palpation of the coelom is possible in chelonians through the prefemoral or inguinal space, though it is typically difficult to access the stomach and structures cranial to the level of the liver. Crocodilians and lizards with osteoderms, gastralia, or heavy scalation are challenging to palpate, with only dramatic abnormalities of the stomach detected.

Clinical Pathology

A minimum database consisting of hematology and plasma biochemistry configured for reptilian species is often indicated. Hematology may show evidence of inflammation via leukocytosis, toxic changes to the leukocytes, and changes in the differential cell count. The differential cell count may show changes to suggest chronicity of the disease process (monocytosis, nonregenerative anemia). Changes in the plasma biochemistry panel that may be associated with disease of the upper gastrointestinal tract should theoretically mirror what would be expected in a mammal with similar pathology. Alkalosis, hypokalemia, and hypochloremia are possible, with vomiting or obstruction of the small gastrointestinal tract. Elevations in creatine kinase and aspartate aminotransferase are also possible due to damage/necrosis of the smooth muscle of the gastrointestinal tract and potentially catabolism of muscular tissues associated with severe catabolic conditions. Elevated nitrogen waste products (ammonia, urea, uric acid) may also be encountered as a nonspecific change associated with dehydration and reduced renal excretion or gastrointestinal hemorrhage. Severely wasted, chronically anorexic reptiles may have low blood uric acid, urea, or ammonia levels despite decreased renal excretion due to decreases in protein catabolism and nitrogen waste production.

Diagnostic Imaging

Various diagnostic imaging modalities are commonly utilized in the evaluation of the gastrointestinal tract and coelomic viscera. Radiography, computed tomography, magnetic resonance imaging, and ultrasonography all have utility in clinical evaluation of the gastrointestinal tract and should be applied based on the specific details of the case. Knowledge of normal anatomy for a particular species is important for thorough and subtle evaluation of the patient regardless of modality. When dealing with unfamiliar species, extrapolation from knowledge of related taxa is often the only course of action.

Administration of contrast material via gavage can highlight the gastrointestinal tract, identify filling defects within, help identify adjacent visceral organs, and determine gastrointestinal transit time. A number of studies are published that describe the radiographic anatomy of the gastrointestinal tract and transit time in various species.[15–19] Gastric emptying and transit times can vary considerably in relation to body temperature, with slower transit times corresponding with lower body temperatures. Parenteral administration of iodinated contrast material may also prove useful in increasing soft tissue contrast when imaging via computed tomography. If administering oral medications or gavage feeding, the author will often add contrast material (barium sulfate or iohexol) to facilitate radiographic documentation of gastrointestinal motility, patency, and transit time if desired (Fig. 73.5). Iohexol provides the benefit of faster emptying and transit time than barium but often becomes diluted in the lower gastrointestinal tract, limiting its usefulness for evaluation of the large intestine.[17]

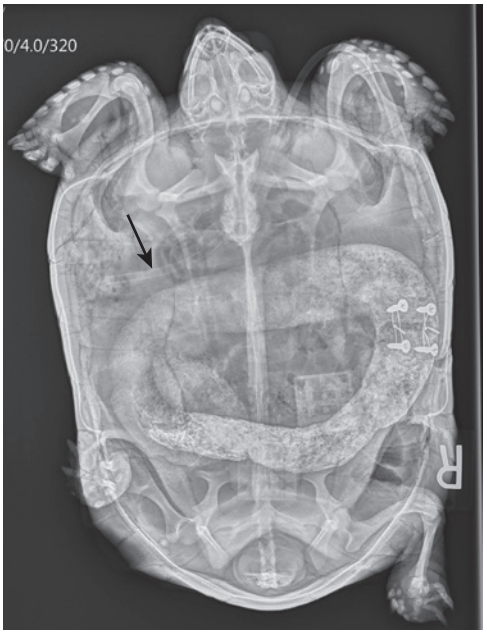

FIG 73.5 Constipated gopher tortoise (*Gopherus polyphemus*) with fecal mass highlighted following administration of barium sulfate via esophagostomy tube at approximately 30 mL/kg. The arrow shows the tip of a tube in the stomach lumen on the left side. Also note the metal screws and wire on the right side (associated with a shell repair). (Courtesy of Ryan De Voe.)

Ultrasonographic examination of the gastrointestinal structures can be useful in certain instances. Infusion of saline into the gastrointestinal tract via gavage to provide contrast is often helpful, especially for novice ultrasonographers. Ultrasonography can also facilitate collection of samples via aspiration for cytology, microbiology, or DNA-based diagnostics. Some reptiles are difficult to image due to characteristics of their skin (heavy scalation, osteoderms, etc.); however, in most cases these challenges can be overcome or at least minimized (see Section 7 for more information on diagnostic imaging).

Endoscopy

Endoscopy is commonly employed in evaluation of the upper gastrointestinal tract. Endoscopic evaluation of the oral cavity allows the clinician to visualize areas and structures that might not otherwise be accessible. Also, the magnification provided by most of the available imaging systems may allow for identification of lesions that would otherwise be overlooked. Endoscopy has the additional benefit of facilitating the collection of diagnostic samples and implementation of therapy.

Endoscopic examination of the esophagus and stomach is routinely performed in many patients with signs of upper gastrointestinal disease.[20] If the correct equipment is available, endoscopic retrieval of gastric foreign bodies can be relatively straightforward.[21] Smaller, rigid telescopes may be adequate for endoscopic evaluation of the oral cavity, esophagus, and stomach in small species/individuals; however, flexible endoscopes will likely be necessary in larger specimens (including most snakes over

approximately 75 cm). The anatomy of certain taxa, such as crocodilians and some lizards, allows relatively easy removal of gastric foreign bodies per os due to the relatively short and broad nature of their esophagus.

Endoscopic biopsy of the oral, esophageal, and gastric mucosa is possible, but caution should be utilized to avoid perforation, as the esophageal tissue is especially thin in certain taxa. A common procedure for screening boid snakes for inclusion body disease is collection of biopsies from esophageal lymphoid aggregates.[11]

CLINICAL DISEASES

Stomatitis, Esophagitis, and Gastritis

Stomatitis, esophagitis, and gastritis are all encountered with relative frequency in reptile practice. In these cases, a thorough diagnostic investigation is paramount, especially when populations of animals are at risk. Collection of swabs and tissue samples for culture, polymerase chain reaction, and cytology/histology (and possibly immunohistochemistry) is typically indicated. Cytology and histology are critical pieces of the diagnostic investigation, as the clinical significance of potential pathogens may be otherwise difficult to assess. Specific diagnostic testing should of course be directed by clinical presentation, though many times no clear direction is recognized early in the investigation. Occasionally a primary infectious etiology can be revealed; however, in most cases the etiology is likely multifactorial with various pathogens involved. Eastern box turtles with stomatitis have been documented with coinfections of herpesvirus, ranavirus, and *Mycoplasma* sp.[22]

Lizard species with acrodont dentition appear uniquely predisposed to the development of periodontal disease due to the relatively thin and fragile gingival tissue found along the lateral surfaces of the maxillary and mandibular bones. When the gingival tissue is disrupted due to trauma or dessication, secondary infection may occur, leading to periodontitis/stomatitis and occasionally osteomyelitis.[23]

Viral Diseases

Herpesviral infections are a common cause of stomatitis and esophagitis in various species. Herpesviruses that cause pathology in chelonians are fairly well described, with novel isolates being commonly encountered.[24] Several chelonian herpesviruses have a predilection for mucoepithelial cells and are commonly associated with stomatitis/glossitis.[24] Herpesvirus-associated stomatitis/glossitis is reported in lizards[25] and may cause predisposition to development of oral squamous cell carcinoma in some species, such as green tree monitors (*Varanus prasinus*).[26] Many viral pathogens can cause oral, esophageal, and/or gastric lesions in addition to other pathology. Adenoviral infection is reported to cause mucosal ulcerations/erosions in Sulawesi tortoises (*Indotestudo forsteni*).[27] Necrotizing stomatitis and glossitis are reported in American alligators (*Alligator mississippiensis*) suffering from West Nile virus infection as part of the disease presentation.[28]

Viral esophagitis is occasionally encountered. Ball pythons (*Python regius*) with nidovirus infections are reported to suffer from esophagitis, as well as tracheitis and pneumonia.[29,30] Ranaviral infections in chelonians frequently cause necrotizing stomatitis and esophagitis[31] (Fig. 73.6). Though esophagitis is not typically part of the disease process, boid arenavirus infections are often detected by biopsies of lymphoid aggregates found in the esophagus of boas and pythons.[11] Atadenoviral infections in colubrid snakes (*Lampropeltis* and *Pituophis* species) are reported to cause gastritis as well as pathology in other organs.[32]

Bacterial Diseases

Bacteria often play a role in reptilian stomatitis, esophagitis, and gastritis, but infections are thought to typically be secondary. Regardless, it may be necessary to provide appropriate antibiotic therapy (based upon culture and sensitivity) to effectively treat a reptile suffering from disease of the upper alimentary tract. A wide variety of bacterial isolates may comprise normal oral/gastrointestinal flora, though the same bacteria can create clinically important infections under certain circumstances. The majority of isolates include gram-negative species such as *Pseudomonas* spp., *Aeromonas* spp., *Alcaligenes* spp, *Acinetobacter* spp, *Stenotrophomonas* spp., and *Salmonella* spp. Gram-positive isolates are also encountered with *Staphylococcus* spp. and *Clostridium* spp., as reported in some investigations.[33–36]

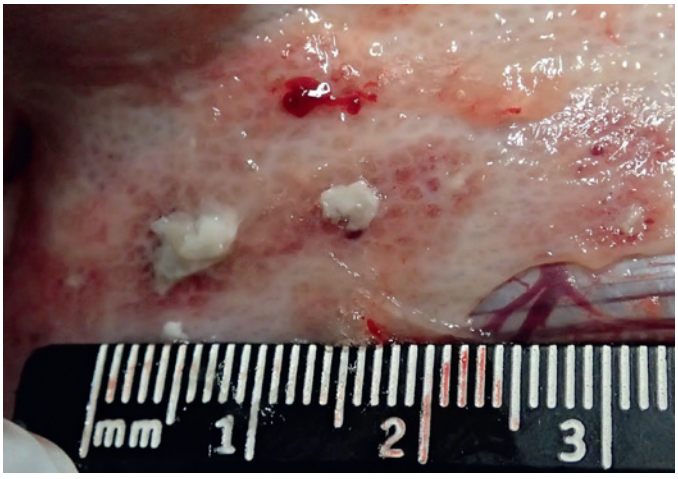

FIG 73.6 Pharyngeal plaques in an eastern box turtle (*Terepene carolina carolina*), associated with ranaviral infection. (Courtesy of Ryan De Voe.)

Cheilitis associated with *Devriesea agamarum* is reported in lizards from the genus *Uromastyx*. *Devriesea agamarum* is considered a facultative pathogenic bacterium and is found in the oral cavity of some healthy bearded dragons (*Pogona vitticeps*) but is also capable of causing infection in abraded skin experimentally in the same species.[37]

Mycobacterial infections of the upper gastrointestinal tract are occasionally reported and are likely more common than the literature suggests. Atypical species such as *Mycobacteria marinum, M. chelonae,* and *M. fortuitum* are usually isolated from mycobacterial lesions. *Mycobacterium* species typically involved in infections are ubiquitous environmental organisms; some manner of predisposition to infection is likely required to effect clinical disease. Histopathology or cytology with acid-fast staining and collection of samples for mycobacterial culture should always be considered, especially in cases that become chronic and/or do not respond as expected to conservative therapy.[38]

Chlamydophila-associated disease is reported in emerald tree boas (*Corallus caninus*) with "regurgitation syndrome," which is a relatively common syndrome in this species. Based on clinical experience and anecdotal data, it does not appear that chlamydiosis is the sole cause of regurgitation syndrome. Gastric atrophy and fibrosis is the end state of emerald tree boas with regurgitation syndrome and can likely occur as a sequela to any condition causing chronic gastritis.[39]

Mycotic Diseases

There are occasionally mycotic components to stomatitis, esophagitis, and gastritis. It is likely that most of these mycotic infections in captive reptiles are secondary to compromised defense mechanisms due to poor husbandry. Mycotic coinfections with other pathogens are also possible, as well as secondary infection of traumatic injuries or neoplastic lesions. Prolonged, broad-spectrum antibiotic use may predispose to dysbiosis and mycosis.

VetBooks.ir

Some fungal organisms capable of causing infections of the upper gastrointestinal tract are thought to be primary pathogens. *Metarhizium viride* and *Metarhizium granulomatis* are reported to cause disseminated mycosis in veiled (*Chamaeleo calyptratus*) and carpet chameleons (*Furcifer lateralis*), panther chameleons (*Furcifer pardalis*), and bearded dragons, including granulomatous glossitis and stomatitis. These fungi are grouped in the family Clavicipitaceae and are thought to be primary pathogens.[40–43] *Purpureocillium lilacinum* (*Paecilomyces lilacinus*) is another potential pathogen of reptiles capable of causing infections of the upper gastrointestinal tract, which is in the family Ophiocordycipitaceae. *Purpureocillium lilacinum* is a ubiquitous, saprophytic fungi frequently encountered in moist, humid environments.[44] *Candida* spp. infections of the upper gastrointestinal tract are reported. Cytology, histology, culture, and PCR are used to detect *Candida* spp. and other yeast species in diagnostic samples.[45]

Parasitic Diseases

Helminthiasis. Parasitism of the oral cavity and esophagus with digenetic trematodes from the families Ochetosomatidae and Plagiorchiidae is relatively common in wild reptiles that consume intermediate amphibian hosts (Fig. 73.7). The adults of these species are also often found in the lungs. There is usually very little if any pathology associated with the presence of oral flukes in healthy animals, although they can cause localized inflammation where they attach to the epithelium. The lesions at the attachment sites may become secondarily infected and lead to morbidity, especially in compromised animals.[46] There are numerous helminths that inhabit the upper gastrointestinal tract of various species and can cause pathology. Parasite-associated gastritis has been reported in a number of species of crocodilians, chelonians, and squamates, free-ranging and captive.[46–48] Ascarids and strongyles, including parasites from the genera *Ophidascaris* and *Kalicephalus*, will infect the esophagus and stomach of snakes, occasionally causing gastritis, ulceration, and secondary bacterial infections.[46] Gastric impactions with helminths have also been reported (Fig. 73.8).[49] Helminths that normally reside in the nasal cavity, esophagus, and stomach may sometimes be encountered in the oral cavity and can be associated with stomatitis (see Chapter 32).

Cryptosporidiosis. Cryptosporidiosis is a potentially devastating disease of captive reptiles. In susceptible species, infection leads to a chronic wasting syndrome caused by the parasite's impact on the stomach or intestinal tract and subsequent maldigestion. *Cryptosporidium* species are ciliated protozoa assigned to the phylum Apicomplexa. A number of *Cryptosporidium* species are identified as reptile pathogens, including *C. serpentis, C. varanii/saurophilum,* and *C. ducismarci.*[50] There appears to be significant variability in the genetic identity of *Cryptosporidium* isolates obtained from reptile species, with novel species/variants routinely identified. It is reasonable to assume that not all *Cryptosporidium* organisms harbored by reptile species are uniformly pathogenic and cause consistent clinical signs. *Cryptosporidium* species than infect reptiles have not been documented as capable of causing infection or disease in mammals and birds and are therefore not known to cause zoonotic infections. Conversely, *Cryptosporidium* species that cause infections and disease in mammals (including *C. muris* and *C. parvum* of rodents) and birds are not known to infect reptiles. *Cryptosporidium* organisms can pass through the gastrointestinal tract of nonsusceptible species with no ill effect to the animal and remain viable.[51] This discussion will focus on cryptosporidiosis in snakes and lizards.

Many species of snakes are fed domestic rodents in captivity, which often harbor *Cryptosporidium* species such as *C. muris* or *C. parvum.* These organisms may traverse the gastrointestinal tract and pass in the feces, being microscopically indistinguishable from *Cryptosporidium* species that are pathogenic to reptiles. Molecular characterization is typically required to identify the species of *Cryptosporidium* and subsequently assign significance to its presence. Coinfections may occur that predispose animals to clinical *Cryptosporidium* sp. infections when they might otherwise not be susceptible.[52–54] A conundrum can occur when novel *Cryptosporidium* species are identified in asymptomatic individuals. Pathogenicity can be difficult to predict both in the species harboring the organism and others that may be exposed.

Clinical signs observed in reptiles suffering from cryptosporidiosis may vary according to host species and likely the particular *Cryptosporidium* species. Vomiting, anorexia, and chronic wasting leading to emaciation (Fig. 73.9) are fairly consistent clinical signs. Diarrhea is also seen; however, decreased fecal output due to anorexia can make observation of this clinical sign difficult. On physical examination snakes with advanced disease will often be emaciated with a palpably firm stomach, which may cause a grossly visible soft tissue mass effect (Fig. 73.10).[46] Snakes with cryptosporidiosis typically suffer from hypertrophic gastritis (Fig. 73.11), which leads to fibrosis and ultimately maldigestion. Occasionally cryptosporidial enteritis with or without gastritis may be encountered in snake species.[55] Infection of the gall bladder and intrahepatic bile ducts has also been reported in corn snakes (*Pantherophis guttata guttata*).[56] Although it is suggested that some animals may be

able to recover from cryptosporidiosis, with or without supportive care and treatment, in most animals the disease process is progressive and eventually leads to death.

Diagnosis of cryptosporidiosis in snakes can be challenging. Examination of feces via direct smear cytology, fecal floatation, and acid-fast staining is useful in screening suspect animals. Polymerase chain reaction of samples for DNA detection is sensitive and specific.[57] In addition to feces, gastric lavage or gastroscopy may provide useful samples for screening snake species. Typically, gastric lavage is performed 2 to 3 days after feeding, as this practice enhances recovery of organisms.[46] The mucus from vomited prey items may also be used for detection of *Cryptosporidium* spp. organisms. Fecal antigen assays for *C. parvum* are occasionally used as a screening tool because cross-reaction may occur with other *Cryptosporidium* species. Confirmation of the *Cryptosporidium* species should be pursued in an effort to assign clinical significance, especially in asymptomatic patients. Species identification is typically accomplished via molecular characterization of the organism. Gastric biopsy with histopathology, performed either surgically or endoscopically, can help confirm a definitive diagnosis of clinical cryptosporidiosis in snake patients.[58] Assays to detect antibodies to *Cryptosporidium* sp. organisms are described in the literature, but antibody titers can fluctuate, showing alternating positive and negative results in infected animals.[59] If antibody titers are measured, diagnosis should not be based only on a single antibody titer to *Cryptosporidium* sp.

Management of asymptomatic animals that are diagnosed as carriers of *Cryptosporidium* sp. (*C. serpentis*, *C. varanii/saurophilum*, *C. ducismarci*, or other species/genotypes) should be based on risk assessment of the specific situation. In cases where the animal is a pet in a single-reptile household, the animal may live an acceptable life, so no actions may be warranted as long as the animal remains clinically normal. If the animal is a part of a larger population, either of the same species or a cosmopolitan collection, the health of the population as a whole must be considered. Culling of carrier animals may make sense if the existing population is devoid of carrier animals or the carriage rate is low. In cases where animals are considered valuable from a genetic/conservation standpoint, a permanent quarantine situation may be indicated.

A number of treatment approaches are described to address cryptosporidiosis in reptiles; however, none are uniformly effective, and usually amelioration of clinical signs for a period of time is the best that can be expected. Treatment with paromomycin can result in improvement of clinical signs and a decrease or cessation of shedding in some animals, but progression of the disease and shedding typically resumes when treatment is discontinued. At least one study reports clearance of *Cryptosporidium* infection in asymptomatic bearded dragons treated with paromomycin, though similar information is not available for snakes.[60] Other therapies such as halofuginone, spiramycin,[61] and trimethoprim/sulfamethoxazole can also induce decreases or cessation of cryptosporidial shedding but do not appear effective in clearing infections. Treatment with hyperimmune bovine colostrum created utilizing *C. parvum* isolates appears effective in clearing infections in subclinical animals but not those showing clinical signs. Unfortunately, this treatment option is not readily available and beyond the capabilities of most clinicians.[62] Supportive care in the form of fluid and nutritional supplementation may improve clinical signs and/or slow progression of the disease.

Disinfection of *Cryptopsoridium* sp. can be difficult. Mechanical cleaning and removal of organic material before application of chemical agents is necessary for effective disinfection. Standard bleach solutions, quaternary ammonium compounds, phenols, alcohol, iodine, and glutaraldehyde are typically ineffective against *Cryptosporidium* oocysts. High kill rates can be reached with application of 3% hydrogen peroxide or ammonium hydroxide solutions for 20 to 30 minutes. Information regarding disinfection is typically based on studies with *C. parvum* isolates, so some variation may exist between different *Cryptosporidium* species.

Due to the lack of consistently effective therapeutics for treatment of cryptosporidiosis in snakes, control hinges on effective screening of animals and implementation of appropriate biosecurity measures.

MALNUTRITION

Hypovitaminosis A can result in squamous metaplasia of tissues of the oral cavity and upper gastrointestinal tract. Structural abnormalities and dysfunction of these tissues can predispose reptiles to secondary infections, cheilitis, and stomatitis. Captive chameleons, geckos, and other lizard species fed diets without supplementation of preformed vitamin A often present with clinical signs suggestive of hypovitaminosis A.[63,64] Nutritional secondary hyperparathyroidism can lead to skeletal deformities of the skull, resulting in chronic exposure of oral mucous membranes. Dessication of mucous membranes and/or increased incidence of trauma may increase risk of developing stomatitis.

MALDIGESTION DUE TO ENVIRONMENTAL AND DIETARY ISSUES

Ingestion of meals that are too large and/or consumed when the animal is too cool, dehydrated, etc. can cause vomiting or even morbidity and mortality due to putrefaction of ingesta in the gastrointestinal tract. Vomiting is typically a protective response when the environment cannot support the physiological conditions necessary for effective digestion. Animals that are not able to expunge a putrefying food item often suffer from associated gastritis/enteritis and potentially endotoxemia and/or septicemia (Fig. 73.12). Gas-producing bacteria often proliferate in these conditions, causing bloating, which can be severe. Passage of fetid gas from the oral cavity or vent may also be appreciated. Effective therapy is based on removal of any decomposing food items in the gastrointestinal tract via lavage or catharsis, correction of dehydration, and improvements in captive management. Local gastrointestinal protectants such as bismuth subsalicylate, and sucralfate may also be indicated.

Handling or significant stress can also induce vomiting, especially in snakes and carnivorous lizards. It is usually advisable to avoid handling of carnivorous reptiles during at least the gastric phase of digestion. Typically, there is no lasting consequence following an isolated incident of handling or stress-induced vomition. However, the event can be quite unpleasant for the personnel in attendance.

FOREIGN BODIES

Foreign bodies are occasionally encountered in the oral cavity, esophagus, and stomach (Fig. 73.13). Sometimes it can be difficult to tell if a foreign body in the stomach is clinically significant and requires intervention. Reptiles, especially those that are not fed frequently, may not show recognizable clinical signs associated with foreign bodies of the upper gastrointestinal tract until the condition is quite advanced. Oral and esophageal foreign bodies may induce ptyalism, retching, clawing at the mouth, and reluctance or inability to feed. Regurgitation or vomiting may occur with esophageal or gastric foreign bodies, but many animals will simply become anorectic and lose body condition.

Many animals will incidentally pick up and swallow small stones or other pieces of substrate when they eat. Pica can also occur due to calcium-deficient diets and nutritional secondary hyperparathyroidism. Calcium carbonate sands that are touted as "digestible" can cause problems as readily as any other particulate substrates. If particle size is small and the material is not consumed in large amounts, incidental consumption of substrate is typically not a problem. Sharp pieces of mulch from the substrate can cause traumatic injury to the mucosa and rarely perforation. Dehydrated polyacrylamide hydrogels can also act as foreign bodies if ingested.

Pet reptiles that are allowed to free-roam in the household often consume inappropriate items they come in contact with. Not only can these items cause trauma or obstruction in the gastrointestinal tract, but toxicosis is also possible. Other animals that are indiscriminate or aggressive feeders will sometimes ingest inappropriate items that require recovery. Snakes will often consume items that smell like a prey item. The classic history is a snake that was fed a rodent on a towel and went on to swallow the towel after the rodent. Egg-eating snakes will occasionally consume indigestible "dummy eggs" that are used in aviculture or other foreign bodies that resemble eggs. Depending on the size of the snake and the foreign body, it may be possible for the animal to naturally pass the item through the gastrointestinal tract. Especially large foreign bodies that are present in the esophagus or stomach for long periods of time can cause pressure necrosis of the esophagus or gastric wall.[65] Recovery of foreign bodies from the stomach of snakes can be relatively easy, and nonsurgical techniques should always be considered before surgical intervention. In many cases, the snake is anesthetized, intubated, and following instillation of a water-soluble lubricant into the stomach via gavage, the item is "milked" orad and removed via the mouth. This

method is not appropriate for items that could potentially cause trauma or those that have traveled aborad to the stomach.

With other taxa, endoscopic retrieval of esophageal or gastric foreign bodies is usually possible. The limiting factor is typically the size of the animal, as with diminutive species the available equipment is simply not suitable. With very large lizards and crocodilians, manual retrieval of foreign bodies may be possible. For both animal and human safety concerns, this technique should only be utilized with a properly anesthetized and/or restrained animal. Surgical removal of foreign bodies via esophagotomy or gastrotomy are both relatively straightforward procedures for competent veterinary surgeons.[65]

NEOPLASIA

A variety of neoplastic conditions are described involving the upper gastrointestinal tract of various reptile taxa.[66–68] Neoplasia should be a differential for any mass associated with the upper gastrointestinal tract, especially in older animals. Nonhealing ulcers/erosions, recurrent abscessation, or nonspecific inflammatory conditions should also raise suspicion of a neoplastic process. Typically, assumptions of how reptilian neoplasms will behave and what treatment is most appropriate are based on information available for domestic animals.

Gastric neuroendocrine sarcomas have been described specifically in bearded dragons (*Pogona vitticeps*). Metastasis to the liver is frequently identified. A number of these neoplasms have been identified as somatostatinomas, though some tumors have exhibited multihormonal expression. Hyperglycemia, weight loss, and anemia are typical symptoms associated with these neoplasms.[69,70]

Gastroenterology—Small Intestine, Exocrine Pancreas, and Large Intestine

Kevin Eatwell and Jenna Richardson

The identification of primary enteric or pancreatic disease in reptiles can be difficult. Clinical signs such as emaciation, anorexia, or altered fecal consistency may suggest disease but are often nonspecific. Confirmation of specific disease processes can be challenging, and overinterpretation of fecal microbiology and parasitology can occur.

ANATOMY AND PHYSIOLOGY

Small Intestinal Tract

Reptiles are adept at surviving and thriving in a variety of environmental niches. To do this, they have evolved selective anatomical and physiological differences compared with mammals and birds. Even within different reptile orders, there can be variation in anatomy and function of the digestive tract. These differences can pose challenges to the practitioner when interpreting physical examination findings, diagnostic imaging, and determining appropriate therapeutic regimes.

The reptilian gastrointestinal (GI) tract has many similarities to higher vertebrates with an oral cavity, oropharynx, esophagus, stomach, small intestine, and large intestine. The terminal GI tract, the cloaca, is similar to that found in avian species. The length of the reptilian GI tract varies between species and generally is dependent on the composition of the natural diet. Carnivorous reptiles have a shorter GI tract length, followed by omnivorous species, and the longest GI tracts are found in herbivores.

Within the intestines, longitudinal muscular folds are present. This allows for distention of the lumen to cope with the consumption of large volumes of ingesta. As the intestines are the primary site for absorption of nutrients, the folds also increase the surface area to facilitate this. The pH of the intestines varies, from being slightly acidic to slightly alkaline (pH 6.5–8).[1]

Chelonian small intestines are located in the caudal coelomic cavity. In many species there is no clear divide between the duodenum, jejunum, and ileum. The small intestines function similar to that of mammals; however, proportionally the tract is shorter. A connection between the blood supply of the intestines and the parenchyma of the liver is seen in most species, creating a hepatoportal system. As would be expected, there is an aborad decline in digestive enzyme activity.[2]

In snakes, the small intestine empties directly into the colon, with the exception of boid snakes, which generally have a small cecum located at the proximal colon. In most reptiles, the large intestines are composed of the cecum and colon, before terminating in the coprodeum of the cloaca. With lizards and chelonians, the cecum is usually found in the right caudal coelomic cavity. The cecum may be difficult to differentiate visually from the colon. It appears as a widening of the colon wall, rather than a distinct separate organ, as seen in mammalian species. In chelonians, the cecum is not well developed.

In herbivorous species, the colon can appear sacculated, with multiple subchambers in which fermentation occurs. Differentiation is seen between juvenile and adult animals of some species. With iguanas, there is a marked difference dependent on age, with more defined saccules in the adult. This accounts for the dietary changes that occur as the lizard matures. Complex carbohydrates—for example, cellulose—are broken down via fermentation to simple sugars and fatty acids. In iguanids, the principle protozoon, *Nyctotherus* sp., are believed to serve as beneficial commensals required for the processing of dietary cellulose and other complex carbohydrates in the sacculated colon.[3] This ciliated organism is an important commensal in hind-gut fermenters. Herbivorous reptiles generally have a higher optimal body temperature range compared with carnivorous reptiles, which helps promote microbial fermentation. Examples of hind-gut fermenters include the iguanas (*Iguana*, *Cyclura*), prehensile-tailed skink (*Corucia zebrata*), spiny-tailed lizard (*Uromastyx* spp.), and chuckwalla (*Sauromalus* spp.) In those species that lack a bladder, urates can travel into the distal colon where they are retained along with fecal material before they are voided.

Pancreas

In lizards, the pancreas is trilobed, with each lobe extending toward the gallbladder, duodenum, and spleen, respectively.[4] In chelonians, the pancreatic and bile ducts enter the pylorus instead of the duodenum. A study characterizing pancreatic lipase in turtles showed no significant differences between it and known mammalian pancreatic lipases.[5] In snakes, the pancreas is located caudal to the stomach in the area of the gallbladder and spleen. It is often pyramidal in shape and is more consolidated than in other reptiles.[4] In some species, it is intermixed with the splenic tissues to form a splenopancreas.[6] Even when closely related species are considered, there are variations of the macroscopic structure.[7]

The function of the reptilian pancreas is comparable to that of mammals, and it produces a similar range of enzymes. The pancreas is composed of both endocrine and exocrine tissue. The endocrine component lacks a sharp demarcation from the exocrine pancreas, as seen in mammals. The pancreatic islets of lizards and snakes are larger than those of crocodilians and chelonians.[7] Alpha cells are more abundant in lizards, with alpha and beta cells equally present in snakes, chelonian, and crocodilians. The exocrine pancreas secretes digestive enzymes, including lipolytic, proteolytic, and amylolytic enzymes. Insectivorous reptiles also produce pancreatic chitinase.[8] The exocrine parenchyma consists of branching tubules, unlike mammalian species that display typical acini.

Reptile pancreatic "juice" contains alkaline secretions, as well as these digestive enzymes. The alkaline secretions neutralize the acidic stomach contents as they enter into the duodenum. This buffer provides an ideal environment for the digestive enzymes to act, further breaking down ingesta. In one study in the Burmese python (*Python bivittatus*), the

effects of feeding on pre- and postprandial pancreatic trypsin and amylase saw respective 5.7- and 20-fold increases in the peak activities following feeding. The pancreas also doubled in mass during this time.[9] The production of the different ratios of digestive enzymes appears linked to the diet and feeding strategy of the reptile.

CLINICAL INTESTINAL DISEASES

Nematodiasis

Clinical Significance and Etiology. Common parasites vary depending on the species of reptile and its origins. Wildlife casualties, recently imported specimens, or those housed outside in their native region have access to intermediate hosts and parasites with indirect life cycles. Long-term captive animals or captive-bred individuals usually lack access to intermediate hosts, and so only parasites with direct life cycles are typically problematic. Parasite identification can prove helpful in determining the origins of a purchased animal. A wide variety of nematodes can be seen, and the important species are summarized in Table 74.1. (See Chapter 32 for more details.)

Clinical Presentation. The clinical presentation of enteric parasites can vary. Parasitism may be identified when performing routine fecal evaluations (fecal flotation, direct smears) in apparently healthy individuals or in patients where enteric disease is a differential diagnosis. For owners, often the first indication of parasitism in their pet is the visible presence of worms in feces. Adult oxyurids are commonly seen, presenting as small white threads, and measure 1.5 to 7 mm in length. Ascarids are large (up to 10 cm in length) and can be yellow in coloration (Fig. 74.1).

Common clinical signs associated with enteric disease include anorexia, emaciation, diarrhea, regurgitation, vomiting, coelomic discomfort, colonic prolapses through the cloaca, stunted growth, and death.[10,11] Heavy burdens of ascarids or strongylids can lead to intussusception, ulceration, avascular necrosis and fatal intestinal impactions.[12–14] Visceral migration can lead to damage in other tissues.[15]

Oxyurids are commonly seen in juvenile lizards and chelonians (Fig. 74.2). Snakes are less commonly affected. Factors such as small enclosures, poor environmental hygiene, or exposure to natural substrate where the nematode eggs can overwinter can be significant.[16] The need for treatment is usually based on parasite load (rather than mere presence) and the physical condition of the reptile. Low levels of oxyurids are often inconsequential.[17] Generally all individuals housed in a group are

treated, and a pooled fecal sample can be used when testing a group. If treatment is not warranted, ongoing routine monitoring of parasite levels is still advised.

Ascarids typically utilize an intermediate host, although some chelonian ascarids have a direct life cycle. These species undergo extensive tissue migration resulting in significant pathology. *Ophidiascaris* and *Polydelphis* are present in snakes feeding on amphibians and rodents, which are intermediate hosts. Ascarids are also a common finding in crocodilians.[18]

Rhabditid nematodes have a direct life cycle and typically inhabit areas outside the intestinal tract, but *Strongyloides* can be found in the small intestine of snakes. Diarrhea and weight loss can be seen. *Kalicephalus* and *Diaphanocehalus* are strongyloid nematodes with direct life cycles. Hemorrhagic ulceration, malabsorption, diarrhea, and obstruction can be seen with heavy burdens. Capillaria can be found in lizards, snakes, and crocodilians. Spiny-headed worms (Acanthocephalans) have an indirect life cycle and can be seen in the small intestine of freshwater turtles.

Diagnostic Confirmation. Fecal analysis remains one of the most commonly performed tests in veterinary practice. Samples should be fresh, free from contamination, and not desiccated. Samples need to be kept moist and can be stored in a plastic container. If not processing the sample immediately, it should be refrigerated to slow bacterial overgrowth and parasite development.

An anorectic presentation, combined with the typically slow GI transit time, can result in difficulty obtaining a fecal sample. This is particularly true for larger, carnivorous reptiles. Assisted orogastric tube feeding can provide nutritional support while also encouraging gastrointestinal motility and the passing of fecal material. Warm water baths may stimulate bowel movement (Fig. 74.3), whereas some patients (i.e., chelonians) may void a fecal sample during handling.

For those patients that are still challenging, cloacocolonic flushes can be performed (Fig. 74.4). The lubricated, smooth-ended tube (an avian metal crop tube, red rubber catheter, or, for small reptiles, a plastic feline urinary catheter is appropriate) should be directed dorsally through the cloaca. Warmed water or physiological saline is infused slowly at a volume determined by the size of the animal (1–2 mL per 100 g body weight).[7] The reptile is gently massaged in the caudal coelom before the sample is aspirated. In this situation, the sample should be centrifuged to allow analysis of the sediment of fecal material.

FIG 74.3 Two sulcata tortoises (*Centrochelys sulcata*) having a warm water bath to encourage defecation for fecal sample analysis. (Courtesy of Jenna Richardson.)

Gross visual assessment is required to first confirm adequate fecal material for analysis but also to evaluate the nature of the feces compared with that expected for the species and the diet fed. Fresh or digested blood, mucus, adult parasites, or segments may be visually apparent.

For fecal parasitology testing, qualitative analyses (wet preparation and flotation) are routine and provide a general overview of the burden of parasites present, including identification of eggs and motile organisms. Flotation methods help concentrate parasite numbers so that low burdens are not missed. A modified McMaster technique can be used to quantify egg counts following qualitative evaluation and can also aid identification by reducing contaminants (Fig. 74.5).[16] Different flotation solutions can be used and are detailed in Table 74.2. Other, less commonly used protocols include fecal sedimentation and centrifugation techniques for small samples (e.g., cloacocolonic wash) or specific parasites (e.g., spiny-headed worm ova). These tests require minimal equipment to perform, with standard protocols readily available (see Table 74.3).[19,20]

Oxyurid ova have a variable appearance but are generally thin-walled, measuring ~130 × 40 µm, and may appear either oval or asymmetrical (D-shaped). Ascarid eggs are round with a thick shell and typically measure 80 to 100 × 60 to 80 µm. Strongylid eggs appear thin-walled with blunt ends, with the developing embryo filling most of the shell. They measure ~70 to 100 × 40 to 50 µm. Rhabditid ova are thin-walled embryonated eggs and measure ~60 × 35 µm. Capillaria ova have a typical lemon shape with end caps at each pole.

Specific Therapy. Owners are often aware of the need for prophylactic parasite control in dogs and cats and therefore may apply similar

VetBooks.ir

principles to their reptile pets. There are many "(de)worming" products available, both online and in pet stores. These can often be purchased and administered without veterinary consultation. Owners should be encouraged to seek veterinary advice and present their reptiles for routine health checks. Routine fecal parasitology testing can be performed at this time, which prevents unnecessary treatments of reptiles without parasite burdens.

TABLE 74.2 Flotation Solutions

Salt flotation	Sodium chloride salt flotations are used most commonly but can severely distort parasite eggs. Heavier eggs (such as fluke eggs) will not float in this solution, and alternative methods would be preferred for imported specimens or wildlife casualties. It is easy and economical to make up the saturated solution from salt, which is added to water until no more dissolves (usually 40 g/100 ml).
Zinc sulfate flotation	Add 371 g of zinc sulfate to 1 liter of water while stirring continuously (mild heating can be used to hasten the dissolution process).
Sodium nitrate flotation	Add approximately 400 g of sodium nitrate to 1 liter of water while stirring continuously (mild heating can be used to hasten the dissolution process).
Sugar flotation	Pour 355 mL of **warm** water into a beaker and place onto a hot plate. Heat water on high but **do not boil**. Slowly add 454 g granulated sugar, stirring constantly until dissolved completely. Remove from heat and cool.

Routine prophylactic treatment for enteric parasites is not advised. Unnecessary treatment courses may not be benign, with side effects reported with commonly used antiparasitic drugs. Instead, treatments should be tailored to the health status of the patient and the results of fecal parasitology screening tests.

Benzimidazoles are commonly used to treat helminthiasis in reptiles, with fenbendazole, oxfendazole, and albendazole being commonly available. Fenbendazole is metabolized by the liver to the more active oxfendazole, and therefore lower doses given daily for 3 to 5 treatments are generally more effective than a single high dose. Fenbendazole toxicity leads to radiomimetic signs and has been reported in a number of reptiles.[21] Oxfendazole is generally considered less toxic in a number of species[22,23] and, as the more active compound, would be expected to be more efficacious following a single dose. Research at the University of Georgia demonstrated the ability of oxfendazole (25 mg/kg PO once) to reduce oxyurid egg counts to zero in green iguanas (Kehoe, Divers, Verocai, unpublished data).

Levamisole has a narrow margin of safety, and so oral treatment is recommended over parenteral use. Neurological signs can be seen with toxic doses.[24] Pyrantel is very similar in action to levamisole and is a substituted imidazothiazole derivative. It has been used orally to treat nematode infections.

Ivermectin toxicity in chelonians is well known.[25] Caution has also been advised in indigo snakes and skinks.[26] Ivermectin is generally not advised for treatment of enteric helminths.

Monitoring fecal samples routinely is important to evaluate the effectiveness of any treatment regimen, and repeat samples are usually recommended 3 to 4 weeks after treatment. Ongoing monitoring to identify any increases in burden from the environment is also advised every 6 months.

After treatment, the worm egg count in the feces must diminish before moving the animal to a new enclosure or placing/replacing the

TABLE 74.3 Common Fecal Analytical Methods

Technique	Details
Wet preparation	A small amount of fecal material is thoroughly mixed in warmed saline on a glass slide. Large pieces of fecal material are removed. This is examined under the ×10 objective for eggs and larvae and then under ×40 for motile protozoa and cysts. If the sample has been chilled, it can be rested on a heated coin to encourage motility on the slide.
Fecal flotation	Feces are added to the flotation solution and gently mixed thoroughly. This is poured through a tea strainer (or alternative), and large particulate matter is discarded. The filtered liquid is titrated into a small container and topped up with flotation solution to form a meniscus. A cover slip is gently placed on top of the tube. The tube is allowed to rest for 20 minutes. The cover slip is then removed by pulling it vertically off the top and is placed onto a glass slide. This is then examined under ×10 and ×40 objectives.
Modified McMaster technique	Weigh out 1 g feces and mix with 15 mL of flotation solution. Strain through a tea strainer and fill up both sides of the McMaster slide. Leave to stand for 20 minutes. Examine both grids. Count all eggs that lie within the lined 1 cm^2 of the counting chamber and repeat for the second side. Each side is filled with 1% of the original volume. So multiplying the total by 50 gives the eggs per gram.
McMaster technique	Weigh out 3 g of feces and mix with 42 mL of flotation solution (approximately 45 mL total volume) and strained through a tea strainer. Leave the solution to stand for 20 minutes. Remove the meniscus with a pipette and load the McMaster chamber on both sides. Count all eggs that lie within the lined 1 cm^2 of the counting chamber and repeat for the second side. The calculation is based on the fact that the depth of the chamber is 1.5 mm, and the volume of fluid examined is 0.15 mL, which is 1/300 of the original volume of 45 mL. Therefore each egg counted represents 300 per 3 g of feces, which is equivalent to 100 eggs/g. When done in duplicate, the total count of the two chambers is multiplied by 100 and divided by 2.
Sedimentation technique	This is ideal if a cloacal flush has been performed and the sample is dilute. Strain the mixture (adding saline if needed) through a tea strainer and pour into a centrifuge tube. Centrifuge the tube for 3 minutes at 1500 rpm. Decant the supernatant off, and transfer a small amount of the sediment to the microscope slide and dilute with saline if needed.
Formalin and ethyl acetate concentration	Place 6 mL of 10% buffered formalin into a centrifuge tube. Add feces and emulsify thoroughly. Leave overnight. Cysts and ova will be preserved by the formaldehyde, although motile forms will not survive. Then mix gently and strain the sample through a tea strainer. Add 5 mL ethyl acetate and mix gently, leave for 10 minutes for the fat globules to dissolve, and centrifuge at 1500 rpm for 30 seconds. Decant the supernatant off, resuspend the deposit by agitation, and place a drop on the slide and dilute with saline if needed.

cage furniture or substrate. This can take a protracted time, up to 31 days in chelonians.[27] Timing of treatment is important, as the reptile must be metabolically active for treatment to be effective. As a result, do not treat close to hibernation or brumation. Those reptiles with high parasite burdens should not be hibernated until treatment has proven effective.

Prognosis and Prevention. Nematode infections can have varying outcomes depending on the health status of the reptile and the level of parasite burden. In severely affected cases, supportive care including fluid therapy and nutritional support may be required, together with antiparasitic treatment.

Environmental management is of utmost importance for prevention of parasites with direct life cycles. Prompt removal of feces from cages is recommended, whereas those maintained in larger outdoor enclosures would benefit from strategic treatment and movement (similar to pasture management of domesticated horses and ruminants). Generally, several days are required for life stages to become infective, and therefore daily cleaning is usually adequate. Fecal material left in the tank can easily be spread around the enclosure and contaminate food sources. Housing reptiles on newspaper with minimal cage furniture is advised for those undergoing antiparasitic treatment until repeat fecal samples have confirmed effective control of the parasite. Live prey can become contaminated with fecal material from the enclosures. To reduce the risk of environmental contamination, the reptile can be fed in a separate area from their regular housing.

Trematodiasis

Trematodes (flukes) can occur in a wide variety of tissues. Only a few species inhabit the GI tract. Of these, *Aspidogastreas* can be identified in chelonians. These require an intermediate host in their life cycle (aquatic snails) and are limited to recently caught, wild reptile specimens. No clinical signs have been reported. Digenetic trematodes are more commonly seen and also rely on an intermediate host (typically snails). Again clinical signs are not reported. Transmission is via eggs passed in the feces or urine of the host animal. Diagnosis is based on the observation of adult fluke in the feces, cloaca, or mouth. Fluke eggs can be found in the feces and are large and yellow/brown with a single operculum.[28]

Flukes can be treated with parenteral praziquantel, with a repeated dose required 14 days later. Prognosis is usually favorable.[12] Prevention involves prevention of access to intermediate hosts. Amphibians (e.g., frogs) fed to reptiles should be frozen for at least 3 days before feeding to prevent potential transmission.[28]

Cestodiasis

Tapeworms are not an uncommon finding in the GI tract of reptiles. All reptilian tapeworms require an intermediate host. Three orders of cestodes are of significance in the GI tract. The proteocephalid tapeworm, *Ophiotaenia*, is the most common tapeworm found in wild-caught North American snakes.[29] Frogs serve as the intermediate host. In reptiles the eggs or adult tapeworms can be identified in the feces. Diphyllobothrid tapeworms (*Bothridium* sp.) are found as adults in pythons, whereas other species use reptiles as intermediate hosts. Mesocestoidid tapeworms can be found as adults in the GI tract of snakes and lizards, but most tapeworms of this family use them as intermediate hosts.

Often reptiles with tapeworm infections are asymptomatic; however, if numbers are large enough, enteritis, malnutrition, and intestinal obstructions can occur. The diagnosis rests on the identification of segments or whole parasites in fecal samples. Adult cestodes are treated using parenteral praziquantel, with a repeated dose required 14 days later.

Cryptosporidiosis

Clinical Significance, Etiology, and Presentation. *Cryptosporidium* is a small coccidian parasite frequently encountered in a wide variety of wild and captive reptiles worldwide. Unlike other coccidia, pathogenicity does not appear to depend on number of parasites, but instead is due to the reduced immunocompetence of the host or presence of concurrent disease. *Cryptosporidium serpentis* causes gastric disease in snakes; however, *C. varanii* and *C. saurophilum* in lizards causes enteric disease.[30] The parasite has a direct life cycle but is also able to replicate within the host. Ingested sporulated oocysts each produce four sporozoites in the intestine that develop into trophozoites in parasitophorous vacuoles within intestinal epithelial cells. Merozoites are formed and further cycles continue alongside the formation of oocysts that arise from sexual reproduction. These can be autoinfective or can be shed in the feces. Shedding in the feces is often intermittent, which can result in false negative fecal results. Cysts shed in the feces are immediately infective and are extremely resistant within the environment. All of these factors make *Cryptosporidium* difficult to eradicate from a collection.

Unlike snakes, in which gastritis is the norm, in lizards enteritis is the more common form, with associated anorexia, diarrhea, weight loss, and death (Fig. 74.6).[31] Passing undigested food and regurgitation are also possible.[32] An asymptomatic carrier state is also common, which can make the diagnosis of clinical disease problematic.[32,33] Enteric disease is unusual in snakes and chelonians.[16]

Diagnostic Confirmation. Cryptosporidia can be identified as part of a routine fecal examination. A simple screening method is to analyze repeat fecal samples, as the agent can be intermittently shed. A thin wet preparation is made and then air dried. *Cryptosporidium* staining kits are available commercially (Pro-Laboratory Cryptosporidium staining kit, Pro-Laboratory Diagnostics, Toronto, Canada) and are essentially a modified cold Ziehl-Neelson stain (see Table 74.4). Oocysts appear as bright red ovals approximately 4 to 8 µm in length, whereas bacteria and yeasts stain pale green (Fig. 74.7). Cryptosporidia can also be detected

1. Make a thin smear of fecal material on the slide and allow to dry.
2. The slide should be placed on the staining rack and covered with methanol (to fix the smear) before being allowed to air dry for 10–15 minutes.
3. Flood the dried slide with strong carbol fuchsin and leave for 10 minutes.
4. Gently wash the carbol fuchsin from the slide with deionized water and before flooding with hydrochloric acid.
5. Wait 1 minute then gently wash the hydrochloric acid from the slide with deionized water.
6. Repeat step 5 until the slide appears light pink in color.
7. Cover the smear with malachite green and leave for 30–60 seconds.
8. Rinse the slide for a final time with deionized water and allow to dry.
9. Examine under the ×100 oil-immersion objective.

by immunofluorescent staining using a commercially available test kit, which is 16 times more sensitive than acid-fast staining.[34]

These techniques do not differentiate *Cryptosporidium* species. This is a concern in species-fed mammalian prey, as *C. parvum* and *C. muris* can be passed incidentally in reptile fecal samples.[35] Correctly identifying the species is important, and this can be confirmed by polymerase chain reaction (PCR).[36] Pathogenicity can also be confirmed using histopathology of gastric or intestinal biopsies or samples collected postmortem, with immunofluorescent antibody testing to confirm the species of *Cryptosporidium*.[32,34]

Postmortem examination findings in lizards with enteric disease often show poor body condition. Cytology of the intestinal lumen can confirm large numbers of oocysts. Ultimately histopathology of the intestine is required to confirm a host pathogenic response. The organisms reside in the brush border of epithelial cells, and typically there is a marked infiltrative enteritis.[32]

Specific Therapy. Effective treatment is challenging, and no completely successful treatment regime has been reported. Paromomycin treatment in a small study of infected bearded dragons (*Pogona vitticeps*) was found to prevent oocyst shedding.[37] Bovine hyperimmune colostrum has shown more promise, with small studies in monitors showing a significant reduction in oocyst shedding, in addition to histopathological resolution of disease after a course of treatment. In geckos, however, in which intestinal cryptosporidiosis is common, colostrum treatment appeared less efficacious, possibly owing to changes to the structure of colostrum immunoglobulins after passing through the stomach.[38] Hyperimmune colostrum is not commercially available.[38] Other treatment options include ionophores, but severe side effects can be seen.[34] Treatments to stimulate the immune system (increasing temperature, immunomodulators) and provide nutritional and fluid support may help support the patient.[26] In severe cases or in collection management, euthanasia may be recommended.

Environmental control is therefore of critical importance to control cryptosporidiosis in a collection. The prompt removal of fecal material with disinfection of the environment is important, but even then oocysts can be difficult to eliminate. Routine disinfectants (iodophors, cresylic acid, sodium hypochlorite, benzalkonium chloride, sodium hydrochlorite) are all ineffective. Ammonia (5%) and formalin (10%) appear effective, but with a contact time of 18 hours at 4°C these may not be the most practical solutions.[39] Currently, moist heat (45°–60°C for 5–9 minutes), freezing, or desiccation appear to be the most effective ways to clear the environment.[40]

Prognosis and Prevention. In reptiles with clinical signs, prognosis is poor, with species-dependent chronic enteritis, and wasting disease seen. Asymptomatic reptiles may never show clinical disease but can act as source of infection with intermittent shedding of oocysts.

Quarantine and multiple testing of new arrivals (three examinations are recommended over a 60-day period) to reduce the risk of introduction to an existing collection is advised. Routine monitoring of animals in the collection by fecal screening and postmortem examination (including histopathology) is also recommended. Animals shedding oocysts should be isolated from the rest of the collection and undergo strict barrier nursing. Intermittent excretion may limit the effectiveness of this method. Removal of positive animals from the collection may be required. Vertical transmission does not appear to occur.

Amoebiasis

Clinical Significance, Etiology, and Presentation. *Entamoeba invadens* is a well-recognized pathogen of reptiles and has a worldwide distribution, although other *Entamoeba* species may also be pathogenic. A number of reports have described fatal amoebiasis in a variety of species, including carnivorous and herbivorous species, although the infection appears less common now than historically.[41] A variety of clinical signs may occur, but mucoid dysentery appears characteristic in most cases. Other signs include anorexia, wasting, dehydration, and eventual death. Tissue invasion by trophozoites is possible, with ulceration of the gastrointestinal tract and abscesses forming in the liver.[41] Entamoeba is spread via the ingestion of feces contaminated with cysts. It has a direct life cycle and can rapidly spread through a collection.

Diagnostic Confirmation. Diagnosis is based on detection of cysts or trophozoites in feces. A fresh wet preparation is made and should be examined immediately. The diagnosis of amoebiasis is possible by identification of amoebae, trophozoites (9–39 µm), or quadrinucleate cysts (9–24 µm) in a fresh fecal smear stained with Lugol's iodine. Carrier animals can be difficult to detect due to the low numbers of parasites shed.

Culture techniques are available but are not practical for clinical settings.[42] PCR is also available.[41] A variety of human diagnostic techniques exist but are yet to be applied to reptile amoebiasis.[32] On histopathology (or postmortem examination), signs of severe pathology

VetBooks.ir

can be seen. *Entamoebiasis* causes thickening and edema of the intestine wall, erosions, ulcers, and infection, which can extend to the liver, creating abscesses. Histopathologically, the organisms can be seen invading the bowel submucosa, causing a marked enteritis and, where infection of the liver is present, hepatitis.

Specific Therapy. Treatment for amoeba should target both trophozoites and cysts (so combination therapy is often recommended). Metronidazole is effective against trophozoites but has no effect against cysts. High doses have traditionally been recommended, but caution is advised in indigo snakes (*Drymarchon corais*), rattlesnakes (*Crotalus* sp.), and king snakes (*Lampropeltis getulus* sp.), as toxicity has been reported.[43,44] Paromomycin, diloxanide furoate, or iodoquinol are used to target cysts.

Adjunctive therapy with antibiotics may be considered due to the opportunistic invasion of lesions by bacteria; however, antibiotics have not been shown to improve survival in cases of gut-associated sepsis in humans.[45] Analgesia should also be considered given the severity of pathology induced by the organism.

Prognosis and Prevention. Morbidity and mortality can be high, with infection most commonly found in lizards and snakes and with chelonians usually acting as reservoir hosts. *Entamoeba* has been identified in herbivorous chelonians with no clinical signs.[43] Quarantine, cleaning, and effective disinfection of the environment is critical alongside routine screening for amoebiasis. Amoebic trophozoites and cysts are resistant and can survive in the environment for more than 14 days.[46]

Coccidiosis

Clinical Significance, Etiology, Presentation, and Diagnostic Confirmation. Coccidia are commonly identified in fecal samples, particularly those from lizards. Various coccidian species may be seen, and types of oocysts are generally differentiated by the number of sporocysts contained within an oocyst.[47] *Eimeria* oocysts normally contain four sporocysts, *Isospora* and *Sarcocystis* contain two, and *Caryospora* contains one. When ingested, the oocyst releases sporozoites that invade the cells and mature into schizonts. The cell then ruptures and releases merozoites that invade more cells. Merozoites also undergo sexual reproduction to form zygotes, which release the oocysts.

Low numbers of coccidia are rarely of concern, but numbers can escalate in juveniles in association with poor hygiene, overcrowding, or concurrent disease. *Isospora amphiboluri* is a common problem in young bearded dragons and may result in enteritis in high numbers (Fig. 74.8). Heavy numbers can also be seen associated with concurrent adenovirus infections.[48] This can lead to a wide range of clinical signs, including anorexia, lethargy, weight loss, diarrhea, tenesmus, prolapses, and death may occur if untreated. Stunting of juveniles is also a feature of heavy burdens. The diagnosis is made by fecal examination using the same techniques as described for helminths.

Specific Therapy, Prognosis, and Prevention. Treatment of coccidia is recommended for young animals or those with a moderate to high parasite burden. There is a variety of treatment options, with toltrazuril commonly used. It is alkaline and best diluted before oral administration. Trimethoprim/sulphonamides are also commonly used and are widely available as oral suspensions. Other options include the use of clazuril (see Chapter 120). Prognosis is dependent on the health status of the individual reptile and the coccidia burden. Prevention involves fecal screening of new reptiles to avoid introduction of disease, and environmental control with prompt removal of fecal material and good hygiene. Oocysts can be inactivated by freezing or exposure to high temperatures.

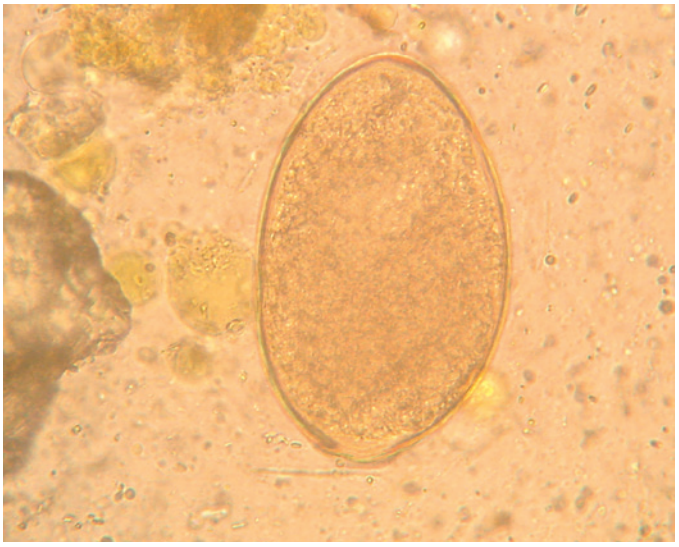

FIG 74.9 Ciliates, such as *Nyctotherius* (400× magnification), are a common finding in fresh fecal samples from chelonians and require no treatment. (Courtesy of Kevin Eatwell.)

Nonpathogenic Protozoa (Amoeba, Flagellates, and Ciliates)

Various amoebae, flagellates (typically *Trichomonas, Hexamita,* or *Giardia*), and ciliates (such as *Balantidium* and *Nyctotherus*) are often found in fecal samples and are generally considered nonpathogenic commensal organisms (Fig. 74.9). Larger burdens, however, can be associated with (but are often not the cause of) anorexia, weight loss, and diarrhea.[26,49] Higher levels may be found in animals housed on soil substrates.[16] Treatment of animals with clinical signs of enteritis is recommended.

A fresh wet preparation is used to detect motility in fecal samples. This ideally should be examined immediately. Once prepared, the slide can be gently warmed to stimulate motility. This is particularly important if the fecal sample had been refrigerated before assessment.

VetBooks.ir

Specific Therapy, Prognosis and Prevention. Although rarely indicated, oral metronidazole or ronidazole can be used to treat flagellates and ciliates. Care is advised in indigo snakes, rattlesnakes, and king snakes, as toxicity has been seen.[42,44] Repeat fecal assessment can be used to confirm effectiveness.

The presence of large numbers of protozoa can be indicative of an underlying disease process; however, mortality from primary protozoal overgrowths is not well supported in the veterinary literature. Good environmental hygiene, along with prompt treatment of episodes of diarrhea and anorexia, may prevent protozoal overgrowths.

Bacterial Enteritis

Clinical Significance and Presentation. Bacterial diseases are often blamed for illness in reptiles; however, clinical reports where specific bacterial pathogens have been implicated as a cause for intestinal disease are rare, with only one report of *Pseudomonas* recorded.[50] *Salmonella* can be isolated from reptile feces. Some reports state prevalences as high as 90%, whereas others have failed to identify any *Salmonella*.[51,52] Routine screening of reptiles for *Salmonella* is not recommended, as they are generally not pathogenic and are considered part of the normal intestinal flora.[53] Eradication is problematic due to vertical transmission and prompt horizontal transmission to juveniles after hatching.[53–56] *Salmonella* is a zoonotic concern, and there are a large number of reports of reptile-associated salmonellosis in humans (see chapter 174).[57–59] *Salmonella* has been associated with clinical disease in reptiles, most notably in an outbreak of Nile crocodiles where *Salmonella* was isolated from the gastrointestinal tract on postmortem examinations.[60] *Salmonella* has also be reported to cause enteritis in red-tailed boas (*Boa constrictor* spp.).[61]

Anaerobic infections are probably more common than currently reported, and consideration should be given to comparing fecal gram stains with culture results. *Clostridium perfringens* has been implicated in a case of diarrhea in a red-footed tortoise (*Chelonoidis carbonaria*).[62] Other agents such as *Mycobacterium* or *Chlamydia* may be identified in cultures or samples from the intestinal tract. *Chlamydia*-like organisms have been implicated in clinical enteritis in snakes and iguanas.[63–65]

Diagnostic Confirmation. Routine culture of feces will invariably yield positive culture results with a combination of aerobic (typically gram-negative, such as *Pseudomonas* and *Escherichia coli*) and anaerobic bacteria likely.[66,67] These often exhibit multidrug resistance. Infections caused by gram-negative aerobes are generally considered more common.[68] It is often assumed that these are primary or opportunistic pathogens that require treatment (Fig. 74.10). Confirming that a specific bacteria isolated from a fecal sample is pathogenic can be difficult. Hematology may yield altered white cell counts or toxic activity on blood films, indicating systemic inflammation. Confirmation of pathology relies on the identification of a host pathological response. This essentially means that serology, cytology, or histopathology (ideally) is required to confirm pathogenicity.

Specific Therapy, Prognosis, and Prevention. Antibiotic therapy, if indicated, should be based on culture and sensitivity results. The local/topical administration of antibacterials that are not absorbed from the GI tract (e.g., aminoglycosides) is often more efficacious. Repeat testing of the reptile is required to determine when treatment can be discontinued. Prognosis is dependent on the severity of dehydration and duration of the disease. Prevention is aimed at appropriate husbandry with suitable temperature ranges, environmental hygiene, and appropriate dietary items. Long-term oral antibiosis should also be avoided.

Fungal Enteritis

Fungal pathogens are typically opportunistic and have been reported in the GI tract; however, none are primary pathogens.[7] Knowledge of the normal intestinal microbiome of reptiles is scant, although likely to be highly varied.[69] In crocodilians and agamid lizards a wide variety of fungal species have been identified.[70,71] Yeasts are considered part of the normal flora, particularly in herbivorous species.[72,73] Overgrowths are often directly associated with the use of prolonged antibiotic therapy in reptiles, and isolates identified include *Aspergillus, Fusarium, Mucor, Candida, Penicillium, Basidiobolus*, and *Paecilomyces/Purpureocillium* (Fig. 74.11).

The diagnosis rests on the growth of organisms on fecal culture or identification of fungal elements on fecal cytology. The decision to treat should be based on the presence of a host pathological response on cytology or histopathology. This is not always possible, and generally clinical judgment is required based on the numbers identified. Nystatin is often used as a locally acting antifungal agent; however, systemically acting agents such as itraconazole or voriconazole may be required in advanced or disseminated cases.

Prognosis is good with low-grade infections but poor with major organ involvement or disseminated disease.[8] Prevention is aimed at

appropriate husbandry with suitable temperature and humidity levels, as well as stringent environmental hygiene.

Viral Enteritis

Viruses may be provisionally or definitively identified within the intestinal tract by the presence of enterocyte inclusion bodies or by viral particles in digesta or feces. In many cases the involvement of viral disease is identified on histopathology of intestinal biopsies or on postmortem examination. The difficulty arises when identifying the significance of the viral infection and relating this to the clinical presentation. Many viral infections are found associated with other pathogens such as bacteria or enteric parasites.[74] A summary of the enteric viral infections of reptiles is listed in Table 74.5 (also see Chapter 30, Virology).

Nutritional Disorders

Clinical Significance, Etiology, and Presentation. Metabolic bone disease, specifically nutritional secondary hyperparathyroidism, is common in captive reptiles. Gastrointestinal transit and motility are dependent on calcium concentrations, and reduced ionized calcium levels can lead to reduced GI motility and ileus. This can lead to increased fermentation of digesta, especially in herbivorous species, with marked gas production. The increased transit time can lead to progressive dehydration of bowel contents, obstipation, and the production of firm fecoliths. Husbandry-related problems can also play an important role in intestinal transit time. When environmental temperatures are too low, they can lead to a reduction in both appetite and fecal output, as the animal's metabolic rate and GI motility are reduced. Sudden dietary change can also lead to diarrhea, primarily due to the increased water or simple carbohydrate content of the food being offered, or associated with dysbiosis in herbivores. Greater levels of dietary fiber also increase transit time.

Diagnostic Confirmation. Investigation of obstipation or diarrhea can include imaging to evaluate the intestinal tract. Plain radiography can be helpful in identifying the quantity of fecal material or the build-up of intestinal gas. Contrast agents such as liquid barium, or barium-impregnated polyspheres (BIPS, Medical I.D Systems, Inc., MI), can be used (Fig. 74.12). Computed tomography can provide detailed images (Fig. 74.13). Ultrasonography of the intestinal tract can yield useful results; however, increased intestinal gas can severely hamper examination.

Flexible endoscopes of appropriate size are typically required to enter the duodenum and small intestine. Cloacal endoscopy is of use in the investigation of patients with obstipation. A rigid endoscope can be passed into the colon under general anesthesia, allowing direct visualization of the colonic mucosa and fecal contents. Coelomic endoscopy can also be used to evaluate the serosal surface of the intestinal tract (see Chapter 64).

Specific Therapy. Resolution relies on improvement in husbandry and nutrition. Providing a suitable diet for the species long term is important. Fluid therapy (initially parenteral, but progressing to oral) to rehydrate and soften GI contents is often a critical first step. Agents such as lactulose have been used as a bulk laxative alongside prokinetic agents such as metoclopramide and cisapride. The use of prokinetics in reptiles may have limited clinical benefit, and the true efficacy is unknown.

If obstipation is severe, then more invasive techniques may be indicated to alleviate the blockage. This can be achieved under general anesthesia, using colonic irrigation with saline and gentle manipulation of the large bowel either externally or per cloaca to remove content. Endoscopic guidance may be useful for direct visualization of the intestinal mucosa and blockage (Fig. 74.14). It is important to evaluate for any signs of iatrogenic damage to the intestinal tract. Long-term oral fluid therapy may be necessary, and in nonresponsive cases, surgical intervention is indicated.

FIG 74.14 Cloacal endoscopy performed on a Hermann's tortoise (*Testudo hermanni*). Endoscopy is a useful tool to examine the distal intestinal tract. (Courtesy of Jenna Richardson.)

Foreign Bodies

Clinical Significance and Presentation. Ingestion of foreign material is relatively common. Pica, lithophagy (ingestion of stones), and geophagy (ingestion of earth or soil-like substrate, e.g., sand, chalk, or clay) are reported in both captive and wild reptiles (Fig. 74.15A).[91] Feeding practices can increase the risk of foreign body ingestion. Housing on sand can result in contamination of food items. Over time, the volume of sand ingested accumulates, which can lead to sand impactions within the intestines (see Fig. 74.15B). Chelonians appear prone to ingesting rocks and wood materials (Fig. 74.16 and Fig. 74.17).[6] They are also attracted to brightly colored objects, which can result in plastic or metal ingestion, particularly in grazing animals or those with outdoor access (Fig. 74.18). Chelonians will also readily accept being hand-fed foreign objects or consume newspaper substrate. Sharper material (e.g., aspen, bark, etc.) can puncture the GI tract and lead to coelomitis or abscess formation. Consumption of skin shed (dermatophagy) (Fig. 74.19) could act as a potential obstructive material, and reptiles may also ingest ectoparasites from the exuvium[92] (Fig. 74.20).[92] In reproductively active females, ingestion of stones, etc. may be associated with an increased demand for calcium. There are many cases reported in the literature of novel and enclosure-related foreign body ingestion in captive reptiles.[93–95]

Snakes do not appear to deliberately ingest foreign material; however, when consuming prey, they can swallow substrate (e.g., aspen or bark) that has become attached to their food. In general, feeding directly on particulate substrates should be avoided. Feeding can occur in a separate container or on particulate-free surfaces (e.g., slate tiles).

Depending on the size and composition of the ingested foreign material, it can either pass through and be voided in feces or lodge within the intestinal tract, leading to a partial or complete obstruction. In many cases this can be life threatening. Rarely impactions can lead to physical distention of the coelomic cavity (Fig. 74.21). Foreign bodies within the large intestine typically continue and pass uneventfully.

Clinical signs are similar to other species with foreign body ingestion; however, the duration can be extended and appear more chronic. The

VetBooks.ir

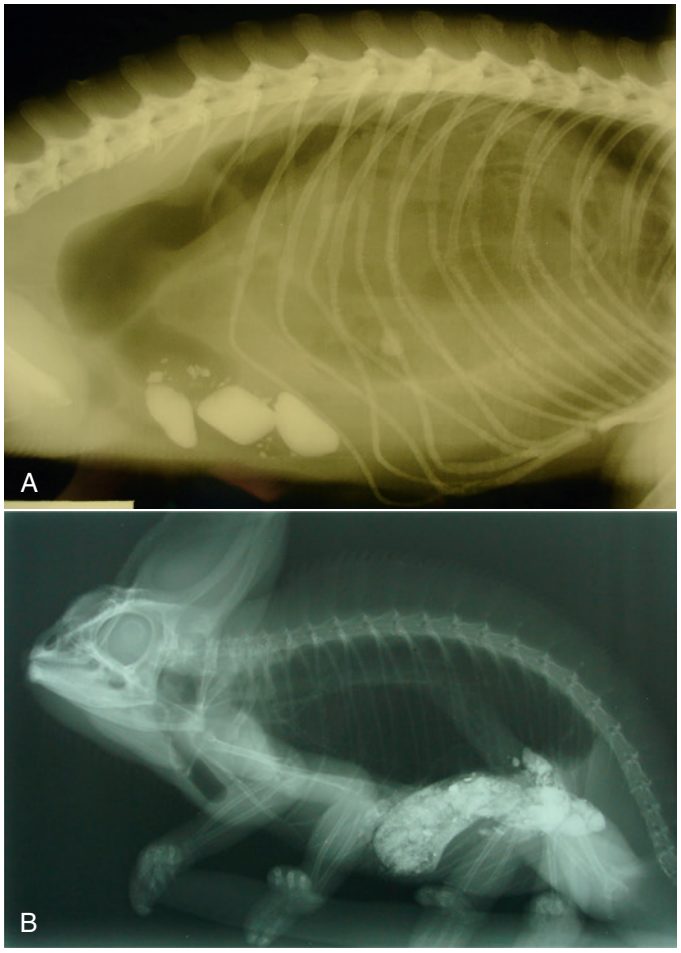

FIG 74.15 Substrate ingestion is commonly seen in reptiles. (A) This green iguana (*Iguana iguana*) had ingested stones that passed uneventfully. (B) This veiled chameleon (*Chamaeleo calyptratus*) had ingested small stones that required surgical intervention. (Courtesy of Kevin Eatwell.)

reptile can appear subdued and lethargic, and there may be a recent history of anorexia. Vomiting can be seen with small intestine involvement. The clinical history may be vague and include anorexia, weight loss, and lethargy, which can extend over weeks to months. Constipation, reduced or absent fecal production, bloating, cloacal prolapse, and diarrhea are possible. Reptiles with chronic disease are often dehydrated and cachectic. Intestinal atony has been reported in green iguanas (*Iguana iguana*), caused by ingestion of foreign bodies.[96]

Diagnostic Confirmation. Survey radiography is useful for the detection of an intestinal foreign body. Horizontal beam radiography can be useful, as foreign bodies are often located ventrally, whereas gaseous distention can lead to dorsal displacement of bowel loops and provides further evidence of possible obstruction (Fig. 74.22). Sand obstipation can be readily identified by radiography; wooden, rubber, or plastic materials can be difficult to detect without contrast or ultrasonography.[95] Coelomic ultrasonography can be used for further clarification; however, a build-up of intestinal gas may affect image quality. Gastrointestinal contrast studies can be performed, but they are not without their own limitations (Fig. 74.23). The GI motility time in reptiles is generally longer than that of mammalian and avian species. In some cases (e.g., large constrictors), transit times can extend over several weeks to more than a month (Fig. 74.24). For smaller species, contrast studies may extend over 2 to 5 days.

Specific Therapy. Foreign body removal requires endoscopic or surgical intervention. Patients should be stabilized initially with fluid therapy, analgesia, and a suitable temperature range. Surgical approach varies with species; for example, a paramedian incision is performed in many lizards, whereas in a chelonian, a large intestinal foreign body may require a plastronotomy. Removal of the foreign material is by standard enterotomy; however, in cases of intestinal devitalization, enterectomy and anastomosis are required.

Prognosis and Prevention. The prognosis is dependent upon foreign body composition and potential toxicity (e.g., heavy metals), location, duration of obstruction, and degree of damage (e.g., perforation, devitalization). In cases with coelomitis, the prognosis is guarded, even with emergency surgery. Prevention is better than cure, and during routine health check consultations, enclosure substrate and furniture should be discussed, with removal of potentially hazardous, high-risk materials recommended.

Intestinal Neoplasia

Clinical Significance and Presentation. With continued advancements in captive management and herpetological medicine, increased reptile longevity is to be expected. This increase in life expectancy leads to an aged population at increased risk of developing neoplastic disease. Based on a necropsy review, captive reptiles have an incidence of neoplasia comparable with that of birds and mammals.[97] Neoplastic disease should always be considered as a differential diagnosis in any unresolving or multifactorial presentation, regardless of the age of the patient.[6] Intestinal neoplasia has been reported in all orders of the Reptilia.[98–100] More commonly, case reports or small case series are published in the literature. Christman et al. published a review of all reported reptile oncology cases between 2004 and 2017.[98] Of the 59 case reports reviewed, only three involved the intestinal tract or pancreas (Table 74.6). Hernandez-Divers reviewed 1287 lizard pathology cases, of which 81 displayed neoplastic conditions.[103] Of these, only four were pertaining to the intestinal tract, of which one animal, a komodo dragon (*Varanus komodoensis*), had multiple tumor types.[104]

The clinical signs attributed to GI neoplasia in reptiles can vary and may include palpable intestinal masses or thickenings, anorexia, weight loss, wasting, caudal coelomic distention, melena, asymmetrical cloacal enlargement, and constipation. If tumor size is large, partial or complete intestinal obstruction can result.

Diagnostic Confirmation. Case investigation and management can prove challenging and expensive. Routine hematology and plasma biochemistries can provide some insight into the physiological status of the patient; however, in many instances results are nonspecific and vague. Where neoplasia results in ulceration or hemorrhage, hematochezia, melena, and anemia may be appreciated. Hematological findings associated with gastrointestinal neoplasia include lymphopenia or lymphocytosis, heterophilia, and monocytosis.[6]

Survey radiography is useful and widely available in practice.[103] Soft tissue structures can be difficult to differentiate from one another due to superimposition and lack of diffuse fat; however, gross enlargements should be readily visible. Ultrasonography can be very useful for both assessing structures within the coelomic cavity and for guiding fine-needle aspirates or core biopsies. Pre- and postcontrast computed tomography (CT) is a superior modality that provides cross-sectional images and three-dimensional reconstructions in conscious or sedated patients. Unfortunately, CT is often restricted to referral institutions.

In stable patients, surgical exploration is advised, either by coelioscopy or coeliotomy. Endoscopy is minimally invasive and can facilitate the collection of biopsy samples while allowing direct visualization of the coelomic cavity. A definitive histological diagnosis and staging is preferred before considering treatment options (surgical resection, chemotherapy, radiation). Where mass removal is warranted, a coeliotomy allows for improved access and visualization. Recovery times and discomfort from incision size are greater with a coeliotomy technique.

Therapy and Prognosis. Sadly, a large number of neoplastic conditions in reptiles are diagnosed postmortem. Our current understanding for treatments of neoplasia in reptiles is limited. Surgical removal of intestinal tumors without prior histological diagnosis and staging is unfortunately the most common clinical approach. Further work is required to assess the use of chemotherapy or radiation therapy in the treatment of

VetBooks.ir

neoplasia in reptiles. In many cases with advanced or metastatic disease, euthanasia is often indicated on welfare grounds.

CLINICAL PANCREATIC DISEASES

Diseases of the reptile pancreas appear to be generally uncommon (or underdiagnosed), with few clinical reports in the literature. Further research may be required to better understand the diagnosis of these conditions.

Pancreatitis

Clinical Significance, Etiology, and Presentation. Pancreatitis is not commonly seen in reptiles, although cases have been reported.[4] Acute necrotizing pancreatitis is similar to that seen in mammals. Digestive enzymes escape from a damaged pancreas, resulting in severe, necrotizing inflammation of the pancreatic tissues. Pancreatic damage can be caused by infection, trauma, or migrating parasites. In severe cases, with extensive inflammation, both the endocrine and exocrine pancreas can be involved. This painful condition can lead to altered posture, reluctance to be handled, lethargy, anorexia, and weight loss.

Intranuclear coccidiosis has been described in a number of chelonian species, with variable clinical signs including anorexia, lethargy, wasting, and oculonasal discharges.[105] Numerous organs may be affected, including the liver, kidneys, and pancreas. Histopathology is required for diagnosis.[106] Treatment with standard anticoccidials so far appears ineffective for nonintestinal coccidiosis. *Cryptosporidium* has been reported in the pancreas of corn snakes.[2]

In a group of red-eared slider turtles (*Trachemys scripta elegans*) pancreatitis was found to be associated with nematode infection.[107] Migratory nematodes and trematodes found in pancreatic tissue are typically walled off and phagocytized.[12] They appear to cause minimal damage to the pancreas but can result in secondary infection with the introduction of bacteria.[4] Diagnosis is often incidental at postmortem examination.

Inclusion body disease (IBD, arenavirus) is a common condition affecting boas and pythons and has also been identified in colubrid snakes and vipers. Clinical signs are varied and can include neurological disease, regurgitation, and weight loss. The disease, believed to be an arenavirus, produces eosinophillic intracytoplasmic inclusion bodies. The diagnosis is largely dependent on histological demonstration of inclusion bodies, which can be found in the pancreas as well as the kidneys, the liver, and, more commonly, the central nervous system. Herpes viral inclusion bodies in the pancreas have been identified in boa constrictors.[108] Two of five wild-caught rough green snakes (*Opheodrys aestivus*) had subacute to chronic pancreatitis associated with orthoreovirus infection.[109]

Diagnostic Confirmation and Therapy. Diagnosis can be complicated, as clinical signs are often nonspecific, with lethargy and inappetance. Coelioscopy to visualize the pancreas, along with biopsy collection, is advised. Treatment is largely dependent on the inciting cause; however, supportive care with nutritional support, fluid therapy, and analgesia should always be considered. Often cases of pancreatitis are diagnosed postmortem.

Radiography, ultrasonography, coelioscopy, or exploratory coeliotomy can be used to assist with the diagnosis; however, biopsy of the affected pancreatic tissue is recommended.[4] Treatment includes aggressive supportive care, alongside addressing the inciting cause.

Pancreatic Neoplasia

Pancreatic neoplasia is not commonly reported.[4] Disease is often advanced by the time of presentation, and treatment options are limited. Euthanasia on welfare grounds is commonplace. Multihormonal pancreatic islet cell carcinomas were found in one female and two male captive geriatric Komodo dragons (*Varanus komodoensis*). The animals presented with lethargy, weakness, and anorexia. Gross changes in the pancreas were visible in two of the three cases.[110]

Gastroenterology—Cloaca

Stuart McArthur and Ross A. Machin

Cloacal organ prolapse is a common veterinary emergency and is seen in both first opinion and referral practice. It occurs in all classes of reptiles. A cloacal prolapse is a clinical sign, not a condition; as in most cases, a pathological prolapse is associated with deeper clinical issues and significant debility. The gastrointestinal, reproductive, and urinary systems end in the cloaca, and therefore a wide variety of disorders may manifest as abnormalities around these anatomic structures, especially if they become obstructed at the cloaca. Prolapses have been described in wild, as well as captive, reptiles (McArthur and Machin, Personal Observation, 2017).[1–12]

Treatment of all cloacal prolapses involves a simultaneous balance of medical and surgical interventions. The presentation draws upon many of the techniques described across all clinical disciplines.[11,12] Information that will assist a clinician facing this presentation is located within several sections of this book; surgical management is covered in Chapter 106 and throughout Section 10. Medical management is included here and throughout Sections 5 and 9, and a case summary of the approach to the cloacal prolapse is described in Chapter 143.

ANATOMY

Three different body systems terminate at the reptilian cloaca. These are the reproductive, urinary, and gastrointestinal tracts. Cloaca anatomy is mildly variable between the orders, but the cloaca is divided into three compartments, which lie between the body of the caudal colon and the vent.[14–22] The cloaca acts as a vestibule to collect, modify, and prepare the output from each of these three organ systems. It therefore helps the reptile to manage both the quantity and the quality of fecal and urinary output, and it is involved in the output of the male or female reproductive systems (i.e., sperm release, live birth, oviposition)[14,22–24] (Figs. 75.1 and 75.2)

The cranial compartment of the cloaca is called the coprodeum. The coprodeum receives the outflow of the large intestine. In chelonians, the ventral surface of both the coprodeum and urodeum also houses the nonengorged male copulatory organ or a similar smaller clitoral organ in the female. During sexual activity, the male organ(s) can enlarge considerably through vascular engorgement.[6,22,23]

The midsection of the cloaca is called the urodeum. The urodeum lies between the coprodeum and proctodeum, which is the most caudal part of the cloaca. The urodeum contains the openings to the ureters (urinary pores), the genital openings of the oviducts/vas deferens (genital pores), and the bladder, when present. Sometimes the urodeum is separated by an incomplete partition where the ureters end. The genital ducts arise from the mesonephric Wolffian duct and the paramesonephric Mullerian ducts. In males, the Wolffian duct develops but remnants of the Mullerian duct may remain. The paired male copulatory organs in snakes and lizards are sacs, extending from and just distal to the proctodeum to be housed within the base of the tail, and in females these regress or are less developed.[14–16,19,20,26]

The proctodeum is the most caudal part of the cloaca and opens to the outside at the vent. This structure receives the outflow of the bladder, urodeum, coprodeum, genital organs, and ureters and serves as the reservoir for fecal and urinary waste before excretion.[15,20–24] The openings of any musk glands are also located within this compartment.[21,24]

Snakes

Cloacal anatomy in snakes is relatively simple as divisions are less defined as other reptile groups. No urinary bladder is present; ureters empty into the urodeum via urinary pores. Paired hemipenes are located as invaginations just inside the mucocutaneous junction medial to the lateral edges of the vent. The functional surface of the hemipenis is the lumen of this invagination. When erect, the hemipenes evert through the vent. Scent glands or anal sacs are found in both sexes in snakes and empty into the caudal proctodeum. Secretions are used in "active" and "passive" marking. Specialized exocrine glands elaborate behaviorally active chemicals, similar to the chin glands of some tortoises (see Chapters 80 and 171).[15,20,21,24–26]

Lizards

Lizards have variable anatomy depending on genre or species. Where a bladder is present, it empties via a short urethra into the ventral urodeum. Hemipenes like those of snakes evert from their usual position within hemipenile sacs, through the vent. Remnants of the Mullerian duct may remain in some males. Some gecko species may have cloacal bones present.[15,20,27]

Chelonians

Chelonians have relatively consistent cloacal anatomy across the species. Cloacal divisions are well defined. The bladder empties via a short urethra into the ventral urodeum, and accessory bladders or bursae, if present, empty into the lateral wall of the urodeum. A single copulatory organ (or a female equivalent) originates from the ventral urodeum, and when engorged, this protrudes through the vent. The chelonian cloaca has extensive physiological interactions with both the bladder and large intestine, enabling fluid recycling, especially in uricotelic and

hibernating species. Such animals may remain relatively healthy, yet not take on fresh fluids for up to 6 months. This feature is virtually unparalleled in any other vertebrate.[6,20,28–31]

PHYSIOLOGY

Reptiles utilize the cloaca as a common outflow for the gastrointestinal, urinary, and reproductive systems. Reptile kidneys cannot form urine that is hyperosmotic to the plasma, and therefore a greater renal water loss is experienced with the excretion of solutes in solution.[30,32] In many species, renal losses are balanced by fluid resorption in the lower urinary tract.[28–32]

Uricotelic reptiles mainly excrete uric acid and urates, whereas ureo-uricotelic reptiles produce uric acid and urea. Typically, uricotelic species live in arid environments or hibernate. Uric acid is barely soluble and therefore can be excreted with minimal volumes of water. Ureotelic animals mainly excrete urea, whereas amino-ureotelic excrete ammonia and urea. Typically, amino-ureotelic species reside in aquatic or fresh water. Reptiles that live in areas of limited water supply will excrete urates, as these are relatively insoluble and therefore require much less water than urea and ammonia to excrete. Excess sodium and potassium may also be precipitated in the cloaca as urate salts.[28–39]

Depending on species and hydration status, reptile urine may be directed toward either the urodeum or proctodeum after exiting the ureters. Water resorption may occur in the colon or proctodeum, and urine may be directed into the bladder where electrolyte and fluid exchange occurs. In species without a bladder, urine ultimately mixes with fecal material, which is then voided simultaneously.[20,28–33]

In chelonians, a bladder connects with the cloaca. This may hold large volumes of water. In many species, postrenal modification of urine occurs as fluid is resorbed across the bladder wall and ions such as potassium are excreted in the opposite direction.[28–33] In these species, the cloaca is often a route of water intake, and dehydration and some electrolyte imbalances can be addressed, at least in part, through regular baths where soak water can be drawn into the bladder, stored for long periods, and then absorbed via the physiological recovery system there.[23,28,29] Some semiaquatic turtles also absorb oxygen through cloacal bursae, a mechanism used during underwater hibernation.[22]

In crocodilians and snakes, the bladder is absent. Therefore postrenal modification of urine occurs in the urodeum or proctodeum. The functions of the accessory bladders in these species may include water and electrolyte regulation, respiration, and absorption of solutes.[35] In lizards, anatomy and therefore physiology is variable with a bladder present in only some species.[20]

For more detail on the role of the lower urinary tract in the management of appropriate hydration, see Chapter 66.

CLOACAL ORGAN PROLAPSE

This common condition is regarded as a true reptilian emergency, because the prolapsed structure will quickly devitalize from ischemic necrosis if not protected and reperfused rapidly following prolapse. With the exclusion of prolapses of the male copulatory organ(s), untreated prolapses involving the colon, bladder and oviduct are likely to be fatal because of the combined effects of ischemic tissue necrosis and compromised body system functions.[1–12] The cloacal organ prolapses encountered in the various reptile classes are summarized in Table 75.1.

Conditions that predispose to a cloacal organ prolapse are also summarized in Table 75.2. It is important to assess both the identity and viability of any prolapse, as well as the underlying health issues that have led to it and that may persist beyond its resolution.

Occasionally a cloacal prolapse case is presented because of the appearance of a normal cloacal structure that is externalized through normal behavior. For example, in chelonians it is not uncommon for a normal engorged clitoris or phallus to protrude through the vent during handling, bathing, urination, or during chemical restraint. Normal structures usually return to the cloaca quickly, without assistance, prior to clinical presentation, whereas a pathologic prolapse does not.

Clinical Presentation

All reptiles with a cloacal prolapse require urgent veterinary examination and attention. Immediate emergency presentation to the nearest suitable clinician is recommened.[1–4,7–12] Structures that can potentially prolapse include the cloaca itself, colon, bladder, oviduct, intestine, rectum, and copulatory organs (phallus or hemipenes) (McArthur and Machin, Personal Observation, 2017).[1–12]

The goal of intervention is threefold:

1) Provide analgesia and emergency stabilization; simultaneous provision of patient support and analgesia, such as the options described in Table 75.3 and Table 75.4, should be the clinician's primary clinical goal.
2) Identify, clean, and protect the anatomic structure and then replace or remove the prolapse. Reduction is described in Table 75.5.
3) Identify, plan, and treat the underlying cause(s) of the prolapse.

Triage

At the first point of veterinary contact, both the prolapse and any systemic health issues should be assessed simultaneously. Information gathered during a primary survey, which may involve telephone triage, questioning a client or the referring veterinarian, and direct clinical examination, allows planning for patient stabilization.[11,12]

TABLE 75.3 Patient Stabilization Measures for a Cloacal Prolapse

- **Fluid support:** Correct perfusion and hydration issues. Where significant intervention and long-term support is anticipated, early placement of an esophagostomy tube or intraosseous, intracoelomic, or epicoelomic fluid administration may be necessary.
- **Nutritional support:** Identify and support any chronic malnutrition and energy deficits.
- **Thermal support:** Provide suitable warmth throughout stabilization transportation and interventions. Few reptiles with prolapses will benefit from desiccating basking heat, so alternative methods of maintaining core body temperature should be employed—maintaining temperatures at the upper end of the preferred optimal temperature zone (POTZ) is generally recommended. This may involve critical vivarium units, heat pads, and similar veterinary thermal heat sources. Continuous measuring thermometer probes are ideal to measure and monitor core body temperatures.
- **Environment support:** Appropriate humidity should also be provided alongside the thermal support plan. Avoid conditions that may lead to dehydration or desiccation of the prolapse.
- **Metabolic support:** Electrolyte imbalances, calcium, or glucose deficiencies may be identified following initial blood work due to dehydration, poor husbandry, sepsis, or other underlying pathologies. Some hypocalcemic reptiles may require vitamin D_3/calcium treatment prior to further intervention.
- **Infection/sepsis:** Topical diluted antiseptics or antibiotics may be considered in combination with systemic antibiotics. When possibl,e antibiotic choice should be choice based on culture and sensitivity. As culture is time consuming, broad-spectrum antibiotics may be prescribed following local and national antimicrobial-use guidelines.
- **Pain management:** Ensure the reptile is being assessed for pain using a local pain score protocol, and ensure analgesia options such as those given in Fig. 75.4 have been considered.
- **Monitoring of in-patients:** Ensure that for all hospitalized in-patients, the hospital records show vital signs, appetite, demeanor, urination, defecation, activity, baths, medications and pain score, fluid administration rates, fluid balance calculations, and weight.

Clinical options available at first presentation following emergency stabilization, may include temporary prolapse protection, prolapse reduction, prolapsed retention, removal of a prolapsed organ, pexy of a reduced structure or euthanasia (McArthur and Machin, Personal Observation, 2017).[1–12] Inexperienced clients and staff should not attempt complex prolapse reduction or removal techniques but should be encouraged to preserve and protect a prolapse, while stabilizing the patient in preparation for referral (McArthur S, Machin R, personal observation, 2017).[11–12]

Prolapse Protection

While developing a treatment plan, prolapses can be cleaned using a saline or warm-water lavage and then protected temporarily by wrapping the caudal body and prolapse in cling film, moist toweling, or dampened swabs. These, in turn, can be taped in place or retained using traditional veterinary dressings. Temporary protective dressings may include an osmotic reduction solution, lubricant, and local anesthetic agents to facilitate future treatment options.[40]

Diagnosis

An initial workup should incorporate a complete history, including husbandry, physical examination, hematology, biochemistry, fecal parasite analysis, radiography and ultrasonography, initially, and if indicated cytology, histopathology, CT scan, MRI, and endoscopy.

History

Attempt to ascertain the patient's general condition and ASA status (American Society of Anaesthesiologists physical status classification)[52] through analysis of a comprehensive history, as covered in Chapter 42. Often owners will report straining associated with an abnormal organ prolapse, and imaging of the caudal body as well as enteric parasite screening is recommended. Survey radiography is recommended in all cases of cloacal organ prolapse. Where possible, use the anamnesis to explore and identify potential disease associations, such as those listed in Table 75.2. The cloacal mucosa is usually moist, and examination

TABLE 75.4 Analgesia Measures Suited to a Cloacal Prolapse

Local Analgesia

Typically, lidocaine and bupivacaine. Local application may aid organ reduction and reduce straining. These can be applied locally, via infiltration or as an intrathecal block.

Consider local anesthesia, topically or by infiltration, especially when there has been persistent tenesmus/straining (McArthur S, Machin R, personal observation, 2017).[49–51]

Systemic Analgesia

Once hydration and perfusion concerns have been addressed, systemic drugs, including tramadol and meloxicam, can be used for pain and are ideal for perioperative use.

- **Tramadol:** 10 mg/kg, PO, q48h (range 2–10 mg/kg, SC, PO, q6–96h or PRN)[42–44,49,50]
- **Meloxicam:** 0.1–0.3 mg/kg PO, SC, IM, IV, q24 h–48 h[45,46,49,50]

Sedation and Anesthesia

Deep multimodal sedation or anesthesia may be required to facilitate handling and reduce stress and may also reduce straining during primary prolapse reduction; IV alfaxalone, or midazolam and ketamine, are preferred by the author. (See Chapters 48 through 51 for more details.)

VetBooks.ir

may help determine the patient's hydration status if considered with other hydration markers.[11–12,23,40]

Because husbandry and nutritional related issues may have led to the prolapse, intervention is usually required, and important husbandry deficiencies or problems should be identified during the anamnesis and reported to the client. The client must also be informed of the costs of diagnostic options, such as serum biochemistry and hematology screening and traditional and advanced imaging, as well as possible surgical costs. While establishing estimated costs, an honest prognosis must be conveyed to the owner.

Physical Examination

Follow a logical examination protocol, such as that covered in Chapter 42. Where possible, ascertain patient species, sex and life stage, core body temperature at presentation, weight, body condition, hydration and perfusion status, and, where realistic, a pain score. Identify the organ that has prolapsed, as this may suggest conditions that have predisposed to prolapse. A guide to prolapse identification is provided in Figs. 75.3 through 75.24.

Combine the physical examination with the data from the anamnesis to help identify signs suggestive of dehydration, emaciation, sepsis, parasitism, hypocalcemia, or toxemia. Immediate management of core temperature, pain, hydration status, sepsis or toxemia, and electrolyte derangements are equally as important as protecting and dealing with the prolapse. Suitable stabilization measures are summarized in Table 75.3 and covered in depth in Chapter 87.

Perform any further diagnostic tests (clinical pathology and imaging) as indicated following the primary survey (anamnesis combined with initial physical examination).

Clinical Pathology

At the commencement of treatment, knowledge of organ function, possible azotemia, the patient's hematocrit, and the systemic inflammatory state will help the clinician to monitor the patient over time.

As fecal and urinary output may both be impaired by the presence of a cloacal prolapse, and severe metabolic derangements, dehydration, and hypocalcemia associated with nutritional or renal secondary hyperparathyroidism may have predisposed the patient to the presentation, a serum biochemistry profile to assess hydration and metabolic stability is recommended. Ideally a complete blood count should also be obtained.

If a parasitic, protozoan, or bacterial infection is suspected as an underlying cause of a prolapse, direct microscopy, cytology, and microbiologic examination of cloacal washes may be helpful. See Section 4 for more details.

Imaging

All reptiles experiencing a prolapse should be examined using some form of imaging. Survey radiography is mandatory in all reptiles with prolapses, and where facilities and experience are available, additional imaging such as sonography, CT, or MRI can be also be performed.

Imaging will help the clinician assess whether cystic calculi, eggs, or space-occupying masses are present, and the presence of unexpected

TABLE 75.5 Summary of Temporary Prolapse Reduction

- Assess the patient and ensure it has been adequately stabilized using the techniques summarized in Table 75.3.
- Ensure that a pain management plan has been made (e.g., through analgesia techniques such as those summarized in Table 75.4).
- Consider the use of additional future local anesthetic agents.
- Examine survey radiographs and pay special attention to evidence of metabolic bone diseases or coelomic states that may have predisposed to the prolapse, for example, cystic calculi, pelvic or ectopic eggs. (In many cases radiographic findings may indicate a need for coeliotomy in addition to any reductive techniques used.)
- Provided the reptile is adequately hydrated and metabolically and thermally stable, consider general anesthesia or deep sedation to mitigate patient distress during handling. Suitable options include multimodal protocols (e.g., combinations of midazolam 1–2 mg/kg, medetomidine 40–200 μg/kg, and ketamine 5–10 mg/kg—either IV or IM),[48,50,51] or alfaxalone (2–7 mg/kg, IV),[47,51] and as detailed in Chapters 48 and 49.
- Ensure the patient remains thermally stable and monitor core body temperature throughout.
- Glove up before handling the prolapse and manage potentially infected or necrotic material carefully to limit cross-contamination.
- Remove all substrate contamination and clean the prolapse using copious warm water or saline lavage.
- Assess prolapse viability. Only employ reductive prolapse-sparing techniques where prolapse tissue is considered viable. Reduce prolapses with caution if the tissue is only regarded as potentially viable.
- Resect and remove any unviable, necrotic, or avascular material (e.g., a traumatized penile organ).
- Apply osmotic reductants as necessary, for example, 50% dextrose or sugar solution, and, at this point, consider the application of temporary pressure dressing across the prolapse if the volume of tissue swelling present needs considerable osmotic reduction. In these cases, it may be necessary to let the patient recover from sedation or anesthesia and then continue reduction at a later point.
- Where conditions for reduction are favorable, apply further sterile lubricant. Mix in a local anesthetic agent(s) and ensure dosages are subtoxic.
- Reduce the prolapse, for example, use through pressure from multiple moist tongue depressors, cotton buds, or swabs. Apply even force over the base and body of the prolapse, as this will often result in significant hydrostatic reduction. The process will be similar to kneading bread.
- Pressure applied evenly across damp swabs can be useful in addition to digital compression, and swabs can be taped in place under pressure, if time is available.
- Once the prolapse has been reduced, consider cloacal flushing with warmed fluids to remove further debris and involute any inverted organ.
- Involution of bladder oviduct and colon will almost certainly require further celiotomy.
- Where reduction is not possible, consider amputation and celiotomy. Ensure the client is comfortable with any surgical escalation to this level.
- Retention sutures or staples can now be used to temporarily support the vent and prevent a recurrence of the prolapse.
- Ensure the patient can still urinate and pass feces.
- Insertion of a damp compression swab/tampon soaked with saline and diluting local anesthetic agent may aid both retention (e.g., reduction for transit to a referral site or during initial stabilizing hospitalization).
- Continue the patient stabilization techniques summarized in Table 75.3.

free fluid within the coelomic cavity may encourage fine-needle aspirate/coelomocentesis and additional cytology and fluid examination.[41] See Section 7 for more detail.

Prognosis

For many reptiles suffering a cloacal organ prolapse, the prognosis for stabilization and future quality of life are reasonable, provided secondary trauma is moderate and response time is short (e.g., within 24–48 hours). The prognosis for a cloacal organ prolapse is dependent on multiple factors; most importantly underlying causes, the patient's condition, and the prolapse viability and duration of the prolapse. Prognosis varies from excellent to grave and euthanasia should be considered in serious cases.

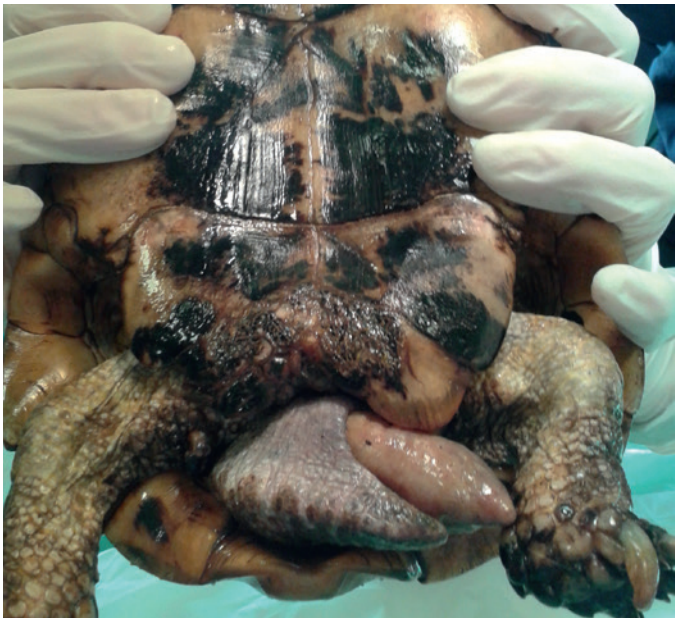

FIG 75.3 *Testudo* sp. tortoise with a phallus prolapse. A mild phallus prolapse like this is typical of a debilitated male *Testudo* species with hypocalcemia. Correction can be achieved by restoring electrolytes, blood calcium levels, and core body temperature. (Courtesy of S. Brown.)

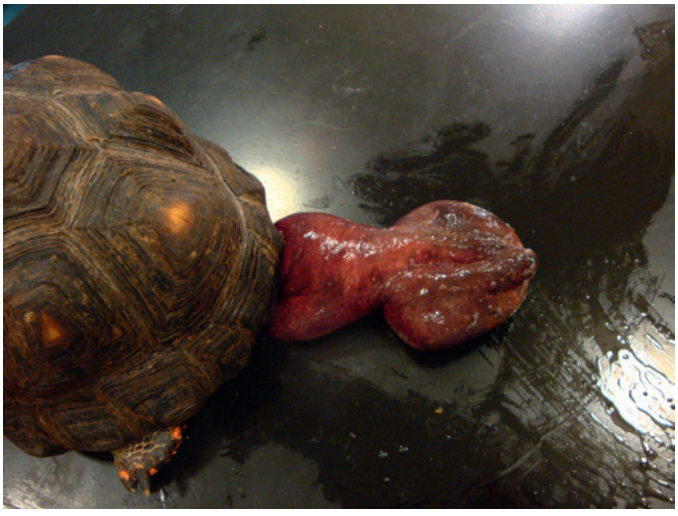

FIG 75.4 Red-footed tortoise, *Chelonoidis carbonaria*, with a large phallus prolapse. This can be amputated with a good prognosis if predispositions are also addressed. (Courtesy of S. Brown.)

An informed decision should be made by the client and clinical team together, to choose between further patient stabilization or euthanasia, and the clinician must recommend the treatment most likely to address patient welfare.

Occasionally, euthanasia may be advised or performed at the initial presentation because no viable welfare-orientated treatment is possible, affordable, or available. Advice regarding reptile euthanasia is provided in Chapter 47.

Treatment

While a reptile experiencing a prolapse may not show obvious indications of pain as mammals do, all will benefit from a carefully considered pain management program.[7–12] Analgesia is always advised (see Chapter 50). Suitable analgesia protocols for managing a cloacal prolapse are provided in Table 75.4.[42–46]

After addressing patient stabilization using techniques summarized in Table 75.3, the prolapse should be protected from desiccation, substrate contamination, or further trauma. This usually involves lavage, application of lubricant gels, application of osmotic gels, and protective wraps such as cling film or toweling. The longer a prolapse is contaminated with substrate, strangulated, engorged, and traumatized, the less likely it is to be viable and the more likely it will require surgical removal or necessitate euthanasia. Early lavage using warm sterile saline, reduction, and stabilization is advised in combination with general patient

stabilization. If prolapse handling is likely to distress the patient, a risk-benefit analysis may favor sedation or general anesthesia (McArthur S, Machin R, personal observation, 2017).[12,40]

Where dystocia or coelomic masses such as cystic calculi have predisposed to a cloacal prolapse, a coeliotomy is always indicated. Prolapses of the large intestine and oviducts are invariably surgical conditions.[8,40] Medical management will help in all cases where there is sepsis or significant local infection, parasitism, nutritional secondary hyperparathyroidism/hypocalcemia, other electrolyte derangements, and dehydration, and often supports future surgical management (McArthur S, Machin R, personal observation, 2017).[12,40]

Prolapse Reduction

It is important that clients understand that simply reducing the prolapse is not comparable with the resolution of the prolapse. Few oviduct or colonic prolapses will resolve by simply forcing them back into the cloaca, and most animals left with a partially reduced prolapse will experience life-threatening future complications.

Initially a prolapse can be irrigated with sterile fluid or even gently washed with warm running water to clean and remove any contamination. Physical manipulation and osmotic reduction benefit from medical lubrication to which a clinician may add local anesthetic agents (e.g., lidocaine or 2.5% bupivacaine).[50,51] Lubricating gels may allow a fresh prolapse to simply be returned to the cloaca for transportation or until an experienced reptile clinician is available. Osmotic reduction of organ swelling is aided by application of sugar, honey, or concentrated dextrose solutions. These shrink edematous tissues, allowing organ reduction through sustained gentle manual compression or surgery. Tissues can be protected during transport using osmotic reduction agents applied beneath dressings.[2,7,8,40]

The male reproductive organs of all reptiles can be reduced and retained, or removed, without the need for coeliotomy. In some cases, where calculi are not involved in the etiology, a bladder prolapse can also be reduced without coeliotomy. However, all tubular or intussuscepted prolapses (those with a lumen) will require coeliotomy to be correctly reduced and retained via sutures or removed along with additional associated structures such as retained eggs, ectopic eggs, cystic calculi, ovaries, follicles, etc.[2,8,40] (see Chapter 106).

Specific Prolapse Management Plans

Phallus (Chelonian)

Known etiological cause(s). Etiological causes of phallus prolapse in chelonians (Figs. 75.3 and 75.4) include male courtship trauma, balanoposthitis, mating injuries, dystocia, chronic sexual activity, constipation, paraphimosis, neurologic dysfunction, substrate contamination, hypothermia, hypocalcemia, dehydration, cloacoliths, and neoplasia. Only males are affected.

Clinical presentation. This prolapse is not life-threatening, but it often indicates deeper issues influencing debility.

Diagnostic confirmation. The prolapsed chelonian phallus presents as a single, large, engorged, nontubular structure protruding through the vent. There is no lumen. The prolapse may be a considerable size in comparison to the animal. The presentation is pathognomonic; however, additional investigations should be made into the underlying etiology. Survey radiography is recommended.

Prognosis. The prognosis with or without conservation of the phallus is good, provided any other underlying issues are correctable.

Suggested treatment. Recent viable prolapses can be reduced and replaced as described earlier in this chapter and in Table 75.5. Plenty of lubrication should be used during reduction, which is accomplished by applying even pressure across the structure. Temporary retaining sutures may be required across the vent opening to hold the prolapse in place for the first 24 to 48 hours (or longer in severe cases or relapses). Surgical removal, as described in Chapter 106, is preferred for avascular traumatized, necrotic, or infected prolapses, where reduction is not regarded as feasible or with relapse. Postoperative care will be minimal.

Prevention. The reptile's environment and nutrition should be optimized. Parasitic infestations require elimination from the patient, cohorts, and the environment.

Hemepenis(es) (Squamate)

Known etiological cause(s). Etiological causes for hemepenal prolapse (Figs. 75.5 through 75.9) include male courtship trauma, balanoposthitis, mating injuries, dystocia, chronic sexual activity, constipation, paraphimosis, neurologic dysfunction, substrate contamination, hypothermia, hypocalcemia, dehydration, cloacoliths, and neoplasia. Only males are affected.

Clinical presentation. This prolapse is not life-threatening but often indicates deeper issues influencing debility.

Diagnostic confirmation. The prolapsed hemipene(s) presents as a single or paired small, nontubular structure protruding through the vent at its lateral edges. It is a small size in comparison to the animal, even when strangulated or desiccated. There is no lumen. The presentation is pathognomonic; however, additional investigations should be made into the underlying etiology. Survey radiography is recommended. Do not confuse cloacitis (Fig. 75.10), cloacal trauma (Fig. 75.11), hemipenile plugs (Figs. 75.12 through 75.14), or scent gland secretion (Fig. 75.15) with hemipenal prolapse.

Prognosis. The prognosis with or without conservation of one or both hemepenes is good, provided other underlying issues are correctable.

Suggested treatment. Recent viable prolapses can be reduced and replaced as described earlier in this chapter. Any plugs or contaminating material should be gently removed. Plenty of lubrication should be used during reduction, which is accomplished by applying even pressure across the structure. Temporary retaining sutures may be required about the vent opening to hold the prolapse in place for the first 24 to 48 hours (or longer in severe cases). Surgical removal, as described in Chapter 106, is preferred for avascular traumatized, necrotic, or infected prolapses, where reduction is not regarded as feasible or with relapse. Postoperative care will be minimal.

Prevention. The reptile's environment and nutrition should be optimized. Parasitic infestations require elimination from the patient, cohorts, and the environment.

Oviduct (Oviparous Species)

Known etiologic cause(s). Etiological causes of oviductal prolapse in reptiles (Figs. 75.16 through 75.19) include hypocalcemia, dehydration, dystocia (e.g., uterine rupture, ectopic eggs, abnormally sized or shaped eggs), infections (parasitic, mycotic, bacterial, or viral), uroliths, and neoplasia. Most animals will have follicular stasis, urinary calculi, or be in dystocia. Only females are affected.

Clinical presentation. A oviductal prolapse is considered life-threatening and usually indicates deeper medical issues.

Diagnostic confirmation. A prolapsed oviduct often presents as a modest flaccid, intussuscepted structure. It is usually solid and linear. It has a lumen. Where tissues are exposed they may have become traumatized and necrotic. It may be large in size in comparison to the animal. Survey radiography is recommended, and additional investigations as indicated should be made into the underlying etiology.

Prognosis. The prognosis with or without conservation of the prolapsed oviduct tissue is poor. Few oviduct prolapse cases will return to a normal quality of life. However, where a prolapse is recent it may be possible to reduce and remove it via a celiotomy.

Suggested treatment. A celiotomy and entire ovariosalpingectomy are advised. Alternatively, the prolapse can be amputated and then the residual tissue addressed via a coeliotomy. These surgical procedures are described in Chapters 80 and 106. Where future breeding of an endangered species is an issue, a minimum of unilateral salpingectomy is advised, and this must include an ipsilateral ovariectomy. Fresh viable prolapses, without coelomic masses (e.g., cloacoliths, dystocia, or ectopic eggs), can occasionally be reduced and replaced without coeliotomy. A coeliotomy is always advised by the authors to correctly unravel any intussusception, correctly return it to the coelomic cavity, and immobilize it to prevent immediate recurrence. Additional conditions, such as uroliths and obstipation, will also require appropriate management. Postoperative care will be significant.

Prevention. The reptile's environment and nutrition should be optimized. Dystocia, follicular stasis, and any concurrent urinary calculi issues will all warrant appropriate investigation and treatment.

Colon (All Species)

Known etiological cause(s). Etiological causes of colonic prolapse in reptiles (Figs. 75.20 through 75.22) include hypocalcemia, dehydration, constipation, infections (parasitic, mycotic, bacterial, or viral), and neoplasia. Some animals may have bladder stones, fecoliths, or uroliths within the urodeum or be in dystocia. Cachectic and emaciated animals with low body fat may be overrepresented.

Clinical presentation. A colonic prolapse is considered life-threatening and usually indicates deeper medical issues.

Diagnostic confirmation. The prolapsed colon often presents as a large, rigid, engorged, and, intussuscepted structure. It is usually solid and linear, has a lumen, and, where tissues are exposed, may have become traumatized and necrotic. It may be a considerable size in comparison to the animal. Survey radiography is recommended, and additional investigations as indicated should be made into the underlying etiology.

Prognosis. The prognosis with or without conservation of the intestinal prolapse is generally grave. Few colonic prolapse cases will return to a normal quality of life. However, where a prolapse such as an ileocolic intussusception is relatively fresh and recent, it may be possible to reduce it via a coelomic celiotomy approach.

Suggested treatment. Recent viable prolapses without coelomic masses (e.g., cloacoliths, ectopic eggs) can be reduced and replaced. However, a celiotomy is always advised to correctly unravel any intussusception, properly return it to the coelomic cavity, and to immobilize it to prevent immediate recurrence. Surgical management is described in Chapter 106. Additional conditions such as uroliths and dystocia will also require appropriate management. Once reduced the colon can be fixed using colopexy sutures to the coelomic wall (see Chapter 106). Postoperative care will be significant.

Prevention. The reptile environment and nutrition should be optimized. If thought to be a contributing factor, parasitic infestations need elimination from the patient, cohorts, and the environment. Predispositions such as constipation, dystocia, or urolith formation should be addressed and managed.

Bladder (All Chelonians and Some Lizards)

Known etiological cause(s). Etiological causes of prolapse of the reptilian bladder (Figs. 75.23 and 75.24) include hypothermia, hypocalcemia, dehydration, uroliths, ectopic eggs, bladder and cloacal infections (parasitic, mycotic, bacterial, or viral), and neoplasia. Cachectic and emaciated animals with low body fat may be overrepresented. Reptiles of any sex or age may be affected.

Clinical presentation. A bladder prolapse is considered life-threatening and usually indicates deeper medical issues.

Diagnostic confirmation. The prolapsed bladder often presents as a large, engorged, fluid-filled structure. It may be thin-walled, and liquid may be apparent within it. There is no lumen and the structure is not tubular. Urate deposits may be apparent within any cystic structures or distributed across any visible prolapsed mucosa. If the bladder wall has ruptured, a bladder prolapse may present as a long, stringy, nonspecific, nontubular structure protruding through the vent. It may be a considerable size in comparison to the animal. Survey radiography is recommended, and additional investigations as indicated should be made into the underlying etiology.

Prognosis. The prognosis with or without conservation of the bladder prolapse is grave. Few bladder prolapse cases will return to a normal quality of life.

Suggested treatment. Recent viable prolapses, without coelomic masses (e.g., cloacoliths and ectopic eggs) can be reduced and replaced, as described in Table 75.5. Fluid can be gently and consistently infused into the cloaca to reverse the organ involution. The sheath of a rigid endoscope is ideal for this, and the scope can be used to visualize appropriate coelomic reduction and cloacal patency. Temporary retaining sutures may be required across the vent opening to hold the prolapse in place for the first 24 to 48 hours (or longer in severe cases). Surgical replacement is preferred for avascular traumatized, necrotic, or infected prolapses and where reduction is not regarded as feasible. (See Chapter 106 for the surgical approach to bladder prolapse repair.) Where the bladder wall is severely damaged, the bladder wall can be resected and viable edges of the bladder wall closed together. Braided suture materials are best avoided in uricotelic species. Postoperative care will be significant.

Prevention. The reptile's environment and nutrition should be optimized. If thought to be a contributing factor, parasitic infestations will need elimination from the patient, cohorts, and the environment. Predispositions such as constipation, dystocia, or urolith formation should be addressed and managed.

Pulmonology

Zdenek Knotek and Stephen J. Divers

The respiratory tract includes the nares, rhinarium, choana, larynx, tracheobronchial tree, and lungs; however, for the purposes of this chapter the focus will be the larynx, trachea, and lungs, with the nasal cavity included in Chapter 72.

Recent movement through the wholesale/retail trade, importation, severe parasitism, malnutrition, and suboptimal temperature are all stressors that can predispose to primary or secondary respiratory disease.

ANATOMY

A basic understanding of the normal anatomy and physiology of the respiratory tract of reptiles is important for clinicians to successfully diagnose and manage respiratory disease in these patients. The reptilian respiratory tract is anatomically and physiologically different among the various taxa.[1–3]

Snakes

The larynx is situated rostrally in the oral cavity. It opens in the floor of the mouth caudal to the lingual sheath opening and is generally easily visualized (Fig. 76.1A). The larynx consists of two small vertical arytenoid cartilages laterally, connected by a large azygous and rounded ventral cricoid cartilage.[1] The glottis is the opening to the trachea and controls airflow and permits hissing. A preglottal keel is obvious in some species (e.g., *Pituophis*) (see Fig. 76.1B). The cranial part of the trachea, or glottal tube, is composed of 3 to 16 fused cartilaginous rings and can, during large prey ingestion, be pushed craniolaterad to maintain ventilation. The glottis is actively opened and closed by the dilator and sphincter laryngis muscles, respectively. Excluding the glottal tube, the trachea is composed of 70 (*Thamnophis*) to 1120 (*Hydrophis*) incomplete cartilageous rings; however, there are exceptions, with *Python bivittatus* and *Crotalus viridis* having up to 30 and 25 complete cartilaginous rings, respectively, following the glottal tube. All the remaining rings are incomplete and possess a significant dorsal ligament, which is thin, composed of collagenous and elastic connective tissue, but lacking muscle fibers (Fig. 76.2). This dorsal tracheal membrane proliferates to form a tracheal lung and is particularly common in the Elapidae, Viperidae, Hydrophiidae, and Colubridae. Tracheal lungs facilitate additional gas exchange and can be used to inflate the neck (but not spread the hood of cobras). The trachea normally courses ventrad or dextrolaterad to the esophagus, and either dorsal or left of the heart. The trachea enters the right lung in two distinct ways (although intermediate variations exist): (1) *subterminal*, in which the trachea enters the medial side of the lung, caudal to the anterior tip or lobe (e.g., boids); and (2) *terminal*, in which the trachea enters the most cranial portion of the lung and an anterior lobe is absent.[1] In most snakes with a single lung, the trachea becomes an intrapulmonary bronchus upon entry into the right lung; however, in boids, the differentiation is at the level of the bifurcation.

The bronchus terminates proximally within the faveolar region but can extend far caudally in some species.[1] The epithelium has relatively fewer cilia, which diminishes the ability to remove foreign material from the respiratory tract. A poorly developed mucocilliary escalator in the airways reduces the ability of the reptile to clear discharges.

All snakes have a right lung, located dorsal to the liver and lateral to the stomach, which typically measures 25% to 60% of the total snout-to-vent length (SVL). The left lung (present in boids) is generally smaller but can be comparable. In all snakes (except some typhlopids) the lung is unicameral (single chamber). The right lung (and left lung of boids) is divided into a thick-walled, highly vascular respiratory portion (vascular lung) and a thin-walled, transparent, avascular, nonrespiratory portion (air sac or saccular lung), which is variably demarcated by a transitional zone (semisaccular lung) (Fig. 76.3D and E). This air sac may act as an oxygen reservoir during periods of apnea and as a buoyancy organ in aquatic snakes.[1]

Three different types of reptilian lung parenchyma have been described: (1) *trabecular,* consisting of a single layer of low-relief branching muscular structures (trabeculae); (2) *edicular,* composed of a single layer of trabeculae with raised walls or septa that form cubicles (ediculae) that are wider than they are deep; and (3) *faveolar,* single- or multiple-layered faviform parenchyma, the compartments (faveoli) of which are deeper than wide and have a honeycomb appearance[1] (see Fig. 76.3D and E).

The vascular lung is typically located starting at 20% to 30% SVL and ending approximately 40% to 60% SVL.[4] This respiratory region is rich in faveolar parenchyma, heavily perfused, and red in color and can easily be distinguished from the reduced vascularization of the

gray-white air sac. This saccular portion extends caudally for a variable length, depending on species.[1] These two clearly defined regions are separated by a transitional zone of varying magnitude in which the parenchyma gradually becomes less concentrated, and the faveoli exhibit larger diameters, lower and thinner walls, and fewer horizontal tiers.[1] In some snake species (*Gonyosoma* sp., *Naja* sp., *Boiga* sp., and other arboreal colubrids) the transition from the vascular lung to the avascular air sac is abrupt. The air sac may constrict to 10% to 20% of its cranial diameter and continue to its tip as a very slender tail. The position of the air sac tip is sexually dimorphic in most species of snakes, with the tip more caudally placed in males than in females.[1]

The respiratory cycle of the snake involves both active and passive components. Elevation of the ribs, caused by contraction of levator costarum and retractor costarum muscles, increases coelomic volume, decreases intrapulmonary pressure, and results in the active component of inspiration. Expiration is controlled by dorsolateral (transverse dorsal and superior internal intercostal) and ventrolateral (transverse abdominal and internal abdominal oblique) muscles. Relaxation of the expiratory muscles results in initial, passive inspiration, whereas limited passive expiration occurs as a result of relaxation of the inspiratory muscles.[1–3]

Lizards

The larynx of the lizard is variable in its location within the oral cavity. It is found in the rostral aspect of the mouth in carnivorous species, or it is located more posterior at the base of the fleshy tongue (Fig. 76.4). The glottis is normally closed except during inspiration or expiration. Gular pumping does not mirror ventilation rate but is associated with forcing air into the lungs (positive pressure ventilation) and may also have a role in olfaction and cooling.[5] The trachea, composed of incomplete rings in most species, remains a single structure until it enters the coelomic cavity near the base of the heart (Fig. 76.5). Some chameleons have an accessory lung lobe that projects from the trachea cranial to their forelimbs. This may fill with secretions when infected, resulting in swelling of the ventral neck.

Most lizards possess single-chambered lungs (Eublepharoidea, Amphisbaenia, Gymnophthalmidae, Teidae, Lacertidae, Xanthusiidae, Scincidae, and Anguidae), whereas others (Chamaelonidae, Agamidae, Iguanidae, Gekkonoidea, Xenosauridae, and Lanthanotus) exhibit transitional lung morphology in which a short, troughlike intrapulmonary bronchus extends from the hilus to the base of a septum, which divides the lung into smaller anterior and larger posterior chambers.[2] The intrapulmonary bronchus present in the *Iguana* is absent in the *Pogona, Uromastyx*, and *Physignathus,* but these species all exhibit a posterior lung that is variably divided by two or three large septae into lobes. Chameleons exhibit specific septal arrangements and caudal diverticulae resembling air sac appendages (see Fig. 76.5). Varanids and helodermatids are unique among lizards in that they possess the most complex, multichambered lungs, which are large, heterogeneously partitioned, and possess cartilage-reinforced secondary bronchi.

Faveolar lung parenchyma is typical in the scinomorph, iguanid, and agamid lizards.[2] Edicular patterns are common in varanid, chamaeleonid, and some gekkonid species but are also present in distal pulmonary regions in iguanid and agamid lizards.[2] The terminal saclike regions of many lizards are lined by trabecular parenchyma (Fig. 76.6).

Lizards lack a diaphragm and move tidal volume with expansion and contraction of the ribs, facilitated by the intercostal muscles. In some lizards, an incomplete (Helodermatidae) or complete (Varanidae) postpulmonary fascialike septum divides the coelom into cardiopulmonary and visceral compartments but does not aid respiratory movements.[3] Most lizards complete the expiratory-inspiratory cycle with a nonventilatory period of varying length.

Chelonians

The larynx is located caudally in the oropharynx at the base of the fleshy tongue, making it difficult to visualize on occasion (Fig. 76.7A). The trachea is composed of complete cartilaginous rings with mucous, ciliated,

and basal cells lining the epithelial wall (see Fig. 76.7B).[6] The chelonian suborder Cryptodira which includes most turtles and tortoises, retract their head and neck straight back into the shell, and the trachea is relatively short and quickly bifurcates into two main-stem bronchi that open directly into the lungs. The cranial bifurcation of the trachea enables chelonians to breathe unimpeded when the neck is withdrawn.[7] The suborder Pleurodira which includes side-neck turtles, fold their necks sideways along the body, and the trachea is generally longer with more caudal bifurcation. The paired bronchi are also significantly longer than those of squamates and enter the lungs cranio medially (see Fig. 76.7C).

The rigid chelonian shell necessitates a unique process of ventilation. Ventilation involves the activity of antagonistic pairs of muscles, which decrease or increase coelomic volume and thus lung volume.[7] This action is supplemented with limb and head movements. Chelonians accomplish the movement of air through a variety of methods. Both inspiration and expiration are active processes. Groups of muscles are involved—contraction of the diaphragmatic and transverse abdominal muscles compress the coelomic cavity, thus causing expiration. The testocoracoidus and abdominal oblique muscles expand the cavity and cause inspiration.[7] In some terrestrial species, movements of the pectoral girdle are the primary muscles of respiration; inspiration occurs with contraction of the serratus and abdominal oblique muscles, whereas expiration occurs with contraction of the transverse abdominal and pectoralis muscles.[7]

The lungs attach dorsally to the ventral surface of the carapace and ventrally to a postpulmonary membrane (*septum horizontale*) that is weighted by attachments to the liver, stomach, and intestinal tract (Fig. 76.8A). Chelonians have no true diaphragm.[7] The membraneous separation is most obvious in terrestrial species and is often indiscernible or lacking in aquatic turtles like the common snapping turtle (*Chelydra serpentina*), where the lungs are attached dorsomedially by means of a broad ligment to the vertebral column (see Fig. 76.7C).

All testudines have multichambered lungs with an unbranched, intrapulmonary bronchus that is reinforced by cartilage (see Fig. 76.8B).[2] Each primary bronchus gives rise to 3 to 11 groups of chambers, most consisting of a medial (to ventral) and lateral (to dorsal) chamber. The *Testudo* tortoises have the simplest lungs, with just four groups of dorsal and ventral chambers, with intermediate forms like *Trionyx* (soft-shelled turtles) having seven groups of medial and lateral chambers (see Fig. 76.8B–D). The most complex lungs are found in sea turtles, with parenchyma-rich, 10 or 11 groups of dichotomously bifurcating medial and lateral chambers.[2] The lung surface is reticular and interspersed with bands of smooth muscle and connective tissue. Edicular parenchyma extends throughout the lung, and unlike most reptiles, testudines possess goblet cells rather than serous secretary cells on the trabeculae and intrapulmonary bronchus.

Crocodilians. The full development of a bony hard palate is seen only in the crocodilians where the nasopharynx opens at the back of the mouth in close proximity to the larynx. The larynx is located caudal to the prominent epiglottal flap (*velum palati*) (Fig. 76.9A). Air can be held in the respiratory tract for an extended period by closure of the glottic valve, allowing submersion for extended periods. The trachea is lined with a pseudostratified, ciliated, columnar epithelium with varying numbers of goblet cells.

Crocodilians have complex, multichambered lungs located in the cranial coelom. Though not a true thorax, the term thorax could legimately be used because of the functional separation between the

lungs and other viscera by a substantial membraneous postpulmonary membrane (see Fig. 76.9B).[2] Ventilation is accomplished with the intercostal muscles and muscles attached to the nonmuscular diaphragm. Active expiration occurs due to a reduction in volume caused by transverse muscles. The cranial aspect of the liver is attached to the postpulmonary membrane. Caudally, the liver is connected to the pelvic girdle by a pair of diaphragmatic muscles. Contraction of these muscles causes caudal movement of the liver, which, combined with the action of the intercostal muscles, causes active inspiration. Parabronchi further divide the lungs into a series of chambers. The *individual* chambers tend to be tubular, and the most cranial chambers extend well craniad of the hilus. The edicular paranechyma appears to be more densely partitioned in alligators than crocodiles.[2]

PHYSIOLOGY

The following is a summary; a more detailed explanation of respiratory function has been published.[3] Although most gas exchange is pulmonary, it is important to appreciate that cutaneous (skin, gular, cloacal) gas exchange may be significant in many terrestrial species (5%–15% of total gas exchange) but is most utilized in aquatic species where it can account for up to 35% of total gas exchange. During periods of inactivity, especially hibernation at low temperatures, it is possible for all gas exchange requirements to be met through nonpulmonary routes.

The arrhythmic breathing pattern of reptiles may appear abnormal compared with mammals. Reptile metabolism and, hence, needs for oxygen and carbon dioxide exchange are reduced, and therefore two options are available for reducing respiration rate: (1) maintain a continuous, but slow, inspiratory/expiratory breathing pattern, or (2) maintain a normal inspiratory/expiratory breathing pattern (largely based on the intrinsic elasticity of lungs and associated tissues) but have periods of nonventilation and therefore breathe intermittently. Option 2 prevails in most resting reptiles because it is more energy efficient, and therefore the respiratory pattern of reptiles can be divided into ventilatory and nonventilatory periods. Nevertheless, reptiles experience and are tolerant of greater variations in blood pH and are capable of prolonged periods of anoxia.

Increasing inspired CO_2 or decreased O_2 results in less or shortened nonventilatory periods. In general, hypercapnia causes an increase in tidal volume (due to suppression of pulmonary stretch receptors), whereas hypoxia acts to increase breathing frequency (due to arterial and pulmonary chemoreceptors) (Table 76.1). However, exceptions exist, and acute hypercapnia can result in sudden breath holding. These

TABLE 76.1 Clinical Effects of Changes in Physiologic Parameters

	Increase Causes	Decrease Causes	Effected by	Clinical Significance
Carbon dioxide	Elevation in tidal volume and minute volume	Decrease in tidal volume and minute volume	Intrapulmonary stretch receptors and chemoreceptors; central chemoreceptors; upper respiratory chemoreceptors	Carbon dioxide generally has a lesser effect on respiration than oxygen
Oxygen	Decrease in respiratory rate	Increase in respiratory rate	Arterial chemoreceptors	Reptiles on 100% oxygen will have dramatically reduced respiratory rates, which complicates spontaneous breathing during anesthetic recovery and nebulization therapy
Temperature	Increased responses to hypoxia and hypercapnia	Decreased responses to hypoxia and hypercapnia	General thermodynamics	Reptiles must be maintained within their POTZ, and this is especially true during anesthesia
pH	Decrease in tidal volume and minute volume	Elevation in tidal volume and minute volume	Intrapulmonary chemoreceptors; central chemoreceptors	pH and CO_2 are intrinsically linked

effects are also significantly impacted by temperature, with more robust responses to hypercapnia and hypoxia at higher temperatures.[7]

Chelonians seem particularly adept at tolerating hypoxia, which is the primary stimulus for ventilation in this group and is most pronounced in the aquatic species, such that increasing inhaled CO_2 has less effect on respiration. Conversely, most (nonaquatic) lizards and snakes appear to be more sensitive to elevations of CO_2 than hypoxia. For most reptiles, $PaCO_2$ values range between 15 to 35 mm Hg and should be maintained during anesthesia.[7]

In aquatic species, there are often significant differences between blood gas measurements from alveolar and arterial sources, which is an indication of the significant intracardiac shunting that can occur. Ventilation-perfusion mismatch can also result in similar differences and can often be induced by placing large reptiles (especially chelonians) into dorsal recumbency.

Numerous studies have demonstrated that dives involving reptiles are performed aerobically, not anerobically, and that most reptiles inhale as the last ventilatory act before submerging. Therefore lung oxygen reserves appear as important (if not more so) as hemoglobin and myoglobin oxygen storage. Arterial PCO_2 is predominantly determined by pulmonary ventilation, and plasma pH shows only minor deviations among reptiles and other vertebrates, provided comparisons are made at identical temperatures. In general, arterial pH decreases consistently with increasing temperature predominantly from an increase in arterial PCO_2 production (due to relative decrease in pulmonary ventilation relative to CO_2 production).[7]

CLINICAL INVESTIGATION

A presumptive diagnosis of respiratory tract disease may be made on the basis of historical analysis, physical examination, and a variety of ancillary diagnostic techniques.[8–11] However, a definitive diagnosis typically requires demonstration of both a host pathologic response (cytology, histopathology, paired rising titers) and the causative agent (microbiology, parasitology, toxicology).

History and Physical Examination

The historical data collected from owners usually confirms significant deficiencies in husbandry or nutrition. Optimal temperature and humidity regimens are often overlooked. Excessively high humidity (often at the expense of ventilation) may result in bacterial and fungal proliferations with heavy environmental exposure predisposing to pneumonia. Nutritional imbalances, particularly hypovitaminosis A, are often anecdotally associated with respiratory disease. Significant ectoparasite loads are often associated with poor environmental hygiene. Snake mites *(Ophionyssus natricis)* have been implicated as vector of several infectious causes of pneumonia, including aeromoniasis. Lack of appropriate quarantine is a common cause of infectious disease outbreaks.

Clinical signs of respiratory disease can include open-mouth breathing, dyspnea, and tachypnea. In addition to upper respiratory obstructions and lower respiratory tract disease, and (because of a poor functional separation between the lungs and the other viscera) space-occupying lesions within the coelom (e.g., ascites, neoplasia, granuloma, gastrointestinal distension, gravidity) can prevent normal lung expansion and cause dyspnea. Agonal respiration in terminal patients may also resemble dyspnea, while pulmonary edema secondary to cardiac or hepatic disease and hypoproteinemia can also occur.

Snakes. Increased respiration or respiratory noise associated with acute disturbance, shedding, or defensive hissing should be differentiated from a disease presentation. Blocked nares from shed, debris, discharge, or trauma can result in open-mouth breathing. Choana must be evaluated to differentiate upper from lower respiratory disease. Abnormal respiratory signs may include abnormal posturing with head and neck elevated, forced nasal exhalations, dyspnea including open-mouth breathing, swollen or distended cervical region nasal/oral/choanal/glottal discharge, and increased respiratory sounds (Fig. 76.10A). Inflammatory debris may accumulate within respiratory (vascular) or nonrespiratory (saccular) portions of the lung. Infectious material can persist within the lower respiratory tract because the saccular lung is minimally vascularized, poor mucociliary transport and ability to cough. Many snakes with respiratory illness are anorectic and lethargic.

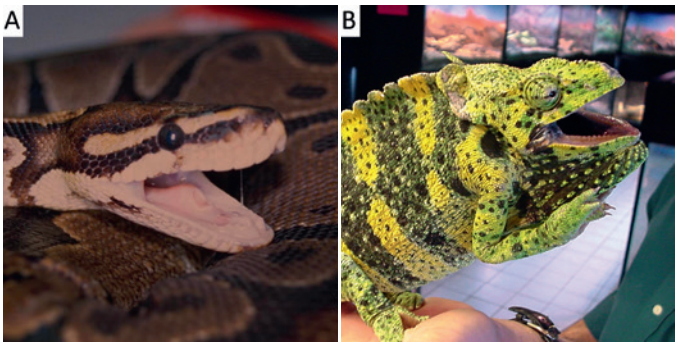

FIG 76.10 (A) Dyspnea and open-mouth breathing in a ball python (*Python regius*) with mycobacterial pneumonia. (B) Open-mouth threat displays and hissing, like this Meller's chameleon *(Trioceros melleri)*, should not be confused with respiratory disease. (Courtesy of Stephen J. Divers.)

Lizards. Open-mouth panting associated with threat/defensive displays, hyperthermia, and nasal salt gland excretion are not considered primary respiratory issues (see Fig. 76.10B). Both the external and internal nares must be examined for discharge, which may be serous, mucoid, or purulent. Blocked nares result in open-mouth breathing. Respiratory sounds may result from any fluids within the respiratory tract as a result of pneumonia, aspiration, or near drowning. These must be differentiated from hissing and snorting as a defensive gesture in response to a perceived threat. Conversely, complete lack of lower respiratory sounds might be noted in a fully consolidated lung.

Chelonians. Clinical signs of upper respiratory tract disease include clear to colored discharge or bubbling from the nares, ocular discharge, and palpebral edema. Concurrent clinical signs of rhinitis, stomatitis, and conjunctivitis are not uncommon. Dietary history is important to exclude hypovitaminosis A in carnivorous and omnivorous chelonians, which can cause squamous metaplasia and predispose to secondary infections. This is not an issue, because hypovitaminosis A is very rarely present. Excess salivation and inhaled irritants such as pollen or foreign bodies, such as foxtails or grass awns, can also lead to foreign body reactions and discharge. Chronic upper respiratory tract disease may erode or depigment the nares. Any lesion that compromises the larynx and glottal opening, such as abscesses or neoplasia of the oral cavity, can cause dyspnea.

Dyspneic chelonians may stretch their necks and open their mouths with obvious labored effort. Abnormal breath sounds, such as slight whistle, may be appreciated. Wheezing, tachypnea, or dyspnea may or may not occur with fungal pneumonia or tracheitis. Clinical signs of pneumonia are often not apparent until they are advanced (Fig. 76.11A). Most patients are depressed and lethargic, but the most dramatic clinical presentation involves inspiratory and expiratory dyspnea. The respiratory rate is generally e1evated with a reduction in the nonventilatory period

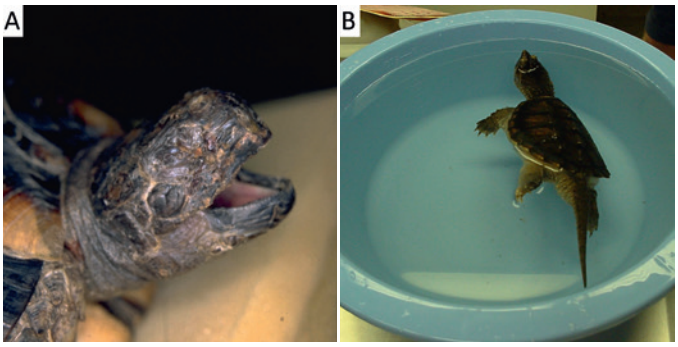

FIG 76.11 (A) Dyspnea in a *Testudo* tortoise due to mycotic pneumonia. and exaggerated respiratory movements of the limbs. Affected tortoises tend to breathe with the head and neck extended, and aquatic species may spend less time in the water. Nasal discharge may or may not be associated with lower respiratory tract disease. Ausculation is often difficult and results vary; however, use of moistened gauze between the stethoscope diaphragm and the shell may be helpful. The clinician should pay particular attention to the presence of abnormal sounds and asymmetry during auscultation. In aquatic species, asymmetrical lung consolidation often results in abnormal position in the water column or an inability to submerge (see Fig. 76.11A). Any unilateral mass (e.g., abscess, neoplasm, bladder stone) or asymmetrical gas presence (e.g. gastrointestinal bloat, obstruction) can cause similar signs. Any serious carapacial fracture that enters the dorsal coelom has the capacity to involve the lungs.

Crocodilians. Clinical signs are often nonspecific and range from subclinical infection to apparent peracute mortality. More often, however, a chronic course of intermittent anorexia with progressive weight 1oss, lethargy, and weakness precedes death. Clinical signs associated with respiratory disease in crocodilians include abnormal swimming (either in circles or on one side of the body), dyspnea, tachypnea, excessive basking, nasal discharge, and anorexia.

Hematology, Biochemistry, and Serology

Collection of blood, before starting therapy, for routine hermatology and plasma chemistry profiles can be informative, although seldom specific. Infectious disease may result in leucocytosis, often charcaterized by hereophilia and monocytosis (including azurophilia). Eosinophilia may be expected but is not invariably associated with verminous pneumonia. Most reptiles with pneumonia are critically ill, and evaluation of hydration, as well as renal and hepatic function, is necessary before initiating specific treatment. Serologic assays (ELISA) and PCR for ophidian paramyxovirus and tortoise mycoplasma infection methods are available in the United States and some European countries.

Radiography

Radiographic evaluation of the respiratory tract requires orthogonal views (see radiology Chapters 53 through 57 for more details). Digital imaging techniques allow the clinician to alter brightness or contrast and reverse the image, which can help highlight otherwise indistinct changes. In addition to dorsoventral views, lateral views should be obtained using a horizontal beam, and, in chelonians, a third craniocaudal view, also taken with a horizontal beam, is required (Fig. 76.12).

Quality radiographs permit the clinician to evaluate the trachea and bronchi in the cervical region and as they enter the lungs in the cranial coelom, often near the heart (Fig. 76.13A). Increased soft tissue densities, focal, multifocal, or diffuse within one or both pulmonary areas suggest exudate or increased tissue presence that can be consistent with infection or tissue proliferation (Figs. 76.13B and 76.14). Horizontal beam projections may reveal fluid lines.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) scans and magnetic resonance imaging (MRI) are useful techniques for evaluating the lungs and localizing pulmonary lesions (Figs. 76.15 and 76.16) (see Chapters 59 and 60).[8,9] Reptiles typically require sedation or short-term anesthesia to ensure the necessary immobility during image acquisition, with both pre- and postcontrast images obtained. CT is most useful for evaluating soft tissue and air interfaces, often at higher resolution, whereas MRI provides detailed images of various respiratory soft tissues, albeit at usually lower resolution (see Chapters 59 and 60). CT and MRI scan data are collected in series and can be reconstructed in a variety of ways. Postprocessing software allows for the reconstruction of the cross-sectional image series into a complete 3D respiratory tract; however, consultation with a diagnostic imaging specialist is strongly recommended to avoid misinterpretation.

Cytology and Microbiology

The ability to diagnose pathologic changes within the respiratory system of reptiles is relatively straightforward if initial reliance is placed on the collection of material for cytology/histopathology and microbiology. Reptiles should not be treated with broad spectrum antimicrobials unless attempts to demonstrate and characterize a bacterial disease have been undertaken.

The upper respiratory tract, including the nares, choana, larynx and cranial trachea, can be visualized and often sampled directly without anesthesia. Small-diameter culturettes permit the collection of samples, direct from the anterior trachea although care is required to avoid contamination by oral commensals. Swabs can be submitted for cytologic evaluation, microbiologic staining, and culture.

The transtracheal lavage is often preferred as the initial diagnostic tool for investigating lower respiratory tract disease and can be safely performed in most reptiles. Patients should be appropriately stabilized before short-term sedation or anesthesia, and the lavage should be undertaken after radiography or CT. The glottis is identified and intubated with a sterile endotracheal tube, then a sterile catheter of appropriate diameter and length is passed through the sterile endotracheal tube and down the trachea, past the bifurcation, and into a lung. If the disease is unilateral then a curved metal stylet can be used to guide entry into the left or right lung (Fig. 76.17A). Sterile saline (5 mL/kg) of 0.9% sterile saline (without any preservative) is instilled into the lung while the animal is restrained in the horizontal position. It is helpful to draw up the saline into a larger syringe to provide greater aspiration ability (i.e., for a 1 kg reptile, draw up 5 mL into a 60 mL syringe). The patient is then gently inverted, rolled, or rocked for 10 to 15 seconds before attempting aspiration. If no fluid is aspirated, then a second dose of saline is infused. It is often helpful to tilt the reptile head down and continue aspiration as the catheter is withdrawn up the trachea. Any residual saline is readily absorbed from the lungs. In cases of severe pneumonia, it may be possible to aspirate without the need for instilling saline, or quantities greater than the amount infused may be retrieved. In snakes the catheter should ideally be inserted to

30% to 40% SVL; however, in larger snakes a tracheal lavage may be all that is possible. In lizards, the catheter is advanced to a point just caudal to the forelimbs, and no further than 1/3 of the length of the coelom. In chelonia, the catheter can be advanced to a midcoelom position. The collected fluid can be used for cytology and microbiology (including bacterial and fungal cultures, or PCR) (see Fig. 76.17B–E). Depending on the volume and quality of the sample obtained, material should be divided and submitted as requested by the laboratory.

In chelonians, a percutaneous lung lavage can also be performed with a long intravenous catheter. Following aseptic preparation and while holding the animal at maximum inspiration, the catheter is positioned in the dorsocranial area of the prefemoral fossa and advanced in a dorsomedial direction. Aspiration of air confirms entry into the lung. The needle is removed before performing lavage through the catheter. Similar techniques are possible in lizards and snakes.

Endoscopy

Depending on the size of the animal and the equipment available, endoscopic examination of the larynx, trachea, bronchi, and lungs are often practical and provide a minimally invasive means of direct examination and biopsy for microbiology and histolopathology (see Chapters 62 through 64 for more details). Routine considerations before general anesthesia and endoscopy should be undertaken. Transglottal endoscopy of the larynx, trachea, bronchi, and lungs is a noninvasive procedure that can be undertaken during short-term anesthesia. Transcutaneous pulmonoscopy requires a more involved, albeit minimally invasive, surgical approach and longer anesthesia times.[10,11]

Transglottal Endoscopy. The use of fine-diameter rigid telescopes and flexible fiberscopes or videoscopes permits endoscopic access to, and biopsy of the lower respiratory tract tissues in many reptiles.[10,11] Semirigid or rigid endoscopes 1 to 4.0 mm can be used to evaluate the larynx and trachea as far as their diameter and length permits (Fig. 76.18A). In small lizards and snakes this may include access to the cranial aspect of the lung(s). However, in chelonians the long, meandering bronchi make rigid endoscopy access to the lungs difficult to impossible in animals <5 kg. In larger reptiles, the 1.9- and 2.7-mm rigid endoscope can be used with an operating sheath to permit the use of 1- to 1.7-mm (3–5 Fr) instruments including biopsy forceps. In smaller animals these instruments can still be used, with difficulty, using the trachea as the sheath to guide the advancing instrument. For deeper access, flexible endoscopes (often uretheroscopes or bronchoscopes) 2 to 6 mm can be used with the instrument channel for biopsy forceps or cytology brushes (see Fig. 76.18B). To avoid handling artefacts, endoscopic biopsies should be gently shaken from the biopsy forceps into sterile saline and then decanted into histology filters before placing into formalin.[10] Individual laboratory requirements should always be followed, but in general biopsies for microbiology are often submitted in enrichment or transport broth, whereas ethanol is generally preferred for parasitology.

Transcutaneous Endoscopy. These endoscopic approaches were developed to permit practitioners that have access to established avian and exotic rigid endoscopy systems the chance to examine the lower respiratory tract of reptiles. For snakes, depending on available equipment and the size of the snake, endoscopic evaluation of the distal trachea, intrapulmonary bronchus, vascular, semiaccular, and saccular lung may be possible (see Fig. 76.18C–H). In most snakes a right lateral approach with the snake in left lateral recumbency is preferred, whereas in boids (with two lungs), left, right, or bilateral examinations can be performed. With the anesthetized snake in lateral recumbency and following aseptic preparation, a small (1–2 cm) skin incision is made at the level of the semisaccular lung (or transitional zone) to avoid

major hemorrhage (approximately 35%–45% SVL) (Fig. 76.19).[10,11] A ventrolateral approach can made after a craniocaudal incision between the second and third rows of lateral scales, or dorsoventrally over an intercostal space. The subcutaneous coelomic muscle and coelomic membrane are bluntly dissected. When the wall of the lung (transparent avascular membrane) is reached, two fine stay sutures can be placed to elevate it to the level of the skin incision (this is often not necessary with the more lateral approach). Following perforation of the lung, the endoscope (rigid with or without the operating sheath, or, in large boids, a flexible scope) is introduced through the incision and directed cranially toward the vascular lung, anterior lung lobe, intrapulmonary bronchus, and distal trachea (see Fig. 76.3C–F). By directing the endoscope caudally, various visceral organs can be viewed through the transparent saccular lung wall. If there are pathologic changes, the affected part of the lungs can be sampled for further testing (cytology, histopathology and microbiology).[10,11]

Subsequent to examination via the ventrolateral approach, the lung is closed with a single simple interrupted suture using absorbable material, with the muscle and skin closed routinely. The lateral, intercostal approach does not typically require closure of the lung or the muscle, just the skin.[10] Biopsies should be gently shaken from biopsy forceps into sterile saline before fixation in 10% formalin (or 2% glutaraldehyde) to ensure the best diagnostic quality.[10] The aforementioned techniques have been performed in colubrids, pythons, and boas with good to excellent results.[10,11] Reevaluation of snakes a year later confirmed complete healing of the previous entry and the biopsy sites.[10] The authors have not experienced any negative consequences associated with pulmonoscopy in snakes; however, greater hemorrhage would be expected if a more cranial approach through the vascular lung was performed.

With the exception of fine diameter flexible endoscopy in large chelonians, the short trachea and long, narrow bronchi make entry into the chelonian lung extremely difficult via an oral approach. Two nonglottal approaches to the chelonian lung can be used, prefemoral (soft tissue) and carapacial (osteotomy). Both approaches require orthogonal radiographs or CT to determine which side is primarily affected, and in the case of carapacial approaches, precise targeting is needed because of the bony restriction to endoscope movements. The prefemoral approach is a soft tissue surgical approach to the caudal lung. The chelonian is anesthetized and placed in lateral recumbency with the pelvic limb retracted caudad and the prefemoral area aseptically prepared. A 2- to 5-cm craniocaudal incision is made close to the craniodorsal margin of the prefemoral fossa. Upon entry into the coelom, the caudal aspect of the lung is identified (aided by increased ventilation rate and maximal tidal volume), gently grasped, and two retaining sutures are placed to hold the lung close to the skin incision. A small stab incision through an avascular window permits entry of the endoscope (Fig. 76.20). Careful advancement of the endoscope can often permit examination of most of the lung, sometimes to the level of the primary bronchial opening. Closure of the lung after biopsy is important to prevent pneumocoelom.

The carapacial approach requires a temporary osteotomy. With the chelonian anesthetized and placed in ventral recumbency, the area of carapace over the site of lung pathology is aseptically prepared. A 3.5-mm (for the 1.9-mm integrated telescope) or 5-mm (for the 2.7-mm telescope and 4.8-mm operating sheath) osteotomy is then created with a sterile orthopedic drill with the patient at maximal expiration (Fig. 76.21). Entry into the lung is accomplished using small straight hermostats with the animal held at maximal inspiration. Escape of gas confirms entry into the lung. Examination proceeds with the endoscope, although there is far less manoeuvrability. After examination and sample collection, the osteotomy site may be closed with an epoxy resin, or a catheter can be secured in place to facilitate intrapulmonic drug administration. Appropriate samples must be submitted for cytology/histopathology and bacterial/fungal cultures before starting antimicrobials. Untreated or inappropriately treated chronic respiratory tract disease often spreads to other areas, resulting in septicemia and systemic abscess/granuloma formation in remote tissues, notably the liver.

Surgical Biopsy

If minimally invasive endoscopic techniques are not possible, then surgical access to the lung can be achieved by coeliotomy. There is no functional diaphragm or negative pleural pressure to preserve. In snakes the vascular lung is typically located between 12% and 45% SVL; however, great species variation exists.[1,2] Preoperative radiography can easily determine the margins of the respiratory tract and should be performed before surgical biopsy to ensure a correct, targeted approach. Biopsy of the vascular cranial lung commonly results in hemorrhage unless appropriate measures are taken. Biopsy of the thinner posterior lung (or air sac) is not complicated by hemorrhage but is seldom a site for primary pathology. In lizards, the cranial lung is also more highly vascularized than the caudal areas. A cranial coeliotomy may permit sufficient exposure; otherwise, a lateral, intercostal approach between ribs may offer better exposure for biopsy of the cranial lung. The tuatara (*Sphenodon punctatus*), some varanids, and crocodilians possess significant postpulmonary membranes that should be respected with large surgical breaches sutured closed. In chelonia, the lungs are protected by the carapace, which makes surgical access more difficult. Creation of a 4-mm to 5-mm temporary osteotomy in the carapace, directly over the area of interest, does permit the use of biopsy needles, either blind or using radiographic/CT guidance (Fig. 76.22). A ventral approach to the chelonian lungs is not recommended due to obstruction by the coelomic viscera and the need to close the lung and septum horizontale if surgically incised or penetrated in any way.

GENERAL APPROACH TO TREATMENT

Early diagnosis and aggressive therapeutic measures, including intensive nursing, are often necessary. Patients should be maintained at the upper end of their preferred optimum temperature zone or range, and with appropriate humidity to facilitate immunologic and mucociliary functions. The use of hospital oxygen cages should be reserved for those cases in which hypoxemia is present or suspected. Fluid therapy is often required due to increased insensible losses from exacerbated respiratory rate and effort. Route of fluid administration should be consummate with urgency and degree of deficit. Anorexia is not uncommon, but

there is rarely an urgent need to provide nutritional support during initial case management. Assisted feedings should be delayed until dehydration has been corrected and diagnostics (that often require sedation or anesthesia) have been performed.

Antimicrobial Therapy

A variety of bacterial and fungal organisms can cause disease and therefore culture (or PCR), and sensitivity (disc diffusion or MIC) testing is important. While awaiting microbiology results, gram-stained smears should be used to direct initial antimicrobial choice. Antimicrobials should only be prescribed when a bacterial or fungal disease has been identified. Inappropriate use of broad-spectrum antimicrobials implies a low level of clinical expertise and predisposes to drug resistance (see Chapters 29, 115 and 116).

Nebulization. Nebulization can be useful to deliver antimicrobials, especially those that may be systemically toxic, topically to the respiratory tract. Small particle size to ensure penetration deep into the respiratory tract, appropriate solution (in sterile water or saline), and air as the carrier are important to maintain ventilation. Using oxygen as a carrier gas tends to suppress respiration and reduce drug delivery. Although there have been no direct studies to date, the results involving avian reptiles suggest that successful nebulization requires particle sizes of ≤3 µm delivered for 30 minutes (if anesthetized and ventilated) or 2 to 4 hours (if conscious).[12,13] Once- or twice-daily treatments are recommended. In addition to antimicrobials (often aminoglycosides, amphoteracin B), mucolytics (acetylcysteine), and benzalkonium-polyhexanide solutions (F10 Antiseptic Solution Concentrate, Health and Hygiene Ltd, South Africa) are often nebulized but should not be mixed (Table 76.2). However, there is no evidence to suggest that antimicrobial nebulization is more effective than intravenous administration or that bronchodilators or mucolytics have any beneficial effects. If nebulization is pursued, a dedicated chamber should be used to facilitate creation of a thick fog for the reptile while preventing human exposure (Fig. 76.23).

TABLE 76.2 Suggested Drugs for Nebulization of Reptiles

Drug	Dose
Amikacin	50 mg in 10 mL saline
Tobramycin	50 mg in 10 mL saline
Ceftazidime	100 mg in 10 mL saline
Amphoteracin B	10 mg in 10 mL saline
Benzalkonium/polyhexanide (F10)	54 mg/4 mg (1 mL) in 250 mL saline
Acetylcysteine	20% solution

In humans the mg quantity of drug is entirely inhaled and therefore most useful. However, reptiles are placed in a nebulization chamber such that drug concentration and duration of exposure (typically 2–4 hours) are more important than the mg of drug used.

The compressor (1) forces air through the drug reservoir (2), located on the external rear wall, to form a fine mist that is delivered through a port (arrow) into the nebulization chamber (3), which has rubber seals around the front access door to reduce drug vapor escape. (Courtesy of Stephen J. Divers.)

Intrapulmonic Treatment. Transcutaneous catheterization of the lung can provide an alternative airway in cases of tracheal obstruction or to provide a route for direct drug delivery to the lungs.[14,15] In one case of tracheal obstruction in a ball python (*Python regius*), local anesthesia was used, and after a 1.5-cm surgical cut-down, the saccular lung was identified, stab incised, and a 4-mm endotracheal tube was inserted and sutured in place.[14] Although this endotracheal tube functioned as an alternative airway for 13 days before being removed and the site surgically closed, a smaller catheter could be employed for drug delivery. Following transcarapacial pulmonoscopy in an anesthetized Greek tortoise (*Testudo graeca*), the osteotomy site was not closed, but a 20-g teflon IV catheter was inserted into the diseased lung, capped, and secured in place using epoxy or acrylic (Fig. 76.24).[15] *Candida albicans* pneumonia was confirmed, and intrapulmonary therapy using amphoteracin B via the catheter for 3 weeks proved effective. Irritating drugs should be avoided; however, this technique can provide a route for delivering drugs that may be systemically toxic but that are poorly absorbed across the respiratory epithelium (e.g., aminoglycosides, amphoteracin B). After removal of the catheter, the site should be covered with acrylic or epoxy and allowed to heal by second intention.

SPECIFIC RESPIRATORY TRACT DISEASES

Tracheitis and Tracheal Obstruction

Clinical Significance. Inflammation, granulomas, chondromas, lymphomas, and exudates can be associated with the trachea.[16–18] If obstructive, these can lead to dyspnea, which tends to be poorly responsive to oxygen; however, dramatic improvement would be expected after creation of an alternative airway (e.g., lung catheter).

Known Etiological Cause(s). *Mycoplasma* have been reported to cause tracheitis in a number of chelonians (*M. agassizii*, *M. testudineum*) and proliferative tracheitis in a Burmese python (*Python bivittatus*).[18] *Salmonella arizonae* was considered the etiologic cause of tracheitis in a double-headed king snake (*Lampropeltis hondurensis*).[19] Nidovirus was seen in association with tracheitis in a group of ball pythons that also had bacterial pneumonia.[20,21] Iridoviral tracheitis was identified in a gopher tortoise (*Gopherus polyphemus*).[16] Tracheal chondromas and lymphoma have been reported in several boid snakes.[17,22,23]

Clinical Presentation and Diagnostic Confirmation. Most publications have involved postmortem evaluations, but lethargy and respiratory compromise, including dyspnea and open-mouth breathing, are common.

Most published reports have described patients as presenting dead or being euthanized shortly after presentation for postmortem investigations. Ideally, endoscopic evaluation of the trachea permits evaluation and selective biopsy of specific lesions for histopathology and microbiology (culture, PCR) (Fig. 76.25). If unavailable, radiography, CT, and tracheal lavage may be useful, but diagnoses may be missed (Fig. 76.26).

Specific Treatment. Exudates should be suctioned from the trachea, whereas firm, space-occupying masses (chondromas, granulomas) typically require endoscopic debridement or tracheal resection and anastomosis. Antimicrobial therapy is based upon culture and sensitivity or MIC results, and treatment for 3 to 6 weeks is often required. Reevaluation is important to determine the effectiveness of treatment.

Prognosis. Endoscopic and tracheal resection have been curative for single chondromas.[23] Multiple masses/granulomas carry a less favorable prognosis. Bacterial tracheitis can often be treated. Fungal infections tend to be more granulomatous and more resistant to medical therapy.

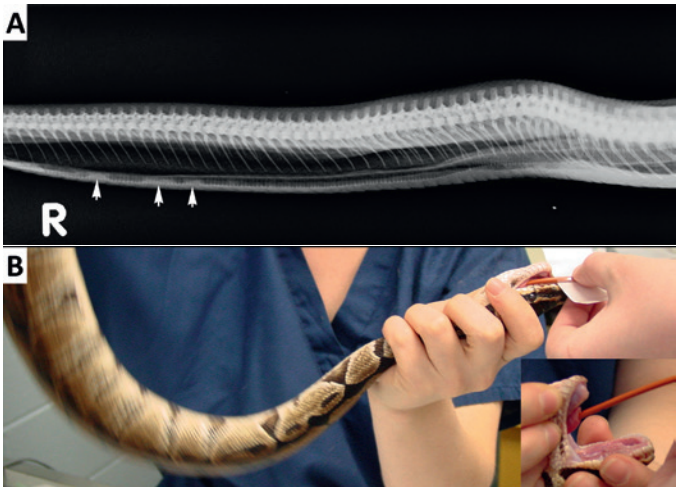

FIG 76.26 (A) Lateral radiograph (horizontal beam) of a ball python *(Python regius)* demonstrating multiple solitary masses within the tracheal lumen, consistent with chondroma. (B) Tracheal lavage in a ball python. In larger reptiles a sterile endotracheal tube should be placed into the trachea before inserting the lavage catheter. (A, Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services; B, courtesy of Stephen J. Divers.)

There are no reports of successful treatment of viral tracheitis, and supportive care is often all that can be provided.

Bacterial Pneumonia

Clinical Significance. Bacterial pneumonia may occur as a primary entity, secondary to stomatitis and aspiration, by hematogenous spread (e.g., endocarditis), or by direct/close anatomic association (e.g., hepatitis, coelomitis). Bacterial pneumonia can be focal, multifocal, or diffuse, and unilateral or, in boids, bilateral. Many infections involve commensal or environmental organisms that become pathogenic in an immunocompromised host.

Known Etiological Cause(s). Bacterial pneumonia is common in snakes, less so in lizards and chelonians. Microbiologic results have

VetBooks.ir

included *Mycoplasma, Aeromonas, Alicaligenes, Chlamydia, Citrobacter, Corynebacterium, Enterobacter, Escherichia coli, Klebsiella, Morganella, Moraxella, Pasteurella, Proteus, Pseudomonas, Acinetobacter, Brevibacterium, Achromobacter, Bacillus, Stenotrophomonas, Empedobacter, Salmonella,* and *Mycobacterium*.[24–29] Compared with healthy snakes with a predominance of *Providencia rettgeri* and coagulase-negative *Staphylococcus* spp., those with pneumonia exhibit moderate to heavy growth of aerobic gram-negative bacilli.[25] Anaerobic organisms (including *Bacteroides, Clostridium, Fusobacterium,* and *Peptostreptococcus*) have been rarely reported.[30]

Mycoplasma (*M. agassizi* and *M. testudineum*) are important respiratory pathogens of tortoises, and pneumonia appears to be intimately involved in the upper respiratory disease complex of these species. Other *Mycoplasma* spp. have been associated with pneumonia in crocodilians (*M. alligatoris*, *M. crocodyli*) and pythons.[28]

Clinical Presentation and Diagnostic Confirmation. Cases of acute or peracute pneumonia may present as sudden death, although lethargy, anorexia, and respiratory signs, including dyspnea and open-mouth breathing, are common.

Although diagnostic imaging may provide convincing evidence of lung disease, a definitive diagnosis relies on the collection of material for histopathology (or cytology) and microbiology. Therefore endoscopic evaluation or lung lavage is typically required.

Specific Treatment. High-volume lung lavage and aspiration, or coupage, have been used to remove considerable quantities of exudate from the lower respiratory tract of anesthetized or sedated squamates (Fig. 76.27). Systemic and local application of antimicrobials are typically required, and selection should be based upon disc sensitivity or MIC results. Prolonged treatment is often required, along with correction of any predisposing husbandry or nutritional components. Pharmacokinetic studies have been performed for clarithromycin and oxytetracycline, which should be used in preference to fluoroquinolones for mycoplasmosis.[31–35]

Prognosis. If left untreated most cases progress to generalized sepsis and death, although chronic granulomata or abscesses can develop. Severe cases, especially involving *Mycobacterium* and *Chlamydia* sp. have a more guarded to poor prognosis.

Fungal Pneumonia

Clinical Significance. Mycotic pneumonia is occasionally diagnosed in captive reptiles (see Chapter 31). Typically, fungal infections occur due to high mycotic exposure (poor environment), immunosuppression (hypothermia, hatchlings, concurrent disease), or long-term, broad-spectrum antibiotic abuse. Environmental temperature appears to be critically important; for example, cold-stunned sea turtles appear particularly prone to fungal pneumonia.[36]

Known Etiological Cause(s). A number of fungi have been associated with pneumonia in reptiles, including *Aspergillus*, *Candida*, *Fusarium*, *Mucor*, *Geotrichum*, *Penicillium*, *Cladosporium*, *Rhizopus*, *Chrysosporium*, *Paecilomyces*, and *Beauveria*.[37–40] The systemic deep mycoses occasionally diagnosed in mammals, such as blastomycosis and histoplasmosis, have not been diagnosed in reptiles to date.

Clinical Presentation and Diagnostic Confirmation. Most cases are presented dead or terminal, but severe respiratory compromise would be expected. A diagnosis of fungal pneumonia is often difficult to make antemortem without biopsy. Recovery of fungal elements, hyphae, or spores or culture of fungal agent (in combination with cytologic evidence of inflammation/infection) from a transtracheal wash is supportive of a diagnosis. However, lesions may be encapsulated and not productive. Endoscopic evaluation and biopsy is more effective and less invasive than traditional surgical approaches. Gross pathologic changes of mycotic pneumonia include pulmonary granulomata, lung consolidation, and occasionally extension of the disease to adjacent organs.

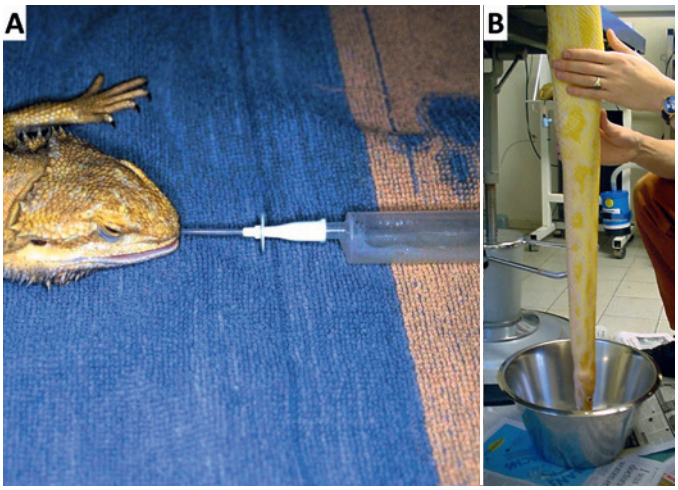

FIG 76.27 (A) Aspiration of large volume of exudate from an anesthetized bearded dragon (*Pogona vitticeps*). (B) Coupage (percussion therapy) in a sedated albino Burmese python (*Python bivittatus*) to facilitate drainage of pulmonary exudates. (Courtesy of Stephen J. Divers.)

Lesions in chelonians typically consist of nodular, caseous to firm masses within the tracheal wall, pulmonary parenchyma, or over the mucosa or serosal surfaces. Sometimes, pale plaques or fungal mats are present over tracheal and bronchial mucosae, and caseous exudate within air passages is less common unless secondary bacterial infection is present. In severe cases, a whole lung or part of the lung may be consolidated and emphysematous bullae may be observed. In crocodilians, pneumonia also presents as multifocal necrotic to granulomatous foci in the substance of the lung.

Specific Treatment. Large encapsulated lesions require surgical removal, and even small encapsulated granulomas are often resistant to drug therapy (Fig. 76.28). In acute cases and those where encapsulation is absent, antifungal medication may be effective, and both local and systemic administration should be combined. It is often wise to obtain antifungal MIC results and to check antifungal drug blood levels to ensure they are exceeded.

Prognosis. Typically the prognosis is poor when dealing with extensive disease. Single granulomas that can be surgically removed carry a fair to good prognosis, especially when combined with postoperative antifungal therapy.

Viral Pneumonia

Clinical Significance. Several viruses have been identified in association with peracute to chronic pathology of the respiratory system; however, the majority of viruses identified have only been circumstantially incriminated as causes of disease, with few studies fulfilling Koch's postulates (see Chapter 30). Therefore the clinician must be cautious and attempt to differentiate between infection and disease. In addition, the clinical picture is frequently complicated by secondary bacterial or fungal infection.

FIG 76.29 (A) Clinical presentation of herpesvirus infection and disease in a *Testudo* tortoise. (Courtesy of Zdenek Knotek). (B) Laryngeal histology demonstrating multiple intranuclear inclusion bodies consistent with herpesvirus. (Courtesy of Stephen J. Divers.)

Known Etiological Cause(s). A variety of viruses have been detected in association with respiratory pathology.[41-45] Herpesviruses have been associated with rhinitis, tracheitis, and bronchopneumonia in green sea turtles (lung, eye, and tracheal virus of green turtles); fibropapillomas in green and loggerhead sea turtles (chelonid fibropapilloma–associated herpesvirus); and rhinitis, stomatitis, pharyngitis, glossitis, tracheitis, bronchitis, and pneumonia of various terrestrial tortoise species (herpesviruses of terrestrial tortoises, e.g., chelonid herpesvirus 4) (Fig. 76.29). Adenovirus infections of chameleons have been reported in association with proliferative tracheitis, whereas bronchopneumonia has been seen in association with poxvirus and secondary bacterial infection. Iridoviruses from tortoises and turtles have been associated with pharyngitis, tracheitis, and pneumonia. Paramyxoviruses (ferlaviruses) have been rarely implicated in saurian pneumonia (e.g., caiman lizards, *Dracaena guianensis*) but are more common pathogens in snakes (*Bothrops, Bitis, Crotalus, Trimeresurus, Vipera, Atheris*), where they have been associated with caseous necrotic debris, lung thickening, and edema (see Fig. 76.29).[43] Other species of colubrids and boids have also been affected.[44] Multiple isolates of "virus x" have been recovered from a variety of European tortoises with gastrointestinal and respiratory lesions. More recently, a nidovirus has been identified as a likely etiologic agent of severe respiratory disease in pythons.[45] It is important to stress, in the majority of cases, the association of virus with respiratory lesions is just that, an association, and a direct causal relationship has not been demonstrated.

Clinical Presentation and Diagnostic Confirmation. Typical signs of upper and/or lower respiratory tract disease are often reported. The extent that clinical signs can be attributed to the virus rather than secondary infections is open to debate in most cases. Many cases of viral pneumonia are determined by histopathology and electronmicroscopy, without virus isolation or genetic sequencing. However, where serologic tests exist (e.g., ophidian paramyxovirus) they should be utilized, and paired rising titers can be useful to differentiate between active infection versus past exposure. PCR testing has revolutionized the ability to identify viruses from oral/tracheal swabs, lung lavage, or biopsy samples. However, positive results only indicate the presence of the virus and not necessarily disease. Therefore it is important to demonstrate host pathologic response by serology, cytology, or histopathology. It may be wise to save additional biopsy or necropsy tissues at −20°C in case virologic investigations are subsequently required.

Specific Treatment. With the exception of acyclovir (and related drugs) against herpesviruses, there are few medical options available (see Chapter 118). There are a number of human drugs that have been developed, but high costs and limited commercial interests have resulted in a lack of efficacy, pharmacokinetic, safety, and clinical trials in reptiles. When dealing with an outbreak, separation of diseased animals, barrier nursing, and disinfection are critical. In many cases, immunosuppression associated with poor husbandry and nutrition may be important and should be corrected. General medical support should include fluid therapy and nutritional supplementation. Appropriate quarantine with PCR and serologic testing (when available), remain the mainstays of prevention. In collections, euthanasia of affected animals should be considered.

Prognosis. Viral infections are able to persist for protracted periods, and treatment of clinical viral disease may not resolve persistent infection. Improvements in husbandry and nutrition may be important factors in the outcome.

Verminous Pneumonia

Clinical Significance. A number of parasites encountered in captive reptiles have a portion of their life cycle associated with the respiratory system. Except in cases with overwhelming parasite loads, most respiratory involvement is subclinical and minor, causing primarily localized inflammation.[46] However, heavy burdens or novel host-parasite interactions can lead to significant disease, often complicated by secondary infections.

Known Etiological Cause(s). Several genera of digenetic trematodes within the Ochetosomatidae and Plagiorchiidae (renifers) commonly inhabit the oral cavity, but adults often migrate via the glottis to the lungs and air sacs (Fig. 76.31A). Adults attach to the epithelial lining in the lower respiratory tract causing focal lesions that can become secondarily infected. Infection of aquatic turtles with digenetic spirorchid trematodes of the genera *Spirorchus*, *Henotosoma*, *Ullicaecum*, *Vasotrema*, or *Hapalorhynchus* may result in clinical signs suggestive of pneumonia. Substantial granulomatous reaction within the lungs may result in an asymmetrical position in the water, with the affected side floating lower than the contralateral side. Large trematodes (Hydrophidae) can infect the lungs of sea snakes, causing mucoid exudate with hyperplasia, hemorrhage, and necrosis.[46]

Migrating nematode larvae have caused respiratory signs or pulmonary lesions in tortoises (*Angusticaecum*), chameleons (*Hexametra*), and pythons (*Ophidascaris*). Adults of the Filarioidea and Dioctophymatoidea inhabit extraintestinal sites, including the lungs.

Adult lungworms (*Rhabdias*) reside within the lungs of snakes and lizards. The parthenogenic females lay their eggs within the lung. The eggs are then transported up the trachea, swallowed, and passed in feces. Migrating larvae (*Strongyloides*) may also be associated with pulmonary lesions.[46]

Pantastomids (parasitic crustaceans commonly known as tongue worms) undergo extensive visceral migrations before locating within the lungs (and less commonly the trachea and nasal passages) (see Fig. 76.31B). The most important genera are *Sebekia* (crocodilians), *Raillietiella* (lizards and snakes), *Kiricephalus, Porocephalus,* and *Armillifer* (snakes). Mammals, including humans, can act as intermediate hosts. Pentastomids can cause localized lesions, whereas moulting can induce

antigenic responses. The adults feed on tissue fluids within the lung and pass embryonated eggs, which enter the oral cavity, before being swallowed and passed in feces.

Rarely, coccidians have been identified in crocodilian lungs, whereas *Hepatozoon* schizonts may be found in the lungs of squamates. Intranuclear coccidia have been reported in captive tortoises (*Geochelone*). The obligate intracellular Microsporidia have been identified within pulmonary cells of inland bearded dragons (*Pogona vitticeps*) dying of the systemic effects of the disease. Although the primary target organs appear to be the liver and kidney, the significance of pulmonary infection is yet to be determined.[46]

Clinical Presentation and Diagnostic Confirmation. Although most trematode infestations are asymptomatic, heavy parasite loads may cause enough damage to predispose the animal to a secondary pneumonia. The diagnosis is made on the basis of the identification of the typical fluke eggs on transtracheal wash. Currently, no effective and safe treatment has been advocated, although praziquantel could be considered.

The diagnosis of spirorchid f1uke infection is difficult. Typical fluke eggs may be identified in direct saline solution mounts from lung washes or by sedimentation concentration of fecal samples. Often, however, the diagnosis is made postmortem with the identification of adults within the cardiovascular system or in squash preparations of pulmonary tissue.

Although most parasitic infections are subclinical, heavy infestations of *Rhabdias* can be associated with open-mouth breathing, extended glottal tube, and severe pneumonia (including secondary bacterial pneumonia) in snakes. A mucus-laden exudate may accumulate around the nares. A proliferative pneumonia may be identified by histopathology. Antemortem diagnosis relies on the demonstration of embryonated eggs (60 × 35 µm) in a lung lavage or biopsy.

Clinical disease associated with pentastomids is rare, and they are often incidental findings. However, they may cause focal irritation and with a host antigenic response, more diffuse inflammation. Antemortem diagnosis depends on microscopic identification of the ova, which appear distended with a thinly walled capsule and may measure up to 130 µm in diameter. Larva and their hooklets may be seen within these eggs.

Specific Treatment. Nematode infections may be treated with ivermectin (not chelonians), benzimidazoles, levamisole, or pyrantal. Pentastomids should ideally be treated by removing (often endoscopic) as anthelmintics such as ivermectin result in parasite death and massive antigenic release. Praziquantel can be considered for trematode infections (see Chapter 120). Prevention relies upon acquisition of captive-bred (instead of wild-caught) specimens, appropriate quarantine including fecal screening; use of captive-bred, clean food items; and sound hygiene.

Prognosis. Cases of uncomplicated verminous pneumonia often respond to medical (anthelmintic and NSAID therapy) or, in the case of pentostomids, surgical removal. Secondary infections, especially if severe, can significantly reduce prognosis.

(B) Generalized gaseous distension throughout the gastrointestinal tract compromising respiratory function in a green iguana (*Iguana iguana*). (Courtesy of Stephen J. Divers.)

Noninfectious Pneumonia

Not all inflammatory diseases are infectious by nature. Aspiration of foreign material, either iatrogenically or by chance, is certain to cause significant inflammation within the lungs. Aspiration pneumonia begins as a foreign body reaction; however, if neglected, progresses rapidly to secondary bacterial pneumonia.

Diseases that compromise tidal volume may mimic primary respiratory disease, even though the respiratory tract itself is healthy. Obesity, ascites, and cranial coelomic space-occupying lesions (e.g., cardiomegaly, hepatomegaly) have the potential to cause respiratory compromise (Fig. 76.32). Significant respiratory disease may result in an increase in pulmonary vascular resistance. The shunting that may occur from pulmonary pathology could decrease oxygen delivery to peripheral tissues. Serious, life-threatening hypoxia and acidosis may result from overwhelming the blood's buffering systems as anaerobiosis becomes prolonged. Conditions as innocuous as the loosening of skin around the nares immediately before ecdysis, which can increase respiratory noise, may be misinterpreted as disease. The "problem" is self-resolving after completion of ecdysis.

Neurology

Simon R. Platt

A variety of clinical syndromes in reptiles have neurological manifestations. Traumatic injury, nutritional deficiencies, neoplasia, and toxicities can all affect the nervous system. In addition, many infectious diseases (e.g., bacterial and viral) may cause neurological dysfunction. Unfortunately, there is a paucity of information on clinical neurology syndromes affecting reptiles. Additionally, available information is often based on individual case reports or extrapolated from mammalian species.[1]

The manner in which a specific disease of the nervous system causes clinical signs depends very much on the functional neuroanatomy of the vertebrate affected. The reptilian nervous system is moderately simple in structure yet allows functional diversity in species-specific behavior. Although there is a certain amount of specialization of the nervous system of various reptilian species, it is more similar among reptile taxa than different. The most important clinical aspects of functional reptile neuroanatomy are detailed here.

The behavior and anatomy of the various reptile species may render the performance of the neurological examination difficult or impossible; in the case of the more dangerous reptiles, examination may be impossible without restraint or anesthesia. However, many of the principles and techniques employed for the examination of mammalian patients with neurological dysfunction can be adapted for use in reptiles, providing useful information on managing these cases. The specifics of how to practically perform and interpret a neurological examination in reptiles is presented.

Diagnostic aids used in mammalian neurology, such as cerebrospinal fluid (CSF) analysis, advanced imaging, and electrodiagnostic evaluations, may also be difficult to acquire and/or of limited value in reptile neurology on the basis of patient size and anatomic and physiological differences.[1] The premise and latest understanding of the diagnostic testing procedures that are possible and helpful are outlined.

FUNCTIONAL NEUROANATOMY

A basic understanding of reptile neuroanatomy helps the clinician understand the clinical manifestations of neurological diseases and provides an opportunity for the clinician to determine the location of a focal lesion.[1–4] The reptilian central nervous system (CNS) is tubular, organized linearly, and has some degree of dorsoventral flexure along its length.[4] (Fig. 77.1) The brain is located midsagitally and is housed within a tubular brain case bounded rostrally by the ethmoid cartilages, laterally by the otic bone series, ventrally by the basisphenoid and laterosphenoid, and caudally by the occipital bones.[4] There is a large amount of space between the brain and the roof and walls of the braincase in many lizards, aquatic turtles, and tuataras and a smaller but still substantial space in tortoises and crocodilians; minimal space exists is snakes. The anatomy of the skull and cervical vertebrae and their relationship to the CNS has been described using computed tomography in sea turtles, snakes, and several lizards.[5–7] The normal anatomy of the head of loggerhead sea turtles has been described using MRI.[8]

Reptiles are lissencephalic (having no cerebral gyri and sulci) but are the first group to have a developed cerebral cortex with two hemispheres that are separated by a deep median fissure.[3] Reptiles are also the first group of animals with a cephalic flexure such that the brain lies off-line with the spinal cord and grows back to partially cover the diencephalon.[3] In most reptiles, the neocortex is absent; however, in chelonians, there is some evidence that the internal dorsal ventricular ridge is homologous to the neocortex of mammals.[4] The brain is roughly divided into a forebrain, midbrain, and hindbrain (see Fig. 77.1). The forebrain is associated with olfaction, taste, and sensorimotor integration and mediation. The midbrain is associated with visual processing and neuroendocrine function. The hindbrain is associated with auditory function, balance, and physiological homeostasis. The cerebellum is part of the hindbrain, which integrates sensory and motor input as well as having a role in maintaining postural equilibrium.

There is a poorly studied blood-brain barrier formed by the meninges—endothelial lining of the brains blood supply—and the choroid plexus.[4,9]

The spinal cord of reptiles extends to the limit of the osseous spine (the tip of the tail), and no cauda equina exists. The cord is housed within the vertebral column but generally only fills a portion of the canal; less than 50% of the canal is occupied by the spinal cord in alligators and 66% to 71% in several lizard species.[4] The spinal cord is organized segmentally as in other vertebrates but lacks some of the functional regionalization seen in higher vertebrates. The cord is structured much like described in other vertebrates, with white matter tracts of myelinated axons surrounding inner gray matter formed of cell bodies and organized into bilaterally symmetrical dorsal and ventral horns. The dorsal horns include the dorsal roots and the ventral horns have motor neurons.[4]

Locomotor centers are found within the spinal cord, giving it a degree of functional autonomy from the brain. Because of this, reptiles with spinal cord injury have been said to have a better prognosis for recovery than higher vertebrates.

Spinal nerves are laterally paired and composed of dorsal nerve roots that are primarily sensory and ventral roots that contain visceral motor and somatic motor roots, comprising the reflex arc.[4] The nerves exit the vertebrae from the spinal cord via intervertebral foraminae. The number of spinal nerves is associated with the number of vertebral bodies, with snakes often having a greater number than other reptiles.[10]

Two networks of interconnected spinal nerves control limb functions; the cervical or brachial plexus and the sacral or lumbosacral plexus formed by ventral nerve roots and their branches.[4] For obvious reasons, snakes either lack or have reduced brachial and sacral plexi.[4] More than one branch of the plexus is usually responsible for individual muscle innervation. The cervical plexus typically includes the median nerve

and the inferior brachial nerve, which divides to form the superficial and deep radial nerves to the shoulder and dorsal thoracic limb. The supracoracoideus, subscapular, and ulnar nerves innervate the pectoral muscles, subscapularis, and ventral thoracic limb muscles, while the deltoideus nerve innervates the shoulder.[4] The sacral plexus consists of up to six branches from spinal nerves associated with the caudal-most lumbar vertebra and the sacral vertebrae.[4] These nerves ultimately pass to the inguinal, pelvic, and pelvic limb muscles. The caudal nerve roots give rise to the obturator nerve innervating the ventral pelvic muscles and the ischiadicus nerve innervating muscles of the ilium before dividing into the peroneal and sciatic nerves. The more cranial nerve roots interconnect to provide major innervations (via crural, femoral, and tibial nerves) to the inguinal muscles, thigh adductors, and limb extensors.[4] There are also sacral branches going to the bladder (when present).

The visceral nerves function as the autonomic nervous system (ANS) with both sympathetic and parasympathetic components. The reptilian ANS differs from that of mammals in that the autonomic visceral nerves are not anatomically segregated into thoracolumbar sympathetic and craniosacral parasympathetic regions.[4] These nerves arise along the length of the spinal cord and may have both sympathetic and parasympathetic components.

Nerve endings in the skin of reptiles are similar to those identified in mammals and serve the same function, being responsible for cutaneous sensation. Some lizards have hairlike structures in the skin with sensory function as well.[1]

Most reptiles have 12 to 13 cranial nerves (CNs), although snakes only have 11 to 12.[4] The terminal nerves (nervus terminalis, cranial nerve 0), discovered after the classical human-based numbering and naming system was in place, travel with the olfactory nerves; these two are the most rostral CNs. The terminal nerve innervates the vasculature of the nasal epithelium and is not tested clinically. The functions of CN 0 are not characterized but are believed to be associated with the gonadotropin-releasing hormones.[4,11] The remaining cranial nerves have well-documented functions, which are summarized in Table 77.1.

The vestibulocochlear system detects sound or vibrations through the auditory apparatus and movement and orientation in space.[4] Auditory nerves from each lagena, which is equivalent to the cochlea of mammals, project to the auditory tectum. The vestibular apparatus (semicircular canals, sacculus, and utriculus) is innervated by branches of the statoacoustic (CN VIII) nerve.[4]

Two meninges are found in reptiles, covering the brain and spinal cord. The outer dura mater is tough and largely avascular. The

TABLE 77.1 Reptilian Cranial Nerve Function and Evaluation[2,4,21,108]

Cranial Nerve		Function	Clinical Test
0	Nervus terminalis	Innervates vasculature of nasal epithelium; chemosensory for gonadotropin-releasing hormone (GnRH)	None
I	Olfactory	Olfaction; carrying sensory information from the nasal sacs and vomeronasal organ	Move head toward food when eyes are covered
II	Optic	Vision, carries sensory information from the retina to the thalamus and optic tectum	Menace response if patient has eyelids and/or behavioral response to threatening gesture
III	Oculomotor	Controls movement of eyes via dorsal, ventral and medial rectus muscles; moves eye medially; controls iris and ciliary body	Check for normal, coordinated eye movement, strabismus, and pupil shape; pupillary light reflex
IV	Trochlear	Controls movement of the eyes via dorsal oblique muscle of eyeball	Check for normal, coordinated eye movement (rotation of globe) and strabismus
V	Trigeminal	Sensory innervation of skin around eyes and mouth; sensory pits of pit vipers and boids; controls jaw adductor muscles, muscles of skin around teeth bearing bones in snakes, and intermandibularis (in floor of mouth). Innervates depressor palpebrae muscle, moving the lower eyelid.	Mandibular branch: check normal jaw closure and buccal pumping. Ophthalmic and maxillary branches: test ability to feel stimulus to face, lower lid, and nasal area with palpebral reflex and stimulus to the cornea with the corneal reflex.
VI	Abducens	Controls movement of eye via lateral rectus and retractor bulbi muscles	Check for normal, coordinated eye movement and strabismus; corneal reflex
VII	Facial	Motor to eyelid muscles and some jaw muscles. Sensory from skin and muscle around the ear, upper jaw, and pharynx, as well as taste receptors on rostral tongue. Controls superficial neck muscles and mandibular depressor.	Normal movement of eyelids if present, which can be elicited with the palpebral reflex. Monitor ability to open mouth voluntarily.
VIII	Vestibulocochlear (statoacoustic)	Balance and hearing: sensory from the inner ear.	Turn head left and right to check for spontaneous nystagmus; check for head tilts and/or poor righting reflex.
IX	Glossopharyngeal	Taste and sensation in the pharynx; controls tongue muscles	Examine tongue for active protrusion and retraction. Observe ability to swallow.
X	Vagus	Sensory and motor to glottis, heart, and viscera	Apply pressure to both eyes for several minutes and check for decreased heart rate. Observe ability to swallow, opening, and closure of glottis.
XI	Spinal accessory	Controls neck and shoulder musculature	Dorsal neck and shoulder muscles should have strong tone in lizards and crocodilians; difficult to assess in snakes and turtles
XII	Hypoglossal	Controls hyoid muscles and tongue	Look for deviation and/or weakness of the tongue to indicate defects

pia-arachnoid layer is vascular and lies in close contact with the surface of the central nervous system (CNS).[4] The space between the pia-arachnoid layer and the dura mater is the subdural space. Reptiles do not have a true subarachnoid space, an important fact in attempts to collect cerebrospinal fluid (CSF); in mammals CSF is collected from the subarachnoid space. CSF is produced by the tela choroidea, a specialized vascular structure located in the dorsal midbrain.[4] The epidural space contains veins located ventral or lateral to the spinal cord.

NEUROLOGICAL EXAMINATION AND LESION LOCALIZATION

Before the reptile patient is restrained, the clinician should observe the patient in its environment to evaluate its mental status, degree of alertness, and presence of abnormal posture. Stimulating the patient to move is helpful to evaluate for postural or ambulatory abnormalities, such as paresis or hemiparesis, likely indicating the presence of a neurological condition. As reptiles are ectothermic, it is important that the examination takes place at appropriate environmental temperatures. Low temperatures can result in reduced nerve conduction, weakness, sluggishness, behavioral changes, or frank neurological deficits.[2,12]

Many neurological diseases in reptiles can be related to inadequate husbandry. Therefore clinicians must be aware of proper dietary and environmental requirements needed for the species evaluated and owners questioned about care.[13,14] As an example, exposure to excessively low temperatures during hibernation or sudden drops in water temperature can result in neurological dysfunction in turtles and tortoises.[2] Additionally, low-calcium diets may lead to hyperparathyroidism, feeding fish-based diets may result in thiamine deficiency, egg-based diets may result in biotin deficiency, and leaf-based diets can lead to vitamin E or selenium deficiency, all of which can result in neurological dysfunction.[2,14] The owner must also be asked about the possibility of toxin exposure, as there are a considerable number of toxicities that can result in neurological dysfunction. Improper bedding, rhubarb or firefly ingestion, lead, ethylene glycol, antibiotics (such as metronidazole, aminoglycosides, and enrofloxacin), ivermentin, or other antiparasitic drugs can all lead to significant neurological disease.[2,15–17]

Assessment of mentation and responsiveness can provide an indication of an animal's level of consciousness, which can be graded as alert, obtunded, stupor, or comatose, which is suggestive of an intracranial lesion (Table 77.2). Such an assessment can be accomplished by opening an enclosure, attempts to handle, prodding with a pole or stick, and offering food.[18,19] However, the ease of assessment is certainly species related and requires knowledge of what behaviors would be expected in a normal animal (Fig. 77.2), some of which may actually mimic neurological disease.[2,12,19] An inappropriate and/or confused mentation would suggest forebrain dysfunction.

The position of the head and neck should be noted. Most reptiles are able to lift and move their head freely (Fig. 77.3). Abnormalities of head position may include head tilts, turns, or dorsal flexion

TABLE 77.2 Lesion Localization Within the Nervous System[2]

Lesion Localization	Localizing Clinical Signs
Forebrain	Seizures, altered mentation, behavioral changes, visual or olfactory deficits, contralateral limb postural reaction deficits
Midbrain	Altered mentation, contralateral or ipsilateral weakness, and/or postural reaction deficits, CN III or CN IV dysfunction
Hindbrain	Altered mentation, ipsilateral weakness, and/or postural reaction deficits, CN V-XII dysfunction
Cerebellum	Ataxia, intention tremors, dysmetria, possible head tilt, and nystagmus
Cervical spinal cord	Paresis and ataxia in all four limbs or trunk caudal to lesion; normal spinal reflexes
Spinal cord at level of the cervical intumescence	Paresis and ataxia in all four limbs or trunk caudal to lesion; reduced to absent thoracic limb spinal reflexes; normal pelvic limb spinal reflexes; possible severe muscle atrophy in thoracic limbs
Spinal cord between cervical and lumbar intumescences	Paresis and ataxia in pelvic limbs or trunk caudal to lesion; normal thoracic limb spinal reflexes; normal pelvic limb spinal reflexes; panniculus and/or righting reflex may be abnormal
Spinal cord at level of lumbar intumescence	Paresis in pelvic limbs or trunk caudal to lesion; normal thoracic limb spinal reflexes; reduced to absent pelvic limb spinal reflexes, cloacal reflex, and/or clasp reflex; possible severe muscle atropy in pelvic limbs
Spinal cord caudal to lumbar intumescence	Weak, paralyzed, and/or flaccid tail
Diffuse neuromuscular	Weakness in all four limbs; possible cranial nerve dysfunction; reduced to absent spinal reflexes in all four limbs; possible severe muscle atrophy in all four limbs

(opisthotonus, stargazing) and ventral flexion.[2] The latter may be related to generalized weakness rather than neurological dysfunction. Abnormal head movements can be due to tremors and seizure activity, although head bobbing while breathing has been associated with respiratory infections in box turtles and tortoises, which could be confused with neurological dysfunction.[2] Abnormal spinal curvature, such as kyphosis, lordosis, and scoliosis, can be due to neurological disease causing alterations in paravertebral muscle tone or caused by vertebral abnormalities, such as congenital malformations.[20]

Ataxia, paresis, or weakness and lameness may all be identified during a gait evaluation. Ataxia always indicates neurological disease but is often very difficult to identify in many reptiles due to their anatomical conformation. Weakness, however, may be due to muscle disease, or a systemic illness and lameness can indicate an orthopedic condition or a localized nerve dysfunction (Fig. 77.4).

An appropriate surface for the animal to move on must be provided, depending on the species, and in some species, evaluation of movement in water will be very helpful.[2,21,22] In most cases, tortoises are able to walk with their plastron suspended off the ground (see Fig. 77.3A). With paresis or motor weakness, this ability may be lost.

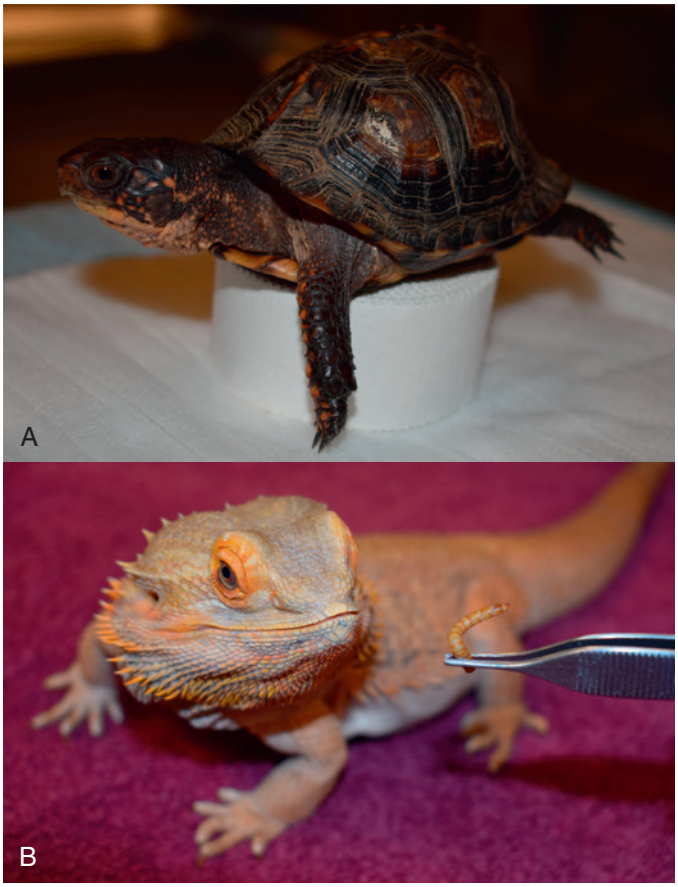

FIG 77.3 (A) The voluntary movement of the head and neck as well as the limbs can be seen in this eastern box turtle (*Terrapene carolina carolina*) by placing it on an object such as a tape roll, raising it off the ground. (B) Using food in species like this bearded dragon (*Pogona vitticeps*) can encourage them to move their head and neck, and it also helps assess vision. (Courtesy of Simon R. Platt.)

FIG 77.4 Injury to peripheral nerves can result in monoparesis, as is seen affecting the right pelvic limb of this crocodilian. (Courtesy of Simon R. Platt.)

FIG 77.5 As this ball python (*Python regius*) wraps around an arm, the movement and gripping ability of its trunk can be assessed. (Courtesy of Simon R. Platt.)

Chelonians with neurological disease frequently circle and are unable to hold up their head or hold their head in cervical hyperextension. They may be unable to prehend food properly and may show dysphagia. With chelonians, the head and legs should be pulled from within the shell to evaluate the muscle tone of the extremities. Sea turtles or other aquatic species presented for swimming in circles, or in one direction, often have asymmetric buoyancy issues as a result of a mass or uneven gas distribution in the lungs or coelomic cavity and not a related vestibular disease.[21]

Snakes with central nervous system disease often have fine motor tremors and are unable to strike at prey with accuracy. Some snakes are unable to constrict prey because of the loss of muscle tone or may be unable to move the prey accurately toward their mouth after a kill. As a snake ambulates across the hand and arm, the gastropedges gripping the skin provide an indication of muscle tone (Fig. 77.5). Palpation is also useful for evaluation of general body muscle tone. When a healthy snake is suspended by its midbody, it should be able to lift its head straight and steady to search for a substrate (Fig. 77.6). With neurological disease, jerky, irregular movements are often present as the snake seeks a substrate.

FIG 77.6 If the snake is held by the midbody, the ability to raise its head should be noted as seen in this picture of a ball python (*Python regius*). (Courtesy of Simon R. Platt.)

In reptiles with limbs the assessment of postural reactions for the evaluation of proprioception can be relatively adapted from what is described in dogs and cats. Hopping, hemiwalking or hemistanding, wheel-barrowing, and tactile placing assessments can be attempted and interpreted based on what would be expected in a normal reptile of the species being evaluated (Fig. 77.7). Limb-placing responses as performed in dogs by turning over the digits and watching for an immediate correction are unlikely to be possible in many reptiles, apart from some of the larger lizards.

Cranial Nerve Examination

Olfaction (CN I) is a chemosensory system in reptiles mediated by sensory cells in the nasal cavity and by the Jacobson's organs, which have ducts that open into the mouth. The tongue brings odoriferous particles to the Jacobson's organ, where the vomeronasal branch of the olfactory nerve is stimulated, providing input to the brain. The Jacobson's organ is absent in crocodilians and modified or absent in chelonians. This system is rarely evaluated in clinical patients. Testing the patient's response to noxious odors such as alcohol may assess the functional status of the olfactory nerve, but care must be taken with interpretation as such substances may stimulate the trigeminal nerve. A healthy patient recoils or moves away from an alcohol-soaked pledget or cotton-tipped applicator. A history of a normal ability to locate food may also indicate a functional CN I, although other sensory functions may also play a role in food recognition.

The optic nerve (CN II) is responsible for vision. Reptiles with eyelids can be tested for vision, with a menace response confirming optic nerve (CN II) and facial nerve (CN VII) function, and this can be performed with a hand, finger, or an object such as a cotton-tipped applicator (Fig. 77.8). Most reptiles have eyelids and nictitating membranes; however, in snakes and some lizards (especially geckos), the eyelids are fused and transparent, forming the spectacle, and the nictitans is absent. Movement of the upper eyelid closes the eyes of crocodilians, and the eyes are closed by movement of the lower lid in other reptiles. One must not create air movement or vibrations; many reptiles are able to sense vibrations that are imperceptible to humans. Vision may also be assessed by observing the patient's ability to navigate around, and react to movement within, the environment. Some reptiles use vibrations or thermal sensors to locate prey and may not rely on their visual senses.

The oculomotor nerve (CN III) controls the iris, which is composed entirely of skeletal muscle in reptiles, allowing voluntary control of

FIG 77.7 Supporting the animal and testing one limb at a time for hopping ability is a good way to test proprioception, demonstrated here in (A) an eastern box turtle (*Terrapene carolina carolina*) and (B) a bearded dragon (*Pogona vitticeps*). Holding the caudal body of the animal higher than the thoracic limbs and slowly pushing them forward encourages a wheel-barrowing test to evaluate the motor function and proprioception, shown here in (C) a bearded dragon and (D) a crested gecko (*Correlophus ciliatus*). Bringing the reptile to a table edge can test visual and tactile placing (E), which assesses vision, motor function, and proprioception, although, it is not uniformly reliable as in mammals. (Courtesy of Simon R. Platt.)

pupil size.[2] Dysfunction of the nerve may result in mydriasis and anisocoria (Fig. 77.9). The pupillary light response, which evaluates CNs II and III in mammals, is not very reliable in reptiles due to this voluntary override capability and the iris not being responsive to traditional mydriatics (Fig. 77.10); however, topical neuromuscular blocking agents can produce mydriasis. Intracameral injection of neuromuscular blocking agents, such as d-tubocurare, produces mydriasis but is somewhat invasive. Topical application of nondepolarizing neuromuscular blocking agents, such as vercuronium, on the cornea of species without a spectacle may produce mydriasis. The oculomotor nerve also innervates the extraocular muscles (dorsal, ventral, and medial rectus and the ventral oblique muscle), so dysfunction of this nerve may result in ventrolateral strabismus.

The trochlear nerve (CN IV) and the abducens nerve (CN VI) innervate the dorsal oblique, and the lateral rectus extraocular muscles respectively and are involved in coordination of ocular movements

FIG 77.8 A threatening gesture is necessary to perform the menace response; in addition to observing for a blink in those species that have eyelids, a behavioral avoidance of the threat may also be observed, manifested in chelonians by withdrawal of the head into the shell. (Courtesy of Simon R. Platt.)

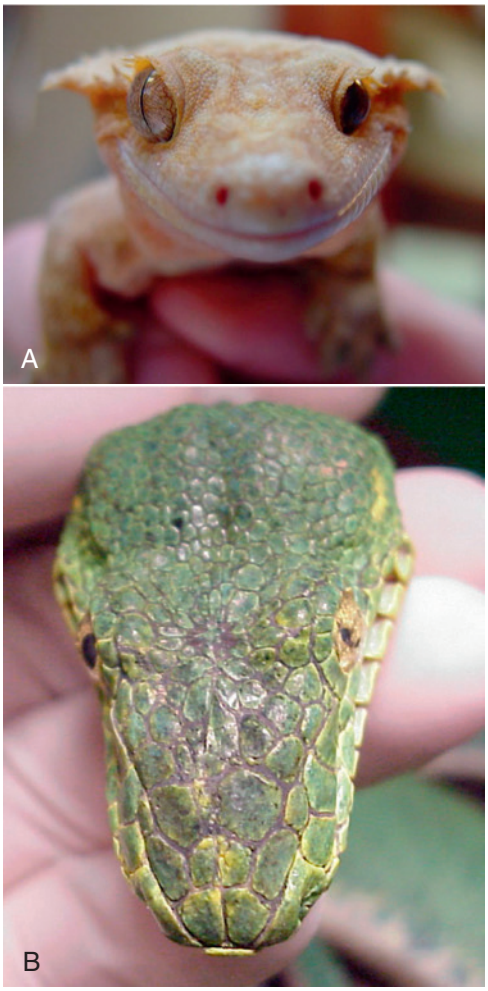

FIG 77.9 Anisocoria can be seen in reptiles due to ocular lesions, optic nerve, oculomotor nerve, or sympathetic supply dysfunction, which may result in either mydriasis or miosis. Anisocoria is seen in (A) a crested gecko (*Correlophus ciliatus*) due to left-sided mydriasis and (B) an Amazon green tree boa (*Corallus caninus*) due to left-sided miosis. (Courtesy of Joerg Mayer.)

FIG 77.10 A bright light shone into each eye may elicit the pupillary light reflex in some, such as this bearded dragon (*Pogona vitticeps*); however, the skeletal muscle of the iris means that there is voluntary control of the pupil size, which makes this reflex difficult to interpret. along with CN III. Some reptiles (chameleons) are capable of moving their eyes independently, which makes assessment for the presence of strabismus difficult. Normal and coordinated eye movements indicate healthy function of these nerves. Medial strabismus may indicate dysfunction of CN VI. A branch of the abducens (CN IV) supplies the nictitans.

The trigeminal nerve (CN V) is composed of both sensory and motor fibers with mandibular, maxillary, and ophthalmic branches. The mandibular branch supplies motor fibers to the muscles responsible for jaw function. The anatomy of the trigeminal nerve has been mapped out in crocodylians using computed tomography.[23]

The presence of normal jaw function indicates healthy nerve function, and dysfunction may result in a dropped jaw if bilaterally affected, and masticatory muscle atrophy may be seen chronically in some species. The ophthalmic branch provides sensory innervation to the skin surrounding the eye and the mucosa of portions of the nasal and oral cavities. The maxillary branch is sensory to the upper jaw, nose, and lower eyelid. Its function may be tested by determining the patient's ability to feel a cotton-tipped applicator around the face; if the species has eyelids, a palpebral reflex may be used to evaluate this nerve in conjunction with CN VII, which causes the eyelids to close in species with eyelids (Fig. 77.11). If necessary, a painful stimulus such as a 27-gauge needle may be used. Additionally, a corneal reflex may be performed to evaluate corneal sensory innervation, resulting in globe retraction due to retractor bulbi muscle contraction, which is innervated by CN VI (Fig. 77.12). In some reptiles (pit vipers), CN V is also responsible for innervating the heat-sensing infrared receptors[2] (Fig. 77.13). In these snakes, the sensory fields overlap, creating three-dimensional heat perception used to locate prey. In boas and pythons, smaller simpler pits are present along the upper and lower labial scales and are innervated by the ophthalmic, maxillary, and mandibular branches of the trigeminal nerve (CN V).

The facial nerve (CN VII) supplies motor function to the muscles of the eyelids and can be assessed with the palpebral reflex. Snakes and many species of lizards have developed cranial kinesis, which is the ability to move the upper and lower jaw, facilitating capture and swallowing of prey. Cranial nerve VII innervates the muscles responsible for opening the jaw. The facial nerve also supplies sensory fibers to the taste buds of the cranial two-thirds of the tongue. These fibers form part of the chorda tympani, which is a branch of the facial nerve that passes through the middle ear.

The statoacoustic or vestibulocochlear nerve (CN III) is responsible for both hearing and the sense of balance or equilibrium. Hearing is well developed in most reptiles, especially those with an externally visible tympanum, although they are best able to perceive lower frequencies. Many reptiles may not have a pronounced response to auditory stimuli. This, coupled with their ability to sense vibration, makes assessment of the cochlear portion of CN VIII difficult. A defect in the vestibular system may manifest itself as spontaneous nystagmus, head tilt, rolling, ataxia, and an abnormal righting reflex[21,24] (Fig. 77.14). As in birds with nystagmus, the whole head may move with the fast and slow phases in conjunction with the eyes. The eyes should also be evaluated for the presence of normal physiological nystagmus and for evidence of positional nystagmus or strabismus, often characterized as a ventral strabismus with head elevation on the side of the lesion.[2]

The glossopharyngeal nerve (CN IX) innervates a chemosensory system analogous to taste with taste buds and sensory papillae throughout the oral mucosa, particularly on the caudal tongue and pharynx. Assessment of the ability of reptiles to taste is difficult. Many patients have a negative reaction to bitter substances placed into their mouth by holding their mouth open, writhing, and pawing at their mouth. This nerve also innervates pharyngeal musculature and so in part is responsible for swallowing function.

The vagus nerve (CN X) in reptiles is responsible for pharyngeal, esophageal, and laryngeal musculature innervation and so is responsible for swallowing in conjunction with CN IX. Dysfunction is manifested as dysphagia and laryngeal paresis or paralysis.

The spinal accessory nerve (CN XI) supplies motor fibers to the larynx, pharynx, and the superficial cervical musculature (sternocleidohyoideus and trapezius) but is apparently absent in some snakes and some lizards.[2]

The hypoglossal nerve (CN XII) innervates the tongue musculature and can be assessed by watching for normal tongue movement, position, tone, and symmetry. Regular tongue "flicking" should be noted in snakes and some lizard species during examination. Opening the mouth to assess the tongue can be achieved using a plastic card, rubber spatula, or an avian beak speculum (Fig. 77.15). Some lizards will open their

mouths in response to tapping on the nose or with gentle traction on the dewlap.[2]

Reflex evaluations. Anatomical studies suggest that reflexes in reptiles should function segmentally in a similar fashion to that seen in mammals.[2] This means that they require afferent (sensory) and efferent (usually motor) peripheral nerves and a connection within the spinal cord at a certain level, without the need for ascending or descending control. Many myotatic reflexes in dogs and cats (and thus reptiles too?) are too subjective to be reliable and so should definitely be interpreted with caution if attempted.[21]

The withdrawal reflex can be elicited reliably from most reptiles with limbs (Fig. 77.16). The stimulus is performed usually by pinching on a digit manually or with hemostats or by pricking the plantar surface of the limb with something sharp. A healthy animal has a brisk withdrawal reflex. These reflexes are known to be temperature dependent. With a decrease in environmental temperature, a corresponding decrease is seen in conduction velocity within the peripheral nerves. During brumation (hibernation), conduction along peripheral nerves almost ceases.[25] Assessment of the patient's body or environmental temperature in conjunction with an evaluation of reflexes is therefore important. Reflexes are best evaluated with the animal in its optimum temperature range.

The cloacal reflex, similar to the anal reflex in mammals, can often be elicited by stimulation of the cloaca with a cotton-tipped applicator or hemostats (Fig. 77.17), resulting in contraction of the cloacal musculature in normal animals. In some reptiles, there may also be ventral movement of the tail as part of the reflex response, and in turtles the pelvic limbs normally will come together in a clasplike response.[21] The segmental nature of the cloacal reflex remains undocumented; a loss of cloacal tone has been reported for spinal cord injuries above the segmental level expected for innervation, which is dissimilar to what is documented in mammals.[2,21]

The panniculus reflex is present in reptiles and is particularly useful in snakes (Fig. 77.18). A hypodermic needle may be used to stimulate the patient's skin along the lateral margins of the body. A healthy patient responds with a twitch of the skin and so is obviously not possible in chelonian species. With spinal cord injury, the panniculus response is present cranial to the lesion and absent caudal to the lesion.

The righting reflex is frequently used to evaluate the neurological status of reptile patients. Squamate reptiles and crocodilians placed on their back should turn their head over first and then roll the body over to the normal position.[1] Chelonians placed on their back generally try to right themselves by pushing their head against the substrate and attempting to get their legs onto the surface (Fig. 77.19).

This provides a good opportunity to evaluate movements of the head, neck, and limbs as the patient attempts to right itself.[21] In snakes, the righting reflex is useful in identifying the location of a spinal cord injury. The snake rights itself to the level of the injury and is unable to right caudal to the lesion. Some animals, especially crocodilians and lizards, when placed on their back with their ventral coelom gently stroked, become sedate or flaccid, inhibiting the righting reflex.[2]

NEURODIAGNOSTIC TECHNIQUES

Imaging

Plain radiography is relatively easy to perform and useful for confirming osseous pathology that may be causing neurological dysfunction.[26–28] Traumatic lesions, congenital malformations, secondary hyperparathyroidism, osteomyelitis, osteoarthritis, and neoplastic disease may all cause visible lesions on radiographs.[14,16,20,29] The normal radiographic anatomy of the skull has been documented in several reptile species[5–7] (Fig. 77.20). Radiographs may be helpful to identify retention of eggs in female chelonians or other space-occupying caudal coelomic lesions, which may be responsible for pelvic limb neurological dysfunction.[2,29]

Intrathecal Contrast-Enhanced Imaging. This contrast-enhanced radiographic technique requires injection of an iodinated medium into the space normally occupied by CSF to identify compressive lesions affecting the spinal cord.[28] Currently, a lack of scientific evidence exists

to confirm the presence of a subarachnoid space in reptiles. With no subarachnoid space, myelography is technically not possible. However, clinical reports indicate that CSF collection and intrathecal contrast-enhanced imaging are useful in examining the central nervous system of reptiles, albeit difficult to perform![2]

Computed Tomography (CT). CT scanning uses radiographs and computer technology to create cross-sectional images of the patient[30,31] (Fig. 77.21). CT scan provides superior soft tissue imaging with no superimposition of structures when compared with conventional radiography and provides good contrast images of calcified structures.[28,30] Contrast enhancement allows for better visualization of soft tissue structures with increased blood flow. CT scan also helps reveal changes in bony tissues and provides greater detail of imaged structures than

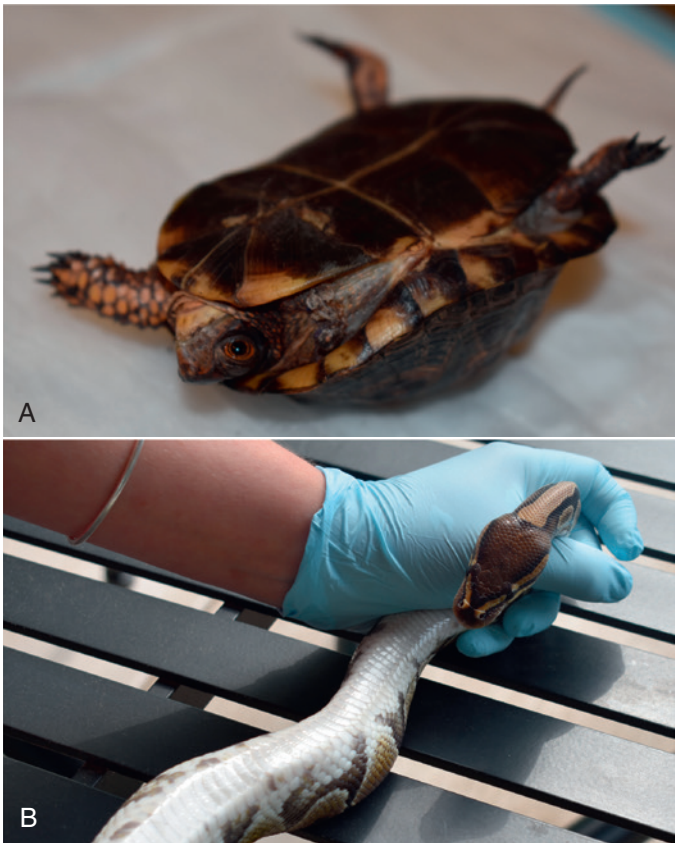

FIG 77.19 (A) Turning a box turtle (*Terrapene* sp.) on its back can stimulate the righting reflex, which is initiated by using the head, neck muscles, and one of the thoracic limbs; this is not possible in turtles with generalized weakness as well as nervous system disease. conventional radiography, even allowing guided biopsy of the lesions once identified.[28,32] Imaging of the caudal abdomen in animals for space-occupying lesions may be better accomplished using CT than radiography in many species.[28,33] The skull, head, and neck anatomy of sea turtles, crocodilians, snakes, and several lizard species has been described using CT, which can be useful to compare to when looking for structural disease.[5–7,23]

Magnetic Resonance Imaging (MRI). MRI uses a pulsating external magnetic field that produces radiofrequency signals to generate images.[34,35] The natural frequency of the hydrogen ion is used as the frequency for the magnetic pulse because of the high content of hydrogen ions in biological tissues.[28,35] Tissues with high hydrogen ion content are imaged, and regions of bone and air appear void. Contrast may also be used with this imaging method. The main advantages of MRI over CT include the ability to image the entire brain, an increase in soft tissue resolution, and the creation of true images in various planes.[28,34] MRI involves long scanning times, and the animal typically is immobilized by using general anesthesia.[34] Alternatively, heavy sedation may minimize respiratory movements and reduce related artifacts sufficiently in some species. General anesthesia poses a risk in all animal species, but the risk is greater in small animals, such as reptiles. Species-specific and interindividual differences may require the adaptation of standard anesthesia protocols. Protocols for the anesthesia and immobilization of reptiles for MRI are available in the literature, and they can be modified to suit individual needs. Turtles typically do not require pharmacological sedation, and only the head and limbs have to be mechanically immobilized during an examination. However, anxious turtles require pharmacological sedation to prevent head and limb movements, and all turtles undergoing direct MRI examinations of the head or limbs must be sedated.[34] All snakes have to be sedated to prevent movement inside the coil.[36]

MRI has potential as an effective tool for reptile medicine and has been used for turtles and snakes in clinical practice.[34] Radiology has limited diagnostic potential in turtles due to the low contrast between soft tissues and shell scales. Similarly, ultrasound scanning is not highly effective in turtles because it does not visualize deep organs or those shielded by bones or gas. MRI appears to be an advantageous method in turtles because it is by far more effective in cross-sectional examinations of internal organs than is CT. The intravascular injection of an MRI contrast agent (gadolinium) further supports the visualization of organ vasculature.[37] Turtles can be placed in the dorsoventral position inside a human knee coil.[38] In low-field MRI, tissues should be scanned in T1-, T2-, and proton-density-weighted sequences in the sagittal, dorsal, and transverse planes.[34] Slice thickness should ideally not exceed 5 mm to enhance the visualization of the tissues; however, in very small patients and where the type of machine used allows, 1-mm slices or less would be necessary. In high-field MRI, a 3D gradient-echo sequence with 0.5-mm slice thickness is recommended.[37] Attention should be paid to the size of coil used to pick up the signal from the patient; specialized "extremity" coils obtain high-resolution images and include wrist and finger coils.

A recent study of a Burmese python (*Python bivittatus*) over time that ranged in weight from 227 to 635 g compared the antemortem MRI results with postmortem findings to describe normal anatomy.[39] The snake was placed inside the coil of a 1.5-T MRI scanner in a ventral position, with distal parts of the body folded parallel to the central part of the body. The entire body was scanned simultaneously, and images were compiled with the use of computer software. Imaging involved 2D, proton-density, multislice spin-echo (slice thickness, 1 mm; repetition time, 4220 ms; echo time, 73 ms, including a prepulse for fat suppression) and 3D, T1-weighted, gradient-echo (repetition time, 9.3 ms; echo time, TE 3.3 ms) sequences.[39] The normal anatomy of loggerhead sea turtles and the normal tail morphology of rattlesnakes have been described; the knowledge of the appearance of normal anatomy is essential when assessing clinical patients for structural abnormalities.[8,40] Clinical use of MRI to confirm cervical spinal cord compression has been described using MRI in Komodo dragons (*Varanus komodoensis*), but the lack of normal anatomical knowledge hindered interpretation of the imaging.[41]

Nuclear scintigraphy may help identify active bone lesions and can be feasible, safe, and relatively inexpensive. This technique uses radioactive tracers, which concentrate in areas of active bone modeling and are subsequently visualized with a detection device. The images obtained are of low-resolution, nonspecific, and come with the issues associated with handling of radioactive materials and waste. Infectious, traumatic, or neoplastic lesions affecting the skull and spine potentially may be identified with this modality.[2] Individual institution protocols regarding isolation of patients post-scintigraphy should be investigated prior to recommendation of this modality in case it is not feasible.

Cerebrospinal Fluid Analysis

Analysis of CSF is an important diagnostic tool in the evaluation of patients with neurological disorders. Reptiles do not have a true subarachnoid space, an important fact in attempts to collect cerebrospinal fluid (CSF); in mammals CSF is collected from the subarachnoid space. However, CSF flows caudally, from the ventricles, in a subdural space in reptiles, which is where the fluid should be collected for analysis.[2] A spinal needle or a hypodermic needle can be used (Fig. 77.22); however, in some species, such as crocodilians, a blood sinus may be present, overlying the dura and subdural space, and a stiletted needle is required

VetBooks.ir

to traverse the sinus to obtain CSF.[2] As challenging as this technique can be, it may be more difficult to obtain an adequate volume of fluid for analysis, even when the needle is in the correct position. It is inadvisable to apply negative pressure to the needle used in an attempt to aspirate CSF; this may cause damage to the CNS.

Currently, no normal values are reported for reptilian CSF. In a study with American alligators (*Alligator mississippiensis*), CSF was collected percutaneously from the dorsal midline near the base of the skull with a spinal needle. The animals consistently showed gross body movement or a muscle twitch when the tip of the needle was in the proper position for fluid collection. The fluid was confirmed to be CSF on the basis of its constitution. Healthy alligator CSF was found to have a higher protein content compared with mammalian CSF.[2] Published reports of CSF analysis in reptiles with neurological disease are lacking, but it is suggested that mammalian values for cell counts should be used as a guideline; however, if a limited quantity is available, analysis should be restricted to cytology (Fig. 77.23). Special staining and PCR analysis may be possible when investigating patients for possible infectious agents.

Electrodiagnostics

Electrodiagnsotic techniques used for the evaluation of neurological disease in veterinary patients include electromyography, motor and sensory nerve conduction velocity, F-wave evaluation, repetitive nerve stimulation, spinal cord–evoked potentials, and electroencephalography. Because of their relative unavailability, these methods have not been used extensively in clinical reptile neurology. Reptiles are poikilothermic, and their nerve conduction velocity varies with the ambient temperature. Information regarding normal velocity for a given temperature and reptile species is lacking. If a specific control is available for comparison, a difference might support a tentative diagnosis of a conduction disturbance. Still, the size of many patients and difficulty finding a nerve to evaluate make this diagnostic tool of limited value.

Electromyography is used to determine whether muscle dysfunction is the result of nerve injury or a myopathy.[1] It is performed by inserting a needle into individual muscle bellies, which produces waveforms that can be visually and acoustically evaluated. The EMG of a normal muscle should be electrically silent, as the procedure is performed under general anesthesia. Denervation of muscle or intrinsic disease of the muscle itself produces abnormal electrical potentials that have characteristic waveforms and sounds. It is easily performed and interpreted in reptiles as in other species. The needle often needs to be directed between dermal scutes or scales, but the muscle underneath typically is accessed without difficulty.[2]

Motor nerve conduction velocity involves the stimulation of a selected nerve at two or more points, with recording of a resulting compound muscle action potential within a muscle innervated by the nerve.[2] A velocity of conduction can be calculated for specific nerves; it is important to perform the test at appropriate body temperatures as low temperatures will reduce nerve conduction velocity.[42] Demyelinating peripheral nerve disease can result in reduced motor nerve conduction velocity, and in patients with trauma this test also can be useful to document anatomical or functional transection of a nerve. To perform this test on reptiles, the operator needs to know the anatomical course of the nerve, and the anatomy of the patient needs to be considered with respect to stimulating and recording site possibilities; it is most useful on appendicular nerves. Normal values for reptiles have not been established.

Spinal cord–evoked response, or somatosensory-evoked potential, is a waveform elicited after stimulation of a nerve of a pelvic or thoracic limb and recorded from the spinal cord itself at a point rostral to the stimulation site.[43] The recording electrode is placed ideally on the dorsal surface of the dura mater, or alternatively in contact with the dorsal lamina of a vertebra. This test may provide information regarding the speed of conduction of impulses in the spinal cord, and it has been used to detect areas of spinal cord injury.[2] The author and others have used this technique in an attempt to identify chelonian patients with functionally transected spinal cords (i.e., complete spinal lesions). Trauma to the shell of the tortoises and turtles can result in spinal cord trauma, because the carapace is closely associated with the vertebrae; this technique may provide an assessment of the integrity of the spinal cord and therefore possibility for recovery in these patients.

Brainstem auditory-evoked response (BAER) is a waveform produced after stimulation of the auditory nerve, and it corresponds to the transmission of impulses from this nerve, through associated nuclei, ascending to higher brain centers from the brainstem.[2] In mammals this response usually is recorded as a six-to-seven-peak waveform, typically elicited by playing a series of auditory clicks through headphones or tubal inserts into the ear canal. Recording, reference, and ground electrodes are placed on the skin of the head. This test may be of limited value in reptiles because of the anatomical variations present (reptiles have very short to nonexistent external ear canals), and the unique range of frequencies, it is believed, are detectable by the reptile auditory

VetBooks.ir

system (1.5–6 kHz).[44] As with other electrophysiological testing in reptiles, auditory responses seemed to be altered by temperature changes. Reports exist of responses in reptiles, including caiman and loggerhead sea turtles, to airborne sound, underwater sound, and vibrational stimulus.[2,45–47] In another study, hearing sensitivity was measured in five geckos and seven anoles.[48] The lizards were sedated with isoflurane, and BAERs were measured at levels of 1% and 3% isoflurane. The typical BAER waveform in response to click stimulation showed one prominent and several smaller peaks occurring within 10 months of the stimulus onset. BAERs to brief tone bursts revealed that geckos and anoles were most sensitive between 1.6 to 2 kHz and had similar hearing sensitivity up to about 5 kHz thresholds, typically 20 to 50 dB SPL. Above 5 kHz, however, anoles were more than 20 dB more sensitive than geckos and showed a wider range of sensitivity, 1 to 7 kHz. Generally, thresholds from BAERs were comparable to those of small birds. Best hearing sensitivity, however, extended over a larger frequency range in lizards than in most bird species.[48]

DISEASES AFFECTING THE REPTILIAN NERVOUS SYSTEM

Neurological diseases in reptiles can result from a variety of causes, some of which have been well characterized, especially those of infectious, nutritional, and toxic origin. These diseases have been categorized below by the mechanism of disease responsible, as much as is possible.

Infectious Diseases

Bacterial, viral, fungal, and protozoan infections are known to cause neurological signs in reptiles.[1,14] In some cases, although an infectious agent is suspected, definitive determination may not be possible. As an example, infectious or toxic etiology was suspected to be responsible for the acute onset of neurological dysfunction seen in 12 Australian water dragons over a 2-month period.[49] The water dragons presented with obtundation, head tilts, loss of proprioception, loss of righting reflexes, ataxia, and hyperesthesia. No treatment protocols were effective, and all dragons died or were euthanized. Histopathology identified multifocal encephalomalacia, which is a nonspecific finding.[49] Diagnosis in such cases may necessitate an exclusion of causes rather than definitive identification of an etiology, and broad treatment regimens may need to be employed.

Protozoa

Acanthamoeba *meningoencephalitis.* Species of *Acanthamoeba* are generally pathogenic to humans[50] but can infect any soft tissue of reptiles.[1] Human infections are most commonly the result of contamination of recreational water sources. Organisms enter via the nasal mucosa and migrate through the cribriform plate or are transported to tissues by the vascular system.[1] Free-living Acanthamoeba have been encountered in the intestinal contents and during necropsies of amphibians and reptiles[1,51] (Fig. 77.24). Clinically, *Acanthamoeba* encephalitis was diagnosed in a boa constrictor (*Boa constrictor*) and a Pacific Coast rattlesnake (*Crotalus viridis oreganus*) with spasmodic opisthotonos.[1] Organisms were contained within the CSF in both snakes. Environmental stimulus exacerbated opisthotonos. The drinking water was proposed as the source of contamination. A diagnosis of *Acanthamoeba* meningoencephalitis is difficult antemortem, and no successful treatment has been reported.

Toxoplasmosis. *Toxoplasma* spp. have been reported to be associated with abscessation within the brain and meningoencephalitis in reptiles.[1,14] Toxoplasma is generally a parasite of homeotherms that can develop in reptiles when their body temperature is maintained near 37°C (99°F). Insects may serve as vectors or fomites for the transmission of toxoplasmosis, emphasizing the need for pest control. Diagnosis is based on histopathology and polymerase chain reaction (PCR); molecular testing of 68 postmortem captive snake brains for *Toxoplasma gondii* revealed 81% to be positive.[52] Clindamycin has appeared to be beneficial in treating mammals with toxoplasmosis.[1] The recommended dose is 5 mg/kg by mouth daily; however, no studies are found regarding its efficacy against toxoplasmosis in reptiles.

Bacteria. Bacterial infections may be a primary cause of nervous system disorders (encephalitis, meningitis, myelitis) or may secondarily affect the nervous system by infection of surrounding structures causing nervous tissue damage.[14] An example of secondary or indirect infection is vertebral osteomyelitis, often seen in snakes;[53–55] spinal cord compression can result from vertebral remodeling associated with the infection (as discussed later).[14] Gram-negative bacteria (e.g., *Salmonella* spp., *Staphylococcus* spp., *Listeria* spp., *Mycoplasma* spp., and *Mycobacterium* spp.,) are the most common isolates from nervous system isolates in reptiles.[14] Based on this, if culture and sensitivity of appropriate samples such as vertebral biopsy,[32] CSF, or blood culture, is not possible, selection of an antibiotic that has treatment activity against gram-negative bacteria and crosses the blood-brain barrier, such as enroflaxacin, should be utilized.

After septicemia, especially from respiratory infections, microabscesses or macroabscesses can develop within the brain. Histologically, these abscesses consist of areas of necrosis usually associated with a large number of mononuclear leukocytes.[1]

Mycobacterium generally produces a multisystemic disease that can involve the nervous system and/or muscles.[56–58] It induces a granulomatous inflammation with granulomas containing caseous cellular debris and acid-fast organisms.[1,57] Cytological preparations of granulomatous debris may be acid-fast stained to determine the presence of the organisms.[59] There is a significant prevalence of *Mycobacterium* species in clinical healthy pet reptiles;[60] treatment of mycobacteriosis in reptiles is controversial because of the zoonotic potential of the infection.

Spinal osteopathy/discospondylitis/osteomyelitis. A lytic proliferative spinal osteopathy has been reported in members of the *Boidae* and *Viperidae;*[1] however, clinically it appears to be more widespread. Some believe it may be caused by a virus of snakes that is transmitted by mice, but other considerations include neoplasia, hypovitaminosis D, and prolonged inactivity associated with cage confinement.[1,20] Septicemia has also been implicated as a cause because often these lesions culture positive for bacterial organisms, leading to the concern that a significant proportion of these cases may have discospondylitis or osteomyelitis.[1,20,53–55,61]

VetBooks.ir

The blood flow in the area of the intervertebral discs may favor seeding of infection in this location during episodes of septicemia. Another theory is that it is an immune-mediated disease caused by a septicemia that stimulates a polyclonal B cell proliferation.[1] *Pseudomonas fluorescens*, *Salmonella arizonae*, and *Staphylococcus* sp. have been implicated in inducing this type of gammopathy.

The potential role of bacteria in proliferative osteoarthritis and osteoarthropathy of the spine has been reported.[20] In all, 10 of the 15 snakes with histological evidence of bacterial osteoarthritis had positive bone cultures, and 8 of 10 snakes with positive bone cultures had corresponding positive blood cultures. *Salmonella* sp. and *Streptococcus* sp. were cultured from these patients. Three distinct groups were identified. Group 1 had strong evidence of active bacterial osteoarthritis, both histologically and on bone cultures. Group 2 was identified as having a noninflammatory osteoarthrosis without histological evidence of bacteria but with positive culture results of the bone. Group 3 had degenerative osteoarthrosis and ankylosis with minimal to no inflammation and lack of positive bone or blood culture results.[20]

Early in the course of the disease, focal or multifocal swellings may be identified along the dorsum associated with the spine (Fig. 77.25). Palpation of the spine may reveal segmental areas of ankylosis and kyphosis.[20] Digital pressure usually induces a pain response. Motor deficits, trembling, torticollis, and spinal deformity may be manifested.[1,20] Radiographically, in the early stages of the disease, sclerosis of the vertebral end plates is seen with evidence of bone proliferation that does not involve the adjacent ribs. The condition progresses with remodeling of vertebrae. The bony proliferation is usually periarticular at the costovertebral joints and the dorsolateral articular facets. As the disease progresses, the ribs may become affected and the costovertebral articulations often show evidence of ankylosis, making this condition different from spondylosis deformans or ankylosing spondylosis.[1,20]

With time, ankylosis of the spine occurs, often affecting large segments of the spinal column. Eventually, the animal becomes unable to move, constrict, or swallow prey. Histologically, the bone trabeculae in the vertebrae are thickened with irregular cement lines, and the intertrabecular spaces are usually filled with blood vessels and fibrous connective tissue.

Blood cultures are recommended for evaluation for septicemia; however, evidence shows that the lesions can develop as late as 22 to 36 months after an episode of septicemia.[1] Local cultures may be obtained with fine-needle aspirate or surgical exploration for debridement and sample collection.[14] Cultures should be submitted for aerobic and anaerobic evaluation and acid-fast staining.

In a California king snake (*Lampropeltis getula*) with vertebral osteopathy at the San Francisco Zoo, *Salmonella* sp., *Proteus mirabilis*, and *Bacteroides* sp. were isolated from samples collected during surgical debridement of the lesion.[1] A section of the spinal column was removed, and the snake remained neurologically healthy after surgery. This snake was followed radiographically for 6 months, during which time no evidence of reossification was found in the area where the vertebrae were removed.[1]

In summary, snakes with radiographic evidence of spinal osteopathy should be evaluated with blood cultures and local aspirates to identify bacteria present within the lesion or systemically. Treatment involves appropriate long-term antibiotic therapy and surgical debridement if lysis predominates. The prognosis of bacterial-induced osteomyelitis is guarded as the condition is often advanced by the time a patient is presented.[14]

Viruses

Paramyxovirus. Ferlaviruses, sometimes referred to as ophidian paramyxoviruses, are a significant viral infection in many snakes and is especially common in viperids, although this virus also affects elapids, boids, and colubrids.[14,62–65] The virus is mainly transmitted by direct contact with respiratory secretions, but there is also potential exposure via snake mites.[14] A variety of respiratory, gastrointestinal, and neurological signs may be observed when snakes are infected, including opisthotonus (Fig. 77.26), torticollis, a reduced righting reflex, and death.[14,66] A progressive central nervous system disorder manifesting clinically as head tremors and loss of equilibrium with opisthotonos has been described in rock rattlesnakes (*Crotalus lepidus*).[67] These snakes also lost the righting reflex and had irregular and slow tongue flick responses. The disease was linked to a paramyxolike virus that was identified with electron microscopy. The disease was believed to have been introduced

to the private collection with the addition of two wild-caught snakes that had signs develop within 14 days of their capture.

Histologically, gliosis and perivascular cuffing were identified in a variety of locations within the hindbrain. Demyelination, axon degeneration, and ballooning of axon sheaths were seen in the brain stem and spinal cord. In addition to the central nervous system lesions, the lungs also showed pathology consisting of cellular debris and exudate filling the primary bronchi and air spaces.[1] Antemortem diagnosis is possible with paired serology or PCR using either an oral or cloacal swab.[14] Supportive treatment may be provided to snakes exhibiting clinical signs, but euthanasia is generally advised.[14]

Sunshine virus is a recently discovered novel paramyxovirus that is associated with neurorespiratory illnesses in snakes.[64,68,69] It does not phylogenetically cluster within either of the two currently accepted paramyxoviral subfamilies. It is therefore only distantly related to the only other known genus of reptilian paramyxoviruses, ferlavirus, which clusters within the Paramyxovirinae subfamily.[68] During a natural outbreak of sunshine virus in a collection of 32 snakes, the virus could be detected in 5 out of 39 combined oral-cloacal swabs that were collected from 23 of these snakes over a 105-day period. All snakes that were infected with sunshine virus were negative for reovirus and ferlavirus by PCR. Snakes infected with sunshine virus reliably exhibited hindbrain white matter spongiosis and gliosis with extension to the surrounding gray matter and neuronal necrosis evident in severe cases.[68]

Inclusion body disease of boids. This condition is believed to be caused by an arenavirus and affects boas and pythons; however, the clinical syndrome is distinct between these two groups.[1,14,70,71] The neurological severity is significantly worse in pythons than in boas, underscoring the recommendation to not mix boas and pythons in the same collection. Boas may be inapparent carriers. The snake mite, *Ophionyssus natricis*, is suspected as one of the vectors incriminated in the spread of the disease. Other modes of transmission include direct contact and venereal spread.[1]

Clinical signs are generally multisystemic, including gastrointestinal, respiratory, and neurological signs. In juvenile boas, the condition is often quickly fatal with an acute onset of flaccid paralysis. Adult boas have a more chronic manifestation of the disease, with central nervous system signs occurring only in the terminal stages. Early in the course of the disease, chronic regurgitation, cachexia, and chronic pneumonia are common.[14] Neurological signs are generally manifest as an inability to strike, constrict, and prehend food items. Dysecdysis may occur as a result of an inability to control body movements to rub off the shed skin.[1]

In pythons, the clinical course is much more rapid, progressing to a fatal CNS disturbance.[14] Pythons also have multisystemic disease, with pneumonia and infectious stomatitis common. Neurologically, they have a loss of righting reflex, hyperreflexia, disorientation, and loss of motor coordination. Some animals develop central blindness.[1]

Currently, a PCR test is available to screen for arenavirus infection from a blood sample and/or an esophageal swab.[14,72] Biopsy results of the liver, kidney, esophageal lymphoid tissue, and skin may show the typical eosinophilic intracytoplasmic inclusions.[14] Histologically, eosinophilic intracytoplasmic inclusion bodies have been identified within epithelial cells of the pancreas, kidney, esophagus, stomach, and liver. Occasionally, inclusion bodies are identified in white blood cells.[14] A nonsuppurative encephalitis with neuron degeneration and mononuclear cell infiltrates characterizes the lesions within the brain and spinal cord. In the white tracts of the spinal cord, areas of gliosis with extensive myelin degeneration and axon loss are seen. Intracytoplasmic eosinophilic inclusion bodies have been found within the neurons of the brain and the gray tracts of the spinal cord. The degree of inflammation is much greater in pythons compared with that found in boas. Perivascular cuffing with degenerative myelopathy is evidence of a viral etiology; however, some bacterial infections also stimulate perivascular cuffing.[1]

No treatment has been shown to be successful for this viral disease. It may be mild in boas and may go undiagnosed. Therefore prevention of exposure of pythons to boas is best as they may be in apparent carriers. Identification and elimination of animals with known positive disease are recommended.

Agamid adenovirus. Agamid adenovirus-1 is considered endemic in the pet bearded dragon (*Pogona vitticeps*) and appears to be associated with both neurological and gastrointestinal signs, reduced growth, and death.[73] Alternatively, in some dragons the infections remain subclinical.[14] Transmission of the virus is via the fecal-oral route, with infection resulting in severe gastrointestinal and hepatic pathology.[14]

Young (6–10 weeks) juvenile inland bearded dragons from a breeding collection in southeast Queensland were recently described with neurological signs, poor growth, and occasional deaths.[74] Histopathological examination revealed that six of eight lizards had multifocal nonsuppurative hepatitis associated with 5 to 10 µm diameter, smudgy, basophilic, hyaline intranuclear inclusion bodies that marginated the nuclear chromatin. These histological lesions were considered consistent with adenoviral hepatitis. A definitive diagnosis is based on PCR testing of an oral or cloacal swab, and treatment is only supportive.[14]

West Nile virus (WNV). Reptiles may serve as reservoir hosts for western equine encephalitis and Venezuelan equine encephalitis.[75–77] WNV has been reported in reptiles as early as the 1960s in Israel.[1] More recently, WNV has been found to occur in alligator and crocodile species in the United States.[14,78,79] The mode of transmission to reptiles is thought to be from the ingestion of, or a bite from, the insect carrier (e.g., mosquito),[80] or from ingestion of infected horse meat.[79] Crocodiles are thought to be an amplyfying host owing to high levels of viremia and viral shedding.[14] Affected animals have an acute onset of paresis, circling, head tremors, neck spasms, and a star-gazing appearance before death.[1,19] In reptiles with neurological disease, the presence of perivascular cuffing within the brain and spinal cord is indicative of viral infection, yet in many instances no agent has been identified.[1] Definitive diagnosis is based on viral isolation and PCR testing of postmortem samples. A WNV vaccine has been recently approved for use in alligators.[14]

Nutritional Diseases

When dealing with a patient with neurological disease, evaluation of the patient's nutritional status is important. Animals being fed intact whole prey diets rarely have nutritional deficiencies.[1]

VetBooks.ir

Thiamine Deficiency. Thiamine deficiency (or thiaminase excess) may be observed in animals fed thawed frozen fish, clams, and some types of vegetation.[1,14] Freezing fish and subsequent thawing decreases the amount of available thiamine and potentially increases the activity of thiaminases.[14] Snakes of the genus *Thamnophis* and *Natrix* are piscivorous, as are some crocodilians and chelonians, which makes them more prone to leukoencephalopathy if fed frozen-thawed fish.[1] The consumption of thiaminase-positive gizzard shad (*Dorosoma cepedianum*), a commonly eaten wild fish, is thought to have been the cause of the low tissue thiamine and resulting mortalities in alligators in central Florida.[81,82] Herbivorous reptiles fed a diet high in vegetation containing phytothiaminases may develop thiamine deficiency.

Clinical signs are generally nonspecific and include muscle twitching, incoordination, blindness, seizure activity, torticollis, abnormal posture, spiral locomotion, jaw gaping, dysphagia, and potentially death.[1,14] Snakes frequently are unable to accurately strike prey. In chelonians, the most striking clinical sign is a sinking of the eye within the bony orbit (enophthalmos).[1] At necropsy, usually no gross lesions are seen. Histologically, cerebral cortical necrosis with peripheral neuritis and cardiomyopathy is frequently encountered.[1] Histological lesions also include a diffuse eosinophilia with severe demyelination and axon sheath fragmentation. Generally inflammatory cells are absent.

Treatment involves oral or subcutaneous supplementation of vitamin B_1 (thiamine) at 25 mg/kg/day. A dramatic response to therapy is usually seen. The longer the duration of clinical signs, the more severe the neurological compromise and the less likely it is to completely resolve. In addition to supplementation, the diet should be evaluated and, if possible, the patient should be placed on a fresh fish diet, although some fish will contain high levels of thiaminase (see Chapters 27 and 84 for more information). If frozen fish must be used, they should be supplemented with thiamine. Fish may also be heated to denature the thiaminase.

Herbivores fed plant material containing phytothiaminase should be placed on an appropriate diet containing alternative plant sources. From a theoretical standpoint, long-term antibiotic therapy has been suggested to induce clinical signs of thiamine deficiency by decreasing the intestinal microflora responsible for producing vitamin B_1 (see Chapter 122). Although this theory has not been confirmed scientifically, some believe placing patients receiving long-term antibiotic therapy on a thiamine supplement may be prudent.[1]

Biotin Deficiency. Biotin is a B vitamin readily supplied in most food sources. Raw egg whites contain avidin, which has antibiotin activity.[1] Deficiency may be induced in reptiles (usually in egg-eating snakes and lizards, for example, varanids) by feeding a diet of whole raw eggs. Because of the ubiquitous nature of biotin, the entire diet must consist of raw eggs to induce deficiency. Free-ranging, egg-eating reptiles do not generally have biotin deficiency because they eat fertile eggs, often with some degree of embryonic development. Embryonic tissue contains biotin, and the avidin in the egg is used up during embryonic development. In addition, most egg-eating reptiles also consume small animals that contain biotin.[1]

Clinical signs of biotin deficiency consist of muscle tremors and generalized muscle weakness. Treatment involves supplementing vitamin B complex orally or via injection and correcting the dietary deficiency by supplementing with biotin or diversifying the diet to include other items that contain adequate biotin.[1]

Hypocalcemia. Hypocalcemia is generally observed as the result of end-stage nutritional or renal secondary hyperparathyroidism.[1]

Inadequate dietary calcium or vitamin D_3, inadequate ultraviolet (UV)-B lighting, or low temperatures may lead to neurological signs in affected reptile patients once the calcium reserves in the bone are depleted.[14,41] In chelonians and crocodilians, the deficiency is usually from a diet of exclusively red meat, which is deficient in calcium. The neurological manifestations of hypocalcemia include weakness, inability to withdraw the tongue, muscle twitching or tetany, and seizures, which may be seen in any class of reptiles.[14] Treatment of hypocalcemic tetany entails the parenteral administration of a calcium gluconate solution after confirmation with a blood ionized calcium level.[29]

Hypovitaminosis E. Vitamin E/selenium deficiency has been described in iguanas exhibiting clinical signs of weakness, paresis, and ataxia, as well as in a veiled chameleon (*Chamaeleo calyptratus*) that was unable to open its mouth and move its tongue.[14] A similar nutritional deficiency has been seen in bearded dragons, which responded to vitamin E supplementation, which is necessary to support the diagnosis of this condition.[14]

Trauma

Reptiles are susceptible to trauma from a variety of causes, which can be direct (e.g., head trauma) or indirect (e.g., chelonians with paraparesis secondary to dystocia).[1,29] Regardless of the etiology, trauma to the nervous system is often categorized for assessment and therapeutic purposes into brain injury, spinal cord injury, and peripheral nerve injury. The clinical signs and prognosis are referable to both the location of the injury and its severity. Grading systems for clinical severity are documented for canine and feline trauma but not for trauma to the reptile nervous system. However, it is proposed that a similar grading system can be applied and a similar prediction of prognosis may be possible. The assessment and management described in the following subsections is predominantly what is documented in canine and feline medicine unless otherwise stated.

Brain Injury. Head trauma pathophysiology can be divided into primary and secondary injury.[83] Primary injury to the brain cannot be reversed, occurs immediately, and describes the physical disruption of brain tissue; this includes contusions, hematomas, lacerations, and diffuse axonal injury leading to vasogenic edema.[84] The underlying vascular and cellular pathophysiology of head trauma is similar to that described for spinal cord trauma but is complicated by elevations in intracranial pressure (ICP). This secondary injury is delayed and progressive, potentially providing targets for treatment. In addition to excitatory neurotransmitter release, ATP depletion results in cytotoxic edema, intracellular calcium accumulation causing activation of intracellular enzyme systems, and oxygen radical production resulting in lipid peroxidation. Traumatic brain injury is associated with a marked inflammatory response. The secondary injury "cascade" is exacerbated by systemic abnormalities present in the patient, which includes hypotension, hypoxia, hypo- or hyperglycemia, hypo- or hypercapnia, and hyperthermia.

After head trauma, the volume of the brain tissue compartment increases, usually due to edema or hemorrhage. As the brain tissue compartment increases, the CSF and the blood compartments must decrease or ICP will increase.[85] Compensation for increased brain tissue volume initially involves the translocation of CSF out of the skull; this is followed by decreased production of CSF and, eventually, decreased cerebral blood flow. These compensatory mechanisms prevent increases in ICP for an undetermined period. Once the ability for compensation is exhausted, a further small increase in intracranial volume will result in dramatic elevations of ICP, with the immediate onset of clinical signs.[85] Increases in ICP are often responsible for clinical decline after head trauma. Marked increases in ICP lead to an elevation of mean arterial blood pressure (MABP) and reflex bradycardia (Cushing reflex). In addition to a drop in heart rate coupled with an elevated MABP,

VetBooks.ir

other clinical manifestations of ICP elevation include anisocoria, miosis, mydriasis, altered mentation, and loss of motor function with the development of vertical nystagmus and extensor rigidity toward the end stages.[85]

Imaging of the patient's head is often indicated, especially in animals that fail to respond to aggressive medical therapy or deteriorate after initially responding. Skull radiographs are unlikely to reveal clinically useful information about brain injury but may occasionally reveal evidence of calvarial fractures. CT is the preferred modality for imaging the head in cases of severe head injury associated with fractures. Even patients with "mild" head trauma can exhibit abnormalities on the CT scan, and so the initial decision to image the patient's head should not be based on the neurological examination alone. CT image acquisition time is faster and often less expensive than MRI, and CT also demonstrates bone detail better than MRI. However, MRI has been shown to provide key information relevant to the prognosis based on its ability to detect subtle parenchymal damage not evident on CT imaging. The detection of midline parenchymal shift and ventricular obliteration on MR images are associated with a poor prognosis for survival, based on a recent canine study.[86] Furthermore, lesions of the intracranial structures that may benefit from surgical therapy, such as hematomas and pneumocephalus, can be accurately identified using advanced imaging. Cervical spinal radiographs or CT are also advised at the time of any skull imaging to rule out concurrent spinal lesions.

Accurate assessment is important for determining the way in which treatment is tailored to the individual patient. Systemic and neurological assessment must be undertaken rapidly and continually reassessed. In humans, traumatic brain injury is graded as mild, moderate, or severe on the basis of an objective scoring system (e.g., Glasgow coma score, GCS). A modification of the GCS has been proposed for use in veterinary medicine.[87] The modified scoring system incorporates three categories of the examination (level of consciousness; motor activity; brainstem reflexes), which are assigned a score from 1 to 6, providing a total score of 3 to 18, with the best prognosis being the higher score.

The most important consideration in head injury is maintenance of cerebral perfusion by treatment of hypotension and elevated ICP. The basic goal of fluid management of head trauma cases is to maintain a normovolemic to slightly hypervolemic state to ensure an adequate cerebral perfusion pressure. Initial resuscitation usually involves IV administration of hypertonic saline and/or synthetic colloids. Use of these solutions allows rapid restoration of blood volume and pressure while limiting the volume of fluid administered. In contrast, crystalloids will extravasate into the interstitium within an hour of administration and thus larger volumes are required for restoration of blood volume. If isotonic crystalloids are chosen for administration (appropriate in mild head trauma), an aliquot of the shock dose can be given rapidly and repeated until improved tissue perfusion is achieved. Hypertonic saline administration draws fluid from the interstitial and intracellular spaces into the intravascular space, which improves blood pressure and cerebral blood pressure and flow, with a subsequent decrease in ICP. Colloid solutions can be administered after hypertonic saline is used to maintain the intravascular volume, possibly due to retention of fluids in the intravascular compartments, maintaining an intravascular oncotic gradient.

Osmotic diuretics are very useful in the treatment of intracranial hypertension. Use of mannitol is recommended once vascular volume has been stabilized. Mannitol has an immediate plasma-expanding effect, which reduces blood viscosity, increasing cerebral blood flow and oxygen delivery. This results in vasoconstriction within a few minutes, causing an almost immediate decrease in ICP. The better known osmotic effect of mannitol reverses the blood-brain osmotic gradient, thereby reducing extracellular fluid volume in both normal and damaged brains. Mannitol should be administered as a bolus over a 15-minute period, rather than as an infusion, in order to obtain the plasma-expanding effect; its effect on decreasing brain edema takes approximately 15 to 30 minutes to establish and lasts between 2 and 8 hrs. These times may be extended in reptiles but are unknown.

Oxygen supplementation is recommended for most acutely brain-injured animals. Supplemental oxygen should be administered via flow-by or oxygen cages, which (although often inadequate for mammals) may be suitable for reptiles with their slower metabolism. The target 40%-inspired oxygen recommended for mammals may cause reptiles to significantly decrease their respiratory rate, and lower levels may be clinically acceptable.

The use of steroids in brain-injured patients is controversial. The original rationale for use of glucocorticoids in central nervous system trauma came from the thought that they would reduce edema and intracranial pressure and counteract oxidative damage.[85] Methylprednisone sodium succinate may exert further actions, such as preventing progressive ischemia and reversing intracellular calcium accumulation.[85] Current human and veterinary literature indicates that the use of steroids in central nervous system trauma shows no specific benefit, and their use may actually increase morbidity.[88] Some of the side effects observed in patients with head trauma or spinal cord trauma treated with steroids include increased blood pressure, lowered seizure threshold, decrease in platelet aggregation, muscle weakness, and gastric ulceration. Glucocorticoids stimulate gluconeogenesis, and hyperglycemia has been associated with increased mortality rates in humans with severe head injury.

Surgical therapy of head-injured patients is suggested when (1) medical therapy has not been successful, (2) there is a penetrating injury, or (3) there is an open fracture with risk of infection necessitating immediate decontamination. A recent report documented an adult male Fly River turtle (*Carretochelys insculpta*) that presented with dull mentation and a proptosed right eye due to severe head trauma.[89] Injuries included rostral mandibular, left mandibular, left maxillary, and bilateral orbital fractures. The right orbital fracture was repaired immediately. Radiography and computed tomography (CT) were performed to evaluate the extent of the fractures. The use of CT provided complete evaluation of the skull fractures, was a guide for surgical planning, and allowed for monitoring of fracture healing. The turtle returned to normal behavior 2 months after surgery. The fractures were either healed or almost healed 6.5 months after surgery.[89] Another recent study evaluated the use of a plant-derived dressing (1 Primary Wound Dressing) in three sea turtles with severe lesions of the skull, exposing the brain.[90] Following surgical curettage, the treatment protocol involved exclusive use of the plant-derived dressing applied on the wound surface as the primary dressing, daily for the first month and then every other day until the end of treatment. The wound and surrounding skin were covered with a simple secondary dressing without any active compound (nonwoven gauze with petroleum jelly). The report described an excellent healing process in all three cases and no side effects due to contact of the medication with the cerebral tissue.[90]

Overall there is not enough data to know what level and speed of recovery is possible following brain injury in reptiles. However, evidence accumulated over the last few decades demonstrates that all healthy reptiles continuously add neurons at a high rate and in many regions of the adult brain throughout their life.[91] This so-called adult neurogenesis has been described in the olfactory bulbs, rostral forebrain, all cortical areas, anterior dorsal ventricular ridge, septum, striatum, nucleus sphericus, and cerebellum. The rate of neuronal production varies greatly among these brain areas. In addition to producing new neurons in the adult brain, lizards, and possibly other reptiles as well, are capable of regenerating large portions of their telencephalon damaged as a result

VetBooks.ir

of experimentally induced injuries, thus exhibiting an enormous potential for neuronal regeneration.[91]

Spinal Cord Injury. Chelonians are susceptible to spinal cord injury secondary to carapace trauma[1,29] (Fig. 77.27). Pathological spinal fractures can occur in association with metabolic bone disease[1] (Fig. 77.28).

Results of the neurological examination are used to determine neuroanatomic localization and severity of the spinal cord injury (Fig. 77.29). Reptiles with spinal cord injury generally have a loss of panniculus response caudal to the site of injury and a loss of tail or vent stimulation reflex.[1] In some cases, they have hypertonia cranial to the site of the injury.[2] It is important to perform the neurological examination with care to prevent further injury and displacement of the spine. The neurological examination findings are most important in establishing the prognosis irrespective of radiographic findings. Plain radiography of the entire spine should be performed. Results of survey radiography are used to determine the precise lesion location(s) and extent, demonstrate multiple lesions, and guide appropriate management[29] (Fig. 77.30). Intrathecal contrast-enhanced imaging or cross-sectional imaging is used when the radiographic findings do not correlate with the neurological examination, to evaluate spinal cord swelling in concussive injuries, and to further assess severity of spinal cord compression. CT or MRI is useful for further evaluating bone and spinal cord tissues, respectively, and provide a three-dimensional configuration of the fracture/luxation extent for assessment of spinal stability.

The critical factor in determining whether conservative or surgical management of spinal fracture and luxation is appropriate depends on the presence of instability. Priority is placed on treatment of extraneural injuries, beginning with management of shock and hemorrhage. Management of an animal with spinal trauma focuses on the prevention of secondary injury to the spinal cord parenchyma. Indications for nonsurgical management include minimal neurological deficits, minimal vertebral displacement, and lack of advanced imaging evidence of spinal cord compression. Principles of conservative management are appropriate confinement for 6 to 18 weeks and use of external coaptation. The aim of external support is to provide immobilization of the vertebral segments cranial and caudal to the damaged area. It is important to follow principles of bandage care when using methods of external support. The patient will need to be carefully managed and kept clean from urates and feces.

Surgical management often provides a better chance for more rapid and complete neurological recovery. However, the role of surgery for reptile spinal trauma remains unclear. Indications include severe neurological deficits and deteriorating neurological status, imaging evidence of compression, and damage of two or more vertebral

compartments. Timely surgical intervention is important to allow for maximal recovery. The objectives for surgical management of spinal trauma are decompression, realignment, and stabilization. The decompressive procedure should be conservative so as not to disrupt further the integrity of the vertebrae but large enough to allow for removal of compressive material. Successful outcome after surgical fixation depends on the type and strength of fixation, the surgeon's skill and knowledge of the spinal anatomy, and the accuracy of vertebral column alignment (which becomes increasingly difficult as patient size decreases). Surgical fixation of a vertebral fracture has been reported in a coastal taipan (*Oxyuranus scutellatus*), and attempts to surgically decompress vertebral disc material to treat cervical subluxation and compressive myelopathy have been performed in Komodo dragons.[41,92]

Careful attention to postoperative care is imperative for the well-being of the patient.[93] Potential complications include cloacitis, urine/fecal retention, urinary tract infections, decubital ulcers, and implant failure. Physical rehabilitation is important in the recovery process (see Chapter 131).

The prognosis for animals with acute spinal injury is dependent on the results of the neurological examination. The prognosis for recovery from a spinal fracture or luxation that results in paraplegia with loss of nociception is considered poor. Patients that maintain pain perception may still require months to recover and have residual neurological deficits, including urinary and/or fecal incontinence.

The prognosis may be better in some reptiles than in mammals due to the documented neurogenesis that occurs within the cord following injury.[94] However, it has been reported that following spinal cord injury in a snake, the cord is repaired by ingrowth of connective tissue, and nerve fibers do not regenerate.[1] The clinical impact of spinal neuronal regeneration in some injured reptiles is currently unknown. Even with complete spinal transection, some reptiles may still exhibit coordinated hind limb movements, and as long as they are able to ambulate, urinate, and defecate, quality of life is often acceptable.

Peripheral Nerve Injury. Trauma to the soft tissues of the limbs or fractures of the extremities can injure peripheral nerves, which may just affect the function of one limb (monoparesis/monoplegia). This can also occur with any trauma that causes traction or stretching of the peripheral nerves. Paraparesis due to bilateral peripheral nerve injury occurs in reptiles, especially chelonians, with dystocia, presumably as a result of nerve compression.[1] A history of forelimb monoparesis after a traumatic incident should raise a high suspicion of brachial plexus avulsion (Fig. 77.31). Every animal unable to use one forelimb after trauma should be examined carefully to detect orthopedic as well as neurological abnormalities. MRI of the affected plexus may provide information on the degree of nerve and associated soft tissue trauma. Electromyography allows detection of spontaneous electrical activity in the denervated muscles 7 to 10 days after the injury. Nerve conduction velocity studies of the radial and ulnar nerves allow determination of the degree of injury. Since the radial nerve is commonly injured in brachial plexus avulsions, serial electrodiagnostic evaluations of this nerve may provide useful diagnostic and prognostic information.

FIG 77.31 Right-sided thoracic limb monoparesis suggestive of brachial plexus nerve injury in a bearded dragon (*Pogona vitticeps*). (Courtesy of Joerg Mayer.)

Treatment of acute peripheral nerve trauma is primarily supportive. Unfortunately, there is no routinely effective treatment for this type of injury. The degree of recovery depends only on the severity of the nerve lesion at the time of injury. In mammals, if nociception is present in the medial and lateral digits, prognosis for recovery is good and aggressive physiotherapy should be recommended. If nociception is absent, prognosis will depend on the severity of the axonal injury, being good for neurapraxic lesions but guarded to poor for axonotmetic (nerve injury to axon while sparing the myelin) and neurotmetic (disruption of axon, myelin sheaths, and connective tissue) lesions. Pure axonotmesis occurs rarely, so the potential for recovery, although present, is low and prognosis poor.

When the proximal branches of the radial and musculocutaneous nerves are spared—so that the elbow flexor and extensor muscles are not denervated—corrective surgery can be used to provide carpal extension and prevent the distal part of the limb from collapsing. Tendon transplantation or carpal arthrodesis procedures could be considered in larger lizards.

Animals with caudal and complete brachial plexus avulsions have a poor to guarded prognosis if neurotmesis has occurred. Only those with neurapraxic (temporary loss of sensory and motor function due to nerve injury) injuries show improvement and recover completely. However, most animals do not improve but go on to show severe limb atrophy, eventually developing serious complications such as trophic ulcers, joint contractures, limb trauma due to loss of control and secondary environmental injury, or abnormal sensation in the affected areas produced by regeneration of sensory nerves. In these cases, amputation of the limb is necessary. The best predictor of complete recovery seems to be nociception. Preservation of nociception is an indicator of a milder type of injury and should prompt the clinician to recommend supportive therapy while waiting for motor function to recover. However, if no improvement is seen during the first 3 to 6 months, recovery is unlikely to occur.

Vascular Diseases and Circulatory Disturbances

Gout may cause neurological dysfunction due to circulatory abnormalities and directly by the formation of tophi within nervous tissue. A decrease in blood flow to the central nervous system as a result of gout may result in neurological signs.[1]

Granulocytic leukemia in a gopher snake (*Pituophis melanoleucus*) at the San Francisco Zoo caused thrombus formation and infarction of the spinal cord. The patient showed paralysis caudal to the site of the infarction, which was identified histologically.[1]

Metabolic Diseases

Xanthomatosis. Xanthomatosis has been reported in captive female leaf-tailed Geckos (*Uroplatus henkeli*) with hydrocephalus secondary to obstruction caused by a brain xanthoma.[1,95] Clinical signs of brain xanthomas, also reported in snakes and water dragons, include opisthotonus, torticollis, dorsal recumbency, and seizures.[1,95–98] Xanthomas are cholesterol-laden granules that develop in various organs and are thought to be caused by hypercholesterolemia and hyperlipidemia.[14] Xanthomatosis is suspected to be frequently accompanied and exacerbated

by renal disease. Metabolic derangements associated with hyperuricemia, hypercholesterolemia, and hyperlipidemia are suspected in cases of xanthomatosis. A dietary correlation is suspected but currently unable to be identified.[14] Most cases occur in females, and the condition is thought to be exacerbated by folliculogenesis, follicular degeneration, and yolk coelomitis. By the time animals are seen with neurological signs, they appear to be unresponsive to supportive care.

Freeze Damage. This condition is most commonly observed in tortoises coming out of brumation (hibernation).[1] The cause is unknown but may be related to water crystals forming in neurological tissue. Additional predisposing factors may include hepatic lipidosis or sepsis and microabscessation within the brain. Clinical signs include circling, head tilt, and blindness with hyphema. Ocular lesions include lenticular change and retinal damage. These lesions may improve with vitamin A supplementation.[1] Many cases improve clinically with time; however, a head tilt usually does not resolve.

Hypoglycemia. A syndrome caused by hypoglycemia that appears to be stress induced has been reported in crocodilians.[1] Clinical signs include muscle tremors, loss of righting reflex, and mydriasis. The pathophysiology of this syndrome is unknown. Animals respond to oral glucose administered at 3 g/kg and elimination of the stress-inducing factor.[29]

Hepatic Encephalopathy. Reptiles with hepatic disease may show a wide variety of clinical signs. Lethargy, chronic anorexia, weight loss, and gastrointestinal and neurological signs are common. The last stage of liver disease often results in hepatic encephalopathy (HE).[99] Clinical signs of HE are extremely variable (e.g., circling, weakness, ataxia, ptyalism, seizures, and coma). The pathophysiology of HE is not completely understood, but there is a proposed synergistic effect involving liver failure and ammonia detoxification, increased cerebral inflammatory proteins, impaired brain perfusion with development of astrocytic swelling, and neuronal edema.[99]

Hematology of the HE-affected patient often shows anemia, heterophilia, and monocytosis. Biochemistries frequently reveal high values of aspartate aminotransferase, gamma glutamyltransferase, alkaline phosphatase, alanine aminotransferase, and lactate dehydrogenase, but none of these analytes are truly liver-specific enzymes in reptiles. Bile acids may eventually prove to be a promising hepatic marker.[99]

Diagnostic imaging techniques are also clinically useful to detect changes in size or appearance of the liver. An endoscopically obtained tissue biopsy sample is considered as a useful diagnostic tool.[99] Prognosis of the patient exhibiting clinical signs of HE is guarded at best. Recommended treatment for snakes that are diagnosed with HE involves fluid administration (avoidance of solutions that contain lactate), along with more specific hepatic therapeutic agents. Carnitine (250 mL/kg orally) is a derivate of the amino acid lysine, which is involved in the transport of the acetyl coenzyme A through the cellular membrane of the hepatocyte. Lactulose is commonly used in treating hyperammonemia, which is believed to be one of the underlying causes of HE. Lactulose (0.5 mL/kg orally) is fermented by the gut flora into metabolites that acidify the colon. An acidic environment turns freely diffusible ammonia (NH_3) into ammonium (NH_4^+), which can no longer be absorbed.[99] Silymarin (milk thistle) has a long history of use in the treatment of liver disease, predominantly in controlling inflammation and limiting uptake of toxins. In the human patient, silymarin exerts membrane stabilizing and antioxidant activity and promotes hepatocyte regeneration; furthermore, it reduces the inflammatory reaction and inhibits fibrogenesis in the liver.[100] The use of silymarin to treat HE in reptiles appears to be promising. Antioxidants, such as SAMe and vitamin E, may also be beneficial, and as no reptile-specific doses have been produced, allometric calculation from mammalian doses may be appropriate (see Chapter 67 for more details).

Congenital Diseases

Congenital neuropathies in reptiles are frequently associated with poor maternal and sometimes paternal husbandry or improper gestational incubation conditions. Most embryonic neuropathies lead to an early fetal or neonatal death.

Caudal Coiling Syndrome. Congenital neuropathic anomalies reported in snakes include axial bifurcation, kyphosis, and fusion of adjacent coils.[1] (Fig. 77.32). A congenital neurological condition exists in newborn boa constrictors that grossly appears like a vertebral malformation. Though the vertebrae are normal, these snakes appear to have kyphosis, scoliosis, or lordosis. Affected snakes are seen with single to multiple coils of their spine, compromised locomotion, abnormal posturing, and anorexia. The condition frequently affects only the caudal half of the snake and has been termed "caudal coiling syndrome."[14] Radiographically, the vertebral bodies themselves appear to be normal and not the cause of the condition. When anesthetized, the snake's body is able to be manually stretched and uncoiled. The condition can be a cause of acute mortality in neonates or a chronic debilitating syndrome in juveniles. Affected animals have shown no response to assist-feeding and supportive care, ultimately progressing and succumbing to the disease. The unaffected portions of the snake's body appear to function normally, and normal voluntary muscle contractions are observed as the snake attempts to drag its disfigured body. The disorder does not appear to involve the brain or CNS, and structures caudal to the lesion maintain sensory and motor function.

Necropsy examination confirms the radiographic findings; no gross abnormalities of the vertebrae are identified. Histologically, the dorsal epaxial musculature contains multiple leukocytic infiltrates surrounding the nerves and vessels within the perimysium.[1] Potential causes of this condition include infectious agents, an inflammatory process, neoplasia, and improper incubation conditions. All attempts to culture or isolate an infectious organism have been unsuccessful, and the husbandry associated with the gestation of the neonates is reportedly appropriate.[1] Further investigations into the cause of this condition are indicated.

Toxicities

Information on toxins that adversely affect reptile species usually originates from case reports, and so the true risks of the various toxins to different reptile species can be difficult to determine.[14] However, with the development of animal poison hotlines and the efforts of the

American Board of Veterinary Toxicology, the knowledge of poisonings in reptiles has blossomed significantly (see Chapter 88 for more details).[101]

Chlorhexidine. There are reports of 0.024% chlorhexidine solution as a topical medication or soaking solution in reptiles with cutaneous disease.[1] At this concentration, the agent appears to be safe. However, the use of the 2% stock solution as a therapeutic bath has caused acute neurological disease and death in reptiles. Chelonians appear to be extremely sensitive to the toxic effects of the solution.[101]

Clinical signs include acute flaccid paralysis and progress to loss of the righting reflexes and diminished withdrawal reflexes. Signs do not resolve, and death from neurological and respiratory collapse readily ensues.

Insecticides. Reptiles appear to be especially sensitive to insecticide toxicosis.[101] Birds are reportedly 10 to 20 times more sensitive to insecticides than mammals, and reptiles appear to be more sensitive than birds.[1] Many forms of insecticides, including sprays, powders, and pesticide strips, have been used to control external parasite problems in reptiles. Their use may result in neurological signs.[1]

Organophosphates are the most commonly used insecticides worldwide. This group of insecticides includes chlorpyrifos (Dursban), dichlorvos (Vapona, No-Pest), diazinon, cythioate (Proban), fenthion (ProSpot), malathion, ronnel, parathion, and metrifonate.[101] The closely related carbamates include aldicarb, carbaryl (Sevin), bendiocarb, methiocarb, propoxur, and carbofuran. As newer, safer insecticides are marketed, these two groups are involved in fewer accidental poisonings, but they still account for a large number of intoxications.[101]

Organophosphates and carbamates interfere with metabolism and breakdown of acetylcholine at synaptic junctions. Acetylcholinesterase is the enzyme responsible for breaking down the neurotransmitter at these sites. Acetylcholinesterase is inhibited by organophosphates and carbamates at these cholinergic sites. As a result, acetylcholine accumulates at the synapses, first exciting and then paralyzing transmission in these synapses.[101] This inhibition of the synapse is irreversible with organophosphates but is reversible with carbamates. Organophosphates are readily absorbed by all routes: dermal, respiratory, gastrointestinal, and conjunctival. Overdose with organophosphates may happen more readily if they are given together with imidothiazoles, such as levamisole.[101] Neurological signs can be autonomic (bronchospasm, bronchosecretion, lacrimation, diarrhea), neuromuscular (weakness, tremors, muscle fasciculations), or CNS related (seizures, depression).

Pyrethrin is the oldest used botanical insecticide originating from *Chrysanthemum cinerariifolium*. Pyrethroids are synthetic derivatives of pyrethrin and are widely available.[101] Pyrethroid insecticides have enhanced stability, potency, and half-life compared with the parent molecule. A variety of dilute pyrethrin- and pyrethroid-containing sprays have been recommended for reptiles, and one is even licensed for reptiles in the United States (Provent-A-Mite).[102] Pyrethrins and pyrethroids have the same mechanism of action. These molecules affect parasites by altering the activity of the sodium ion channels of nerves. These poisons prolong the period of sodium conductance and increase the length of the depolarizing action potential, resulting in repetitive nerve firing and death. With the right conditions or at higher doses, these compounds can intoxicate exposed animals. Because of the potential for transcutaneous absorption, pyrethrin and pyrethroid sprays must be thoroughly rinsed from the animal immediately after their application.[101] Rinsing with lukewarm water usually is sufficient. Clinical signs have been reported for pyrethrins and pyrethroids, particularly with the use of sprays that also contain insect growth regulators (e.g., methoprene).[101] Signs can develop in animals within 15 minutes of application and include salivation, ataxia, inability to right themselves, and muscle fasciculation;[103] the reptile's body temperature can influence the sensitivity to toxicity.[104] Idiosyncratic reactions to pyrethrins can happen at much lower doses than expected. If caught early enough, treatment for pyrethrin and pyrethroid toxicity involves dermal decontamination (bathing in copious amounts of water), isotonic fluids, and diazepam for tremors and seizures.[101] Care must be taken to keep pyrethrin and pyrethroid sprays away from the reptile's eyes and mouth to prevent intoxication. The prognosis depends on the strength of the agent used, the duration of the exposure, and the size of the animal involved.

Ivermectin. Ivermectin is a macrocyclic lactone derived from *Streptomyces avermitilis*, which acts at gamma-aminobutyric acid (GABA) synapses to stimulate excess release of GABA.[17] In nematodes, GABA is an inhibitory neurotransmitter. It binds irreversibly to the receptors, thus requiring that it be metabolized before its effects diminish. In most mammals, unless there is ap-glycoprotein abnormality, ivermectin is not able to cross the blood-brain barrier and therefore shows no effect. Ivermectin has been used successfully in a variety of reptilian species; however, it appears to be toxic primarily in chelonians, with crocodilians, lizards, and snakes also occasionally affected.[14,16,17] Ball pythons (*Python regius*), in particular, may show mild neurological signs when treated.[101] Ivermectin has been postulated as able to cross the blood-brain barrier in chelonians, or GABA may be a more important peripheral neurotransmitter in chelonians.[17]

Clinical signs associated with ivermectin intoxication are primarily related to general neuromuscular weakness.[14] Death is a function of paralysis of the respiratory muscles. Some variation appears in species susceptibility, and leopard tortoises (*Stigmochelys pardalis*) are especially sensitive, with paresis occurring at a dose as low as 0.025 mg/kg.[17] Because ivermectin binds irreversibly, it takes at least 7 days for reversal of clinical signs. Further, a cumulative effect may be observed if the drug is administered at frequent intervals. Treatment is primarily supportive, with particular attention paid to the respiratory, hydration, and nutritional status. Most animals need ventilatory support for several days. In general, the use of ivermectin in chelonians is contraindicated.[1,101]

Milbemycin is safe and effective for use in some chelonians.[1] This agent is related to and acts similar to ivermectin on the GABA receptors and was effective in red-eared sliders (*Trachemys scripta elegans*), Gulf Coast box turtles (*Terrepene carolina major*), and ornate box turtles (*Terrepene ornata*).[1] No toxic side effects have been observed, but the drug has not been evaluated in all chelonians. Milbemycin was effective at 0.5 to 1 mg/kg subcutaneously.

Antimicrobials. Metronidazole is an antibiotic and antiprotozoal agent commonly used in reptile medicine. The half-life of metronidazole in iguanas is longer (12.7 +/- 3.7 hours) than that reported for mammalian species (dogs, 4–5 hrs; humans, 6–10 hrs).[1] At high doses, metronidazole may induce clinical signs of vestibular disease with head tilt, circling, and dysequilibrium[101] (Fig. 77.33). In snakes, severe neurological signs and death have been associated with administration of metronidazole above 100 mg/kg.[1,14] Treatment is supportive and clinical signs are reversible.

Polymyxin and the aminoglycocides (streptomycin, kanamycin, gentamicin, and neomycin) at high doses cause neuromuscular blockade and may induce neurological signs such as paralysis.[1]

Heavy Metal Intoxication. Plumbism was diagnosed in a tortoise after ingestion of lead-based paint chips.[1] Diagnosis was made on the basis of clinical signs of generalized central nervous system disease and

FIG 77.33 Metronidazole toxicity resulting in a loss of righting in this ball python (*Python regius*).

supported by high blood lead levels. Blood samples from a control animal must be submitted for comparison purposes. Treatment should involve eliminating the lead from the gastrointestinal system with gastric lavage and catharsis in conjunction with calcium ethylenediamine tetraacetic acid therapy at 10 to 40 mg/kg intramuscularly twice a day.

Apparent zinc toxicity was observed in a green iguana (*Iguana iguana*) that had ingested pennies.[1] The patient was seen with anorexia, weakness, and anemia. Blood zinc levels were elevated compared with normal ranges published for other species. The iguana recovered uneventfully after chelation therapy and surgical removal of the pennies from the cecum.

Bromethalin. Bromethalin is one of the newer rodenticides. It is formulated in baits of pelleted grain and may be dyed green or turquoise. Bromethalin is a neurotoxin, but because of its name it can be confused with the long-acting anticoagulants bromadiolone and brodifacoum. Clients should be encouraged to bring in original containers to obtain valuable label information concerning ingredients.[101] The mechanism of action of bromethalin is the uncoupling of oxidative phosphorylation. The brain is the primary target for bromethalin because of its unique dependence on oxidative phosphorylation. The drug causes brain electrolyte disturbances and results in the development of cerebral edema.[101] Clinical signs include hind-limb paralysis, abnormal postures, fine muscle tremors, and seizures. Severely poisoned animals are comatose. Clinical signs are usually seen within 24 hrs of ingestion. Bromethalin is a nonselective vertebrate poison. No antidote exists, and treatment is directed initially at reducing gastrointestinal absorption and providing supportive care. Treatment also must aim at controlling cerebral edema seen in severe poisonings. Administration of dexamethasone and mannitol has been recommended to control bromethalin-induced cerebral edema. Unfortunately these agents are not very effective in controlling bromethalin-poisoned animals. Animals showing severe signs, such as seizures, paralysis, or coma, generally have a grave prognosis.[101]

Other Toxins. A variety of other environmental agents are potentially toxic to reptiles and amphibians, including iodoforms, nicotine, naphthalene, paraffin, and paint solvents.[1] Sometimes toxicity can only be suspected even after extensive investigations. An example of this situation is described in a report on loggerhead sea turtles presenting with neurological dysfunction in south Florida.[105] Despite a heavy spirorchiid parasitism existing in these turtles, a chronic exposure to a novel toxin in the diet was suspected. Similarly, severe neurological signs in a group of Australian water dragons (*Physignathus lesueurii*) with encephalomalacia was suspected to be due to a toxic etiology, although a viral infection could not be excluded.[49]

Wood shavings with high resin content such as cedar shavings may cause a reversible ataxia. Ingestion of fireflies of the genus *Photinus* is lethal to inland bearded dragons.[1] These fireflies contain lucibufagins, a steroidal pyrone, and ingestion of one insect is enough to be fatal to an adult bearded dragon. The toxin is actually thought to be cardiotoxic, but affected animals show signs of focal facial seizures, violent head shaking, mouth gaping, and protrusion and biting of the tongue. Although fireflies have been shown to be nontoxic in certain lizards, it is recommended not to use fireflies as food items.

Neoplasia

Neoplasia affecting the nervous system is uncommon in reptiles, but brain and spinal cord cancers have been described.[14,106,107] Pituitary adenomas have been reported in multiple snake species with clinical signs of brain dysfunction becoming evident in the late stages of the disease.[14] Advanced imaging techniques such as MRI are necessary to detect CNS neoplasia antemortem.

A 22-year-old red-tailed boa constrictor was evaluated for neurological abnormalities, including cervical weakness and right-sided optical and thermal blindness.[107] Magnetic resonance imaging (MRI) with the use of both a 7-T research unit and a 1.5-T clinical unit was performed and confirmed the diagnosis of a large mass within the diencephalon and mesencephalon causing hydrocephalus and asymmetry of the lateral ventricles. Necropsy and histopathology confirmed the presence of an intracranial mass likely to have an ependymal or astrocytic origin based on immunoreactivity of neoplastic cells to glial fibrillary acidic protein.[107]

CONCLUSION

Much remains to be learned about neurological diseases of captive reptiles. In many instances, neurological manifestations are caused by improper husbandry, trauma, or infectious disease. Clinical signs associated with neurological disease in reptiles are often nonspecific, and localization of the site of the lesion and the etiology may be difficult. Evaluating the patient for known causes of neurological dysfunction helps the clinician develop a diagnostic and therapeutic plan appropriate for the species. A complete diagnostic evaluation both antemortem and postmortem is vital especially in treatment of animals within a collection.

Oncology

Joerg Mayer and Antony S. Moore

While some of the earliest evidence of cancer in humans dates back to the time 2000 BC,[1] some of the earliest recorded cases date back 70 million years.[2] It is not surprising then to realize that cancer can affect even the most primitive animals such as corals.[3] Contrary to older beliefs, which suggested that cancers are rare in reptiles, more systematic analysis and longitudinal studies have noted that cancers in reptiles have an overall prevalence of 9.8%.[4]

In veterinary oncology, quality of life for the patient is always the top priority. Some cancers can be cured by treatments compatible with good quality of life. In other cases, anticancer treatment may significantly extend good quality survival time even if the patient is not permanently cured. However, for other patients, palliation may be a more appropriate goal, and because it delays the need for euthanasia, effective palliation can significantly enhance survival time as well as quality of life in veterinary medicine. Even in those cases where hospice care or euthanasia is the best option, performing this with compassion and skill can be one of the most valuable services a veterinarian can provide to help both patient and client.

As a subspecialty, oncology is increasingly important in veterinary practice, as client demand for advanced cancer care increases. To meet that need, the treatment of cancer in pets has evolved to parallel treatment in humans, with certain differences. One of the most important differences is in the goal of therapy. In humans, many cancers are cured, and cancer survivors may enjoy many decades of comfortable life. For this reason, treatment of cancer in humans is aggressive and often associated with severe side effects. On the other hand, most pet owners prefer to avoid severe side effects and prolonged hospitalization for quality of life reasons. In addition, the intense, specialized supportive care units and strategies for human cancer patients are not available for pets even in private practice specialty centers and university veterinary hospitals. Therapies are therefore primarily directed at maximizing quality of life, and the aim is often tumor control, or remission, rather than cure at any cost. "Remission" means partial or complete reduction of any outward evidence of cancer on examination or routine laboratory analyses and imaging (i.e., radiography, ultrasonography, CT, MRI), and relief of any clinical signs, making the pet appear as normal as possible. It is important for the veterinarian to inform the owner of the differing goals for cancer therapy in pets with cancer; that is, that the treatment (including surgery) should not cause the patient what is considered undue toxicity, as defined by the veterinarian and the owner. For some owners this definition may be *any* loss of quality of life, for others it may be hospitalization. In either situation the veterinarian should establish the goals of therapy in advance of starting treatment. If owners understand that quality of life will take precedence in their pets' treatment, they are more likely to trust the veterinarian and to treat their pets. It is important to recognize that although a pet's cancer may not be curable, he or she can enjoy a high quality of life. In this sense cancer is similar to other chronic illnesses such as nephrosis or cardiomyopathy, which can often be controlled providing a high quality of life, although they may not be curable.

DIAGNOSIS

The finding of a mass on any species does not immediately mean the lesion is neoplastic (Fig. 78.1), and without a histologic or cytologic confirmation of the neoplasia appropriate management is not possible. This is particularly true of reptiles. Due to the slow metabolic rate, a slow-growing mass can actually be an abscess or a granuloma. If such a process is suspected, biopsy material should be processed for bacterial and/or fungal culture and sensitivity, as well as histology. Some parasites, such as plerocercoids, larval dracunculids, acanthocephalans, cryptosporidiosis, and spiruroids, can mimic tumors. Other conditions associated with poor husbandry, such as steatitis, or infectious stomatitis, may also mimic neoplastic diseases (Fig. 78.2). Being able to obtain diagnostic samples and establish definitive diagnoses are crucial to developing an effective treatment plan. Therefore identifying veterinary pathologists that excel in zoologic/oncologic pathology is a major priority. The two main areas of pathology important in cancer diagnostics are

cytopathology and histopathology. Cytopathologists are specialists at examining individual cells obtained by fine-needle aspirate or impression smear to determine the identity of a disease process. Histopathologists examine intact tissue samples and associated architecture to determine the underlying pathologic process.

Choosing either diagnostic modality, or both, to apply in a given reptile with cancer depends on the individual case variables. Some of the advantages and disadvantages of cytopathology compared to histopathology include:

- Cytopathology samples of peripheral tissues can be easily obtained preoperatively, often without general anesthesia and sometimes even without sedation, and can be used to screen patients for more comprehensive diagnostics.
- Fine-needle aspiration cytology is less costly than surgical biopsy in both sample collection and laboratory analysis.
- The procedure of fine-needle aspiration is less likely to result in adverse effects when compared to tissue biopsy.
- Cytopathology requires less sample processing than histopathology and thus provides earlier results than histopathology.
- Cytopathology is more difficult to interpret and more prone to sample damage and "non-diagnostic" results.
- Surgical biopsy is generally more accurate and more representative of the entire tissue of concern than fine-needle aspiration cytology.
- Surgical biopsy provides information on tissue architecture, which cannot be obtained from cytological specimens. In some neoplasms evaluation of tissue architecture/tissue invasion is essential to differentiate between benign and malignant neoplasms.
- The relatively large tissue sample provided by biopsy enables further specialized testing such as histochemistry (special stains), immunohistochemistry, electron microscopy, and polymerase chain reaction to be performed, if required, to achieve a definitive diagnosis.
- For these reasons histopathology is generally more likely to provide a definitive diagnosis and is preferred; although the "investment" in time, client cost, and invasiveness of sample collection is greater.

A definitive diagnosis will help guide the treatment plan and, with staging, allow an estimate of the prognosis for any given patient. For example, knowing whether a tumor is a benign sebaceous adenoma or a malignant soft tissue sarcoma is extremely important. This is because, even though they may have the same outward appearance, the latter requires an extensive surgical resection and additional staging procedures to determine the extent of disease. In contrast, a benign adenoma may need a simple resection. The methods that the surgeon can use to diagnose the malignant condition or the extent of this disease are needle-core biopsy, punch, incisional biopsy, and excisional biopsy (Figs. 78.3 and 78.4).

A needle-core biopsy can be obtained with a simple needle or with a spring-loaded device (e.g., TruCut) and is primarily useful for externally palpable masses. In many reptiles with a thicker epidermis, it might be wise to cut down to the mass prior to the biopsy procedure. A spring-loaded 14-gauge needle will collect a piece of tissue, about 1 mm wide and 1.0 to 1.5 cm long. If these devices are used on internal masses the procedure should be performed with ultrasound guidance and with the reptile anesthetized; however, iatrogenic trauma and severe hemorrhage are significant risks. An alternative approach is to use endoscopy guidance to collect biopsies from internal lesions; such techniques are well described in the herpetologic literature.[5] Endoscopic biopsies of internal structures are often faster than traditional coeliotomy approaches. Although surgical mass resections can be performed endoscopically in humans and some domesticated animals, they are not routine in reptiles. Endoscopic biopsies should be large, or multiple smaller biopsies should be collected to ensure an accurate histologic diagnosis.

When performing a biopsy, it is important to plan the procedure with future definitive treatment in mind.

1. Needle tracts or biopsy incisions should be placed with careful thought so that the entire biopsy tract can be removed when the definitive surgical procedure is performed.
2. Care should be taken to not distribute cancer cells into surrounding tissues or through tissue planes during the biopsy procedure. For example, care must be taken to avoid the formation of a hematoma or a seroma, because the hematoma or seroma might spread cancer

cells as it dissects between fascial planes, which would require a more extensive definitive resection. When multiple biopsy specimens are taken from different sites, care should be taken to change instruments so that tumor cells are not transplanted from one site to another by the surgeon (Figs. 78.5 and 78.6).

3. Biopsy techniques should be carefully selected to allow the acquisition of sufficient tissue to make a histopathologic diagnosis. Obtaining multiple biopsy specimens increases the likelihood of an accurate diagnosis if an excisional biopsy is not being planned. significantly alter tissue, preventing an adequate evaluation of the margins, and may even hinder a diagnosis.[6] In general, such surgical devices should be reserved for controlling hemorrhage following the biopsy procedure but not used for harvesting the biopsy.

4. The biopsy specimen should be handled carefully to prevent crushing, artifact, or alteration of the orientation of the tissue specimen. Submitted tissues should be prepared in such a manner as to allow adequate evaluation of the tissue by the histopathologist using different procedures, such as immunohistochemistry. Specimens should be placed in enough preservative to allow complete fixation (a good rule is 1 part tissue to 10 parts formalin); however, prolonged fixation or storage in formalin may reduce the chances for future successful immunohistochemical staining. Using inked margins or sutures may give the pathologist information regarding orientation of biopsy tissue within the body, which can be helpful when planning a further procedure for an incompletely excised tumor. Check with your pathologist to determine their preferred method of marking tissue.
5. The surgeon should have an understanding of reptile anatomy and the biologic behavior of malignant conditions to ensure that all possible sites of metastases are evaluated prior to a definitive procedure being performed (Figs. 78.7 and 78.8).

SUITABILITY OF THE PATIENT FOR TREATMENT

When evaluating an animal for treatment of cancer, it is important not only to obtain a definitive diagnosis but also to assess the general health

of the patient by clinical examination and ancillary diagnostics. The prognostic information gained by determining the extent of organ involvement with the tumor, as well as identifying unrelated or secondary conditions that need to be treated or controlled before instituting appropriate therapy is mandatory to determine the suitability of a patient for chemotherapy. This information is also vital for individualizing the type and intensity of a treatment regimen. A full diagnostic investigation of the patient is essential due to the stoic and cryptic nature of reptiles and to assess the animal's condition prior to any therapy.

STAGING

Staging is a clinical process that enables the veterinarian to quantitate the extent of cancer involvement in the patient. Staging is sometimes confused with *grading*, which characterizes histopathologic features of the tumor. Staging often carries prognostic significance and enables the veterinarian and client to make informed and rational decisions as to the type of therapy best suited for the patient. In mammalian species, most staging systems are based on an assessment of three major components of the malignant process (TNM): the size of the primary tumor (T), lymph node metastasis (N), and distant metastasis (M). However, because most reptiles lack a well-defined lymphatic system, a modified TM process is more appropriate here.

Most of the information can be obtained from physical examination, but ancillary diagnostics (radiography, ultrasonography) are very important and can often incorporate sophisticated imaging techniques (CT, MRI) (Figs. 78.9, 78.10, and 78.11). Particularly for patients where superimposition of structures hinders interpretation of regular radiographs and access to internal viscera by ultrasonography is limited (e.g., carapace in chelonians), CT may be very helpful and is rapidly becoming established as a primary imaging modality. The value of cross-sectional imaging can be in identifying unsuspected metastatic disease (that can influence the types of treatment being offered and their likelihood of success), or it may allow assessment of resectability of a tumor, which can help in planning surgery. This information may help with a decision not to proceed with surgery based on a poor likelihood of success, allowing the veterinarian and owner to focus on other approaches or

TABLE 78.1 Definitions of Objective Tumor Remissions and Responses Following Anticancer Therapy

Tumor Response	Criteria
Complete (CR)*	Disappearance of all evidence of cancer in all sites for a defined period of time (e.g., one intertreatment interval of 3 weeks).
Partial (PR)*	Decrease in size of all tumors by 30% or greater as measured by the sum of the products of two diameters for target lesions. There should be sustained decrease in tumor size, as defined for CR, and no new tumors should arise.
Stable disease (SD)	Decrease of <30% or an increase of <20% in the sum of the products of the target diameters as measured for PR.
Progressive disease (PD)	Increase of 20% or more in the sum of the target diameters *or* the appearance of a new tumor.

*CR + PR = Objective or overall response rate.

palliative strategies. If radiation therapy is available, CT or MRI will allow the treatment field to be defined and the risk for side effects to be reduced or avoided, improving outcomes for the patients.

The majority of patients for whom chemotherapy may have therapeutic benefit will have systemic or metastatic disease that is either physically evident or presumed through historical knowledge of tumor behavior (e.g., osteosarcoma,[7] hemangiosarcoma[8]) (Fig. 78.12).

The likelihood of a successful outcome for a patient treated with chemotherapy is as dependent on drug metabolism and elimination (and drug absorption for orally administered chemotherapy) as it is on the sensitivity of the tumor. This information is severely lacking for reptiles. In addition, information gained during staging (hematology, serum chemistry profile, and urinalysis) may identify problems that will impact the type and dosage of chemotherapy to optimize efficacy while limiting toxicity. For example, hepatic dysfunction may lead to delayed drug elimination (e.g., vinca alkaloids, doxorubicin) and therefore lead to greater toxicity such as myelosuppression. In contrast, cyclophosphamide is activated in the liver, so hepatic dysfunction may result in poor efficacy.

Similarly, renal dysfunction may worsen toxicity for some drugs that are themselves renally toxic. For example, cisplatin should not be used in patients with renal azotemia. Reduced renal excretion of carboplatin will exacerbate myelosuppression. For more details regarding chemotherapy side effects, see Chapter 123.

DESCRIBING THE PROGNOSIS WITH STATISTICS

Some terms that are often used when describing the prognosis for a patient with cancer follow. These are statistical terms and provide a guide as how the population of animals with the same cancer type will respond to treatment; such numbers can never tell you how an individual patient will respond to therapy, and how long they will survive.

The currently used criteria for response assessment by anatomic imaging modalities (World Health Organization [WHO] and response evaluation criteria in solid tumors [RECIST]) are defined in Table 78.1. In RECIST, only 1 to 5 "target lesions" that are greater than 10 mm in the longest dimension (for clinical examination or CT/MRI), or >20 mm (for radiographs or ultrasonography) are measured for response.

TREATMENT

Some private practice specialty centers and university veterinary hospitals are equipped to provide high levels of care to animals with a wide variety of malignancies. For the primary care veterinarian it is important to have resources to provide information that will allow the caregivers to decide between rational, evidence-based treatments that will maximize their pet's quality of life. It is important to remember that every patient can be helped regardless of finances, time, and the specific diagnosis with supportive care, curative treatment, palliative therapy, and hospice care or euthanasia. Furthermore, the veterinarian should provide realistic, honest information in both written form and thorough face-to-face discussions with the owner/caretaker.

In the setting of zoologic practice, that information may need to be extrapolated from similar tumor types in other species and often is based on single case reports or small series of cases. In addition, many reptiles are valuable for their breeding potential, and that may limit the type of treatment and the intensity of treatment for some patients. On the other hand, reptiles can live a long time, and for pets where breeding is less important, there is potential for meaningful outcomes from more aggressive treatment.

Palliative Intent Treatment

For many older veterinary patients, the diagnosis of cancer is obtained at a time when other diseases may limit their long-term survival already. For these patients, palliative care may be most appropriate, and the choice of chemotherapy must be weighed against the risk of toxicity. Such patients may benefit from supportive care and pain relief.

Curative Intent Treatment

For younger patients that are in good health, have no concurrent illnesses, and for which treatment holds the possibility of a long tumor control with little risk of toxicity, curative intent therapy may be undertaken.

Surgery

Surgery is still the modality most likely to cure an animal of cancer if the tumor is localized (not metastasized and not invading into sensitive structures). However, it is not only with curative intent that surgery is

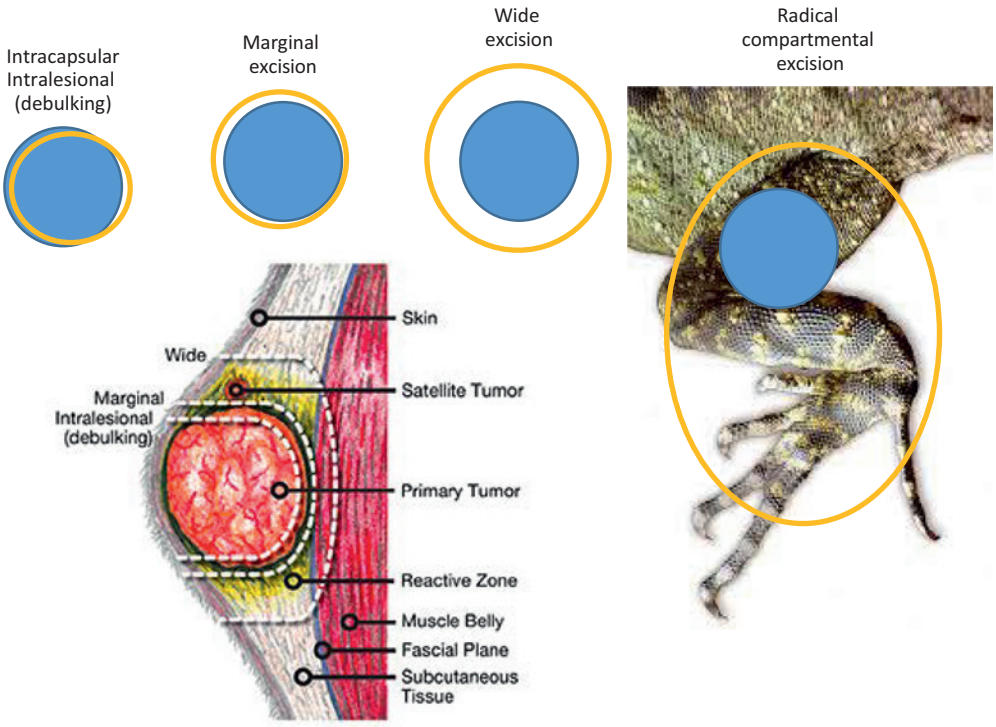

FIG 78.13 Intracapsular/intralesional and marginal surgery are very likely to fail to control a malignancy but can provide palliation for pain or bleeding. Curative intent surgery is preferred whenever anatomically possible, with radical excisional surgery preferred if a more localized curative surgery is not possible. Surgical margins should be confirmed by histopathology, whichever method is chosen.

applied to pets with cancer. Biopsy, debulking, and palliation are achieved through surgery, and each needs to be carefully performed to minimize the impact on the patient's quality of life while still achieving the appropriate goal.

Careful preparation of the patient, as well as anticipation of complications (especially dehiscence), can be as important as the surgery itself in leading to a good outcome for the patient. Fig. 78.13 illustrates the different excisional techniques that could be used to treat cancer in reptilian patients.

Intracapsular Surgery. Also known as debulking or cytoreduction, this technique will never lead to a cure for a cancer but can have a role in preserving surrounding normal tissues and structures that, if damaged, could negatively affect the patient's quality of life. Debulking will often leave behind visible tissue at the site but can provide palliation when a tumor is causing obstruction (say to the upper respiratory tract or the gastrointestinal tract) or pain (retrobulbar tumors or spinal tumors). Most debulking surgeries require adjunctive therapy if the patient is to be cured or have a long-term remission. For some cancer types, debulking of the tumor, followed by radiation therapy (see Chapter 124), could be considered to have a high probability of long-term control.

Marginal Surgery. By this surgical technique the tumor is removed along the pseudocapsule. The pseudocapsule is formed when the tumor expands, compressing the peripheral tumor cells against the surrounding normal tissue. Grossly, the tumor appears to "shell out," but microscopic compressed (but viable) tumor cells remain and will regrow if no further treatment is performed. Again radiation therapy is indicated for marginally removed tumors where metastasis has not occurred, and cure is still a possibility with that additional therapy.

Curative Intent Surgery. When preparing a patient for curative intent surgery, it is important to plan the surgery to include any biopsy needle tracts and incisions, as well as drain holes and tracts, which will need to be removed as these could be a source of future recurrence.

Wide Excisional Surgery. Excisional surgery removes a "cuff" of normal tissue along with the tumor contained within. Ideally, the tumor is removed en bloc, and the lateral or deep margins of the tumor are never exposed. If the margin is wide enough, a cure is possible. However, often what appears to be a wide surgery to the cancer care team may still not be adequate. Placing ink or sutures at the areas the surgeon feels least confident about will assist the pathologist to specifically section and examine those sites.

Most investigators feel a clear histologic margin of 5 mm to 10 mm (depending on the tumor type) is adequate. To achieve this, wider surgical margins of macroscopically normal-appearing tissue need to be removed. Clearly in very small reptiles this will not be feasible, especially for larger tumors or those located around sensitive or vital structures. For these smaller patients, surgery should have the aim of achieving the maximum margins that will allow quality of life to be preserved. In mammalian species a technique of proportional margins has been successful for smaller patients, where the peripheral and deep margins are equal to the measured diameter of the tumor.[9] This may be a reasonable approach, if feasible, in smaller reptiles. For larger patients, similar criteria to those used for other pet animals apply. The margins reported in the pathology report should always be interpreted in light of the clinical impression

VetBooks.ir

of the surgery. If the surgeon was not confident that clear margins were achieved, the best option is a second, "scar revision" surgery to remove margins around the remaining scar. If the surgeon feels confident, but the pathologist finds tumor cells at the margin, the pathology report should take precedence; whereas if the surgeon feels it is unlikely the excision was complete, but the pathology report does not find tumor cells at the margins, the surgeon's impression should take precedence. On the other hand, if the deep margin includes underlying fascia or muscle that has not been penetrated, these may act as a barrier to tumor invasion, particularly early on in tumor growth. Aggressive surgery such as partial pneumonectomy and/or partial hepatectomy are feasible and may be curative in some reptiles.[10]

Radical Excisional Surgery. Radical surgery removes a complete compartment organ or structure to achieve complete margins. The most commonly seen example is a limb amputation that could cure a soft tissue sarcoma and be palliative for pain from, or curative for, a bone cancer such as chondrosarcoma or osteosarcoma.[11,12]

Such aggressive surgical procedures may be viewed as "mutilating" by some owners, as they anthropomorphically project their interpretation of their own well-being onto their pets. It is important to remember that animals often have a great quality of life with little regard for the cosmetic changes such surgeries cause.

Chapter 123 of this book focuses on the chemotherapy of various tumor types in the reptilian patient, and Chapter 124 focuses on the option of radiation therapy. Much more scientific data must be collected in an attempt to fully understand how reptilian physiology is affected by cancer cells and how it responds to chemotherapy and radiation treatment. The authors encourage clinicians to collect and publish data on reptilian oncology patients, especially in cases involving chemotherapy or radiation therapy.

Endocrinology

Paul Raiti

Similar to other vertebrates, the reptilian endocrine system consists of ductless glands that synthesize, store, and release polypeptide hormones directly into the circulatory system. Specific target cells form surface complexes with these hormones prior to intracellular metabolism. This chapter includes the hypothalamus, pituitary, thyroid, ultimobranchial, parathyroid, splenopancreas, and adrenal glands. Gonadal physiology and reproduction are discussed elsewhere in Chapter 80.

HYPOTHALAMUS AND PITUITARY GLAND (HYPOPHYSIS)

The hypothalamus is the ventral part of the anterior brainstem or diencephalon. On the ventral surface of the hypothalamus is the optic chiasma and just caudal to this the pituitary stalk emerges. The pituitary gland is located in a boney cavity of the floor of the cranium (sella tursica).[1] In reptiles, as in other vertebrates, the hypothalamus controls the pituitary gland, through nerve impulses and secretion of neurohormones. The hypothalamic/pituitary axis regulates the endocrine system via positive and negative feedback systems. Several hypothalamic-pituitary axes have been described, including the hypothalamic-pituitary-thyroid (HPT) axis, the hypothalamic-pituitary-adrenal (HPA) axis, and the hypothalamic-pituitary-gonadal (HPG) axis.[2] Release or release-inhibiting hormones produced by the hypothalamus controlling the pituitary gland are thyrotropin-releasing hormone (TRH); corticotropin-releasing hormone (CRH); dopamine (DA); prolactin (PRL)-inhibiting hormone; growth hormone–releasing hormone (GHRH); GH-release-inhibiting hormone (GHIH), also called somatostatin (SS); gonadotropin-releasing hormone (GnRH), melanocyte-releasing hormone (MRH); and melanocyte release-inhibiting hormone (MRIH).[2]

The anterior lobe (adenohyphysis) of the pituitary gland is composed of three structures (pars intermedia, pars tuberalis, and pars distalis) and produces growth hormone, prolactin, ACTH (adrenocorticotropic hormone), TSH (thyroid stimulating hormone), MSH (melanophore-stimulating hormone), beta endorphans, and gonadotropins.[2] Beta endorphins influence temperature regulation, respiration, and cardiovascular function.[3] Beta endorphins are also thought to act synergistically on chromatophores to potentiate the action of MSH in promoting physiological color change.[3] Prolactin is involved in a wide variety of physiological functions, which are mainly associated with reproduction, behavior, osmoregulation, and immunoregulation.[4] In squamates (lizards and snakes), injections of ovine prolactin-releasing hormone increased appetite, growth, tail regeneration rate, and frequency of sloughing.[5] The posterior lobe (neurohypophysis) of the pituitary gland produces vasotocin (arginine-oxytocin),[6] a hormone similar to mammalian antidiuretic hormone.

Several cases of pituitary neoplasia have been reported in snakes.[7,8] Pituitary adenomas and cystadenoma were described in adult snakes with variable clinical signs, including decreased mentation, postural abnormalities, ataxia, decreased muscle tone, enterolipidosis, polydipsia, cutaneous mycotic infection, and partial-to-complete loss of righting reflexes consistent with central nervous system disease. Diagnoses were made on postmortem with tumors located in the anterior lobe of the pituitary, causing compression of adjacent pituitary and brain. To date, no cases of diabetes insipidus have been reported in reptiles. Improved brain evaluation at necropsy and further investigation into the diagnostic value of ACTH are required.

THYROID GLAND

Chelonians and snakes possess single thyroid glands. The thyroid glands of lizards may be single, bilobed, or paired among different members of the same family.[9] In the green iguana and crocodilians, the paired thyroid glands are joined by a narrow bridge of tissue (Fig. 79.1). In snakes, the thyroid gland is located ventral to the trachea, cranial to the heart base, and caudal to the thymus (Fig. 79.2).[9] In chelonians and lizards, the thyroid gland is generally located ventral to the trachea and near the base of the heart (Fig. 79.3). The Nile crocodile (*Crocodylus*

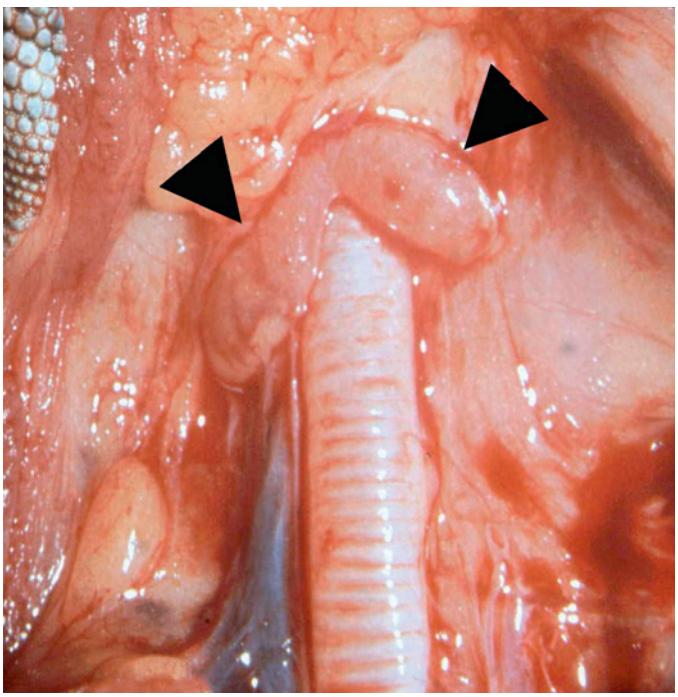

FIG 79.1 The bilobed thyroid gland (*arrows*) of the green iguana (*Iguana iguana*) is located in the cervical area immediately ventral to the trachea.

niloticus) posseses two separate asymmetric lobes found not on the trachea but attached to the lateral side of each bronchi, the right closer to the right bronchus where it enters the lung and the left closer to the bifurcation of the trachea.[10] The tuatara has a single transversely elongate thyroid gland.[9] Unlike mammals, the reptilian thyroid glands are anatomically distinct from the parathyroid glands.[9] Thyroid glands are capable of regeneration if damaged or incompletely removed.[11]

Though small, the thyroid gland receives one of the largest relative blood supplies of any organ.[9] The thyroid gland has dual arterial supplies on both sides. In *Lacerta* and *Xantusia* the superior thyroid arteries (or right and left thyroid arteries) branch off the external or internal carotid's (respectively) and attach to the lateral thyroids.[9] The inferior thyroid arteries (or right and left laryngotracheal arteries) are short, large vessels that attach to the dorsal thyroid body. The thyroid glands are drained by one or two medial thyroid veins into the right tracheal or right internal jugular veins. The thyroid gland itself is contained in a large lymphatic sac and surrounded by lymph tissue.[9] Innervation of the thyroid gland is from the laryngeal branches of the vagus nerve and fine branches of the cervical sympathetics.[9] The thyroid gland has a dense irregular connective tissue capsule enveloping it. It consists of follicular acini of varying size lined by simple cuboidal or columnar epithelium that may show seasonal/cyclic variation association with reproduction.[12] In mammals, the thyroid gland also secretes calcitonin; however, in reptiles calcitonin is secreted by a separate gland called the ultimobranchial gland.[13]

Reptile thyroid physiology is similar to other vertebrates; however, mammalian thyroid shows greater secretory activity than the reptilian thyroid.[14] Thyroid function is mediated centrally via TRH from the hypothalamus and TSH released from the pituitary gland. TSH controls the synthesis and release of T_4 and T_3 from the thyroid gland. Dietary iodine, an essential trace element, is absorbed in the small intestine and plays an essential role in metabolism as a component of thyroid hormones.[15] The follicular cells concentrate iodides from the thyroid's vascular supply and convert iodide to iodine. One or two molecules of iodine then attaches to the amino acid tyrosine to form either monoiodotyrosine (MIT) or diiodotyrosine (DIT). MIT and DIT can be coupled to form triiodothyronine (T_3), or two DITs can couple to form tetraiodothyronine (thyroxine or T_4).[16] These reactions depend on a glycoprotein that the follicles produce called thyroglobulin. As the thyroglobulin is secreted into the follicular lumen, iodination and coupling occurs and thyroglobulin stores all these molecules as eosinophillic colloid. In reptiles, T_4 accounts for approximately 80% of thyroid hormones in the thyroid gland and plasma. Hence, T_4 is considered a storage and transport form of thyroid hormones, while T_3 is the more metabolically active form.[16] T_4 is converted to T_3 in skeletal muscle, liver, brain, and other target tissues by removal of an outer layer ring 5′iodine (deiodination).[16] Among reptiles, thyroid levels in snakes are generally the lowest and chelonians the highest; crocodilians are similar to birds.[14] In sea turtles and other reptiles, most T_4 in plasma is bound to carrier proteins; only the unbound or "free" T_4 (fT_4) is available to tissues for conversion to T_3 via deiodinases.[17] Free T_4 has been recommended as the most informative measure of thyroid function in reptiles, yet most publications have measured total T_4 due to a lack of validated fT_4 assays for reptiles.[17]

In reptiles, the hypothalamic/pituitary/thyroid axis influences many processes, such as shedding, growth, development, reproduction, metabolic rate, nutrient assimilation, and activity. The studies on cyclic changes in the thyroid in connection with the reproductive cycle indicate that thyroid activity may play a part in sexual behavior as well as gonad maturation depending on day length and temperature.[18] Thyroid hormones are critical for normal bone growth and development, as T_3 stimulates both osteoblast and osteoclast activities.[19,20] The thyroid gland exhibits both direct and indirect effects on the heart and cardiovascular system (i.e., influences myocardial contractility and hemodynamics).[21] The effects caused by thyroid hormones on the heart result from interactions with specific nuclear receptors in cardiac myocytes.[21] Low thyroid hormones are known to inhibit activity and feeding in many ectotherms, with thyroidectomized individuals generally showing sharp reductions in activity, feeding, and metabolic rate. In lizards (*Lacerta*, *Hemidactylus*, *Gekko*), thyroidectomy caused either a decrease or cessation of shedding with a build-up of the horny layer, while administration of thyroxine caused increased shedding frequency.[9] In snakes (*Thamnophis*, *Python*, *Natrix*, *Ptyas*, *Chionactus*) excess thyroxine caused shedding to cease, while hypophysectomy or thyroidectomy increased shedding frequency.[9]

Many factors influence thyroid values including age, sex, diurnal changes, seasonal changes, day length, shedding, illness, stress, and breeding.[18] Chelonians (*Agionemys*, *Lissemys*, *Trachemys*) exposed to prolonged or continuous illumination exhibit a gradual decline in T_4, while shorter or variable conditions stimulate T_4 production.[9,22] Interestingly, the genera *Chrysemys*, *Pseudemys*, and *Trachemys* appear to have significantly higher thyroid values than other reptiles (see Table 79.1), and females in these genera have higher levels than males, perhaps

because of a thyroxine-binding protein (TBP), which may cause marked seasonal variation.[23,24] This high-affinity T_4-binding protein (TBP) appears to be the major component of T_4 transport in these turtles.[23,24] Thyroxine-binding protein was minimal upon emergence from hibernation and maximal in late summer (July–August), about a month after the peak in plasma T_4.[23,24]

Seasonal thyroid patterns are typical in reptiles and are believed to be necessary for the normal functioning of the thyroid gland and immune system. In a wide variety of temperate reptiles (*Lacerta*, *Dipsosaurus*, *Natrix*, *Vipera*, *Gopherus*, *Chrysemys*, *Trachemys*, *Pseudemys*), thyroid activity is high during summer's higher temperatures and low during winter's lower temperatures.[25–29] Tropical species (*Anolis*) have higher thyroid values in the cooler months and decreased values in the warmer months when they are often less active.[9] Both T_4 and T_3 tend to decline during stress, particularly if the stressor involves decreased body temperature, starvation, or both.[30]

Thyroid Testing

Mammalian thyroid function is assessed using basal total and free thyroxine (T_4, fT_4), basal total and free triiodothyronine (T_3, fT_3), T_3 suppression, TSH response, and TRH stimulation tests. High TSH levels with low T_4 concentration and accompanying symptoms are considered diagnostic for hypothyroidism; however, this test has not been validated in reptilian species.[17,31] Conversely, low values of TSH and high T_4 concentration are indicative of hyperthyroidism. Total T_4 and T_3 values in reptiles are roughly 20% and 25%, respectively, of the average values in mammals; however, determining/detecting thyroid hormone values for reptiles is complicated because assays are designed for the higher levels found in mammals.[17] T_3 is often undetectable even by radioimmunoassay (RIA). For these reasons, total T_4 is most typically assayed in reptiles, and ranges have been published for several species.[31] (See Table 79.1.) Significant "normal" variations in T_4 are seen in reptiles, which complicates interpretation; hence, subnormal T_4 levels alone may be suggestive of but not diagnostic for hypothyroidism. In the past, reptilian fT_4 values (i.e., *Testudo* spp.) were frequently below the limits of detection (<0.45 pmol/L) of mammalian thyroid assays.[32] Total T_4 and T_3 concentrations circulate at nanomolar (nmol) concentrations and are considerably easier to measure than fT_4 and fT_3, which circulate in minute concentrations that are measured at picomolar (pmol/L) or picogram (pg/ml) concentrations.[33] (Note: pg/ml × 1.287 = pmol/L.) "Free" hormone immunoassays are based on the principle of using a specific antibody to sequester a small amount of the total hormone such that the fractional occupancy of antibody binding sites is determined by the free hormone concentration.[33] Currently, the Society for Comparative Endocrinology encourages the use of Standard International (SI) units (e.g., molar units such as nmol/L, pmol/L). Some veterinary laboratories still report T_3 and T_4 values as μg/dl. This unit of measurement can be converted to nmol/L by multiplying μg/dl by a factor of 12.87. Thyroid autoimmunity testing against thyroid-specific antigens (thyroid peroxidase [TPO], thyroglobulin [TG], and TSH receptors) is useful for the diagnosis of autoimmune thyroid disorders (hypothyroidism) in dogs and humans.[31] Currently, this diagnostic test is not available for other animal species.

In 2001, a high-sensitivity RIA procedure was validated to measure and establish initial reference ranges for T_4 concentration in select species of snakes.[17] Nuclear medicine has been used for the diagnosis of human thyroid dysfunction, specifically cases of hyperthyroidism. Taking advantage of the physiological iodine/iodide cycle, an isotope with high affinity to the thyroid gland is administered, and uptake by the thyroid gland is either quantified or compared with another organ.[31] Other imaging modalities used for thyroid diagnostic testing include ultrasonography (US), scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI), mainly for the diagnosis of neoplasia.[31] Although these tests have been used to assess the thyroid gland, they may not provide information regarding glandular function.

Overview of Thyroid Disease

Vertebrates with goiter or, more correctly, thyromegaly may be clinically hyperthyroid, euthyroid, or hypothyroid. In reptiles, thyroid malfunction has been associated with hypertrophy/hyperplasia (adenomas, colloid goiters), malignancies, euthyroid sick syndrome, and hypothyroidism. Proposed etiologies for proliferative thyroid disease (adenomatous disease) include iodine deficiency or toxicity, goitrogenic substances (e.g., *Brassica* spp. plants), endocrine-disrupting compounds, trace vitamin and mineral deficiencies (e.g., vitamin A, selenium, iron, and zinc in humans), autoimmune disease, genetic predisposition, age, temperature, and photoperiod.[34] Histological features of adenomatous hyperplasia consist primarily of hypertrophy of the follicular epithelium.

A zoo colony of Kirtland's snakes (*Clonophis kirtlandii*) were evaluated due to a historic high prevalence of thyromegaly (goiter) and mortality unrelated to gender.[36] Subjective thyromegaly was noted in most, while microscopic thyroid lesions (ademomatous changes) were observed in all snakes. Unfortunately, antemortem thyroid hormone testing was not performed due to small patient size. But suspected etiologies included suboptimal dietary iodine, other nutritional deficiencies, exposure to goitrogenic substances, exposure to and bioaccumulation of endocrine-disrupting contaminants from the environment, genetic predisposition, or a combination thereof. Supplementation with iodine was attempted in some snakes in various ways but was generally unsuccessful. In reptiles, most reported cases of hyperthyroidism are associated with thyroid neoplasia.

Thyroid adenomas and carcinomas have been reported in lizards, snakes, and several chelonian species.[35] Histological features of carcinomas include nuclear pleomorphism, mitotic figures, necrosis, local invasion, and metastases to the liver and lungs. Affected reptiles have evidence of concurrent diseases, including stomatitis, rhinitis, uveitis, conjunctivitis, cellulitus, epicarditis, pancreatic atrophy, pancreas islet cell tumor, colonic carcinoma, renal disease, and articular gout; however, no cause or effect relationships have been established. A group of three diplodactylid geckos with signs of intraoral mass, ventral throat swelling, oral bleeding, and weight loss were diagnosed with proliferative thyroid lesions.[37] Thyroid hormone assays were deemed impractical in these geckos due to their limited size. Thyroid carcinomas were confirmed in two geckos, with metastases to the liver and lungs in one animal. Thyroidectomy with replacement levothyroxine therapy was curative in the third gecko (marbled velvet gecko, *Oedura marmorata*) with adenomatous hyperplasia. Given the size of the animal, clinical response was used to assess therapy. Five other diplodactylid geckos in the collection remained unaffected, giving a 38% prevalence of proliferative thyroid lesions (3/8). The etiology remained undetermined. Many cases of thyroid disease have been serendipitously identified during necropsies of reptiles that presented with nonspecific symptoms of illness, hence the relative lack of abnormal T_4 values reported in the literature (Fig. 79.4).

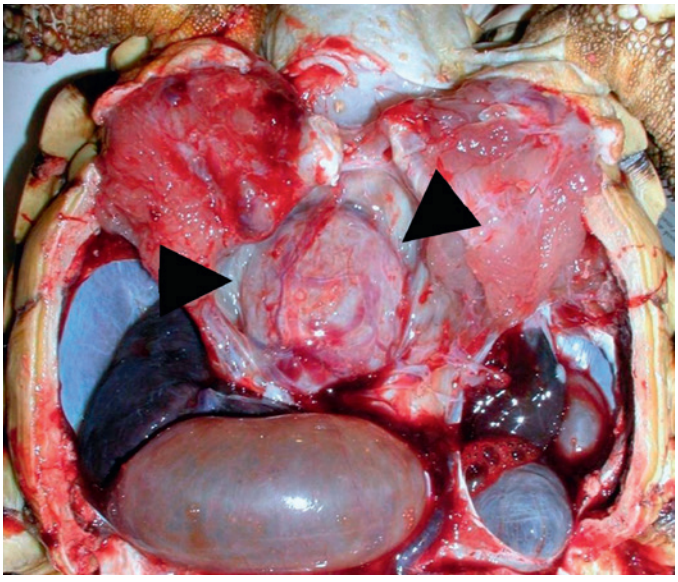

FIG 79.4 Massive thyromegaly due to an adenoma (arrows) in a Chaco tortoise (*Chelonoidis chilensis).* The heart lies beneath the adenoma and is not visible.

Euthyroid Sick Syndrome

"Euthyroid sick syndrome" or "nonthyroidal illness syndrome" refers to changes in serum TSH, serum thyroid hormones, and tissue thyroid hormone levels that occur in patients with various nonthyroidal conditions.[31,34] In humans, this syndrome occurs in cases of starvation, sepsis, surgery, myocardial infarction, bypass, bone marrow transplantation, and probably any severe disease.[31,38] In endotherms and probably in ectotherms, this shut-down of thyroid function at low ambient temperatures is thought to be an adaptive strategy to reduce energy costs.[31] Food restriction reduces thyroid hormones in green sea turtles (*Chelonia mydas*), desert tortoises (*Gopherus agassizii*), and several other reptiles.[31] It is thought that the relative hypothyroid state produced is a physiological means of conserving energy during times of food deprivation (starvation) and hibernation. In red-eared sliders (*Trachemys scripta elegans*), for example, low temperatures caused in vitro pituitary tissue to become almost completely unresponsive to hypothalamic TRH, and in vitro thyroid tissue also became less responsive to pituitary TSH.[30] In cold-stunned Kemp's ridley sea turtles it was found that upon admission, affected turtles' fT_4s were usually undectable.[39]

Hypothyroidism

Primary hypothyroidism, the result of idiopathic thyroid atrophy or lymphocytic thyroiditis, and secondary hypothyroidism, the result of iodine deficiency in the diet, are most commonly implicated in mammalian disease. The most commonly reported causes of hypothyroidism in reptiles have been associated with conditions that were thought to interfere with normal thyroid function, such as iodine deficiency or toxicity and feeding excessive amounts of goitrogenic food items. Proposed etiologies include feeding plants grown in iodine-deficient soil and/or dietary goitrogens found in bok choy, broccoli, cabbage, cauliflower, kale, mustard seed, rapeseed, soybean sprouts, and turnips. Iodine deficiency leads to decreased thyroxine levels, which subsequently activates the hypothalamo-pituatary axis leading to increased TSH production and resulting thyromegaly (goiter).[15] Clinical signs may be suggestive of hypothyroidism, but proper diagnosis should be based on measurements of total T_4 and TSH levels. In one study, thyroid values from normal Galapagos tortoises housed at the Oklahoma City Zoo were compared with suspected hypothyroid conspecifics that had been on loan to another zoo for 2 years. Results indicated reduced T_3 values (0.07 nmol/L compared with euthyroid controls of 0.51–2.53 nmol/L). Additionally, T_4 values (2.43–6.02 nmol/L were reduced compared with euthyroid controls of 13.9–19.82 nmol/L) (DiGesualdo CL, unpublished data). For the tortoises with cervical myxedema, treatment was instituted with levothyroxine at 0.02 mg/kg PO every 48 hrs. Previously, hypothyroidism has been suggested primarily in Galapagos (*Chelonoidis nigra)* and Aldabra (*Aldabrachelys gigantea*) tortoises that were thought to possess a higher metabolic requirement for iodine, which was deficient in diets formulated for captive animals.[40] Clinical symptoms have included anorexia, lethargy, and myxedema of subcutaneous tissues generally involving the head, neck, and proximal forelimbs. However, it should be noted that the chelonian thyroid gland is located just anterior to the cardiac base within the shell; hence, an enlarged thyroid is not visible or palpable in the ventral cervical area. In addition, thymic hyperplasia has been reported to cause cervical swelling in giant tortoises.[41]

Interestingly, a clinical syndrome has recently emerged based upon observations of captive F1 offspring from founder Galapagos tortoises over the past 30 years characterized by incorrect feeding combined with insufficient exercise, abnormal hind limb ambulation, inability of the tortoise to raise itself squarely on its limbs, and an edematous neck lesion (Hairston-Adams C, unpublished data). Thyroid testing of affected

animals is currently being done to distinguish if these tortoises represent true hypothyroid cases or perhaps euthyroid sick syndrome secondary to poor husbandry practices.

Hyperthyroidism

Hyperthyroidism is a multisystemic disorder characterized by a state of abnormally high metabolism due to elevated concentrations of T_3 and T_4. Hyperthyroidism is most commonly caused by hyperfunctional thyroid nodules (adenomas), malignant thyroid neoplasms, oversupplementation of exogenous thyroid hormone, and/or increased TSH secretion due to pituitary dysfunction.[34] The diagnosis of hyperthyroidism is characterized by an elevated T_4 level and accompanying clinical symptoms. Current laboratory assays are able to measure reptilian T_4 by RIA; however, validated assays to test samples from many reptilian species have not been reported. Treatment options for proliferative thyroid disease in mammals include thyroid hormone inhibitors (e.g., methimazole, propylthiouracil), radiotherapy with injectable iodine (I-131), or surgical resection.[34]

Hyperthyroidism was reported in a 7-yr-old female green iguana with weight loss, polyphagia, hyperactivity, increased aggression, loss of dorsal spines, tachycardia, and a palpable bilobed mass in the ventral cervical region near the coelomic inlet.[42] The diagnosis was based on an elevated T_4 level (30.0 nmol/L; 2.33 µg/dl); controls 3.81 ± 0.84 nmol/L (0.29 ± 0.06 µg/dl). Excision was curative, and histopathology confirmed thyroid adenoma. Interestingly, T_4 values of the affected iguana returned to normal after surgery despite the absence of thyroid replacement therapy, suggesting incomplete removal or extraneous thyroid tissue.

A case of hyperthyroidism in a 14-yr-old female leopard gecko (*Eublepharis macularius*), with clinical symptoms consisting of anorexia, diarrhea, increased shedding frequency, and a unilateral midline cervical mass, was reported (Boyer T, unpublished data). Serial T_4 levels were elevated (20.59, 64.35 nmol/L; 1.59 µg/dl, 5.0 µg/dl) compared to normal conspecific levels (6.05–19.31 nmol/L; 0.47–1.5 µg/dl). Computed tomographic findings revealed a unilateral thyroid gland enlargement. Iodine-131 (0.1 mCi), injected subcutaneously in the ventral neck, decreased T_4 levels at 1 month (14.16 nmol/L; 1.1 µg/dl), 3 months (6.44 nmol/L; 0.5 µg/dl), and 5 months (12.61 nmol/L; 0.9 µg/dl). Diarrhea resolved posttreatment; the gecko resumed feeding and gained weight. The radioactive I-131 treatment resulted in a euthyroid state for 5 months posttreatment, resolution of diarrhea, return to normal appetite, and weight gain, but then T_4 increased again. This gecko later died of complications of systemic disease. Boyer and Bourdon subsequently recommended a dose of radioactive Iodine-131 of 0.2 mCi in affected geckos.

Miscellaneous Thyroid Conditions

Intranuclear coccidiosis with thyromegaly was diagnosed in a radiated tortoise, *Astrochelys radiata* (unpublished data), and a Bowsprit tortoise, *Chersina angulata*.[43] In the radiated tortoise the T_4 was 11.5 nmol/L and 0.89 µg/dl 11 days prior to necropsy, and the ventral neck, head, and front legs were edematous. Coccidial infections were systemic and involved alimentary, urogenital, respiratory, lymphoid, endocrine, and integumentary systems. Moderate numbers of birefringent calcium oxalate crystals, based on infrared and electron microscopy, were considered incidental findings identified in the thyroid glands and kidneys of necropsied wild desert tortoises (*Gopherus agassizii*).[44] The source of calcium oxalates was suspected to be of plant origin.

ULTIMOBRANCHIAL GLAND

The ultimobranchial gland (UBG) in vertebrates is derived from the pharyngeal pouch epithelium during embryonic development and secretes calcitonin (CT) from C-cells.[54,55] The gland is either separately located (nonmammalian vertebrates) from the thyroid gland or embedded in the thyroid (mammals). Adult reptiles possess one (usually on the left side) or two UBGs UBG's just anterior to the heart. The functional aspects of these glands in reptiles are similar to those of birds and mammals.[54,55] Calcitonin is involved in calcium and phosphorus homeostasis and skeletal remodeling, along with parathyroid hormone (PTH) and vitamin D_3.[54] Administration of mammalian CT had no effect on plasma calcium in turtles, snakes, or lizards.[57] In contrast, administration of salmon CT resulted in hypocalcemia and hypophosphatemia in young iguanas and snakes.[57] However, when salmon CT (200 IU/ml) was administered as a single dose at 50 IU/kg in the front leg of eight healthy adult green iguanas, and blood was collected at 0, 24, 48, 72, and 96 hours, plasma Ca concentrations were within reference intervals at all times and calcitonin did not appear to have influenced Ca concentrations on a long-term basis.[57]

Light and electron microscopy have shown the gland contains follicles and cell cords (cell aggregates). The follicular epithelium is lined by simple cuboidal or pseudostratified columnar cells. Ciliated and goblet cells may be present in the follicular epithelia in some groups. The lumen contains a colloid-like substance with desquamated cells or debris. Functions of calcitonin include neurotransmission, blood volume regulation, phosphate balance, and promotion of bone calcification.[55,58] Its secretion is regulated by serum calcium levels; elevated serum calcium levels stimulate the secretion of CT.[59] Calcitonin inhibits calcium resorption from the bone and acts in opposition to parathyroid hormone to reduce serum calcium levels.[58,59]

PARATHYROID GLANDS, VITAMIN D_3, AND CALCIUM HOMEOSTASIS

Unlike in mammals, the parathyroid glands (PTGs) of reptiles are not closely associated with the thyroid gland.[13,34,56] The location of the parathyroid gland varies among different reptilian species; generally, the anterior pair is associated with the carotid artery and the posterior pair is associated with the aortic arch.[13,34] In snakes, the anterior pair is associated with the carotid artery near the mandibular ramus. Lizards may have one or two pairs of PTGs (Fig. 79.5A and B). In green iguanas, the anterior PTGs are located along the medial surface of the mandibular rami, and the posterior pair is located at the origins of the internal and external carotid arteries.[13] Chelonians have two pairs of PTGs. The anterior pair is located within the thymus, and the posterior pair is caudal to the aortic arch and cranial to the heart. Crocodilians may have one or two pairs of PTGs located near the common carotid artery.[13] The parenchyma of the parathyroid gland in reptiles consists largely of chief cells, which are arranged in cords separated by connective tissue that contains a capillary network.[13] The chief cells are involved in the production and release of parathyroid hormone (PTH). The PTGs have a similar role to those of mammals and are responsible for the minute-to-minute regulation of calcium.

Within the body, calcium exists intracellularly in all tissues and extracellularly as brushite and hydroxyapatite (in bone).[60] Skeletal bone comprises >99% of total body calcium, while nonbone calcium is <1%.[60] Nonbone calcium is generally maintained within a narrow range.[60] The total calcium in the general circulation is composed of two fractions: protein bound and ionized. The biologically active ionized calcium (iCa) plays a major role in many biological processes, including muscle contractions, blood coagulation, enzyme activity, neural excitability, hormone release, and membrane permeability.[60,61] It is preferable to evaluate iCa levels for an accurate evaluation of

calcium status (Table 79.2). Serum calcium, magnesium, and phosphate levels are closely regulated by the combined effects of several hormones (e.g., PTH, vitamin D_3, calcitonin, and cortisol), the gastrointestinal tract, bone, and kidneys.[59] Magnesium, also essential for proper function of muscles and nerves, is a cofactor in over 300 enzymatic reactions, particularly those involving the metabolism of food components, and it is required by all enzymatic reactions involving the energy storage molecule ATP.[61] Phosphorus is a structural component of nucleotide coenzymes: ATP and creatine phosphate.[61] Hypomagnesemia can cause a secondary hypocalcemia, which remains resistant to calcium supplementation until magnesium levels are corrected.[61] Magnesium deficiency in humans induces reversible failure of PTH secretion and increases peripheral PTH degradation and resistance to PTH.[59,61]

Decreased levels of ionized calcium in the blood stimulate the release of PTH, which results in calcium resorption from the bones and kidneys and increased intestinal absorption.[59] Increased iCa in the general circulation has a negative effect on the release of PTH. Parathyroidectomy will result in hypocalcemia and tetanic convulsions.[62]

The two naturally occurring vitamin D forms are cholecalcifrol (vitamin D_3) from animal sources and ergocalciferol (vitamin D2) from plants. Vitamin D can also be synthetized in exposed skin. Provitamin D_3 (7-dehydrocholesterol, 7-DHC), a cholesterol-like precursor, is converted into previtamin D_3 (cholecalciferol) by sunlight (ultraviolet B [UVB] radiation, 290–315 nm) and temperature-dependent isomerization (Fig. 79.6).[63] PTH stimulates hydroxylation of cholocalciferol to 25-hydroxycholecalciferol (25-OH-D_3) or calcidiol in the liver. Calcidiol is the major metabolite of vitamin D and represents the storage form, which is then converted to 1,25-hydroxycholecalciferol (1,25 OH-D_3 or calcitriol) in the kidney by renal 1α-hydroxylase.[59,64] Calcitriol has a very short half-life and is the active form of vitamin D_3, which is responsible for maintaining calcium balance in the body. Major physiological effects of 1,25-OH-D_3 are increasing calcium, magnesium, and phosphate intestinal absorption; increasing renal calcium and phosphate reabsorption; and increasing bone resorption.[59,60] In general terms, 1,25-OH-D_3 assists PTH in performing its functions.

Calcidiol is generally measured for determining vitamin D status because its longer half-life makes it more stable and reliable (Table 79.3).[64–66] Liquid chromatography–mass spectrometry (LC/MS/MS) represents the gold standard, is preferred over radioimmunoassay, and is available commercially (Heartland Assays, Ames, IA). In juvenile black-throated monitor lizards (*Varanus albigularis*), deprivation of dietary vitamin D_3 resulted in significant decreases of circulating levels of calcidiol (25-OH-D_3) (25%–35%), calcitriol (1, 25-OH-D_3) (73%–76%), calcium (60%), and phosphorus (16%).[67] The half-life of circulating calcidiol during deprivation was estimated to be from 128 to 139 days. Single weekly doses of 10 to 20 minutes of UVB exposure to a Spectroline EB-28 UVB lamp (Spectronics Corp., Westbury, NY) failed to prevent 25-OH-D_3 decline; however, the rate of decline was reduced. Conversely, weekly oral vitamin D_3 (10,000 lU/kg) caused an excessive increase (600%) in circulating calcidiol levels that could result in intoxication.[67] Levels of vitamin D were restored and maintained in monitors by (a) daily exposure to UVB gradients generated with a Westron 100-watt mercury-vapor lamp (Westron Corp., Oceanside, NY) and (b) feeding crickets gut-loaded with a commercial vitamin D–supplemented diet along with whole mice. Experimental evaluation of UVB sources in Hermann's tortoises (*Testudo hermanni*) concluded that exposure to sunlight was superior to UVB-emitting mercury vapor and fluorescent lamps.[68] Mean calcidiol concentrations for tortoises exposed to the mercury vapor and fluorescent lamps were significantly lower (155.69 ± 80.71 nmol/L and 134.42 ± 51.42 nmol/L, respectively) when compared to sunlight (411.51 ± 189.75 nmol/L).

Studies of UVB and dietary calcium/vitamin D in several reptile species have shown that there is considerable variation in the requirement for dietary vitamin D and for UVB.[31] Some species are able to modulate their endogenous D_3 production to complement dietary intake by adjusting their UVB exposure, while crepuscular species may exhibit increased skin sensitivity to UVB.[69] High concentrations of vitamin D within iguanid embryos and egg yolks suggest a role for this compound in embryogenesis in these species and perhaps indicate that there is a mechanism for vitamin D delivery to eggs comparable to that found in the domestic chicken.[65,69] Vitamin D status may be important in animals that are being affected by infectious diseases such as ranavirus and mycoplasma, since vitamin D can play a significant role in immune function. It has been thought that snakes were capable of obtaining their vitamin D exclusively through dietary means rather than photobiosynthesis. However, corn snakes (*Pantherophis guttata*) can increase plasma calcidiol concentrations significantly when provided with supplemental UVB.[70] No association was demonstrated between exposure of ball pythons to UVB radiation, plasma calcidiol, and iCa concentrations.[71]

Hyperparathyroidism

The most common conditions that lead to PTG disorders in reptiles are inadequate calcium or vitamin D_3 (nutritional or UVB) leading to nutritional secondary hyperparathyroidism (NSHP) or, less commonly, severe chronic renal disease causing a disturbance in the production of calcitriol and calcium/phosphorus homeostasis, leading to renal secondary hyperparathyroidism (RSHP).[72] Common predisposing factors for the development of NSHP include decreased dietary calcium, vitamin D_3 deficiency, improper dietary calcium/phosphorous ratio, inadequate thermal provision, and/or inadequate exposure to ultraviolet radiation in diurnal/nocturnal species.[31,72] Common clinical signs associated with NSHP include thickening and swelling of the long bones and mandibles, pathological fractures of long bones and spine, tetany, muscle fasciculations, hyperreflexia, constipation, cloacal or rectal prolapse, anorexia, and stunted growth.[31] Initial therapy should address presenting complaints, such as fractures and life-threatening hypocalcemia. Many cases require husbandry (adequate UVB light and thermal provision) and nutritional improvements (oral calcium supplementations) for months before recovery is complete. Initial supplementation of parenteral vitamin D_3 (100 IU/kg IM once and repeat in 2 weeks) may be useful, followed by UVB exposure.[72]

Renal secondary hyperparathyroidism (RSHP) is a condition that is a consequence of chronic renal failure. Two mechanisms have been

proposed. The first is that impaired renal function leads to hyperphosphatemia.[64] As the concentration of phosphorus increases, blood calcium levels decrease, leading to increased PTH secretion and subsequent decreased calcium absorption from the intestines. The second mechanism is that kidney disease results in a relative or absolute deficiency of calcitriol.[64] Since calcitriol is necessary to enable intestinal absorption of dietary calcium and phosphorus, less calcitriol leads to progressive hypocalcemia, which then stimulates PTH secretion. Both ionized calcium and calcitriol must be present in the blood at appropriate levels to inhibit gene transcription of PTH; reduction in either or both leads to PTH synthesis and secretion.[64] Uncontrolled release of PTH leads to skeletal demineralization (rickets, osteomalacia), nephrotoxicity, and subsequent metastatic mineralization. The prognosis for RSHP is guarded. In reptiles, RSHP has been managed with fluid therapy, phosphorus binders, xanthine oxidase inhibitors, and carefully titrated calcitriol supplementation.

While administration of excess vitamin D_3 can result in hypercalcemia and metastatic mineralization, soft tissue mineralization associated with hypovitaminosis D_3 has also been reported in *Iguana* and *Uromastyx* (Richman LK, unpublished data; Raphael BL, unpublished data). In cases of hypovitaminosis D_3, reduced negative feedback by calcitriol commonly associated with RSHP leads to excessive production of PTH with subsequent metastatic mineralization. The provision of vitamin D_3 through UVB (especially sunlight) is certainly safer than routine D_3 supplementation; however, most, if not all, artificial lights are a poor substitute for natural sunlight.

Primary hyperparathyroidism is a disease in which excessive and inappropriate secretion of PTH occurs, and it is most often associated with a solitary functional adenoma or, less commonly, a PTG carcinoma. Parathyroid adenomas or adenocarcinomas have been identified in green iguanas, red-foot tortoises (*Chelonoidis carbonaria*), spur-thighed tortoises (*Testudo graeca*), and desert tortoises (*Gopherus agassizi*).[73–75] Parathyroidmegaly was present in all cases, and affected animals had significant osteomalacia presumably due to elevated levels of PTH. The blood calcium and phosphorus ratios were often reversed and renal calcinosis was present.

PANCREAS

The exact location and anatomical relationships of the pancreas show much variation among reptile species. The pancreas of lizards is more complex than snakes in that it is extended and often trilobed (Fig. 79.7).[83] One portion runs along the bile duct toward the gallbladder, one portion runs to the small intestine, and typically a thin limb with a distinct distal lobe runs to the spleen.[83] In some lizards, such as the house gecko (*Hemidactylus*), a thin diverticulum of pancreas tissue extends anteriorly from the ventral portion of the pancreas and encircles the common bile duct. This is known as the hepatic portion and may actually enter the hepatic parenchyma.[83]

The pancreas of snakes is consolidated and simpler, often pyramid shaped, and attached to the first portion of the duodenum.[83] It generally lies posterior to the spleen and may be in contact with the spleen. The pancreas is usually posterior or adjacent to the gallbladder and lies just posterior to the caudal tip of the liver. In snakes, the association of the pancreas, spleen, and gallbladder is often referred to as the "triad" (Fig. 79.8). There are differences in the amount of pancreatic association with the spleen among species of snakes. In some snakes, such as some members of the Boidae, there is a limb of pancreas that runs forward to the spleen. In others, such as the emerald tree boa (*Corallus caninus*), this limb is interrupted or there is no splenic limb at all. In some snakes the spleen and pancreas are adjoined to form a splenopancreas.[83]

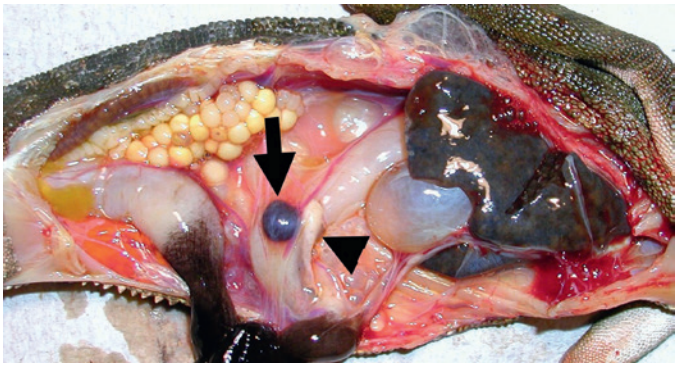

FIG 79.7 The pancreas of this Senegal chameleon (*Chamaeleo senegalensis*) is located between the stomach and duodenum. Note the proximity of the spleen (arrow) to the pancreas (arrowhead).

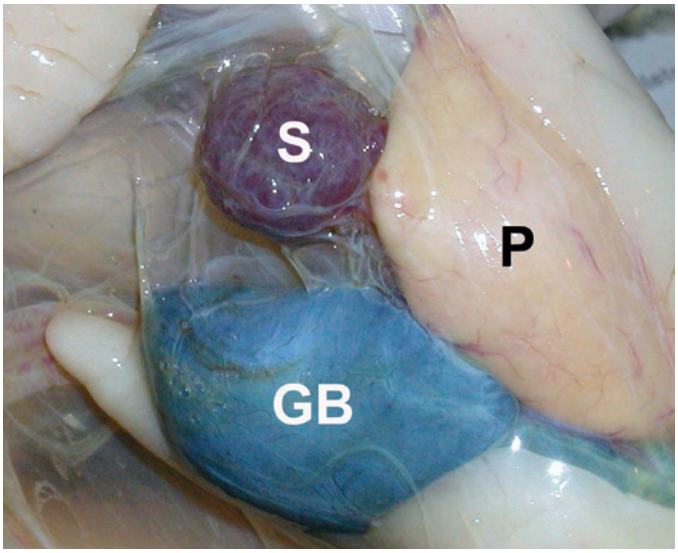

FIG 79.8 Gallbladder (GB), pancreas (P), and spleen (S) ("triad") of an indigo snake (*Drymarchon couperi*).

In the painted turtle (*Pseudemys scripta*) the pancreas is attached to the mesenteric border of the duodenum starting at the pylorus and ends by splaying out over the spleen (which is dorsal and more posterior).[83] In the snake-headed turtle (*Chelodina longicollis*) the proximal pancreas is associated with the proximal portion of the spleen.[83] Some turtles, such as the South American side-necked river turtle (*Podocnemius unifilus*), lack an association between the pancreas and the spleen.[83] In the alligator, *Alligator mississippiensis*, the ventral portion of the pancreas is between the limbs of the ventral duodenal loop. The body of the pancreas follows the dorsal portion of the duodenum and ends on the spleen, which is attached to the descending limb of the dorsal duodenal loop.

There is great variation in the pancreatic islet morphology among different reptile orders.[84] Lizards have large islets usually confined to the dorsal lobe and localized primarily in the splenic portion of the pancreas. In lizards and snakes there is no segregation of alpha and beta cells as in mammals, birds, or fish.[84–86] These cells lie adjacent to each other in an alternating pattern along vascular spaces. In snakes large islets are composed of both alpha and beta cells distributed in a

mixed pattern.[85] Taxa-specific distributions of endocrine tissue have been reported and may be focal, regional, or evenly dispersed throughout the pancreas of most squamates or the spleen of colubrid snakes.[85] In some species insulin-immunoreactive (IR) cells have been located in the intestinal mucosa.[86]

The pancreatic islets of turtles are not as large as lizards and snakes, and they tend to be diffusely distributed throughout the pancreas.[83–84] In chelonians there is a marked segregation of the alpha and beta cells—similar to fish, some birds, and mammals. The endocrine cells of *Testudo graeca* are present throughout the pancreas; however, alpha and beta cell islets are larger and more numerous in the splenic region than in the duodenal one.[87] The alpha cells are peripheral in their distribution as opposed to a mixed distribution in most lizards and snakes. Seasonal and reproductive cycles can also influence cell-type prominence and distribution.[87] The relative number of alpha cells in reptiles is noticeably higher than in mammals, and the same is true for glucagon content.[84] In the alligator islet tissue is associated with first-order ducts at the periphery of the pancreas. Beta cells are often aggregated at the central portion of the islet, and alpha cells are clustered around the periphery.[83]

The endocrine pancreas secretes hormones for the regulation of blood glucose. Alpha cells are responsible for glucagon production, beta cells produce insulin and amylin, delta cells produce somatostatin, and F cells produce pancreatic polypeptide.[31,88] Insulin promotes the absorption of glucose from blood to muscle and adipocytes.[89] In the liver insulin promotes glycogen biosynthesis by stimulating glycogen synthetase and inhibiting glycogen phosphorylase.[89] Concurrently, insulin suppresses fuel mobilization by inhibition of glycogen breakdown by the liver, amino acid release from muscle, and free fatty acid (FFA) release from adipose tissue.[89] In adipose tissue glucose is converted to fatty acids, which provide hydrocarbons for triglyceride formation.[89] Mammalian adipose tissue is considered a metabolically dynamic organ that not only is the primary site of storage for excess energy but additionally serves as an endocrine organ capable of synthesizing a number of biologically active compounds that regulate metabolic homeostasis.[90] It is currently unknown if the same is true for reptiles. Glucagon, also a peptide hormone, has the opposite effect of insulin, leading to an increase in blood glucose when the animal is deprived of food.[31] This effect is mainly executed by the liver, because few glucagon receptors are found on other tissues. Somatostatin, also known as growth hormone inhibiting hormone, regulates insulin and glucagon release in a paracrine fashion.[31] In other areas of the body somatostatin can affect neurotransmission and cell proliferation.

Due to the variability of pancreatic islet cell location in various taxa, submission of the entire pancreas, spleen, stomach, and small/large intestines is required at postmortem evaluation to ensure distant, nonpancreatic sites of islet concentration are not missed.[91] Furthermore, untargeted pancreatic biopsy may not be as useful to evaluate islet presence or activity, because the limited tissue available for antemortem analysis may or may not be representative of tissue pathology.[91]

Pancreatitis

Pancreatitis is defined as inflammation of the pancreas and in reptiles is typically the result of the presence of bacteria or metazoan parasites.[91,92] Acute necrotizing pancreatitis has been associated with trauma to the pancreas, abscesses or pyogranulomatous conditions, migrating helminthes, and obstruction of the pancreatic outflow ducts by masses or calculi.[92] Depending on the location and severity of the inflammation, both the exocrine and the endocrine portions of the pancreas may be involved. Pancreatic fibrosis or chronic fibrosing pancreatitis is a common histopathological finding (Fig. 79.9A and B).[92] On histopathology, the disease is characterized by fibroblasts and fibrocytes invading the interlobular septa. Clinical management of acute and chronic forms of pancreatitis includes supportive care such as fluid therapy, assisted alimentation, antimicrobials, and pain management. Unfortunately, due to the difficulty in diagnosing these cases, the disease is often not identified until necropsy.[91] Complete obstruction of the ductal outflow of a portion of the pancreas may result in either atrophy or autodigestion and resulting necrosis.[92] Frye describes two specific cases, one in a northern diamondback terrapin (*Malaclemys t. terrapin*), where complete obstruction of the interlobular ducts by amorphous crystalline material resulted in a loss of pancreatic tissue including islet tissue.[92] In another case involving a Pacific rattlesnake (*Crotalus viridis oreganos*), the majority of the pancreatic duct system was occluded, which resulted in chronic pancreatitis followed by pancreatic fibrosis.[92]

Trematodes and nematodes have occasionally been found to migrate into pancreatic tissue and are typically seen at histopathology.[91,92] The

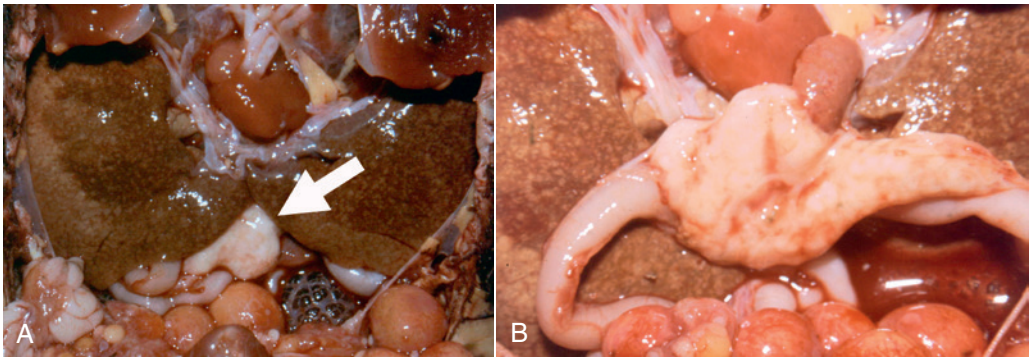

FIG 79.9 (A) Pancreatic fibrosis (arrow) associated with an unidentified protozoan infection in a wild-caught moribund Blanding's turtle (*Emydoidea blandingii*); (B) magnified view of the pancreas.

diagnosis is usually made at necropsy and histopathology by finding the helminthes or their characteristic ova on cross-section. Cryptosporidiosis involving the pancreas and biliary ducts has been reported in corn snakes (*Pantherophis guttata*).[93] Another report describes intranuclear coccidiosis in two radiated tortoises (*Geochelone radiata*) with histopathlogical evidence of pancreatitis.[94] Nephritis, hepatitis, and enteritis with similar intranuclear coccidiosis were also found in these tortoises. Intracytoplasmic inclusions are often present within the pancreas of snakes with boid inclusion body disease.[95] Pancreatic neoplastic diseases have been reported in snakes and are typically carcinomas or adenocarcinomas of the acinar or ductular epithelium.[96] A Komodo dragon (*Varanus komodoensis*) was reported to have a pancreatic islet cell tumor along with several other neoplasms, including a colonic carcinoma, a metastatic adenocarcinoma involving the spleen, and a thyroid adenoma.[96] Additional cases of pancreatic neoplasia are discussed in the following section.

HYPERGLYCEMIA

Reptile blood glucose appears to be regulated by insulin and glucagon as it is in mammals.[31,97] Reptiles with hyperglycemia are often presented for a variety of nonspecific clinical signs, including anorexia, weight loss, lethargy, and severe depression. Polyuria and polydipsia may be present but are not consistent.[97] Physical examination findings may also be nonspecific but may include loss of muscle mass, weakness, loss of righting reflex, stupor, and severe depression.[97] Some reptiles may present over-conditioned or obese. It is important to obtain a complete history, because blood glucose values in reptiles can be affected by physiological and environmental factors.[98] Husbandry information obtained should include housing, lighting, heating, diet, vitamin and mineral supplementation, and feeding history. Any recent changes in the environment, previous medical history, and treatment with any drugs should also be reviewed. Seasonal cycles including hibernation and reproduction, both past and present, are important variables that may reflect on blood glucose and thus should be noted.[99] Multiple sampling and/or serial sampling can be valuable in confirming true hyperglycemia, establishing general trends, and helping determine the clinical progression of the reptile patient.[97] Also, if other reptiles of the same species, in the same collection and kept under similar environmental conditions, are sampled, it can help establish a baseline for reptiles in the group.[97] Glucosuria may be noted in reptiles with persistent hyperglycemia.

Variations in blood glucose may be more common in reptiles due to variable metabolic rates, environmental influences and adaptations, and relative insulin resistance.[97] Stress-associated hyperglycemia has been reported in a number of species.[98] A normal seasonal variation in blood glucose levels may occur in many taxa.[99] Temperate reptiles generally have higher blood glucose levels during the breeding season.[99,100] In the fall when most temperate species are increasing fat storage, peripheral blood glucose is low. Tropical reptiles, however, may not show seasonal blood glucose variations.[100] In a study involving captive Mediterranean tortoises (*Testudo graeca* and *T. hermanni*) blood glucose values were found to have a statistically significant peak in April and May upon emergence from hibernation.[99] This elevated blood glucose provides a readily available energy source for tortoises until they begin to feed again. Fresh water turtles were found to show a marked hyperglycemia when diving, which is probably related to increased anaerobic metabolism.[100] Other studies indicate reptiles may exhibit hyperglycemia of several days' duration after a meal.[101] In a laboratory setting, 2 months of starvation (at approximately 21°C [70°F]) was necessary before blood sugar levels became hypoglycemic.[102] By contrast, in a study on savannah monitors (*Varanus exanthematicus*), starvation altered beta cell constituents, resulting in a reduction in the biosynthesis of insulinlike material and subsequent hyperglycemia.[103] This may be clinically relevant in cases of sick reptiles that have been anorexic for extended periods. The inanition may result in damage to beta cells, with a subsequent reduction in insulin and possible clinical hyperglycemia.

It appears that reptile insulin has a high affinity for human and mammalian insulin receptors and may favorably react with mammalian radioimmunoassays.[104] The affinity of python insulin for human insulin receptors appears similar to that of human insulin.[105] Furthermore, a mammalian insulin radioimmunoassay was used with apparent success in a hyperglycemic bearded dragon (Griswold WG, unpublished data). In general, blood glucose values for normal reptiles are between 3.3 to 5.5 mmol/L (60–100 mg/dL).[106] In one study, a range of blood glucose values in various species was found to be between 1.6 to 11.3 mmol/L (30–205 mg/ dL), with average values usually in the range of 5 to 5.5 mmol/L (90–100 mg/dL).[107] Blood glucose values above 300 mg/dL should prompt further investigation. In reptiles, hyperglycemia has not been established as a consistent or specific indicator of pancreatic disease or diabetes mellitus.[97] Reported cases of hyperglycemia have been associated with hepatic lipidosis, hepatic carcinoma, renal adenocarcinoma, chronic glomerulonephritis, interstitial nephritis, granulomatous pancreatitis, gastrointestinal adenocarcinoma, pancreatic glucagonoma, gastric somatostatinoma, and diabetes mellitus (Table 79.4). Gastric somatostatinoma (neuroendocrine gastric carcinoma) is a recently identified neoplasia of bearded dragons and usually arises from the gastric or pyloric mucosa with aggressive metastasis to the liver, kidney, heart, pancreas, ovary, and oviduct.[108,109] A genetic etiology for this disease is suspected. Although delta cells that produce somatostatin are found in the pancreas and stomach, the stomach appears to be the primary site of tumor origin. Reported cases have been young animals (less than 3.5 years old), and severe hyperglycemia is the most significant clinicopathological abnormality. The most clinically significant aspect of these tumors is the immunohistochemical demonstration of large reservoirs of somatostatin in the tissues.[108,109] Somatostatin suppresses the pancreatic secretion of insulin and lowers insulin receptor sensitivity, resulting in the hyperglycemia.[109]

Management of Hyperglycemia

Initially, management of a reptile with hyperglycemia should focus on making a diagnosis of what may be causing an elevation of blood glucose. The goal of the veterinary investigation should be to rule out physiological factors affecting blood glucose and identify underlying pathologies such as specific organ disease, particularly neoplasia.[97] Most reported cases of hyperglycemia in reptiles have been associated with malignancy.[97] Physiological effects that induce hyperglycemia do not appear to cause the severity of glucose elevations seen with neoplasia. Physical examination, biochemical analysis, radiology, ultrasonography, endoscopy, and surgery are all modalities that are utilized to identify diseases resulting in hyperglycemia. Research indicates that compared with mammals and birds, reptiles respond very slowly to the administration of mammalian insulin.[97] Currently it is unknown if the potential exists for inducing immune-mediated (islet-targeted) pancreatitis following the injection of heterologous insulin products in reptiles. Lizards and alligators have been shown to be much less sensitive to insulin than snakes or turtles.[97] If all factors indicate that the patient is truly a strong candidate for diabetes mellitus (a rare diagnosis in reptiles), and the clinician feels some glucose-regulating agent must be initiated, Stahl recommends the following as a starting point using regular mammalian insulin: Lizards and crocodilians 5 to 10 IU/kg body weight IM every 24 to 72 hours; snakes and chelonians 1 to 5 IU/kg body weight IM every 24 to 72 hours.[97] These doses are empirical and should be adjusted based on response to therapy and serial glucose sampling.

HYPOGLYCEMIA

In reptiles, hypoglycemia has been associated with starvation, hepatobiliary disease, and septicemia.[106] Reported symptoms include weakness, depression, loss of righting reflex, mydriasis, and tremors.[106] A pancreatic islet cell tumor (beta cell insulinoma) with hepatic metastases and multifocal hepatic cholangiocarcinomas was reported in a 7.5-year-old captive born savannah monitor (*Varanus exanthematicus*) presented with lethargy, anorexia, constipation, and narcolepsy-like behavior.[110] Interestingly, multiple glucose levels obtained during a 2-month period (5.2, 2.9, 4.7, 3.7 mmol/L; 95, 53, 85, 67 mg/dL) (ISIS range: 2.2–8.8 mmol/L; 40–159 mg/dL) were considered unremarkable. Insulin immunoassay values from the affected monitor were compared to normal conspecifics. Serum insulin concentrations from the normal monitors were <2 µU/mL. Serum collected during clinical manifestation revealed an insulin level of 8.78 µU/mL. Normalized means and standard deviations for serum insulin analytes were based on information from Cornell University (Ithaca, NY). It should be noted that serum insulin reference ranges have not been established for *Varanus exanthematicus*.

ADRENAL GLANDS

In reptiles the adrenals are paired and vary in color from yellow to pink to red. In chelonians the flattened adrenals are adjacent to the craniomedial poles of the kidneys.[111] In crocodilians the adrenals are retroperitoneal and dorsolateral to the gonads.[111] In squamates the adrenals are located within the gonadal mesentery (mesorchium or mesovarium) (Fig. 79.10A and B). Blood supply includes a venous portal system.[111] The "medullary" tissue occupies a peripheral position, and the "cortical" tissue is centrally placed.[111] Currently, reptilian adrenal tissue is still called "interrenal," a term created by Balfour (1876) for the cytological and functional equivalent in other vertebrates of the adrenal cortex of mammals.[111] In reptiles hematoxylin and eosin staining reveals the presence of predominantly two cell types: interrenal and chromaffin cells.[13] The pale-staining interrenal cells may either be located toward the periphery of the gland or scattered throughout the adrenal parenchyma. These cells are interspersed with clusters of basophilic-staining chromaffin cells. The interrenal cells secrete glucocorticoids (cortisol and corticosterone).[111] The chromaffin cells secrete catecholamines (epinephrine and norepinephrine).[111] It is suspected that reptiles possess a renin-angiotensin system that causes vasoconstriction, aldosterone release, and a subsequent increase in blood pressure.[112] Corticosterone is the primary glucocorticoid secreted in amphibians, birds, and reptiles.[113,114] In mammals corticosterone is the precursor molecule to the mineralocorticoid aldosterone, which with the renin-angiotensin system regulates blood pressure and sodium and potassium levels.[114] Sufficient serum levels of glucocorticoid hormones provide negative feedback to the hypothalamus and pituitary, causing a decrease in CRH and ACTH.

Glucocortocoids are subject to a circadian rhythm with maximum secretion occurring during the most active period. For example, free-living diurnal Galápagos marine iguanas (*Amblyrhynchus cristatus*) have lower corticosterone concentrations during the night than during the day while the opposite pattern occurs in nocturnal reptiles.[115] Corticosterone levels in reptiles may also vary between adult males and females and have been documented in crocodilians,[125,126] desert tortoise,[127] and Galápagos tortoise.[128] However, these differences were not found when comparing juvenile male and female loggerhead sea turtles (*Caretta caretta*) in Florida (Table 79.5).[129]

Stress can be defined as a normal biologically adaptive response of an individual to internal or external stimuli representing a threat to homeostasis.[113,116] The physiological response to stress includes activation of the sympathetic nervous system (SNS) as well as the HPA axis.[117,121]

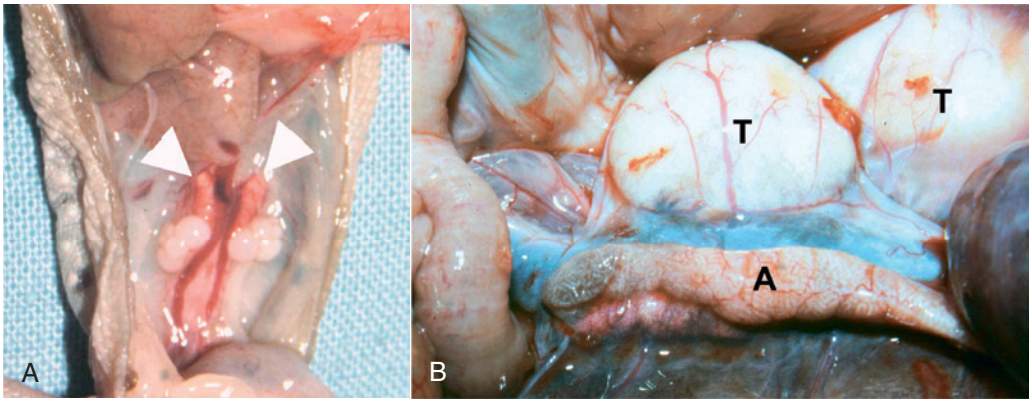

FIG 79.10 (A) The paired adrenal glands (arrowheads) of a female leopard gecko (*Eublepharis macularius*) are suspended in the mesovarium and located anteromedial to the gonads. (B) The paired adrenal glands (A) of a male green iguana (*Iguana iguana*) are suspended in the mesorchium and located medial to the testes (T).

Accurate measurement of catecholamines (i.e., epinephrine and norepinephrine) released as a result of SNS activation is difficult because these substances are only available for transient periods of time.[120] Thus, evaluation of the HPA axis, most commonly by measurement of its end-product glucocorticoids, has traditionally been the primary means to evaluate the stress response in animals.[121] Glucocorticoids (GCs) are metabolized by the liver prior to excretion both through urine and feces via bile.[118] Glucocorticoids are normally bound to a carrier protein, corticosteroid-binding globulin (CBG), and only the free form (5%–10% of the total) is biologically active.[119] In mammals, free unbound cortisol has been measured in conjunction with total cortisol levels. However, to obtain free levels, it is necessary to measure both the CBG levels and to know the binding coefficients.[119] This author is unaware of any published "free" glucocorticoid levels of reptiles.

In reptiles, studies have shown that corticosterone and cortisol increase dramatically during stressful events coordinated by the hypothalamus and anterior pituitary.[113] In most vertebrates, this response is triggered by a wide variety of stressors such as cold stress, nutritional stress, social aggression, crowding, predator presence, transport, drought, infection, and injury.[113,121] Evaluating hormone responses to stress in reptiles relies on acquiring baseline corticosterone levels; however, restraint stress associated with blood collection can obviously affect results.[122] It is important to obtain a blood sample in a relatively short time after capture. In some avian and reptilian species, a "3-minute rule" has been determined, suggesting that blood samples collected within 3 minutes of capture are more likely to represent baseline corticosterone levels.[122] In reptiles, increased glucocorticoids levels are associated with heterophilia and lymphopenia (stress leukogram), and in some species glucocorticoids can affect degranulation of the granulocytes (e.g., heterophils and eosinophils).[124,131,132] Creatine phosphokinase also increases during stress due to capture.[130] Hyperglycemia has been reported in stressed crocodilians and ophidians, while increased hematocrit, red blood cell count, sodium, chloride, and potassium levels have been reported in aquatic chelonians subjected to hyperosmotic stress.[131]

Although corticosterone levels are usually determined through blood sample measurements, fecal, urine, and saliva samples have also been used to measure stress in nonreptiles.[123,133,134]

Various sea turtle species have shown a significant corticosterone stress response on exposure to stressors such as capture and handling, coeliotomy, infection, overcrowding, overheating, and being inverted.[131–132] A study of cold-stunned Kemp's ridley sea turtles demonstrated that affected turtles had significant elevations of corticosterone and excessively decreased levels of thyroxine.[39] Plasma corticosterone concentrations were determined by quantitative radioimmunoassay (Corticosterone Double Antibody 125-I RIA Kit #07–120103, MP Biomedicals). During recovery from cold-stunning, all Kemp's ridleys showed a significant decrease in corticosterone.

An alternative method to assess stress levels is the use of fecal glucocorticoid metabolite concentrations.[134] Fecal samples offer the advantage that they can be easily collected and the procedure is feedback free. Studies have shown that fecal glucocorticoid metabolites reflect free, biologically active glucocorticoid concentrations in the blood, and that fecal glucocorticoid metabolites are an excellent predictor of the responsiveness of an animal to a stressor.[133–134] In a longitudinal study (analyses on repeated individual measurements), fecal corticosterone metabolite levels (FCM) in captive green iguanas were quantified during periods of rest and exposure to hypothesized stressors.[135] FCM levels were measured using the Corticosterone ELISA Kit (DRG Instruments, Marburg, Germany). FCM quantification was combined with behavioral analysis to further interpret the measured increases. It was shown that both daily 5-minute handling/restraint as well as housing devoid of climbing opportunities resulted in increased FCM excretion. Behavioral analysis suggested that the iguanas were chronically stressed by the lack of climbing opportunities, whereas handling induced only a transient stress response. The study provided insight into the functioning of the hormonal stress response in green iguanas for refining housing and handling practices.

Adrenal neoplasia has been reported in green iguanas (Fitzgerald SD, unpublished data), Komodo dragons,[35] and woma pythons (*Aspidites ramsayi*).[136] Tumors were identified as carcinoma, pheochromocytoma, and interrenal cell adenocarcinoma, respectively. Neoplasms were highly malignant with metastases. The Komodo dragon also had a colon carcinoma, thyroid gland adenoma, and pancreatic islet cell tumor. Ultrasonography of the woma python revealed significant tumor regrowth eighteen months postsurgery.

Theriogenology

Scott J. Stahl and Dale F. DeNardo

The reptilian reproductive tract has similarities in structure and function to other vertebrates but also differs in many ways. The most obvious are two diverging reproductive strategies, oviparity, similar to avian species, and a more evolved mammalian-like strategy with varying degrees of viviparity.

With continued advances in husbandry and nutrition, captive reptiles are living longer, are healthier, and are better adapted and thus exhibit natural reproductive drive and activity. The successful breeding of many species of reptiles has become common both commercially (pet market and herpetoculture) and for conservation efforts in zoos and private institutions to establish captive colonies of threatened and endangered species. Reproductive disease is common in captive reptiles, and clinicians must familiarize themselves with their normal reproductive anatomy and physiology. A review of important unique parameters of reptile reproductive biology will be discussed in this chapter. Additionally, reproductive diseases will be reviewed, including diagnostic and management considerations for these conditions. Surgery of the reproductive tract is covered in Chapter 105.

Many advances in reptile theriogenology have occurred in the last 20 years, especially with the successful captive reproduction of many species for the first time. This is the result of a better understanding of breeding strategies, including environmental manipulation, cycling, hormonal influence, and an improved knowledge in perinatology, including egg incubation and neonatal management (see Chapter 85). Additionally, with concerns on preserving and protecting the growing number of endangered species, developments in semen collection, semen storage, and artificial insemination have advanced and are summarized. Identifying the sex of many reptiles has always been challenging, and many novel and less invasive techniques have been developed and are discussed.

Popularity of reptiles as pets has grown tremendously, resulting in a dramatic increase in animals presented to veterinarians. Single female pets with follicular activity or true dystocia involving infertile eggs, and sexually mature males exhibiting aggressive hormonal behaviors, are common clinical problems. Clients and institutions that are attempting to breed reptiles may rely on their veterinarian as a resource to understand a reptile's general reproductive physiology, captive breeding strategies, and husbandry requirements. Reptile clinicians must familiarize themselves with this information and be prepared to provide both consultation and important theriogenology services such as sexing, routine sterilization, health assessment of breeding animals, gravidity determination/management, and assistance with artificial insemination, as well as diagnosis and correction of reproductive disease.

ANATOMY AND PHYSIOLOGY

Male Reproductive Tract

Testes. The reptilian testes are paired organs that are embryonically derived from the medullary region of the germinal ridge.[1,2] The testes are located dorsally in the mid to caudal coelom adjacent to the adrenal glands and near the cranial portion of the kidneys in chelonians (Fig. 80.1), crocodilians, tuatara, and most lizard species. In lizards with intrapelvic oriented kidneys the testes are considerably more cranial to the kidneys. In chelonians, crocodilians, and the tuatara the testes are generally symmetrical.[1,2] In snakes and many lizard species the right testis is cranial to the left. In snakes the right testis is located just caudal to the gall bladder in the cranial portion of the lower one-third of the body. In a study on anatomical organ positioning in multiple snake species the right and left testes were found between 65% to 82% of the total snout-to-vent length (SVL) depending on taxa, with the right testis cranial to the left but with a high degree of overlap.[3] The testes vary in color from white and yellow to tan-brown and black (e.g., old world chameleons) and are generally smooth and ovoid or flat in shape except in snakes and legless lizards where they are elongated. In mature reptiles the size of the testes varies seasonally and correlates with reproductive activity. Active spermatogenesis results in testicular enlargement whereas a reduction in size is associated with spermatogenic quiescence.[1,2,4] The mesorchium supports and attaches the testis, surrounded by a protective tunica albuginea, to the dorsal wall of the coelom. In squamates the adrenal glands are contained within the mesorchium.[1] The dorsal aorta gives rise to the testicular arteries, which then extend to the ductus deferens. The testicular vein empties into the renal vein, which then drains into the post cava.[1,5]

The testis proper consists primarily of seminiferous tubules and the interstitium, which is made up of interstitial cells, fibroblasts, blood vessels, and lymphatics. The seminiferous tubules have a lining of epithelium containing Sertoli cells and germ cells in different stages of development. Generally, there are three organized layers of germinal cells from immature, along the basement layer (spermatogonia); to developing, the middle layer (spermatocytes); to mature, in the center (spermatids and free spermatozoa).[1,2]

Epididymis/Vas Deferens. The genital ducts of reptiles arise initially from the mesonephric Wolffian ducts and the paramesonephric Mullerian ducts. In males, the Wolffian duct develops and persists with the Mullerian ducts regressing under the influence of testosterone; however, in some species remnants of the Mullerian duct may remain.[1] The epididymis is a flat tubular structure lateral to each testis and makes up the anterior

portion of the ductus deferens (see Fig. 80.1). The epididymis is not typically present in snakes.[1] The ductuli efferentia from the testis passes through the mesorchium into the epididymis. The seminiferous tubules release sperm into ductuli efferentia, which are lined with a single layer of flattened cells and then into the ductus epididymis, and finally sperm empties into the ductus deferens. To assist in movement of sperm, the walls of these ducts contain ciliated cells and a muscular layer.[1,2] The vas deferens courses caudally, generally running along the ventral portion of the kidney, then empties into the urodeum at the genital papillae (see Fig. 80.1). In some species the vas deferens and the ureters will join to form a common urinogenital papillae in the urodeum.[1,4,5]

Renal Sexual Segment. The kidney of male squamates possesses an enlarged (when active) sexual segment, which is composed of hypertrophied distal and collecting tubules. It is absent in crocodilians and chelonians.[1] Seasonal activity in this portion of the kidney can dramatically change gross renal appearance (to a white-yellow color change) and should not be mistaken for pathology. During sexual quiescence the sexual segment of the squamata kidney is involuted and cannot be distinguished from other tubular regions of the kidney. However, in response to seasonal change and hormonal (androgen) influence this sexual segment hypertrophies, and secretory cells fill with numerous granular inclusions.[1] Lizards appear to have more of a seasonal change in the activity of this renal sexual segment than snakes.[1] The large secretory granules of these cells produce a secretion that varies from holocrine to merocrine and contains proteins, amino acids, and phospholipids.[1] The true role of these sexual segment secretions in squamates is not understood. However, some functions have been confirmed, including a role in the production of copulatory plugs in some snake species (*Thamnophis* spp. and *Nerodia* spp.). In these species, after breeding a copulatory plug remains in the female's cloaca and prevents rival males from copulating with the same female.[6] Renal sexual segment secretions have also been shown to activate sperm,[7] serve as a source of energy for sperm, and help with survival of sperm in the female oviduct.[8] This renal sexual segment is thought to correlate well with the mammalian seminal vesicle due to similarities in embryologic origin, relationship with the vas deferens, and response to androgens.

Copulatory Organ(s). Copulatory systems are different among reptile taxa, with chelonians and crocodilians having a single median phallus that originates from the floor of the urodeum and resides in the ventral aspect of the proctodeum of the cloaca (see Fig. 80.1).[1,4] However, squamates have elaborate paired copulatory organs known as hemipenes located laterally in the ventral tail base and held there by retractor muscles. The morphology of the hemipenes is variably ornate, with structural differences utilized for taxonomy purposes in squamates.[4] The tuatara has no specialized copulatory organ.[1,4] The copulatory organs do not contain a urethra and have no direct connection with the ductus deferens. However, the hemipenes of squamata have a seminal groove, the sulcus spermaticus, located on the everted surface (eversion occurs for copulation and no actual erectile tissue is present), which functions to direct sperm into the female cloaca.[4,5] In chelonians and crocodilians, the copulatory organ does not invert, but the tissue becomes engorged and a pair of spongy longitudinal ridges on the dorsal surface form a seminal groove that directs semen toward the vent. In chelonians these longitudinal ridges are formed from coelomic canals and the corpus cavernosa. With erection the corpus cavernosa become engorged with blood (from the internal iliac vessels) resulting in dorsal and medial curling of the seminal ridges forming a tubelike seminal groove to direct sperm down the phallus (Fig. 80.2).[1] Additionally, the chelonian phallus has a spade-shaped glans at the distal end with three folds, the plica externa, plica media, and plica interna, which direct sperm and help maintain the phallus in the female's cloaca.[1] The erectile ability combined with muscle action extends the phallus out of the vent and into the female cloaca.[4]

Female Reproductive Tract

Ovaries. The ovaries are paired and embryonically derived from the cortex region of the germinal ridge.[1,2] They are located dorsally in the mid to caudal coelom adjacent to the adrenal glands and near the cranial portion of the kidneys in chelonians, crocodilians, tuatara

and most lizard species.[1] In lizards with intrapelvic-oriented kidneys the ovaries are more cranial to the kidneys (Fig. 80.3), as in the green iguana (*Iguana iguana*) with the right ovary just caudal to the tip of the right liver lobe.[5] In chelonians, crocodilians, and the tuatara the ovaries are generally symmetrical; however, in squamates the right ovary is cranial to the left.[1] In snakes the cranial pole of the right ovary is located just caudal to the gall bladder in the cranial portion of the lower one-third of the body (Fig. 80.4). In a study on anatomic organ positioning in multiple snake species the right and left ovaries were found between 58% to 80% of the total SVL length depending on taxa, with the right ovary cranial to the left but with a high degree of overlap.[3] The ovaries vary in color depending on maturity and seasonal activity. Immature ovaries are flat and granular in appearance but with adulthood the presence of different stages of maturing follicles results in a variable appearance (see Fig. 80.4). The ovary is made up of intrafollicular stroma with an associated hierarchy of follicles at different stages of development and atresia.[1,2] Previtellogenic follicles are small and clear to white in color, whereas vitellogenic follicles are larger and yellow to orange in color as they develop yolk. Depending on the species and the reproductive cycle, generally the ovary will be inactive for large portions of the year with only previtellogenic follicles present during these periods.[1,2]

The ovaries are supported by the mesovarium, which is attached to the dorsal wall of the coelom. In squamates the adrenal glands are contained within the mesovarium (see Fig. 80.3). In crocodilians and chelonians, the adrenals are retroperitoneal, dorsal to the gonads, and closely related to the kidney.[2,9] The dorsal aorta gives rise to the ovarian

arteries. The ovarian vein empties into the renal vein, which then drains into the post cava.[1,2]

The ovary proper consists of epithelial cells, connective tissue, nerves, blood vessels, and germinal cell beds encased in an elastic tunic.[1,2] The primordial follicles of the ovary are made up of a nucleus, ooplasm, and a simple squamous follicular epithelial layer.[2] Inactive (previtellogenic follicles) do not contain yolk as do vitellogenic follicles. Within the follicle the ooplasm and the granulosa are separated by the acellular zona pellucida.[1,2] Ovarian follicular development (influenced by season) has two distinct phases known as previtellogenic and vitellogenic. Vitellogenesis is the movement of yolk into a maturing ovarian follicle, and the liver is hormonally influenced to produce yolk precursors to support vitellogenesis.

Much variability occurs in this follicular cycle in reptiles but eventually vitellogenic follicles will either ovulate, regress, or rarely become static and potentially inspissated (follicular stasis). Once ovulation occurs, actively proliferating granulosa cells establish the corpora lutea, producing progesterone and remaining active through the gravid cycle.[2,10] After oviposition or birth the corpora lutea regresses, becoming a corpora albicans, which can remain for years.[2] If vitellogenic follicles do not ovulate they will typically begin a cycle of regression (atresia). During this atresia phase the granulosa becomes variable with associated hypertrophy and hyperplasia as granulosa cells, infiltrative histiocytes, and leukocytes phagocytize yolk material.[2,10] The occurrence and frequency of follicular atresia is variable by species and influenced by exogenous factors such as season.[2,10]

Oviducts. The genital ducts (oviducts, salpinges) of female reptiles arise from the mesonephric Wolffian duct and the paramesonephric Mullerian ducts.[1] Reptiles generally have a right and left oviduct; however, there are two genera of snakes (*Typhlops* and *Leptotyphlops*) that are missing the left oviduct.[1] The oviducts are flattened tubular structures positioned adjacent to each ovary (see Figs. 80.3 and 80.4). In immature reptiles the structures appear as thin bands of tissue; in adults with previous reproductive activity the oviduct is more distinct, with notable "concertina" or "accordion" appearance demonstrating contraction from previous enlargement/stretching of gravidity. The mesosalpinx is the supportive mesentery of the oviduct and may contain a prominent oviductal ligament. The presence of this ligament can be useful in determining the sex of some immature reptiles endoscopically as no grossly recognizable ligament is present in males, and the gonads may be difficult to differentiate at this age.[11] The infundibulum is the opening of the oviduct located on the dorsal body wall just craniad to each ovary. The oviducts then course caudally, passing ventromedial to the kidneys and terminating individually in the dorsal wall of urodeum at the genital papillae (see Fig. 80.3).

Histologically the oviduct is made up of two layers of smooth muscle enclosed by an outer serosa. Five regions of the oviduct (from cranial to caudal) are recognized histologically: the infundibulum, the uterine tube, the isthmus (a-glandular portion), the uterus (glandular), and terminally the vagina (thick muscular portion).[2,12] Not all species have each oviduct division, and there is variability. Fertilization takes place near the cranial end of the oviduct (infundibulum) and occurs before deposition of the egg envelopes by the oviduct glands. Copulation occurs before ovulation, and sperm must be stored by the female; seminal receptacles for this purpose have been identified in the posterior uterine tube, isthmus, and anterior vagina of many reptiles.[1,13]

The oviduct has ciliated and nonciliated mucous cells, along with glands below the epithelial lining. These glands generally have both an albumen-secreting and calcareous-secreting (shell and shell membranes) function, and no true uterus exists. However, differences among reptile orders exist.[2,12,13] Generally, the albumen layer provides both physical support to the embryo and assists with water storage. Additionally, a recent study reported that antimicrobial peptides, secreted by the oviduct and found in the albumen of some avian and reptile species, may protect the developing embryo from infection.[14]

In oviparous reptiles the oviduct contains mucosal glands that produce calcium and fibrous portions of the shell membrane and the egg shell.[1,2,12] In viviparous species these glands are few or not present. A relationship exists between the types and abundance of glands and glandular activity in the oviduct and the reproductive strategy of the female. One difference in the evolution of viviparity in reptiles relates to the origin of calcium for the developing embryo. In oviparous species mineral for bone is primarily derived from the shell and shell membranes; however, with viviparity calcium minerals are derived from the yolk material.[1]

The last portion of the oviduct is represented by the vagina, which contains ciliated cuboidal cells with no glandular structures.[1] The vagina empties into the urodeum through the genital papilla (see Fig. 80.3).

Copulatory Homologue. Female reptiles have a phallic/hemipenal homologue, which is located anatomically in the same position as the male. The clitoris and hemiclitoris (squamates) are smaller and less elaborate structures than the copulatory organs of males. However, in some female squamates the hemiclitores are more developed, such as in monitor lizards (*Varanus* spp.),[15] larger skink species (*Tiliqua*, *Corucia*), and some boids (e.g., short-tail pythons, *Python curtus*).

Cloacal Scent Glands (Snakes)

Cloacal scent glands in snakes are specialized exocrine glands that produce a thick semiliquid material containing pheromones (intraspecific) and/or semiochemicals (interspecific) used to actively mark an object/substrate/organism.[16] These paired cloacal scent glands are uniquely ophidian and generally larger in females, but present in both sexes and in all species of snakes.[16]

Some snakes such as the copperhead (*Agkistrodon contortrix*) have a unique liquid gland material with an ability to void the material as a defensive spray.[17] These paired glands are located within the tail base just dorsal to and attached to the hemipenes in males and in a corresponding position in females (see Chapter 171, Fig. 171.1A). A duct positioned at the anterior portion of the gland curves laterally and opens adjacent to the opening of the hemipenis/hemiclitoris.[16] The glands are ovoid to spherical in shape and vary in color from white/yellow to tan/brown. A muscular sphincter is associated with the duct itself, and the entire gland is surrounded by a muscular sheath, which assists in discharge of contents. Cloacal scent glands are holocrine and the tan brown to black material consists of mostly (90%) free fatty acids (the source of the musk odor), primarily palmitic, oleic, and linoleic acids with mucopolysaccharides and mucoproteins also present.[18]

The function of these glands is complex and more research is necessary, but secretions are likely associated with behavior, including sex attractant, defensive/repellant, aggregation cues, alarm/alert, and territorial marking.[16] The fatty acid composition of these secretions are different among species and within the same species depending on sexual maturity; however, only some species have differences in composition *between* sexes.[18] Therefore these secretions may not represent an intraspecific sexual attractant effect in all species, but may be valuable to assess sexual maturity within the same species or useful to identify the presence of a different species. An example of the complexity and multifunctional properties of these cloacal secretions is evident in the burrowing blind snake (*Leptotyphlops dulcis*). When attacked by ants these snakes will cover their bodies in a thin film of cloacal scent-gland secretion, which repels and thus protects them from ant predation. In this same species, these secretions were found to function as an *intraspecific* sex attractant and an *interspecific* snake repellant.[18] The uniqueness

of these scent gland lipids in snakes may prove useful as taxonomic indicators.[19]

REPRODUCTIVE CYCLES

The timing of reproductive events in reptiles is influenced by endogenous and exogenous factors. Examples of exogenous factors include the effects of environmental temperatures on spermatogenesis and embryogenesis, availability of nutritional requirements for vitellogenesis, and timing of oviposition or birth with favorable conditions for newborn survival.[20] These seasonal changes in temperature, photoperiod, and rainfall (food availability) affect endogenous control of reproductive cycles by influencing the hypothalamic-pituitary-gonadotropin endocrine system, similar to mammals.[1,4,21,22] In temperate species the breeding season is short and occurs during the annual cycle. In the tropics, however, reptiles may breed more frequently and may remain reproductively active throughout the year; however, seasonal cycles of rainfall and food availability can influence reproduction.[4,21,22]

Spermatogenic Cycle

The spermatogenic cycle is quite variable in reptiles and has been studied in many species.[1,4,21,23] A full discussion of all spermatogenic cycle strategies utilized by reptiles is not within the scope of this chapter but basic concepts are summarized. In temperate reptiles the breeding cycle typically begins with individuals emerging from hibernation in the spring. Active spermatogenesis is usually associated with increased testicular size; however, the timing of gonadal recrudescence and regression in the annual cycle varies greatly among species.[2,21] These differences often relate to the ability of males to store sperm in the epididymis or vas deferens for extended periods of time, even overwinter. This ability allows insemination and fertilization to occur even when testes are in regression. The three most important environmental factors that influence endogenous control of spermatogenesis and thus breeding cycles are temperature, rainfall, and photoperiod.[21,23] The hypothalamic-pituitary-gonadotropin endocrine system is influenced by these environmental cues, and the spermatogenic cycle and thus sexual steroid production is controlled by the release of pituitary gonadotropins (see Vitellogenic Cycle discussion). Many variations in the reptile spermatogenic cycle exist, but two basic strategies commonly utilized are termed "prenuptial" and "postnuptial" spermiogenesis.[1] With prenuptial spermiogenesis testicular recrudescence occurs in the spring after emerging from hibernation and ends in late spring or summer *before* mating. With postnuptial spermiogenesis testicular recrudescence begins in the spring but continues through the summer, with spermiogenesis occurring at the end of summer. In this case spermatozoa are often *stored* overwinter in the vasa deferentia for use the following spring. This allows reptiles to breed immediately on emergence from hibernation, often when females are present in abundance (communal hibernation), and is an effective strategy utilized by many species and is well studied in garter snakes (*Thamnophis* spp.).[1] An example of the environmental influences on the spermatogenic cycle (even within a species) is the common snapping turtle (*Chelydra serpentina*). Snapping turtles in Tennessee store spermatozoa overwinter in the vasa deferentia for breeding in the spring (postnuptial), but snapping turtles living in the warmer climate of Louisiana have sperm in the vasa deferentia year round (prenuptual and postnuptial).[1] Tropical and subtropical reptiles may have more frequent reproductive cycles, often have a second breeding season, or may breed throughout the year.[20]

Vitellogenic Cycle

As with the spermatogenic cycle the vitellogenic cycle in female reptiles varies greatly among species. One major difference is the dependence on adequate amounts of energy required for folliculogenesis compared with spermiogenesis.[1,20] A major step in the maturation of the ovarian follicle is the accumulation of yolk, or vitellogenesis. The energy for vitellogenesis comes primarily from fat stores in the body of the female but in some species can also be derived from calories taken in during vitellogenesis.[20] However, many reptiles, especially snakes, are capital breeders where energy necessary for reproduction is derived exclusively from fat stores rather than food intake. This regulation ensures that a female can complete a reproductive effort without consuming a meal, which is critical when food availability is unpredictable.[24] If females have insufficient energy stores, they may forego reproduction that season.

As with mammalian species the vitellogenic cycle including follicular development, ovulation, and the production of sexual steroids is controlled by pituitary gonadotropins. This hypothalamic-pituitary-gonadotropin endocrine system is influenced by the environmental cues mentioned for males but also with a greater dependence on energy reserves in females. In squamates a follicle-stimulating hormone (FSH)–like pituitary gonadotropin has been identified, and in crocodilians and chelonians gonadotropins similar to FSH and luteinizing hormone (LH) have been identified.[10] These gonadotropins appear to play similar roles in reptiles as with other vertebrates and an increase in LH, progesterone, and testosterone levels have been documented with ovulation in many chelonian species.[2,21]

Additionally, like mammals, the steroid hormones estrogen, progesterone, and testosterone (androgens) are important in the reproductive cycle of female reptiles. The secretion of intrafollicular estrogen in anolis lizards (*Anolis carolinensis*) with active vitellogenesis results in increased follicular hyperemia and encourages the progression of folliculogenesis.[25] Additionally, this increased vascularity leads to greater yolk deposition in the most hyperemic follicles.[2,25] The mature ovum becomes 10 to 100 times larger than its previtellogenic size.[26]

In a group of captive female veiled chameleons (*Chameleo calyptratus*) fecal hormone values were utilized to evaluate sex steroid hormonal patterns associated with both nonovulatory and ovulatory phases of the reproductive cycle.[27,28] Estrogen levels were found to rise during vitellogenesis and peaked in late vitellogenesis. Progesterone concentrations rose during the late vitellogenic cycle, peaked at midgravidity, and fell to baseline values at oviposition. Testosterone levels varied during the previtellogenic and vitellogenic phases, but similar to progesterone reached peak concentrations during ovulation and gravidity. Ovulation was found to occur in these chameleons with a decreasing estrogen/progesterone ratio.[27,28]

Estrogen (and progesterone) plays a role in vitellogenesis but also in stimulating the liver to convert lipid from the body's fat stores to vitellogenin. Estrogen receptors have been identified in the liver of painted turtles (*Chrysemys picta*), with levels varying during the year but highest in the spring (preovulatory activity) with a smaller peak in the fall (vitellogenesis).[29] During this time the liver enlarges dramatically and takes on a yellow color (physiological increase in intrahepatic fat, not pathological hepatic lipidosis). This vitellogenin (yolk protein) is then selectively absorbed from the bloodstream by ovarian follicles. Calcium is predominantly supplied to the embryo via the yolk in reptiles, and plasma calcium levels are elevated during vitellogenesis.

Progesterone is important in supporting egg and embryo development in reptiles.[29] After egg deposition, concentrations of estrogen, progesterone, and testosterone have been found to decrease in many chelonian species.[2,21] Other hormonal factors affecting reproduction in reptiles include thyroid activity with the hypothalamic/pituitary/thyroid axis influenced by temperature and photoperiod, resulting in effects on gonadal maturation and sexual behaviors.[30] (See Chapter 79.)

There is much variation in the ovarian cycles of reptiles and a detailed discussion is not within the scope of this chapter, but some basic concepts

VetBooks.ir

are summarized. As described for the testicular cycle many external and internal factors affect the ovarian cycles. The estrus period usually corresponds with active vitellogenesis, occurring early in the vitellogenic cycle in snakes and in the later stages in lizards.[20] However, vitellogenic cycles do not necessarily coincide with active spermatogenesis, as stored sperm from previous months is often used for breeding.[1,2,4,21] Temperate species tend to have a single seasonal estrus cycle, with an interseasonal period of hibernation. Although temperate males are often consistent with annual spermatogenic cycles, females may have a biennial estrus cycle, dependent on energy sources. These energy sources are often affected by climate, and one example includes the variable cycling of the female European viper (*Viperia berus*) from southern Britain.[1,20] Tropical and subtropical species have more frequent reproductive cycles, are often polyestrous, may have a second breeding season, or breed throughout the year.[20] Exceptions in reproductive cycling do exist, and one noteworthy variation includes tropical boids.The common boa (*Boa constrictor*) and Burmese python (*Python bivittatus*) tend to breed during the cooler periods of the year; however, temperature variations in their natural habitat is mild compared with temperate species. In habitats where rainfall is seasonal, many species key their reproduction cycle to rainfall rather than temperature.[20] Even when environmental cues are appropriate, reproduction may still be inhibited due to other limiting factors. The role of the male in influencing the reproductive cycle of females is not well understood but varies between species. In some species (parthenogenic), females can proceed through the entire oogenic cycle in the abscence of a male (although in some species psuedo-copulation between females is required to stimulate follicular growth), but in other species female snakes may require the male's presence, and possibly the act of copulation, to proceed beyond previtellogenic follicular growth.[31,32] Although the requirement for male presence before vitellogenesis is premature for fertilization, it assures the female of a mate before mobilizing substantial energy stores into reproduction.[32]

FECUNDITY AND CLUTCH DYNAMICS

Differences in reproductive strategies exist for females of different species and are dependent on exogenous and endogenous factors; however, three basic ovulation strategies have been described.[10,33] Polyautochronic ovulation refers to simultaneous ovulation of many ova from both ovaries and includes many squamata and chelonian species seen in clinical practice, including iguanids, bearded dragons (*Pogona vitticeps*), boids, colubrid snakes, red-eared sliders (*Trachemys scripta elegans*), and many box turtle and tortoise species. Monoautochronic ovulation involves a single ovum simultaneously from each ovary and is common in Gekkonidae. Lastly, monoallochronic ovulation results when one ovum from either the right or left ovary ovulates, and the ovaries alternate between each single egg clutch. This is the reproductive strategy for *Anolis* spp.[2,25]

Clutch size or fecundity is related to and controlled by anatomical and physiological limitations of the species.[1,2] A limited amount of energy is available for reproduction, and consequently, a trade-off is seen between offspring size and clutch size. As described previously, some species have predetermined clutch sizes that may be limited to one, two, or many with polyautochronic ovulators. Thus, a small amount of energy can be allocated to each of many offspring, or large amounts of energy to only a few. The total amount of energy utilized for reproduction can be extraordinary in reptiles, especially in snakes where more than 40% of a female's body mass can be allocated to reproduction. Clutch size is extremely variable, ranging from one (Anoles [*Anolis* spp.], pancake tortoises [*Malocochersus tornieri*]) to 200 (green sea turtles [*Chelonia mydas*]) in oviparous species, and one (shingleback skinks [*Tiliqua rugosus*]) to up to 92 (garter snakes [*Thamnophis radix*]) for viviparous species.[34] Experimental techniques have been developed to alter the clutch size of reptiles. Ablating some developing follicles during early vitellogenesis reduces clutch size and allows for a greater allocation of energy to the remaining ova.[35] The result is the production of larger and presumably hardier offspring. Alternatively other studies have shown that the use of FSH at the onset of the reproductive cycle will increase clutch size while decreasing offspring size.[35] These manipulative strategies could be useful in the preservation and conservation of endangered species.

COURTSHIP

Copulation is usually preceded by specific and often elaborate courtship behavior in reptiles. A great deal of variability exists in the courtship interactions and behaviors. Intermale rivalry with visual displays (of colors and/or head and leg movements), vocalizations, physical fighting, and chemical cues (pheromones) are utilized to establish territory or influence females to breed.[4,34] Male snakes use their bodies and especially their tail and spurs for tactile stimulation of the female, and male lizards use species-specific postures and movements to impress females. Chelonians use both visual and tactile stimulation in the form of head bobs (tortoises), forepaw fluttering (turtles), and biting. Minor injuries are relatively common during courtship and copulation and can become quite serious in the confines of captivity (Fig. 80.5A). Chelonians often bite at the limbs and shell of females to discourage them from walking

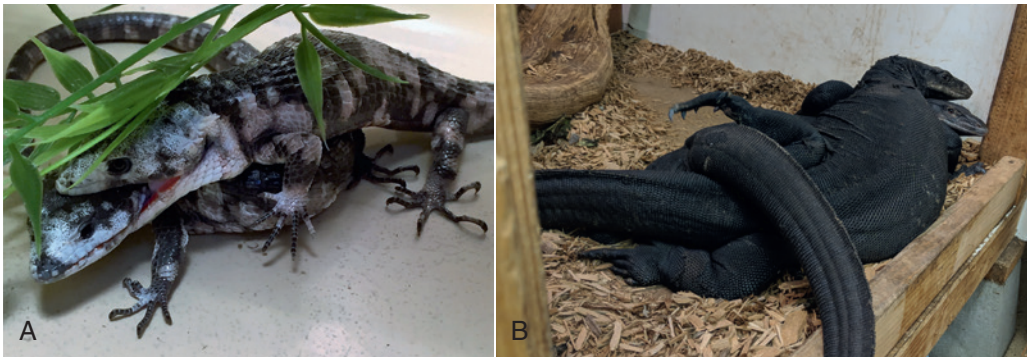

FIG 80.5 (A) Courtship can be aggressive in reptiles. A male alligator lizard (*Ambronia lythrochila*) bites a female's nape to hold her in position while attempting copulation. (Courtesy of Scott J. or swimming. Some species of squamata have evolved to engage in mate-guarding behavior as a technique to improve sexual selection. See Chapter 13 for a more detailed discussion.

COPULATION

All fertilization in reptiles occurs internally. Copulatory behavior in males does not necessarily coincide with peak spermatogenesis and testicular development, as sperm for reproduction is often stored in the epididymides or vasa deferentia for extended periods of time.[1,28] Copulation frequently occurs during mid vitellogenesis in females but may occur before vitellogenesis in some species. Male chelonians and crocodilians use their single phallus, whereas male squamates use one of their paired hemipenes to facilitate movement of sperm from the vasa deferentia into the females' cloaca during intromission (see Fig. 80.5B). The tuatara has no copulatory organ and like many avian species copulates by pressing the vent lips together for sperm transfer.[1] Copulation behavior is quite variable. It can be quite short as with many lizards (seconds) or longer (hours to days) in chelonians and snakes (Fig. 80.6A). Aquatic turtles breed in the water, box turtles and tortoises on land. The chelonian phallus is quite elaborate and increases in size dramatically to lock into the female cloaca whereas the more concave plastron allows the male chelonian to "fit" on top of the female's carapace. Male box turtles will utilize their rear feet by placing them between the plastron and carapace to keep the female from closing the plastron on the phallus (see Fig. 80.6B). Male lizards routinely bite and hold the nape of the neck to secure a position on the back of the female during copulation. Additionally, male lizards and chelonians will bite at a female's limbs and tail if she is avoiding advances. Generally, females are more likely to receive the brunt of the trauma during courtship; however, female blue-tongued skinks (*Tiliqua* spp.) are known for aggression toward advancing males. Snakes are less aggressive with courtship and copulation; however, they may intertwine their bodies, often with the male biting (colubrids) the neck area in an attempt to secure the female while inserting a hemipenis into the female's cloaca. Some male snakes (primarily boas and pythons) will use cloacal spurs as a tactile tool to stimulate females during courtship and copulation. Injury during courtship and copulation may be exacerbated by the confinement of captive reptiles to a cage that limits their ability to escape.

FERTILIZATION

Fertilization is internal in all reptiles and takes place near the cranial end of the oviduct (infundibulum) before any deposition of egg envelopes. The timing of fertilization, in terms of the female's reproductive cycle, is not well understood. Because copulation occurs before ovulation, sperm must be stored by the female, and seminal receptacles have been identified in many species in the posterior uterine tube, isthmus, or anterior vagina.[1,13]

Some reptiles can store sperm for up to 6 years; however, fertility is highest when copulation occurs in concert with the female's reproductive cycle.[34] Similarly, second clutches can be produced without a second mating, but fertility is greater if copulation occurs during the development of the second clutch.[34] Using copulation as the onset of gestation often results in exaggerated times for fetal and egg carriage. To further complicate the issue of gestation time, multiple breedings are commonplace. This is especially true for boid snakes, where a pair may repeatedly copulate over a period of 1 to 2 months. In these instances, copulation is obviously occurring at varied stages of the female's reproductive cycle. Additionally, female chelonians are known to store sperm from several males, simultaneously resulting in clutches of eggs with multiple paternity.[36,37] To accurately determine the gestation of a reptile, more advanced techniques such as ultrasonography must be used. The postfertilization developmental pattern a female follows will involve one of two basic reproductive strategies, reptiles that lay eggs (oviparous) and those that are live bearers (viviparous).[38]

REPRODUCTIVE STRATEGIES

Oviparity

Oviparity represents the ancestral mode of reproduction in reptiles and characterizes all living chelonians, crocodilians, the tuatara, and most squamates (Fig. 80.7). Once ovulation takes place, usually little transfer of nutrients is thought to occur between the female and the ova. However in squamates embryos have often completed 25% to 30% of their development at oviposition. This is clinically relevant because the health of the offspring is dependent not only on environmental conditions during (external) egg incubation but also (as with viviparous species) on the conditions a female experiences post-ovulation and prior to

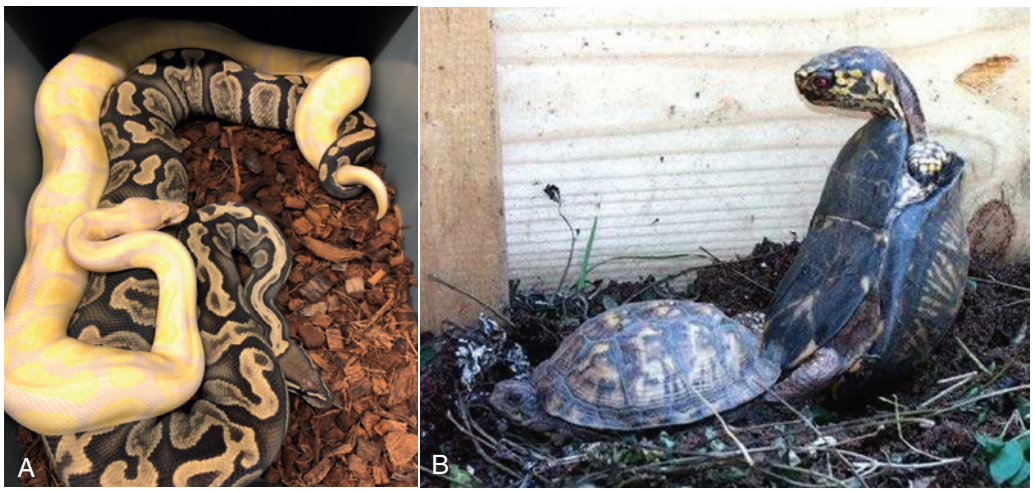

FIG 80.6 (A) Ball pythons (*Python regius*) copulating. This pair is "locked up" as breeders refer to it, with the amelanistic (lavender GHI) male on top and tails intertwined, with the male having one hemipenis inserted into the female's cloaca. (B) Male box turtles (*Terrapene* spp.) often incline the body beyond the vertical to achieve intromission during breeding. The male will wedge his rear feet between the plastron and carapace to keep the female from closing the plastron on his phallus. (A, Courtesy of J. Kobylka Reptiles.)

FIG 80.8 One of the most commonly kept captive snakes is the boa constrictor (*Boa constictor* spp.), which is a live-bearing (viviparous) species. This female died, and dead, full-term fetuses were found at necropsy. The fetuses show normal orientation in the oviduct. The kidney can be seen just above the mesosalpinx and oviduct/fetuses. oviposition. The ovum becomes an egg when albumin and a shell are added in the oviduct. The degree of shell calcification varies among species, ranging from minimal, resulting in pliable eggs (snakes, most lizards, and some turtles) to pronounced, resulting in rigid eggs (crocodilians, tortoises, and many geckos). An example of the variation in shell rigidity is evident in geckos, in which egg type is phylogenetically based. Geckos in the family Gekkonidae have rigid eggs, however, Diplodactlidae (i.e., Australian and New Zealand geckos) and Eublepharidae (eye-lid geckos) have pliable eggs. Clinically, ultrasonography can be used to distinguish the general stages of gonadal inactivity, early previtellogenic follicle growth, vitellogenesis, ovulation, and either shelling or fetal development. See ultrasonography later in this chapter and in Chapter 58.

Viviparity

Many species of lizards and snakes have developed the ability to produce live young (Fig. 80.8). These live-bearing reptiles are often subdivided into ovoviviparous and viviparous, depending on the degree to which the female contributes nutrients to the developing embryos.[39,40] In this chapter the term viviparous will be synonymously used with live-bearing. In addition, although the term pregnant is oftentimes reserved for viviparous species and gravid for oviparous species, in this chapter the term gravid will include all females, whether incubating eggs or fetuses. Nutrients are provided to the developing embryos either by lecithotrophy (via yolk during follicular development) or matrotrophy (during embryonic development such as across a placenta). The degree of matrotrophy in squamates can be variable, with the most extreme example being skinks (*Mabuya* spp.) that contribute more than 99% of the neonatal mass through a chorioallantoic placenta.[41] Besides providing gas and possibly nutrient exchange to the developing offspring, viviparity provides some protection to the developing embryos and permits a female to adjust developmental temperature by simply moving between warm and cold locations.[42] Viviparity also has energy costs, and by retaining the developing fetuses within the body for an extended period of time, the female is limited to a single clutch per year.[39] The space occupied by fetuses (and eggs in oviparous species) also limits the function of the gastrointestinal tract, and females usually reduce intake or cease feeding during the latter stages of gestation. Postpartum females are often in poor condition, having mobilized virtually all energy stores for production of offspring. Because sufficient lipid stores are necessary for reproduction, reptiles that are unable to rapidly restore lipid often reproduce biennially or even triennially (see Vitellogenic Cycle and Fecundity and Clutch Dynamics).[43] In captivity, however, extensive postpartum feeding may allow for naturally biennially breeding species to produce annually. Oviparous species may also suspend feeding during the latter stages of egg development; however, the length of time is shorter (weeks versus months) and less significant. Although all viviparous species cannot possibly be listed, Table 80.1 provides a list of common viviparous and oviparous species seen in practice. Clearly, the reproductive mode of a reptile has a phylogenetic component (e.g., all pythons are oviparous, all rattlesnakes are viviparous). However, reproductive mode is a plastic trait that has evolved independently at least 100 times in squamates,[41,42] and both viviparity and oviparity can be present within a genus (e.g., *Rhacodactylus*, *Eryx*, *Charina*) and even a single species (e.g., *Sceloporous aeneus*).

Parthenogenesis

Although not widespread, parthenogenesis, or asexual reproduction, has been reported in about 30 plus species of lizards and has been extensively studied in whiptails (*Aspidoscelis* [*Cnemidophorus*] spp.), where parthenogenic species have evolved from the hybridization of two species. These lizards reproduce asexually, but females still show courting and pseudocopulation, and these behaviors have a positive effect on reproductive output.[44]

More recently the Komodo dragon (*Varanus komodoensis*) has also been found to have the ability to reproduce by parthenogenesis.[45] Genetic finger printing was utilized to determine this in captive hatchling Komodo dragons, and the use of this technology will likely result in identifying more species with this ability. Parthenogenesis has also been discovered in snakes, and all blind snakes (*Indotyphlops* [*Rhamphotyphlops*] *braminus*) are triploid females.[46] Other snake species can switch between asexual and sexual reproduction, and a recent report indicates there may be an emerging phylogenetic pattern for parthenogenesis in snakes, especially with more species being continually identified.[47] Some species with this ability include certain garter snakes (*Thamnophis elegans* and *T. marcianus*), rattlesnakes (*Crotalus horridus* and *C. unicolor*),[47] copperheads (*Agkistrodon contortrix*) and cottonmouths (*Agkistrodon piscivorus*),[47] file snakes (*Achrochordus arafurae*),[48] and Burmese pythons (*Python bivittatus*).[49]

Parental Care

Most reptiles show no parental care of their eggs or offspring beyond choosing an appropriate nesting site and concealing the eggs; however, some degree of care has been documented in more than 100 species.[50] In the few cases of parental care, the investment is usually limited and nonessential for survival of the offspring.

Many female pythons coil around their eggs until hatching, protecting eggs from predators and providing temperature and humidity regulation (Fig. 80.9). Some python species have the ability to twitch muscles to generate heat.[51] Recent research with children's pythons (*Antaresia childrenii*) showed this maternal brooding instinct to be strong, as female pythons were willing to brood the eggs of other females or even rocks similar in size to their eggs.[52]

Nest building and guarding has been documented in several species, including turtles (e.g., Burmese mountain tortoise [*Manouria emys*]), lizards (e.g., skinks [*Eumeces* spp., *Mabuya* spp.] and glass lizards [*Ophiosaurus* spp.]), snakes (e.g., king cobra [*Ophiophagus hannah*] and cobras [*Naja* spp.]), and especially crocodilians (virtually all species). Female king cobras use their coils to build an elaborate nest out of branches and bamboo leaves and will guard their eggs for up to 3 months.[53]

Crocodilians guard their nest but also assist neonates in emerging from the nest and guard them for some time after hatching. Some viviparous species also show some maternal care. Rattlesnakes remain with their offspring until the neonates first shed, which is approximately 1 week after birth.[54] In addition, some females assist neonates in escaping from their amniotic sacs (skinks [*Mabuya* spp.] and night lizards [*Xantusia* spp.]) or consume infertile yolk sacs (common boas [*Boa constrictor*] and sand boas [*Eryx* spp.]). More extensive postnatal, parental care has also evolved in many species. A study on wild populations of long-tailed skinks (*Eutropis longicaudata*) found that populations with a higher predation pressure on the offspring provided maternal care, whereas populations under less predation pressure did not.[55] See Chapters 13 and 85 for more discussion on maternal and paternal behaviors.

SEXUAL MATURITY

Sexual maturity in reptiles is determined primarily by size, with age playing a less significant role.[34] Although standard ages for sexual maturity can be found in the literature, these numbers are usually based on free-ranging reptiles, where all individuals in a population have similar environmental influences. However, in captivity, care and diet can vary dramatically, often resulting in captive reptiles reaching sexual maturity at considerably different ages. For example, many boid species are "power fed" by ambitious breeders to encourage them to grow quickly to reach early maturity with the hope to breed them as young as 18 months to 2 years. In contrast, reptiles provided with poor husbandry and diet can have slow and stunted growth, delaying sexual maturity.

The interspecific variation in maturation size is greater than the intraspecific variation in growth rate, making discussion on specific maturation sizes difficult. To provide some reference, the following generality is provided; snakes raised under optimal conditions usually mature in 2 to 3 years, small lizards take 1 to 2 years, and large lizards 3 to 4 years. Chelonians take longer to mature, usually 5 to 7 years.

SEX IDENTIFICATION

Reptiles do not possess external genitalia, so sex identification is not always obvious. The proper method to identify the sex of a reptile varies greatly among species and the age of the individual. Sex can often be identified with various methods that differ in simplicity or accuracy. When choosing a sexing method, understanding the accuracy of that method is important. If identifying the sex of an individual is not critical, such as a pet reptile not utilized for breeding, safety and simplicity

TABLE 80.2 Practical Techniques for Sex Identification by Major Taxa

Snakes

Sexual dimorphism
- Thickened and longer tail in males (paired hemipenes located in the base of the tail)
- Larger spurs in males (boas and pythons)
- Size (females of some species may be larger as adults, e.g., ball python, *[Python regius]*)

Everting hemipenes ("popping") (primarily neonates/juveniles)
Probing (most reliable technique)

Lizards

Sexual dimorphism
- Larger head, jowls, crests, spines, body size in males
- Thicker tail, paired hemipenes located at base of tail in males
- Femoral/preanal pores larger in males
- Color
- Unique anatomy (male), rostral horns (Jackson's chameleon, *Trioceros jacksonii*), heel spur (veiled chameleon, *Chamaeleo calyptratus*)

Probing (not reliable in most species)
Everting hemipenes "popping" (more reliable/safest with anesthesia)
Transillumination (light-colored species, several to compare differences between male/female)
Radiography
- Some monitor species calcified hemipenal hemibaculae with maturity
- Contrast solution introduced into hemipenal/clitoral sulcus (male spiral, female flat/straight)

Ultrasonography
- Mature females may note clusters of anechoic ovarian follicles
- Male more difficult to identify testes
- If ovary not seen, identification of sex not definitive, not useful for immature lizards
- Not useful in large monomorphic skinks (*Tiliqua, Corucia*) due to keratinized scales

Endoscopy (coelioscopy)
- Most definitive with visualization of the gonad, and biopsy possible
- Requires anesthesia and is more invasive

Chelonians

Sexual dimorphism
- Longer nails on front feet in male aquatic turtles (e.g., red-eared sliders and painted turtles)
- Concavity to plastron in males
- Tail larger and longer, vent opening more distal on tail
- In some tortoises the plastron anal scutes curve inward in female, outward in male
- Female larger body size in some species (e.g., leopard tortoises, *Stigmochelys pardalis*)
- Male larger body size in some species (e.g., eastern box turtle, *Terrapene carolina*)
- Red/orange iris color in male eastern box turtle

Ultrasonography (mature females but not immature/juvenile)
Endoscopy
Coelioscopic, gonad is directly visualized, most definitive for immature/juveniles
Cystoscopic, gonad visualized through bladder, can be definitive but not direct visualization
Procedures require anesthesia and are more invasive

are important considerations. However, when captive breeding is intended, one must choose an identification method that provides virtually 100% accuracy. Obviously, accuracy of a given procedure is dependent on the ability of the individual performing the procedure, and proper training and experience enhances success.

The various methods used to identify sex in reptiles are discussed. Important variables to consider when choosing a particular technique include: species, age, safety versus invasiveness, and need for high acuracy. Table 80.2 provides a quick reference to the preferred method(s) of sex identification in common species maintained in captivity.

Secondary Sexual Characteristics

In some species, sex can be easily identified based on obvious secondary sexual characteristics that anatomically distinguish adult males from females. This is most prevalent in lizards and to a lesser extent chelonians. Other than differences in maximal body size, secondary sexual characteristics are rare in snakes and crocodilians. The accuracy of secondary sexual characteristics in sex identification varies dramatically, depending on species, age, characteristic being examined, and the experience of the observer.

Some species have obvious coloration or ornamentation that distinguishes the sexes. This is best exemplified in chameleons, such as Jackson's chameleon (*Trioceros jacksonii*), where the male possesses 3 large rostral horns that are absent in females. Unfortunately, most secondary sexual characteristics are more subtle, involving minor differences between sexes.

Generally, male reptiles have a larger more robust appearance, especially of the head area. This may include ornamentation of the head such as crests, spikes, protruberences, jowls, dewlaps, (Fig. 80.10A) and increased coloration in these areas; examples include the colorful dewlap of the male anolis and the black beard of an alarmed bearded dragon (*Pogona vitticeps*). However, these differences are often minor and large females can easily be confused with small males. Common species where general appearance and head size are frequently used in sex identification, with mixed accuracy, include iguanas, Gila monsters (*Heloderma suspectum*), and beaded lizards (*Heloderma horridum*), and many of the larger skinks (*Tiliqua* spp., *Egernia* spp.).

A recent study in eastern blue-tongued skinks (*Tiliqua scincoides*) utilized morphometrics of head size compared with body size to establish an accurate technique for identifying sex.[56] This large popular lizard has unique, heavy keratinization of body scales, which makes ultrasonography and other sexing techniques challenging. Sexual dimorphism in this species is subjective but typified by mature males having a larger head than females, and females generally having a longer snout-to-vent length (SVL) than males. The study evaluated 69 free-living eastern blue-tongued skinks and utilized noninvasive body measurements to develop a formula

for sexing them. Ratios of morphometric measurements—head width measurement/SVL (H/SVL)% and head/trunk (H/T)%—showed significant predictability with respect to sex identification in both adult and subadult skinks.[56] Smaller numbers of other blue-tongued skink species were also evaluated and similar results found, suggesting these ratios may be useful in other *Tiliqua* species. To apply the technique, measurements of the H, SVL, and T are taken (Fig. 80.11). Ratios are then calculated for H/SVL% and H/T%, and these measurements are then compared with the confidence intervals (CI) found in the study to identify the sex of the skink.[56] The CI ranges found were for H/SVL% (males: 15.35–15.99; females 13.20–13.94) and for H/T% (males: 23.79–25.31; females 20.03–21.35).[56] Further work may validate the use of this noninvasive technique in other lizard species.

In chelonians, the plastron of males is often concave (Fig. 80.12A and B). This plastron concavity allows the male to closely appose his cloaca to the female's during mounting. The degree of plastron concavity and gender differences show considerable intraspecific and interspecific variation.

Many inconspicuous but notable secondary sexual characteristics are located near the cloaca. Many iguanid and gekkonid lizards possess either femoral or preanal pores that excrete a waxy substance used for marking territory. Although present in both sexes, these pores are more pronounced in mature males and even moreso with seasonal hormonal influence (see Fig. 80.10 B and C).

Many boas and pythons possess spurs located just lateral to the vent. The spurs are vestigial hind limbs, and in males, they are used for tactile

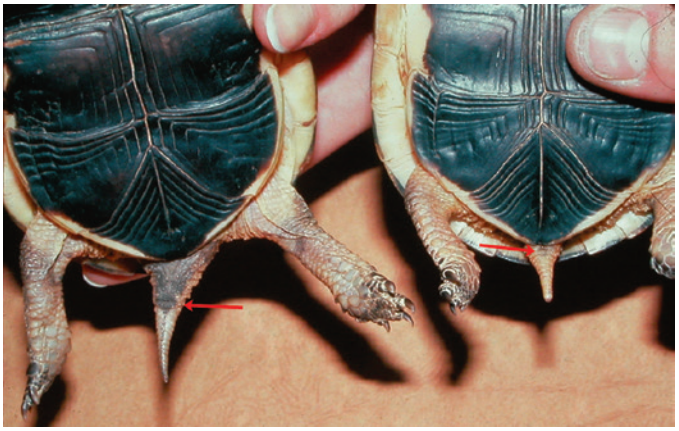

FIG 80.14 One consistent distinguishing characteristic between male and female turtles and tortoises is the length of the tail. In these box turtles (*Terrapene* spp.) the male's tail is longer and broader and the vent opening is further out on the tail, usually past the edge of the carapace. In the female the vent opening is between the edges of the plastron and carapace. See red arrows identifying the vent. (Courtesy of Douglas R. Mader.)

stimulation of the female during courtship. Spurs are usually larger in males, but the difference in size is variable by species. In some species, such as the rosy boa (*Charina trivirgata*) and sand boas (*Eryx* spp.), spur size is a highly reliable predictor of sex. However, in other species, the reliability is reduced. In the ball python (*Python regius*), spur size is extremely variable in both sexes and therefore has little value as a sex identifyer.

The tail is a critical reproductive structure for many male reptiles, because it provides both a storage location for hemipenes (squamates) and a muscular appendage to help position the male's cloaca adjacent to the female's. Because of these traits, the size and shape of the tail is often sexually dimorphic. In squamates the prescence of hemipenes may result in symmetrical bulging at the base of the tail, which can often be quite dramatic, sometimes visible without picking up the individual. The extent of this dimorphism is usually greater in lizards than snakes, especially smaller species like geckos (Fig. 80.13).

Male chelonian tails, although not enlarged due to housing the phallus, are usually much larger and longer than the females'. In addition, the vent is usually located more distally along the tail of males (Fig. 80.14). The larger tail provides better access to the female's cloaca, which, with the presence of the shell, is important. Some tortoises also use the tip of the tail for tactile stimulation of the female's cloacal region.

Other secondary sexual characteristics located near the tail but specific to individual species include enlarged postanal scales of many iguanid lizards (e.g., spiny lizards [*Sceloporus* spp.]) and the pelvic protuberances of the banded geckos (*Coleonyx* spp.). In some chelonians, especially many tortoises the anal scutes on the plastron, tend to curve inward toward the cloaca in females and point outward in males (see Fig. 80.12A and B).

In many mature male aquatic turtles, notably the red-eared slider and painted turtle (*Chrysemys picta*), the nails on the front feet grow significantly longer than females and are used in courtship by waving them in front of females as they swim backward in front of them. Male box turtles (*Terrapene* spp.) often have a much brighter red/orange iris color compared with females (Fig. 80.15). Veiled chameleons (*Chameleo calyptratus*) can be sexed at hatching, as the male has a definitive spur pointing caudally at the heel of the rear foot.

In addition to the challenge of being familiar with species-specific dimorphism these (hormonally influenced) secondary sexual characteristics are usually not developed in juveniles. Thus juveniles of many species that may have obvious sexual differences as adults will not develop these features until maturity and must have their sex identified by other methods. Some of the sexing techniques described later,such as endoscopic sex determination, were developed as a result of the need

to definitively sex these neonatal and juvenile animals for economic or conservation reasons.[11]

Tail-Base Transillumination

A novel, noninvasive technique popular among reptile breeders for sexing small lizards, especially those with light-colored skin, involves tail-base transillumination to visualize the hemipenes. This technique is especially useful if several reptiles of the same species are evaluated at the same time to compare differences between sexes. With transillumination the males' hemipenal structures have an increased tissue and vascular prescence compared with the females' hemiclitores. Smart phones with a "flashlight" mode can be used to transilluminate smaller species such as geckos. The cool light source is placed dorsally at the tail base with the light passing through the base of the tail and peri-cloacal area to highlight tissues. Stronger flashlights or an endoscopy light source in the veterinary practice may be useful in larger lizard species such as bearded dragons. Caution must be used to avoid thermal damage to the lizard when utilizing this technique, as some light sources can produce significant heat (http://www.beardeddragon.org).

Cloacal Probing

Probing the cloaca with a slender blunt instrument is the most common method of sex identification in adult snakes and some large lizards (e.g., monitors [*Varanus* spp.]) and was first described by Lazlo.[57] This procedure identifies the presence of the hemipenes. The particular instrument used is not critical as long as it is long, smooth, and blunt on the probing end. Commercially manufactured probes are available in various sizes from several sources (Fig. 80.16A). Cloacal probing is a straightforward technique that can be easily mastered with practice.

(B) A female showing the scent gland "papillae" but no distinct tubular structure as with the male. This technique takes practice but can be quite accurate in experianced hands with juvenile snakes. With the reptile properly restrained, the probe is inserted into the cloaca and directed caudally. Many lubricants have been found to be spermicidal, so caution must be used when probing reptiles that are actively breeding or are expected to breed in the near future.[58] Saline is the safest lubricant to use in these cases.

With gentle maneuvering of the probe just lateral to midline, the probe enters the inverted hemipenis in a male and freely advances within the hemipenal sulcus (see Fig. 80.16 B and C). The depth to which the probe enters the tail is dependent on the species. Probing females results in shorter depth of penetration because the female has a hemipenal homologue or hemiclitoris, which is shorter in depth and smaller in diameter than the hemipenis. A properly sized probe allows the probe to enter the inverted male hemipenis and the female hemiclitoris without puncturing or damaging the tissue. If a probe is too small or sharp or excessive force applied a female could inadvertently be probed as a male as the probe perforates through the hemiclitoris. Common species in which female hemiclitores are well developed and misidentification of sex is likely include short-tailed (blood) pythons and monitor lizards (*Varanus* spp.).[15] This technique does not work as well in lizards as in snakes because many lizards have increased musculature in this area and contraction hinders probe advancement.

Manual Eversion of Hemipenes

The most common method used for identifying the sex of neonatal colubrid snakes is to manually evert the hemipenes. This procedure, frequently referred to as "popping" by snake breeders, entails firmly rolling one's thumb proximally up the tail base toward the cloaca. The pressure forces the hemipenes to evert laterally at the caudal edge of the cloaca (Fig. 80.17A). To avoid injury, care must be taken to roll the thumb rather than simply apply pressure.

In females, the scent gland openings/papillae can sometimes be identified during popping with the openings located laterally in the cloaca (see Fig. 80.17B). These scent gland papillae are especially visible in female king snakes (*Lampropeltis* spp.); however, females of most species are identified merely by the lack of hemipenes. This negative result in identifying females can lead to the misidentification of males as females. However, with experience, the sex of most neonatal colubrids can be determined with nearly 100% accuracy using this technique. Sometimes this technique can be utilized in juvenile or small- to medium-sized lizards, but care must be taken not to injure the lizard, and it should not be used in species that perform tail autotomy. For heavy-bodied juvenile snakes, including many of the boas and pythons and some colubrids (e.g., hognosed snakes [*Heterodon* spp.]), everting the hemipenes is more difficult or not possible and may risk injury.

This same technique can be performed under anesthesia (see Chapter 49) to relax the reptile enough to overcome the retractor muscles (usually sedation alone is not enough) and allow eversion of the hemipenes or hemiclitores. This approach is more definitive, may eleviate stress and discomfort, and reduces the likelihood of injury from an awake reptile struggling during eversion attempts. On evaluation the hemiclitoris of the female can look similar to the hemipenis of a male in some species, and close examination may be necessary to differentiate the two, especially in neonatal specimens. Hemipenes are more ornate and larger in length and diameter compared with the hemiclitores of females (Fig. 80.18).[15]

The partially everted right hemipenis in this figure looks similar to the hemiclitoris in female monitors, showing the importance of completely everting the structure to see the male spiral portion to acurately identify the sex with this method. (Courtesy of Juliet Mejia, Stahl Exotic Animal Veterinary Services.)

Hydrostatic Eversion of the Hemipenes

Hydrostatic eversion by saline injection is more invasive and uncomfortable and has increased risk for injury; therefore other techniques discussed should be considered first. However, if done properly this technique can be accurate and safe.

Like manual eversion, this procedure relies on the eversion of the hemipenes from the base of the tail to identify males. However, unlike manual eversion, the technique provides a definitive anatomic indicator of females rather than the mere absence of the male trait. Procedurally, sterile isotonic saline solution is injected into the tail just distal to where

the hemipenes would be located if the individual was a male. The fluid is injected into the tail until either sufficient eversion has occurred or resistance can be felt at the plunger. Placement of the needle too proximally on the tail may direct the fluid into a hemipenis rather than behind it, therefore making the procedure not only ineffective but also potentially injurious. The hydrostatic pressure created within the tail not only forces the hemipenes to evert but also causes swelling of the tissue surrounding the cloaca. This swelling partially everts the cloaca through the vent, allowing visualization of the oviductal papillae in females.This technique is useful for neonatal snakes in which manual eversion is ineffective and for many lizard species. For large specimens, including monitors, iguanas, and heloderms, the strength of the retractor penis muscle can counteract the hydrostatic pressure and prevent eversion of the hemipenes. In these species, the muscle must be relaxed using a surgical level of anesthesia. With eversion the hemipenis is more ornate and larger in length and diameter compared with the hemiclitoris of females (see Fig. 80.18).

Digital Palpation of Cloaca

The preferred method for sex identification of crocodilians involves digitally palpating the ventral aspect of the cloaca for the presence of a phallus. With the animal appropriately restrained in dorsal recumbency, the cloaca can be easily explored with a gloved finger. The presence of a phallus is obvious, because it is the only structure that can be felt in the otherwise smooth-walled cloaca. If desired, the phallus can be everted through the vent for visualization.

Plasma Sex Hormone Evaluation

Sex hormone evaluation to identify sex may be valuable in chelonians and lizards. In a study in hatchling and immature desert tortoises (*Gopherus aggassizii*), tortoises that were confirmed to be males by visualizing testes endoscopically had significantly higher plasma testosterone levels than female tortoises, with a 98% correletion between the two different techniques.[59] A hormone stimulation study was described for sexing hatchling giant river turtles (*Podocnemis expansa*) where one unit of FSH was injected intracoelomically and blood was drawn 4 hours later to measure plasma testosterone. Male chelonians had testosterone levels >0.5 ng/mL, whereas females had plasma testosterone values <0.2 ng/mL.[60]

A study in monitor lizards evaluated the use of plasma sex hormone levels in conjunction with hemipenal eversion as a possible technique to increase the accuracy of sexing Merten's water monitors (*Varanus mertensi*) in the field.[61] This monitor species is semiaquatic with significant tail musculature for swimming, and thus traditional hand-pressure-induced hemipenile eversion is difficult and may result in inaccurate sexing. Sixty-two different, field-captured adult monitors were examined between January 2001 and February 2003 in the tropical north of Western Australia. On examination manual hemipenal eversion was attempted and recorded as eversion (yes or no) and plasma was collected and later measured for androgen (An) and estradiol-17β (E2) levels. The final sex of individuals was determined using a combination of plasma (An: E2) ratio and field eversion result. With the additional plasma hormone information, it was possible to determine the sex of 37.0% of males and 31.2% of females that could not be determined through hemipenal eversion and thus increased the accuracy of sex identification in the field.[61] More work needs to be done in evaluating plasma sex hormone levels as a reliable technique for sexing monomorphic reptile species (knowing that many extrinsic and endogenous factors affect these hormones), but this report shows there may be clinical value, especially when combined with other sexing techniques. Several studies evaluating fecal sex hormone levels to monitor the ovarian follicular cycle in a group of captive female veiled chameleons was successful and this same technology (less invasive and expensive then blood analysis) could possibly prove useful in sex identification in sexually monomorphic reptiles.[27,28]

Radiography

Many but not all species of monitors (*Varanus* spp.) possess mineralized hemibacula within their hemipenes, which are easily recognizable on radiographs.[62] Monitor species in which these structures occur are listed in Chapter 9, Table 9.2, and depicted in Fig. 9.13 in that chapter. Unfortunately this calcification occurs with age and maturity and is not often evident in young monitors when sex identification is most valuable. Another study found pelvic measurements taken from radiographs in Gila monsters (*Heloderma suspectum*) was useful to differentiate the sexes.[63]

A recent study involving 20 eastern blue-tongue skinks (*Tiliqua scincoides scincoides*) utilized a noninvasive radiographic technique for sex identification by introducing radio-opaque solutions into the hemipenal/hemiclitoral sac (Mallett, Proc UPAV, 2015a, pp 40–46). Contrast medium (1 mL of iohexal; Omnipaque, GE Healthcare) was introduced into the postcloacal sulcus with a syringe and attached tom-cat catheter or 22 g intravenous catheter with stylet removed (similar to the sexing probe technique with insertion of the catheter to the full depth of the sulcus), and the contrast material was injected continously as the catheter was slowly withdrawn. Excess contrast was wiped away, and the skinks were radiographed utilizing horizontal beam lateral and dorsoventral views. The positive contrast images showed repeatable differences in the definition of the hemipenes and hemiclitores in the skinks. On the dorsoventral view the hemipenes were wider and showed a spiralling outline compared with the hemiclitores, which had a thinner and sharply angled outline. On the horizontal view the hemipenes were larger and showed a spiral shape (related to the ornate nature of the hemipenis), whereas the hemiclitores were thin and straight/horizontal (Fig. 80.19A–D). The technique had 100% correlation with the definitive sex identification of skinks using breeding records or coeliscopic sexing. This procedure was felt to be effective for skinks of 15 cm SVL and larger.

Another imaging study looked at the sensitivity of hemipenes identification with several imaging modalities, including ultrasonography,

radiography (with contrast introduced into the cloacal sulcus), and CT (with and without introduced contrast) in four different lizard species (*Pogona vitticeps*, *Uromastyx aegyptia*, *Tiliqua scincoides*, *Gerrhosaurus major*).[64] In this study 19 lizards were evaluated and the accuracy of cloacal sulcus contrast radiography was 94.7%. In male lizards radiographs showed distinct spindle-shaped opacities associated with the contrast medium within the inverted hemipenis lumen. This study concluded that contrast radiography and contrast CT (see later) were effective, noninvasive, but more costly, techniques for gender identification in lizards.[64]

Ultrasonography

The value of ultrasonography is limited to identifying females, as ovarian follicles (spherical anechoic to hypoechoic structures based on cycle) are the only easily recognized reproductive structures (Fig. 80.20). Therefore only reproductively active females can be identified with confidence, leaving immature females, acyclic females, and all males often undistinguishable.[36,65]

One study in mature heloderms found ultrasonography to be useful for identifying the presence or absence of hemipenes in the proximal tail base.[66] However, a more recent study evaluated hemipenal identification using several imaging modalities in 19 lizards of 4 different species and concluded that the accuracy of ultrasonography to identify gender was poor at 64.3%.[64]

CT/MRI

Advanced imaging techniques such as CT and MRI are becoming more affordable technologies in clincal practice and can be offered to clients as a possible tool for sexing reptiles. Resources and guidance on the normal imaging anatomy of many reptile species with these advanced imaging modalities is increasingly available. In the hemipenal imaging study mentioned earlier noncontrast CT had poor accuracy (63.1%), and hemipenes were identified in only two lizards, both of which had spindle-shaped kinked structures consistent with smegma within the hemipenal sulcus.[64] However, with the use of contrast, CT accuracy improved to 100% with hemipenes being correctly identified in all 9 males. With more research CT and MRI may continue to prove to be valuable, noninvasive, but more costly, tools to accurately sex monomorphic reptile species.

Stahl, Stahl Exotic Animal Veterinary Services.)

Surgical or Endoscopic Sex Determination

Visualization of the gonads via surgery or coelomic endoscopy (coelioscopy) is a definitive method for determining the sex of reptiles.[67,68] Endoscopy is less invasive than traditional surgery, and the basic rigid endoscopic equipment (2.7-mm telescope and 4.8-mm sheath system) in most veterinary facilities can be utilized for gender identification in many reptiles, even at an early age. Coelioscopic sexing is indicated in monomorphic reptile species (lizards and chelonians) where less invasive techniques lack accuracy. It is especially useful to breeders and for endangered species breeding programs, where early gender determination in juveniles is critical.[11,59] Coelioscopy using saline infusion was shown to be accurate in identifying sex in hatchling and neonate chelonians. A study in Chinese box turtles (*Cuora flavomarginata*) concluded that gonads could be visualized and sex identified in animals as small as 10 g (Fig. 80.21A–C).[11] More than 300 individual juveniles of various chelonian species have been safely and successfully subjected to early gender identification by coelioscopy (Divers SJ, unpublished data). Coelioscopic sexing is not useful in snakes because of their unique anatomy and the intimacy of coelomic organs. Along with accurately identifying sex through direct visualization of the gonad, in mature reptiles coelioscopy can provide feedback on the status and health of the reproductive tract.

Another endoscopic approach to sexing reptiles was recently published and involved evaluation of the gonads through the transparent bladder wall of juvenile tortoises (*Testudo marginata*).[69] This technique has the advantage of being less invasive (coelom is not entered) but does not provide the same degree of visual acuity as direct coelomic examination and has been found to be unsafe in juvenile sliders (Proenca L, unpublished data).With more research this technique may prove useful in many chelonians but in species where the immature gonads appear similar, or the bladder wall is less transparent, accuracy may be decreased. For details on coelioscopic and cystoscopic sexing techniques in reptiles, see Chapter 64.

Temperature-Dependent Sex Determination

Many reptile species have temperature-dependent sex determination (TDSD), where the sex of the developing embryo is determined by the temperature at which the eggs are incubated. TDSD occurs in all crocodilians, most chelonians, and a few species of lizards, most notably for clinical practice the bearded dragon (*Pogona vitticeps*), leopard gecko (*Eublepharis macularius*), and crested gecko (*Correlophus ciliatus*).

The exact temperatures at which each sex is produced is species-dependent. In some, warmer temperatures produce males, and in others, warmer temperatures produce females. In still other species, bimodal variation is seen, with one sex produced at moderate temperatures and the other sex produced at high and low temperatures. In all cases, the shift from one sex to the other is not absolute, but instead a range of temperatures exists at which both sexes are produced in varying proportions. Because these intermediate temperature ranges exist and incubator thermometers may not be accurate, predicting sex solely based on incubator temperature can be flawed. Sex should be confirmed in these species using one of the previously mentioned techniques. See Chapter 85 for more information on TDSD.

Genotyping (DNA/Molecular Sexing)

For reptile species where sex is determined genetically, identifiying the sex of an individual using a genetic code unique to their heterogametic chromosome is possible.[70] Unlike mammals where the male is the heterogametic sex in all species, the heterogametic sex varies among

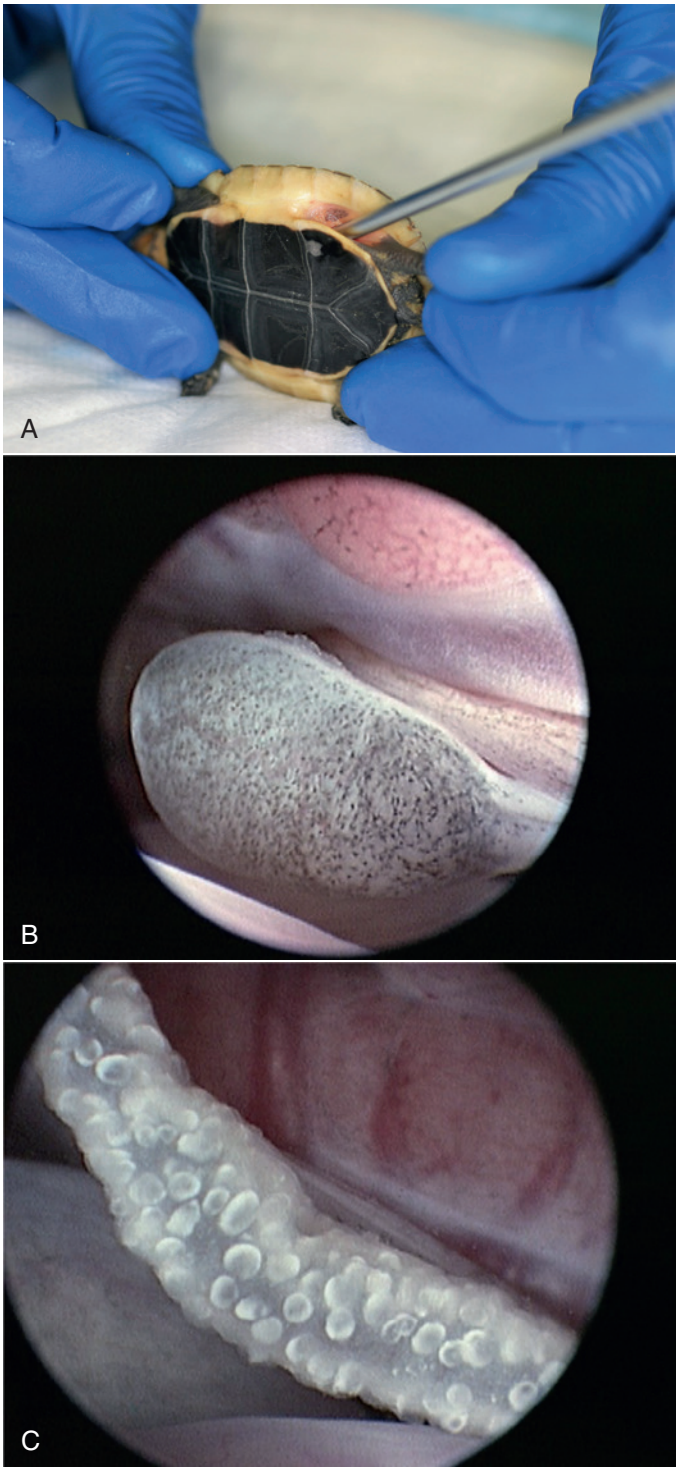

FIG 80.21 (A) A juvenile Chinese box turtle (*Cuora flavomarginata*) undergoing coelioscopy for sex identification. (B) Coeloscopic image of immature testis in a juvenile male Chinese box turtle. species of reptile. Reptiles have different modes of sex determination, including both temperature-dependent determination and chromosomal sex determination. With chromosomal determination in reptiles some genera have XY sex chromosome, some genera have ZW sex chromosome, some genera have no recognizable sex chromosome, and some may show all three variations.[70] Therefore it is unlikely that a DNA marker found in one species or genus will be sufficiently conserved to be broadly applicable to other reptiles.[70] Thus this technology, at least currently, may be limited to threatened or endangered species and has been reported as a potentially useful conservation tool.[70] In the Komodo dragon specifically, these molecular techniques have been further evaluated, and PCR analysis consistently resulted in the amplification of a male-specific longer fragment found to be useful for molecular sex identification.[71]

CAPTIVE BREEDING

Understanding the anatomy and reproductive physiology of reptiles, along with the ability to accurately identify their sex, are clinically important. Knowledge of reproductive anatomy and physiology of reptiles is considerd a science; however, the captive reproduction of these animals in many ways is an art. Veterinarians must have the ability to combine the science and art to effectively help clients with captive breeding and management of their reptiles. References on captive breeding are readily available, and an exhaustive discussion of all captive-breeding parameters is beyond the scope of this chapter but some important principles are summarized. Much of the information shared here is derived from the snake-breeding industry, which has historically been successful and can be used as a template for other taxa.

Breeding Stock

The three components of good breeding stock are: (1) at least 1 individual of each sex is needed, (2) the individuals in question must be sexually mature, and (3) they must be healthy. Although these points seem obvious, it is not uncommon for owners to present breeding "pairs" of the same sex or breeding individuals in poor health. These three requirements are essential for captive breeding but are not sufficient to ensure positive results. Successfully breeding reptiles involves a series of events occuring in succession, and failure of any one may lead to poor results.

Seasonal Cooling

As discussed previously, a period of cooler temperature is necessary for most species to initiate reproductive behavior. This seasonal cooling is commonly referred to as brumation, hibernation, or cycling. A reptile's physiology is greatly affected by the imposed cooler ambient temperature. Most body systems, including the immune system, operate best at an optimal temperature. When body temperature differs substantially from the optimal temperature, such as during seasonal cooling, these systems are less effective. The goal is to safely provide the seasonal cooling stimuli necessary (based on natural history) while putting the reptile at the lowest risk. To stimulate an appropriate reproductive response in the spring, temperate species must be subjected to lower temperatures reaching a constant low winter temperature of 10° to 13°C (50° to 55°F) for 8 to 12 weeks. High latitude and high elevation species may need lower temperatures. Subtropical and tropical species need less drastic temperature drops, usually to 20° to 24°C (68° to 75°F) and primarily at nighttime with an available (yet optional) focal heat source during the daytime hours. Significant nighttime cooling appears to be the critical component to stimulating reproduction in many subtropical and tropical species. A similar cool night, with an available (yet optional) focal heat source during the day, approach to seasonal cooling can also be effective and safer for small temperate lizards.

All reptiles should undergo a physical examination and fecal evaluation before seasonal cooling. Unhealthy animals should not be cooled. Both the immune system and digestive system are dramatically affected by body temperature. For temperate reptile species that will experience a dramatic/constant temperature reduction, first ensuring that the digestive tract is empty is essential. Lower body temperature reduces

VetBooks.ir

the ability to digest food; therefore any material in the gut can lead to severe and sometimes fatal enteritis. Snakes should have food withheld for at least 2 weeks before extended cooling, and lizards and chelonians usually require several days to a week to clear the intestinal tract. Seasonal cooling is usually coordinated with the natural weather pattern, but animals can be phase-shifted to respond at other times. The required duration of the cooling period to assure reproductive conditioning is unknown. Common lengths range from 4 to 12 weeks. Energy demands of a cooled reptile are variable; however, losses in body weight during seasonal cooling are usually less than 10%.[72]

All reptiles seasonally cooled at a constant low temperature should be checked weekly or biweekly. Although reptiles may be sluggish, they should not show any physical or behavioral signs of illness. In addition, water, if not offered ad libitum, should be offered during these evaluations. If water is offered continuously, precautions must be taken to assure that it does not spill. High humidity during seasonal cooling is a frequent cause of respiratory infections. Reptiles showing any signs of potential illness must be returned to an optimal temperature immediately. Most importantly, caution must be utilized during these temperature transition times, because maintaining reptiles at intermediate temperatures, between the optimal temperature and a target cooling temperature, may be deleterious as such temperatures are nonconducive to feeding or immune function. Reptiles held at these intermediate temperatures may lose significant weight and be prone to illness. Like the precooling period, the postcooling period is a time of careful observation. Many problems occurring before or during seasonal cooling often fulminate with the return to active temperatures. Quick detection and correction of such problems is essential for maximizing reproductive potential and even survival.

Other Stimuli of Reproduction

Other environmental parameters that may also affect reproductive activity can also be utilized in conjunction with or as a possible alternative to seasonal cooling. Such stimuli include increased cage humidity, artificial raining, increased feeding, repeated introduction to multiple potential mates, adding shed skins from conspecifics, and male-male combat. Although these methods seem to provide benefits in certain species, the details and the universality of their use are not well known.

Frequency of Reproduction in Captive Reptiles

The frequency with which a captive reptile reproduces is dependent on species, environmental conditions, and nutritional status (see Reproductive Cycles and Fecundity). These factors can be manipulated in the captive situation to influence breeding, reproductive cycling, and fecundity. Most importantly the female must be in good health with adequate energy stores to reproduce. Reproduction is costly and nonessential for individual survival, so it is usually bypassed when body condition is poor.

Many oviparous species have the ability to produce more than one clutch per year. This is true for many turtles and lizards but is less common in snakes. Some tropical geckos produce a clutch of two eggs once a month throughout the year. More commonly, however, only two to three clutches are laid during a more defined breeding season, lasting only a few months. Whether a second clutch is laid is dependent on the time of year and the condition of the female. Although females may not attain the weight they were before producing the first clutch, females must regain sufficient energy stores after oviposition to commit to another clutch. Reinsemination is not necessary between clutches, but it can lead to increased fertility. Viviparous species commit a greater amount of time to a single reproductive event. Gestation lasts from 1.5 to 6 months, and the female feeds sparingly or not at all during this time. As a result of this lengthy investment, viviparous reptiles are generally limited to the production of a single clutch per year.

Determination of Gravidity (Pregnancy)

See earlier in this chapter for details on courtship, copulation, and fertilization, which all lead to gravidity. Gravidity can often be determined by observing the appearance and behavior of a captive female. Midbody swelling is apparent in gravid snakes and lizards; however, obese animals can cause both false-negative and false-positive assessments. The change in appearance is more obvious in smaller and less robust species. In some geckos, the eggs can be seen through the semitransparent skin covering the ventral aspect of the coelom. Realizing that the right ovary/oviduct is located more cranial to the left aids in differentiating developing follicles/eggs from similarly colored but symmetrically located fat bodies (Fig. 80.22).

Behavioral signs can be used in conjunction with appearance to aid in gravidity determination. Classic behaviors of gravid reptiles include an increase in basking time that correlates with an increase in selected body temperature, partial or complete anorexia, and a change in body positioning. In snakes, body-positioning changes often include looser coiling and lying in semilateral or even dorsal recumbency. Later in gravidity, restlessness and nesting behavior can be observed.

Coelomic palpation can provide a more reliable determination of gravidity and is straightforward in most snakes (except heavy-bodied ones) and with practice sometimes possible in lizards. In chelonians, the shell makes palpation difficult but not impossible. Holding the chelonian vertically (head up), fingers are directed craniomedially in the prefemoral fossa and the chelonian is gently tilted side to side, often allowing detection of shelled eggs (Fig. 80.23).

In snakes, a firm but careful thumb is run down the ventrum from approximately midbody to the cloaca and may reveal the presence and often an estimate of the number of follicles, eggs, or fetuses. Follicles

FIG 80.22 A female mourning gecko (*Lepidodactylus lugubris*) showing eggs through the ventral skin over the coelom. are firm and often easily differentiated from softer eggs or fetuses. Lizards are palpated with a thumb and forefinger placed ventrolaterally on the relaxed coelom. As with snakes, follicles are differentiated from eggs by their firmness. Lizards are more difficult to palpate than snakes, leading to an increase in false negatives, and if one is not gentle, possible iatrogenic injury with follicle or egg rupture.

Currently radiography and ultrasonography are the most accessible and exacting methods of gravidity determination in reptiles. Radiography is useful in determining gravidity in chelonians, because the hard calcium-rich eggshells are clearly visible on radiographs and alternative methods are more limited. There are no reports to date that (limited) radiographic exposure has any detrimental effects on the developing embryos.

For lizards and snakes, the lower amount/lack of calcium in the softer eggshell makes radiographic identification more difficult. Therefore ultrasonography is often preferred and can reveal all stages of ova development. In snakes the gallbladder can be used as a marker, because it is readily identified as a large echolucent sphere about 60% SVL. The right ovary is located just distal to the gallbladder and the left ovary just distal to the right. Vitellogenesis in squamates is signified by the follicles becoming larger and progressively more echogenic but remaining clustered (lizards). In chelonians similar changes occur except the follicles are not as clustered due to a larger fan-shaped mesovaria. Ovulated follicles and eggs are linearly arranged, occupying nearly the entire caudal half of the reptile. With practice, the pliable egg shells of squamates can be detected, and the densely mineralized shelled eggs of chelonians are readily identified on ultrasound scanning (Fig. 80.24). The ultrasonographic appearance of viviparous species is similar in appearance to oviparous species until after ovulation. Immediately after ovulation, developing fetuses are dominated mostly by yolk and therefore appear similar to ovulated eggs. However, as the embryo grows, an amniotic sac is seen as a small echolucent sphere on the periphery of the larger echogenic yolk mass. Eventually, in larger specimens, fetuses can be seen (Fig. 80.25A and B). See imaging under Reproductive Diseases, Clinical Investigation later in this chapter and Section 7 for more information on imaging of the reproductive tract.

Gestation and Oviposition

Gestation is a critical time for both the female and the developing offspring. A great demand is placed on a gravid female because gravidity requires energy (although much of the energy reserve was already invested with folliculogenesis prior to ovulation) but oftentimes limits food intake. The drastic imbalance between energy intake and energy demand is satisfied by energy reserves, including the breakdown of muscle mass. In addition, gravidity can affect immune function.[73] The combined effect of the energy deficit and altered immune function can lead to clinical disease during gravidity. Persistent, low-grade infections often fulminate during gravidity, jeopardizing both the female and the offspring. No reports have been found nor have the authors observed any negative effects of any drugs on gravidity, neither as an abortifacient nor a teratogen.

True gestation time can be difficult to determine in reptiles for a multitude of reasons. Among these are (1) the temporal separation between copulation and ovulation, (2) the prevalence of multiple copulations, and (3) the temperature-dependent effect in which warmer temperatures may decrease gestation time. Reported gestation lengths for viviparous reptiles range from 1.5 to 6 months. Most snakes undergo ecdysis before oviposition, which is likely associated with concurrent thyroid hormonal activity and influence.[30] This "prelay shed," as it is termed, provides a relatively reliable predictor of oviposition date for snakes. Snake breeders utilize this prelay shed (also called postovulatory shed) along with other markers to estimate oviposition. Much data appear in the popular literature describing these markers, and veterinarians should be familiar with these reproductive parameters for the most common snakes seen in practice. These and other useful reproductive parameters for commonly bred snakes are listed in Table 80.3.

However, colubrid snakes usually oviposit 8 to 14 days after this prelay shed, and pythons oviposit 24 to 49 days after, with some variation. The prelay shed date is used by many reptile breeders as the time to offer the female a nesting site.

Van Mierop and Bessette first reported another gestation marker in ball pythons, which they described as a notable "midbody swelling" and concluded was associated with ovulation.[74] Many snake breeders utilize this marker and, like the "prelay shed," use it to estimate oviposition. The Barkers' in their book on breeding the ball python call this gestational marker "the lump" and describe its appearance as a dramatic midbody swelling that lasts 8 to 24 hours and is the result of ovulation (Fig. 80.26).[75] They describe the female using her posture to compress her posterior body, creating tight serpentine coils just posterior to the mass of ova, and this action pushes the ova toward the infundibula. The movements are pulsatile, with long periods of rest between contractions (an action similar to that seen in the anterior portion of the body when a snake is regurgitating). During this time females are stoic and unresponsive to stimuli. Subsequently, female pythons appear smaller afterward, which is supposedly associated with the eggs becoming more linearly arranged and spread out in the oviduct. This midbody swelling

Species	Introduction for Breeding	Gestation Markers*	Ovipositon/Gestation/Fecundity
Ball python[75–76,79] *Python regius*	Pairs placed together in late December, 1 male with up to 4/5 females continuously or introduce males/females weekly for 3-day intervals until late March (breeders may manipulate cycle to breed year-round) Ultrasound: introduce males when female follicles (15–25 mm)	Ovulation from mid-March to April or typically 6–30 days after the last observed copulation Ovulation lasts about 24 hours Approx. 20 days after ovulation start of postovulatory shed cycle Ultrasound: once follicles at 30 mm ovulation likely occurred, move male to another female	Oviposition 24–34 days after postovulatory shed (avg. 28 days) Eggs usually laid at night Females will coil around eggs Average clutch size is 6.5 eggs Range of 1–11 eggs Clutch 17%–65% female body wt. Avg. clutch 50% female body wt.
Boa constrictor[163–164] *Boa constrictor*	Males are introduced to females 1–2 weeks after females' last meal One strategy is to introduce for 3–5 days if no courting activity then separate, offer female a small meal, and reintroduce in 3 weeks Keep repeating this cycle until courtship behavior begins Several different males can be introduced at different times during these cycles	Typically 3–8 weeks after courtship behavior a preovulation swelling in posterior midbody will be observed, and this takes place about 2–3 weeks before ovulation Female boas will appear uncomfortable during ovulation, laying in unusual positions Female boas may ovulate from each ovary at different times, thus extending the opportunity to observe ovulation Boas shed 16–20 days after ovulation	Boas give birth approx.105 days after postovulatory shed Approx. 123 days after final ovulation Most babies born June/July Usually give birth at night, associated with barometric pressure change/rain Birthing takes 10 min to 6 hours A 6 foot boa will give birth to 25 neonates (avg.) Litter size represents between 10%–40% female body wt.
Corn snake[165] *Pantherophis guttata* **Rat snake**[165] *Pantherophis obsoleta* spp. **King snake**[166] *Lampropeltis getulus* spp.	Introduce males and females after female's first posthibernation shed Females are at maximum receptivity after this first shed	Ovulation may or may not be observed in colubrids, but females usually lay their eggs 7–14 days after prelay shed	Oviposition 31–45 days after mating (avg. 39), 7–14 days after prelay shed Typically all eggs are laid within 24 hours Average clutch size is 20–25 eggs Range 1–50 Can produce 2nd clutch in same season (smaller clutch size)

*Gestation markers: Ovulation in this table is used synonymously for "midbody swelling" or "the lump," which has anecdotally been thought to be an indicator for ovulation. Postovulatory shed is used synonymously for "prelay" shed. See discussion under Captive Breeding for more information about these markers.

has been witnessed in more than 20 python species and several boa and colubrid species.[75] More recently, a ball python ultrasonography study has challenged this theory and suggests that this midbody swelling occurs *after* true ovulation and may be associated with egg shell deposition/mineralization.[76] In this study ovulation was thought to occur once follicular size was 20 to 25 mm, with consistent changes seen on ultrasound scanning at this size, including the appearance of an anechoic outer ring (presumed free fluid around follicles), a more elliptical shape versus round shape, evidence of a hypoechoic outer rim, and a hyperechoic inner ring with soft tissue echogenecity centrally (Fig. 80.27). The sonographic changes for these presumed postovulatory follicles were consistent with sonographic descriptions for postovulatory ova in studies in Borneo short-tailed pythons (*Python curtus*)[32,77] and red-tailed boas (*Boa constrictor occidentalis*).[78] Furthermore, in the ball python study, the "midbody swelling" was associated with oviductal eggs reaching their maximum size of 40 to 45 mm with a notable anechoic center (Fig. 80.28).[76] Within 1 to 2 weeks after the midbody swelling, mineralization and egg shell formation was identified sonographically as a thin hyperechoic rim surrounding each ova (Fig. 80.29).[76]

Many snake breeders are utilizing ultrasonography, not only to detect gravidity but also to evaluate a female's follicular cycle to determine the best time for pairing.[75,79] If a female has ovulated or has follicles undergoing atresia, pairing will be less beneficial. Snake breeders often use one male to breed multiple females, and ultrasonography provides an effective tool to improve the efficiency of a limited number of males.

Sonographic studies on multiple snake species describing ovarian anatomy, follicular activity, and gravidity have been reported,[32,75,77,78] but a description of the *entire* follicular cycle and gestation period in a single species, the ball python, has only recently been published.[76] This sonographic study identified three distinct stages of the follicular cycle, which could routinely be found in ball pythons, and they described

VetBooks.ir

them as follicular quiescence, atresia, and development to oviposition (maturation).[76] Follicular quiescence involved nonvitellogenic (anechoic) follicles that were generally less than 10 mm in size. Follicles that reached 10 mm had two possible end points; they could increase in size to become dominant follicles and proceed to ovulation, or they will undergo follicular atresia. Follicular atresia was characterized by nonvitellogenic follicles that developed into vitellogenic follicles between 10 to 20 mm but then remained static for 50 days or more and eventually regressed.[76] Oviposition (maturation) was predictable for follicles that reached 20 mm in diameter, and follicles that reached 22 to 27 mm allowed an acurate determination for timing of oviposition. In this study, once follicles reached 30 mm in size it was possible to predict with 100% accuracy the number of eggs at oviposition. Based on this study the best timing to ensure fertilization of the female ball python would be to introduce the male when follicles are between 15 to 25 mm in size.

A sonographic study describing follicular development and ovulation in the viviparous lizard *Barisia imbricata* has been published,[80] and studies in some chelonian species[81] are described as well. More studies similar to these will prove beneficial to the future of captive reproduction, especially involving threatened and endangered reptile species. See Imaging in Reproductive Diseases, Clinical Investigation later in this chapter and Section 7 for more information.

Nesting Sites/Ovipositoria

Provision of an appropriate oviposition site is critical for many species. Not providing a female with the proper laying conditions can lead to dystocia in an otherwise healthy reptile. Many reptiles use an ovipositorium or "nest box." A nest box can simply consist of an opaque container with a small entrance hole in the side (for lizards) or top (for snakes). The container should be half filled with lightly moistened substrates; the most commonly used are sphagnum moss, vermiculite, or a sand/soil combination (for a proper consistency) to allow nest site excavation, which is important for some species (lizards, chelonians). For most species the nest box should be situated so that the temperature inside is 28° to 30°C (82° to 86°F). Although snakes usually use the provided nest box, lizards oftentimes ignore it, laying their eggs in another area of the cage where they can rapidly desiccate. To avoid this, gravid lizards can be moved to a separate cage that is set up entirely as an ovipositorium. In such setups, the substrate, moistened vermiculite, or soil/sand combination should be reasonably deep, and a basking platform should be provided. The platform, a tray that covers approximately one-quarter to one-third of the substrate allows the lizard to avoid the moist substrate if desired and provides an object under which to dig. A basking light is provided over the platform. Properly designed large-scale ovipositoria can house lizards for extended periods and greatly increase the success in obtaining viable eggs. Dystocias are common in green iguanas and other lizard species, including monitors and old-world chameleons, and frequently are a result of inadequate nesting sites. For example, in nature, gravid iguanas and monitors exhibit extensive nesting behavior, including migration to a suitable nest site and digging a relatively deep nest for the eggs (Fig. 80.30A–C). In captivity, homologous conditions to allow such behavior are difficult to replicate. Minimally, gravid iguanas and other large lizards should be provided a large ovipositorium with substantial amounts, 30 to 60 cm (1–2 ft), of substrate. Chelonians lay eggs in excavated holes, which they carefully cover. A general rule for chelonians is to provide a nest box depth that is 1 to 2 times the length of the female's carapace. A week or two before oviposition, chelonians usually show increased activity, commonly digging several incomplete nest holes before selecting the ultimate nest site. This preovipository behavior can be used to signify that a female is gravid. See Chapter 85 for a discussion of egg evaluation, incubation, and neonatal management.

ARTIFICIAL INSEMINATION

With greater than 1000 species of reptiles considered threatened and more than 250 species critically endangered, there is a need for the development of artificial insemination (AI) techniques. Reptile

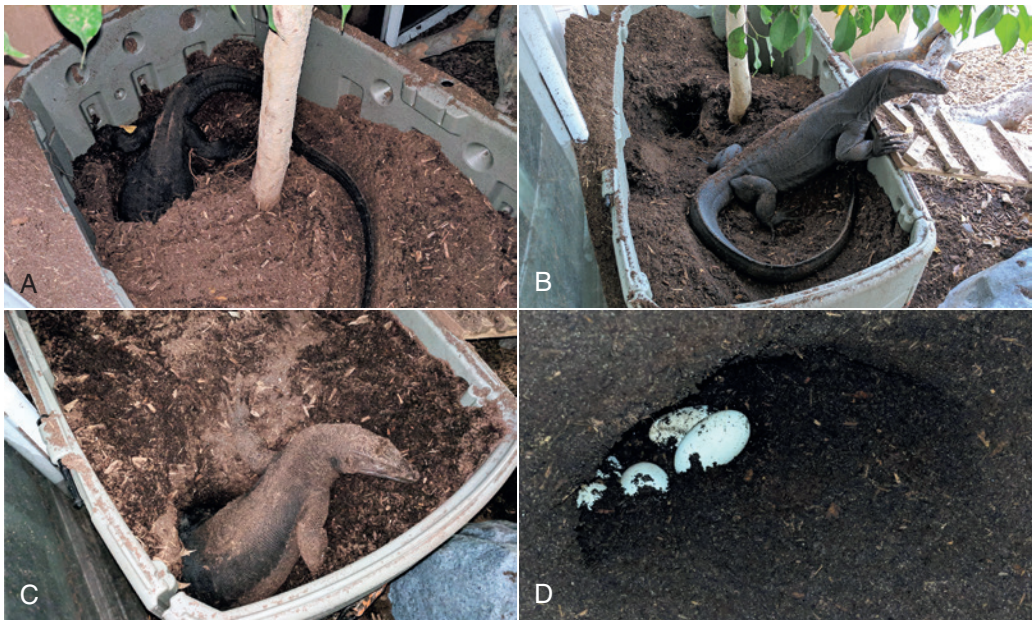

FIG 80.30 Adequate nesting sites must be provided for gravid reptiles, especially lizards and chelonians. The lack of an appropriate nest site can result in egg retention and dystocia. conservation and breeding programs continue to increase, and the success of these programs is dependent on maintaining genetic variation. Important techniques to ensure and protect such genetic diversity include identifying genetically significant males through sperm sampling, utilizing techniques such as cryopreservation for long-term sperm banking, and successfully using that sperm to fertilize females.[82–84] Unfortunately, sample collection, cryopreservation, and successful fertilization are all challenging and limiting factors with AI. A full discussion of all parameters of artificial insemination in reptiles is not possible in this chapter, but some basic concepts and recent advances will be summarized. Some of the earliest work with artificial insemination included the American alligator (*Alligator mississipiensis*), the Angolan python (*Python anchietae*), Gaboon viper (*Bitis gabonica*), and the checkered garter snake (*Thamnophis marcianus*), and was met with limited success.[58,85,86] Since that initial work, AI in many species has been evaluated to help advance these capabilities. Successful techniques developed for avian, fish, and amphibians have not worked well in reptiles. One complicating issue relates to the unique effects of seasonal, environmental factors (and thus hormonal influences) on the reproductive cycle of reptiles, including temperature, photoperiod, rainfall, and barometric pressure changes. Another critical obstacle with AI has been the fragile nature of reptile spermatozoa and poor results from cryopreservation techniques and storage.[58,85,87,88] Finally, insemination timing and techniques have not been fully elucidated for maximal fertilization ability. Ideally, to maximize success, artificial insemination should be coordinated with the female's follicular cycle, and more work is necessary in this area.

Semen Collection

One of the most important factors for successful AI is the safe collection of sperm. A variety of techniques have been utilized in reptiles to accomplish semen collection with varying results. In crocodilians success has been achieved with manual collection.[85] The manual technique involves placing the crocodilian in ventral recumbency and manipulating the phallus digitally. Sedation can be utilized in crocodilians if necessary but often alligators can be trained to allow the procedure.[85] Electroejaculation (EEJ) can also be utilized in crocodilians, but the less-invasive manual technique is often successful and EEJ unnecessary.[89] In chelonians EEJ has been utilized to successfully collect semen from many different species including the green turtle (*Chelonia mydas*),[90] hawksbill turtles (*Eretmochelys imbricata*),[91] the black marsh turtle (*Siebenrockiella crassicollis*),[92] and the leopard tortoise (*Stigmochelys pardalis*).[93] A vibrational device (vibrator) was successfully utilized to collect semen in three different species of turtle, the painted turtle (*Chrysemys picta*),the wood turtle (*Glptemys insculpta*), and Blanding's turtle (*Emydoidea blandingii*).[94] Generally, an erection was elicited by setting the vibrator at the highest frequency and moving it along the carapace in a linear or circular motion.[94] In snakes, manual sperm collection has been successful in many boids, colubrids, and vipers.[58,88,95] This manual collection technique can be performed in conscious snakes and involves a repeated stripping/stroking motion with firm pressure starting in the lower third of the coelom and continued distally toward the cloaca in a smooth repeated fashion. The hemipenes are often everted, and semen samples can be collected at the cloaca.[58,88,95] EEJ was also successfully used to collect sperm from the checkered garter snake (*Thamnophis marcianus*) and may be a useful technique for larger snakes, where size and strength may not allow manual stripping.[86] In lizards a manual extraction technique has been described for the collection of spermatozoa in the McCann's skink (*Oligosoma maccanni*).[96] A similar manual technique has been described for many Australian skinks.[97] EEJ has been successfully performed in the green iguana and other lizards under anesthesia to reduce stress and minimize any discomfort (Perry S, Mitchell M, personal communication).[98] In one study, weekly EEJ events were evaluated in veiled chameleons (*Chamaeleo calyptratus*) over a 1-month period (Fig. 80.31A and B). The EEJ procedure showed only transient cloacal mucosa inflammation after each EEJ event, and no chronic changes were observed. All animals included in this study survived, and these repeated EEJ events were determined to be safe (Perry S, personal communication).

Sperm Analysis

Sperm analysis is important to evaluate male fertility and sample quality for insemination. Techniques developed to evaluate sperm in mammals

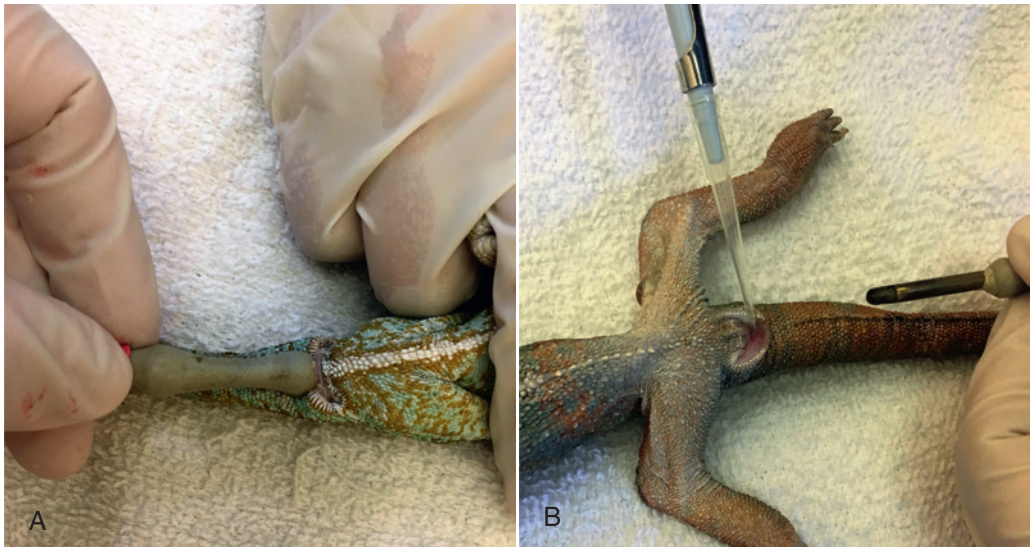

FIG 80.31 (A) An ejaculation probe is placed within the cloaca of a veiled chameleon (*Chameleo calyptratus*). Mild pressure is placed dorsally to engage nerve roots innervating the reproductive tract, stimulating ejaculation into the cloaca. can be utilized in reptiles. Ejaculates must be evaluated for three major parameters: concentration, motility, and morphology. Evaluating a neat (fresh/direct) sample is difficult because of the high spermatozoa concentration. As an example, snake semen has approximately 1.5 billion sperm cells/mL compared with dog semen at 500 million/mL.[58] The average volume of ejaculate from adult Angolan pythons and Timor pythons (*Malayopython timorensis*) was found to be only 0.1 to 0.4 mL.[58] In leopard tortoises spermatozoa samples collected with EEJ techniques under sedation averaged 0.26 ± 0.16 mL.[93] Reptile ejaculates collected either manually or by EEJ are comparatively much lower in volume than those produced by mammals, and for proper evaluation, reptile ejaculate should be extended to a 1:10 dilution or 1:100 dilution to facilitate accurate counts (although clumping may still be exhibited). Due to the spermatozoa's fragility extender type (yolk based, milk based, etc) should be taken into consideration. Each chamber of a hemocytometer is loaded with 10 µL of diluted sample. A Maklersperm counting chamber can be used to evaluate concentrated samples. Formal buffered saline can be used to extend a sample to inhibit motility for counting. Spermatozoa/mL is the standard for most animals when quantifying sperm concentration; however, it is more correct to quantify it per ejaculate (spermatozoa/ejaculate) because of the small volumes reptiles produce.[88,93,95,98] Motility of spermatozoa in semen samples can be estimated by placing a drop of semen or diluted semen on a slide with a coverslip (2 µL is the recommended minimum) and estimating the percentage of progressively motile spermatozoa to the nearest 5% in 5 hpfs (magnification, 400×).[58,88,98] Motility is dramatically affected by time and cooling and should be evaluated as quickly as possible. In leopard tortoises where spermatozoa were collected with EEJ, average motility at time of collection was found to be 57.3%, similar to other reptiles.[93] In a study evaluating sperm motility as a determination of sperm quality in the Argentine boa (*Boa constrictor occidentalis*) samples manually collected had 63% motility at the time of collection.[99] Generally a lower spermatozoa motility percentage (compared with higher vertebrates) may be normal/acceptable for reptiles. In the checkered garter snake a 0.05 mL sample of spermatozoa with 50% motility was successful in producing offspring via artificial insemination.[86] Morphology should be evaluated 1000× magnification under phase contrast or normal microscopy. Generally, a 100-cell count can be performed with morphological abnormalities noted, including bent tails, coiled tails, detached heads, and presence of droplets.[58,88,93,98] More research is needed to understand and validate spermatozoa abnormalities in reptiles and whether they truly compare with those described for other vertebrates. Advanced systems (computer-assisted analysis and epifluorescences microscopy) do exist and may prove applicable for evaluating reptile semen in the future.[93]

Sperm Storage and Cryopreservation

Much research is still needed in this area, as reptile semen has generally been difficult to preserve. Extenders or media for short-term storage that have been utilized include Hamm's F-10, egg yolk buffer, lactated ringers solution, phosphate-buffered saline, and TCG-Tris-citrate-glucose. Extenders have only been scientifically evaluated in crocodilian species. Storage temperature has been evaluated in snakes, lizards, and chelonians.[88,93,98] Cooled short-term semen storage has been successful in crocodilians for up to 2 days[85] and for a shorter duration in snakes.[88,100] Chelonian semen appears to be quite fragile and does not store well.[93] Cryopreservation techniques utilized for other vertebrates have not worked well for reptiles. The most common cryopreservatives utilize glycerol and dimethyl sulfoxide (DMSO), and results with these and other extenders have been poor with reptiles.[58,85,87,88,98] More research is needed into the use of extenders, cryopreservatives, and associated techniques, which may be species specific. For example, semen from Argentine black and white tegus (*Salvator merianae*) extended in 12% DMSO and frozen at a slow rate (0.3°C min) exhibited the best post-thaw viability.[101] Vitrification, a technique where spermatozoa are frozen quickly in liquid nitrogen, may be a promising technology but is not yet tested in reptiles. This procedure prevents ice crystal formation, thus eliminating damage to the spermatozoa plasma membrane.

AI Procedures and Techniques

Reports of successful artificial insemination in reptiles are rare. Difficulty with sperm extension and preservation are important reasons for these limitations. Hopefully, as semen-handling techniques are further refined, improved capabilities with AI will follow. Artificial insemination does show promise, fresh semen and short-term cooled semen has been successfully used in the American alligator.[85] In the saltwater crocodile (*Crocodylus porosus*), AI was successful with oviductal catheterization. Visualization of the oviduct was achieved with a tilt table and vaginal speculum. Semen was deposited using either a sheep AI pipette or a 3.5-Fr gauge "tom-cat" catheter. Success was low, with only one out of five inseminated females producing fertile eggs and only one egg hatching.[89] AI has also been successful in corn snakes using fresh semen.[100,102] In the checkered garter snake, artificial insemination utilizing sperm collected by electroejaculation was also successful.[86] Artificial insemination of the giant Yangtze softshell turtle (*Rafetuss winhoei*) has been attempted several times both via cloacoscopy into the urodeum and then via coelioscopy into the oviduct. To date, the female has laid clutches of eggs; however, none have been fertile (Kuchling, Turtle Survival Alliance Symposium, 2016). Successful AI has recently been reported in two corn snakes and an Amazon tree boa (*Corallus hortulanus*).[103] Semen was collected from males using the massage method and diluted 1:5 with normal saline and stored short term at room temperature. Females were monitored with ultrasonography, and insemination was timed with the presence of preovulatory follicles. Fresh diluted semen was introduced with a catheter into the females' oviduct using cloacoscopy. Two out of three corn snakes inseminated with this method laid 14 and 16 eggs, respectively, and all went on to successfully hatch. One Amazon tree boa inseminated with this technique gave birth to two healthy babies and five infertile ova 4 months after AI.[103] Much work is still needed in the field of artificial insemination in reptiles. However, as this most recent successful study indicates, endoscopically guided semen deposition, delivered to specific regions of the oviduct, with timing based on sonographic monitoring of the female's follicular cycle, may improve AI success.

REPRODUCTIVE DISEASES

Clinical Investigation

Historical Information and Presentation. Historical information and presentation can vary dramatically; however, regardless of the issue, clinicians must obtain a detailed history, complete a thorough husbandry review, and have a good understanding of species-specific reproduction. All chelonians and crocodilians are oviparous, as are most squamates; however, some lizard and snake species are viviparous (see Table 80.1). It is often challenging to differentiate normal reproductive activity (expected seasonal behavior for healthy intact reptiles) from reproductive diseases such as a follicular stasis or dystocia. For example, chelonians are known to be able to retain eggs in the oviduct for extended periods of time in their natural environment waiting for the right nesting site or conditions to lay.[104] Therefore differentiation between pending oviposition and true dystocia is often difficult. Historically owners often report reproductively active reptiles as becoming restless in their cages, pacing and climbing, presumably looking for possible mates or nesting sites. Oviparous lizards and chelonians may dig in planters or substrate.

VetBooks.ir

Aquatic turtles may spend extended time out of the water. Appetite and water intake are often reduced or absent. Coelomic distention in females may be noted in conjunction with reduced body condition, and owners may or may not be aware of their animal's gender, let alone reproductive activity. For dystocia cases, tenesmus without successful oviposition or parturition may occur or females may have produced a smaller clutch or litter than expected and still appear gravid due to retained eggs/fetuses. Alternatively, the breeder's records may indicate that the female is past her due date. With more serious or chronic conditions such as yolk coelomitis, ectopic ova, oviductal or hemipenal/phallic prolapses, reptiles may present lethargic, depressed, and even obtunded. Seasonally, owners may present mature male reptiles for increased aggression, especially large lizard species such as the green iguana. Many of these lizards are free roaming in the home and can become territorial, attacking humans or other household pets.[105]

Physical Examination. Detailed information on performing a physical examination is covered elsewhere (see Chapter 42); however, reproductive specific parameters are discussed here. First and foremost, the sex of the animal in question should be identified. In reproductive female squamates, palpation of preovulatory ova may be possible, but it may be difficult to differentiate large preovulatory follicles from postovulatory ova. Ovarian follicles tend to be more dorsal and spherical and not as mobile as oviductal eggs. Preovulatory follicles are generally not palpable in chelonians and crocodilians. Postovulatory ova (oviductal eggs) in squamates can often be differentiated from follicles because eggs are less firm, larger, more oblong, and more caudally located in the coelom. However, in some oviparous lizards and viviparous squamates it can be difficult to differentiate between the two. Chelonians are more difficult to palpate but in smaller species digital palpation in the prefemoral area with the patient held vertically (head up) and gently tilting the chelonian side to side may allow shelled eggs to be detected (see Fig. 80.23). This technique is not accurate for determining numbers of retained eggs, and clinicians must be cautious to avoid personal injury from the powerful retraction of a rear limb or shell hinge closure. It is usually not possible to palpate developing fetuses in viviparous squamates and imaging will be necessary. The cloaca should be evaluated for any abnormalities as the reproductive tract terminates at the urodeum. Blood, discharge, and abnormal odors could all be indications of possible cloacitis or salpingitis. A digital cloacal examination may reveal an ova or mass in the pelvic area.

In males, evaluation of the phallus in chelonians or crocodilians is important to exclude trauma or infection as a source of abnormal cloacal signs (asymmetry, swelling, odor, or prolapsed tissue). Asymmetry or bilateral swelling distal to the vent is often associated with scent gland adenitis in both male and female snakes and hemipenal abscessation, impaction, or prolapse in male squamates. Seasonally active males may show increased evidence of secondary sexual characteristics (eg, green iguanas with increased orange coloration, bearded dragons with a black beard, larger femoral and preanal pores in many lizards, and increased mental gland size and activity in chelonians) and show an increase in seasonal sexually driven territorial behaviors such as head bobbing, dewlap displays, increased aggression, and mounting behaviors. With more serious and/or chronic conditions such as yolk coelomitis, ectopic ova, and oviductal or hemipenal/phallic prolapses, animals may be depressed, weak, cachexic, dehydrated, and obtunded.

Hematology and Biochemistry. Abnormalities in the hemogram with reproductive disorders are usually associated with inflammatory changes and infection. Yolk coelomitis, ectopic ova, chronic dystocia with associated salpingitis, oviduct prolapse, or hemipenal/phallic prolapse/infection are conditions that can be associated with a leukocytosis and toxic morphological changes to granulocytes. Azurophils may also be elevated. In more chronic or severe cases, a leukopenia, heteropenia with left shift, and anemia may be present.[106,107] Serial hematology may be useful in monitoring response to procedures and therapy.

Plasma biochemical changes often include elevations of albumin, total protein, and alkaline phosphatase. Total calcium is usually elevated consistent with active folliculogenesis in females, but ionized calcium typically remains normal. However, in females with severe nutritional secondary hyperparathyroidism or hypovitaminosis D, ionized calcium may be low (<1.3 mmol/L). Normal females undergoing vitellogenesis will exhibit increases in cholesterol, triglycerides, and lipids. With laboratories making these tests more readily available, cholesterol, triglycerides, and lipoproteins could become a useful tool to monitor reproductive activity in females (see Chapter 34).

Radiography. Radiography is an important tool in diagnosing reproductive activity, diseases, and disorders in reptiles.[108] Radiology can also be utilized in sexing some monomorphic species (see Sex Identification earlier in this chapter). Basic principles of radiography should be utilized including orthogonal studies and, for lateral views, horizontal x-ray beams for squamates and chelonians (see Section 7 for a review of proper techniques). Radiography is useful for determining the presence of, and differentiating between, preovulatory follicles and postovulatory eggs (Fig. 80.32). Radiographically preovulatory follicles (rarely seen in chelonians) are more spherical with no mineralized shell, clustered, and more dorsally positioned. With oviparous species, radiographs are useful to determine normal gravidity and, in cases of suspected dystocia, to identify obstructive or pathological conditions. Radiographs will identify mineralized eggs (squamate egg shells are generally much less calcified than chelonian eggs) and confirm egg numbers, abnormalities (e.g., shell thickening, breaks), ectopic eggs, comparative egg size, and pelvic diameter versus egg size. Additionally, radiography can identify underlying metabolic issues that may be contributing to the dystocia, including nutritional secondary hyperparathyroidism or concurrent coelomic pathology, such as cystic calculi, obstipation, or organomegaly. Oxytocin should not be used without radiographic confirmation that an obvious obstruction does not exist. With viviparous squamates radiography can still be useful, but not until late in gestation when skeletal structures become mineralized (see Section 7 for more information).

Ultrasonography. Ultrasonography is well documented as the imaging modality of choice to evaluate the reproductive tract in squamates (see Chapter 58).[108,109] In chelonians, it is also useful for preovulatory conditions; however, radiography is preferred for postovulatory diagnostic evaluation.[108] Ultrasonography is noninvasive, can often be performed without sedation or anesthesia, allows evaluation of ovarian follicular activity (previtellogenic and vitellogenesis) and oviductal egg/fetus development, and can help identify reproductive disease and disorders such as follicular stasis and dystocia. Numerous reports on the use of ultrasound to evaluate the reproductive anatomy of reptiles have been published (see Chapter 58). A summary of some of this information is shared here. The immature gonads are difficult to visualize with normal clinical ultrasound machines and are generally not useful for sexing immature reptiles. Sonographically, the paired mature testes may be identified dorsally in the mid to caudal coelom as round to ovoid structures (elongated in snakes) that often vary in size and echogenicity depending on season and activity. Generally, the testes have a granular homogenous hyperechoic echogenicity similar to the liver and hypoechoic compared with the echogenicity of the kidneys. Hemipenes were also identified and described sonographically in Gila monsters.[66] With sexual maturity, ovaries are sonographically identified dorsally in the mid to caudal coelom and become obvious during follicular activity. Generally, early in the reproductive cycle previtellogenic follicles are small, distinctly round, and anechoic. In snakes they appear as a long chain of variably sized round anechoic structures, and in lizards as a cluster of round anechoic structures (like a bunch of grapes) (see Fig. 80.20). Ultrasonography has been utilized to determine the sex in mature female monomorphic lizards.[65] Chelonian ovaries are similar in appearance to lizards but are not as closely clustered, and follicles have an increased echogenicity even during the early stages of development.[108] As follicles mature and become vitellogenic they enlarge with yolk deposition and their echogenicity increases from anechoic to more hypoechoic. Depending on species, much of the coelom can be filled with large ovaries containing preovulatory follicles. Follicle size as an indicator for ovulation has been reported in the ball python, short-tailed python, boa constrictor, the viviparous lizard *Barisia,* American alligator, and many chelonian species.[76–78,80,81,110] See the Captive Breeding section of this chapter for more details. Postovulatory eggs become more elongated (squamata), and a hyperechoic wall is noted depending on the degree of species-dependent egg calcification (if oviparous) (see Fig. 80.27). Additionally, postovulatory eggs tend to be more uniformly linear, and anechoic material may be noted between and around the ova, indicating a small amount of normal fluid within the oviduct (see Fig. 80.28). Egg maturation within the oviduct can be monitored in oviparous reptiles depending on the degree of eggshell development, more so in squamates than chelonians (Figs. 80.24 and 80.29).[108,109] The anechoic albumin portion can be differentiated from the more uniform hyperechoic yolk, which decreases with maturation. Late in development a small embryo may sometimes be identified. For viviparous squamates, ultrasonography can be valuable late in gestation to determine whether fetuses are alive as fetal movement and heartbeats may be observed. Additionally, the loss of these indicators late in gestation may help to differentiate dead fetuses and dystocia (with the need for intervention) versus a normal pregnancy. Birth can be reasonably predicted with ultrasonographic monitoring of the loss of yolk. Birth usually occurs about a week after yolk is no longer detectable.

Ultrasonography is an invaluable tool for evaluating obstetric disease and/or complications.[108,111,112] Ultrasonography can be utilized to monitor the status of follicular stasis, as with active resorption or degenerate change the ova progress from a homogenous hypoechoic appearance to a more mixed heterogenic (hypoechoic and anechoic) echogenicity (Fig. 80.33). This progresses to a loss of shape, and follicles are no longer smooth and well demarcated. With resorption they continue to reduce in size; however, with stasis and degenerative change the follicles appear to coalesce, and anechoic fluid often surrounds the follicles. If echogenic free-floating debris is noted within this anechoic fluid, the follicles are likely degenerate and inflamed, and surgical intervention is indicated.[108]

With postovulatory disease such as dystocia or salpingitis, the normally smooth wall of the egg may become irregular with a notable heterogenous echogenicity change, and an increase in free fluid within the oviduct(s) and/or the coelom itself may be noted.[108] In these situations normal oviposition/birth is unlikely, and medical or surgical management is needed.

Ultrasonography can also be valuable for the identification of testicular abnormalities, including cystic or neoplastic changes (see Chapter 58).

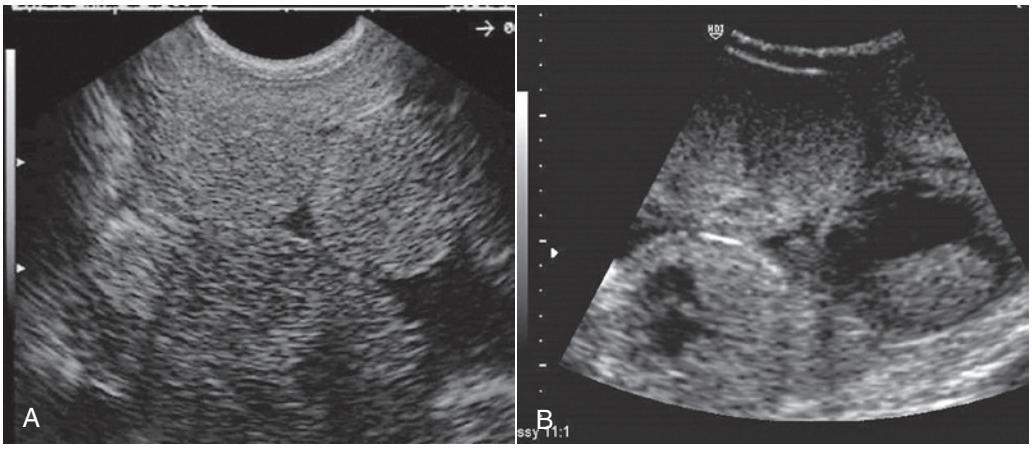

FIG 80.33 (A) Sonographic appearance of normal, homogenous, and hypoechoic, preovulatory ovarian follicles in a bearded dragon (*Pogona vitticeps*). (B) Sonographic appearance of ovarian follicles in a bearded dragon that are degenerative from chronic follicular stasis. Note the irregular hypoechoic/anechoic echogenicity of the follicles that several weeks earlier were uniformly hypoechoic. These changes are similar to those seen with normal follicular resorption so multiple sonographic examinations over time, along with monitoring the lizards condition, may be necessary to determine which condition is occuring. Computed Tomography (CT) and Magnetic Resonance Imaging (MRI). Advanced imaging techniques such as CT and MRI are becoming more affordable technologies in clincal practice and thus can be useful for evaluating reproductive disease. In a recent report on imaging of the reproductive tract of reptiles, CT (compared with other imaging modalities such as radiology and ultrasonography) was most informative with regard to the chelonian reproductive tract.[108] Another advantage with CT over radiolography is its ability to evaluate each ovarian follicle and oviductal egg individually. Specifically CT was useful to identify advanced changes in follicular stasis, as a distinct horizontal leveling of the contents of static ovarian follicles was noted once degeneration started. Horizontal leveling was also evident in retained oviductal eggs with CT, and with more chronic retention a gas cap often formed within, and gas pockets around, the egg (Fig. 80.34A and B).[108] Unfortunately these advanced imaging modalities are not avaialable in most private clinical practices but are routinely available in referral hospitals. Resources for imaging techniques, normal anatomy, and diseases are becoming increasingly available.[108,113] See Section 7 for more information on advanced imaging.

Endoscopy. Endoscopic techniques for the evaluation and surgical manipulation of the chelonian and saurian reproductive tracts have been well described (see Chapters 64 and 65). Endoscopy is minimally invasive compared with traditional surgery, and the basic rigid endoscopic equipment (2.7-mm telescope with 4.8-mm operating sheath system) utilized in most veterinary facilities works well to allow coelomic evaluation of the reproductive tract. Unfortunately, due to unique anatomy, the intimacy of coelomic organs, and multiple membranes/compartments restricting movement, coelomic evaluation of the reproductive tract is more challenging in snakes and crocodilians except via cloacoscopy for evaluation of the urodeum and oviducts.

As described earlier, endoscopy is useful for sexing monomorphic species but coelomic evaluation of the gonads can also provide feedback on reproductive activity and disease or disorders. This is especially valuable when working with threatened or endangered species programs or private breeders relying on production.[114,115]

Generally, the gonads of chelonians and lizards are located dorsally in the mid to caudal coelom; the testis appears as ovoid and smooth and may dramatically vary in size with season and reproductive activity. Some lizard species (e.g., monitors) have thin, pigmented, posthepatic, or postpulmonary membranes that may obscure the gonads and must be incised to allow direct gonad visualization. In cases of male infertility or abnormal appearance of the testes, endoscopic biopsies can be taken for histopathology and microbiological sampling. Depending on follicular activity, ovarian biopsy may be more challenging unless neoplastic or granulomatous changes have replaced the large yolk-filled follicles. Cloacoscopy may also be utilized to evaluate the urodeum, and in some situations the oviduct may be entered for evaluation and possible manipulation of retained eggs/fetuses.

Cytology/Biopsy. A definitive diagnosis of reproductive disease often requires demonstration of a host pathologic response and an etiologic agent. The diagnostic value of cytology is often more limited compared with histopathology, and tissue biopsy is preferred whenever possible. Where it is critical to maintain breeding ability and the abnormal reproductive tract cannot be removed, tissue biopsies can be used for cytology, histopathology, microbiology, parasitology, and even toxicologic evaluation. Biopsy samples may be collected at surgery using biopsy needles (eg, Tru-Cut), endoscopically with biopsy forceps, or with standard wedge or excisional surgical techniques. With reproductive disease, especially in nonbreeding pet or display animals, surgical removal and submission of the entire reproductive tract for laboratory evaluation is recommended.

Coeliotomy. In cases of reproductive disease/disorders surgical evaluation and the removal of all, or part, of the reproductive tract can provide valuable diagnostic information and therapeutic guidance and aid resolution. For pet or display reptiles this is likely the appropriate action either endoscopically or with traditional coeliotomy. With reproductive disorders such as follicular stasis, dystocia, oviductal disease/prolapse, ectopic eggs or yolk coelomitis, coeliotomy is the best surgical option because (1) the use of minimally invasive keyhole techniques are not practical if large amounts of biologic material must be removed, and (2) it allows a more thorough evaluation of the coelom. If one side of the reproductive tract is diseased or damaged (unilateral ovarian or testicular pathology and/or oviductal disease, damage, or prolapse), a unilateral procedure can be performed to preserve reproductive ability in valuable animals. The removed tissue is submitted for

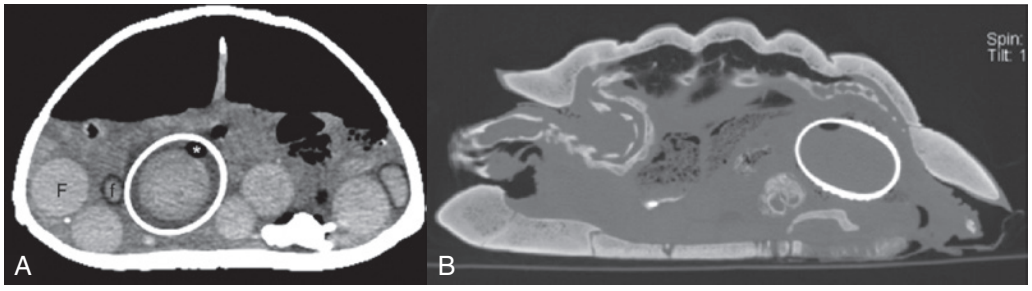

FIG 80.34 (A) Transverse CT image (soft tissue window) of a Hermann's tortoise (*Testudo hermanni*). A normally calcified shell with an unremarkable yolk is seen. A tiny dorsal gas cap suggests dystocia (asterisk). Adjacent to the egg some follicles (F) are visible. One small follicle (f) shows a hypodense peripheral rim indicating atrophy. (B) Sagital CT image (bony window) of another Hermann's tortoise. A thickened egg-shell (being denser then the skeleton) with a rough spiculated surface is positioned within the pelvis. The egg is wider than the maximal diameter of the shell opening near the cloaca. Chronic dystocia is not only indicated because of the egg-shell formation but also by the loss of proper egg contents, a gas cap within the egg shell, and multiple gas pockets around the egg shell. Surgery proved severe inflammation and adhesion of the egg shell to the oviduct. histopathology and microbiological analysis. For the surgical approach to the coelom, see Section 10, Surgery, and for details on surgery of the reproductive tract, see Chapter 105.

General Approach to Treatment

Prevention. During health examinations of juvenile and subadult reptiles, clinicians should discuss maturation and hormonal influences on behavior, familiarize owners with signs of reproductive activity, and offer preventative options for management. Initial studies evaluating hormonal therapy to suppress reproductive activity in reptiles have had mixed results. Captive studies in female veiled chameleons and leopard geckos were performed to evaluate the clinical value of GnRH implants (deslorelin 4.7 mg) and were found to be ineffective in suppressing reproductive activity in these lizards.[116] Tamoxifen (antiestrogen) has been experimentally used to inhibit reproductive activity in leopard geckos, but its clinical value remains untested.[117] Mixed results have also been reported in the use of gonadotropin releasing hormone (GnRH) therapy in males to decrease aggression.[118,119] More research is necessary to determine whether medical hormonal therapy can be clinically useful in the management of reproductive activity and diseases in reptiles. Therefore at this time, offering owners preventative ovariectomy for lizards and chelonians may be the best option to avoid future reproductive problems. Surgical orchiectomy of those species that are particularly aggressive as adults may also be warranted[120] (see Chapter 105).

Initial Therapy. It is important initially to stabilize the patient by providing species-specific thermal support and correcting hydration (see Chapters 46 and 87). Initial therapeutic choices must also be considered carefully to not invalidate future diagnostic testing. For example, blood samples should be collected before fluid therapy and antibiotics delayed until after biopsy and culture whenever possible.

The reproductive tract is not essential for survival and in cases of severe disease, especially in reptiles where reproduction is not important, partial or complete surgical removal of the reproductive tract is often the most effective therapy. If not possible, treating the diseased and/or damaged reproductive tract with the most specific therapy is recommended. Therapy should be based on results of appropriate diagnostic procedures (described earlier) and when possible a well-established connection between pathophysiology and medicinal effects.

COMMON REPRODUCTIVE DISEASES/DISORDERS

Male

Seasonal Behavioral Aggression

Clinical significance. Seasonal *interspecies* aggression toward owners and keepers is a problem with larger species, such as green iguanas, rock iguanas (*Cyclura* spp.), and monitors (*Varanus* spp.).[105] This is a normal seasonal (hormonal) *intraspecies* behavior for these lizards in the wild and allows males to establish territorial hiearchies (see Chapter 13). However, in captivity humans or other family pets are perceived as an "intraspecific threat,"and territorial aggression often ensues with physical attacks, including biting and tail whipping.These behaviors are generally not acceptable to pet owners. Seasonal intraspecies male aggression can also occur with cagemates and is usually associated with breeding groups of reptiles or when multiple mature males are housed together.

Known etiological cause(s). Androgen (testosterone and dihydrotestosterone) elevations associated with sexual maturity can result in seasonal behavioral aggression in male lizards.[120,121] Often, these male lizards are allowed to roam free in the owner's home. In these situations, the entire home becomes the lizard's territory, compared with confinement to a cage. During the breeding season these lizards may become extremely territorial, and humans in the home domain are attacked. Male iguanas have been reported to be aggressive specifically toward women during their menstrual cycle.[122] Presumably male iguanas are detecting pheromones produced by their female owners. Human females are often bitten by iguanas in attempts at breeding, with attacks oriented toward the face or neck, as female iguanas' necks are often bitten and held to secure them during copulation. Often any human males in the household are considered competition, and aggression is oriented toward moving them out of the lizard's (the dominant male's) territory, and when this fails aggressive behavior escalates.[123] Conspecific aggression is usually associated with mature males being housed together during the breeding season. Male combat rituals are common in lizards, snakes, and chelonians. In the wild these interactions end in the submissive male fleeing; however, in captivity the subordinate male may not be able to escape the attack of the dominant male and serious injury or death can result. Owners may unknowingly be housing multiple males together and, with sexual maturity, combat and injury often occurs.

Clinical presentation and diagnostic confirmation. Seasonal aggression must be differentiated from defensive aggression, which occurs in response to being provoked or threatened, or from an animal that is generally aggressive with no seasonal influence. In the northeast United States, breeding typically occurs from the fall to the spring. However, this aggressive behavior can occur any time of the year, often associated with changes in temperature, light cycle, and barometric pressure changes. With conspecific aggression the owner usually presents an injured reptile, from a group (often of an unknown sex ratio) or after introducing an incorrectly sexed pair of reptiles for breeding.

History, presenting complaint, signalment, and proper sexing of the reptile are often diagnostic for this behavioral problem. Some species of lizards can be difficult to sex and may require advanced techniques for identification. Often the aggressive behavior change can be related to reaching sexual maturity, and there is a defined seasonal pattern to the aggression.

Preferred treatment(s). It is important to educate clients, so they can understand that this seasonal behavior is quite normal for a healthy mature (intact) male lizard. Behavioral management options can be considered to reduce seasonal hormonal aggression in lizards; however, often they are unsuccessful. Most importantly, reducing and/or controlling "territory" by not allowing the lizard to free roam in the house may help reduce aggression or allow more control of the behavior, and the owner can take protective measures when working with the lizard in the confined space or cage. Providing a surrogate object for the lizard to mate with such as a stuffed animal or colorful towel may help. Reducing the light cycle to 10 hours or less, avoiding red clothing/objects (or other colors that result in aggressive responses), and not having female family members work with the iguana during their menstruation cycle are all important to implement.[123]

Medical management. There are several reports in the literature evaluating the effectiveness of antiandrogens such as gonadotropin-releasing hormone (GnRH) agonist compounds to chemically castrate lizards and thus help manage aggression, and results have been mixed. In one study involving 18 captive, mature, male green iguanas, three groups were established, a control group, a group that received 0.2 mg/kg of mammalian leuprolide acetate IM, and a group that received 0.4 mg/kg IM. Blood was collected and testosterone levels were determined using radioimmunoassay at day 0, 1, 4, 7, 14, 21, 28, and 35 posttreatment.[118] No significant differences in testosterone levels were found between the groups, and although there were some statistical differences between days of sampling (all involving comparisons with day 0 vs. other days), in all cases testosterone levels were lower on day 0. This study concluded that mammalian leuprolide acetate at these doses did not significantly reduce testosterone levels in captive male

green iguanas.[118] A male bearded dragon was implanted with a 4.7 mg deslorelin (GnRH agonist) implant, and subjectively appeared to be less aggressive toward the owner for 2 months after implantation, but no further follow-up was available.[119] Anecdotal reports have also indicated that GnRH agonist may be helpful in managing seasonal (testosterone driven) aggression in reptiles, but more research is necessary to determine efficacy of these hormones.

Surgery. Currently orchiectomy is the treatment of choice. Before considering orchiectomy, it is important to characterize the aggressive behavior. If before or after sexual maturity the lizard is consistently aggressive (year-round), then orchiectomy may not be effective, as the behavior is not likely solely androgen driven. However, in males where aggressive behavior began after sexual maturity and appears to be seasonal, orchiectomy may be beneficial. In iguanas the best results are achieved when orchiectomy is performed in prepubescent males.[124] Once iguanas are sexually mature and aggressive behavior has become established, orchiectomy may be less effective. One study involving 16 adult mature male iguanas, 3 experimental groups were studied; one group was castrated before the onset of breeding season aggression, another group was castrated during the breeding season while exhibiting aggressive behavior, and the last group was sham operated but no orchiectomy was performed.[120] The study found a statistically significant reduction in the aggressive behavior in the group orchiectomized before the onset of the breeding season. No significant reduction in aggression was found between the group orchiectomized during the breeding season and the control group. Thus orchiectomy was less succesful in managing aggression once hormonal behavior was initiated. However, the same authors reported that more than 60 male green iguanas were subsequently castrated and monitored for up to 3 years afterward, and orchiectomy reduced or eliminated aggression in 70% of the iguanas.[123] See Chapter 105 for details on performing orchiectomy.

Prognosis and prevention. Prevention provides the best prognosis, with orchiectomy being performed before sexual maturity.[124] Once sexually mature and aggressive hormonal behavior has already been established, orchiectomy may be less effective. For conspecific aggression, the prognosis is good if injuries can be successfully treated, reptiles are then properly sexed, and males separated to minimize future problems. In breeding colonies, providing enough space and visual barriers within the enclosure may reduce male combat interaction and aggression.

Veterinarians should educate owners about these potential behavioral changes at sexual maturity and discuss elective orchiectomy during young (male) lizard consultations (value of identifying the sex). However, with early orchiectomy, and the subsequent loss of testosterone influence, male secondary sexual characteristics will not develop. For example, prepubescent orchiectomized male iguanas will not develop the same large body and head size, larger dewlap, jowls, or crests and spikes that owners may desire with owning a "majestic" mature male iguana. This information should be understood by the owner before orchiectomy.

Having the owner initiate environmental changes before the start of the "season" may help to manage hormonal aggression. If the lizard is free-roaming in the house, restricting the lizard's territory to a single room or caging them, during this time of the year, may help with management. In some instances rehoming or euthanasia may have to be considered, often as a result of a severe injury to a (human) family member.

Testicular Disorders

Orchitis

Clinical significance and known etiological cause(s). Orchitis in male reptiles is uncommon. Presentation for low fertility or reproductive-related issues may result in evaluation of testes and a possible diagnosis of orchitis. However, damage and pathology of the copulatory organs in male reptiles *is* common and infectious agents associated with these problems can result in cloacitis and scent gland adenitis with possible ascending infection. In breeding males venereal transmission of bacterial (and other infectious agents) organisms is possible. Adjacent coelomic pathology may involve the testes, and a variety of neoplasms have been described (see Neoplasia section later).

Clinical presentation and diagnostic confirmation. Physical examination may reveal coelomic distention/guarding, weight loss, lethargy and depression, pale mucous membranes, and dehydration. Orchitis may mimic changes associated with normal reproductive activity, such as seasonal testicular recrudescence, and must be differentiated from normal physiological changes.

Ultrasonography may be useful to detect morphological changes, especially in unilateral cases of orchitis. Ultrasound-guided aspiration may be possible but is potentially high risk. Radiography or advanced imaging modalities such as CT and MRI may be useful in some cases (see imaging in Clinical Investigation earlier).

Coelioscopy is minimally invasive and is useful to diagnose orchitis (less so in snakes) by allowing direct visualization. Most importantly, diagnostic confirmation can be achieved by collecting aspirates or biopsies for cytology, microbiology, and histopathology. Additionally, coelioscopy may allow therapeutic procedures as well. See Chapters 64 and 65, for more details on these endoscopic procedures. Exploratory coeliotomy is more invasive but can confirm a diagnosis, provides the most thorough coelomic evaluation, and allows therapeutic procedures.

Preferred treatment(s), prognosis, and prevention. In a reptile that is not part of a breeding program, surgical sterilization (orchiectomy) offers the best chance of resolution. In breeding males with unilateral disease, a unilateral orchiectomy can be performed. In these cases, microbiology and histopathology should be performed on removed tissues to direct therapeutics for any remaining reproductive tract (see Chapter 105). In mild cases or cases where future reproduction is critical and diagnostic evaluation has indicated that treatment may be effective, antiinflammatories and appropriate antimicrobial therapy may be initiated based on microbiology and histopathology.

The prognosis depends on the condition of the reptile at presentation, the duration of the condition, and the extent of pathology. Prognosis for survival may be good if orchiectomy is performed but eliminates future reproduction if bilateral. For breeding reptiles, providing appropriate husbandry, nutrition, preventive health programs (including quarantine), implementing safe breeding practices (breeding environment hygiene, not overextending males, etc), and regular veterinary evaluations (including necropsy and histopathology of losses and culls) can help reduce the incidence of reproductive disease.

Copulatory Organ Pathology(Prolapse and Abscessation)

Clinical significance and known etiological cause(s). Trauma, prolapse, and infection of the phallus or hemipenes is a common clinical presentation. In one study involving a review of 3000 reptiles presented for cloacal prolapses, 35% of the prolapses involved the male reproductive organ.[125] A good understanding of the anatomy and function of this organ is important for management. The organ does not house the urethra and plays no role in the urinary system, thus management is not as complicated as with mammalian species.

Typically prolapse occurs as a result of trauma. Traumatized tissue becomes engorged, making retraction difficult, and the exposed tissue is subjected to further damage, infection, and necrosis.

Prolapse, trauma, and infection/abscessation is seen most commonly in sexually mature, often actively breeding males. Thus the incidence of prolapse and trauma increases during the breeding season or with perceived seasonal changes. If breeding animals are housed on rough

VetBooks.ir

or contaminated particulate substrates such as mulch or wood shavings, the likelihood of trauma and infection is increased. Male snakes breeding too many females in a season (breeders typically move males from female to female) may develop hemipenal trauma, infection, and possible prolapse (Fig. 80.35). Single housed male chelonians may repeatedly attempt to mount and breed females or even inanimate objects in their environment, resulting in phallus trauma.

Trauma or pathology associated with the vertebral spine and spinal cord can result in neurological damage/dysfunction and organ prolapse. Prolapse of the hemipenes is common in young growing herbivorous and insectivorous lizards due to nutritional secondary hyperparathyroidism (NSHP) resulting in spinal deformities and fractures. NSHP in chelonians often results in carapacial deformities involving the vertebrae and spinal cord, resulting in neurologic damage/dysfunction and prolapse. Hypovitaminosis A in lizards may also contribute to hemipenal abscess and prolapse as squamous metaplasia may increase the incidence of hemipenal plugs (accumulation of seminal material and sloughing skin).[116,126] This retained material results in swelling, inflammation, and secondary bacterial involvement with possible abscessation (Fig. 80.36).

Other known causes include metabolic disease, colonic/cloacal obstruction associated with urinary calculi, and renomegaly in lizards with intrapelvic kidneys (e.g., green iguana) resulting in obstipation and tenesmus.

Clinical presentation. Owners are frequently alarmed by the appearance of a prolapse, and reptiles are often presented as an emergency. The prolapse is usually engorged and hemorrhagic with associated discharge from exposure trauma and, in severe cases, necrotic. The prolapsed phallus/hemipenis must be differentiated from other possible prolapsed tissue, including cloaca, colon, or bladder (in chelonians and some lizards). See Chapter 75 for details on determining the origin of prolapsed cloacal tissue. In squamates the hemipenal tissue is located within the base of the tail, so prolapsed tissue will originate from the caudal margin of the vent (Fig. 80.37A). In chelonians the phallus may be more difficult to differentiate as it originates from the floor of the urodeum but is generally a large, tubular, often elaborate structure (see Fig. 80.37B).

Squamates with hemipenal abscesses and impacted seminal plugs may be presented for asymmetry (although can be bilateral) and swelling

at the base of the tail, often with discharge and in severe cases ulceration of the skin. In snakes, scent gland adenitis may be concurrent.

Diagnostic confirmation. For copulatory organ prolapses, examination of the structure is usually diagnostic. For partial prolapses, hemipenal abscesses or hemipenal plugs, sedation, or anesthesia may be required for thorough evaluation. In cases with infection and abscessation, culture and sensitivity is useful to determine specific pathogens and direct therapy. In breeding squamates with hemipenal abscessation (especially if housed on mulch or soil) biopsy of debrided tissue or an amputated hemipenis (if not salvageable) can be collected for histopathology and microbiology. Radiography or advanced imaging such as CT or MRI may be useful to look for spinal involvement in cases where prolapse may be the result of neurological dysfunction. Also, imaging may be helpful to rule out other causes of prolapse such as coelomic obstructive disease (e.g., bladder stone, obstipation).

Preferred treatment(s). Evaluating the prolapsed copulatory organ to assess the extent of the damage, determining the underlying reasons for the prolapse, and understanding the goals of the owner are all important considerations when developing a therapeutic plan.

Often at presentation the prolapsed organ has extensive damage with desiccation and necrosis, and for most nonbreeding animals, amputation is often preferred. Amputation of the phallus/hemipenis does not affect the urinary system, and in squamates (with paired copulatory organs) reproductive potential is maintained with a second hemipenis. Anesthesia or sedation is required; see Chapters 105 and 106 for surgical techniques.

For breeding reptiles, attempting to repair and replace the copulatory organ(s) may be necessary. If the organ appears viable it can be gently cleaned with saline and the swelling reduced using hypertonic solutions such as 50% dextrose. Topical lidocaine or bupivacaine may help minimize discomfort during replacement. When replacing a prolapsed hemipenis it is critical for the tissue to be inverted back into the base of the tail rather than simply replaced into the cloaca. General anesthesia is often required for proper replacement, and stay sutures can be placed across the vent opening, either unilateral or bilateral, to help hold the copulatory organ in place. This allows organ protection and healing while underlying causes are addressed. With recurrent or chronic prolapse, amputation is recommended.

In lizards with hemipenal plugs, gentle removal of the adhered material and flushing of the hemipenis is necessary. Topical anesthesia or general anesthesia may be necessary to facilitate cleaning and evaluation. Topical wound gels or creams (e.g., 1% silver sulfadiazine cream) can be applied to the damaged tissues. With severe inflammation and secondary bacterial involvement, systemic NSAIDs and antimicrobials may be indicated. Dietary improvement and vitamin A supplementation in lizards is often important (see Chapter 122).

In breeding snakes with hemipenal trauma, cellulitis, and abscessation, general anesthesia is required to thoroughly evaluate the hemipenes. Magnification is helpful because delicate debridement of infected tissue is necessary to attempt to maintain normal architecture. Often hemipenal infections in these snakes present as invasive multifocal nodular abscesses (see Fig. 80.35); the organ is quite vascular, and hemorrhage makes it difficult to see all lesions as surgery progresses. Several surgeries may be necessary to ensure removal of all affected tissue and maintain as much healthy hemipenal tissue as possible.[127,128] One or both hemipenes may be involved, and sometimes one hemipenis may need to be amputated, based on severity, but the other hemipenis can be salvaged as described. Systemic broad-spectrum antimicrobials should be initiated based on initial cytology and modified based on microbiology and histopathology results.

Prognosis and prevention. Prognosis is good for survival as the phallus and hemipenes are not part of the urinary system and can be removed if they cannot be repaired. Additionally, because squamates have two hemipenes, amputation of one will still allow copulation and future breeding. Chelonians only have one copulatory organ thus amputation results in a loss of reproductive ability. If prolapse and damage of the copulatory organ is the result of neurological dysfunction due to spinal pathology, the prognosis is guarded to poor because obstipation and prolapse of the cloaca and colon often follow.

Breeding male reptiles should not service too many females as overuse of the phallus or hemipenis may increase the incidence of trauma, abscessation, and prolapse. Keepers should maintain a clean breeding environment and avoid using rough particulate substrates to minimize trauma to the copulatory organ. Maintaining adequate levels of vitamin A is important to reduce the incidence of squamous metaplasia and associated hemipenal plug problems in lizards.

Providing a diet with adequate calcium and vitamin D_3 in growing lizards and chelonians is important to prevent spinal abnormalities resulting from NSHP and subsequent prolapse from neurologic dysfunction.

Female

Behavioral Aggression.

In the authors' experience ovariectomy in female iguanas (and other lizard species), usually performed for preventative or medical reasons, may result in the development of androgen-driven characteristics, including the development of male secondary sexual characteristics and aggression.[126]

In a study involving free-living female mountain spiny lizards (*Sceloporus jarrovi*), females were ovariectomized and returned to their natural environment for behavior observation.[129] Females of this species aggressively defend territories from other females, and the effects of ovariectomy itself and the administration of a testosterone implant to ovariectomized females was evaluated. The study determined that estrogen and testosterone were both necessary to elicit the normal territorial aggression displayed by females of this species.[129] Interestingly, however, postovariectomized lizards' plasma estrogen levels in the study were reduced, but testosterone plasma levels remained the same as the sham ovariectomized lizards. This may explain what is seen clinically, as ovariectomized female lizards appear to develop androgen-driven changes associated with persistent testosterone but reduced estrogen. More research is necessary to understand what is occurring hormonally in these cases. Clinically, however, ovariectomy in lizards has been found to sometimes result in these issues, and owners must be warned about the potential for these behavior and morphological changes before surgery. Ovarian neoplasia/or disease could also result in pathological changes in sex hormone production which may also result in hormonal-based aggression.

Clinical presentation, preferred treatment(s), prognosis, and prevention. Generally, females presenting with this condition have a history of ovariectomy. Often these females will show evidence of male secondary sexual characteristics such as an increase in head size, larger jowls, dewlap, dorsal spines, and more obvious femoral/preanal pores. History, signalment, and presenting complaint will typically confirm a diagnosis. With ovarian neoplasia or pathology, signalment and presentation may be similar but without history of ovariectomy.

See discussion on male hormonal aggression for environmental changes that can be used to help reduce and mediate these behaviors. Many of these suggestions are based on utilizing safer practices to protect the owner when working with these aggressive lizards. Mixed study results and anecdotal reports have indicated that GnRH agonist may be helpful in managing seasonal (testosterone-driven) aggression in reptiles and thus may help these females, but more research is necessary. In cases where ovarian pathology is suspected to be causing hormonal changes, a thorough evaluation of the ovary and likely surgical ovariectomy is indicated.

VetBooks.ir

Prognosis is good for survival; however, depending on the lizard's response to environmental manipulation or possible hormonal therapy, the prognosis for compatability as a pet or display animal may be poor. Prevention is a challenge, as in most cases these females have been ovariectomized due to reproductive diseases or disorders as a life-preserving procedure. It does add caution to the general recommendation of preventative ovariectomy in some lizard species. Eliminating one condition (reproductive disease) could create new issues with aggressive behavior. Owners should be forewarned about this possibility before ovariectomy.

Ovarian Disorders

Follicular stasis

Clinical significance and known etiological (causes). Ovarian (preovulatory) follicular stasis in reptiles occurs when mature follicles develop but do not ovulate or resorb, becoming static and eventually degenerative. This condition occurs commonly in lizards, chelonians, and less often in snakes kept as single pets or display animals. Follicular stasis is usually a seasonal problem because hormonal cycles, and thus reproductive activity and breeding of most captive reptiles (temperate species), occurs at specific times of the year. However, in captivity environmental factors may result in reproductive activity in reptiles at any time of the year.

Follicular stasis has an increased incidence and risk with single or pet reptile where, if the female is healthy and has adequate energy reserves, she will often proceed with active folliculogenesis. Under normal conditions the female would likely be courted and bred by a male and proceed to ovulation and oviposition. However in the captive environment this may not occur (although some of these females will ovulate and produce infertile eggs). In these captive single females, does the lack of a male play a role in contributing to this condition? A study using ultrasonography to monitor the development of ovarian follicles in captive short-tail (blood) pythons found that at the onset of the reproductive season all females initiated early follicular development; however, only females that were already housed with males actually initiated vitellogenesis, ovulated, and oviposited viable eggs.[32] Perhaps in other reptiles the male's presence is not always necessary for progression to vitellogenesis but plays an important role in influencing ovulation or resorption. Metabolic disease such as NSHP may contribute to follicular stasis because calcium plays an important role in the vitellogenic cycle. More research is needed to better understand this condition, as the etiologies for follicular stasis are multifactorial and complex, and the definitive cause in many of these cases is not determined.

Clinical presentation. Distinguishing follicular stasis (at least initially) from normal folliculogenesis can be challenging, and a diagnosis is sometimes made prematurely, and unnecessary treatment instigated. A clear understanding of the reproductive biology of the species, a thorough history, physical examination, and, in some cases, supplemental diagnostic tests may be necessary to determine the need for intervention.

Historically, reptiles with follicular stasis may be restless, pacing and climbing, looking for possible mates or nesting sites. Oviparous lizards and chelonians may dig in planters or substrate. Female aquatic turtles may spend extended time out of the water. Appetite and water intake may be reduced or absent. Coelomic distention with reduced body condition, anorexia, and behavior changes may be noted. Differential diagnoses for a coelomic mass include fecal masses, cystic calculi, abscesses, and tumors and should all be considered or ruled out.

On physical examination palpation may confirm preovulatory follicles in squamates, but sometimes it may be difficult to differentiate preovulatory follicles from postovulatory eggs. Ovarian follicles tend to be more dorsal and spherical and not as mobile as oviductal eggs, which are usually more oblong and ventral/caudal in the coelom.

Diagnostic confirmation

Hematology and biochemistry. Plasma biochemical changes often include elevations of total calcium; however, ionized calcium is often normal. Hematology may show a stress leukogram or, in cases of inflammation or infection, a leukocytosis, or leukopenia with left shift due to sequestration may be present. In more chronic cases anemia may be observed. In captive tortoises, clinical pathological findings consistently included elevations of calcium, albumin, total protein, alkaline phosphatase, and hematological changes including anemia, leukopenia, and heteropenia.[107]

Imaging. Radiography is an important tool to differentiate between follicular stasis and dystocia in squamates. (See Section 7 and associated radiography chapters.) Radiographically squamate follicular stasis often appears as a cluster of spherical, dorsal, homogenous, soft tissue structures that lack a shell. Radiography can also identify contributing, and/or concurrent, coelomic pathology, such as cystic calculi, obstipation, or organomegaly. Radiography may also help to identify abnormalities of bone associated with metabolic diseases such as NSHP or renal secondary hyperparathyroidism (RSHP) and the resulting calcium metabolism issues that may contribute to follicular stasis.

Ultrasonography is preferred for identification of follicular stasis and to differentiate between follicular stasis and poorly shelled postovulatory eggs. Sonographically, vitellogenic follicles show no hyperechoic shell and are uniformly hypoechoic and clustered. Ultrasonography can be utilized to monitor follicular progress. With active resorption or degenerate changes the ova progress from homogenous and hypoechoic to a more mixed (hypoechoic and anechoic) echogenicity (see Fig. 80.33A and B). This progresses to a loss of shape, and follicles become less spherical and poorly demarcated. With resorption they continue to reduce in size, but with stasis and degeneration the follicles coalesce with surrounding anechoic fluid often evident. If echogenic free-floating debris is noted within this anechoic fluid the ova are likely degenerate and inflamed, and surgical intervention is indicated.[108,111]

CT and MRI may also be indicated in some cases, and this technology is becoming more accessible. Specifically in managing follicular stasis, CT (versus radiography) allows each ovarian follicle to be individually evaluated. CT is more useful for identifying advanced changes, including distinct horizontal leveling of the contents of degenerating follicles indicating the need for intervention.[108]

Preferred treatment(s). Treatment for follicular stasis may differ depending on the species and objectives of the owner. If the reptile is a pet or display animal then ovariectomy as soon as (safely) possible is preferred. If maintaining the reptile's breeding ability is important, using the least invasive technique(s) to resolve issues and still allow future reproduction is the goal.

For pet or nonbred squamates, and chelonians with follicular stasis where the patient is considered healthy, a nest box can be provided and the reptile (except snakes) sent home on calcium glubionate (23 mg/mL) at 1 mL/kg PO SID-BID for 2 to 3 weeks depending on dietary history. Appetite and behavior should be monitored, and reevaluation is recommended in 2 to 3 weeks to determine whether resorption or ovulation has occurred. Ovariectomy may also be offered at initial presentation, as this may be the safest way to ensure health (owners often choose this option). If a breeding female (and healthy on examination), she can be paired with a male and a nesting/laying environment provided.

Once stable, or if returning with no change or follicular degenerative changes evident (utilizing ultrasonography or CT), ovariectomy is recommended. For follicular stasis cases if the patient is not considered

healthy they must be stabilized by providing appropriate thermal support (for the species) and addressing hydration issues. After warming and hydrating the patient as necessary, additional medical therapy may be initiated, including calcium (lizards and chelonians), nonsteroidal antiinflammatories (NSAIDS), opiates (analgesia and mild sedation if necessary), and antimicrobials if infection is present. Once considered stable, ovariectomy is recommended (Fig. 80.38A and B). It is not useful to use oxytocin in cases of follicular stasis as ova are not in the oviduct. See Chapter 105, for details on performing ovariectomy.

Prognosis and prevention. Prognosis and outcome are favorable for follicular stasis cases with early diagnosis and intervention. Chronic cases are more likely to have associated pathology, including degenerative changes, and may require surgical intervention. The prognosis is good for survival but ovariectomy obviously renders the animal sterile, which may be unacceptable for breeders.

During health examinations of female reptiles, clinicians should discuss the likelihood of eventual hormonal influences, familiarize owners with signs of reproductive activity, and offer preventative ovariectomy to clients as an option to avoid future reproductive issues (see Chapter 105).

Since calcium plays an important role in successful reproduction, the diet of reproductively active reptiles should be reviewed to ensure adequate levels of calcium and vitamin D_3 (see Chapter 27). Breeding females that mature quickly (lizards) should be monitored closely for reproductive activity, and if noted, providing access to a male may help reduce the incidence of follicular stasis.

Oophoritis

Clinical significance and known etiologic cause(s). Oophoritis is usually associated with folliculogenesis or dystocia in captive reptiles. Follicular stasis often results in oophoritis when static follicles become degenerate and secondarily infected. Ovarian follicular stasis, yolk coelomitis, dystocia, and ectopic ova can be inflammatory disorders that predispose to opportunistic bacterial or fungal oophoritis.

Clinical presentation and diagnostic confirmation. See Clinical Presentation for Follicular Stasis and Ectopic Follicles and Yolk Coelomitis. Physical examination findings may include coelomic distention and sensitivity, weight loss, lethargy and depression, pale mucous membranes, and clinical dehydration.

As with follicular stasis, ultrasonography can be useful for diagnosis. Sonographically degenerate and inflammatory changes in ovarian follicles may include a loss of their typical round, well-demarcated shape, and follicles may appear to coalesce, often resulting in rupture and leakage (see Ectopic Follicles and Yolk Coelomitis). Ultrasound-guided aspirates of the ovary are possible but higher risk. Radiography or other advanced imaging modalities such as CT and MRI may be useful in some cases.

Coelioscopy is minimally invasive and is useful for allowing direct visualization of the ovary. Most importantly, diagnostic confirmation can be achieved with endoscopy by collecting aspirates or biopsies for cytology, microbiology, and histopathology. Additionally, coelioscopy may allow therapeutic procedures (see Chapters 64 and 65 for more details).

However, in cases of active coelomitis, yolk coelomitis, and ectopic eggs, exploratory coeliotomy is preferred over coelioscopy, because, in addition to diagnostic confirmation (direct sample collection), it facilitates complete coelomic evaluation and more extensive surgical intervention (e.g., removal of inflammatory material and ovariectomy). In the authors' experience microbiologic sampling using these techniques often results in the identification of gram-negative bacteria.

Preferred treatment(s), prognosis, and prevention. For a reptile that is not part of a breeding program, surgical sterilization (ovariectomy) is the best resolution. In breeding reptiles with unilateral disease, a unilateral ovariectomy can be performed. In these cases, microbiology and histopathology should be performed on removed tissues to direct therapy for the remaining reproductive tract. See Chapter 105 for details on performing these procedures.

In mild cases and/or cases in which future reproduction is critical and diagnostic evaluation has indicated that treatment may be effective, antiinflammatories and appropriate antimicrobial therapy may be initiated based on culture and sensitivity testing and histopathology.

The prognosis depends on the condition of the reptile at presentation, the duration of the disease, and the extent of the pathology (see Prognosis for Follicular Stasis and Ectopic Follicles and Yolk Coelomitis).

Additionally, for breeding reptiles, providing appropriate husbandry, nutrition, and preventive health programs (including quarantine) and implementing safe breeding practices (e.g., breeding environment hygiene, not overextending males) and regular veterinary evaluations (including necropsy and histopathology on losses and culls) can help reduce the incidence of reproductive disease.

Ectopic follicles and yolk coelomitis

Clinical significance and known etiological cause(s). Chronicity or complications associated with preovulatory follicular stasis can lead to ovarian follicles becoming degenerate or damaged, resulting in leakage or rupture, with the release of free yolk into the coelom resulting in coelomitis. Follicular stasis, and thus yolk coelomitis, is most commonly seen in lizards, followed by chelonians and less frequently in snakes.[37,116,126,130–132] Free yolk material results in an inflammatory response in the coelom, often with secondary bacterial infection and sepsis (Fig. 80.39).

See previous discussion for a description of follicular stasis and etiologies, however once the condition occurs the static ovarian follicles become degenerate, often coalescing and becoming friable. Trauma, continued degeneration, and secondary bacterial involvement can increase the risk of rupture and yolk leakage into the coelom.[37,116,130–132]

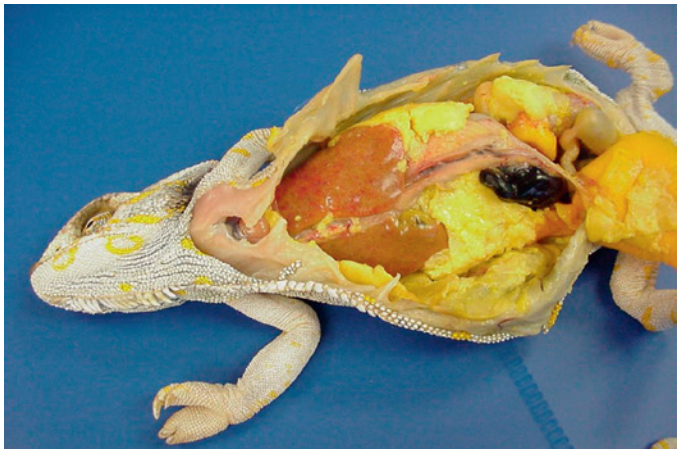

FIG 80.39 A female veiled chameleon (*Chamalaleo calyptratus*) with severe yolk coelomitis identified at necropsy. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

Clinical presentation and diagnostic confirmation. This condition is often a sequela to follicular stasis as previously discussed. Owners may have appreciated behavioral changes such as restle ssness, nesting, and aggressive behaviors. Tenesmus, anorexia, weight loss, and weakness may occur, and more advanced cases may present obtunded. Additional physical examination findings may include coelomic distention and sensitivity, pale mucous membranes, and dehydration.

Abnormalities in the hemogram and biochemistry are the same as described for follicular stasis and reflect severe inflammatory changes associated with coelomitis and sepsis. Dramatic leukocytosis (or leukopenia and a left shift) with toxic changes and azurophilia are common in squamates, whereas in more chronic cases anemi a and leukopenia may be noted.[106,107]

Imaging, especially ultrasonography, can be useful in diagnosing this condition. Sonographically degenerate follicles will have a loss of their round, well-demarcated shape and appear to coalesce (see Fig. 80.33A and B). Free anechoic fluid in the coelom with echogenic free-floating debris may indicate degenerative changes associated with the inflammatory response to yolk.[108,111,112] Ultrasound-guided aspiration of free coelomic fluid often yields yellow flocculent material, which is cytologically consistent with inflammation and proteinaceous debris. Other advanced imaging modalities can be utilized when necessary and available.

Coelioscopy may be used to confirm these conditions, but complications associated with free fluid, yolk, and possible adhesions make endoscopy more challenging, and coeliotomy is often preferred. Exploratory coeliotomy will confirm the diagnosis, facilitate thorough coelomic evaluation, and allow therapeutic procedures. Samples can be collected for micriobiological and histopathological evaluation during these confirmatory procedures.

Preferred treatment(s). Surgical intervention is usually required for treatment and resolution of yolk coelomitis. Once the patient is stable and under general anesthesia a coeliotomy is performed. The entire coelom is evaluated, paying particular attention to the reproductive tract, and any ectopic or diseased material debrided and removed. For pet or display reptiles a bilateral ovariectomy is performed to eliminate reoccurrence. In breeding reptiles a unilateral ovariectomy and salpingectomy can be performed if one side of the reproductive tract is diseased or damaged and cannot be repaired. Any damaged/abnormal reproductive tissue can be removed and submitted for microbiological analysis and histopathology to guide therapy. The coelom is thoroughly and copiously lavaged before closure. Aggressive postoperative support and systemic antimicrobials, antiinflammatories and analgesics are initiated as necessary.

Prognosis and prevention. Prognosis depends on the reptile's condition at presentation and duration, and the extent of the coelomic pathology. With surgical evaluation of the coelom; removal of the reproductive material; copius lavage of the coelom; aggressive postoperative support; and systemic antimicrobials, antiinflammatories, and analgesics, the prognosis is guarded to good. Lizards generally have a better prognosis than chelonians, likely due to easier access to the coelom and earlier detection.[37,126] In severe cases and/or chronic cases where the patient is presented in a debilitated state the prognosis is poor.

For pet or display reptiles, bilateral ovariectomy can prevent these conditions. For breeding reptiles, providing optimal management is important to reduce reproductive complications. Prebreeding health evaluation of females may be valuable to ensure they are sound before the stress of reproduction. In some species with high fecundity, alternating years of breeding may reduce reproductive complications.

Oviductal Disorders

Salpingitis and pyosalpinx

Clinical significance and known etiological cause(s). Dystocia, especially chronic egg retention, often results in inflammatory changes in the oviduct, with secondary bacterial involvement and subsequent salpingitis (Fig. 80.40A).[133] Yolk coelomitis, dystocia, and ectopic ova can all be inflammatory disorders that predispose to opportunistic bacterial salpingitis. Actively breeding females may develop cloacitis associated with copulation and develop an ascending bacterial salpingitis. This often occurs in snakes bred on unsanitary particulate substrates.[127] Venereal transmission of bacteria (and other infectious agents) to females by male snakes with hemipenal abscesses and/or scent gland adenitis is possible.

Clinical presentation and diagnostic confirmation. See clinical presentation for Dystocia, Oviduct Prolapse, and Oviductal Rupture and Ectopic Eggs. Ultrasonography can be useful, and the oviduct(s) may be thickened with increased echogenicity, with evidence of accumulated fluid or flocculent debris. Ultrasound-guided aspiration of fluid within the oviduct is often consistent with inflammation and proteinaceous debris. Sampling often results in the identification of gram-negative bacteria by culture and cytology of gram-stained slides. Radiography is often unrewarding unless there is mineralization or bacterial gas production within the oviducts. With CT/MRI especially, postcontrast studies may demonstrate increased size and volume of the oviducts and increased blood flow due to inflammation.

Coelioscopy can help directly visualize the serosal surfaces of the oviduct and detect gross enlargement, fluid accumulation, and abnormal soft tissue masses; however, salpingoscopy can provide access to the luminal surfaces via cloacoscopy using saline infusion. Careful evaluation of the oviductal mucosa and collection of biopsies for diagnostic evaluation are possible (see Chapters 64 and 65 for more details). Exploratory coeliotomy is more invasive but can confirm a diagnosis, provide the most thorough coelomic evaluation, and allow therapeutic procedures.

Preferred treatment(s), prognosis, and prevention. In nonbreeding reptiles, surgical sterilization (ovariosalpingectomy) is the best resolution (see Fig. 80.40B). In breeding reptiles, if conditions are unilateral, a unilateral ovariosalpingectomy can be performed. In these cases, microbiology and histopathology should direct additional therapeutics. In mild cases or cases where future reproduction is critical and diagnostic evaluation has indicated that treatment may be effective, antiinflammatories and appropriate antimicrobial therapy may be initiated based

FIG 80.40 Exploratory coeliotomy performed on a green iguana (*Iguana iguana*) with a history of chronic dystocia (after laying a partial clutch of eggs weeks earlier). on culture and sensitivity and histopathology.[133] Contrary to dogs and cats, there appears to be little to no information on the medical treatment of salpingitis/pyosalpinx in reptiles; however, if surgery is not possible, endoscopic oviductal lavage and progestogen therapy could be considered.[134]

The prognosis after ovariosalpingectomy is generally guarded to good, but dependent on the extent and severity of the condition. Preventative ovariosalpingectomy will help avoid future disease. Furthermore, salpingitis has not been reported in ovariectomized reptiles, where healthy oviducts were left in situ.

Oviductal rupture and ectopic eggs

Clinical significance and known etiological cause(s). Ectopic eggs usually occur with complications of dystocia involving rupture of the oviduct, releasing eggs into the coelom, and possible associated oviduct prolapse.The condition can be iatrogenic with owners attempting to manipulate retained oviductal eggs and/or damaging the oviduct with inappropriate use of oxytocin for obstructive dystocia.[127,131,135]

Chelonians may present with an ectopic egg(s) in the bladder; initially the egg is passed normally into the cloaca before being retropulsed into the bladder and retained.[37,132] Ectopic eggs often result in an inflammatory response in the coelom (or bladder), often with secondary infection and sepsis. Ectopic eggs in the coelom and bladder can contribute to retention of other eggs still present in the reproductive tract. See discussions on Dystocia and Oviductal Prolapse for more information on these conditions.

Clinical presentation and diagnostic confirmation. The clinical presentation, diagnostic testing, and confirmation are similar to those for the Dystocia discussion and should be reviewed for more detail.

Imaging is useful in diagnosing these conditions. Radiography can identify retained shelled or mineralized eggs or fetuses, but it may be difficult to determine whether they are within the oviduct or free in the coelom. Ectopic eggs in the bladder are not uncommon in chelonians and may have an abnormal shape, with irregularly thickened shells and a lamellar appearance due to uric acid and mineral deposition (Fig. 80.41).[108,132] Ultrasonography can also detect ectopic eggs/fetuses and the prescence of free anechoic fluid in the coelom. Echogenic free-floating debris indicates degenerative changes associated with the inflammatory response to ectopic eggs.[108,111,112] Ultrasound-guided aspiration of free

coelomic fluid often yields flocculent material, which on cytology is consistent with inflammation. Other advanced imaging modalities can be utilized when necessary and available (see CT and MRI in Dystocia section). However, with most imaging modalities it can still be challenging, due to the thin bladder wall, to differentiate between eggs in the bladder and any free in the coelom.

Coelioscopy may be used to confirm these conditions, but complications associated with free fluid, and possible adhesions, make endoscopy more challenging and coeliotomy is often preferred. Exploratory coeliotomy facilitates confirmation of diagnosis, thorough coelomic evaluation, and therapeutic/surgical resolution.

Preferred treatment(s). Coeliotomy and surgical removal of ectopic eggs is required. The coelom and especially the reproductive tract are thoroughly evaluated but it it not always possible to find the oviductal injury (which may have healed before diagnosis). Any ectopic eggs must be removed, and the coelom copiously lavaged before closure. If the oviducts are healthy, a bilateral ovariectomy is performed to eliminate reoccurrence. If there is any doubt regarding the status of the oviducts, then complete ovariosalpingectomy should be performed. In valuable breeding reptiles, surgical repair of the damaged salpinx can be undertaken using fine absorbable suture or, if the damage/disease is extensive, a unilateral ovariectomy and salpingectomy can be performed (see Chapter 105). Any damaged/abnormal reproductive tissue removed should be submitted for microbiologic analysis and histopathology to guide additional therapy. Aggressive postoperative support, antiinflammatories, and analgesics are initiated. Antimicrobials may be required and should be directed by sensitivity testing.

Prognosis and prevention. For simple ectopic eggs without evidence of coelomitis, surgical removal is typically curative. Lizards generally have a better prognosis than chelonians, likely due to easier access to the coelom and earlier detection.[37,126] In severe cases or chronic cases where the patient is presented in a debilitated state, the prognosis is guarded to poor. Ovariectomy or ovariosalpingectomy performed at the same time as egg removal prevents recurrence in pet or display animals. For breeding reptiles, providing optimal nutrition and husbandry practices is important to reduce reproductive complications. Prebreeding health evaluation of females may be valuable to ensure they are sound before the stress of reproduction. In some reptile species with high fecundity, alternating years of breeding may reduce reproductive complications. Veterinarians should educate snake clients not to attempt to manipulate eggs in cases of dystocia. Oxytocin should not be used for obstructive or chronic dystocias, and chelonians that appear to have nonobstructive dystocias but do not respond to oxytocin should be evaluated for possible ectopic eggs.[37,132]

Oviductal prolapse

Clinical significance and known etiological cause(s). Oviductal prolapse usually occurs as a result of dystocia and is primarily seen in oviparous reptiles.[125,127,131] Snakes are overrepresented with this condition, as oviduct damage and prolapse is a common sequela to breeders attempting to "manipulate" retained eggs out through the cloaca. Additionally, the inappropriate use of oxytocin in cases of obstructive dystocias or in squamates with chronic dystocia (see Medical Management in Dystocia) may result in oviduct torsion, rupture, and prolapse.[127,131,135] Other specific reproductive-related issues, including salpingitis, oviduct rupture/tear, abnormal shaped or sized ova, ectopic ova, and follicular stasis can lead to prolapse. Concurrent underlying metabolic disorders and diseases at the time of reproductive activity that may also predispose to oviductal prolapse include hypocalcemia (lizards and chelonians), dehydration, systemic or obstetrical infections (parasitic, mycotic, bacterial, or viral), uroliths/obstipation, and neoplasia.

Clinical presentation and diagnostic confirmation. Owners are frequently alarmed by an oviductal prolapse, and reptiles are often presented on emergency. An oviductal prolapse is a life-threatening concern and requires aggressive support and therapy. Snake owners may have attempted to manipulate retained eggs, resulting in iatrogenic damage and prolapse. Owners or referring clinicians may have attempted inappropriate oxytocin use in obstructive or chronic cases. Any history of reproductive activity, in conjunction with the physical appearance of the exposed organ, is confirmatory. If presented acutely the organ may be engorged, hemorrhagic, or discolored (Fig. 80.42A), but in more chronic cases it is often dark, necrotic, or even desiccated. Often the eggs are still retained within the prolapsed tissue (see Fig. 80.42B). A prolapsed oviduct appears as a linear soft tissue structure, often with a concertina appearance, and must be differentiated from other possible tissues including cloaca, colon, or bladder (see Chapter 75 for details on determining the origin of prolapsed cloacal tissue). Survey radiography is useful to determine whether more eggs are retained or whether other contributory issues may exist (e.g., cystic calculi). Hematology and biochemistry are useful to evaluate the patient before surgical intervention and assess for underlying conditions such as sepsis.

(B) A green tree python (*Morelia viridis*) that presented with oviductal prolapse. Two eggs are still evident in the oviduct, and the cloaca and a portion of the colon are also prolapsed. Stahl, Stahl Exotic Animal Veterinary Services.)

Preferred treatment(s), prognosis, and prevention. Initially evaluating the prolapsed oviduct to assess the extent of the damage, determining the underlying reasons for the prolapse, and understanding the goals of the owner must all be considered when developing a therapeutic plan. Often at presentation the prolapsed oviduct has extensive damage, with desiccation and necrosis evident, and the ability to repair or replace the organ is not possible and amputation/removal is necessary (Fig. 80.43A and B). Where breeding is not important, amputation of the prolapsed oviduct followed by coeliotomy and ovariosalpingectomy is the best resolution. For breeding reptiles, attempting to repair and replace the oviduct may be considered if the tissue appears viable. Only acute, mild, partial oviductal prolapses can potentially be replaced per cloaca. The fragile externalized tissue must be kept moist, clean, and protected before being gently inverted and replaced; it cannot simply be pushed back into the cloaca. Inversion of tissue is best accomplished by placing a relatively large diameter blunt instrument through the exteriorized opening and carefully working the tissue back through the cloaca. Endoscopic assistance may be of value to assess replacement, but coeliotomy may be required for full evaluation and ensure proper replacement. However, even with fresh viable oviductal prolapses, rarely can the oviduct be reduced and replaced without concerns for adhesions, fibrosis, and reoccurrence. Often the prolapsed tissue is amputated at the cloaca and exploratory coeliotomy utilized to identify the remaining damaged oviduct internally. In most cases involving pet or display reptiles, in the likely event that the damaged oviduct cannot be repaired, a ovariosalpingectomy is performed. In important breeders, unilateral ovariosalpingectomy, leaving the undamaged ovary and oviduct intact, will maintain some breeding potential. See Chapters 105 and 106 for details on surgical techniques.

The prognosis after oviductal prolapse is poor to guarded but can be improved with early presentation and immediate surgical manipulation. Long-term survival improves after complete ovariosalpingectomy. Future reproductive potential of the affected oviduct is poor. If the oviductal prolapse is bilateral, future reproductive ability is lost and sterilization for survival is necessary. Veterinarians should educate clients not to attempt to manipulate eggs from dystocic females and ensure that oxytocin is used appropriately.

Dystocia

Clinical significance and known etiological cause(s). Dystocia is the inability to successfully expel term eggs or fetuses from the lower reproductive tract. The reasons for dystocia are poorly understood in reptiles but may include abnormal (especially large or fused) eggs/fetuses, failure of the distal reproductive tract to contract (especially metabolic causes), lack of suitable nesting/birthing sites, and lack of viable embryos. Dystocia has been rarely reported in wild reptiles.[136–138] This may be related to the inability to routinely detect dystocia before death in a wild reptile, however the lack of reports of dystocia in reproductive studies of wild reptiles suggests it is uncommon. Unlike conditions in the natural setting, dystocia is relatively common in captive reptiles and complications with laying or birthing are common. Additionally, like avian species, follicular activity and ovulation can occur without male presence/copulation in some species, often resulting in the production of infertile ova in solitary females. Dystocia in squamates and chelonians involving these infertile ova is common.

Dystocia is seen more commonly in oviparous reptiles than in viviparous species, but this could be related to captive population demographics. Dystocia is usually a seasonal problem because hormonal cycles, and thus breeding of temperate species (especially those exposed to seasonal changes), occur at specific times of the year. However, in captivity, environmental control may result in reproductive activity at any time of the year. The causes for dystocia in captive reptiles are often multifactorial and complex, and a definitive cause in many of these cases is not determined. Dystocias are divided into two broad groups: obstructive and nonobstructive.

Obstructive dystocia. An obstructive dystocia is the result of an anatomical barrier that prevents passage of one or more eggs/fetuses through the oviduct and cloaca. The cause may be a fetal or maternal abnormality. Fetal abnormalities include oversize, malformations, and adhesions. Maternal abnormalities include misshapen pelvis, oviductal stricture, or coelomic pathology, including cystic or cloacal calculi, obstipation, organomegaly, abscesses, or neoplasia. In addition, obstructive dystocias may result from complications during oviposition, such as malpositioning of eggs or broken/damaged eggs. Chronicity and salpingitis can result in fibrinous adherence of eggs to the oviduct mucosa.[127]

Nonobstructive dystocias. A large number of dystocias occur with no evidence of obstruction. In these cases, the eggs or fetuses appear to be of normal size and shape and the female appears anatomically normal. These nonobstructive dystocias have been attributed to many etiologies, unfortunately based primarily on association rather than proven causation. Improper nesting sites (common with lizards and chelonians), improper temperature, malnutrition, and dehydration may

lead to dystocia. Females must be provided with the proper environment during gestation and at oviposition/parturition, and often environmental requirements for gravid females are different than those of nonreproductive conspecifics.[139,140] One of the most common causes of nonobstructive dystocia in lizards and chelonians relates to calcium deficiency. High-energy diets fed in large volume to pet or breeder reptiles result in accelerated growth and early pubescence. However, these diets, usually low in calcium and with inadequate environmental lighting (or vitamin D_3), result in marginal or deficient levels. Hormonal activity ensues and mobilization of calcium for vitellogenesis causes a subclinical condition to become apparent. Depletion of bone calcium leads to orthopedic changes and associated weakness, lameness, anorexia, and dystocia due to poorly mineralized ova or weak contractions at oviposition/birth. Such conditions are most prevalent in herbivorous and insectivorous species where dietary balance is most challenging (see Chapter 84).

Another cause of dystocia may relate to poor physical condition of the female.[127,141] Captive reptiles are extremely sedentary compared with their wild counterparts and often possess poor muscle tone. In addition, some species may reproduce excessively and become exhausted throughout the season. Oviposition requires a substantial muscular effort, and if a female is in poor condition she may fail to complete the task. The predominant presentation in many dystocia cases involving oviparous snakes supports this theory where obese, poorly conditioned females will lay the majority of the clutch without complication but retain the last egg or two without any evidence of an obstruction. Infectious diseases may cause infection with resulting salpingitis, causing egg/fetus retention. The authors have seen several cases of dystocia and fetal death in several species of boa with a confirmed diagnosis of boid reptarenavirus.[127]

Although challenging and not always possible, it is important to attempt to determine the cause(s) of dystocia. The information can help define the prognosis for the case and guide prevention or recurrence in this patient and other females in the breeding collection. Regardless of the etiology the authors have found an increased prevalence of dystocia in snakes and lizards that are first-time breeders, have had a previous dystocia, or are carrying a predominantly infertile clutch.

Clinical presentation. Distinguishing a dystocia from a normal reproductive cycle/gravidity can be challenging. Mischaracterization of normal gravidity and inappropriate treatment is common and unnecessary. An example of the complexity of determining a true dystocia versus normal gravidity is evident with chelonians, where individuals may voluntarily retain oviductal eggs for up to 6 months until conditions are ideal for oviposition.[104,106] A clear understanding of the reproductive biology of the species, a thorough history, physical examination, and diagnostic tests may be necessary to ensure appropriate management. Historically, dystocic reptiles may be restless, pacing and climbing, looking for possible nesting sites. Oviparous lizards and chelonians may dig in planters or substrate. Female aquatic turtles may spend extended time out of the water. Appetite and water intake may be reduced or absent. Coelomic distention with reduced body condition and anorexia may be noted. Differential diagnoses for a coelomic mass include fecal masses, cystic calculi, abscesses, and tumors. Tenesmus without successful oviposition or parturition is a clear sign of dystocia. Females that have produced a small clutch or litter may still appear gravid due to retained eggs/fetuses. Alternatively, the breeder's records may indicate that the female is past her due date. Diagnosis of a true dystocia in females that contain the entire clutch can be challenging (Fig. 80.44).

Postovulatory retained eggs are usually palpable in most snakes and many lizards. However, in some oviparous lizards and in viviparous squamates it can be difficult to differentiate between ovarian follicles and oviductal eggs/fetuses. Postovulatory ova (oviductal eggs) in squamates can often be differentiated from follicles because they are less firm, larger, more oblong in shape, and more caudally located in the coelom. Chelonians are more difficult to palpate, but in smaller species digital palpation in the prefemoral area with the patient held vertically and gently tilted side to side may allow shelled eggs to be

detected (see Fig. 80.24). This technique is not good for determining numbers of retained eggs, and clinicians must be cautious to avoid injury as their fingers can be crushed by a retracting chelonian limb or hinged shell. It is usually not possible to palpate developing fetuses in viviparous squamates and imaging is necessary.

Diagnostic confirmation. Plasma biochemical changes often include elevations of total calcium; however, ionized calcium is often normal. Complete blood count may show a stress leukocytosis or, in cases of inflammatory/infectious change, a leukocytosis with left shift. In more chronic cases anemia and leukopenia may be observed.[106]

Radiography is essential and can help differentiate between follicular stasis (spherical, soft tissue structures) and dystocia (thinly shelled, oblong eggs) in squamates (see Fig. 180.33A–C). Radiographs are important to exclude obstruction (before the use of oxytocin); identify mineralized eggs (considerably less calcified in squamates, compared with chelonians); and confirm egg numbers, shell abnormalities (e.g., thickening, broken), ectopic eggs, and comparative egg-to-pelvic dimensions. Radiography can also identify contributing, and/or concurrent, coelomic pathology, such as cystic calculi, obstipation, or organomegaly (see Fig. 80.41). With viviparous squamates radiography can be useful late in gestation when skeletal structures become visible (see Fig. 80.44B). Typically, viable fetuses are coiled, whereas an uncoiled or linear appearance likely indicates fetal death and the need for surgical intervention (Fig. 80.45A and B).[127] Radiography may also help to identify abnormalities associated with nutritional or renal secondary hyperparathyroidism, with derangements in calcium homeostasis likely contributing to the dystocia.

Ultrasonography can be useful to differentiate between follicular stasis and postovulatory eggs. Sonographically, postovulatory eggs exhibit hyperechoic mineralized outer shells, and, in squamates, a more oblong appearance. A small amount of anechoic fluid may be visualized around and between eggs. With dystocia and salpingitis the normally smooth wall of the egg may become irregular, with a notable change in heterogenous echogenicity and an increase in both oviductal and coelomic free fluid.[108,112] In these situations normal laying/birth is unlikely, and medical or surgical management is needed. Late in gestation, ultrasonography is valuable in viviparous squamates to determine whether fetuses are alive, as they may be seen moving with an obvious heartbeat (see Fig. 80.25A and B). The loss of these indicators can also be helpful to differentiate a true dystocia from normal gravidity.

Compared with radiography, CT allows individual egg evaluation and can demonstrate indicators of dystocia such as distinct horizontal leveling of egg contents and oviductal gas accumulation (see Fig. 80.34A and B).[108] Thus, CT can be clinically useful to determine when intervention is necessary, especially in chelonians that can electively retain eggs for extended periods.

Preferred treatment(s). Dystocia is rarely, the acute emergency that it is in mammals and birds. If the reptile is a pet or display animal then surgical removal of the reproductive tract (as soon as safely possible) is best. If maintaining breeding ability is important then the least invasive intervention required to resolve the issue while maintaining future reproduction is the goal. Often the procedures can be performed in a step-by-step fashion starting with the least invasive and safest procedures and proceeding to more invasive and/or surgery. In chronic or complicated cases, surgery may be preferable.

If a possible dystocia situation is suspected (versus normal gravidity) but the female appears healthy, a nest box and (depending on species, dietary history, radiographic, and clinicopathologic results) oral calcium therapy can be provided. These cases must be monitored closely and may need reappraisal within a few days to 1 to 2 weeks if no action occurs or sooner if tenesmus or deterioration becomes evident.

For dystocia cases where the patient is not considered healthy, medical stabilization should be prioritized, followed by additional medical therapy as indicated (e.g. calcium, nonsteroidal antiinflammatories, opiate analgesics, antimicrobials).

Medical management. Although studies have indicated that laying/birthing appear to be controlled by arginine vasotocin, it is rarely available, and oxytocin is used in cases of nonobstructive dystocia.[142] Inappropriate use of oxytocin may result in egg fracture, oviduct rupture, eggs forced into the bladder, or severe hemorrhage. This drug should only be used in individuals with a confirmed nonobstructive dystocia. Oxytocin is most effective if some portion of the eggs have been recently laid, attempts at oviposition are occurring, or obvious nesting behavior is ongoing. Because temperature influences the effect of oxytocin on oviductal muscles,[143] patients should be maintained at or near their optimal body temperature during treatment.

In squamates there is a small window of efficacy, usually within 48 to 72 hours of normal laying. Chronically retained eggs often develop a fibrinous adherence to the oviduct and oxytocin may be ineffective or result in oviduct torsion and damage (Fig. 80.46A, B).[127,130,135] Viviparous snakes may have a longer window of effectiveness, up to a week after a partial birthing.[144]

Chelonians are more responsive to oxytocin, even in more chronic cases of dystocia (Fig. 80.47). This may be related to their ability to electively retain eggs for extended periods of time from 9 days to 4 to 6 months depending on the species.[37,104] Oxytocin dosing differs considerably with chelonians responding well to lower doses (1–4 IU/kg)

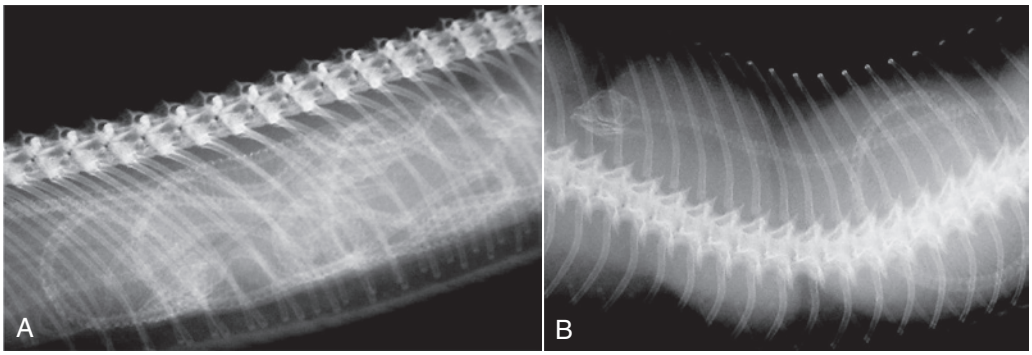

FIG 80.45 (A and B) With viviparous squamates radiography can be useful late in gestation when skeletal structures become visible. Typically, viable fetuses are coiled (see Fig. 80.44B), when fetuses are uncoiled or have an obvious linear appearance, as in these radiographs of a Boa constrictor (*Boa constrictor* spp.), it is usually an indication of fetal death and the need for surgical intervention. Radiographs had ruled out an obstructive dystocia and supportive medical treatment (fluid and thermal therapy) initiated followed by oxytocin resulting in oviposition. Stahl, Stahl Exotic Animal Veterinary Services.)

compared with higher doses necessary for squamates (10–20 IU/kg). Oxytocin administration should be slow and can be given intravenously or diluted in saline and given subcutaneously (SQ).[130] A nest box or nesting material should be offered after oxytocin treatment, however often eggs are expelled without nesting behavior. Dosing can be repeated and the dose increased (start at lower dose initially) every 6 to 12 hours; however, after 2 to 3 doses with no response oxytocin will likely not be effective.

Oxytocin causes elevations in prostaglandins and likely plays a role in lysis of the corpora lutea and is important in the physiology of laying/birthing.[145,146] Therefore, administration of prostaglandins F2a (injection) and E (gel administered per cloaca) may be helpful in augmenting the oxytocin response. Prostaglandin F2 alpha (1.5 mg/kg) administered SQ was used in combination with oxytocin (7.5 IU/kg) and found to be effective in inducing oviposition in red-eared sliders.[147] Additionally, topical use of prostaglandin E gel via cloaca in conjunction with oxytocin has been successfully used in many chelonian species.[132]

Beta-blockers may potentiate the effects of oxytocin, and atenolol has been used in conjunction with oxytocin successfully in many chelonian species for dystocia. McArthur recommends giving atenolol (7 mg/kg PO, in the evening) approximately 12 hours before giving oxytocin at 1 to 3 IU/kg SQ the following morning, repeating the dosing of the same drugs in the same pattern until all eggs pass.[148]

In cases of absolute or relative hypocalcemia, calcium can be given before oxytocin dosing, and NSAIDS may be indicated for inflammation and analgesia. In chelonians where eggs have been chronically retained and/or there is a suspicion of salpingitis, NSAIDS and antimicrobials may be indicated, especially when surgery is not an option.[130]

External egg manipulation. Due to the linear anatomy of snakes, egg manipulation may be possible and is noninvasive.[127] General anesthesia is required to determine whether retained eggs are adhered to the oviduct or can be gently manipulated toward the cloaca. If the first egg moves freely toward the vent, a vaginal speculum can be used to dilate the cloaca and allow visualization of the egg at the oviduct opening. Sometimes it can be gently grasped and removed with forceps, or ovocentesis, using a large-gauge needle (14–18 G), may be necessary to reduce size. The collapsed egg can then be removed with forceps or hemostats, and the procedure repeated for the remaining eggs (Fig. 80.48A–D). This procedure is only recommended in lizards and chelonians if the egg is visible within the cloaca. In these cases, however, the egg often breaks, requiring piece-meal removal of shell fragments.

Cloacoscopy. Cloacoscopy may be utilized to manipulate retained eggs/fetuses out of the cloaca if medical and/or less-invasive techniques have failed or are not appropriate.[127,130] This procedure can be useful in snakes and chelonians, less so in lizards, and is best utilized when only one or a few ova or fetuses are retained. General anesthesia is required, and standard rigid endoscopy equipment (2.7-mm rigid endoscope with 4.8-mm working sheath system) and warm saline infusion is utilized. The openings into the oviducts are located dorsolateral in the urodeum. In some cases, the oviduct(s) may be entered and eggs/fetuses identified. Gentle manipulation of the egg/fetus with the endoscope and/or grasping forceps, along with the infusion of warm saline, may allow all or portions of the egg/fetus to be removed. However, in some cases endoscopic entry into the oviduct is not possible, as the

(B) Under general anesthesia the egg was manipulated toward her cloaca, and a vaginal speculum was used to dilate the cloaca allowing visualization of the egg at the opening of the right oviduct. oviduct opening is tightly closed. Sometimes entry into the oviduct is possible but adhesions are present and cannot be safely broken down. If there is severe inflammation or infection of the oviduct and/or degenerative eggs/fetuses are present, then treatment with antimicrobials and NSAIDS for 14 to 21 days may be required to manage the active salpingitis before repeating endoscopy.[127,130] See Section 8 for more details on cloacoscopy.

Percutaneous ovocentesis. Percutaneous ovocentesis is a technique that can be considered in snakes. This technique has risks (possible leakage of egg contents into the coelom or iatrogenic needle trauma) and should be utilized only if other options are not feasible. Deep sedation to general anesthesia is recommended. The egg is isolated against the lateral body wall and the area aseptically prepared. The use of sonographic guidance is recommended. A 16- to 20-gauge needle (depending on the size of the patient) is inserted between the first and second row of lateral scales and into the egg (Fig. 80.49). The contents of the egg are aspirated using caution to avoid leakage of egg material into the coelom. After collapse, the snake will usually pass the egg within 12 to 24 hours of aspiration. Eggs cranial to the collapsed egg may pass on their own after the first egg passes or may also need aspiration. Postoperative analgesics such as NSAIDs are recommended. Antimicrobials are unlikely to prevent coelomitis if leakage occurs, but coverage using a first-line drug can be considered. Eggs retained more than several weeks are not likely to aspirate as the contents solidify, and surgical removal is required.[127]

Surgery. Surgical management by ovariosalpingectomy offers a permanent solution for resolving dystocia in chelonians and lizards (Fig. 80.50A and B).Where future reproduction is important, salpingotomy can be attempted if less-invasive methods have failed. Coeliotomy and salpingotomy often provides the best evaluation of the reproductive

Due to economic constraints not allowing coeliotomy, a percutaneous aspiration of the egg was performed. tract to allow a more informed therapeutic decision and improve the chances of future reproduction. If significant oviductal pathology is identified, a unilateral ovariosalpingectomy can be performed. See Chapter 105, for details on performing these procedures.

Prognosis and prevention. Prognosis and outcome are favorable for dystocia cases with early diagnosis and intervention. Chronic cases are more likely to have associated pathology and may require more invasive surgical intervention. Successful reproduction 1 year after a surgical correction of a dystocia has been reported,[149–150] but minimally a 1-year nonbreeding rest period is recommended. Dystocia involving prolapse of the oviduct(s) and/or cloaca is a more serious condition (see Oviductal Prolapse). The prognosis may be good for survival but poor for continued reproductive performance.

Although countless numbers of retained (and often fertile) eggs have been removed from reptiles, successful incubation of these removed eggs is rare. However, eggs passed after oxytocin induction are often successfully incubated.[151] The removal of viable fetuses during salpingotomy in snakes has been reported.[152]

Preventative ovariectomy should be considered for lizards and chelonians (see Chapter 105). Providing an appropriate environment and nesting site (ovipositoria) based on a good understanding of the natural history of the species is important to reduce the incidence of dystocia (see Nesting Sites/Ovipositoria/ in the Captive Breeding section). Since calcium plays an important role in successful reproduction and may contribute to issues with dystocia the diet of reproductively active reptiles should be reviewed to ensure adequate levels of calcium and vitamin D_3 (see Chapter 27).

For breeding reptiles, dystocias are often thought to be related to overconditioning and small cage size (reduced activity). Breeders and veterinarians should address these issues when evaluating dietary strategy and housing in the reptile breeding facility. Veterinarians working with squamate breeders should explain the limited time window for the use of oxytocin and encourage females be presented urgently if complications are suspected.

Reptiles that have presented for dystocia (notably snakes) may be more likely to present with dystocia in the future. Correcting associated husbandry issues or not actively breeding an affected female may be important to prevent recurrence. It is recommended that reptiles that have had eggs/fetuses removed from the oviduct should not be bred the next season but given a rest period of at least 1 year before breeding again.

Scent Gland Adenitis (Snakes)

Clinical Significance and Known Etiological Cause(s). Cloacal scent gland adenitis has been reported in snakes and is not an uncommon presentation.[128] Clinically, scent gland adenitis appears to be more common in older female colubrids, and actively breeding snakes.[128] Causes include impaction of the gland, infection of the gland, and neoplastic changes. A recent review of six cases of cloacal scent gland impaction in snakes at several zoological collections included four colubrids, one viper, and one boid (Couture et al, Proc ARAV, 2017 p 352). The colubrids were all greater than 20 years old, all had bilateral involvement, and three of four were females. Three of four colubrids also had bacterial adenitis, one had mineralization of the affected gland, and one, a Taiwan beauty snake (*Orthriophis taeniura freese*) had a fibrosarcoma associated with one of its bilaterally affected glands. Increased frequency of scent gland adenitis in older snakes may be related to reduced general activity, and/or reduced muscular ability in the lower body. Without release the impacted scent material becomes thick and inspissated and the gland becomes secondarily infected, swollen, hard, and may rupture. If impaction is bilateral it may indicate functional issues associated with an inability or difficulty in the release of material. Captive-related environmental factors affecting glandular release include humidity, substrate (paper or carpeting versus a natural substrate), and presence or absence of conspecifics. Bacterial infection of the scent gland is a common cause of adenitis.[128] The opening of the scent gland is located at the caudal margin of the cloaca, near passing fecal and urate material that may predispose to infection. This is exacerbated if snakes are housed under poor sanitary conditions. The authors have found an increased incidence of scent gland adenitis associated with captive breeding in snakes.[128] Cloacitis in females and cloacitis and/or hemipenis infections in males are common during courtship and breeding, especially if housed on soiled particulate substrates, and can predispose to scent gland adenitis. Neoplasia should be considered with scent gland adenitis, especially in older snakes that present with unilateral involvement. One author (SJS) has seen several cases of neoplasia associated with scent glands, and a fibrosarcoma was associated with a scent gland adenitis in a colubrid (Couture et al, Proc ARAV, 2017, p 352).

Clinical Presentation and Diagnostic Confirmation. Typically, older and/or actively breeding females are overrepresented. Physical examination is often diagnostic, with snakes presenting with unilateral or bilateral swellings caudal and lateral, and in chronic situations craniolateral to the cloaca. In severe cases rupture of the gland may occur (Fig. 80.51). On palpation the gland may be soft to hard depending on duration. Fine needle aspiration and cytology can confirm gland involvement and may indicate neoplasia. Radiography is less useful except to confirm mineralization. Ultrasonography can differentiate between neoplastic tissue and impaction. Biopsy for histopathology and microbiological testing at surgery is often necessary for a definitive diagnosis.

Preferred Treatment(s). In cases of mild impaction gently massaging the gland (after warm water soak) to move material toward the gland opening may allow release. In larger snakes, with sedation and/or local anesthesia, cannulation of the duct opening can be attempted with a urinary catheter or metal lacrimal duct cannula.[128] Unfortunately, with retention, gland material becomes thick, grainy, often inspissated, and cannot pass out of the narrow duct opening, necessitating surgery.

Under general anesthesia, surgery is performed by making an incision between the lateral scale rows over the enlarged gland. The gland is opened, impacted material removed, and biopsies of the gland collected for histopathology and microbiological culture. The gland can then be gently lavaged with saline and a catheter passed normograde through the opening of the duct to ensure patency. If the gland was successfully cannulated it can be closed or marsupialized to allow continued flushing and treatment.[128] Systemic antimicrobials and/or topical antimicrobials may be initiated based on histopathology and microbiological results along with local flushing with antiseptics. Surgical removal of the entire affected gland(s) is often the curative choice in cases that are severe, reoccurring, bilateral, or if neoplasia is suspected/confirmed (Couture et al, Proc ARAV, 2017, p 352).[128]

Surgical removal of the gland, if required, is performed by making an incision between the lateral scale rows over the enlarged gland. Sharp and blunt dissection is used to separate the gland from the associated muscle and connective tissue. When possible, the gland is left intact to minimize contamination of the surgery site and ensure removal of all glandular material. The gland is elevated out of the incision and hemostasis managed with hemoclips or radiosurgery. The duct is then ligated as far cranially as possible where it curves toward the vent opening. The other gland can be removed through the same incision by transecting the midline muscle that separates the left and right glands. Muscle and skin closure are routine. Postoperative analgesics are indicated. A recent review of six cases of cloacal scent gland impactions of snakes in several zoos found that surgical removal of the affected glands was successful (Couture et al, Proc ARAV, 2017, p 352).

Prognosis and Prevention. Prognosis is good with complete surgical removal of the gland(s) and if underlying conditions leading to blockage and/or adenitis are corrected after successful medical treatment. If neoplasia is confirmed, the type of neoplasm determines prognosis. Prevention involves correcting husbandry issues that may be contributing factors. Snakes should be observed closely during breeding to ensure they are kept in sanitary conditions and are not overbred.[128] Owners and keepers should be aware of this possible condition in older snakes and watch for indications of increased material in the cloacal scent glands.

Neoplasia

Clinical Significance. In one report involving 3500 reptile necropsies performed at a zoo over a 100-year span (1901–2002) showed neoplastic incidence to be only 2.3%; however, the study found there was a trending increase in neoplasia in the last 30 years especially in snakes and lizards.[153] In another study 5000 biopsy samples submitted to a specialty pathology service between 1994 to 2002 found a cancer incidence of 9.8% in reptiles, with snakes having the highest incidence of neoplasia (15.0%) followed by lizards (8.5%), chelonians (2.7%), and crocodilians (2.2%).[154] However, in this same study reproductive neoplasms were most commonly found in lizards, except for granulosa cell tumors, which were more common in snakes. No reproductive tumors were found in chelonians or crocodilians.[154] Ovarian adenocarcinomas were the most common reproductive tumors found, with an incidence of 3.7% in lizards and 2.7% in snakes. Ovarian adenocarcinomas had a higher incidence of metastasis in snakes compared with lizards. Granulosa cell tumors were more prevalent in snakes (1.5%) than lizards (0.6%), and the overall incidence of oviduct neoplasia (adenocarcinoma) was low in the study, with lizards having a higher incidence at 1.2% compared with snakes (0.6%).[154] Many individual case reports and reviews have reported ovarian carcinomas, fibromas, hemangiomas, dysgerminomas (red-eared sliders), and teratomas.[153–157] Oviductal neoplasms reported include leiomyosarcomas and leiomyomas.[153–156]

Testicular neoplasms are rare, with seminomas being the most prevalent (1.2% in lizards and 0.6% in snakes).[154] Interstitial cell adenomas, Sertoli and Leydig cell tumors, have also been reported[153–155,158] (see Chapter 78).

Known Etiological Cause(s). No known carcinogens have been determined for reptiles; however, genetic/taxa predispositions were suggested for a group of Egyptian spiny-tailed lizards (*Uromastyx aegyptius*) with a high incidence of lymphoid neoplasia.[159] The authors have seen multiorgan lymphoid neoplasia in snakes involving the reproductive tract. A malignant granulosa cell carcinoma was reported in a green iguana after an incomplete ovariosalpingectomy, suggesting a possible relationship with neoplastic change and an ovarian remnant.[160]

Clinical Presentation and Diagnostic Confirmation. Reproductive neoplasia may mimic changes associated with reproductive activity such as folliculogenesis or testicular recrudescence and must be differentiated from these normal physiological changes. Additionally, presentation may resemble other more common reproductive disorders, including follicular stasis, dystocia, yolk coelomitis, or ectopic eggs. Infertility and

VetBooks.ir

low fecundity could also result from reproductive tract neoplasia. Behavioral changes may also be noted if gonadal neoplasia affects sex hormone production.

Physical examination findings may indicate activity or enlargement in the mid to caudal coelom, where reproductive tract activity would occur. Radiography, ultrasonography, and/or advanced imaging including CT and MRI may be useful to identify reproductive tract neoplasia. Ultrasonography was valuable in diagnosing an ovarian teratoma in a green iguana.[157] A 13-year-old spur-thighed tortoise was diagnosed with a testicular seminoma antemortem using ultrasonography and MRI. Comparable MRI imaging changes in the affected tortoise's testis were similar to those seen in testicular seminomas in humans. The diagnosis was confirmed at postmortem and after histopathology.[161] In most cases endoscopy or coeliotomy with biopsy will be necessary to confirm an antemortem diagnosis. If histopathology confirms neoplasia, staging is recommended whenever possible.

Preferred Treatment(s), Prognosis, and Prevention. Oncologic treatments can include surgery, chemotherapy, and radiation, with specific recommendations dependent on a histologic diagnosis and staging. Surgical removal of the reproductive tract may be curative if diagnosed early, especially for benign disease. In cases where surgical removal of the affected reproductive tract is not possible, or metastasis has occurred, oncologic therapy will be aimed at prolonging the patient's quality of life rather than curing the patient (see Chapter 87).

The prognosis is dependent on histopathology and determination of malignancy. Since the reproductive tract can be removed, if a diagnosis is made before metastasis, the prognosis may be favorable. For advanced carcinomas with likely metastasis, the prognosis is poor even with aggressive surgery. Ovariectomy and orchiectomy at a young age may be preventative.

Infertility/Low Fecundity

Clinical Significance. The successful breeding of many species has become common both commercially (pet market and herpetoculture) and in conservation efforts to establish captive colonies of threatened and endangered species. Reptile veterinarians can play an important role in assisting these efforts by providing guidance on production management issues such as infertility and fecundity.[162] Interestingly, this has been an important veterinary service for the livestock and poultry industry for decades. Infertility can be divided into two basic categories: disorders of fertility (absence of egg/fetus production or production of infertile eggs/ova) and disorders of fecundity.[132,163] Infertility is generally defined as the inability to conceive, whereas fecundity measures reproductive performance and is determined by the number of live young produced. Infertility typically is the result of events that occur in either the male or female before conception.

Known Etiological Cause(s). Factors that influence fertility in reptiles include improper reproductive cycling (particularly temperature), an incompatible pair (incorrectly sexed, size mismatch, different species), an under- or overconditioned male or female, stress with excessive or aggressive copulation or copulatory attempts, abnormal (nonfunctional) reproductive anatomy of the male or female, and reproductive disease. External factors that may affect fertility include exposure to extreme temperatures (high or low), use of spermicidal lubricants during hemipenal probing, exposure to environmental toxins such as insecticides or disinfectants, and potentially excessive exposure to radiation (with diagnostic imaging) similar to mammals.[132,163]

Specifically, male infertility may be related to a lack of interest in copulation, inability to succesfully copulate, and a true lack of spermatogenesis.[132] A desert tortoise (*Gopherus agassizii*) diagnosed with a testicular intersticial cell adenoma did not produce viable sperm and was considerd sterile.[158]

Infertility in females is more commonly associated with a lack of appropriate environmental stimuli and/or underlying nutritional deficiencies. Females that commonly produce infertile eggs or (in viviparous species) infertile ova may have underlying nutritional issues or reproductive disease, assuming male issues have been excluded.[37,132]

In disorders of fecundity, conception occurs, but the clutch or litter size is smaller than normal. There may be high numbers of infertile eggs or stillborn young. The same environmental factors that affect fertility can be responsible for damage or death to developing embryos. Embryonic death is common and warrants a review of incubation conditions (oviparous species) and maternal nutrition/husbandry. A review of protocols for egg care/incubation and embryonic death investigation is disscussed in Chapter 85. Health issues that affect the female during gestation and result in embryonic death/decreased fecundity include low fat reserves, underlying disease (oophoritis, salpingitis, cloacitis, neoplasia), abnormal reproductive anatomy, and any other issues resulting in dystocia.

Clinical Presentation and Diagnostic Confirmation. If the reptile breeder has kept detailed records on breeding stock, problems associated with fertility and fecundity will become evident. A review of all aspects of the reproductive strategy for any given pair or breeding group must be performed and individual animals must have a thorough physical examination. Accurately identifying the sex of an individual is important, especially in monomorphic species where misidentification of sex is common (see (Sex Identification, earlier in this chapter). Additional tests to specifically evaluate the reproductive tract of the breeding individual may be required and include hematology and biochemistry, ultrasonography (allows evaluation of testicular, ovarian, and oviductal architecture) and other imaging modalities (CT and MRI), cloacoscopy and coelioscopy/celiotomy for biopsy/histopathology, and microbiological evaluation. See clinical investigation for reproductive diseases earlier in this chapter for more information on these procedures. Specifically for males the copulatory structure(s) should be evaluated for pathology. If males appear to copulate effectively, evaluation of semen may be necessary. A variety of manual techniques and/or electroejaculation can be utilized to collect semen samples from males (or the female's cloaca postcopulation), and the semen can be evaluated (see Artificial Insemination earlier in this chapter to review these techniques).[37] If no abnormalities are detected during semen evaluation then coeliscopy/coeliotomy may be necessary to evaluate the testes and perform a testicular biopsy for histopathology/microbiology. It is important to understand that spermatogenesis in most males occurs seasonally, and serial biopsies and plasma testosterone levels may need to be evaluated over time (several years) before a definitive diagnosis of sterility can be determined.[132]

For females, monitoring the vitellogenic cycle (over several seasons) with the use of ultrasonography will provide noninvasive information on seasonal folliculogenesis and cycling; however, coeliscopy/coeliotomy to evaluate the ovary and biopsy may be necessary to confirm disesase.

Preferred Treatment(s). Specific treatment for infertility and fecundity issues will be based on the confirmed diagnosis. If, on evaluation, breeding reptiles are appropriately sexed and determined healthy and "fit" for breeding then a discussion on managing external variables (based on natural history of the species involved), such as proper cycling techniques, minimizing social stress, providing a conducive breeding environment, etc., may result in improved success. However, in cases of reproductive disease and pathology specific treatment based on the diagnosis will

VetBooks.ir

be necessary. See previous sections on reproductive diseases for a review of the management of these conditions as they may contribute to infertility and reduced fecundity, especially in the early stages. In a breeding situation reptiles with poor reproductive performance or advanced reproductive pathology may need culling or rehoming (to a nonbreeding situation) to improve results in facility production.[162]

Ultimately the reptile veterinarian should approach the breeder with a comprehensive plan involving a review of proper husbandry, nutrition, record keeping, reproductive strategies utilized, and a thorough prebreeding evaluation of breeding reptiles. In addition, providing ultrasonography services (or instruction) to assist with timing of male introduction during the female follicular cycle, confirming and monitoring gestation, and reviewing any potential reproductive complications can improve reproductive success for the breeder or facility. See earlier section, Captive Breeding, for more details.

Prognosis and Prevention. If, on evaluation, the breeding reptiles are appropriatley sexed and determined healthy and "fit" for breeding, the prognosis is good, as management of external variables may resolve issues. However, in cases of reproductive disease and pathology the prognosis may be more guarded depending on possible resolution of these conditions.

For breeding reptiles, providing appropriate husbandry, nutrition, preventive health programs (including quarantine), implementing appropriate breeding practices (understanding natural history of species, breeding environment hygiene, not overextending males, etc), and regular veterinary evaluations (including necropsy and histopathology on losses and culls) can help reduce the incidence of reproductive disease and thus infertility and fecundity issues.

Musculoskeletal System

S. Emi Knafo

Musculoskeletal pathology and common disease states will be presented in this chapter, as well as the normal musculoskeletal anatomy and physiology of amphibians and reptiles. Musculoskeletal system reviews of amphibians and reptiles have mostly focused on disease processes, particularly metabolic bone diseases, traumatic injuries, and fractures. However, there is a paucity of information in the veterinary literature on the normal musculoskeletal anatomy and physiology. Therefore this chapter will also describe the form and function of reptiles by integrating basic biology, zoology, and physiology literature as it applies to clinical medicine. The author has attempted to present the anatomical features most likely to be of clinical significance in relation to medical and surgical procedures.

ANATOMY AND PHYSIOLOGY

Muscle

Across different orders of reptiles, there exists a general anatomical organizational plan, likely established with the first tetrapodal terrestrial vertebrates.[1] This musculoskeletal body plan served as the origin, from which modifications arose, connected to the shape and natural history of the species (i.e., carapacial or limbless body forms). Characteristics of the musculature of each reptile group reflect these modifications. Ophidia have highly specialized axial muscles, including subvertebral musculature, visceral cephalic muscles that insert more caudally, and hypaxial musculature of the body wall that extends cranially with the abdominal oblique and rectus abdominis muscles reaching the skull.[2] Amphisbaenia have subvertebral muscles restricted to the cervical region and lack musculature of the limbs as would be expected.[1] Sauria presents the greatest diversity, particularly in the hypaxial muscles, owing to the different respiratory mechanisms. Subvertebral musculature is restricted to the neck as described in legless lizards. Rhynchocephalia possess epaxial muscles with transverse linkages dorsoventrally via a network of tendons and aponeuroses.[1] The chelonians generally have reduced or absent axial muscles yet have well-developed hypaxial and subvertebral muscles in the neck. Lastly, the crocodilians have similar muscular anatomy as other saurian reptiles, with subvertebral musculature restricted to the cervical region, yet have well-developed, multilayered epaxial and hypaxial muscles.

Amphibians, reptiles, and birds possess three types of muscle fibers: broad white, narrow red, and intermediate. These fiber types may correspond to mammalian muscle fiber types, but this has not been clearly demonstrated.[3] Reptile muscle fibers are also classified as twitch and tonic fibers. The tonic fibers are slow, and their ultrastructure includes a sarcotubular system that is much less extensive than even the slow-twitch fibers of mammals.[3] The myofilaments are poorly bundled into fibrils. The membranes of these tonic fibers only support junction potentials, not action potentials, and show graded, rather than all-or-nothing, contractions.[3] It is likely that mammalian slow-twitch fibers may be tonic fibers that acquired characteristics of fast-twitch fibers but maintain lower ATPase levels.[3] More generally, the skeletal muscles of vertebrates follow a similar pattern in myofibrillar structure but differ in sarcomere length.[3] Longer sarcomeres may be characteristic of slower muscles. Within sarcomeres, the thick filaments (A bands) are conserved and similar in size across reptile groups, whereas thin filaments (I bands) demonstrate more variability and do not seem to correlate with speed of contraction.[3] Chelonians have longer thin filaments, which are believed to allow for greater ranges of length over which the muscle may contract.[3] The orientation of T tubules is such that two cisterna of the sarcoplasmic reticulum come together with the T tubules to form triads. Fast-twitch fibers of leg muscles typically have two triads regularly spaced between A and I bands to increase sensitivity to electrical stimulation and improve excitation-contraction coupling.[3] In contrast, the tonic fibers have few triads and often have diads (T tubules associated with a single sarcoplasmic cisterna). Twitch fibers also show distinct myofibrils in cross-section, whereas tonic fibers are more loosely organized. Lizard muscles typically have fewer tonic fibers compared with muscles of snakes, and tonic fibers are more common in postural muscles.[3]

Bone

Haversian bone is considered the basic structural unit of bone in mammals. However, the classic Haversian system is absent in many reptiles, including lizards and snakes, yet can be found in certain localized areas of cortical bone in chelonians and crocodilians.[4] Reptile bone can be primary vascular or nonvascular bone. The primary vascular bone has primary canals, which are oriented longitudinally when they are of periosteal origin. This is characteristic of bone that has been quickly laid down during periods of growth. Nonvascular bone is found in virtually all adult reptiles to some degree. Nonlamellar, woven, or fibrous bone is composed of a fibrous matrix with randomly oriented collagen fibers within. This is characteristic of parts of the skeleton undergoing rapid growth or fracture repair (deposition of bone in a short period of time). When nonlamellar bone is present on the cortex, it is considered fine-cancellous bone. This is in contrast to the coarse-cancellous bone of the medullary cavity. Fine-cancellous bone has small cancellous spaces that are filled with bone deposits and form standard diameter canals. Ultimately, this bone becomes compact. The process of compaction within the medulla also occurs by bone deposition within cancellous spaces. However, in the case of the medullary coarse-cancellous bone, it becomes engulfed by the growing, inward-moving cortex as it becomes compact. This compacted coarse-cancellous bone is identified in all reptiles.[4] As bones grow, new bone is deposited on periosteal or endosteal surfaces, depending on the direction of growth in a particular bone or part of a bone. Therefore the entire cortex, in different parts of any reptilian bone, may be made of periosteal tissue or endosteal bone. The alternating inward and outward direction of cortical growth produces a distinctive layering pattern.[4]

VetBooks.ir

Chelonians and crocodilians have more comparable bone structure and conform to a basic body plan of organization. They undergo skeletal remodeling, which is similar to all tetrapods. The bones are composed of an outer cortex enclosing a central medullary cavity with cancellous trabeculae. The compact cortical bone lacks outer and inner lamellae and does not contain a Haversian system.[4] The more common cortical bone pattern in chelonians and crocodilians is a laminar structure containing laminae and primary vascular canals. This laminar structure is more pronounced as the animal matures, and circumferentially arranged laminae are accumulated during periods of growth.[4] Skeletal growth, and therefore cortical lamination itself in chelonians and crocodilians, takes place in seasonal waves, often corresponding to alternating periods of hibernation and activity, or seasonal differences in feeding habits or nutrition.[4] Metaphyseal and epiphyseal cortical bone can be thin and composed of mostly endosteal bone. Cancellous bone is found throughout the medullary cavities of long bones, including the metaphysis and diaphysis.[4] In mammals, cancellous trabeculae of the medullary cavity of long bones undergo remodeling and reorganization by way of resorption and secondary deposition of new bone. This secondary rebuilding of primary cancellous bone is limited or completely absent in the bones of chelonians and crocodilians.[4] Instead, reptilian bones grow as the endosteal cortex is expanded upon and moves inward. The process is followed by growth of the periosteal layer of the cortex, which creates diaphyseal widening.[4] By this mechanism, the cancellous trabeculae of the medulla can be composed of bone originating from the periosteal cortex rather than endosteal origin and has been relocated to the medulla by the increasing diameter of the bone.[4] Additionally, it is possible that the bands produced earlier in bone growth can be progressively removed by endosteal resorption as the bone continues to grow in size. Therefore there is no reliable way to correlate the number of bands of bone with the age of the individual.[4] This conversion from compact to cancellous bone, without secondary remodeling and reorganization, is exceedingly rare or entirely absent in mammals.[4] Haversian systems can be found in specific areas involving the insertion of muscle or tendon to the cortex. This is advantageous to a growing animal, as the secondary Haversian remodeling within this section of cortical bone provides continuous attachment by the formation and reformation of new Haversian systems, which are continuous with the inserting muscle or tendon.[4]

The bones of squamates differ from those of chelonians and crocodilians in two notable ways. First, the cancellous trabeculae in the mid diaphysis of long bones is limited (compared with chelonians and crocodilians); however, the ends of long bones have extensive cancellous trabeculae. This is because as bones grow longitudinally, there is a transition from metaphysis to diaphysis by decreasing bone diameter. Therefore the composition of bone at the metaphyseal-diaphyseal transition is compact cancellous bone of endosteal origin.[3,4] The cortices of snake and lizard bones contain a mix of both endosteal and periosteal origin, as in chelonian and crocodilian bone.[4]

The second main difference is that the compact bone of periosteal origin in lacertilians and ophidians is virtually nonvascular. Vascular canals do exist but are located in the endosteal deposits of the metaphysis.[4] Within compact bone, the sparse distribution of vascular canals results in a process called osteocytic necrosis. This cellular necrosis is usually isolated to the more remote locations between vascular canals where blood supply is distant. As a direct consequence of osteocytic necrosis, the network of canaliculi become filled with mineral deposits. The middiaphyses of long bones typically have a broad cortex, therefore this location is most likely to demonstrate cell necrosis in lacertians given the increased distance between the inner and outer surface blood supply.[4] This condition has been described in the *Iguana,* as well as in the nonvascular areas of chelonian and crocodilian bone. Avascular bony tissue likely represents the result of a slower growth rate. The reduced cancellous trabeculae means that the previously described conversion from compact cortical to cancellous medullary bone seen in chelonians and crocodilians is not as prevalent in squamates. Additionally, since primary vascular canals are not present, the resorptive enlargement of primary cortical canals to form medullary spaces cannot occur, and formation of Haversian systems does not take place.[4]

Musculoskeletal Anatomy

Amphibia. The discussion of musculoskeletal anatomy of amphibians will focus on adult, postmetamorphosis amphibians. Caecelians resemble an earthworm in their body form and lack pelvic and pectoral girdles. No sacrum is present, and the ribs are uniquely double-headed.[5] The skull is solid compared with salamanders, which have a more intermediate skull. Siren salamanders lack a pelvic girdle, and some species of salamander lack digits.[5] Anurans are the most highly modified of the amphibians. Their skull is reduced, and there is no bony separation between the globe and oropharynx.[5] The sacrum is reduced, and there is a modified pelvic girdle. As an adaptation for jumping, many of the long bones are fused to create stronger bones to absorb landing impact or to add length to the legs to facilitate liftoff. These adaptations give rise to unique anuran anatomical terminology. The urostyle is composed of fused tail vertebrae retained within the pelvis; the radius and ulna are fused to form the radioulna; the tibia, fibula, and tarsal bones are fused to form the tibiofibula; and metatarsal bones are elongated and fused to form the calcaneum and astralagus.[5] The ileum is elongated and forms an additional joint with the sacrum, which is believed to aid in jumping.

Ophidia (Snakes). The most defining characteristic of the snake musculoskeletal system is the lack of legs for use in locomotion. Most snakes have pelvic remnants; however, only snakes in the infraorder Alethinophidia (e.g., Boidae) have vestigial limbs or spurs. The kinetic skull of snakes is a unique feature in which the ligamentous mandibular symphysis along with the quadrate bone allow the snake to open its mouth almost 180 degrees. The quadrate bone is an extra bone that articulates between the mandible and the skull, thus providing an extra joint.[6] Interestingly, snakes do not have cervical vertebrae yet have retained cervical musculature (Fig. 81.1).

Lacertilia, Amphisbaenia, and Sphenodontia (Lizards, Legless Lizards, and Tuatara). The Amphisbaenia are specialized in their morphology, as they are generally limbless. The total number of their vertebrae varies from 82 to almost 160, and the vertebrae themselves are typically flattened with no neural spines in the trunk region.[2] Differentiating the regions of the vertebral column is difficult. Although the vestigial pectoral and pelvic girdles are present, they have no connection to the vertebral column and serve as poor markers of anatomical region.[2] As the body form becomes more serpentine and the vertebral column elongates, lateral undulation as the main mode of locomotion increases. In contrast, bipedal lizards show shortening of the presacral vertebral column along with increased tail length. This serves as a counterbalance to the body, as locomotion becomes less reliant on lateral undulation. The shorter trunk increases lateral stability and moves the center of gravity over the hind limbs and pelvic girdle.[7] In lacertilia, the shoulder and pectoral girdle is complex, owing to its role in locomotion, ventilation, and feeding (Fig. 81.2). The pectoral girdle forms a system of braces to transfer forces and brace against forces. There is an indirect connection to the vertebral column, which includes the scapulocoracoid complex, interclavicle, clavicles, and sternum. The sternum meets the coracoid in a horizontal plane to brace the girdle from axial or inward-driving forces, whereas the clavicle braces against

(B) *Chameleo* showing the relative level of the glenohumeral joints (upper dashed line) and coracosternal articulation (lower dashed line). These different orientations affect weight transfer as depicted in (C) *Iguana* and (D) *Chameleo.* (C) Limbs in *Iguana* act as transverse struts and push coracosternal articulations together. *M. triceps* and *M. pectoralis* assist in this motion and actively force closed the coracosternal articulations. Weight bearing is only possible due to this active force applied. (D) Limbs in *Chameleo* are oriented more vertically, with the glenoid dorsal to coracosternal articulation. craniomedial forces. The exception to this arrangement is the chameleon, where the orientation of the articulation is turned dorsally (Fig. 81.3).[7] Finally, the scapulosternal ligament resists lateral forces. These three braces form a triangle around the scapulocoracoid to increase stability of the girdle in the absence of direct articulation with the vertebral column.[7] In the *Iguana* the clavicle articulates dorsally with the suprascapula, and the scapula does not bear a distinct acromion process. The suprascapula may or may not possess an acromion process depending on the body form of the species. In *Elgaria* it far exceeds the length of the scapula, whereas in *Xantusia* it is very short. In the *Uromastyx* and *Gallotia,* the suprascapula exhibits a number of holes along its dorsal border.[7] The clavicle attaches dorsally at the acromion zone, which is a calcified cartilaginous prominence on the suprascapula or an ossified process of the scapula. In dorsally compressed species, the scapula is fenestrated and the suprascapula bears the acromion process. Most fenestrae are occluded by a membranous tissue and are believed to be associated with the origin of muscles.[7] In laterally compressed species the scapula is thin, elongated, and bears the acromion process.[7] A great variety of fenestration anatomy has been described, including the presence or absence of fenestrae and foramina; the extent of osseous or cartilaginous borders surrounding the fenestrae; the shape and angle on the scapula; the fenestration of the suprascapular itself; and the form of the coracoid.[7] However, the clinical significance of these anatomical details is unclear. Therefore the reader is encouraged to consult cited resources for more thorough discussions of this anatomy.[7] In lacertilians the interclavicle is associated with muscles of the neck and shoulder that attach in patterns responsible for the shape of the bone.[8] The interclavicle acts to link the sternum to the clavicles, the two elements that brace the pectoral girdle. The median strut of bone resists compression between the ventral ends of the clavicles and transfers this force to the sternum.[7] Laterally, there are paired ligamentous processes that support and prevent lateral bending between the girdle elements. Both the ligamentous and the bony portions of the interclavicle serve as attachment sites for muscle fibers. Stresses exerted on the clavicle at the acromion are directed caudally onto the median process of the interclavicle, and thus the major role of the median process is to resist this compression.[7] A relatively short interclavicle increases stability of the clavicle relative to the sternum because rotation forces are minimized. This, however, has a cost in terms of lateral undulation locomotion. A longer interclavicle process may be related to greater lateral undulation locomotion.[7] Clavicles are never straight, but the degree of curvature varies between species. Expanded clavicles generally are recognized in

VetBooks.ir

species that are strong climbers with robust forelimb musculature. In general, the pectoral girdle is capable of displacement relative to the body wall in arboreal species but to a lesser extent in terrestrial ones.[7] The relative immobility of the girdle in some terrestrial forms is an adaptation to enhance lateral undulation locomotion. In *Varanus,* however, there is considerable movement of the primary girdle during locomotion. The degree of mobility of the primary girdle varies with the magnitude of the coracosternal angle, and it is greatest when the angle is low.[7] In arboreal species, increased mobility of the pectoral girdle provides greater range of limb postures.[7] The humerus is a complexly sculpted bone that is able to swing back and forth in the glenoid fossa while also undergoing long axis rotation.[7] One of the most noticeable features of the lacertian humerus is its apparent torsion, in which the proximal and distal expansions do not lie in the same plane. The flat surface of the proximal end is at an almost right angle to the distal end, and this torsion is thought to ensure transition of muscle forces from the distal part of the brachium to the antebrachium, owing to the characteristics of a sprawling forelimb locomotion.[7]

The glenoid is defined dorsally by a supraglenoid buttress and ventrally by an infraglenoid buttress. The glenoid surface itself is saddle-shaped, and the humeral condyle matches the glenoid fossa. The articular capsule of the glenohumeral joint is thin, composed of four ligamentous bands that form cruciate pairs.[7] In arboreal species, the glenohumeral joint is modified to permit greater range of motion. The cranioventral ligament is oriented so that it is placed more laterally beneath the glenoid and does not tighten when sliding occurs (as occurs in terrestrial species). This, in addition to expansion of the articular surfaces, permits the humerus to slide laterally during extreme abduction. Excursion into the cranial quadrants of the glenoid is also increased by the more lateral orientation of the articular surface. In terrestrial species, the glenoid fossa faces caudolaterally, whereas in arboreal species it is turned laterally on the girdle and affects lateral orientation of the limb. In chameleons the glenoid faces ventrally, giving a more vertical limb orientation. The major articulatory condyle of the distal humerus is the radial condyle, whereas the rim of the ulnar condyle forms by a pulleylike structure to guide the action of the elbow joint. The depression separating the condyles is the condylotrochlear gutter. The proximal radius and ulna bear two facets, each separated by a ridge, thus creating two articular cavities.[7]

The long axis of the radius is slightly curved, such that it is gently turned around the long axis of the ulna. Thus, with the forelimb in the standardized position, the curvature carries the long axis of the radius from proximolateral to distomedial.[7] Pronation of the antebrachium is manifested by the curvature of the radius in conjunction with the relationship of the proximal versus the distal ends of the radius and ulna.[7] The elbow joint axis moves from medial to lateral, whereas the wrist joint operates dorsoventrally. The net result is the maintenance of a constant position of the manus as the humerus undergoes backswing because the glenoid, elbow, and wrist joints permit compensatory movements of the limb.[7] In standardized posture the ulna is functionally the lateral-most element of the antebrachium. At its proximal extremity, there is a prominent olecranon process on which inserts the common tendon of the triceps complex.[7] The ulna of chameleons differs from most other lizards in that the olecranon is not well developed, with a flat proximal aspect and a lateral buttress at the distal extremity, which is unique.[7] This allows the elbow joint to more fully extend and permit an erect posture. In the *Iguana,* there are nine carpals: three in the proximal row, one in the middle row, and five in the distal row. The proximal row, from medial to lateral, consists of the radial, ulnar, and pisiform. The middle row consists of the central only. The distal row consists of a series of carpal elements, each associated with a single metacarpal bone.[7] The carpus of chameleons is the only major departure from the typical lacertian morphology. There are only two rows of carpals present; a proximal row of three elements consisting of a radial, ulnar, and pisiform, and distal row including a large central cartilage (postulated to be distal carpal 4) and a distal carpal 5.[7] No fusion of any distal carpals with metacarpals is observed. The functioning of the carpus in chameleons is very different from that in other lizards. Articulation takes place largely between the ulnar carpal bone and the large element of the distal carpal row. The wrist joint is thus mesocarpal and may be interpreted as mechanically equivalent to a ball and socket.[7] Only in chameleons is there any marked divergence from the basic plan of metacarpal structure. The metacarpals are depressed and expanded extremities and are divided into two bundles that articulate with the largest element of the distal carpal row. The first three digits comprise the medial aspect, whereas the fourth and fifth form the lateral parts of a "pincer" system.[7] The phalangeal formula varies somewhat both within and between families, but in general, phalanges are shorter than the metacarpal of their respective digit and also generally exhibit a progressive shortening distally.[7] The proportions of phalanges along the length of the digit vary between taxa, and the shortness of the intermediate phalanges in the longer digits (three and four) of certain taxa has been proposed as a modification associated with climbing.[7] Most geckos show digits of a more primitive type, with the acquisition of subdigital adhesive pads. The short metacarpals (and metatarsals) are important in the equalization of digit length and the spreading of the digits over a wide arc.[7]

The pelvic girdle has a direct connection to the vertebral column and includes the ilium, ischium, and pubis. Each of these elements, in part, compose the acetabulum. The pubis and ischium are separated ventral to the acetabulum by the thyroid foramen or fenestra.[7] The architecture of the lacertian pelvic girdle facilitates horizontal limb action, along with the adductor muscles, which aid in limb recovery (return to normal position).[7] Variations in pelvic girdle width have been correlated with locomotor patterns in lizards. Specifically, species that exhibit bipedalism generally have a narrower pelvis to allow the limbs to be adducted closer under the midline of the body.[7] The ilium of *Sphenodon* projects dorsocaudal, whereas in lizards it projects caudally. This arrangement results in the sacral vertebrae being located just above the acetabulum in *Sphenodon* and caudal to the acetabulum in lizards. Varanids have a steep, horizontally oriented iliac blade, whereas chameleons have an almost completely vertical iliac blade. The subsequent orientation of the hind limb is largely determined by pelvic girdle conformation and morphology of the femur.[7] In general, the femoral head is turned upward compared with the axis of the shaft, and the femur itself has a sigmoid curvature, which becomes clinically significant during fracture repair. The shaped femoral head is oval and confines the movement of the thigh to the horizontal plane. The acetabulum is larger than the femoral head, and therefore there is never complete contact over the entire acetabular surface at any one time.[7] In relation to bipedal locomotion, the internal trochanter acts as a lever on the ventral acetabular edge, which tends to pull the femoral head from the acetabular socket. This positioning precludes, to some degree, pulling the legs completely underneath the body, which would result in a more vertical posture during bipedal locomotion.[7]

The lacertian stifle is bicondylar as in mammals, yet it differs significantly. Mammalian femoral condyles are typically symmetrical and arranged in line with the long axis of the femur. Among lizards, this orientation is only seen in chameleons. In all other lizards, the femoral condyles are asymmetrical, with separate contact surfaces for the tibia and fibula.[7] The lateral femoral condyle has a cone or wedge shape in *Varanus*, *Tupinambis*, and *Lacerta* but takes a more cylindrical shape in *Basiliscus* and *Iguana.* Similarly, the patellar surface is well defined in *Varanus* and *Tupinambis* but is a shallow groove in

Lacerta and *Iguana*. In *Basiliscus* and *Chamaeleo* the patellar groove is essentially absent.[7] These differences in distal femur anatomy affect the structure and function of the stifle in different species. Within the stifle, the articular surfaces are defined proximally by the lateral and medial femoral condyles and distally by the meniscus and proximal tibial epiphysis. The meniscus increases the stability and congruence of the joint while aiding in lubrication. Laterally, the proximal fibula forms the margin of the stifle by articulating with the lateral femoral condyle via the cyamella sesamoid. The exact location and presence of a cyamella sesamoid is variable between species. The stifle joint is stabilized by the joint capsule, collateral ligaments, and cruciate ligaments, and part of the joint capsule is formed by the quadriceps femoris muscle. Continuous with the synovial cavity is a bursa created between the quadriceps tendon and the intercondylar groove.[7] The collateral ligaments are formed by the two lateral femorofibular collaterals and the medial femorotibial collateral ligaments.[7] The femorofibular collateral ligaments cross, and all collaterals are in tension throughout normal range of motion to maintain position and contact of the stifle joint.[7] The two cruciate ligaments originate in the ventral intercondylar groove of the femur and insert on the proximal tibial epiphysis, just medial to their point of origin.[7] The cruciate ligaments cross each other and are oriented lateral to medial.[7] This is in contrast to cruciate ligament anatomy in most small mammals (dogs and cats), which have two cruciate ligaments named for their insertion on the proximal tibia—the cranial and caudal cruciate ligaments. In reptiles, the fibula and tibia are well attached by the proximal and distal tibiofibular ligaments. Additionally, these bones are constrained from rotation due to their articulation with the astragalocalcaneum. As a result of this cumulative anatomy, and most importantly the asymmetry of the femoral condyles, the stifle joint is not perpendicular to the long axis of the femur. Rather, the line of motion of the joint runs parallel to the contact surface between the meniscus and the femoral condyle, passing in a distolateral to proximomedial orientation.[7] The tarsus is reduced with only two tarsal bones in lizards (the third and fourth tarsals), and three in *Sphenodon* (the second, third, and fourth tarsals), which gives asymmetry of the tarsus and foot. The distal tarsals are functionally firmly bound by ligaments to the first four metatarsal bones and can be viewed as a tarsometatarsus. These metatarsals are enclosed in a cutaneous sheath and form the sole of the foot. The fifth metatarsal is specialized, shorter, and has an offset articulation with the fourth distal tarsal bone, which lends a "hooked" appearance to this toe.[7] This consolidation of the tarsus may improve transfer of forces into forward propulsion. There is an increase in metatarsal length, such that the distal tips of the first three metatarsals lie on a straight line, the metatarsophalangeal line (Fig. 81.4).[7] This striking asymmetry of the lacertian foot is an adaptation for sprawling locomotion and stands in contrast to the near symmetrical feet of crocodilians.[7] Phalangeal morphology is fairly uniform and the phalangeal formula is 2-3-4-5-4. Geckos, especially those species that exhibit subdigital adhesive pads, are unique in that they are the only group of normal-limbed lizards to exhibit claw loss, which may occur on one or all digits.[7]

Some species of lizards are capable of tail autotomy (iguanids, geckos). This is considered a predator avoidance strategy, in which the tail is self-detached along a preexisting fracture plane and is cast off with minimal hemorrhage.[9] The tail will regenerate in time, and the autotomized tail will wiggle on the ground, presumably to distract the predator. In species that undergo tail autotomy, each caudal vertebra has a cartilaginous fracture plane through the vertebral body and neural arch. Fracture planes are absent in the cranial part of the tail to protect the hemipenes and fat deposits.[9] The lost tail is regenerated with a

cartilaginous rod for support and is covered with smaller darker scales in an irregular pattern compared with the original tail.[9] Tail autotomy is clinically relevant, as stress and handling can cause tail fracture. Additionally, tail autotomy should be considered in cases of surgical tail amputation. A study in leopard geckos, *Eublepharis macularius,* demonstrated that tail autotomization along a preexisting fracture plane or surgical amputation outside of a fracture plane resulted in scar-free wound healing and regeneration of the tail regardless of location or mode of detachment.[10] In leopard geckos, wound healing is characterized by transient myofibroblasts and highly proliferative wound epithelium, which is immunoreactive for wound keratin marker WE6.[10] New tails form from a blastema, which is a mass of mesenchymal cells. Unlike mammals, transforming growth factor B3 is not involved in wound healing in these lizards.[10] Tail autotomy generally does not occur in agamid lizards, monitors, or true chameleons, and these species do not regenerate tails that are lost from trauma or amputation. Other species of lizards may have prehensile tails, which aid arboreal movement.

Chelonians. The most unique anatomical feature of chelonians is the presence of a shell, including a dorsal arched disc, the carapace, and a ventral plate, the plastron. (See Chapter 70 for more detailed information.) Most turtles can retract their heads and necks into their shell, though *Pleurodira* species retract their head and neck horizontally, and *Cryptodira* species retract their head and neck vertically. Sea turtles cannot fully retract their head and neck under their shell.[11]

The vertebral column in chelonians is quite specialized, with 18 presacral vertebrae (8 cervical, 10 trunk; the lowest number among reptiles).[2] In the neck, the vertebrae are mobile, whereas within the carapace they are ankylosed to each other, and the ribs are connected to the carapace. Unique cervical anatomy is present in *Cryptodira,* in which the vertebrae articulate in such a way as to permit sagittal flexure of the neck.[2]

Within the carapace, the rigid ribs originate from the spine and extend laterally. They are engulfed in dermal bone. Each rib has a dorsal and ventral cortex, which enclose cancellous bone.[12] This arrangement aids in weight reduction of the shell. The ribs are also attached to each other via soft, unmineralized collagenous suture lines, which make up a zig-zag pattern.[12] This enables displacement caused by minor loads.[12] The sutures are located in such a way that the tissues take on a rib-suture-rib pattern in order to protect the compliant sutures from failure upon cranial-caudal bending forces. This further prevents any possible cracking from being propagated in a cranial-caudal direction. Cracks (from a focal force) typically originate in the brittle ribs and advance laterally, not from one rib to another. This pattern of rigid and compliant features helps to protect the carapace from catastrophic failure.[12]

The pectoral girdle of chelonians is unusual (Fig. 81.5). Dermal bone elements are incorporated into the plastron, with the clavicle contributing to the epiplastron, the first pair of lateral bony plates in the plastron.[13] The interclavicle is incorporated into the entoplastron, a median bony plate of the cranial part of the plastron.[13] The pectoral girdle is a triradiate complex within the cranial portion of the shell.[13] The scapula has long projections, which make it unique anatomically. The scapular prong is columnar and extends dorsomedially toward the carapace. A suprascapular cartilage connects the scapular prong by way of a ligament, to the cranial border of the first rib and carapace. The acromion is on the cranioventral aspect of the scapula, which extends craniomedially and ventrally almost perpendicular to the scapular prong. The acromion has a cartilaginous cap, which attaches to the entoplastron via a ligament.[13] The two almost vertical scapular prongs form a truss for the transfer of body weight from the vertebral axis and shell to the limbs. The scapula articulates with two small joints on the shell, between which the pectoral girdle rotates. This pectoral girdle rotation normally occurs with respiratory movements as well as locomotor patterns. A coracoid, which is considered the equivalent of a procoracoid of other

reptiles, extends from the scapula caudomedially in approximately the same plane as the acromion.[13] The coracoid is broader than the acromion and has a sickle-shaped epicoracoid cartilage on the medial edge. There is no ligament between the coracoid and the plastron, yet a connection exists between the acromion and the coracoid, the acromiocoracoid ligament.[13] In sea turtles, the coracoid is longer than the scapula, and this is correlated with swimming ability.[13] In some other families (mainly terrestrial), the coracoid is as wide as it is long, and there is also variability in the size of the epicoracoid cartilage. Limb morphology of chelonians also varies between species. Marine species have more flattened appendages with reduced or absent claws adapted for swimming, whereas terrestrial species may have flattened forelimbs with claws adapted for burrowing. Freshwater species have interdigital webbing to aid swimming, whereas this webbing is absent in terrestrial species.[11]

The chelonian humerus is unique in that the diaphysis arches and rotates around the long axis relative to the humeral head so that the morphological dorsal surface is directed cranially.[8,13] This unique feature allows the humerus to be protracted very far forward during locomotion and as the animal retracts into the shell. This degree of arching can vary slightly between species, and sea turtles have a notably stouter and flatter humerus compared with freshwater and terrestrial species.[8] These anatomical differences in humeral arching and rotation become clinically significant during fracture repair and other procedures. The ulna is broad and dorsoventrally flattened. The radius is more columnar and slender, and these forearm bones tend to vary less between species. The carpus is typically short. The metacarpals are unspecialized, with a row of five metacarpals proximally, and a phalangeal formula of 2-3-3-3-2. All toes are clawed and the foot is webbed in freshwater aquatic species. Terrestrial groups have further reduction of the phalangeal formula of 2-2-2-2-2 or 1, and no webbing is present. In highly aquatic species, the manus is elongated to form a flipper. The claws are retained (though reduced) except in the most aquatic species (*Dermochelys*).[8]

The pelvic apparatus includes the pelvis and bones of the hind limbs. The pubis and ischium act as struts to support a vertical ilium, which extends dorsally to the sacrum. The ilium of *Pseudemys* inclines posteriorly and expands distally to create an iliac blade. This articulates with the three sacral vertebrae and ribs. These caudal ribs expand to form a buttress with the carapace, which also articulates with the ilium. In species with reduced tail musculature, the iliac blade has smaller posterior expansion.[8] A thyroid fenestra (also called obturator fenestra or puboischiadic foramen) separates the pubis and ischium. This thyroid fenestra is associated with passage of the obturator nerve and the origin of the puboischiofemoralis externus muscle.[8] The degree of convergence of the pubis and ischium medial to the thyroid fenestra varies with species, thus affecting the distance between the fenestrae. The degrees of convergence are described as complete, nearly complete, partial, and no convergence. Emydinae and Testudininae have nearly complete convergence separated only by a small piece of cartilage. *Dermochelys* also has near-complete convergence, though the fenestrae are much smaller than other groups. In Cryptodira, the convergence is complete and the ischium and pubis are continuous. The most common conformation is partial convergence with separation achieved with a rod of cartilage as seen in Dermatemydidae, Chelydridae, Staurotypinae, and Plastysterninae. There is essentially no convergence in Cheloniidae, Carettochelyidae, and Trionychidae, where the fenestrae reach midline separated only by a ligament or a very thin rod of cartilage.[8] The pubic symphysis is separated from the ischiadic symphysis by a rhomboid cartilage. The caudal border of the ischium curves ventrally to rest on the plastron, and the pubis is extended cranially by epipubic cartilage. This epipubic cartilage can be ossified in Chelydridae, Kinosternidae, and some emydines. All pelvic girdle elements contribute to the formation of the acetabulum, though the ilium has the largest facet. The pelvic girdle in Pleurodira is uniquely fused. The ilium ankyloses with the last one to two pleural plates, and the pubis and ischium are fused with the xiphiplastron.[8]

The femur is similarly shaped as the humerus but is longer, with a typically oval-shaped femoral head (except in testudinines, which have a round femoral head). The femoral head is offset from the long axis of the bone at an angle of approximately 120°.[8] Proximally, the minor trochanter corresponds to the internal trochanter seen in other reptiles. The major trochanter is unique to chelonians but is likely originated from the ventral ridge, as seen in other reptiles. The intertrochanteric fossa is deep, and the femoral shaft arches dorsally to a lesser extent as the humerus. The distal femur fans out and forms the large tibial condyle. A small fibular condyle is located caudoventral, with a fibular epicondyle located dorsal and proximal.[8] The typically arched femur is nearly flat in sea turtles. In aquatic species, in which the hind legs presumably have greater propulsive thrust than the forelimbs, the femur is subequal or longer than the humerus. In terrestrial species, in which the forelimbs are more important for burrowing, the femur is significantly shorter than the humerus.[8] The tibia and fibula are of similar length, though the tibia is somewhat thicker. The tibial head expands to articulate with the tibial condyle of the femur. The longitudinal cnemial crest, to which the patella tendon attaches, extends along the tibia's dorsal surface.[8] The fibular head articulates with the tibia and femur proximally and the tarsus and tibia distally. The stifle has less range of motion than in other reptiles and is limited to extension, flexion, and minimal rotation.[8] The crurotarsal joint has essentially no movement, whereas the tarsometatarsal joints do move.[8] The foot is bent at the mesotarsal joint, which keeps the sole of the foot flat on the ground. The astragulus and calcaneum of sea turtles is unique and provides extra flexibility to the ankle.[8] The additional rotation achieved allows the distal appendage to be used as a rudder. In other species, the astragulus and calcaneum are fused to form a single unit. The metatarsals are unspecialized, except for the fifth metatarsal, which is flattened, L-shaped, and broadens the foot.[8] This aids webbing, particularly between digits four and five. The fifth toe is clawless as it is completely included in the webbing.[8] During locomotion, the medial aspect of the foot makes firmest contact with the ground. The most common phalangeal formula is that of freshwater turtles, 2-3-3-3-3, though the fifth digit does not bear a claw and therefore the terminal phalanx is often very small or not present. Terrestrial species have short toes with stubby claws and no webbing. The reduced phalangeal formula is 2-2-2-2-1(0). In marine species, there is a tendency toward toe elongation and hyperphalangy. The phalangeal formula is 2-3-3-3-4 in *Chrysemys* and *Malaclemys* and 2-3-3-4(5)-3(4) in Trionychidae. *Pelomedusa* demonstrates fusion of the proximal two phalanges on the second digit, giving a stiffer foot and a phalangeal formula of 2-2-3-3-3. Most aquatic species have four claws, but Trionychidae has three, *Carettochelys* has two, Cheloniidae has one or two, and *Dermochelys* has none.[8]

The rectus abdominus muscle arises from the plastron and inserts on the lateral pubic process. This muscle is important because it, along with the testoiliacus muscle, which originates from the carapace and inserts on the ilium, helps anchor the pelvis to the shell.[8] The rectus abdominus muscle also plays a minor role in respiration. Both of these muscles are absent in *Pelomedusa,* in which the pelvic girdle is fused to the shell.[8] Typically, dorsal muscles are innervated by dorsal nerves (from the brachial and lumbosacral plexuses), and ventral muscles are innervated from ventral nerves from the plexus.[8] There are some muscle groups, typically large muscles like those in the thigh, which receive double innervation.[8]

Crocodilians. Likely, the most striking feature of crocodilians is their uniquely adapted skull. The general skull characteristics include an

elongated snout and expanded premaxilla, which isolates the external nares from the maxilla.[14] The elongation of the jaw and narrow snout reflects adaptations to prey, with the longest-snouted species being specialized for ichthyophagy and the species with more moderate length snouts feeding on a greater variety of animals (reptiles, birds, fish, mammals).[14] As the elongation of the snout increases, so does the mandibular symphysis.[14] Width of the external nares is inversely related to length of the snout, as is orbit size. The skull is flattened, particularly the dorsal postorbital segment of the cranium (often called the cranial table), and has caudolateral protrusions.[14] The temporal fossa and middle ear are highly modified, with the quadrate and pterygoid bones expanded medially to contact the lateral aspect of the cranium.[14] The squamosal bones are laterally expanded to overhang the external ear, creating deep "pockets" across which the tympanic membranes are stretched.[14] These overhangs are thought to protect the tympanic membrane from injury. Further, the quadrate bones are inclined, which causes the jaw articulation to be displaced caudally, yet crocodilians do not possess a kinetic skull.[14] Thecodont teeth are found on the premaxilla, maxilla, and dentary bones. The most rostral teeth prehend prey, whereas the middle of the tooth row crushes the prey item.[15] Strong, quick muscles are necessary for feeding, and the placement of these muscles must not restrict the gape.[15] Therefore the adductor muscles are spread over the ventral surfaces and outside surfaces of the jaw.[15] There is a secondary palate formed by the palatal process of the premaxillae, maxillae, palatines, and pterygoids.[15] The long, narrow snout has undulations along the lateral margins.[14] These lateral margin undulations form three convex and two concave arches on each side. The convex arches of the mandible are opposed by concave arches of the maxilla and vice versa.[14] These undulating arches let the crocodilian hold captured prey more firmly and are more developed in shorter-snouted crocodilians than those species with longer snouts.[14]

The nasal passages are extended caudally and run the full length of the snout.[14] The palatine and pterygoid bone extensions permit this nasal passage extension, where they terminate in the secondary choanae ventral to the cranium.[14] The orbits themselves are displaced dorsally along with the external nares, which leads to confluence of the external nares into a common opening. This, along with the previously described flattening of the dorsal surface of the skull, permits the animal to remain inconspicuous in the water, as only the nostrils, eyes, and flat cranial roof are exposed.[14] The bones of the crocodilian skull are pneumatized, though the function is not completely understood. It has been hypothesized that this feature may increase the isolation of the internal ear from sounds transmitted by water.[14]

The appendicular skeleton has many distinguishing features. The femoral head is prominent and deviates medially from the shaft.[16] Distal condyles are also prominent and project caudally, though the fibular condyle is less prominent. The proximal tibia is flat, whereas the distal end is sloped.[16] This all serves to reduce the complexity of the stifle and hock to permit increased range of motion of these joints seen in crocodilian locomotive patterns.[16] The tarsal joints are characteristically oblique, and when the ankle is flat on the ground, the crus is angled medially.[16] The metatarsals overlap at the proximal end, creating a functional metatarsal wedge, which increases strength of the foot.[16] The foot is also mediolaterally compressed with reduced external digits to further increase lever capability. Interestingly, in the belly walk (described later), crocodilians may evert the fourth digit to use as a pivot point for pedal rotation, similar to the use of the fifth digit in lizard locomotion.[16]

Locomotion

Snakes. Snakes use five (at least) described modes of locomotion. The specific locomotion method depends on the surface on which the snake is moving and its speed. Remarkably, an individual snake can utilize different modes in different body segments. The five described modes of locomotion are lateral undulation, sidewinding, concertina, rectilinear, and slide-pushing.[17,18] Lateral undulation is the propagation of waves of lateral bending along the body. Sliding friction is a critical component of lateral undulation. The defining feature of lateral undulation is that as objects are contacted, a force is exerted against the object and deforms locally around it.[18] When a snake pushes against multiple objects simultaneously, the lateral force vectors are canceled out, which results in forward propulsion. Snakes possess fine sensorimotor control over the direction of force exertion by utilizing postural adjustments.[18] The large dorsal epaxial muscles are activated sequentially. These muscles are unilaterally activated with each bend of the body, from the convex side toward the straight and concave regions. This continues and each part of the body follows the path of the head and neck.[18] Sidewinding resembles lateral undulation in the pattern of bending but is otherwise quite different. The snake body segments are sequentially placed in static friction with the surface (vs. sliding), and the body segments are physically lifted off the ground between regions in static contact with the ground surface.[17,18] This moves the body forward by rolling from the neck to tail. The body moves diagonally relative to the track formed, and the tracks left by sidewinding snakes correspond to snake length. Epaxial muscles are active as in lateral undulation, though many times the muscles are active bilaterally during trunk lifting.[18] Concertina locomotion is when the front and back halves of the body alternate between bending and straightening. Forward movement is achieved as the body straightens away from the bends in a forward direction. This mode is used for moving through a narrow space or climbing.[19] The muscles are activated in bending segments unilaterally. Rectilinear locomotion is when the snake moves in a straight line. This is more typical of large snakes (boas, pythons, large vipers). The ventral scales are lifted up and forward, then pressed back down and backward, thus propelling the body forward over the scales. This occurs simultaneously in multiple body segments, and when the body has moved forward enough to result in stretching of the scales, the pattern repeats. This mode is reliant on the static friction between the ground surface and the ventral scales.[20] Bilateral muscular activity, specifically of the muscles connecting the skin to the skeleton, permit this locomotive pattern. It is dependent on active ribs and ventral scales and is not seen in *Tropidonotus*.[18] Slide-pushing is the result of vigorous lateral undulations as the body slides over a smooth surface. Irregular body bends and tail-pressing result in enough downward force onto the surface to move the body in a stepwise pattern. The movement is not regular, and slipping is encountered throughout the movement. There are moments of static contact, but slide friction is most important in slide-pushing. This is typically seen when a snake is startled on a smooth surface and tries to flee.[17]

Lizards. Lacertian locomotion is fundamentally different from mammalian locomotion, as lateral bending of the trunk is a defining feature. Limbless lizards rely entirely on lateral undulation for forward propulsion.[17,21] This may suggest that the limbs of lizards play a less important role in locomotion than in mammals. The typical posture of lacertians can be described as "sprawling," with the body slung between laterally oriented limbs, or "erect," with the limbs pulled more vertically under the body (Fig. 81.6).[7] The morphology of the femoral head and its relation to the acetabulum (as described previously) permit this change from horizontal to vertical femur orientation.[7] Hypaxial trunk muscles of *Iguana iguana* stabilize the trunk during slow speed walking, and lateral trunk bending is the result of activity of the rectus abdominus and external oblique muscles in *Varanus salvator*.[7] Lateral bending at low speeds serves to increase stride length, whereas at higher speeds it

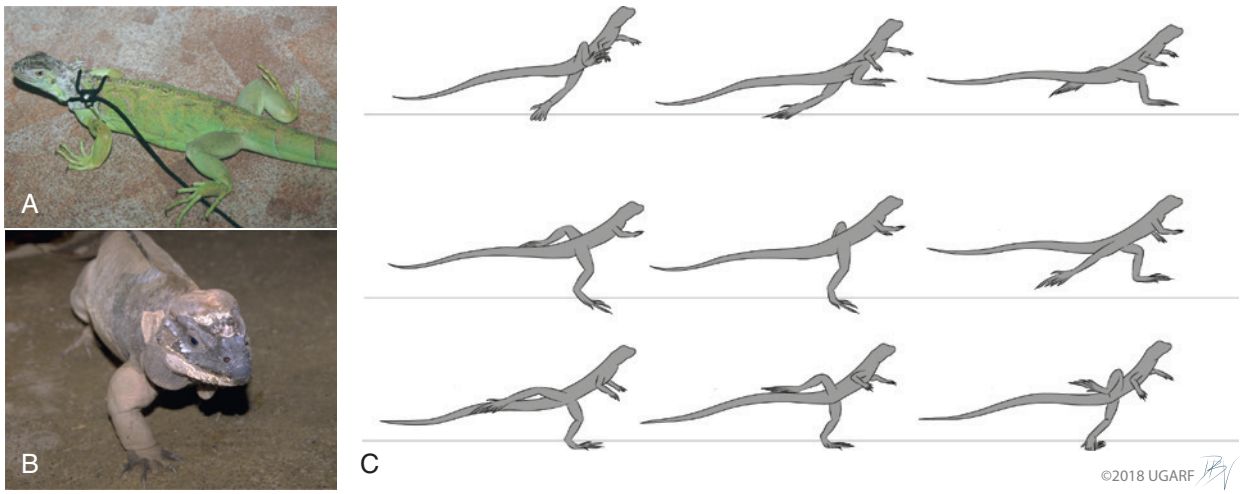

FIG 81.6 Lacertian locomotion. Sprawling, erect, and bipedalism. (A) Sprawling posture. (B) Erect posture. (C) Bipedal locomotion. Bipedal locomotion is accomplished by thrusting one or both hind limbs, rapidly followed by one hind limb swinging around in a lateral arc to catch and support the weight of the body, thus creating the first bipedal step. The forelimbs do not play a significant role, and the tail is used as a critical counterbalance to achieve coordination and propulsion. serves to produce propulsive force and provide limb support and coordination.[7] Simply, lizards typically use an "inverted pendulum" gait at slow speeds, and a bouncing gait (trot) at high speeds, similar to the main two gait types observed in mammals.[21] The inverted pendulum corresponds to walking and refers to the pendulumlike movement of the legs, as well as the exchange between the kinetic energy and the gravitational potential energy of the lizard's center of mass, with the legs acting as stiff struts.[21] As a result of this arrangement, the pendulum-like energy exchange reduces mechanical energy requirements in this gait by as much as 70%, thus making walking an energy-efficient mode of locomotion.[21] At higher speeds, bouncing gaits are used in which the legs behave as more compliant springs. There is no significant energy savings (between kinetic and gravitational potential energy) in bouncing gaits; however, the elastic energy storage present in muscles, tendons, and ligaments provides some energy savings in these higher-speed gaits.[21]

Sprawling posture has also been defined as a posture or gait in which the humerus and femur cannot attain an orientation with their long axes directed vertically. It has been considered "primitive" based on its evidence in the earliest tetrapods; however, it may offer an advantage in climbing; inclined movement; sprinting; and frequent, rapid acceleration of small-bodied lizards.[7] The propulsive limb stroke has five phases: humeral/femur backswing, long axis rotation, forearm/crus rotation, forearm/crus flexion, and forearm/crus extension.[7] The limb movements are coordinated in a diagonal manner, which allows the body to remain in equilibrium during all phases of the movement cycle. This diagonal coordination during walking means the diagonal forelimb leaves the ground before and touches back down before the diagonally opposite hind foot.[7] As previously described, the anatomy of the lacertian stifle is asymmetrical and prevents significant rotation of the crus. Therefore rotation of the crus occurs at the cruropedal articulation.[7] The asymmetrical tarsometatarsus permits enough flexion for the crus to orient almost perpendicular to the pedal long axis, and thus the foot can act as an additional limb lever.[7] In larger-bodied lizards, and as the limbs increase in length, this sprawling posture/gait is less effective, because the horizontal action of the limbs fails to vertically lift the center of body mass, and the hind limbs can physically interfere with the action of the forelimbs.[7] This means the span of time in which the body is "suspended" is very short or absent.[7] The inherent problems of sprawling posture and gait in large-bodied lizards can be overcome by bipedal locomotion, as this provides vertical lift of the cranial body mass and increased stride length yet does not increase speed.[7]

Bipedalism, which is classically associated with *Basiliscus basiliscus*, is a locomotive behavior exhibited by more than 50 species of lizards.[22,23] During bipedal locomotion, the trunk is elevated and the hind limbs power forward movement. The epaxial muscles allow for the cranial torso to be elevated, and there is no significant contribution from the forelimbs.[24] *Basiliscus* can begin bipedal motion from a resting position by thrusting both hind limbs, rapidly followed by one hind limb swinging around in a lateral arc to catch and support the weight of the body, thus creating the first bipedal step. The hind limbs arc laterally with each step, the pelvis rotates to increase body length, and the spine undulates laterally.[22] The proximal portion of the tail is elevated during bipedal locomotion, though the tip of the tail may drag. Though the hind legs actively participate in propulsion, the tail is critical for bipedalism and acts as a counterbalance to the trunk and head of the body. With decreasing tail length, bipedal locomotion is negatively affected.[24] When the caudal one-third of the tail was removed, bipedalism was only possible for a short distance, and when the caudal two-thirds was removed, bipedalism was not possible.[7] This is because the most powerful muscles causing hind-limb retraction (including the caudofemoralis muscle) are in the base of the tail, and tail removal may also disrupt neural feedback mechanisms to coordinate bipedal locomotion.[7] There is no difference in bipedalism based on substrate; however, there are differences in terrestrial and aquatic bipedalism. Lateral undulation of the spine is exaggerated in the water, likely to counter drag.[24] Locomotion analyses have not shown any energy or speed advantage of bipedalism over quadrupedal locomotion, though bipedalism may be utilized as a defensive posture or when escaping predators.[21–25] *Varanus* species specifically have been noted to take a tripodal stance balancing on the hind limbs and tail during times of intraspecific aggression.[7]

In species that display a more erect posture, like chameleons (and crocodilians during rapid locomotion), the humerus and femur are further depressed during the stance phase compared with sprawling lizards.[7] The humerus and femur undergo backswing in a vertical orientation, which requires less muscle bracing because upward thrust is braced by skeletal components. This transition to a more erect posture in chameleons was

VetBooks.ir

likely associated with the need to navigate narrow branches and is further associated with the grasping modifications of the feet.[7]

Other modes of lacertian locomotion include aquatic and sand swimming. No physical adaptations or modifications have been observed to accommodate aquatic locomotion, even in the marine iguana, *Amblyrhynchus*.[7] Many species are able to swim and do so by using body and tail lateral undulations. Species that burrow and move over shifting sand display a variety of toe fringes. These fringes can exist in various shapes and be present on one or all toes. Fringe morphology has been strongly correlated with substrate and enhances locomotor performance over loose sand, which is likely to be advantageous in escaping a predator or apprehending prey.[7]

Crocodilians. Crocodilians utilize a belly walk in a sprawling posture and a high walk in an erect posture (Fig. 81.7).[26] The crocodilian sprawling posture is functionally different than the sprawling posture of more primitive lizards and amphibians (where limbs are held laterally to the body). Kinematic analysis of the crocodilian sprawl has suggested it is actually just a lower version of the high walk and could more correctly be termed a "low walk."[26] The transition from the belly or low walk to the high walk in crocodilians occurs as speed increases and as they transition from wet and muddy substrates (belly walk) to drier substrates (high walk).[26] The belly walk is only used for short distances, usually as a transitional behavior to a high walk. They can also transition into a gallop at higher speeds or on heterogeneous substrates.[26] Crocodilians increase speed by recruiting the distal limb elements rather than of the proximal limb.[26] This strategy is completely different from that of other terrestrial vertebrates.[26] The percentage of the stride that the foot maintains contact with the ground (duty factor) does not change as speeds increase but rather stride length increases. This is quite unique, as most tetrapods increase speed by altering the swing and stance proportions of the stride and decreasing duty factor.[26] In addition to a constant duty factor, axial bending does not alter as speed increases.[26] In order to accomplish this, the ankle must attain a more plantar-flexed position at high speeds to allow quick ankle extension to generate propulsive force and stride elongation.[26] As speeds increase, the knee is flexed less in the swing phase, which results in a longer limb at the foot-down stance phase. The stride length and speed are increased as the longer limb (resulting from a more extended knee) is retracted, and the more flexed ankle is more quickly and forcefully extended against the ground.[26] Given these unique features of posture and locomotion, it is postulated that crocodilians evolved from erect ancestors and independently evolved a variable semierect posture.[26]

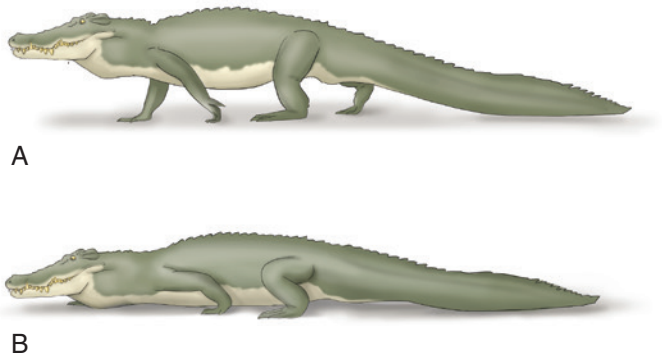

FIG 81.7 Representations of the "high walk" and "belly walk" or "low walk" postures of crocodilians. The "high walk" (A) is the primary posture for travel, whereas the "belly walk" or "low walk" (B) is a transitional posture typically used on wet or muddy surfaces. Bone Healing

A slower rate of fracture repair is expected, owing to the ectothermic nature of reptiles. The typical sequence of events in reptilian bone healing includes rapid epithelialization, sequestration of dead bony fragments, proliferation of the dural periosteum, organization and fibrosis of the callus, osteoblast differentiation, osteogenesis, and bony union.[27] Early fracture repair is defined by formation of proliferative periosteal, medullary, and intermuscular (parosteal) connective tissue (blastema) around the hematoma at the fracture site (Fig. 81.8A).[28] Cartilage and new bone are first deposited in the periosteal blastema, and later new bone is placed in the medullary blastema (Fig. 81.8B). The parosteal blastema develops similarly to granulation tissue. Cartilage is the primary tissue type in the periosteal blastema of amphibians and reptiles, whereas new bone replacement occurs slower than in mammals. New bone formation is also less regular, with invasion of new bone from all sides of the fracture. The vascular spaces are wider, with coarser endochondral bone trabeculae compared with mammals. The vascular spaces are eroded slowly, and the new bone matrix is deposited along the walls of these spaces. Calcification lags behind this process and depends on new ingrowth of blood vessels.[28] There is no evidence of secondary cartilage development in the fracture callus in reptiles and amphibians.[27] It is theorized that secondary cartilage arose late in vertebrate evolution and is limited to endothermic animals.[27]

GENERAL APPROACH TO CASE MANAGEMENT

Examination

A thorough clinical history and physical examination are critical to successful case investigation and management. Important husbandry data to discuss includes diet offered and diet eaten; vitamin and mineral supplementation including amounts, feeding method, and frequency; humidity range; temperature range; substrate; enclosure furniture; presence and type of water available (bowl, moving/filtered water feature, mister, fogger, dripper, etc); type of supplemental heat (heat mat, ceramic basking bulb, etc.) including location in/out of cage; use of thermostat, light timers, and associated settings; and light type (UVA, UVB, fluorescent, etc.), light cycle provided, and frequency of bulb replacement. It is also essential to establish a relationship of trust with the client or caretakers to permit effective client education in cases of inappropriate husbandry conditions. Management of caretaker expectations regarding case prognosis, time frame, required nursing care, need for referral, and financial investment is also critical.

Diagnostic Imaging

Clinical suspicion of musculoskeletal disease should warrant pursuit of diagnostic imaging for further injury or disease assessment. Radiographs are useful in evaluating bone cortical thickness and integrity, as well as presence and conformation of traumatic and pathological fractures and luxations. Osteomyelitis can also be evaluated radiographically, but it cannot be diagnosed solely based on radiographs. To diagnose osteomyelitis, demonstration of infection with histopathology and culture is required. In reptiles, osteomyelitis presents radiographically as lytic lesions. The periosteal reaction typically appreciated in mammals is not always a key feature in reptiles. Characteristic osteomyelitis in reptiles is defined as osteolysis with or without new bone formation or proliferation. This can resemble the appearance of neoplastic change in mammalian bone and can be misinterpreted as such in reptiles.

Computed tomography is often necessary to evaluate complex anatomical regions, fractures, osteomyelitis, and neoplasia. Chelonians may present a challenge to interpret bony structures radiographically due to the degree of bony superimposition with the carapace and plastron.

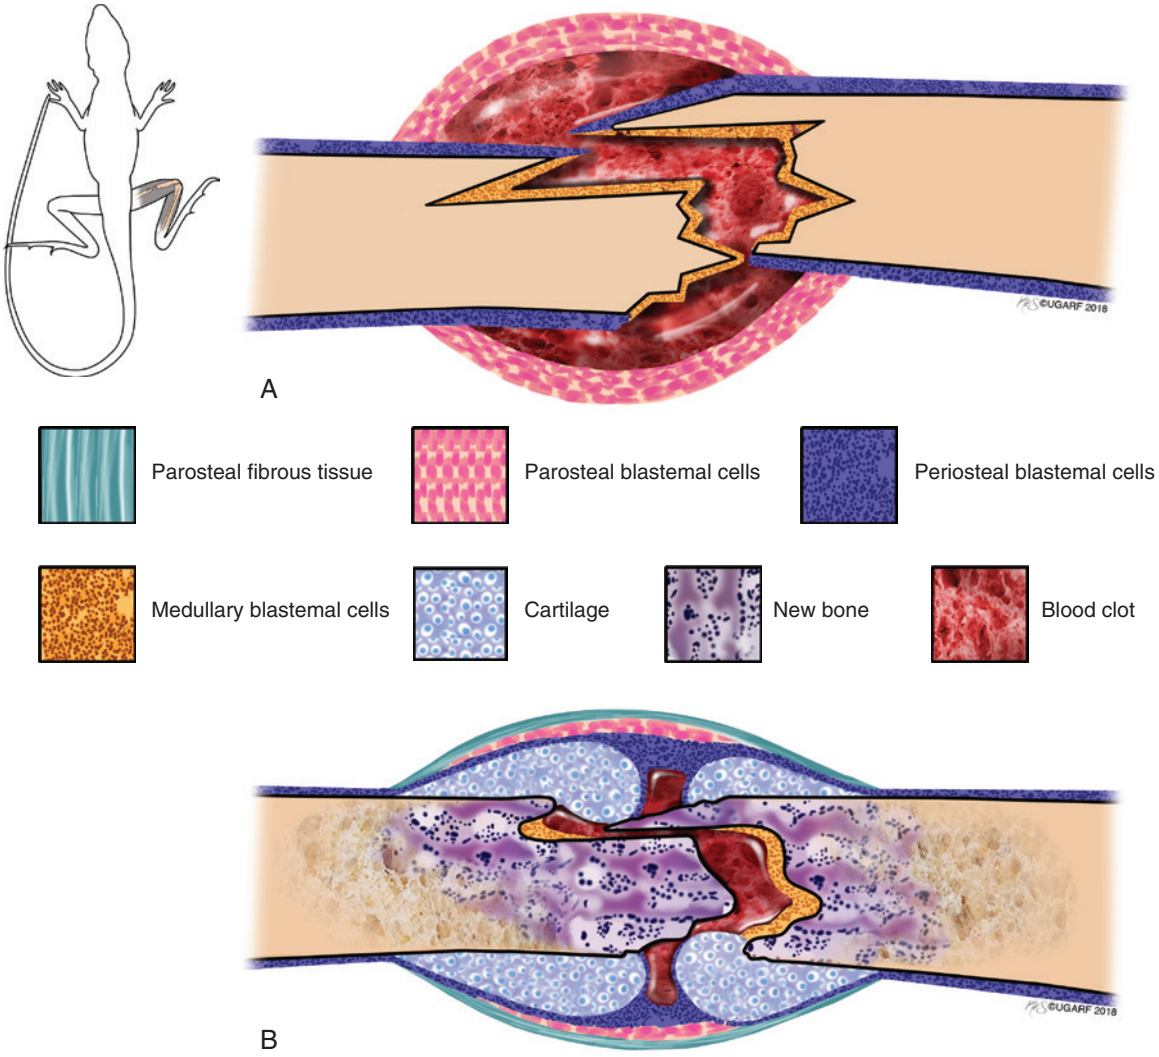

FIG 81.8 (A) The periosteal, medullary, and parosteal blastemal response of a fracture at early stage. (B) New bone, cartilage, and fibrous tissue at later stages of bone healing. (Redrawn with permission by Educational Resources, University of Georgia.)

Osteoderms in crocodilians can pose a similar challenge. Therefore CT may offer superior imaging in these species. For a more detailed discussion, see Chapters 53 through 57, 59 and 61.

Therapeutics

Therapeutics will depend on the underlying diagnosis. General assessment of patient condition by way of physical examination, clinical history, baseline clinicopathologic data (hematology and biochemistry profile), and imaging is important in guiding appropriate therapeutic choices. The most common therapeutics used in various musculoskeletal injuries or diseases include rest (strict confinement), splints, bandages, surgical fracture repair, amputation, low level laser therapy, physical therapy, nonsteroidal antiinflammatories, and correction of underlying mismanagement. Nutritional, thermal, and fluid support are critical in cases of metabolic bone diseases. In most cases, the use of analgesics and, when infectious agents are involved, antimicrobials is important. Appropriate tissue samples should be collected for cytology, histopathology, and culture to best guide antimicrobial choice, but initial selections with good bone penetration include tetracyclines and lincosamides.

MUSCULOSKELETAL DISEASES

Vitamin E and Selenium Deficiency

In reptiles, steatitis, fat necrosis, and muscular degeneration can be clinical and pathological signs of vitamin E deficiency. This typically occurs in animals fed diets high in polyunsaturated fatty acids (PUFAs) and/or rancid fats/oils. In crocodilians, deficiencies have been attributed to diets comprised of fish with high levels of PUFA and/or oxidative rancidity.[29] Vitamin E and selenium are antioxidants and protect from inflammatory damage. When diets high in PUFAs, rancid fish oils, or rancid fish are fed, these can cause fat necrosis, saponification, and resulting inflammation. Mortality from pansteatitis has been reported in crocodiles.[30] Clinical presentation is often vague, including lethargy, decreased intestinal motility, and presence of firm swellings (hardened fat deposits in coelom or tail).[10]

Diagnosis is made by biopsy or necropsy. Lesions may include yellow to brown discolored granulomatous steatitis and fat necrosis. Histological findings may include circumscribed zones of macrophages, multinucleated giant cells, ceroid, and hemorrhage.[31]

VetBooks.ir

There is no effective treatment, though if caught early, vitamin E and selenium supplementation may be beneficial. However, steatitis generally carries a poor prognosis. Prevention is best accomplished by appropriate freezing and storage of fish fed to captive reptiles. Fish should be frozen between −18° to 30°C (0°–22°F) and used within 4 to 6 months, as storage at higher temperatures for longer durations can lead to oxidation and degradation of fish lipids.[32]

Metabolic Bone Diseases

Clinical Significance. Metabolic bone disease is a general term used to describe a collection of medical disorders that affect the integrity and function of bones. The term metabolic bone disease (MBD) should always be accompanied by a qualifier such as "nutritional" or "renal." Metabolic bone diseases (MBDs) of various origins are the most common causes of lameness, skeletal, and spinal abnormalities in reptile patients. MBDs can manifest with a range of pathology, including nutritional secondary hyperparathyroidism (NSHP), renal secondary hyperparathyroidism (RSHP), fibrous osteodystrophy, osteomalacia, osteoporosis, osteopetrosis, pathological fractures, and more (see Chapter 84).

Known Etiological Cause(s) and Clinical Presentation

Nutritional secondary hyperparathyroidism. The most common of the MBDs is nutritional secondary hyperparathyroidism (NSHP). The layterm often used for NSHP, "rubber jaw," comes from the fact that animals with NSHP often have facial deformities that affect and soften the lower jaw. NSHP occurs as a result of an inappropriate diet and/or husbandry, with the most common factors being deficiency of dietary calcium or vitamin D_3, imbalance of the calcium-to-phosphorus ratio in the diet (usually an excess of phosphorus), or inadequate exposure to ultraviolet (UVB) radiation in diurnal animals. Nutritional secondary hyperparathyroidism can potentially affect all reptilian and amphibian species, but it is most commonly described in diurnal (herbivorous and insectivorous) lizards and chelonians. Affected animals may show thickening and swelling of the long bones and mandibles (Fig. 81.9), lameness, pathological fractures of the long bones and spine, horizontal (rather than the normal vertical) rotation of the scapulae, hypocalcemic tetany, tremors, muscle fasciculations, paralysis, paresis, hyperreflexia, cloacal or rectal prolapse, anorexia, inability or unwillingness to ambulate, and stunted growth. Swelling of the toes without evidence of external trauma may be noted. Fibrous osteodystrophy, trauma, gout, infection, and neoplasia should be considered as differential diagnoses. Affected joints are often firm, swollen, and have a limited range of motion. Long bone and/or joint swelling can result from healed or healing fractures, luxations, gout, pseudogout, neoplasia, osteomyelitis, septic arthritis, or NSHP. Degenerative joint disease related to trauma or aging may also be an underlying cause of digital swelling. Chelonians often present with a misshapen and/or soft shell. Radiographs can reveal a variety of findings, including reduced cortical thickness and opacity of long bones, fibrous or periosteal proliferation, soft tissue swelling, and pathological or folding fractures (Fig. 81.10).

In most snakes, crocodilians, some chelonians, and some amphibians, a nocturnal lifestyle or ingestion of whole prey have allowed vitamin D_3 to be primarily or completely obtained from the diet.[33] However, diurnal, insectivorous, or herbivorous reptiles (particularly lizards, some chelonians, and some amphibians) require UVB exposure to activate the cholecalciferol pathway.[33] Under natural conditions, reptiles synthesize vitamin D_3 when exposed to sunlight. Ultraviolet light in the spectrum (290–320 nm) reacts to convert cholesterol to the inactive form of vitamin D_3 in the skin. This vitamin D_3 is then converted to 1,25 dihydroxycholecalciferol (calcitriol) through the liver and kidneys. Calcitriol is then used to facilitate absorption of calcium from the intestinal tract. In captivity, an alternative to natural sunlight that mimics the spectrum of natural light is required. A number of artificial lighting systems are available that provide an ultraviolet light spectrum (see Chapter 17). However, these UV lights are often a poor replacement for natural sunlight, and natural sunlight should be provided whenever possible. When an animal cannot be provided with proper exposure to ultraviolet light, vitamin D_3 supplementation can be considered; however, there are serious risks associated with hypervitaminosis D.

In clinical cases of NSHP, excessive production of parathyroid hormone from the parathyroid gland occurs in response to the diet or husbandry-related hypocalcemia. Calcium is then resorbed from the bones to compensate for this deficiency. Osteopenia results and weakens

the bones. Clinical pathology findings often reveal low normal blood calcium levels late in the course of disease. As blood calcium decreases, parathyroid hormone (PTH) increases, which increases blood calcium by stimulating bone resorption and renal tubular reabsorption of calcium. Phosphate excretion in the urine is also increased. PTH stimulates formation of 1,25 dihydroxycholecalciferol, which increases absorption of intestinal calcium. Calcium deficiency can increase the threshold potential of nerves and muscles, thus causing partial depolarization. This can present as spastic tremors and twitching of the digits.

Various metabolic bone diseases are seen in young crocodilians and may manifest in different ways depending on the cause (e.g., nutritional, renal). Weakness, lethargy, kyphosis, scoliosis, paresis, tooth decalcification, and other skeletal abnormalities can be observed in crocodilians as well. This is seen less often as improved diets are offered to captive crocodilians. Nonetheless, some crocodilian operations may still fail to offer a source of calcium in the diet. The innate requirement of ultraviolet-B light as a source of vitamin D_3 in crocodilians is not known. They appear to be able to obtain appropriate levels from their diet, but research in this area is still needed. There are reports of adult alligators raised in enclosed buildings and offered a pelleted diet with some meat supplement that show no evidence of metabolic disease. However, anecdotal comments from various ranchers indicate that the animals appear to thrive better if exposed to sunlight. This is also true of captive amphibians, as historically it has been suggested they do not require UVB exposure. However, MBD is commonly diagnosed in amphibian species, and it is believed that exposure to UVB lamps or natural sunlight is important to overall health.

Renal secondary hyperparathyroidism. Renal secondary hyperparathyroidism (RSHP), a consequence of chronic renal disease, is characterized by hyperphosphatemia. The hyperphosphatemia is associated with low calcitriol levels, soft tissue calcification, renal osteodystrophy, and hypocalcemia. Because excretion of phosphorus is a sum of glomerular filtration and tubular resorption, in renal failure the decreasing filtration rate leads to phosphorus retention and resulting hyperphosphatemia. Phosphate retention along with decreased production of calcitriol result in low normal or low serum calcium levels.

Diagnostic Confirmation. Diagnosis is typically based on signalment and historical information regarding species, age, husbandry (temperature, humidity, UVB lighting), diet, clinical signs, and radiography. Radiographs typically show poor mineralization of the cortices and deposition of fibrous tissue and may show evidence of pathological fractures, either recent or healed. Exaggerated or abnormal long bone shape and curvature can be suggestive, as well as irregularity, lysis, or fractures of the ribs, jaw, spine, and other bones. Clinical pathology is also useful in advanced cases as changes in calcium, phosphorus, electrolytes, and other metabolites may further support the diagnosis. It is important to remember that total calcium may not accurately reflect the metabolically available calcium, and an ionized calcium level is much more informative but seldom decreases until the final stages. In cases of swollen joints, radiography, arthrocentesis, or fine-needle aspiration with cytology, culture, and fluid analysis are all warranted diagnostics to help guide appropriate treatment.

Most discussions of MBDs in reptiles focus on UVB light exposure, diet, and calcium supplementation. Although these are critical for overall health of captive reptiles, it has also been demonstrated that there is a critical interaction with vitamin A in the development of MBDs in captive chameleons.[34] UVB exposure is one of the most important aspects of proper captive reptile husbandry. Oral vitamin D_3 supplementation given to bearded dragons, even at high doses, was ineffective in producing plasma vitamin D_3 levels similar to bearded dragons who were exposed to UVB radiation.[35] Further, if previously adequate UVB exposure is provided, plasma vitamin D_3 levels can be maintained up to 83 days in bearded dragons.[36]

Specific Therapy. Initial treatment for NSHP should focus on stopping bone loss and promoting new bone production. Low blood calcium stimulates PTH secretion, and when the blood calcium concentration is above normal, PTH secretion is halted. Calcitonin, which is produced from the ultimobranchial bodies, then increases. Therefore the mainstay of treatment for MBDs includes oral or parenteral calcium supplementation. Some practitioners warn of increase risk of adverse effects with IV, IM, or SQ administration and recommend oral calcium supplementation.[33] The authors have not had any known adverse events from administering diluted subcutaneous calcium gluconate at 100 mg/kg every 24 hrs during the initial critical period. However, care should be taken to monitor calcium and phosphorus levels during treatment, with special attention paid to the solubility index, as renal function may be compromised. The ratio of calcium and phosphorus is a reliable indicator of (early) renal disease. The solubility index is calculated as the product of Ca (mmol/L or mg/dL) x PO_4 (mmol/L or mg/dL) and is normally less than 9 mmol/L (55 mg/dL). If the solubility index rises above 12 mmol/L (70 mg/dL), then healthy tissue will start to mineralize, whereas between 9 mmol/L (55 mg/dL) and 12 mmol/L (70 mg/dL), mineralization of diseased tissue (kidneys) occurs.[37]

Affected animals should be housed in enclosures with padded substrate or soft towels, and climbing branches and other enclosure furniture should be removed or lowered to a height that will reduce risk of fractures or other trauma should the animal fall. Hydration and oral supplementation of vitamin A are also important to support renal health. Parenteral supplementation of vitamin D_3 is not generally recommended, because overdose and vitamin D_3 toxicity may occur. Thorough evaluation of current husbandry and clear recommendations for corrections must be made to caretakers. In cases of long bone fractures, these may heal quickly once calcium homeostasis returns, but surgical repair should be avoided or considered carefully as the bones may be too soft to hold hardware, and any reptile suffering from MBD is at a higher risk for an anesthetic complication. Splints and bandages are typically best in these cases.

Prognosis and Prevention. Prognosis generally depends on the stage of disease at the time of diagnosis, as early intervention in some cases can result in resolution of clinical signs and provide a near-normal life expectancy when underlying causes are addressed. When there is significant organ function impairment (e.g., renal secondary hyperparathyroidism) and/or systemic infection, prognosis is guarded to poor. Tremors, ataxia, and cloacal prolapses are all early signs, whereas fibrous osteodystrophy, pathological fractures, and paralysis suggest significant disease and carry a worse prognosis. Female lizards and turtles that have severe deformities resulting from NSHP may have difficulty laying eggs due to the deformity of the pelvis and may benefit from elective ovariosalpingectomy. Fractures of the spine carry a more guarded to poor prognosis, especially if limb, intestinal, or bladder function is compromised.[33] In these cases, euthanasia may be appropriate. It is important to note that even animals with severe resulting scoliosis may survive, and although they will be deformed, they tend to do well as pets. Owners should be well advised of the nursing care required, risks of further complications, and realistic prognosis for recovery given the disease state of the individual. Pain medication and nutritional support should also be included in any treatment plan for MBD.

Trauma and Fractures

Fractures can be traumatic, infectious, or metabolic in origin. Traumatic causes can include bite wounds, closure in a cage door or lid, fall from

VetBooks.ir

a perch or branch, or interaction with a prey animal. Fractures should be accurately described as traumatic or pathological, complete (transverse, oblique, spiral, comminuted), incomplete (bowing, buckle, greenstick), or Salter-Harris (types I to V). In addition, the location of the fracture (diaphysis, metaphysis, epiphysis), whether it is displaced (angulation, translation, rotation, distraction, or impaction), open or closed, and whether there is any joint involvement should be documented.

Clinical Significance, Known Etiological Cause(s), and Clinical Presentation. Trauma and fractures are common presentations in captive reptiles and can be the result of a myriad of causes. Demineralization, osteomyelitis, abscessation, or neoplasia can weaken a bony area and result in an associated fracture. Large breeding male chelonians may traumatize a limb by falling off the female's carapace during courtship and copulation. Trauma is also common in captive crocodilians, usually the result of fighting, transport, or restraint. Limb fractures and partial amputations can be seen after altercations. On some crocodilian farms, animals have reportedly lost limbs after fights and demonstrated complete healing. Similar lesions can also be observed in wild alligators. These may also lead to nerve or muscle damage and consequent paresis or paralysis.

Fractures or trauma can also result in paresis or paralysis. However, paresis and paralysis can also result from neurological abnormalities. Spinal cord or vertebral lesions including those secondary to MBD, spinal abscesses, ossifying spondylosis, and spinal tumors have been reported.[38–42] Fecal and or urolith impactions can present as a caudal paresis and usually resolve with treatment. Neurologically related postural abnormalities may be mistaken for musculoskeletal signs. See Chapter 77 for a more detailed discussion.

Diagnostic Confirmation and Specific Therapy. Diagnosis is most often made using a combination of data obtained through a thorough clinical history, physical examination, and imaging. Radiography is the most common imaging modality, though ultrasound, computed tomography, and nuclear scintigraphy may all have utility (Fig. 81.11).

Principles of fracture fixation are similar to those utilized in mammals and are described in more detail in other chapters (including Chapters 108 through 110). Rib fractures generally do not need to be treated unless they are protruding or penetrate an organ. Head fractures in snakes may be difficult to detect on skull radiographs, and CT is preferred. However, the presence of pain, swelling, or palpable abnormalities may suggest trauma or fracture. Lower jaw fractures may heal if they are closed, reduced well, and the snake is not fed for a period of time to allow callus formation. Esophagostomy tube feeding may be required. External fixators can be constructed, but the cage must be kept bare so the fixators do not get caught on cage furniture or bedding.

Prognosis and Prevention. Prevention of trauma and fractures depends on maintenance of safe, secure, and appropriate enclosures, adequate husbandry, social groupings, and safe handling/restraint. Prognosis depends largely on the nature of the traumatic injury or fracture. When the animal is to be released back to the wild, there will be a different set of criteria used compared with a captive animal. Therefore careful consideration of the species, animal "occupation," healing potential, quality of life, and owner commitment should all be included when determining an individual animal's prognosis.

Osteomyelitis and Arthritis

Clinical Significance. Osteomyelitis is the localized or generalized inflammation and destruction of bone from pyogenic infectious agents (Antinoff, Proc ARAV, 1997, pp 149–152). Osteomyelitis can cause local inflammation, periosteal proliferation, stiffening of joints, bone destruction, reduced range of motion, septicemia, and death (Fig. 81.12). Septic arthritis and tenosynovitis refer to inflammation of the synovial structures, particularly joints. Most cases are infectious but articular gout can also cause joint inflammation. Clinical presentation of osteomyelitis and septic arthritis is unfortunately quite common, as inadequate husbandry and associated immunosupression are predisposing factors in many captive reptiles.

Known Etiological Cause(s) and Clinical Presentation. In most cases, trauma and/or immunocompromise are predisposing factors. Inappropriate husbandry including low temperature, poor/unhygienic substrate, overcrowding, excessive humidity, poor diet, and stress all contribute to immunosuppression and bacterial colonization by opportunistic organisms (e.g., *Salmonella* spp., *Proteus*, *Pseudomonas*, *Citrobacter*, *E. coli*, and *Staphylococcus* spp.). Most microbial organisms involved in infectious processes in reptiles are normal flora, which become opportunistic pathogens during times of stress and immunosuppression. Introduction of pathogens to tissues and secondary vascular dissemination can occur as a result of traumatic injury.[43] Infection of the toes from external trauma and vascular compromise is common in reptiles that get caught in the wire mesh of the enclosure, or in carpeting/fabric in their environment, or in relation to dysecdysis with retained skin constricting the toes. Trauma and secondary infection of the mandible is also seen frequently in lizards (Fig. 81.13). When combined with poor husbandry, these local infections may progress and often become systemic. Generalized signs of illness, such as inappetence and lethargy, may result. Microorganisms such as *E. coli*, *Salmonella*, and other coliform bacteria are often found in blood or joint cultures in such cases. Cuts and open wounds caused by improper housing often result in swelling, even once the external wounds have healed. In crocodilians, *Mycoplasma alligatoris* and *M. crocodyli* can cause polyarthritis, which may be evident antemortem. *Mycobacterium* spp. are common in the environment. Potentially pathogenic species in reptiles include *M. marinum*, *M. chelonei*, and *M. thamnopheos.* These bacteria are commonly isolated or identified from interdigital lesions. In addition to causing localized dermal infections, mycobacteria can also cause systemic disease that is usually fatal.

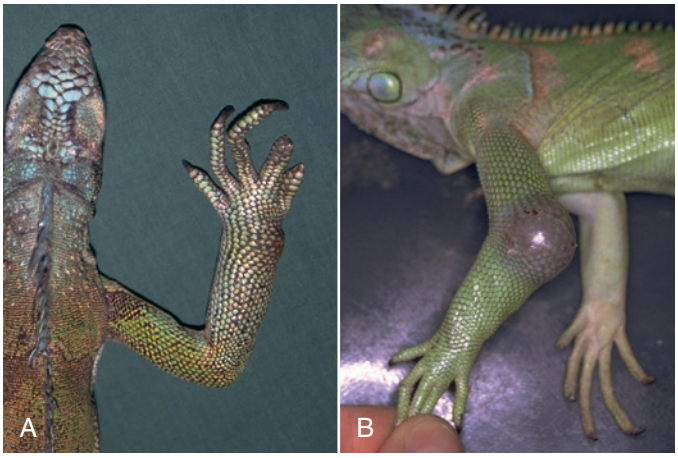

FIG 81.12 (A) Pronounced soft tissue swelling associated with distal ulnar and carpal osteomyelitis in a green iguana (*Iguana iguana*). (B) Pronounced elbow swelling due to septic arthritis in a green iguana. (Courtesy of Stephen J. Divers.)

Diagnostic Confirmation. Diagnosis is typically made using a combination of clinical history, physical examination, radiography, culture and sensitivity, histopathology, and clinical pathology data. Radiographic changes associated with osteomyelitis in reptiles are quite different than mammalian lesions. Osteomyelitis in reptiles appears radiographically as lytic lesions, and this lysis may persist long after the infection has been cleared (Fig. 81.14).[43] Although mammals typically display a periosteal reaction on radiographs, this is often less recognizable in reptiles.[43] Lysis without new bone formation is often characteristic of osteomyelitis in reptiles. This can resemble neoplasia in mammalian bone, and it is important not to misinterpret this finding in reptiles. Arthritis if often associated with enlarged joint spaces and can progress to destruction of the articular surfaces and subchondral bone.

Bone biopsy and histology can be useful in demonstrating the presence of organisms, though special stains may be needed in cases of fungal or mycobacterial involvement. Affected bone may be osteolytic or osteoporotic.[43] Joint aspiration for cytology and microbiologic cultures are often useful. Microbial cultures or MIC levels are useful to direct antimicrobial therapy. Hematology may show a systemic heterophilia, indicative of an active inflammatory response. Toxic heterophils may also be present in cases of advanced bacterial infections. Monocytosis or azurophilia may be present in cases of infectious disease.[43]

Specific Therapy. Treatment should focus on surgical debridement of affected bone and soft tissues followed by aggressive antimicrobial therapy based upon culture and disc sensitivity, or better still, MIC testing. Given the granulomatous nature of the reptile inflammatory response, antimicrobial penetration of affected tissue and bone may be limited. Antimicrobial selection should be based on cytology (gram

stain), culture and sensitivity (or MIC), and histopathologic analysis. Oral versus injectable medications need to be selected with the species and owner abilities in mind. Antimicrobials should be selected for their ability to penetrate bone and initial gram-stain results. Acceptable initial choices include tetracyclines, first- and second-generation cephalosporins, basic and potentiated penicillins, potentiated sulfonamides or aminoglycosides. Modification of therapy should be based on culture and sensitivity data and may require fluoroquinolones, third-generation cephalosporins, or advanced penicillins. Intravenous or intraosseous administration of the first doses should be administered whenever possible, as this may establish therapeutic concentrations more rapidly than other administration routes. Thereafter, intramuscular, subcutaneous, or oral administration should be continued for a minimum of 4 weeks.[43] Cultures should ideally be repeated every 2 to 4 weeks to monitor response to treatment. Repeat radiographs may also aid case management decisions, though it is important to remember that radiographic changes can lag behind clinical changes. Septic joints should be thoroughly lavaged and antimicrobials can be instilled into the joint space. When the articular cartilage and subchondral bone have been destroyed, joint function cannot be regained. Therefore even if infection can be resolved, arthrodesis or amputation is typically required because of a persistently nonfunctional, painful joint.

Appropriate analgesia and supportive care should be included in the treatment plan as needed. Amputation, when necessary, may be a viable alternative to euthanasia in some patients. Treatment of mycobacterial infection is not recommended because of the risk of creating antibiotic resistance to a potentially zoonotic organism. If only the distal portions of an extremity are associated with the infection, amputation may be a realistic alternative to euthanasia.

Prognosis and Prevention. If diagnosis is made early and infection remains mild or localized, then aggressive treatment can be successful. However, clinical disease can also be severe and debilitating. If the diagnosis is made late in the disease process, where significant bone is affected or septicemia is present, then therapeutic efforts may not be successful. Mycobacterial infections carry a poor prognosis and euthanasia is typically recommended.

Noninfectious Arthropathy and Gout

Clinical Significance. Gout is a metabolic disease characterized by overproduction or underexcretion of uric acid resulting in hyperuricemia and deposition of positively birefringent monosodium urate (MSU) crystals in tissues.[44]

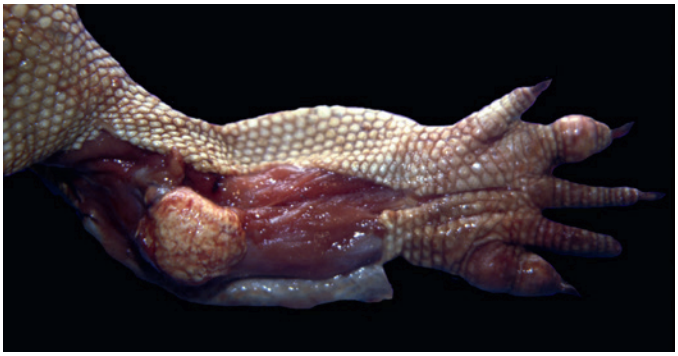

FIG 81.15 Periarticular gout in a savannah monitor (*Varanus exanthematicus*). Note the periarticular accumulation of tophi around the elbow and the swelling of several digits. (Courtesy of Jorge Orós.)

The most common noninfectious arthropathies seen in reptiles are articular/periarticular gout (MSU) and pseudogout (hydroxyapatite deposition disease, calcium pyrophosphate dihydrate deposition). These disease entities are significant in pet reptiles, as they often reflect deficiencies in captive husbandry and nutrition (e.g., dehydration, high-protein diets, inbalances of vitamins and minerals) or severe renal dysfunction.

Known Etiological Cause(s) and Clinical Presentation. Articular/periarticular gout and pseudogout have been reported in many lizard species. Gout consists of radiolucent MSU deposits in or around the joints, whereas pseudogout consists of radiopaque calcium deposits (Fig. 81.15). Deposits of urate crystals are called tophi and consist of a complex of MSU crystals surrounded by granulomatous inflammation. Differentiating between these diseases can be difficult with lysis and deposition of crystals/material often seen in the metatarsal/carpal-phalangeal joints. Gout also occurs in crocodilians as either the articular or visceral form. High-protein diets, dehydration, and stress are contributing factors. Deficiencies of vitamins A, B, C, or E can also lead to a variety of musculoskeletal disorders. These are not commonly seen when commercial diets are fed in addition to meat products. Clinical signs can be nonspecific in nature, but limb paresis/paralysis and joint

enlargement may be observed. Tophi may also be noted in mucous membranes during the oral examination.

Diagnostic Confirmation. Plasma biochemistry, diagnostic imaging, fine-needle aspirate cytology, and often surgical biopsy and histopathology may be necessary to confirm a diagnosis. Whole-body survey radiographs or CT may demonstrate mineralization in other organs. CT shows crystal aggregates but does not enable specific identification of urate acid crystals. Dual-energy CT distinguishes urate crystals from deposits containing calcium.[45] Ultrasonography shows urate crystal deposits as hyperechoic images without posterior acoustic shadowing, which enables their differentiation from calcifications.

Cytological examination by phase contrast microscopy of joint aspirates is also useful to identify urate crystals. When using polarized light, the tissues must be fixed in absolute ethanol, because urate crystals tend to degrade and wash out during formalin (aqueous solution) fixation.[46] Determination of the glomerular filtration rate using iohexol excretion can also be useful to evaluate the renal function.[47] Differential diagnoses include hydroxyapatite deposition disease and pseudogout or calcium pyrophosphate dihydrate deposition and can be differentiated based on histological appearance, histochemical staining for calcium, and birefringence under polarized light.[46,48,49] See Chapters 66 and 84 for a more detailed discussion.

Specific Therapy, Prognosis, and Prevention. Treatment is aimed at slowing or stopping further progression rather than reversing existing damage or curing the disease. Fluid therapy and rehydration, as well as analgesic and antiinflammatory drugs, are typically indicated. Uricostatic drugs reduce uric acid production through competitive inhibition of xanthine oxidase, and allopurinol is most commonly used and has been shown to effectively reduce uric acid levels in iguanas.[50] Other uricostatic drugs (e.g., oxypurinol and febuxostat) are used in humans, but their efficacy in reptiles is unknown. Uricosuric drugs (e.g., sulphinpyrazone, probenecid, benzbromarone) are also used in human medicine to increase urinary uric acid excretion by blocking urate anion reabsorption by proximal renal tubule epithelial cells. However, such reabsorption is likely very low in reptiles, and so the efficacy of this therapeutic approach may be poor. Pegylated uricase therapy (pegloticase and pegadricase reserved for selected human patients) reduces urate levels by increasing its metabolism.[45]

In cases of localized gout, surgical removal by arthrotomy or amputation may be curative. Correction of vitamin deficiencies and any husbandry inadequacies is important.

Localized articular or periarticular gout carries a fair to poor prognosis depending on the state of progression and extent. When visceral gout or renal compromise is present, the prognosis tends to be poor to grave. In all cases of gout, the comfort of the animal and quality of life should be considered, as it is known to be a painful process in humans.

Spinal Osteopathy

Definition and Clinical Significance. Spinal osteopathy has been described in turtles, lizards, and snakes. Although it has been compared with osteitis deformans (Paget's disease) in humans, the condition in reptiles is believed to be a chronic bacterial osteomyelitis of the spine in most cases.[51] In reptiles, the lesions are progressive and proliferative, resulting in variable ankyloses. Eventually, reptiles are unable to move or feed.

Known Etiological Cause(s) and Clinical Presentation. In humans, a similar condition is known as osteitis deformans (Paget's disease), which is a localized disorder initially marked by excessive bone resorption followed by deformity and then excessive bone formation. These cycles cause the bone to become dense and fragile. Pathological fractures are common, and the condition is believed to be painful. Cases of osteitis deformans are most often associated with a septic or autoimmune condition of the spine.[51,52] Many snakes with this disorder have active inflammatory changes from which bacteria have been isolated, such as *Salmonella*, *Klebsiella*, *Morganella*, and *Providencia*.[51] Therefore this condition in reptiles is believed to be a chronic bacterial osteomyelitis of the spine (Fig. 81.16).[51]

Affected animals may present initially with focal swellings visible along the dorsum or sides of the body. Palpation of the spine may reveal segments of ankylosis, kyphosis, scoliosis, or lordosis. Digital pressure may also prove painful, with the animal resenting palpation. Kyphosis and scoliosis of the spine are often observed in green iguanas and other lizard species (Fig. 81.17), resulting from genetic defects, malnutrition, or pathology of the epaxial muscles. Spinal osteopathy, osteomyelitis, or metabolic abnormalities can all cause a lizard's spine and tail to become stiff, resulting in an altered gait. However, older iguanas may present with similar changes to the tail, which do not appear to be

related to bacterial involvement. Therefore a thorough history and clinical investigation should help differentiate these disease processes.

Diagnostic Confirmation. Definitive diagnosis is accomplished by radiography or CT, biopsy, and bone or blood culture. Radiography is useful to confirm the presence of spinal disease but cannot identify active infection or inflammation. Comparison between pre- and postcontrast CT can assist in identifying inflammatory lesions. Bacterial culture (and sensitivity testing) of blood, bone biopsies, or joint fluid may help isolate bacteria and guide treatment. Histopathologic lesions include chondro-osseous metaplasia, active osteomyelitis, epidermal ulceration and necrosis, subperiosteal reactive bone, fibrocartilaginous metaplasia with bone resorption and osteoclasis, vascular thrombosis, infarction, spondylosis, granulomatous inflammation, and thrombosis.[53]

Specific Therapy, Prognosis, and Prevention. Most described therapies have been unsuccessful. However, effective treatment depends on early identification of causative agents, aggressive treatment with appropriate antibiotics, and delivery of antimicrobials to the affected bony site. In lizards, particularly green iguanas, amputation of a large portion of the tail can be a useful therapeutic option to help with pain.[53] Long-term antibiotic therapy may be helpful at slowing progression of disease, but the long-term prognosis is guarded to poor. Reptiles with spinal osteopathy carry a poor to grave prognosis, as most animals have advanced lesions by the time of diagnosis.[53]

Neoplasia

Clinical Significance. Neoplasia is defined as an abnormal growth of tissue.[54] The growth of neoplastic tumors may form a space-occupying lesion, invade organs, or inhibit or alter the function of the immune system.[54] Neoplasia is relatively uncommon in the literature, likely because it is underreported, with the incidence of neoplasia in reptiles reported as 12% to 26%.[55,56] Snakes are most commonly reported as affected by neoplasia. Reviews of reported tumor types in reptile species provide more thorough details on disease presentations and management.[54,56,57]

Known Etiological Cause(s) and Clinical Presentation. Most tumors in reptiles are spontaneous in origin, but some tumor types have a known cause. Several viruses have been identified for their carcinogenic potential in association with tumors, including herpesvirus, papovavirus, and poxvirus.[56] Reported tumors of musculoskeletal origin include chondrosarcoma in two related monitor lizards and a corn snake (*Pantherophis guttatus*), osteosarcoma in Woma python (*Aspidites ramsayi*), undifferentiated sarcoma in a radiated tortoise (*Astrochelys radiata*), periosteal chondroma in a spiny-tailed lizard (*Uromastyx*), chondroblastic osteosarcoma in a spiny-tailed monitor (*Varanus acanthurus*), rhabdomyosarcoma in a Galapagos tortoise (*Chelonoidis nigra*), adenocarcinoma in an Asian leaf turtle (*Cyclemys dentata*), and mucinous melanophoroma in a red-bellied cooter (*Pseudemys rubriventris*).[55,56] Musculoskeletal neoplasia often presents as a swelling or growth, lameness, or both (Fig. 81.18). Other clinical signs can include tremors, ataxia, lethargy, and anorexia.

Diagnostic Confirmation. Diagnosis is made based on histopathology; however, a thorough history, physical examination, clinical pathology, imaging, and cytology may be important diagnostic aids. Complete blood count and plasma biochemistry results should be performed to assess overall health of the patient, to determine the presence and degree of systemic involvement of disease, and for preanesthetic evaluation. Some hematopoietic tumors (lymphoma and leukemia) may also be associated with marked lymphocytosis.[56]

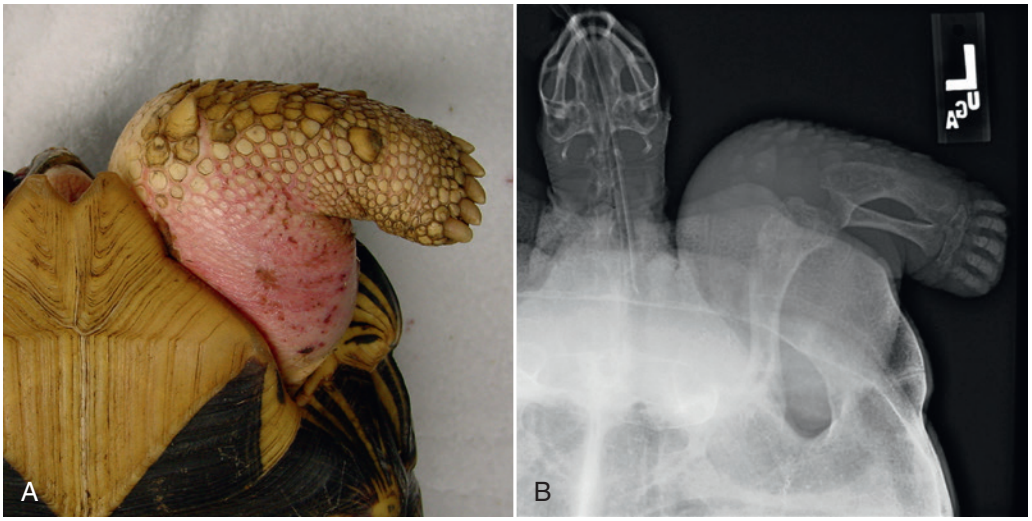

FIG 81.18 (A) Radiated tortoise (*Astrochelys radiata*) with gross swelling associated with the left pectoral limb. (B) Dorsoventral radiograph of the same limb demonstrating a pronounced increase in soft tissue associated with the limb musculature, which is causing subluxation of the left elbow. Orthogonal radiographs are always required for appropriate interpretation. Dorsoventral and horizontal beam lateral views of the whole body should be obtained, along with a cranial-caudal view in chelonian species. More advanced imaging technologies, especially pre- and postcontrast CT, often aid in diagnosis, assessment of the extent of disease, and surgical planning.

Specific Therapy, Prognosis, and Prevention. Cancer treatment plans for reptiles are similar to those of other species. Local disease is best treated with local therapy, whereas systemic disease should be treated with systemic therapies.[56] Chemotherapy and radiation may be curative or palliative, where the differences in protocol intent dictates different dosing strategies in terms of intensity and frequency of the chemotherapeutic agent or radiation. Thorough, well-documented client communication is important before pursuing chemotherapy or radiation so that the intent and goals are clear. There is a paucity of information available on effective chemotherapy and radiation in reptiles. Therefore it is important that owners understand that extension of life span or improved quality of life cannot be guaranteed.[56]

Surgical excision may be curative in cases of local tumors, and all excised tumors should be submitted for histopathology and margin evaluation. In some cases, amputation may be recommended, or follow-up treatment with chemotherapy or radiation may be indicated if there is evidence of tumor extension beyond the surgical margins. Prognosis depends on the tumor type, grade, and stage. Given the lack of information in published literature regarding case management, general prognostic guidelines may be borrowed from the small animal literature until more data are available regarding the outcomes of various neoplastic types in reptiles.

Disorders of the Tail

Clinical Significance, Known Etiological Cause(s), and Clinical Presentation. Disorders of the tail may result from a variety of causes, including mechanical or infectious agents. Tails generally hold an important function, either for social signaling or as a locomotive aid. Damage to, or disorders of, the tail are usually the result of congenital defect, nutritional secondary hyperparathyroidism, trauma, or infection. Avascular necrosis of the tail is relatively common in lizards. The distal tail becomes hard, dry, stiff, and discolored. A zone of devitalized tissue characterized by swelling, erythema, and occasional serous discharge often exists between necrotic and healthy tissue. More than one etiology can cause these clinical signs. When the clinical signs occur after venipuncture of the ventral caudal vein, iatrogenic vascular damage may be a factor. Likewise, trauma and hematogenous spread of infection can be involved (Fig. 81.19). Swelling of the ventral tail base, adjacent and caudal to the cloacal opening, in male lizards usually involves the hemipenes. Some male lizards, such as green iguanas and various species of chameleons, undergo dramatic enlargement of the hemipenes with sexual maturity.

Diagnostic Confirmation, Therapy, Prognosis, and Prevention. Diagnostics should focus on determining an underlying cause and include a detailed history, physical examination, and husbandry information. Radiography, CT, hematology, biochemistry panel, tissue culture, blood culture, cytology, and/or histopathology should all be considered. Specific therapy depends on a definitive diagnosis but would likely include wound cleaning and debridement, treatment of any fractures or other trauma, appropriate selection of antimicrobials based on culture and sensitivity testing, analgesics, and modification of the environment if indicated. Additionally, in cases of poor peripheral circulation, low-level laser therapy has been used successfully by the author and is believed to increase perfusion and help support healing.

Supernumerary Limbs

Clinical Significance. Supernumerary limbs are caused by digenic trematodes, specifically *Ribeiroia ondatra,* and the condition most commonly affects the hind limbs of amphibians. It is a particularly prevalent cause of limb deformities in the western United States, including California, Oregon, Washington, and Montana, although the parasite has been detected across much of the United States.[58] In multiple species of frogs and toads, laboratory and field studies show that even low levels of *Ribeiroia* infection can induce 30% to 95% mortality, and frogs often do not survive to sexual maturity.[58–60] This high mortality has grave consequences for affected frog populations.

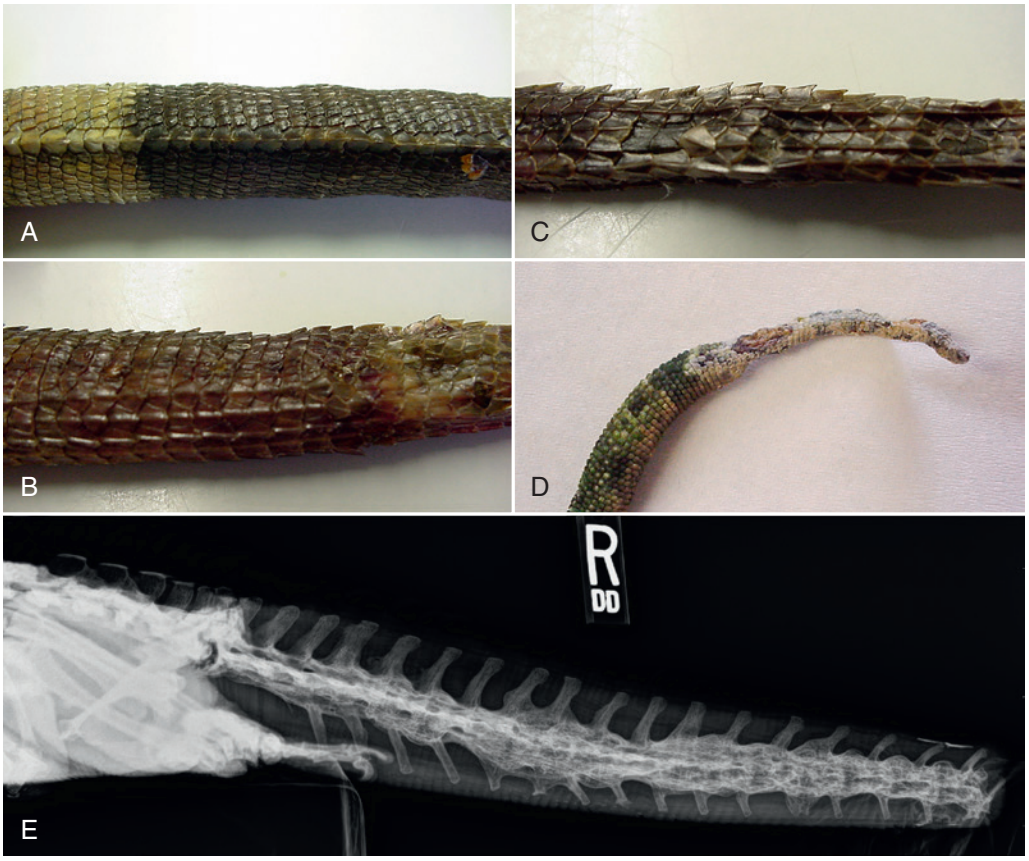

FIG 81.19 (A) Undulations and swellings along the tail of a green iguana (*Iguana iguana*) with bacterial osteomyelitis. (B) Sepsis and necrosis associated with the tail of a green iguana. (C) Ischemic, dry necrosis of the distal tail of a green iguana. (D) Tail necrosis in a chameleon several weeks following repeated venipuncture. (E) Lateral radiograph of a green iguana tail demonstrating proliferative and lytic changes characteristic of (but not pathognomonic for) osteomyelitis. (Courtesy of Stephen J. Divers.)

Known Etiological Cause(s) and Clinical Presentation. *Ribeiroia* has a predilection for limb buds and has been shown to cause polydactyly, polymelia, and jaw malformations in many anuran species.[58–60] The cercarial larval stage of the trematode penetrates the skin to form cysts (metacercariae), which are preferentially localized in the cloacal region, including the developing hind limb regions in larval amphibians. Frogs with parasite-induced deformities are less able to jump, swim, obtain food, or survive to maturity. Deformities have been reported in threatened or endangered amphibian species, including the California red-legged frog (*Rana draytonii*).[58] Given the high mortality associated with this deformity, the impact of infection on a given population can be significant. A single case report exists of encysted digenetic trematodes of the genus *Clinstomum* causing scoliosis in a tiger salamander (*Ambystoma tigrinum*).[61] The herbicide atrazine is the best predictor of larval trematode exposure in northern leopard frogs (*Rana pipiens*).[62] Field study data also supported a causal mechanism where agrochemicals atrazine and phosphate, which are used commonly in corn and sorghum production, increased exposure and susceptibility to larval trematodes by increasing snail intermediate hosts and suppressing amphibian immunity.[62]

Diagnostic Confirmation, Therapy, Prognosis, and Prevention. Little is known about the best strategies for early diagnosis and intervention. Currently, there is no effective treatment once supernumerary limbs have formed. Efforts should be focused on minimizing exposure of larval amphibians to trematodes and pesticides.

Spindly Leg

Clinical Significance, Known Etiological Cause(s), and Clinical Presentation. Spindly leg is a developmental abnormality of the forelimbs and occasionally hind limbs of amphibians, defined as skeletal and muscular underdevelopment. This disease process is only appreciated in captive anurans, which initially appear healthy as tadpoles and often initially develop normal hind limbs. As metamorphosis progresses, the forelimb buds may appear, and the hind limbs may develop valgus or varus deformity. Often one or both forelimbs will fail to erupt normally, and the limbs produced will be thin and delicate. Several factors are known to affect or interrupt metamorphosis, including antibiotics, goitrogenic substances, and other toxins. Additionally, limb malformation in froglets can result from trauma, environmental crowding, genetics, and nutrition. The exact nutrients that may be involved in normal metamorphosis are yet to be determined, but it is believed that deficiency in one or more B vitamins may be a contributing factor in spindly leg.[63] Criteria for staging the disease has been proposed from stage 0 (normal limbs) to 5 (rear limbs extremely stunted and forelimbs do not emerge) (Fig. 81.20).

Diagnostic Confirmation, Therapy, Prognosis, and Prevention. Froglets that survive complete metamorphosis typically die within a few days. The degree of severity can vary from mildly affected forelimbs with normal hind limbs to complete absence of forelimbs with deformity of hind limbs (see Fig. 81.20). It has been recommended to supplement

Stage	Affected Limb	Description

In stages 1 to 5 affecting forelimbs: continued development up to tail resorption may occur while limbs remain stunted, although most will perish before reaching this point. Stages 1 to 4 affecting rear legs: most metamorphs are unable or struggle to hold their head above water or climb out of water, and they may not be able to pursue prey. water with B complex for eggs and developing larvae. Most information to date has focused on tadpoles and froglets, but the nutrition of the parents must also be considered.[5]

Rhamphotheca and Digits

Overgrowth of the rhamphotheca and toenails may indicate an underlying nutritional deficiency such as nutritional secondary hyperparathyroidism or protein excess. Lack of wear in captivity has been suggested as a cause, yet overgrowth is generally not a problem in captive turtles on balanced diets.[4] Elongated nails (but not rhamphotheca) on the front or rear feet (not both) is a normal secondary sex characteristic in some aquatic chelonians. Overgrown nails and rhamphotheca may reflect lack of wear or protein excess.

Problems in the feet can be related to deficient husbandry, whether it be incorrect temperature, humidity, or diet. In cases of missing toes or nails, husbandry and shedding history of the patient should be obtained. Retained shed (dysecdysis) around the digits can form strictures that compromise circulation to the appendage, resulting in necrosis and sloughing of the toe. This condition can be exacerbated with inadequate humidity in the enclosure, which impedes proper shedding. Additionally, carpet fibers or hair can wrap around the digits with a similar effect. Chameleons frequently catch their nails in the mesh of the cage as they climb up the sides, which may lead to infections of the digits and joints.

Congenital Deformities

Congenital malformations of the head may include foreshortening of the upper jaw, cleft palate, and microphthalmia. Short, absent, or kinked tails may also be seen. Many of these deformities are seen in captive-bred snakes, including shortened jaws, restricted orbits, domed cranial vaults, arched necks or spines, and various types of spinal kinks and bends. Congenital defects may be a result of genetic defects or improper environmental conditions during incubation, primarily temperature levels that are too high or too low for some or all of incubation (see Chapter 85). Gravid ovoviviparous or viviparous females subjected to improper temperatures might also produce dead or deformed young. A possible role of inbreeding is often postulated but rarely well-documented. Defects that appear later in life may be genetic or the result of external factors, including infection, trauma, neoplasia, and malnutrition. Tail tips may be damaged by parasites, such as *Alaria* flukes or ticks, or by trauma (prey or predator bites).

Vascular, Hematopoietic, and Immune Systems

Simon Girling

This chapter deals with the medical aspects of disease associated with the vascular, hematopoietic, and immune system. Discussion of the normal anatomy and physiology of these systems may be found in Chapters 7 through 12.

VASCULAR ANATOMY AND PHYSIOLOGY

Chemoreceptors

Chemoreceptors have been identified in the aortae, common carotid artery, and pulmonary artery of turtles, with oxygen-sensing cells innervated by the tenth cranial nerve.[1] The morphology and size of the cells resemble glomus cells in mammals and are thought to have a similar function in sensing changes in blood oxygenation and regulating respiration and blood cardiovascular shunting.

Vascular Shunting

It has been shown that reptiles can shunt blood through the heart and between the great vessels emanating from the heart depending on lung function and blood gas levels (see Chapter 68 cardiology). Blood flow from the caudal half of a reptile's body may pass through the parenchyma of the kidneys via the caudal, hypogastric, or iliac veins (renal portal system, RPS). Any drugs injected into the caudal half of the body may therefore potentially be excreted by the renal tubules (but not the glomeruli) before entering the general venous circulation. Nephrotoxic drugs (such as the aminoglycoside family) administered in the caudal half of the body may have greater nephrotoxicity, because it is theoretically possible for the drug to be directed into the kidney parenchyma very rapidly and at high concentrations, leading to enhanced toxic effects. The RPS shunting mechanism is not as straightforward as this, and many facets have not been fully elucidated. Common practice has been to avoid giving potentially nephrotoxic medications, or medications primarily removed from the body via the kidneys (e.g., ketamine), in the caudal half of the reptile patient.

In snakes, blood flow volume to the intestines and hepatic portal system can increase by up to 30% and portal venous flow up to 300% following feeding.[2–4] Blood flow may also be shunted preferentially to peripheral limbs and extremities when the reptile is warm or to the core of the reptile when its body temperature is cool, suggested to be due to decreased or increased vasomotor tone, respectively.[5]

VASCULAR DISEASES

Metabolic Vascular Disease

Hypervitaminosis D_3 or abnormalities associated with the calcium/phosphorus ratio (which may be caused by secondary or primary hyperparathyroidism) can lead to metastatic mineralization. In green iguanas (*Iguana iguana*) and a plumed basilisk (*Basiliscus plumifrons*), pulmonary vessel metastatic calcification in association with an erythroid response has been described.[6] The plumed basilisk also showed evidence of aortic mineralization. In the majority of these cases the following pathologic abnormalities were also noted: hyperphosphatemia with an inverted calcium/phosphorus ratio; chronic renal failure; and renal gout. Dystrophic vascular mineralization has also been suggested as associated with stress, high lipid diets, hypercholesterolemia, hepatic lipidosis, and low daily activity levels.[7,8]

Bacterial Thromboembolic Disease

Embolic septicemia caused by *Salmonella* spp. has been reported as a cause of atrial thromboembolism in a green iguana.[6] This may lead to showers of microthrombi in the bloodstream, likely affecting other vessels and vital organs. Other sources of bacterial thromboemboli include severe periodontal disease, which is commonly seen in lizards with acrodont dentition. One such example resulted in hepatic artery thromboembolism in inland bearded dragons (*Pogona vitticeps*) associated with *Pseudomonas* spp. bacteria seeding from the periodontal infection[9] (Fig. 82.1).

Congenital and Developmental Vascular Diseases

Congenital aortic stenosis has been reported in a green iguana with secondary ventricular dilation.[10] The iguana presented clinically with a history of inappetence, lethargy, increased respiratory rate, and a change in skin coloration.

Aneurysms have been reported in bearded dragons and Burmese pythons (*Python bivittatus*).[10,11] This author has seen aneurysms arising from the internal carotid artery or the aorta. A firm but fluctuant swelling is often seen on the dorsolateral neck or cranial coelomic cavity respectively. The etiology of aneurysms in reptiles is currently unknown.

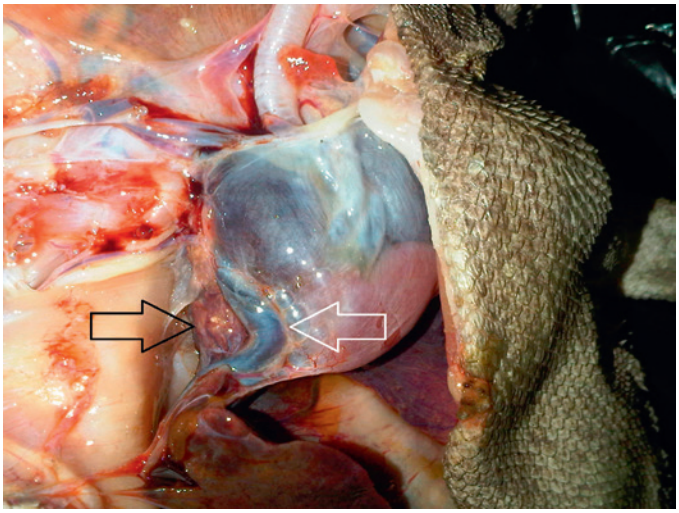

FIG 82.1 Lung bacterial granuloma due to *Pseudomonas aeruginosa* (black arrow) in a bearded drago, which had migrated into the wall of the caudal vena cava (white arrow). (Courtesy of Simon Girling.)

VetBooks.ir

It has been suggested they may be the result of trauma to the affected vessels due to the superficial position of the carotid arteries in the dorsolateral pharyngeal area. However, this does not fully describe all cases of aortic aneurysms, and some may be associated with congenital wall defects in a high blood pressure vessel, as is seen in mammals and birds. These aneurysms have been successfully surgically removed, with patients surviving months to years afterward.

HEMATOPOIETIC SYSTEM AND IMMUNOLOGY

Cellular Immunology

Cellular immunity can be specific or nonspecific. Specific cellular immunity in vertebrates is associated with lymphocyte function. In reptiles, evidence of B and T lymphocyte equivalents has been known for some time.[12] There is also evidence of subsets of T and B lymphocytes, for example, T-helper lymphocytes.[13] Additionally, it has been found that variations exist in the population of subsets of lymphocytes and in the lymphocyte numbers themselves over the course of the year, particularly in species that undergo hibernation or aestivation. Nonspecific cellular immunity is seen with mononuclear leucocytes, such as monocytes and azurophils, and granulocytes, such as heterophils, basophils, and eosinophils. Blood and bone marrow cell types are described in more detail in Chapters 33 and 37.

Humeral Immunology and Acute Phase Proteins

Humeral immunity may be specific or nonspecific. Specific humeral immunity is clearly associated with immunoglobulins and in lower vertebrates is assumed to be comprised of IgY (the equivalent of mammalian IgG but has facets of IgE activity) and IgM (which functions in reptiles as a combination of the IgM and IgA antibodies in mammals). So far IgE and IgD have not been proven to exist in reptiles, but subsets of IgY may cover some of their spectrum of functions.[14] Nonspecific humeral immunity is associated with interferons, transferrins, lysozymes, complement, and other acute phase proteins. As with birds, the accurate determination of albumin and globulin levels in reptiles should be performed using plasma protein electrophoresis. Standard dry chemistry systems are frequently inaccurate in this assessment because many reptiles, particularly but not exclusively chelonians (as with birds), have prealbumin and other proteins that appear to the left of albumin on the electrophoretogram. Many act as a carrier protein often for thyroxine.[15] Plasma is preferred for protein electrophoresis in reptiles, as one of the major acute phase inflammatory proteins is fibrinogen. As there are few serodiagnostic tests available for reptiles through commercial laboratories, plasma protein electrophoresis can be a useful aid to detecting infectious/inflammatory disease[16] (Figs. 82.2 and 82.3).[16]

HEMATOPOIETIC DISEASE

Hemoparasites

Hemoparasites are commonly seen in pet reptiles, particularly in wild-caught species. The majority of these parasites are nonpathogenic. Table 82.1 lists some of the more commonly seen protozoal hemoparasites of reptiles (see also Fig. 82.4). For further and more detailed information, readers are urged to consult Chapter 32.

Helminths—Family Ascarididae

Nematodes (e.g., Ophidascaris). A Papuan python (*Apodora [Liasis] papuana*) that was in captivity for a number of years died after a brief period of anorexia and at postmortem had adhesions between the aorta and esophagus.[22] The aortic wall contained numerous aneurysms and fibrous nodules along its length from which large nematodes were removed and identified as *Ophidascaris papuanus.* Similar nodules were seen in the peritoneum of the coelomic cavity.

Helminths—Family Onchocercidae, Subfamily Dirofilariinae

Microfilaria (e.g., Foleyella, Oswaldofilaria). Microfilaria are commonly seen in lizards but may affect any reptile. The intermediate host range includes ticks, mites, and mosquitoes. Filarid wormlike organisms may be seen free in the plasma. The parasite may cause blockage of terminal vessels. Treatment is by maintaining the affected reptile at environmental temperatures of 35° to 37°C (95°–99°F) for 24 to 48 hours to kill the adult worms, although with large worm burdens anaphylaxis may occur, and care should be taken to monitor the reptile for signs of heat stress.[23]

Trematodes—Family Spirorchidae

Digenetic Spirorchid Flukes (e.g., Spirorchis, Henotosoma, Vasotrema). These are seen most commonly in chelonians, particularly marine turtles. Aquatic snails (e.g., *Lernea* spp.) are believed to be the intermediate hosts. Trematode eggs are rarely seen in peripheral blood smears. Pulmonary tissue biopsy and squash preparation are often required to diagnose infection.[24] Adult flukes rarely cause clinical disease,

TABLE 82.1 Common Protozoal Hemoparasites of Reptiles

Hemoparasite Genus	Vector	Reptile Species Reported	Pathogenicity and Appearance in Blood	Treatment Reported
Order Haemosporida				
Plasmodium	*Aedes* or *Culex* spp. mosquitoes or *Culicoides* spp. midges. Other blood-sucking ectoparasites may also act as vectors, but scant information available.	Mainly chelonians but also reported in snakes, and *Plasmodium relictum* has resulted in fatalities in juvenile lizards.	In the blood, schizonts, micro-, and macrogametocytes in the cytoplasm of erythrocytes may be observed, as well as in mononuclear cells and endothelium of blood vessels.[17] These are often refractile. They can cause severe hemolytic anemia. It is possible to see extramedullary hematopoiesis, as well as vascular occlusive disease in the brain, heart, and so on due to swelling of the endothelium of vessels.	Treatment of chelonians with chloroquine at 125 mg/kg, orally every 48 hours for 3 treatments/occasions has been suggested as effective[18]
Haemoproteus	Dipteran biting flies and mosquitoes, possibly mites.	Mainly lizards, some turtles, and occasionally snakes.	Gametocytes seen in erythrocytes and are refractile. It is rarely pathogenic.	Rarely pathogenic, therefore treatments not reported.
Saurocytozoon	Believed to be mosquitoes.	Mainly lizards.	Resembles *Leucocytozoon* spp. in birds with gametocytes in leucocytes and immature erythrocytes. The organism lacks pigmentation. It is rarely pathogenic.	Rarely pathogenic, therefore treatments not reported.
Order Eucoccidiorida				
Haemogregarina	Leeches and possibly dipteran flies. On American alligators (*Alligator mississippiensis*) the leeches are *Placobdella multilineata* and *P. papillifera*.	It has been reported in aquatic species—mainly freshwater turtles (e.g., *Haemogregarina stepanovi* in *Emys orbicularis*), tortoises of the genera *Geomyda* and *Testudo*, the tuatara (*Sphenodon punctatus*), many snakes, and some crocodilians. Pathogenicity is seen occasionally with *Haemogregarina crocodilinorum* in wild American alligators.	Sporogeny occurs in an invertebrate ectoparasitic intermediate host (often leeches). The hemoparasite may also accumulate in the liver, spleen, and lung of the reptile as well as the bloodstream. Blood smears demonstrate erythrocytic inclusions, micro-, and macrogametocytes, which are rarely refractile.	Rarely required as considered nonpathogenic, with the exception of American alligators, which have occasionally resulted in disease, therefore treatments not recorded.
Haemolivia	Chelonian tick *Hyalomma aegyptium* is the definitive host (the reptile is the intermediate host).	Tortoises act as the intermediate host (e.g., *Haemolivia mauritanica* in *Testudo graeca* and *T. marginata*).[19]	Blood smears demonstrate erythrocytic inclusions, micro-, and macrogametocytes, which are rarely refractile.	Rarely pathogenic, therefore treatments not reported.
Hepatozoon	Arthropods such as the snake mite, *Ophionyssus natricis*, act as the vector.	Mainly seen in terrestrial snakes.	Sporogeny occurs in an invertebrate intermediate host. The organism may also accumulate in the reptile's liver, spleen, and lung, as well as the bloodstream. Blood smears demonstrate erythrocytic inclusions, microgametocytes, and macrogametocytes. (See Fig. 82.4).	Rarely pathogenic, therefore treatments not reported.
Karyolysus	Arthropods (e.g., the lizard mite, *Hirstiella trombidiiformis*) can act as vectors. It is transmitted through the feces of the intermediate host.	Mainly seen in old world lizards and tree snakes.[20]	Sporogeny occurs in an invertebrate intermediate host. The organism may also accumulate in the reptile's liver, spleen, and lung, as well as the bloodstream.	Treatment in snakes with quinacrine at 20–100 mg/kg orally every 48 hours for 2 weeks has been shown to be effective.[21]

TABLE 82.1 Common Protozoal Hemoparasites of Reptiles—cont'd

Hemoparasite Genus	Vector	Reptile Species Reported	Pathogenicity and Appearance in Blood	Treatment Reported
Lainsonia	Mites of dipteran biting insects thought to be intermediate hosts.	Primarily seen in lizards.	Clinical pathology shows unpigmented inclusions in leucocytes and thrombocytes. The parasite enters the reticuloendothelial system and sporozoites may be refractile. No pathology has been reported.	Rarely pathogenic, therefore treatments not reported.
Schellackia	Mites of dipteran biting insects thought to be intermediate hosts.	Generally seen in new world reptiles.	Clinical pathology demonstrates the parasite in leucocytes, but it is most commonly seen in erythrocytes. Ovoid unpigmented inclusions tend to deform the host nucleus. There may also be parasitism in the gut of lizards as a schizont. Sporozoites are released into the bloodstream and may be refractile. It has been reported to occasionally cause anemia.	Rarely pathogenic, therefore treatments not reported; quinacrine could be tried in cases of associated anemia.
Order Achromatorida				
Sauroplasma	Ticks and biting flies thought to be intermediate hosts.	Primarily seen in lizards.	Vacuoles with inclusions may be seen in circulating thrombocytes and erythroid cells.	Rarely pathogenic, therefore treatments not reported.
Serpentoplasma	Ticks and biting flies thought to be intermediate hosts.	Primarily seen in snakes.	Vacuoles with inclusions may be seen in circulating thrombocytes and erythroid cells.	Rarely pathogenic, therefore treatments not reported.
Order Kinetoplastida				
Trypanosoma	All forms of reptiles may be affected.	Intermediate hosts are thought to be dipteran and phlebotamine flies, and leeches for aquatic species.	The parasite may be seen free in plasma as a trypanomastigote with a classical undulating cellular membrane. It is rarely pathogenic.	Rarely pathogenic, therefore treatments not reported.
Leishmania	Common in wild-caught lizards.	Phlebotamine sandflies thought to be intermediate hosts.	Amastigote form is seen in erythrocytes; promastigote form found free in plasma. It is rarely pathogenic.	Rarely pathogenic, therefore treatments not reported.

although occasionally endothelial hyperplasia in major arteries have been reported. The main pathology is associated with blockage of end arterioles with fluke eggs and resultant ischemic necrosis.[25] Treatment with praziquantel at 8 mg/kg, orally, once has been suggested, but due to the embolic nature of the condition may not be effective in preventing clinical disease.[26] Controlling the aquatic snails, which act as the intermediate host, can reduce exposure and infection rates.

Other Parasites. A debilitated or sick reptile, as with any vertebrate, may as a consequence of its disease develop a chronic, generally non-regenerative anemia. Some parasites may cause anemia more directly, however, and may include:

- The ectoparasite *Ophionyssus natricis* (the snake mite) may cause anemia due to its blood-sucking nature.
- The endoparasite hookworm *Kalicephalus* spp. may also be associated with anemia and malnutrition, particularly in snakes.
- Leeches (Hirudinae) may cause anemia in aquatic species if the burden is sufficiently high. They may also act as vectors for hemogregarines and trypanosomes, which in turn may lead to hemolytic anemia.

Viruses Causing Anemia

Pirhaemocyton spp. was originally classified as a protozoal hemoparasite. However, it is now known that the erythrocytic metachromatically staining inclusions are associated with viral assembly factories, consistent with viruses of the family Iridoviridae. High levels of infection are known to cause hemolytic anemia, although morbidity is only occasionally reported and usually associated with another underlying medical condition. There has been a report of spontaneous resolution of the viremia in a chameleon.[27] A report of an erythrocytic virus causing an anemia with a PCV of 7% in a diamond python (*Morelia spilota spilota*) had nearly 100% of the erythrocytes demonstrating acidophilic intracytoplasmic inclusion bodies.[6]

Neoplasia of the Hemopoietic System

Lymphoid or other hemopoietic origin neoplasia has been reported with an incidence rate between 0% and 30.8% of cancers in reptile species.[28,29] Indeed, one report suggests that the hemopoietic system is the body system most commonly affected by neoplasia.[30] Another publication states that snakes (e.g., cobras and urutus, *Bothrops alternatus*)

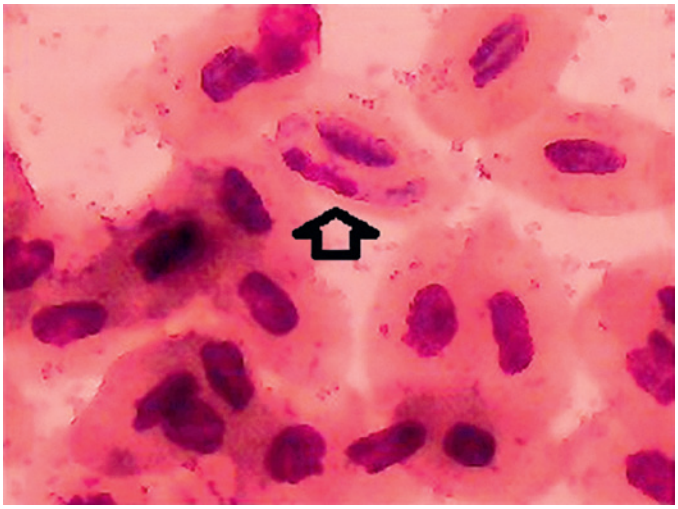

FIG 82.4 *Hepatozoon* spp. hemoparasite in the cytoplasm of an erythrocyte from a sand boa (*Eryx* spp.) (black arrow) (x1000 oil immersion, Romanowsky stain). (Courtesy of Simon Girling.)

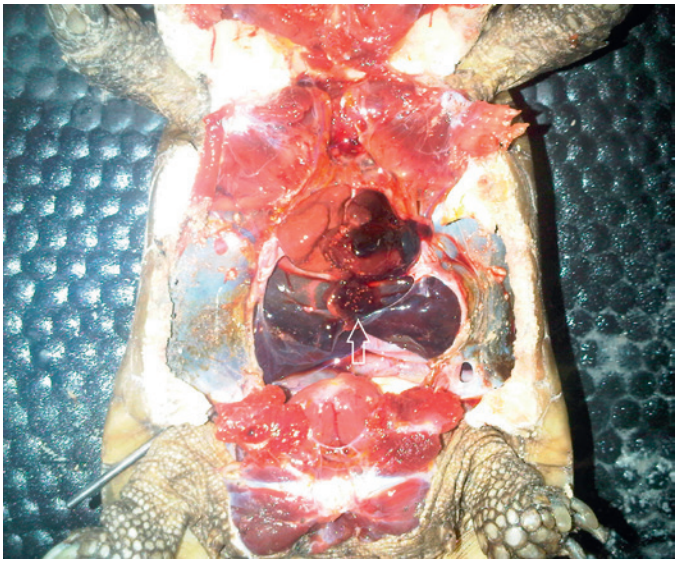

FIG 82.5 A hemangioma (white arrow) associated with the liver of a Greek tortoise (*Testudo graeca*) remained subclinical until rupture when cardiovascular collapse and the death of the reptile ensued. (Courtesy of Simon Girling.)

and lizards (e.g., savannah monitors, *Varanus exanthematicus*, and bearded dragons) are the most commonly reported species with hemopoietic system neoplasia.[31] It should be noted that lymphoid neoplasia may involve infiltration of body organs and often may not involve the bloodstream directly. Lymphoblasts are rarely found in the bloodstream of healthy reptiles and so, if seen in moderate to large numbers, are indicative of leukemia.

Leukemia has been reported in red eared sliders/terrapins (*Trachemys scripta elegans*) (in a myeloblastic form); a helmeted turtle (*Pelomedusa subrufa*) (in a myelogenous form); bearded dragons (chronic monocytic form; myelogenous form); a green iguana (immunoblastic form); a savannah monitor (associated with lymphosarcoma); a desert spiny lizard (*Sceloporus magister*) (in an undifferentiated form); an Indian python (*Python molurus*) (lymphocytic form); a common boa (*Boa constrictor*) (lymphocytic form); a broad banded copperhead (*Agkistrodon contortrix laticinctus*) (lymphocytic form); a diamond python (lymphocytic form with multicentric T-cell lymphoma); an Aruba Island rattlesnake (*Crotalus unicolor*) (lymphoid form in association with lymphosarcomas); a Russell's viper (*Daboia russelii*) (myelogenous form); and a Honduran milksnake (*Lampropeltis triangulum hondurensis*) (myelogenous form).[6,21,32–40]

Tissue-associated lymphomas/lymphosarcomas have been reported in a loggerhead turtle (*Caretta caretta*) (multicentric form, including the heart and aortae); green iguanas (disseminated form; pharyngeal lymphoma); East Indian water lizard (*Hydrosaurus amboinensis*) and an Asian water monitor (*Varanus salvator*); a savannah monitor (with leukemic profile); Egyptian spiny-tailed lizards (*Uromastyx aegyptius*) (multicentric form); a diamond python (multicentric T-cell lymphoma with leukemic overspill); an Aruba Island rattlesnake (lymphosarcomas associated with leukemia); and a red-tailed boa (*Boa constrictor constrictor*) (lymphoblastic lymphoma).[21,30,36,40–45] Plasma cell tumors have been reported in a Nile monitor lizard (*Varanus niloticus*) and an East Indian water lizard.[46,47]

Treatment of leukemia and lymphoma in reptiles is very much in its infancy. A number of reports have been published with differing regimes. In a case of lymphoma in a green iguana, radiation therapy at 10 Gy focused on the cervical lesion was used in combination with chemotherapy using vincristine, cyclophosphamide, and prednisolone.[42] The regimen was altered to doxorubicin (0.75 mg/kg IV once every 3 weeks) and prednisolone (2 mg/kg every 24 hours) after a relapse, and the case appeared in remission by day 1008. Another case of lymphoma in a king cobra (*Ophiophagus hannah*) used a regimen of prednisolone 40 mg/m^2 orally every 48 hours with L-Aspargine aminohydrolase at 10,000 IU/m^2 given subcutaneously once during week one.[6] This was altered to prednisolone (40 mg/m^2) orally every 48 hours with vincristine (0.5 mg/m^2) intravenously once for week two. For week three the same regimen as week one was repeated. This regimen appeared successful, but regrowth occurred. A new regimen of 40 mg/m^2 prednisolone orally once every 48 hours plus chlorambucil at 2 mg/m^2 subcutaneously every 24 hours for 30 days was instituted. This seemed successful, but poor sloughing, anorexia, hypoalbuminemia, and hyperglycemia were noted side effects.

Neoplasia of the Vascular System

Hemangiomas have been reported in the corn snake (*Pantherophis guttatus*) and red-eared slider.[48,49] Most are subclinical until they rupture, usually after some form of blunt trauma, and with profound internal hemorrhage may result in the death of the reptile (Fig. 82.5).

Immune-Mediated Hemopoietic Disease

Immune-mediated hemolytic anemia has been reported in a Parson's chameleon (*Calumma parsonii*).[6] Clinically the chameleon showed signs of profound anemia (PCV 7%–8%), slide autoagglutination of erythrocytes, hemolytic serum with marked anisocytosis and polychromasia, and signs of lethargy and weakness. Therapy was initiated with prednisolone at 4 mg/kg, orally twice daily, and a blood transfusion was performed from sibling chameleons via the intraosseous route. Clinical resolution of signs was rapid but iatrogenic effects included osteomyelitis, which did respond to antibiotic therapy.

Toxic Anemia

Nonregenerative anemia has been seen in reptiles such as chelonians in association with the consumption of lead or other heavy metals. Chelation therapy is required and sodium calcium edetate has been advocated; however, there have been side effects with its usage (hemolysis). Care should be taken to ensure the reptile is well-hydrated, as renal damage is another sequela to both heavy metal and chelation agent toxicity.[50]

Clinical Behavioral Medicine

Teresa Bradley Bays and Leticia Mattos de Souza Dantas

Like many exotic species, reptiles have evolved to hide signs of illness as a survival mechanism. With their slower metabolic rates and physiological processes, reptiles exhibit a more gradual progression of clinical disease. This is especially true for prey species with which practitioners and caretakers are often presented. Behavioral changes that indicate illness are often not detected until late in the course of the disease. Frequently kept as single pets, with the lack of healthy conspecifics with which to compare, changes in behavior may not be detected until advanced.

Practitioners need to have a good understanding of the natural behavior of reptiles and amphibians but also how that behavior is affected by captivity. Understanding the medical implications of abnormal behavior can then help practitioners to diagnose medical conditions, assess captive welfare, and make recommendations to foster psychological well-being.[1,2] This chapter will focus on captive-related behaviors and relevant points of abnormal behavior in the most commonly kept species.

ANATOMY AND PHYSIOLOGY OF THE BRAIN AND BEHAVIORAL RESPONSES

As in other higher vertebrates the reptile brain can be divided into three sections: the forebrain (telencephalon and diencephalon), midbrain, and hindbrain.[3,4] The forebrain aids in smell, taste, rhythms, and sensory-motor integration and mediation. The diencephalon houses, among other things, the hypothalamus, thalamus, infundibulum, pituitary gland, and the pineal complex.[3] The midbrain or mesencephalon contains the areas for neuroendocrine roles and visual processing.[3,4] Hearing, balance, and physiological homeostasis are associated with the hindbrain.[4] Stress in all species induces activation of the sympathetic nervous system and also directs a neuroendocrine response, derived from activation of the hypothalamus/pituitary/adrenal (HPA) axis.[5] This neuroendocrine axis regulates physiological functions such as immune competence, reproduction, metabolism, and behavior.[5] The HPA axis is activated when the corticotrophin-releasing hormone produced by the hypothalamus is released following a threat, stimulating the pituitary to secrete adrenocorticotropic hormone (ACTH), which acts on the adrenal cortex to stimulate the production of glucocorticoids that effect the alteration of circulating levels of sex steroids and other hormones.[5] This stress response then maximizes energy available to body systems to face physiological challenges and simultaneously inhibits nonessential systems that, although critical for long-term survival, are not essential for the day-to-day survival of the animal, including growth and reproduction.[6]

Behavioral changes noted in reptiles in captivity are often a result of a response to stress. Most species are adapted to cope with specific, evolved challenges in their natural environment.[7] A single, sustained stress occurrence, whether physical (thermal), psychic (perceived predator), or physiological (adrenal response), may have long-term adverse consequences on the health and welfare of reptiles and amphibians.[7] Acute or intense stressors may predispose reptiles to emaciation, immune depression, and reproductive difficulty.[5] If the stressor continues, abnormal nonfunctional behaviors may occur, including stereotypical behavior, that can help the animal face the psychological aspect of the event and also reduce some of the associated physiological responses.[5] Chronic stress in reptiles may also predispose to obesity and hepatic lipidosis, aggression, anorexia, displacement behaviors,[8] and, in some lizards, a change in their skin color created by variations in the deposition of carotenes.[9]

Capture and restraint, and even the inability to escape from captivity, has been found to increase stress-related corticosterone levels in reptiles.[9] Captive conditions also typically replace many features of the natural world with artificial and frequently poorly matched alternatives that deprive animals of known normal behavior and associated biological needs.[7] Reptiles in captivity are also often kept in conditions that create understimulation, and the associated stress has been shown to be difficult to assess through more common physiological measurement such as corticosterone levels.[8]

APPROACH TO BEHAVIORAL APPOINTMENTS

A basic assessment of behavioral issues should be included with every reptile and amphibian examination. However, for dedicated behavioral consultations a behavioral history form (Table 83.1) should be filled out by the owner or caretaker prior to the visit, so pertinent information on which to make a diagnosis is not missed.[10] Photos of the enclosure and videos of the altered behaviors and postures should also be requested for the appointment. A visit to the animal holding facility may be necessary to assess conditions that may be causing behavioral issues and medical problems.

Anamnesis, Physical Examination, and Behavior

Most health problems in reptiles are the result of deficiencies in captive management, especially in relation to the environment and diet. Therefore a thorough, detailed history is vital for the evaluation of these patients. Information on any behavioral changes the owner or caretaker has noted is essential. While collecting the history, it is prudent to observe the behavior and posture of the patient before any handling (by the

client or doctor) (Figs. 83.1 and 83.2A). Watching how the patient responds during the physical examination and how it recovers postexamination is important (see Fig. 83.2B and C). The clinician's observations of the patient's behavior during the consultation are critical, as otherwise the patient's behavioral issues are solely dependent upon what is disclosed by the owner or caretaker, which may be inaccurate or biased.

CLINICAL DISEASES

Husbandry-Related Behavioral Disorders

Understanding the importance of how husbandry affects reptile behavior is paramount to successful practice. Environmental decisions are often guided by the clients desire to make enclosures aesthetically pleasing without knowledge of species-specific needs or behaviors. Important husbandry factors that must be considered include substrate, heat sources, light, humidity, spatial needs, and dietary choices.

Assessing husbandry practices and having knowledge of enclosure size and design is necessary for understanding if behavior is affected by environmental conditions (see Section 3). Because reptile enclosures are often too large to bring into the veterinary clinic, it is helpful to encourage clients to bring in pictures of enclosures for evaluation. Several examples of how husbandry can affect behavior and therefore affect the practitioner's ability to best make a diagnosis are listed below.

Observation: Not moving away from direct heat sources despite thermal burns or hyperthermia.

Clinical significance: Reptiles not provided with radiant heat for basking may seek out a heat source, especially if ill, and could burn themselves on a hot rock or other in-the-cage heating element if this is the only heat source provided. This thermal nociception latency is not completely understood, but it is believed that heat receptors are not the same as pain receptors in reptiles, so they may not perceive pain until thermal damage has occurred, or they do not associate the pain with the object causing the thermal burn. Under-tank heaters may be especially

(B) Bearded dragon continuously holding itself up on enclosure furniture due to respiratory compromise from gastrointestinal obstruction and severe ileus compressing lungs. The distended coelomic cavity is evident in this profile. Intermittent behavioral changes should not be attributed to primary respiratory system pathology. inappropriate for burrowing reptile species that may expose themselves directly to the heat and be more likely to develop ventral burns.

The constant illumination associated with an incandescent light as the sole heat source, especially in nocturnal species, may result in creating conditions that result in stress and immune supression. Understanding the environmental needs of reptiles and amphibians, including whether they are nocturnal or diurnal and how they thermoregulate in their natural environment, is important. This information is helpful when evaluating the current captive enclosure to identify how thermal burns may have occurred and how to prevent them in the future.

Understanding how behavior can be affected by the environment can be useful in diagnosing medical issues. For example, gaping in a reptile patient can be associated with aggression or a response to a threat, overheating or thermoregulation, respiratory disease, pain, or a sign of nausea or other gastric or esophageal discomfort (especially if associated with repeated swallowing). However, if that patient is suffering from nutritional secondary hyperparathyroidism (NSHP) it may have difficulty ambulating and may be unable to move away from the heat source. A client or caretaker may interpret gaping in this patient as a respiratory or other issue when in fact the gaping is a direct result of hyperthermia. Resolution of the signs with cooling when removed from the enclosure, examination, clinical history, and diagnostics, including radiographs, can aid in a correct diagnosis.

Prevention: Providing a temperature gradient (horizontally or vertically depending on species) in an appropriately sized enclosure allows reptiles to thermoregulate as they move about the enclosure, as they would if free-ranging. In general, diurnal species fare better if given radiant heat sources from above with an appropriate day/night cycle. Nocturnal species may thrive better when under-tank heaters are provided, but care must be taken that they are not able to be burned by these heaters.

Observation: Shy or stressed species such as chameleons remain hidden rather than exposing themselves in order to bask or eat.

Clinical significance: If the shy reptile is spending most of its time in a hide box that is placed on the cooler side of the tank, then it may not thermoregulate, as the need for security may outweigh its desire to spend time basking. Also, the presence of other domestic pets such as cats, dogs, and birds can be perceived as threatening to captive reptiles and amphibians and create psychological stress that will lead to immune suppression and failure to thrive.

Thorough historical review about where the patient spends most of its time in relation to heat sources and hide boxes, and a description of exactly how the enclosure is set up, is needed to evaluate the problem.

Prevention: Appropriate space and hiding places for reptiles may alleviate some of the stress associated with captivity and provide for behavioral enrichment. Hide boxes, carved-out logs, or plants should be placed throughout the enclosure, allowing a shyer reptile to have the ability to thermoregulate and eat without feeling exposed. The clinician must have detailed knowledge of enclosure setup to know if the environment is adequate to avoid medical issues.

Observation: Rostral abrasions and other injuries from escape behaviors.

Clinical significance: Stereotypical behaviors related to escape attempts can cause rostral abrasions and other traumatic lesions in captive reptiles.[8] It has been found that the inherent psychological organization and adaptational constraints present in reptiles result in failure to recognize the abstract invisible barriers.[8] Chinese water dragons (*Physignathus concincinus*) are particularly prone to escape attempts that create rostral wounds. Mirrors, glass, and other reflective surfaces should be avoided in enclosures containing less social species, because a reptile's reflection may be perceived as a conspecific and create undue stress because it is perceived as competition (Fig. 83.3). The reptile may attack the reflection, causing injury as it strikes the surface of the enclosure. Mandibular lesions can also be seen and may be associated with arboreal species diving or dropping onto hard surfaces.[8]

FIG 83.3 Glass and mirrored surfaces in enclosures can create reflections that can be stressful to reptiles such as this male bearded dragon (*Pogona vitticeps*) that perceives the reflection as a male conspecific and induces undue social stress.

Prevention: Placing a visual barrier such as black tape on a transparent enclosure and minimizing glare and reflection in an enclosure, as well as providing adequate space and hiding places, may decrease this behavior. Covering the glass with a less reflective paper, or using one-way glass can help to eliminate this problem.

Observation: Obstruction due to substrate ingestion and pica.

Clinical significance: Substrate ingestion can lead to intestinal impactions and may be associated with understimulating environments that are commonly found in captivity.[8]

Medical problems noted with substrate ingestion include obstruction, perforation, coelomitis, and cloacal prolapse from tenesmus. Particularly common in young bearded dragons (*Pogona vittiveps*), the authors have also seen it in chameleons, geckos, and uromastyx lizards.

Historical details are needed regarding substrates used currently and previously, as well as exposure to areas outside of the enclosure. Radiography and ultrasonography are useful to identify obstruction, impaction, and ileus. Pica can be noted secondary to mineral deficiency as seen with NSHP, so blood work should be performed to evaluate total calcium, ionized calcium, phosphorous, and vitamin D_3 levels. Radiography also allows for visualization of bone density to aid in diagnosis.

Prevention: A substrate that is not easily ingested, or is safe if ingested, is important in species that flick their tongues to investigate their environment or get substrate mixed in with food items as they are ingested. Even substrates that are designated as safe for reptiles, including bark, corncob, and calcium-containing sands, can cause gastrointestinal problems if ingested in large amounts. If a more naturalistic substrate is used to enhance environmental enrichment, then food should be offered on a plate or tray to minimize substrate ingestion.

Observation: Stress related to the environment.

Clinical significance: Many situations can create stress for reptiles and amphibians that can lead to immune suppression and disease over time. Captivity-related chronic stress behavior may be evidenced by increased abnormal behaviors, including behavioral inhibition, vigilance behavior, hiding, and fearfulness.[11] Additionally, an increased frequency of startle, aggression, and freezing behavior can be seen, as well as decreased exploratory behavior and reproductive behavior.[11] Green iguanas (*Iguana iguana*) are arboreal in nature and should be provided with a vertical enclosure to facilitate climbing. They also tend to be less

VetBooks.ir

stressed when their enclosure is at a reasonable height. Rock iguanas (*Cyclura* spp.) are ground dwellers and look for places to dig and burrow. Knowledge of whether a species is arboreal, terrestrial, or aquatic is necessary to provide the most natural environment for a reptile.

Captive conditions often deprive animals of known normal behavior and associated biologic needs, including hunting for food, spatial range, and macro-habitat exploration.[8] Home-range studies of reptiles in their natural setting have shown that reptiles are highly active and that they have been known to travel from several hundreds of square meters to hundreds or thousands of kilometers looking for food.[8] In addition, insectivorous species often need to feed more frequently and require a great deal of activity to catch their prey.[8] It is normal and healthy for an animal to spend hours of exploratory locomotor activity hunting for food[8] and interacting with the environment, and stress is created when small enclosures in captivity with plentiful food and minimalistic unnatural furnishings are substituted for a more natural environment.

All reptiles appear to seek out and occupy "angles" and orientation that allows them to find comfort in their environment and appear to play roles in delivering comfort and focused thermal needs, as well as in the amelioration of discomfort.[8] A snake that needs to adopt a straight-line posture to relieve intestinal discomfort cannot do so in a cage or enclosure that is shorter than the snake itself (Fig. 83.4).[8]

FIG 83.4 A reticulated python (*Malayopython reticulatus*) assuming a position that may indicate coelomic discomfort because it is unable to stretch out in this small container. Subtle changes in position of the body and placement in an enclosure can indicate medical issues or deficiencies in the environment.

Mimicry, or blending in with the environment, is a strategy used by reptiles, and the chameleon is one of the more popular species using this method of crypsis (Fig. 83.5). When housing a species that relies on visual mimicry, it might be best to use cage furniture that has natural colors to afford the animal the opportunity to blend in with its environment.

FIG 83.5 A panther chameleon (*Furcifer pardalis*) using visual mimicry of its environment as a form of crypsis. Using neutral and natural colors in the enclosure helps to make them feel more secure.

Dramatic or rapid changes in ambient temperature may induce a stress response in an animal, whereas a slow change/increase over a period of time allows for physiological adjustments that allow the individual to better tolerate the change.

When advising on changes in the temperature of an enclosure, it is imperative that cage dimensions, existing temperatures, temperature gradients, and humidty levels are all considered. Without specific recommendations, clients may misconstrue directions, and inappropriate thermal changes in the enclosure could be detrimental to the patient.

It has been shown that snakes use pheromones in their environment to mark their territory. Thus constant rearrangement of cage furniture or cleaning the cage might add additional stress to captive snakes. Used in moderation, however, rearranging enclosures has been found to increase foraging and exploration behavior in snakes.

Prevention: The natural behaviors of the species kept in captivity must be taken into consideration when creating and furnishing enclosures appropriate for reptiles and amphibians. Also, the practitioner should have a working knowledge of enclosure set-up before making recommendations on changes in temperature and humidity. Experience has shown that some reptile species are easier to maintain in captivity, including leopard geckos (*Eublepharius macularius*), crested geckos (*Rhacodactylus ciliatus*), fat tail geckos (*Hemitheconyx caudicinctus*), bearded dragons (*Pogona vitticeps*), corn snakes (*Pantherophis guttatus*), king snakes (*Lampropeltis getulus*), and milk snakes (*Lampropeltis triangulum*). Reptiles have been found to possess the cognitive ability to be trained using desensitization and operant conditioning.[12] This training not only helps to facilitate veterinary care, it can also aid in eliminating some of the psychological stress associated with captivity.[12]

Providing environmental enrichment and creating foraging opportunities can decrease stress-related behavioral issues. A Nile soft-shelled turtle, *Trionyx triunguis*, at the National Zoo (Washington, DC) was given objects such as balls, sticks, and hoses in an attempt to reduce self-mutilation behavior often noted in response to stress.[13] The turtle spent considerable time interacting with the objects, and the level of self-mutilation behavior decreased greatly over many months. Based on video recordings, an ethogram of the turtle's behavior was developed and showed that the turtle interacted with the objects for 20.7% of the time and was active for 67.7% of the time, much more time than was expected.[13]

Behavioral Issues Related to Feeding

Knowledge of how and what reptiles and amphibians naturally eat and drink, and how these are provided to captive reptiles, is imperative for helping them thrive. Understanding specifics about the diet, as well as how the food is prepared and presented, is helpful in aiding the practitioner to best serve the needs of the patient. Awareness of ontogenic shifts in feeding behaviors also allows practitioners to better advise clients. This is seen in bearded dragons (*Pogona vitticeps*), which are significantly more insectivorous as juveniles and more herbivorous as adults. Below are examples of how the knowledge of normal behavior can affect the decisions that should be made for feeding captive reptiles.

VetBooks.ir

Observation: Anorexia, inappetance.

Clinical significance: Many situations lead to anorexia in reptiles and amphibians, including infection and other disease processes, competition from conspecifics, as well as overly restrictive and inappropriate environments[11] and maladaption to captivity. Social stress or intraspecific aggression from the presence of individuals that are aggressive or become aggressive or protective around resources may keep cage mates from eating as well or as often and cause failure to thrive. This is commonly seen in groups of captive lizards and in colonies of aquatic turtles. Overhandling shy species (e.g., chameleons, ball pythons) can cause anorexia due to stress. It is also not advisable to examine or perform diagnostic procedures on a snake shortly after feeding due to increased risk of regurgitation.

Undetected disease processes, often evidenced by behavioral changes that may go unrecognized by the owner or caregiver, may lead to anorexia. Pathologic conditions of the upper gastrointestinal tract that negatively impact the feeding response and oral, dental, and beak disorders of reptiles are common presentations.[14] Many reptile species become anorectic in cooler months, so it is important to distinguish seasonal anorexia/hypophagia from a pathologic etiology. Hormonal activity during the breeding season in both male and female reptiles and in gravid females may result in decreased appetite or anorexia. Feeding nocturnal species during the day may lead to anorexia. Knowledge of normal feeding behaviors will also help the owner to pick appropriate prey items and, with some imagination, help with behavioral enrichment.

Both infectious and noninfectious disease processes will often result in associated anorexia.[15–17] Incubation of these infectious diseases can be long (up to 6 months), making it difficult to associate anorexia with an infectious exposure or injury that leads to the infection. Medical problems can ensue if live prey items are left in the enclosure with uninterested or ill reptiles for lengthy periods of time. Crickets have been known to create conjunctival or corneal lesions in geckos, chameleons, bearded dragons, and anoles[18] as they look for a source of moisture. Rats and mice can chew on a snake, causing extensive damage to skin, underlying muscle, and even vertebrae. An anorexic blood python (*Python curtus*) that hasn't defecated for several weeks and has a distended caudal ceolomic cavity could have a gastrointestinal impaction, a foreign body, parasites, or a neoplastic mass. Because this species needs a particularly high humidity of 60% to 70%, constipation and impaction is a common problem when kept at temperatures too high and humidity too low.

Snakes, especially those that are wild caught, may refuse to eat albino laboratory rats or mice but be more likely to strike at brown rodents. Gerbils are often substituted for white mice in smaller snakes, especially ball pythons (*Python regius*), for which gerboas and other brown-colored rodents are natural prey. Anorectic reptiles that are hospitalized should be supported with species-appropriate food items. Syringe-feeding supplements are available for herbivores (i.e., Critical Care, Oxbow Pet Products), carnivores (i.e., Carnivore Care, Oxbow Pet Products), and insectivores (i.e., Insectivore Diet, Walkabout Farms). Esophagostomy tubes can be placed for long-term supplemental feeding or in those species that are difficult or dangerous to feed orally (see Chapter 45).

Prevention: Knowledge of the captive feeding habits is essential. Home-range defensive behavior appears to be most prevalent in the iguanian and gekkotan lizard,[19] so it is important to provide adequate resources (space, basking areas, hiding spaces, and food) for all communally housed individuals. Providing multiple feeding stations can reduce competition in enclosures that contain several reptiles, otherwise cage or tank-mate aggression can lead to severe injuries. Placing food in open, as well as visually protected, areas will encourage feeding even for shy species. It would be inappropriate and inhumane to place predators and prey in the same enclosure. Crickets and other insects should not be left in the enclosures of lizards in large quantities over long periods.

The feeding of live vertebrate prey is illegal in most countries; however, if live prey is provided to snakes, it is preferred that they be fed in a separate enclosure and removed if the snake has not eaten them within a few minutes. Captive reptiles and amphibians that are not eating prey quickly should be evaluated for clinical signs of disease and have the diet and environment scrutinized for problems that may be causing anorexia. Preferably frozen, thawed prey items should be provided.

Healthy lizards kept in proper environments may experience seasonal or hormonal anorexia that will not usually result in weight loss of more than 5% to 10% of body weight.[20] Monitoring weight during this normal physiological process is therefore important in assessing health status. Many captive lizards, however, are already somewhat compromised by poor diet, dehydration, less-than-optimal environment, and parasitism such that this period of anorexia may not be tolerable. Because of the risks associated with reproduction in females, consideration should be given to ovariectomize pet reptiles to avoid compromise created by reproduction.

Knowing the details of the environment and understanding the specific environmental needs of the species, as well as performing diagnostics including radiographs, ultrasound, intestinal parasite examination, and blood work, can lead to a quicker diagnosis, resolution of the problems involved, and prevention of reoccurrence. Providing adequate humidity and opportunities to soak help with constipation. Routine wellness checks and intestinal parasite exams may help with early diagnosis of other etiologies of anorexia.

Observation: Inability or unwillingness to drink water.

Clinical significance: How water is provided to different species must be taken into consideration when determining the cause of dehydration. Box turtles and many species of tortoises normally drink from water pooled on the ground during and after rain. The water is consumed by filtering it through overlying vegetation, so they may not recognize or be stimulated to drink from a bowl. In many lizards and most snake species, hydration is maintained more from moisture in the diet than from drinking. This is especially true for those reptiles on moist and vegetative diets, so appreciable amounts of free water may not be consumed. To provide water in a bowl to a species that naturally gets water from lapping morning dew, such as chameleons, may act as a stressor and lead to chronic dehydration over time. Such species often fare better if a misting or drip system is provided.

Dehydrated reptiles and amphibians will have dry (if skin is normally moist), loose skin, sunken eyes, and tacky mucous membranes. Diagnostic testing includes hematology and plasma biochemistry, including hematocrit. Treatment includes correcting fluid imbalances, evaluating how water is provided, and ensuring that competition for procuring water is minimized.

Prevention: For many species, a sprinkler system outdoors can be utilized to simulate rain if lack of water consumption or dehydration is of concern. Lizards that do not drink from a water bowl may lap water that has been spray misted on the inside of the enclosures or from a continuous drip system. Water can also be spray misted on food items to help maintain hydration.

Observation: Inactivity and overeating leading to obesity.

Clinical significance: Obesity is a common consequence of captivity due to lack of exercise, inappropriately small cage size and inappropriate or excessive calories. It is especially prevalent in sit-and-wait predators such as captive monitors and boids (Fig. 83.6A and B), which are offered frequent high-caloric food items without exercise to obtain the food. A lack of variety of diet items, especially those containing lower caloric value, may also contribute to obesity. Obese reptiles are more likely to

(B) A lateral radiograph of the savannah monitor (*Varanus exanthematicus*) seen in A. suffer from hepatic lipidosis if they become anorectic due to stress or disease.

Prevention: Obese reptiles do not live as long as healthy conspecifics and tend to be more immune suppressed. Providing variety in the diet, feeding less, and allowing the captive reptile to forage for food to increase exercise are all helpful in preventing obesity. Other forms of environmental enrichment also aid in prevention, including placing food in multiple areas around the enclosure and creating other foraging opportunities.

Social Behavior

It has been found that amphibians and reptiles exhibit traits commonly seen in birds and mammals, including sophisticated communication, problem-solving abilities, signs of parental care, as well as play and complex sociality.[21,22] Understanding the normal behavior of reptiles and amphibians that are kept in captivity is necessary in providing them with enclosures and a social structure that will allow them to thrive.

Sudden changes in the social structure of a group of animals, with the addition of conspecifics, can lead to stress and immune suppression. The animals within the group may readjust their social dynamics as the group changes and as new individuals are added, potentially leading to conflict around acquisition of mates and resources. It is also essential that caretakers are aware that if one or more of the reptiles in an enclosure is not developing as fast as the others, it may need to be separated in order to thrive. Wellness exams at least every 6 months, along with obtaining periodic weights, are helpful in determining if such discrepencies exist and if changes in social structure need to be made.

Observation: Intraspecific aggression and agnostic behaviors.

Clinical significance: Most reptiles are not considered to be social animals, and relatively few reptiles live constantly in social groups. The social tendencies of reptilian behavior vary both with species and with ontogenicity. While many reptiles show a significant increase in social behavior at breeding time, for most of the year even these species prefer a solitary lifestyle.

Social behavior of a given species must be taken into consideration when deciding on whether to cage conspecifics or members of different species together. Turtles appear to be solitary for most of the year and live only socially during the breeding season. Sick or injured chelonians should be housed individually, as the presence of another animal might be an additional stressor to these animals. Severe injuries and fatalities from fighting occur more commonly in captivity with less opportunity to flee. Reptile species that are naturally gregarious such as leopard geckos (*Eublepharus macularis*) and bearded dragons (*Pogona vitticeps*) thrive better when kept in groups, especially when a single male is kept with multiple females. Lizards housed together for months to years may become aggressive toward each other and should be separated if such behavior is noted. Keeping male reptiles in cages that allow for visualization of other males is often socially stressful, so a setup where direct visual contact can be established should be avoided, especially for chameleons and iguanas. Sexual aggression toward humans by reptiles has been reported most commonly with the green iguana (*Iguana iguana*)[23,24] during the breeding season, when hormone levels are fluctuating, and is often initiated by the presence of a menstruating human female. After the breeding season is complete, some will revert back to their normal docile behavior, while others remain aggressive.

Individuals of any given species that control resources will often thrive more and grow faster than subordinates in the same enclosure. Since onset of adult behavior patterns is related to body size, the larger males also display adult behaviors much sooner, so separation of the other individuals is not only necessary for them to thrive but may become necessary for them to survive. The presence of aggressive conspecifics, predators, and perceived predators will significantly alter daily behavior in reptiles and amphibians. For instance, it was noted that eye contact between human observers and free-living iguanas resulted in significant disruption of normal hierarchical perching in the iguanas being observed.[25]

Prevention: Having a working knowledge of species-specific behaviors allows caretakers to provide an environment and social structure that better mimics what is seen in nature and more likely to be successful. Providing multiple basking areas for groups of reptiles may minimize social stress, as some individual males tend to take and defend the preferred spots,[26] grow more rapidly, and use the supplemental heat sources more often than subordinate males. Social stress can also be minimized when housing nongregarious reptile species together in environments by providing sufficient space, appropriate hiding spaces, visual barriers, and multiple feeding stations.

It has been suggested that sexually mature male iguanas that are showing signs of aggression may have some of these behaviors reduced by decreasing daylight hours, eliminating exposure to other male animals

VetBooks.ir

and female conspecifics, and decreasing environmental temperatures slightly. The practitioner should stress to the client, however, that aggression is a normal expected behavior for iguanas and that efforts to control behavior should not be extreme enough to cause harm to the iguana. Depo-Lupron and Depo-Provera have both been used with mixed results to decrease human-directed aggression in male iguanas. Castration of male iguanas prior to sexual maturity may help to decrease the chance of reproductive-related aggression toward people and other pets.[27] Clients should be counseled that castration prior to puberty would also decrease the development of secondary sexual characteristics including large jowls and crests. Castration after sexual maturity has occurred has variable but limited effect on decreasing aggression (see Chapter 80).

In green iguanas femoral gland pore size was positively correlated with the frequency of head-bob displays and the plasma levels of testosterone during the breeding season in males older than 12 months of age.[28] This behavior is part of the normal agonistic repertoire for this species.

These head bobs, not present when the iguana is first acquired as a juvenile, may be mistaken by a novice caretaker as an indication of illness such as hypocalcemic tetany or central nervous system disease. Because they are intermittent and stimulated by the presence of other male iguanas or in response to a threat makes them easier to distinguish as a normal behavior and not a clinical sign.

Handling and Behavior

As wild creatures, reptiles are not domesticated and may act and react instinctively and defensively. Any reptile that is approached too quickly or handled inappropriately may show signs of aggression or flight. Defensive aggression in reptiles can represent a safety hazard for your staff if employees are not instructed in proper restraint and handling. Early recognition of a stressed individual can help to deescalate the situation or to anticipate the next step and to avoid injury to the animal, the handler, or the examiner. Despite attempts to decrease stress, behavioral issues may be "masked" by acute arousal states in the clinical environment, which may make an accurate diagnosis more difficult.[8]

Observation: Behavioral issues related to handling.

Clinical significance: A green iguana (*Iguana iguana*), as well as other lizards, may sit with its head extended and its eyes closed as it is being petted. This behavior is often considered to be a sign of contentment; it may, however, be a sign of fear, illness, learned helplessness, or even the dissociative behavior of a patient that is highly stressed. The lizard may be "zoning out" in a strange environment riddled with strange sounds, smells, and potential predators, or it may be too ill to respond with curiosity to a new environment. This could also be a lizard that will readily strike if provoked—using teeth, claws, and whipping tail to defend itself against predators. This lizard may also be much sicker than it would appear, and any stressor such as handling, diagnostic procedures, or treatment may prove to be detrimental.

Defensive aggressive behaviors in reptiles include posturing that makes the aggressor appear to be more threatening, such as inflation of the body, standing more erect on all four legs, broadside posturing, dewlap extension, open-mouthed threat, and head bobbing. Biting, striking, and tail whipping may also be seen. Male frill-necked lizards (*Chlamydosaurus kingii*) will also kick and bite at each other while displaying extension of the frill around their necks.

Handling by owners, as well as by practice staff for medical diagnostics, causes pyschological stress similar to that created by predators. Lizards that become frightened may roll like a crocodile in attempts to escape restraint or predators. Some lizards such as the basilisk lizard (*Basiliscus vittatus*) that normally ambulate with all four legs are able to run bipedally on their rear legs to escape predators, even across water.

FIG 83.7 This Chinese water dragon (*Physignatus cocincinusis*) forming a u-shaped posture toward the perceived predator as a defense mechanism, ready to strike if necessary.

Chuckwallas (*Sauromalus obesus*) will crawl into crevices in rocks to escape predators and then inflate their bodies so that they cannot be pulled out from their hiding place. During manual restraint, snakes will usually exhibit negative taxis to the restrainer and try to work the body out of the grasping hold with constant forward movements and/or rotation on its own axis. Iguanas and other lizards that are placed on an exam table may assume a u-shaped position with their tail pointed toward the practitioner (Fig. 83.7), ready to defend themselves if needed.

All reptiles will struggle if not well supported during handling and may cause injury to the handler or to themselves (i.e., loss of tail, damage to vertebrae). Most lizards will exhibit a serpentine-type motion when struggling that can be minimized if both the thoracic and pelvic girdles are well supported and firmly but gently restrained. Turtles will often urinate during handling. This may be associated with fear, pain, a defensive behavior to repel a predator, or as a part of a flight reaction in an attempt to quickly decrease body weight. It has been proposed that the bladder in tortoises can function as a water reservoir,[29] so, when a chelonian patient has forcefully emptied the bladder, it is important to make sure the animal has proper facilities to replenish fluid. Snakes can empty their musk glands in the cloacal area when frightened during handling, especially milk snakes, which might detract predators due to the foul smell and taste.

Overhandling of shy species can lead to stress, anorexia, and ill health. Species such as chameleons and ball pythons may not be the best pet choice for owners that wish to handle their pets frequently. Snakes, especially ball pythons, that are handled soon after feeding often regurgitate. Regurgitation may also be seen in certain diseases such as cryptosporidia, cardiomyopathy, or various metabolic diseases. Chelonians or lizards will not normally regurgitate in response to handling.

It is advisable not to handle snakes and lizards just before a shed. The old keratin layer that is shed comes off after the new keratin layer beneath has completely formed, so shed should never be pulled off prematurely. In snakes that are preparing to shed, the eye caps will

VetBooks.ir

often become opaque, and the snake may be more apt to strike, probably due to decreased vision during this time. After a few days the eye caps will clear, and the skin over the entire body may appear dull. A novice snake owner may think that eye caps are retained when these changes are first noted.

Many lizards, including monitors and iguanas, will become more active and even aggressive when exposed to natural sunlight,[30] and owners must be warned that they may become dangerously aggressive or escape if they are not handled carefully. Usually once the lizard is out of the sunlight, normal behavior resumes. Much individuality in personality can be seen in different reptiles of a given species, depending on how much social contact they have been exposed to, how much environmental enrichment is provided, and how they are treated and handled. Frequently owners and caretakers, however, may mistake some atypical behaviors as a sign of domestication while not understanding that the aberrant behavior or new behavior may be a sign of illness, fear, or stress.

Prevention: Successful treatment of reptiles and amphibians must include not only treatment of disease but also the reduction or elimination of stressors while in the care of the practioner and, most importantly, in the animal's home environment. Teaching the staff and owners how to handle each species appropriately, as well as when it is best not to handle them, is important in ensuring their well-being. It has been found that reptiles possess the cognitive ability to be trained using desensitization and operant conditioning to facilitate veterinary care[12] and handling (see Chapters 14 and 121). Providing mental stimulation with this type of training may also help to eliminate some of the psychological stress for reptiles maintained in captivity.[12]

Reproduction and Behavior

Knowledge of normal reproductive behaviors in any given reptile or amphibian species that is kept in captivity is important for both providing optimal care, as well as for successful breeding and reproduction. Without the proper environment and nutrition, for instance, many reptiles cannot successfully reproduce, and pathologic conditions such as dystocia or preovulatory follicular stasis may result.

Observation: Behavioral issues related to seasonal/hormonal influence.

Clinical significance: Gravid females not provided with a proper place to lay eggs or kept under conditions of inappropriate temperature, humidity, and diet will often suffer from preovulatory stasis, egg binding, or dystocia. Gravid female reptiles will often initially be hyperactive, and, as they become visibly gravid, females of many lizard species tend to become lethargic and anorectic, spending more time basking. They may also become more aggressive and active as they attempt to find an appropriate nesting site. Gravid green iguanas will protect a nest site by acting aggressively toward cage mates, including biting and hissing.

As discussed previously (see Feeding and Behavior section), there are many etiologies that lead to anorexia. If anorexia is a presenting complaint, it is important for the clinician to be able to distinguish whether it is pathologic or associated with breeding condition in males or gravidity in females. The throat of male bearded dragons becomes dark black (Fig. 83.8), much darker than the females, during the breeding season.[31] Female chameleons will often become darker in color during gravidity. Female bearded dragons will perform an arm waving behavior where they stand on three legs and wave one front leg in a slow circular motion from front to back. It is thought that this is an appeasement display toward aggressive males during the breeding season and during copulation.[31]

Prevention: It is imperative to assess whether a reptile is in adequate physical condition to undergo what would be a normal period of anorexia associated with reproductive activity in that species. Environmental clues such as a proper moist or sandy substrate are needed for some females to induce egg-laying behavior. Knowledge of species-specific behaviors related to reproduction is important in ensuring the welfare of reptiles and amphibians in captivity, as well as in recognizing reproductive problems and responding to them sooner.

FIG 83.8 Black beards in bearded dragons (*Pogona vitticeps*) can signify many things. It can be present in males in breeding condition and can also be seen when bearded dragons are stressed, fearful, or in pain. This female is suffering from an intestinal obstruction and is presumably in significant pain.

Behavioral Changes Associated With Medical Issues

Depressed demeanor in reptiles and amphibians is exhibited by half-closed, unfocused eyes, inability or unwillingness to move, extended head and limbs, lack of interest in the surroundings, and the lack of righting and proprioceptive reflexes. Many lizards will sit quietly with head extended, eyes closed, and feet planted firmly when being handled or placed on an examination table. The practitioner must be able to discern between what is normal and abnormal, as even subtle changes in behavior can be significant. Knowledge of abnormal behaviors in light of other clinical signs will aid the practitioner in determining if diagnostics such as blood work, radiographs, and/or ultrasound are needed to rule out the presence of medical issues.

Observation: A normally skittish or aggressive lizard that has suddenly become docile.

Clinical significance: A lizard that does not try to escape as it lays on its owner's chest may in fact be attracted to the warmth of the body in a situation where there is no other heat source. Lizards that suddenly allow handling may also have developed difficulty in ambulation. This is often a chronic gradual process that has been undetected by the caretaker. This could also be a lizard that is stressed or ill and may be perceived as becoming more "tame" to a novice owner or handler. If the lizard is typically more difficult to handle and suddenly becomes "tame," this behavior change may actually indicate lethargy or illness, and a complete physical exam and a full medical workup is needed, including blood work, radiographs (especially if ambulation is a problem), and intestinal parasite exam.

Observation: Snake soaking excessively in a water bowl.

Clinical significance: Rule-outs include a snake enjoying this behavioral enrichment, a stressed or insecure snake that has nowhere else to hide, or a snake that is infested with snake mites (*Ophionyssus natricis*) or trombiculid mites (*Hirstiella spp.*) that is trying to soothe irritated skin. Environmental temperatures may also be too high or humidity may be too low.

Along with a complete physical examination, a husbandry evaluation, including information on how the enclosure is set up and where in the

VetBooks.ir

temperature gradient of the enclosure the snake spends most of its time is helpful in determining a diagnosis. This may give the practitioner clues to environmental conditions that are causing immune suppression and disease.

CONCLUSION

Having a working knowledge of normal and abnormal behaviors of reptiles and amphibians is essential for successful practitioners. This information is useful to assess the general well-being of the patient, the appropriateness of the environmental enrichment and husbandry provided to the patient, and as an indicator of clinical disease when abnormal behavior is recognized.

It is important for us as clinicians to establish a "whole patient" approach to the presenting reptile or amphibian, providing guidance on their captive environment, handling, care, and behavior, and not just focusing on the specific presenting sign or symptom.

Nutritional Diseases

Thomas H. Boyer and Peter W. Scott

The most common reasons people seek veterinary care for reptiles and amphibians are for nutritional-related diseases. Thus nutritional disorders continue to be important in captive herpetologic medicine, from the all-too-common nutritional secondary hyperparathyroidism (NSHP), hypovitaminosis A, and obesity to the less common thiamine, biotin, vitamin E/selenium deficiencies, steatitis, gout, and corneal lipidosis. This chapter covers significance, etiology, presentation, diagnostic confirmation, and specific therapy of nutritional diseases. To better understand guidelines and recommendations for nutrition, see Chapter 27. For general nutritional therapy guidance, see Chapter 122.

NUTRITIONAL SECONDARY HYPERPARATHYROIDISM

NSHP, particularly rickets and osteomalacia, are the most common of the metabolic bone diseases seen in reptiles and amphibians. Renal secondary hyperparathyroidism (RSHP) was commonly seen in practice in older green iguanas (*Iguana iguana*) presenting in renal failure but is less common currently, as green iguanas are less frequently kept as pets. Hypertrophic osteopathy and osteopetrosis-like lesions have been described in lizards.[1,2] These unusual presentations need to be considered alongside others, such as gout and tumoral calcinosis (pseudogout), as potential differential diagnoses when investigating metabolic bone disease.

Clinical Significance and Known Etiological Cause(s)

NSHP, unfortunately, is still common, especially in amphibians and growing reptiles, except snakes. The most commonly affected reptiles include young growing tortoises (Testudinidae), leopard geckos (*Eublepharis macularius*), and bearded dragons (*Pogona vitticeps*), which is probably a reflection of demographic bias. In the 1990s green iguanas were popular and most commonly affected. Calcium (Ca) deficiency arises from inadequate dietary Ca, an unbalanced calcium:phosphorus (Ca:P) ratio, and/or a lack of vitamin D_3. Diagnosing a calcium deficiency would appear to be straightforward, but it can be a complex and multifactorial issue.

Reptiles require vitamin D_3, cholecalciferol, either in the diet or from dermal ultraviolet B (UVB) photochemical production. Vitamin D_3 is biologically inactive; activation requires hydroxylation in the liver and kidney. Synthesis of vitamin D_3 from UVB is regulated by a negative feedback loop that prevents toxicity. In the liver, D_3 is converted to calcidiol, or 25-hydroxyvitamin D_3, which is typically measured in serum/plasma to determine an animal's vitamin D_3 status. Calcidiol is converted by the proximal renal tubules of the kidneys to calcitriol, or 1,25-dihydroxycholecalciferol, the biologically active form of vitamin D_3. The conversion of calcidiol to calcitriol is catalyzed by the enzyme 1α-hydro, levels of which are increased by parathyroid hormone (PTH) due to low levels of Ca or increased P. Calcitriol circulates in blood as a hormone, regulating the concentration of Ca and P in the bloodstream, promoting growth and remodeling of bones and also affecting neuromuscular and immune function. Secondary hyperparathyroidism is due to excessive secretion of PTH in response to hypocalcemia, usually from Ca or vitamin D_3 deficiency, or excessive P intake (such as with a low Ca:P ratio diets) and occasionally from chronic kidney failure and inadequate calcitriol production.

Dietary supplementation of D_3 is problematic because recommended daily allowances are unknown for reptiles and amphibians, and given the likely taxonomic variabilities, toxic hypervitaminosis D_3 would be a concern. For example, in growing bearded dragons plasma concentrations of UVB-exposed dragons, for just 2 hours/day, were 18 times higher for calcidiol and 5 times higher for calcitriol than in vitamin D_3-supplemented dragons at 6 months of age. This work is interesting in that whatever period of UVB exposure was used, the blood levels remained within a relatively close range, approximately 10x that of the highest level of supplementation.[3] Natural sunlight or artificial UVB exposure of Komodo dragons (*Varanus komodoensis*) significantly increased calcidiol levels compared with dietary supplementation of 450 IU vitamin D_3/kg feed, which resulted in no increase in any of the measured vitamin D metabolites.[4] Green iguanas also do not seem able to efficiently utilize dietary vitamin D without high doses, likely to cause toxicity in other species, and are dependent on UVB radiation for vitamin D synthesis.[5–7] Most of the iguanas housed indoors at the National Zoo in Washington, DC, fed a diet with 2000–3000 IU vitamin D_3/kg, dry matter basis (DMB), developed NSHP after 2 years (about 25% died) and had extremely low levels of calcidiol (0 to 20 nmol/L [0–8 ng/mL]), which increased rapidly after exposure to artificial UVB (mean = 746 nmol/L [299 ng/mL]) to levels of iguanas housed outdoors (374 to 998 nmol/L [150–400 ng/mL]).[7] Dietary vitamin D levels for other species range from 140 to 2500 IU/Kg, although some primates require higher levels.[7] In humans, serum calcidiol levels less than 50 nmol/L (20 ng/mL) are considered vitamin D deficient, and toxic effects of vitamin D are seen when vitamin D levels are greater than 374 nmol/L (150 ng/mL).[8] As arboreal folivores, iguanas appear far more dependent on UVB for vitamin D_3 production than on dietary vitamin D_3.[6,7] In contrast, researchers found that UVB was not required for western fence lizards (*Sceloporus occidentalis*) for normal bone growth.[9] The differences in metabolic routes of sourcing and use of D_3 shown by such diverse species undoubtedly implies differences will exist in other species, which, as yet, have not been identified. Vitamin D_3 is a fat-soluble vitamin, which means D_3 is stored in hepatic and adipose tissue for long periods of time and generally poses a greater risk for toxicity, when consumed in excess, compared with water-soluble vitamins. This, however, may not be a straightforward assumption because D_3 is inactive without kidney and liver activation.

For captive-raised veiled chameleons (*Chamaeleo calyptratus*) ideal calcidiol levels, based on bone mineral density, were thought to be >250 nmol/L (>100 ng/mL), but levels of 102 nmol/L (41 ng/mL) were

sufficient to prevent NSHP.[10] Mean ± SD calcidiol levels of red-eared sliders (*Trachemys scripta elegans*) exposed to UVB for 1 month (71.7 ± 46.9 nmol/L, 29 ± 19 ng/mL) were significantly higher than those without UVB for a month (31.4 ± 13.2 nmol/L, 31 ± 13 ng/mL).[11] Mean ± SD plasma concentration of calcidiol in corn snakes (*Pantherophis guttatus*) that were provided with UVB (196 ± 16.73 nmol/L, 79 ± 7 ng/mL) differed significantly from values in corn snakes without UVB (57.17 ± 15.28 nmol/L, 23 ± 6 ng/mL).[12]

For years UVB light in the 280 and 320 nm wavelength has been recognized as essential for most reptiles, with peak vitamin D synthesis occurring between 295 and 297 nm in mammals. The only reptiles that do not seem to require UVB light, if they have dietary sources of vitamin D_3, are snakes and nocturnal geckos (such as leopard geckos and New Caledonian geckos [*Correlophus* spp. and *Rhacydactylus* spp.]). However, plasma calcidiol levels were increased with UVB radiation in corn snakes[12] but not in ball pythons (*Python regius*).[13] Some snakes (diamond pythons, *Morelia spilota spilota*; indigo snakes, *Drymarchon couperi*; water snakes, *Nerodia* spp.; and green snakes, *Opheodrys* spp.) seem to anecdotally do better with UVB exposure. In one study measuring the effects of UVB radiation on leopard geckos, erythema and increased ecdysis, consistent with sunburn, was noted.[8] Breeding colonies of leopard geckos have been maintained with no UVB exposure and only dietary sources of D_3; others have maintained leopard geckos in excellent health under UVB light without dietary supplements (Boyer T, personal observation., 1982–1994; Baines F, personal communication, 2016). One study suggested that some nocturnal geckos may rely on photobiosynthesis of vitamin D_3 and that they might have a more sensitive mechanism than diurnal lizards to compensate for their limited exposure to natural UVB radiation.[14] In general, broad-spectrum (including UVB) light is recommended for all reptiles and amphibians.

Six sources of ultraviolet light are currently available for reptiles: unfiltered sunlight, fluorescent tubes, compact fluorescent bulbs, mercury vapor spot lights, mercury vapor flood lamps, and light emitting diodes. Recent investigations have demonstrated the ability for LED lights to produce UVB and maintain calcidiol plasma levels in bearded dragons.[15] Sunlight is always recommended as the best source of UVB light, and although short periods may be sufficient, this is not always practical due to temperature. Hermann's tortoises (*Testudo hermanni*) exposed to mercury vapor or fluorescent UVB lights had significantly lower calcidiol plasma levels after 35 days (155.69 ± 80.71 nmol/L, 62.38 ± 32.34 ng/mL, and 134.42 ± 51.42 nmol/L, 53.85 ± 20.60 ng/mL, respectively) compared with tortoises with natural sunlight exposure (411.51 ± 189.75 nmol/L, 164.87 ± 76.02 ng/mL).[16] UVB light is almost completely filtered by glass or plastic, unless these materials are specifically UVB transmissible. UVB transmissible glass or plastics are available but costly, and rarely used outside zoos. Fluorescent tubes and compact fluorescent bulbs produce UVB light but little heat, thus the demand for and use of mercury vapor lights that can produce both heat and UVB light. This may be advantageous because vitamin D_3 activation requires both UVB light and heat. All spot lights seem prone to burning because they produce a focused beam. Mercury vapor flood lamps produce more diffuse heat. Manufacturers' recommended minimum distances should always be followed. UVB light intensity decreases with the inverse square law ($1/\text{distance}^2$), so a light that is twice as far away has one-fourth the UVB intensity. Consequently lights, especially those of lower power like fluorescents, should be kept close to the animal, no more than 30–60 cm (12–24 inches) away. UVB lights should be replaced every 6 to 12 months or when UVB output drops below 70% of the original output. UV meters are now available and are an important tool for testing bulb output and assessing efficacy of basking areas. Not all reptile lights produce UVB; practitioners must check products individually. Many reptile lights state "daylight," "broad spectrum," or "UVA" (320–400 nm) but lack critical UVB. See Chapter 17 for more information.

Bones are the main storage site of Ca in the body (99%). Total plasma Ca concentration consists of three fractions: 40% total Ca (which is albumin bound), 15% anion bound (Ca sulfate, phosphate, lactate, or citrate), and 45% as ionized (or free) Ca. The wide range in normal total plasma Ca concentration is probably due to variations in plasma albumin concentrations. When ionized Ca levels drop in blood, the parathyroid gland releases PTH, which increases Ca resorption from bone, reabsorption from kidneys, and absorption from intestines. If bone levels are not replenished from Ca intake, chronic hyperparathyroidism weakens bones, sometimes causing pathological fractures and/or fibrous osteodystrophy (lizards) or shell softening (chelonians). Life-threatening reductions in blood-ionized Ca can lead to seizures, tetany, and flaccid paresis (Fig. 84.1A and B). Mean ionized calcium concentrations in blood for iguanas were 1.47 ± 0.105 mmol/L (5.89 ± 0.44 mg/dL) and for Mediterranean tortoises (*Testudo* spp.) were 1.32 ± 0.14 mmol/L (5.29 ± 0.56 mg/dL). Significant differences were not detected among juveniles, males, and females.[17,18] When ionized Ca levels are high, calcitonin, from the ultimobranchial bodies, inhibits osteoclast activity and reduces renal tubular reabsorption of calcium and presumably provides negative feedback to the parathyroid glands to reduce PTH secretion. Ca is often deficient in the diets of insectivores (insects have little Ca), omnivores, and herbivores (vegetables and fruits are typically low in Ca) but usually not carnivores, because the bones within the whole animals they are feeding on generally provide a balanced source of Ca. Exceptions include feeding organs, meat without bone, or neonatal rodents (pinkies). Neonatal rodents have a borderline low Ca:P ratio depending on age and how long they have been nursing. Most carnivores grow quickly enough that they outgrow pinkies and begin to take larger prey with more calcified bone and avoid Ca deficiency. For more information on this, see Chapter 27.

Clinical Presentation and Diagnostic Confirmation

Symptoms of NSHP vary widely by individual and species. Common signs include lethargy, weakness, anorexia or decreased appetite, lack of growth, sprawl (Fig. 84.2A–D), and reduced ability to raise the body during ambulation. Lizards are prone to spinal injury from pathological vertebral fractures, which may result in paraparesis, paraplegia, or quadriplegia, depending on the location of the spinal lesion.

NSHP can cause the ribs and scapuli of lizards to flatten horizontally, away from the more normal vertical orientation. Iguanas and leopard geckos have similar clinical signs, including bowed long bones (especially the radius and ulna), walking on the antebrachiums (not plantigrade), long bone fractures, pliable mandibles and maxillae (Fig. 84.3A–D), kyphosis, scoliosis, lordosis, or rhoecosis (all three of the former). Iguanas sometimes bloat, can prolapse their colon/cloaca, and are particularly prone to fibrous osteodystrophy (Fig. 84.4), especially of the mandible.[19]

FIG 84.2 Sprawl (A–C) and lack of truncal (A and B) or shell lifting (D) are common signs of nutritional secondary hyperparathyroidism in lizards and chelonians. (Courtesy of Thomas H. Boyer.)

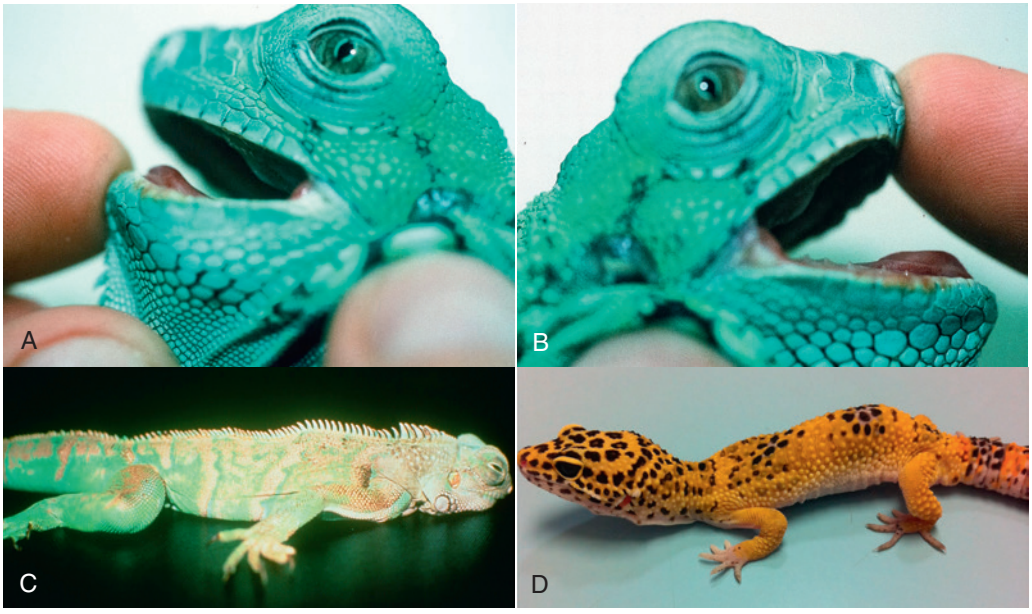

FIG 84.3 Iguanas (*Iguana iguana*) and leopard geckos (*Eublepharis macularius*) have similar clinical signs of nutritional secondary hyperparathyroidism, including pliable mandibles and maxillae (A and B); kyphoscoliosis, lordosis, or rhoecosis (C and D); bowed long bones (especially the radius and ulna, D); and walking on the antebrachium (not plantigrade, D). (Courtesy of Thomas H. Boyer.)

FIG 84.4 Fibrous osteodystrophy (in the left femur and right tibia/fibula of this iguana [*Iguana iguana*]) is common in lizards with nutritional secondary hyperparathyroidism but is not seen in chelonians. (Courtesy of Thomas H. Boyer.)

Chameleons have a noticeably weakened grip, fall repeatedly, and have bowed, distorted or fractured long bones, scoliosis of the parietal crest or vertebrae, cloacal distention, and tail weakness (Fig. 84.5A–D). In iguanas, bearded dragons, and monitors (Varanidae), when ionized Ca can no longer be maintained, tremors (especially in the digits, limbs, or large muscle masses), spasms, seizures, flaccid paresis, or death can occur (see Fig. 84.1A and B).[20]

NSHP is obvious in tortoises with soft or deformed shells, inability to lift the shell while walking, splayed legs, and decreased appetite. Tortoise shell should feel very much like skull, with no soft areas (except pancake tortoises and chelonians with shell kinesis [Fig. 84.6]. Shell pliability of neonates typically disappears within 6 to 18 months. Calcium-deficient females probably produce calcium-deficient eggs/hatchlings. Chelonians rarely develop fibrous osteodystrophy; they simply calcify their shell poorly. This is typically followed by anorexia and a reduced ability or inability to move, likely in relation to muscle weakness, from associated hypocalcemia, or bone pain. Clinical signs vary depending on age of exposure to a calcium-deficient diet. Small tortoises fail to grow or gain weight, have normal shell morphology except it is soft, splay out their legs, and have overgrown nails. Black areas beneath the scutes may represent normal coloration, but if the shell is soft, decreased shell ossification can result in transparency of scutes to an underlying darker tissue ("black spot disease") (Fig. 84.7A and B). In general, tortoises that are not eating carry a poor prognosis and typically die. In adult tortoises there is curving of the normally straight ventral or dorsal midline scutes, and the epiplastron projection may curve dorsally instead of anteriorly (Fig. 84.8A and B). The convex carapace may develop lordosis (Fig. 84.9). The central plastron may be flexible, or the anterior and posterior plastron flexes more than it should during palpation. The medial nails of the pelvic limbs wear excessively whereas the lateral nails overgrow because the tortoise walks on its heels, not plantigrade (Fig. 84.10). Pyramidal shell growth may accompany calcium deficiency; however, it appears to be multifactorial in origin, with humidity and growth rate also involved (see Fig. 84.9).[21,22] In box turtles (*Terrapene*), the marginal scutes curl dorsally; the seams between scutes collapse inwardly; the plastrocarapacial bridge widens vertically; the anterior rhamphotheca may curve more like a parrot's beak; the body may appear too large for the shell; and phallic, clitoral, or cloacal prolapse may occur (Fig. 84.11A–D). Curling of the posterior plastron also occurred experimentally in red-eared sliders fed a protein-deficient diet (10% crude protein).[23] Protein deficiency may accompany Ca deficiency in chelonians and contribute to shell softening or curling.

Crocodilians with NSHP may move freely in water but are weak, sluggish, or ataxic on land and eventually are unable to come out of the water.[24] The upper jaw softens so much it can be bent upward. Long bones soften and deform, and posterior paralysis, kyphosis, scoliosis, lordosis, or rhoecosis may be present. The teeth may be translucent or diaphanous (glassy teeth), deviate horizontally, or fall out.[24] Disturbance may result in tremors or seizures; seizures in water may lead to drowning.[24]

Clinical signs in amphibians include abnormal posture (lack of truncal lifting, dorsal curling of the toes) and locomotion, anasarca/dropsy/subcutaneous edema, vertebral deformity, mandibular deformity, pathological fractures of long bones, and absence of radio-opaque calcium carbonate in the endolymphatic sacs.[25] Early signs may be limited to fractured bones, tetany, or subcutaneous (lymph sac) fluid accumulation; advanced cases have decreased bone demineralization and skeletal deformities.

Clinical signs and nutritional histories are typically informative in reaching a presumptive diagnosis of NSHP. Radiographs are useful to confirm suspicion of NSHP and whole body assessment of fractures. Only severe reductions in bone density are radiographically obvious, because 40% to 50% of bone mineralization must generally be depleted before it is visible radiographically.[26] In lizards with NSHP there is a general decrease in bone opacity and cortical thinning of long bones and flat bones, especially appreciated with poor contrast of pelvic bones.[20] Decreased opacity in thin bones, such as the caudal vertebral transverse processes and dorsal spinous processes, can result in poor contrast from the associated soft tissue. There may be bowing of long bones, absent metaphyseal trabecular markings or more radiolucent metaphyses, and extensive soft tissue swelling involving the limbs (fibrous osteodystrophy).[20] Transverse folding fractures of long bones and compression fractures of vertebrae may be present. In chelonians decreased opacity is difficult to appreciate in the shell and limb bones but may be present in the pectoral and pelvic girdles, which typically are in good contrast to the overlying shell.

Usually, total Ca is within normal limits until skeletal reserves have been depleted, whereas ionized Ca levels are maintained until terminal. One study found total serum Ca levels of veiled chameleons with NSHP to be 2.0 to 2.2 mmol/L (8.0–8.8 mg/dL), slightly below the reference range of 2.3 to 3.5 mmol/L (9.2–14.00 mg/dL).[10] Elevated nitrogenous byproducts (ammonia, urea, or uric acid) may indicate renal secondary hyperthyroidism or dehydration. Calcium-deficient females may have elevated Ca levels because of egg production. Conversely, a gravid oviparous female with normal Ca levels may be calcium deficient. With obvious clinical signs, further diagnostics, apart from radiography, are seldom required. The definitive diagnosis of hyperparathyroidism requires demonstration of elevated PTH, but commercially available mammalian assays do not appear to be accurate for reptiles and cannot be recommended. Plasma calcidiol values can be more easily measured to assess the potential deficiency of UVB or dietary D_3 deficiency.

The best ways to measure bone density are via quantitative computed tomography[27] or dual-energy X-ray absorptiometry (DEXA).[20] The latter has been described experimentally in green iguanas,[20] leopard tortoises (*Stigmochelys pardalis*),[28] and Hermann's tortoises.[27] Regression equations of bone density as a function of body weight are available for normal iguanas and iguanas with NSHP, with the skull, lumbar spine, and femurs being most useful.[20] In Hermann's tortoises, decreased bone mineral density of the shell was apparent with DEXA but not in the axial and appendicular skeleton,[27] which may explain why spinal and appendicular fractures or fibrous osteodystrophy are not seen in chelonians.

Preferred Treatment(s)

Patients with NSHP should be strictly cage rested and handled carefully to prevent fractures or spinal trauma. All patients should have exposure to unfiltered sunlight (preferred, but be wary of overheating) or artificial UVB light (290–300 nm). Treatment includes calcium (Ca) supplementation, nutritional support, improved husbandry, analgesia, and calcitonin (although cost and availability may be an issue with the latter). Oral Ca supplementation is easiest via Ca-rich syrups, either Ca glubionate (1.8 gm/5 mL) or Ca gluconate (23% w/v); both are dosed at 1 mL/kg PO BID. Calcium doses are given in mL/kg, rather than mg/kg, because different Ca products vary in the amount of elemental Ca available and how Ca is measured (Ca salts vs elemental Ca, mg vs mEq, or mmol), which can lead to confusion, potential sources of medication errors, and delayed treatment. As mentioned, Ca gluconate is labeled as 23% w/v, which is 24 mg/mL elemental Ca, and Ca glubionate as 1.8 gm/5 ml, which is 21 mg/mL elemental Ca; neither is labeled as mg/mL (see Tables 27.10 and 27.11 in Chapter 27). Calcium supplementation is typically continued for 1 to 3 months or until the patient is consistently eating calcium-enriched foods, moving normally, and, if growing or in poor body condition, gaining weight. Powdered calcium supplements on foods are not recommended as a sole treatment unless the patient has minimal clinical signs and continues to eat voluntarily; however, if a viable option, it does reduce the risks associated with handling to medicate the patient. Calcium sprays available through pet stores have so little Ca present (1700 ppm Ca or 0.17% Ca) that they are of poor therapeutic value. Ideally, patients with hypocalcemic tetany should be treated by slow intravenous (or intraosseous) infusion (100 mg/kg 10% Ca gluconate), but this is often impractical. If IV or IO therapy is not possible, then intramuscular or intracoelomic administration at

FIG 84.11 Nutritional secondary hyperparathyroidism in chelonians affects the shell and often spares the axial and appendicular skeleton. As a result, the turtle's body outgrows its shell, and chronic prolapse of the cloaca, phallus, or clitoris may result (A). Note the upturned marginal scutes (B), increased space between carapace and plastron bridge (C), and the anterior rhamphotheca, which may curve more like a parrot's beak. (Courtesy of Thomas H. Boyer.)

100 mg/kg 10% Ca gluconate q 6 hours can be continued until tetany ceases and the patient can be given oral Ca.

Nutritional support is critical, allowing the patient to gain weight and begin to grow as a normal process. Although pathological fractures will usually heal, angular deformities typically persist. Weight loss in an already cachexic patient continues a downward spiral. Nutritional support is critical for successful treatment, and the use of nutritional enterals via stomach tube (or gentle hand feeding in some cases) once daily for most reptiles and up to twice daily for small lizards until the patient is eating unaided and maintaining or gaining body weight is important. These foods may contain vitamin D_3, so a vitamin D injection is not required.

Analgesics are recommended. Salmon calcitonin (SCT) injections have been recommended at 50 IU/kg IM; repeated in 1 week if normocalcemic, or 1 week after starting calcium supplementation.[19,29,30] Calcitonin is thought to act by stimulating negative feedback on the parathyroid gland, reducing parathyroid hormone, decreasing osteoclastic activity, stimulating osteoblasts, and decreasing blood Ca concentration, and may have an analgesic effect on skeletal pain.[31,32] However, there is little research to evaluate efficacy of SCT in reptiles. One study in aquatic turtles (*Pseudemys scripta*, *Graptemys kohni*, *Chelydra serpentina*) found that 4 micrograms/kg SCT 3x/wk for 11 to 19 weeks enhanced bone growth in turtles under Ca-deficient conditions by inhibiting osteolysis.[33] In green iguanas, a single dose of SCT (20 milliunits intracoelomically) stimulated a significant decrease in total plasma Ca levels from 20 to 120 minutes; blood Ca levels were back to normal at 240 minutes.[34] In another study with green iguanas, a single dose of SCT (50 IU/kg) had no effect on total Ca concentration long term; however, ionized Ca was not measured (which SCT affects) (Wagner and Bodri, unpublished manuscript, 1996). Do not give calcitonin if the patient is hypocalcemic or Ca status is unknown. Research evidence would suggest salmon calcitonin should be given more frequently.

Fractures can be treated with external coaptation (see Chapter 108). Lizards with dramatic spinal cord deformities can maintain an acceptable quality of life as long as paralysis, or urinary or fecal retention does not occur. Treatment generally takes months, so a long-term commitment by the owner is required. Reevaluations should be considered at 1, 2, 4, and 8 weeks, until weight is improving and it is clear the patient is recovering. Progress evaluations are important to discuss husbandry and ensure that clients are adopting permanent improvements to prevent recurrence. Radiography can help track response to therapy, especially with fractures, but are insensitive to subtle changes in bone radiopacity.

Prognosis and Prevention

Prognosis is dependent on severity of clinical, radiographic, and clinicopathologic changes. Multiple deficiencies, such as calcium and vitamin A deficiency, common with chameleons, are difficult to recover from. Lizards and crocodilians often respond better than chelonians. Early diagnosis and aggressive treatment is essential; chronic NSHP has a worse prognosis. Owners must be committed to several months of daily treatment. If no decreased radiopacity of bone is visible, the prognosis is good. Decreasing radiopacity of bone and hypocalcemia worsen prognosis. Paralysis, urinary retention, and obstipation are poor prognostic indicators. For small chelonians with soft shells, if they are not eating at presentation or soon after, the prognosis is typically poor. Even with intensive care, they typically die. NSHP can be prevented by good nutrition with adequate Ca and UV supplementation (for more information, see Chapter 27).

HYPOVITAMINOSIS A

Clinical Significance and Known Etiological Cause(s)

Vitamin A was the first fat-soluble vitamin to be discovered and is an essential nutrient required for normal vision, embryonic development,

reproduction, immune function, bone metabolism, hematopoiesis, and epithelial tissues in all vertebrates.[35] In humans, vitamin A deficiency (VAD) causes nyctalopia (night blindness initially), xerophthalmia, keratomalacia, and eventually complete blindness.

There are several forms of vitamin A. Retinol is the alcohol form; replacement of the alcohol with aldehyde gives retinal, and replacement by an acid group produces retinoic acid.[36] Retinal combines with the protein, opsin, to form rhodopsin, the light-absorbing molecule of the retina, vital for vision. The retinoic acid form is an important hormone-like growth factor for normal epithelial cell differentiation. In humans, retinoic acid switches on genes that differentiate keratinocytes (immature skin cells) into mature epidermal cells.[37] Without retinoic acid, hyperkeratosis (an abnormal thickening of the outermost layer of the epidermis, the stratum corneum, associated with excess keratin) and squamous metaplasia (transformation of cuboidal, columnar, or ciliated glandular, or mucosal, epithelium into keratinizing stratified squamous epithelium) affect new epithelia, especially in the respiratory, ocular, endocrine, gastrointestinal, and genitourinary systems.[38]

Carotenoids (carotenes and xanthophylls) are fat-soluble pigments found in plants, many of which have provitamin A activity, especially the β-carotenes. Herbivores and omnivores, such as tortoises, iguanas, and bearded dragons, are apparently good at converting carotenoids to retinol because they do not suffer from hypovitaminosis A; plants are excellent sources of carotenoids. Enterohepatic circulation is an important means of vitamin A conservation before fecal excretion. Secondary hypovitaminosis A is rare but possible, with chronic malabsorption of lipids (such as with pancreatitis) or impaired bile production and release. In foods of animal origin, the major form of vitamin A is primarily retinyl palmitate, which is converted to retinol in the small intestine. Retinol is transported mainly with lymph chylomicrons to the liver, where it is converted back to retinyl palmitate for storage. In most species, more than 80% to 90% of the vitamin A in the body is stored in the liver.[35]

Clinical Presentation

In general, insectivorous and carnivorous reptiles and amphibians cannot convert carotenoids to vitamin A and rely on animal sources of vitamin A. Fish and mammalian liver are rich sources of retinyl palmitate, thus snakes, carnivorous reptiles, and amphibians that consume whole vertebrate prey regularly do not get VAD. Unfortunately, insects are deficient in vitamin A unless gut-loaded or dusted with multivitamins containing vitamin A and not β-carotene. VAD is well recognized in emydid turtles (aquatic turtles and box turtles) and is also seen in insectivorous lizards such as chameleons, leopard geckos, fat-tailed geckos (*Hemitheconyx caudicinctus*), and *Anolis* lizards not supplemented with preformed vitamin A.

Amphibians, being insectivores, are also prone to VAD. It is thought that amphibians do not synthesize vitamin A from β-carotene, but scientific evidence to support this is sparse.[25,38–40] Cane toads (*Bufo marinus*) and Cuban tree frogs (*Osteopilus septentrionalis*) were not able to convert β-carotene to retinol in liver and small intestines samples, suggesting a lack of β-carotene 15,15'-dioxygenase activity (Comb-Renjifo et al, unpublished data, 2011). However, tadpoles of the Asian common toad (*Duttaphrynus melanostictus*) and Indian bullfrog (*Haplobactrachus tigerinus*) were capable of converting β-carotene and lutein (another carotenoid) to retinol and dehydroretinol, respectively.[41] Mixed carotenoid (β-carotene, lutenin, canthaxantin, and xanthophylls) dietary supplementation for 9 weeks did significantly raise plasma retinol levels in tomato frogs (*Dyscophus guineti*), however, β-carotene alone did not.[39] Chiricahuan leopard frogs (*Rana chiricahuaensis*) developed conjunctivitis in the lower eyelid that was responsive to vitamin A supplementation because of a diet that lacked vitamin A (the multivitamin supplement contained β-carotene but not vitamin A).[42,43] Carotenoids are not without benefit; they have been shown to improve development, fecundity, and reddish coloration in amphibians.[39,44–46]

In amphibians, VAD causes short tongue syndrome (STS).[43] STS results from replacement of the normal mucus-producing epithelium of the tongue tip with a keratinizing stratified squamous epithelium (squamous metaplasia), which makes their tongues less sticky. Anurans with STS repeatedly strike prey items with their tongue but are unable to prehend food, giving the appearance of a shortened tongue.[42,43,47] STS has been recognized in Bufonidae (toads), Dendrobatidae (poison dart frogs), Hylidae (tree frogs), Ranidae (true frogs), and Rhacophoridae (foam nesting frogs).[38] Amphibian lingual squamous metaplasia develops rostrally, then progresses caudally, therefore the entire amphibian tongue, bisected longitudinally, should be submitted for histopathology. Transverse sectioning could overlook early cases.[38,42,43] In addition to lingual and oronasal mucosal squamous hyperplasia, VAD also variably affects epithelium of the skin, conjunctiva, gastrointestinal, urinary, and reproductive tracts, contributing to poor reproductive success, reduced survival of tadpoles, and immune dysfunction.[38,47] For instance, lingual squamous metaplasia was not present in lemur leaf frogs (*Hyomantis lemur*) that had extensive squamous metaplasia in the cloaca and urinary bladder.[38] Periocular and conjunctival swelling, responsive to vitamin A supplementation, has been observed in ranid and dendrobatid frogs, as well as a tiger salamander (*Ambystoma tigrinum*).[38,43]

Many reptile multivitamins contain β-carotene instead of preformed vitamin A, a lasting influence of several inaccurate hobbyist articles (Chameleon Information Network Newsletter 1993, #9, pp 18-25, and #10, pp 15-18 that concluded consumption of small amounts of preformed vitamin A caused edema in the neck and throat areas of chameleons, bone decalcification, and birth defects. Currently about a third of the reptile and amphibian multivitamins on the market lack vitamin A or retinol esters (retinyl acetate or retinyl palmitate) and instead carry only β-carotene in the misguided notion that vitamin A is unnecessary, or dangerous. Several years after these hobbyist articles, researchers objectively demonstrated hypovitaminosis A induced gular edema in 15/16 panther chameleons given low dietary levels of vitamin A.[48] Although it is true that a high intake of carotenoids does not produce vitamin A toxicity,[35] many insectivores and carnivores cannot convert β-carotenes to vitamin A and thus require dietary vitamin A. Excess vitamin A has been shown to be toxic in most species studied, typically from chronic intakes of 100 to 1000 times the nutritional requirements, but also has been observed with intakes as low as 10 times the specific dietary requirement.[35] Presumed upper safe levels are 4 to 10 times the nutritional requirements but remain unknown for reptiles and amphibians. However, estimates for other species are useful, with estimated dietary levels of 8000 IU/kg feed or 56 IU/kg body weight daily for green iguanas (*Iguana iguana*).[6] Estimated dietary levels for cricket gut-loading diets were 5000 to 8000 micrograms retinol equivalents/kg as fed (8% moisture).[49]

In reptiles, hypovitaminosis A causes a series of changes, most noticeably to the eyes. The normal lacrimal and mucus-secreting cuboidal to columnar epithelium of the eye is replaced by a flattened keratinized epithelium (squamous metaplasia), which continually desquamate followed by the buildup of keratin debris (hyperkeratosis), which blocks lacrimal, salivary, and mucous glands. Plump amphophilic mucus-secreting cells are replaced by flattened, scalelike, keratinized squamous epithelium. Gland lumina dilate and fill with keratinaceous and cellular debris.[50] In *Anolis*, VAD caused decreased numbers of conjunctival goblet cells.[50] Decreased lacrimal production induces xerophthalmia (dry eye). In emydid turtles and leopard geckos, the lacrimal glands block and slowly swell, expanding under the palpebra, gradually swelling the palpebral fissure shut (Figs. 84.12 and 84.13). In chameleons, early signs are

decreased tear production with blepharospasm, thick ocular mucus, and thickened palpebral margins (Fig. 84.14A–C). Chameleons frequently have a history of worsening eye disease unresponsive to antibiotic therapy and eventually keep their eyes shut unless disturbed. Owners report poor aim and prehension, perhaps from squamous metaplasia of mucous glands in the tongue tip and/or retinal damage. With chronicity, multifocal minute distended glands swell and irregularly thicken the lips (see Fig. 84.14C) and sometimes the jaw commissures, and tail tip necrosis may develop.[48] Leopard geckos can have periocular glands distended with solid cellular debris and diffuse massive cellulitis (Fig. 84.15A and B). Decreased tear production causes keratitis, corneal erosion and ulceration, keratomalacia, and eventually permanent corneal scarring and perhaps blindness (Fig. 84.16). With chronic VAD, the eyelids swell shut and, in leopards geckos and emydid turtles, white to yellow, semisolid to solid, keratinaceous, inflammatory cellular debris and bacteria accumulate under the palpebrae (Fig. 84.17A–C). VAD in insectivorous lizards also results in decreased appetite, difficulty catching prey, retained and recurrent hemipenal plugs, dysecdysis, dull coloration (particularly in chameleons), and stomatitis (leopard geckos). Emydid turtles may have concurrent tympanic ear abscesses, pneumonia, or dystocia. Hatchling aquatic turtles typically have enough vitamin A yolk reserves for 6 months.[51]

Farm-raised freshwater and saltwater crocodiles (*Crocodylus johnsoni* and *C. porosus*) fed a vitamin A–deficient diet (125 IU vitamin A/kg dietary dry matter) had multifocal brown dorsal lingual nodules, up to 5 mm in diameter, as well as renal and visceral gout. Gout was thought to be induced by renal tubular squamous metaplasia and hyperkeratosis, classic symptoms of hypovitaminosis A.[52]

Vitamin A is also involved in osteoclast and osteoblast activity in epithelial cartilage. In mammals, joint involvement is associated with VAD. Constriction of nerve foramina during embryonic and early growth may result in blindness, deafness, and cerebellar herniation; other congenital malformations have also been seen in soft tissues.

Diagnostic Confirmation

Most cases in clinical practice are treated based on dietary history, clinical signs, biopsy histopathology, and response to therapy. Determining normal levels of Vitamin A is fraught with error based on what is measured (i.e., total Vitamin A [retinol + retinyl ester] vs. vitamin A [retinol]) and the method of measurement (high-performance liquid chromatography is currently the standard; techniques before the early 1980s were prone to experimental error and should be interpreted with caution), and assay differences among laboratories may give disparate values for similar levels.[53] Vitamin A also degrades with light exposure, high temperatures, and patient autolysis.[43] A study in amphibians found that determining a normal level of vitamin A is also problematic, as asymptomatic captive amphibians often have lower values than wild amphibians.[53] Patient size may prevent collection of sufficient blood for vitamin A analysis. With VAD, blood concentrations of vitamin A drop below 20 µg/100 mL but only after depletion of hepatic reserves.[35] Thus plasma vitamin A concentrations do not provide a linear indication of liver/whole body vitamin A status or intake.[35,54] As most vitamin A

is stored in liver (≈80%–90%), liver levels are the best indication of whole body vitamin A status. Therefore liver biopsy, or postmortem liver analysis, are effective methods for diagnosis. Captive Wyoming toads (*Anaxyrus baxteri*) with STS had mean liver retinol levels of 1.5 µg/g, compared with free-ranging Wyoming toads without STS, which had mean liver retinol levels of 104.6 µg/g.[38,43] vitamin A levels <5–10 µg are suspicious for hypovitaminosis A.[43] However, captive-born marine toads (*Bufo marinus*) without STS had significantly lower mean liver retinol levels of 0.58 µg/gram compared with wild-caught marine toads without STS of 61.89 µg/gram, so species variability likely exists with regard to critical levels and propensity to develop clinical signs.[54]

Preferred Treatment

Response to treatment is slow because mature epithelium cannot be repaired and must be replaced by differentiation of resident stem cells.[38] In effect, epithelium must be turned over to be repaired in an animal that has been chronically nutritionally compromised.

Vitamin A Therapy in Reptiles. One author (TB) has been using 0.01 mL of fat-soluble vitamin A and D SC (500,000 IU vitamin A palmitate/mL, 100,000 IU vitamin D/mL), repeated in 2 weeks, then discontinued (two doses total), for reversal of hypovitaminosis A in reptiles for several decades without visible signs of toxicity. Patients take 2 to 4 weeks to recover (Fig. 84.18A and B). This dose arose from the desire to give the smallest effective dose that can be measured and given with a 0.3 mL U-100 insulin syringe. For a 1 kg reptile this provides 5000 IU vitamin A/kg, but for a 50 gram reptile, this provides 100,000 vitamin A IU/kg, which is still at the lower end of dosages (100,000 or 400,000 IU vitamin A/kg) that did not elicit any clinical or histopathologic signs of hypervitaminosis A at 10 and 14 days with parenteral fat-soluble vitamin A in Hermann's tortoises (see Hypervitaminosis A section).[55]

Alternatively, a parenteral fat-soluble vitamin A and D solution (100,000 IU vitamin A palmitate/mL, 10,000 IU vitamin D_3/mL, and

20 IU vitamin E/mL) has been shown to work clinically in lizards and box turtles given orally at a dosing rate of 2000 IU/30 gm body weight once and repeated in 7 days. Clinically, the parenteral drug appears to be absorbed by the oral route and may be less toxic when given in this manner.[56]

Cellular debris under the eyelids can be carefully removed with a blunt probe or hemostats and digital pressure (see Fig. 84.17A–C).[57] The eyes should be flushed regularly with saline or ophthalmic rinses and kept moist with ophthalmic antibiotic ointment or drops, without steroids, as ulcerative keratitis is common. Patients do not resume feeding until their eyes are open, so fluid therapy followed by nutritional support should be provided.

Vitamin A Therapy in Amphibians. For amphibians topical or oral vitamin A can be given, or fresh mouse, rat, or fish liver can be fed whole or pureed. Many larger amphibians will eat whole pinkies. Prey insects should be fed a good-quality, gut-loading diet, with preformed vitamin A, before being fed to insectivores.

Parenteral treatment of amphibians is different compared with reptiles, most likely because smaller body size necessitates use of a less concentrated vitamin A formulation (such as 1:10 diluted Aquasol A) to improve dosing accuracy. Topical treatment with water soluble vitamin A (Aquasol A, Mayne Pharms, Paramus, NJ) at 50 international units every other day raised whole body levels of vitamin A in foam-nest tree frogs better than dusting insects with vitamin A.[58]

Prognosis and Prevention

Patients recover in several weeks, unless secondary disease is present, and resume feeding. Death is not uncommon. Severe corneal scarring and blindness worsens the prognosis. Insectivores and carnivores require preformed vitamin A in their diet. The liver in whole vertebrates is adequate to prevent VAD in carnivores. Insectivores must be fed a variety of insects that have been dusted with multivitamins that contain preformed vitamin A and mixed carotenoids (not just β-carotene), and/or insects fed a good-quality, gut-loading diet with vitamin A and mixed carotenoids. Additionally some insectivores can be fed pinkies. Most herbivores and omnivores seem resistant to VAD, perhaps because they can convert carotenoids into vitamin A.

HYPERVITAMINOSIS A

Clinical Significance and Known Etiological Cause(s)

Vitamin A injections continue to be given to tortoises in the mistaken notion that it may help with upper respiratory tract disease or improve appetite. Tortoises, being herbivores, are good at converting carotenoids to vitamin A and rarely, if ever, develop primary VAD. Emydid turtles, such as box turtles and red-eared sliders, being more carnivorous to omnivorous, are prone to VAD, either because they may be less capable of carotenoid conversion to vitamin A or from dietary deficiency. Chelonian differences are important, and veterinarians should be aware

that giving vitamin A injections to tortoises is unnecessary and can cause iatrogenic toxicity.[51]

Clinical Presentation and Diagnostic Confirmation

Experimentally, hypervitaminosis A has been produced in Hermann's tortoises at doses of 100,000 to 400,000 IU/kg IM water-soluble vitamin A palmitate, but not with fat-soluble vitamin A palmitate at identical doses.[55] Blisters, or bullae, started forming around the neck and extremities, usually by 14 days, as the outer epithelium sloughed in large pieces.[51,55] Light and electron microscopy detected the stratum corneum separating from the stratum germinativum, subcorneal acantholysis (loss of intercellular connections, such as desmosomes, resulting in loss of cohesion between keratinocytes), intercellular edema, parakeratosis (retention of nuclei in the stratum corneum), and well-differentiated acanthosis (thickening of the skin).[55] Essentially, hypervitaminosis A causes chelonians to slough their outer epidermis (Fig. 84.19A and B).

Water-soluble vitamin A is resorbed more quickly than fat-soluble vitamin A from injection sites and accumulates faster in the liver, which may lead to greater potential for toxicity; until more is known, it may be prudent to avoid water-soluble vitamin A in reptiles.[55,57] With highly concentrated vitamin A products, empirical dosages, and unknown requirements, iatrogenic hypervitaminosis A is possible. Vitamin A injections will not boost immune status in reptiles, improve appetite, or treat upper respiratory tract disease, unless signs of hypovitaminosis A are present.[51] High intake of carotenoids from vegetables and fruits does not cause hypervitaminosis A, as conversion from carotenoids to the active form of vitamin A is regulated by the body.[35] The safest approach is to treat a nutritional disease with improved nutrition and oral supplementation. Injectable therapy should only be given to reptiles with clinical signs and dietary histories that support treatment.[51]

In amphibians, hypervitaminosis A is rare, but has been noted in African clawed frogs (*Xenopus* spp.) that were fed vitamin A–rich mammalian livers or whole immature rodents. In these circumstances, hypervitaminosis A may play a role in the development of metabolic bone disease and may cause anemia, liver damage, and chronic weight loss.[59]

Preferred Treatment

Treatment is similar to that of partial-thickness burns. The epidermal barrier is compromised, causing extracellular fluid loss and bacterial invasion. Hypovolemia and infection are primary concerns. Fluid support, nutritional therapy, and analgesics are indicated until the patient resumes drinking and eating. The patient, and areas where skin has sloughed, should be gently and thoroughly cleaned and flushed, initially with dilute chlorhexidine in sterile saline (1:30) and then 0.9% saline. Adherent necrotic skin should be debrided. Sloughed areas may or may not be treated with topical salves, such as aloe vera, 1% silver sulfadiazine cream, or antibiotic ointment. A number of dressings are thought to have some benefits over alternatives for the management of superficial and partial-thickness burns. There is some research evidence in humans to suggest that superficial and partial-thickness burns heal more quickly with silicon-coated nylon, silver containing dressings, and biosynthetic dressings (such as hydrogel) than with silver sulfadiazine cream.[60] Burns treated with hydrogel dressings healed more quickly than those treated with usual care.[60] The same recommendations apply to hypervitaminosis A patients; however, tortoises are difficult to bandage. Wounds should be flushed with sterile saline, and all residual topicals removed and redressed daily. Treatment should continue until skin has healed, which may take weeks to months.

Vitamin E appears to be an effective treatment for hypervitaminosis A, and in chicks and rabbits may prevent side effects of high doses of vitamin A.[61,62] Taurine significantly reduced vitamin A toxicity in rats, perhaps because retinoids can be conjugated by taurine, then excreted in the bile; conjugated retinol has little biological activity.[63–65] These supplements may be beneficial for treatment of hypervitaminosis A in reptiles as well.

Prognosis and Prevention

Avoid the use of injectable vitamin A in tortoises and other herbivorous species. The prognosis is dependent on the extent of clinical care, dosage, and type of vitamin A supplement used. Widespread epidermal sloughing carries a guarded prognosis. For amphibians, reduce feeding whole rodents and discontinue feeding whole liver.

OBESITY

Clinical Significance and Known Etiological Cause(s)

Obesity in captive reptiles is a common problem. As with humans, and many companion animals, it is usually the result of excessive caloric intake over expenditures. Captive animals forage less, are usually overfed, and are rarely exposed to reproductive demands, estivation, or hibernation. Limited cage space discourages activity and exercise. Some producers push-feed reptiles for rapid growth and early breeding. Excess caloric

intake also influences folliculogenesis, which is a substantial nutritional demand; however, many captive females are then not bred, leading to resorption of follicles, which may result in adding to fat reserves.[66]

Clinical Presentation and Diagnostic Confirmation

Obesity is especially common in monitors, bearded dragons, red-eared sliders, and larger boid snakes. Body condition scoring and graphing has been described for leopard geckos and chelonians.[67–73] As with all creatures, obesity is not a healthy state and often decreases longevity. Obesity is thought to predispose to hepatic lipidosis, yolk coelomitis, and dystocia. In obese monitors and other lizards, the coelomic fat pads can enlarge to such an extent that they constrict and compromise coelomic organs. For bearded dragons, fruits and berries rich in sugars are avidly, and eventually preferentially, consumed, as are high-fat mealworms, superworms, and waxworms (with a mean fat content of 31%–51% DM compared with 10%–23% DM for juvenile to adult crickets).[74] The consumption of these rich foods gradually results in a loss of interest in mobile insects and greens, less activity, and only consuming foods placed directly in front of them or hand-fed. For carnivores, domestic mice and rats produced for the market may well have larger fat stores than wild mice and rats. Similarly, older, larger, ex-breeder rats and mice have relatively greater fat stores than juvenile wild animals. Young, leaner rodents with lower fat levels (17% crude fat DM) are a better food source for obese reptiles than older animals (24% crude fat DM); however, pinkies may have a lower Ca content, which may not be ideal for rapidly growing animals.[75]

Preferred Treatment

Weight loss treatment consists of decreased caloric intake and increased caloric expenditure. Owners are skeptical that their pet is obese, so accurate monthly to quarterly weights and encouragement will help keep the owner on track. Gradual weight loss is the goal. It is difficult to increase exercise in reptiles, but providing a larger cage, more climbing surfaces, localized hotspots, and live insects, or insects hidden throughout the exhibit will help. Supervised time out of the cage helps, and large tractable monitors can be walked on a leash attached to a body harness, indoors, in an enclosed yard (be wary of predators), or be trained to chase retrieved objects. Treatment for bearded dragons consists of eliminating all fruits in the diet, restricting diet to gut-loaded crickets and Dubia cockroaches (avoid insect larvae that are high in fat), dark leafy greens, and flowers. Encourage activity and foraging behaviors by discouraging hand feeding. Feeding should be reduced to every other day and then twice weekly. If healthy, when winter approaches, dragons and red-eared sliders should be hibernated/brumated to consume excess lipid reserves. For adult sliders, feed less and offer more greens. For monitors, reduce rodents and meat (even low-fat turkey) and provide at least 50% mobile insects.[76] For further details, see Chapter 67.

Prognosis and Prevention

If the patient is still eating well, the prognosis is good and more dependent on owner compliance. If the patient is not eating, the prognosis is more guarded, and hepatic lipidosis is a frequent sequela. Reptiles that normally hibernate should be hibernated if healthy. Most reptiles are overfed in captivity, feeding less, less frequently; periodic fasting and increased exercise can help avoid obesity.

HEPATIC LIPIDOSIS

Clinical Significance and Known Etiological Cause(s)

Hepatic lipidosis is a pathological accumulation of lipid within hepatocytes. Storage of fat in reptiles is primarily divided between the fat bodies in the coelom and the liver. Squamates do not store subcutaneous fat. Chelonia tend to use hepatic storage, although the prefemoral fossa is also used. Fat stores are used for vitellogenesis and as an energy source during hibernation, aestivation, or fasting. In hepatic lipidosis, the normal storage and use of lipids becomes disrupted; the metabolic changes are not well understood. Inciting factors include diets high in fat and carbohydrates, obesity, chronic hyporexia, lack of exercise, hibernation, or reproductive activity (see Chapter 67 for more information).[77] Certain vitamin or amino acid deficiencies may impact liver function. Reptiles that are chronically stressed (leading to higher corticosteroid production) may be more likely to become obese and develop hepatic lipidosis.

Starvation is a common cause of hepatic lipidosis in mammals. In cats, guinea pigs, and rabbits, even short periods of anorexia may cause hepatic lipidosis. This may be true for certain species of captive reptiles as well. Shortage of dietary glucose causes hormonal changes and sympathetic activity, resulting in decreased insulin release. This promotes increased peripheral lipolysis and release of free fatty acids into the circulation. The free fatty acids are taken up by the liver and metabolized into triglycerides. Because protein shortage causes a parallel decrease in lipoprotein synthesis, triglycerides are not efficiently converted to very-low-density lipoproteins (VLDL), thus triglycerides accumulate in the liver. Deficiencies of active amino acids such as methionine, arginine, and carnitine, which all play important roles in lipid metabolism, can result in the development of hepatic lipidosis. Insufficient or poor-quality dietary protein, exposure to hepatotoxins, anoxia, impaired carbohydrate, or volatile fatty acid metabolism can all lead to hepatic lipidosis (see Chapter 67 for more details).

Clinical Presentation and Diagnostic Confirmation

In general, early signs include developing lassitude; females may develop preovulatory stasis, as repeated lipogenesis and resorption occur. Liver function becomes deranged. Sudden-onset lethargy and anorexia are seen. Pathologically there is excessive accumulation of lipid within hepatocytes. The problem is determining when this is excessive because hepatic fat storage is normal and varies by gender and season. Pathologists inexperienced with reptiles may erroneously identify the normal increase in prehibernation or prereproductive hepatic fat as lipidosis. In hepatic lipidosis some degree of inflammatory reaction may be seen.

Dietary history of affected bearded dragons usually includes large amounts of fruit and non-gut-loaded insects, especially insect larvae. Dietary history for tortoises includes heavy reliance on grocery store fruits and vegetables (which are high in carbohydrates and protein) and insufficient hay. Clinical signs, other than anorexia and high body condition scores, are vague. Tortoises typically have a gradual reduction in appetite and activity; the tortoise may have a more selective appetite, eating only fruits. Posthibernation anorexia often involves hepatic lipidosis. Weakness, often present, manifests as dragging the plastron while walking. In advanced cases the patient may be flaccid, edematous (Fig. 84.20A and B), lethargic, weak (head and legs easily extended), anemic, hypoalbuminemic, or hypocalcemic, and rarely may have neurological symptoms from hepatic encephalopathy (altered mentation, stupor, incoordination). Hypoalbuminemia (<1 g/dL, 10 g/L), hypercholesterolemia, and hypertriglyceridemia are common. If the patient is dehydrated, packed cell volume (PCV) may be elevated. Leopard geckos may have a ventral, grossly visible, white liver surrounding the dark green gall bladder (Fig. 84.21A and B). In lizards, radiography and ultrasonography may reveal liver enlargement or hyperechogenicity; the liver can be readily compared with coelomic fat bodies. From clinical experience, the lateral liver silhouette of lizards should be less than half the dorsoventral coelomic space. Reptiles rarely vomit with hepatic lipidosis unless there is gastrointestinal obstruction or other causes. Elevated bile pigments (green urine or urates) and diarrhea are variably present. Anemia is not uncommon. Liver enzymes are often normal,

FIG 84.20 (A and B) Desert tortoise (*Gopherus agassizii*) with edema, lethargy, weakness (head and legs easily pulled out from shell, not lifting shell while ambulating), anemia, hypoalbuminemia, and hypocalcemia, all suggestive of hepatic lipidosis. (Courtesy of Thomas H. Boyer.)

as there is no breakdown of liver cells, whereas triglycerides and cholesterol may be elevated (but must be differentiated from vitellogenesis and prehibernation). One study found statistically higher levels of triglycerides in red-footed tortoises (*Chelonoidis carbonaria*), with endoscopic and histopathologically confirmed hepatic lipidosis, but no differences in AST, ALT, or GGT.[78] There are few studies on the diagnostic use of bile acids in reptiles; one study did not detect 24- and 48-hr postprandial increases in normal red-eared sliders,[77] another study detected significant increases in preprandial fasting bile acids at 3 and 7 hours postprandial in normal green iguanas.[79] The 3α-hydroxy-bile acid levels should be less than 60 µmol/L; unfortunately lipemia can interfere with analysis. Most reptiles (excluding some snakes) do not convert biliverdin to bilirubin. A definitive diagnosis can be obtained by liver biopsy and histopathology. Fatty livers are pale white, tan, or yellow (see Fig. 84.21); friable with swollen rounded edges; ooze greasy yellow brown fluid on cut surfaces; and float in formalin. Affected reptiles represent higher anesthetic risks, and drugs that rely on hepatic metabolism should be avoided.

Preferred Treatment

Treatment consists of long-term nutritional support via stomach tube for lizards or via esophagostomy tube for chelonians until the patient is eating well on its own, which may take weeks to months. Multiple small feedings are better than less frequent larger feedings. Several commercially available products have worked well, including Emeraid Omnivore or Herbivore (LaFeber Co., Cornell, IL), Critical Care and Critical Care Fine Grind (Oxbow Animal Health, Murdock, NE), and Critical Care Formula (Vetark Professional, Winchester, UK). Carnivore diets tend to be too high in fat. Other supplements, such as L-carnitine, methionine, taurine, S-adenosylmethionine, lactulose, and milk thistle extract, can also be used if not present in aforementioned foods (see Chapter 127 and 128 for dosages); however, no prospective clinical trials have been conducted to evaluate efficacy of any of these drugs in reptiles. The goal of dietary therapy is to maintain body weight until the patient starts eating on its own.

Prognosis and Prevention

The prognosis for patients that are still eating is guarded and guarded to poor for anorexic patients, depending on the extent of pathology. Prevention involves better nutrition. For tortoises this means less greens, vegetables, or fruits and more hays, grasses, and commercial tortoise diets. For bearded dragons, less fruit and more variety of gut-loaded insects, and the latter is also recommended for leopard geckos. Increasing opportunities for caloric expenditures (e.g., exercise, hibernation, reproduction) can also be beneficial. See Chapter 67 for additional information.

PYRAMIDAL SHELL GROWTH (PSG)

Clinical Significance and Known Etiological Cause(s)

PSG is a growth deformity of many tortoise species, resulting in pyramidal scute growth of the carapace (Fig. 84.22A and B). Many etiologies have been suggested, including improper humidity, various nutritional and mineral imbalances (particularly Ca and protein), endoparasites, overeating, lack of sunlight, increased growth rate, improper environmental temperature, lack of mechanical abrasion on the shell, and lack of exercise.[22] One of the few scientific studies on PSG was in African spurred tortoises (*Centrochelys sulcata*), reared under different humidity conditions ("dry" 24–58%, "mid" 31–75%, and "humid" 45–99) and different protein levels (14%, 19%, and 31% DM), and Ca:P ratios of greater than 3.7 : 1.[21] The study showed a trend for greater pyramiding under drier conditions, with higher protein having only a minor impact. Higher protein levels did lead to more rapid growth, and larger size, however, which led to the erroneous impression of more pyramiding to the researchers, which, when measured, were not relatively larger.[21] The least pyramiding was found in the experimental group with environmental humidity between 45% to 99%, and the most pyramiding was found in the group with 24% to 58% environmental humidity; both groups had identical dietary

protein levels (19% DM). The authors concluded that to keep PSG minimal, hiding areas with relatively high humidity should be provided at all times.[21] The nutritionists speculated that during humid seasons there is a concurrent increase in growth of plants with better nutritional value that can support rapid growth. Conversely, during dry seasons, nutritional quality decreases and growth slows. Many tortoises naturally seek humid refuge in burrows or under foliage at soil level. Thus, providing a dry environment with constant rich nutrition, in captivity, is unnatural and may contribute to PSG.[21] Another study with African spurred tortoises and leopard tortoises found increased nocturnal heat exposure leads to increased growth rate and a subsequent significant increase ($P < 0.05$) in PSG. Humidity and diet were the same between treatment and control groups (no nocturnal heat).[22] The authors suggested that an unnatural growth rate may lead to deposition of material between keratin scutes faster than the bone shell can spread, leading to a conical upgrowth of carapacial scutes.[22] Both studies point out that increased growth rates lead to more PSG. Most likely PSG has multifactorial etiologies but is largely independent of dietary calcium and phosphorus. Another study looked at animals using DEXA scans and demonstrated higher bone mineral density in affected tortoises.[27]

Clinical Presentation and Diagnostic Confirmation

PSG is a common affliction in captive tortoises but can be a normal morphological feature of some species, such as Indian star tortoises (*Geochelone elegans*) and some tent tortoise species (*Psammobates* spp.). PSG affects primarily the carapace, especially the central vertebral scutes (see Fig. 84.22), which have a knobby pyramidal shape rather than an evenly rounded smooth carapace. There is thicker bone underlying the scute annuli, and with pronounced PSG the vertebral column may separate from the dorsally domed dermal bone.[22] Diagnosis is via presenting clinical signs and husbandry review.

Preferred Treatment

There is no treatment for PSG. Shell deformities are permanent, and only new shell growth can be corrected.

Prognosis and Prevention

The prognosis is favorable, although shell deformities cannot be corrected. Future PSG can be reduced with better nutrition, such as more hay, grasses, and commercial tortoise diets (see Chapter 27), humid retreats for growing tortoises, and slowing growth rate, such as with a night time temperature drop. Concurrent anorexia or nutritional secondary hyperparathyroidism can also complicate treatment and prognosis.

THIAMINE DEFICIENCY

Clinical Significance and Known Etiological Cause(s)

Thiamine (Vitamin B_1) deficiency is probably the first documented deficiency disease (beriberi), described in China as early as 2600 BC. It has been reported across the animal kingdom as associated with feeding shellfish and fish-containing thiaminases, which destroy thiamine. Thiaminase is heat labile and boiling or cooking will destroy it. Freezing does not destroy thiaminase, and over time it will continue to break down thiamine. Phytothiaminases found in plants, such as bracken ferns (*Pteridum aquilinum*), horsetails (*Equisetum arvense*), nardoo (*Marsilea drummondii*), rock ferns (*Cheilanthes sieberi*), and kochia (*Kochia scoparia*), could also contribute to thiamine deficiency but are not typically fed to reptiles. Thiamine, being water soluble, is not generally stored in the body, thus deficiency can develop and resolve rapidly. No gross lesions are seen at necropsy; however, histopathology may reveal necrotizing encephalopathy.[80]

Clinical Presentation and Diagnostic Confirmation

Diagnosis is based on dietary history, clinical signs, and rapid response to thiamine therapy. Listlessness and acute loss of righting reflex was attributed to suspected thiamine deficiency in 20 out of 100 2- to 3-month-old juvenile farmed saltwater crocodiles (*Crocodylus porosus*) that were fed thawed frozen donkey meat and chicken heads, supplemented with calcium and multivitamins containing a low concentration of thiamine (3 mg/kg).[81] These juvenile crocodiles were found floating, or lying on their sides or backs, with their jaws open and responded quickly to thiamine injections within 1 to 2 days. Addition of dried Brewer's yeast, with 95 mg/kg thiamine, resulted in no further cases. Torpor, depression, and uncoordinated behaviors in alligators (*Alligator mississippiensis*) have also been related to thiamine deficiency.[80] Neural lesions characteristic of thiamine deficiency were noted in the telencephalon, particularly the dorsal ventricular ridge. Liver and muscle tissue concentrations of thiamine (vitamin B_1) were low, and the consumption of thiaminase-positive gizzard shad (*Dorosoma cepedianum*) was thought to have been the cause. Suspected thiamine deficiency has also been reported in garter snakes (*Thamnophis* spp.) and brown water snakes (*Nerodia taxisplilota*) fed frozen fish (Fig. 84.23). Clinical signs include anorexia, lack of accurate striking reflex, opisthotonus/torticollis, frantic curling, tremors, seizures, mydriasis, blindness, dysphagia, enophthalmia, and eventually death.[82–84]

Preferred Treatment

Initial thiamine injections followed by dietary thiamine supplementation results in rapid reversal of clinical signs. Saltwater crocodile juveniles

FIG 84.23 Neurological deficits and mydriasis in a mole kingsnake (*Lampropeltis calligaster*) fed goldfish (*Carassius auratus*). The clinical signs resolved within 24 hours of an injection of 100 mg/kg thiamin B1 and were prevented by converting to a rodent diet. (Courtesy of Stephen J. Divers.)

responded rapidly to 30 mg thiamine HCL (100 mg/mL) IM SID for two treatments. Recovery of righting reflex occurred within 24 hours, with full recovery by 48 hours.[81] Frye recommended 25 mg/kg thiamine tablets in the body cavity of fish for 3 to 7 days.[82]

Prognosis and Prevention

The prognosis is excellent if diagnosed and treated early. Long-term prevention includes feeding a better balanced, more diverse diet, and supplementation of 25 to 30 mg thiamine per kg of wet fish.[85] Thiaminases are not restricted to marine or freshwater fish; they can be found in either (see Chapter 27, Table 27.13, for more information). Trout do not contain thiaminases and do not require thiamine supplementation.

GOUT AND HYPERURICEMIA

Gout refers to the deposition of uric acid in tissues. Hyperuricemia refers to elevated blood levels of uric acid and may precede gout. Hyperuricemia and gout can be associated with excessive uric acid production (e.g., excessive dietary protein) and/or reduced uric acid excretion (e.g., renal failure).

Clinical Significance and Known Etiological Cause(s)

Most snakes and lizards are primarily uricotelic (>90% uric acid excretion), so anything that reduces renal excretion of uric acid can lead to gout. Many chelonians, including terrestrial species, produce significant urea, whereas marine and aquatic reptiles may produce significant ammonia levels. Contributing factors that can lead to elevations of uric acid are high intakes of purine-rich proteins, severe dehydration, and suboptimal temperature. Most carnivores eat a relatively high-purine diet; however, wild reptiles obtain food less frequently than captive reptiles. Overfeeding is typically a captive issue. Push feeding for rapid growth is a common risk factor, thus gout is a common problem seen in commercial alligator production. Nephrotoxic drugs, severe dehydration, and VAD can lead to uric acid deposition in renal tubules.

Clinical Presentation and Diagnostic Confirmation

Many reptiles with gout are hypophagic or anorexic, as well as dehydrated. Uric acid is relatively insoluble and can easily form white tophi deposits in any tissue but predominantly in joints, spleen, kidneys, pericardial sac, liver, and even the CNS. Tophi, especially once mineralized, are often visible radiographically as areas of increased opacity around distal joints and surrounding tendons and tissues. Tophi may lead to chronic arthritis, due to bone erosion, and predispose to secondary infection. Hyperuricemia is suggestive, but not all patients with gout are hyperuricemic; severe dehydration can also cause hyperuricemia. Diagnosis of gout may be confirmed by seeing monosodium urate crystals in joint fluid or tissues. Under polarized light microscopy, urate crystals are needlelike and have strong negative birefringence. Synovial fluid must be examined relatively soon after aspiration, as temperature and pH affect solubility. Uric acid is routinely removed by formalin and histological processing, leaving characteristic "holes" with associated inflammation in tissue sections. Articular gout can be distinguished from pseudogout, abscesses, or septic arthritis by synovial fluid analysis or biopsy.

Preferred Treatments

Medical treatment of gout is indicated if uric acid levels are elevated. Allopurinol at 25 mg/kg PO SID in green iguanas (*Iguana iguana*) reduced uric acid levels by 45%[86] while 50 mg/kg PO SID x 30 days, then q 72 hours thereafter has been recommended in Mediterranean tortoises (*Testudo* spp.) (Kolle Proc ARAV, 2001, pp 185–186). Allopurinol blocks the enzyme xanthine oxidase, reducing breakdown of xanthine to uric acid, leading to the excretion of xanthine and hypoxanthine. These require more water for successful excretion, so fluid therapy and frequent soaking are recommended during treatment. These may be combined with judicious use of analgesics (e.g., colchicine, meloxicam, tramadol), although care should be exercised with NSAIDs if renal compromise is present. Visceral gout is difficult to treat and typically carries a poor to hopeless prognosis; however, there are scattered case reports of success.[87–89] Surgical removal of urate tophi from critical areas (e.g., joints, pericardial sac) may be beneficial. Unilateral renal gout was successfully treated in a monocellate cobra (*Naja kaouthia*) with unilateral nephrectomy.[89] See Chapters 66, 151, 163, and 164 for more information.

Prognosis and Prevention

Prognosis is poor as advanced gout is often an end stage state and generally considered incurable, with significant pain and suffering. Early cases with few indicators other than hyperuricemia, that are not dehydrated, often respond well to long-term allopurinol and dietary modulation. Prevention is through good husbandry, including access to water, appropriate humidity, diet, temperature, and avoiding overfeeding.

VITAMIN E/SELENIUM DEFICIENCY

Steatitis, fat inflammation, and necrosis, also known as yellow fat disease, occurs in carnivores fed diets high in polyunsaturated, or rancid, fat, or low in tocopherols or selenium.

Clinical Significance and Known Etiological Cause(s)

Crocodilians are most commonly affected, but steatitis, fat necrosis, and muscular degeneration have been reported in lizards and snakes.[24,90–95] Vitamin E and selenium are both antioxidants that protect against toxic effects of rancid fats.[96] Fish high in polyunsaturated fats, rancid fish, or rancid fish oils (either from putrification, overlong, or inadequate freezer storage) are toxic and cause fatty tissue in crocodilians to undergo necrosis and saponification (hardening).[24] Saponified fat elicits an inflammatory response (steatitis). Inadequate amounts of vitamin E or selenium can also cause muscles to degenerate (white muscle disease).

VetBooks.ir

Widespread mortality from idiopathic pansteatis was noted in Nile crocodiles (*Crocodylus niloticus*), fish, and other apex predators in the Olifants River system in South Africa, including Kruger National Park.[97] Other studies suggest that an alien-invasive silver carp (*Hypophthalmychthys molitrix*) with high levels of n-3 polyunsaturated fatty acids, which other fish and crocodiles feed upon, could be the culprit.[98] Steatitis was also reported in three captive olive Ridley turtles (*Lepidochelys olivacea*), where it was ascribed to a long-term diet of frozen fish (Manawatthana and Kasorndorkbua, unpublished data, 2005).

Clinical Presentation and Diagnostic Confirmation

Hardened fat reduces tissue elasticity and can cause restriction of physical activity, which may be confused as lethargy. In crocodilians, large saponified intermuscular fat deposits in the tail may render the tail immobile, palpably firm, and the animal unable to swim. Saponification of intracoelomic fat may reduce intestinal motility.[24] In a *Ctenosaurus* lizard, bilateral hind-limb ataxia with muscle degeneration, interstitial fibrosis, and focal lymphocyte infiltration were consistent with white muscle disease.[90] A green iguana, with similar clinical signs, responded to vitamin E-selenium supplementation.[91] Feeding obese laboratory rodents raised on sunflower seeds also led to clinical signs of deficiency in a *Boa constrictor*.[82]

Diagnosis is typically postmortem with obvious round, red to yellow to brown, indurated, encapsulated nodules of granulomatous steatitis and fat necrosis; however, antemortem biopsy would be expected to be definitive in the live patient. Indurated fat has a greasy soaplike feel. Histologically, circumscribed zones of macrophages, multinucleated giant cells, ceroid, and hemorrhage are present.[93–95]

Preferred Treatment

There is no effective treatment to reverse fat saponification.

Prognosis and Prevention

Prognosis is poor for steatitis; most cases are diagnosed postmortem. Vitamin E is abundant in fresh fish, but fish lipids have a lower freezing point than mammalian fats and much of the vitamin E may be destroyed by oxidation after only a few weeks of freezing.[85,99] Degradation and oxidation of fish lipids, resulting in rancidity, can be accelerated by inappropriately high freezer temperatures, and therefore fish should be frozen between −18° to −30°C (0° to −22°F). Frozen fish should be used within 4 to 6 months.[85] Suggested levels of supplementation are 100 IU of vitamin E per kg of wet fish or 1 IU/kg/day for reptiles.[85,100]

Requirements and dosages of selenium for reptiles are largely unknown; mammals do best with diets containing 0.3 ppm selenium and should not exceed 0.5 ppm.[100] Several studies found exposing banded water snakes (*Nerodia fasciata*) and brown house snakes (*Lamprophis fuliginosus*) to diets containing about 1, 10, or 20 ppm Se, for 10 to 24 months, resulted in accumulation of Se in target organs and maternal transfer of Se to eggs at levels that exceeded established toxicity thresholds for other vertebrates.[101] A vitamin E–selenium responsive muscle condition in a green iguana was treated with 28 to 56 mg/kg vitamin E with 0.14 to 0.28 mg/kg selenium for 3 treatments.[91]

PROTEIN DEFICIENCY

Clinical Significance and Known Etiological Cause(s)

Protein deficiency usually results in hypoalbuminemia. Albumin is synthesized in the liver, and low albumin may be indicative of liver failure, such as with hepatic lipidosis, cirrhosis, or chronic hepatitis. Hypoalbuminemia can also result from malnutrition, protein-losing nephropathy, and enteropathy.

Clinical Presentation and Diagnostic Confirmation

Protein deficiency, from hepatic lipidosis, chronic malnutrition parasitism or renal insufficiency is common in tortoises. Tortoises are often less active, weak, eating more selectively, or anorexic, and may have peripheral edema or rarely signs of hepatic encephalopathy, such as stupor (see Fig. 84.20A and B). Long-term captive desert tortoises on inadequate diets often have blood albumin levels less than 1 mg/dL, as well as anemia and hypocalcemia. Measurement of albumin by the bromocresol green dye–binding method may lead to inaccurate results for plasma albumin concentration, especially in sick emydids and testudinids. Therefore for health assessment, in chelonians, albumin should be measured by protein electrophoresis.[102,103]

Preferred Treatment

If the tortoise is eating, dietary improvement, such as adding grasses, hays, and good-quality commercial pellets, will correct the problem. For patients that are not eating, further diagnostic investigation is indicated, as hepatic lipidosis, parasitism, or renal insufficiency may be present. Long-term nutritional support may be indicated (see Chapters 45 and 122).

Prognosis and Prevention

The prognosis is excellent if the tortoise is eating and the caregiver commits to improving the diet (see Chapters 23 and 27 for more information). If the patient is not eating the prognosis may be guarded to poor, depending on the extent of concurrent disease(s).

GEOPHAGY

Clinical Significance and Etiological Causes

Both free-ranging and captive tortoises, lizards, and crocodilians may consume stones (lithophagy), soil, and sand (geophagy). Desert tortoises, especially females, in the Mojave Desert, were found to selectively seek out and consume white calcite stones (not brown, gray, or other dull-colored stones), which were mostly calcium carbonate.[104] Eating bones, stones, and soil may be important for calcium acquisition, detoxification of toxic plants, or to expel parasites. Many reptiles incidentally ingest sand or gravel while eating.[104] Crocodilians ingest stones that may stay in their stomachs for months to years, and their significance is much debated. Some believe gastroliths are incidentally ingested and are nondetrimental, others believe they assist with ballast and/or mechanical breakdown of food.[105]

Clinical Presentation and Diagnostic Confirmation

Many tortoises have large numbers of stones in their GI tract normally; 60% of a large sample of free-ranging desert tortoises (n = 185) had stones in the gastrointestinal tract.[104] Intestinal obstruction is common in reptiles housed on sand, gravel, decomposed granite, aspen wood chips, or crushed walnut shells. Radiography and ultrasonography should be considered if complete obstruction is a concern.

Preferred Treatment

If the reptile is eating and defecating (therefore no obstruction is present), then no treatment is needed. If the reptile is not eating or defecating, but no complete obstruction can be identified, then aggressive rehydration (soaking, parenteral, and oral), enemas or stomach tubing with water, or mineral oil, may help. Many lizards will defecate with gentle colonic palpation. Severe cases often need an esophagostomy tube for long-term fluid and nutritional support. Regurgitation, or cases exhibiting radiographic or ultrasonographic evidence of complete obstruction, should be considered surgical. Gastroliths are not treated in crocodilians.

VetBooks.ir

Prognosis and Prevention

Do not house reptiles on sand or gravel. As long as the reptile continues defecating, most stones can be defecated over time, and the prognosis is good. With surgery, the prognosis is good if secondary complications, such as hepatic lipidosis or colonic perforation, are not present.

GOITER

Goiter is the enlargement of the thyroid gland in an attempt to compensate for a deficiency in iodine. Toxic goiter refers to thyroid enlargement associated with alteration in thyroid function, whereas nontoxic goiter represents thyroid enlargement that does not result from an inflammatory or neoplastic process and is not associated with abnormal thyroid function.[106]

Clinical Significance and Known Etiological Cause(s)

Goiter is commonly misdiagnosed in Galapagos (*Chelonoidis nigra* complex) and Aldabra (*Aldabrachelys gigantea*) tortoises. More commonly these cases of ventral neck swelling represent thymic hyperplasia.[107] In other animals nontoxic goiters are the result of a dietary deficiency in iodine, or feeding foods high in iodine-binding goitrogens, which are found in cabbage, kale, broccoli, rapeseed, turnips, mustard seed, cauliflower, Brussels sprouts, and bok choy.[100,108] Excess dietary nitrates, the result of ingestion of fertilized grasses and hays, vegetables grown hydroponically, and iodine intoxication—the result of oversupplementation—have also been noted to predispose animals to goiter.[100,106] However, dietary goiter appears to be exceedingly rare in reptiles (see Chapter 79 for more information). Case reports of nontoxic goiter have been documented in giant tortoises, an eastern diamondback rattlesnake (*Crotalus adamanteus*), and Kirtland's snakes (*Clonophis kirtlandii*).[106,108,109] Two cases of intranuclear coccidiosis had nontoxic goiter, a radiated tortoise (*Geochelone radiate*) (Boyer, T, personal observation), and a Bowsprit tortoise (*Chersina angulata*).[110] Toxic goiter can be secondary to neoplasia.[111]

Clinical Presentation and Diagnostic Confirmation

A single (unpublished) case of nontoxic goiter in a Greek tortoise (*Testudo hermanni*) that was making whistling respiratory sounds had a sonographically enlarged thyroid gland compressing both atria (Buehler, 2006, unpublished data). Blood parameters and thyroid hormone concentrations were within established normal ranges. Biopsy of ventral cervical neck masses in giant tortoises can confirm thymic hyperplasia.[107]

Preferred Treatments

In the Greek tortoise, after 1 month of 1 mg/kg of potassium iodide PO daily, the whistling sound ceased and the sonographic thyroid diameter had decreased from 34 mm to 23 mm, and the atria were no longer compressed. After 4 months of therapy the ultrasonic thyroid diameter was 16.8 mm and remained 17.0 mm ± 0.2 mm for several more months, at which point the potassium iodide was reduced to twice weekly doses. The thyroid size remained unchanged sonographically for 6 additional years (Buehler I, unpublished data, 2006). See Chapter 79 for more information.

CORNEAL LIPIDOSIS/XANTHOMATOSIS

Corneal lipidosis, more properly termed corneal arcus, is a lipid storage disease in anurans associated with corneal lipid (especially cholesterol) deposition and, less commonly, deposition of cholesterol granulomas (xanthomas) elsewhere in the body (the later also in female lizards).[112–115]

Clinical Significance and Known Etiological Cause(s)

Corneal arcus is the most commonly reported corneal disease of captive amphibians, especially hylid frogs such as Cuban tree frogs (*Osteopilus septentrionalis*), and White's tree frogs (*Litoria caerulea*). Females are overrepresented in case reports. Experimentally, Cuban tree frogs fed diets high in cholesterol had significantly elevated serum cholesterol and LDL levels, which lead to significantly more corneal cholesterol deposition than in frogs on a lower cholesterol diet, or wild Cuban tree frogs.[113] Folliculogenesis, with associated hypercholesterolemia, nutrition, genetic predisposition, or trauma (cholesterol may be released from damaged cell membranes and induce a granulomatous response) may be involved in the pathogenesis of xanthomas.[110,115,116] Xanthomas are not neoplasms, but they can be locally invasive.[116]

Clinical Presentation and Diagnostic Confirmation

In anurans, corneal arcus starts as perilimbal, small, white, crystalline foci, which become denser, more raised, and slowly progress centrally, resulting in corneal haziness that progresses to opacity and blindness. Diagnosis is apparent with ocular examination. Xanthomas have been identified postmortem in the brain, viscera (especially liver), peripheral nerves, periarticular soft tissues, and digital pads. In lizards, xanthomas have been reported in coelomic surfaces and viscera, as well as the brains of female lizards (a northern green gecko, *Naultinus grayi*; leaf-tailed geckos, *Uroplatus* spp.; leopard geckos, a great plated lizard, *Gerrhosaurus major*; and green water dragons, *Physignathus cocincinus*), and associated with progressive neurological signs, such as seizures, vertigo, stargazing, circling, and/or torticollis (Boyer T, personal observation, 2013).[110,115,116]

Preferred Treatment, Prognosis, and Prevention

There is no treatment, and although low-cholesterol diets, such as limiting or avoiding larval insects, and improved husbandry may slow progression, existing lesions do not regress. Prognosis is poor for amphibians, as most patients eventually become blind, cannot feed independently, and die within 18 to 24 months of diagnosis. Lack of normal biology (e.g., thermoregulation, vitellogenesis, egg laying, mating behavior, hibernation, estivation), decreased activity, overfeeding, and poor diet (reduced dietary diversity, high cholesterol) may all predispose anurans to excess fat disposition.[113,117] The prognosis is poor for lizards with neurological signs, as xanthomas continue to expand within the confines of the skull; coelomic xanthomas may be amendable to surgical resection.

BIOTIN DEFICIENCY

Biotin (Vitamin B_7) deficiency can result from feeding raw unfertilized eggs exclusively. Raw eggs contain avidin, a tetrameric biotin-binding protein; cooking denatures avidin, and fertile eggs have embryos that are rich in biotin. Occasionally diagnosed in egg-eating species such as helodermids, varanids, teids, and egg-eating snakes (*Dasypeltis* spp.),[82] principle signs are muscle tremors and generalized weakness. Diagnosis is via clinical signs and dietary history. Multi-B injections should reverse clinical signs rapidly, and prognosis is typically excellent. Biotin deficiency can be prevented by feeding fertilized eggs and varying the diet to include whole prey, and by vitamin supplementation.

VetBooks.ir

FIBER-RELATED DISORDERS

Most commercial greens, vegetables, and fruits are lower in fiber and higher in carbohydrates compared with their wild counterparts, which results in soft, semiformed, or liquid stools in captive herbivores. Clinical significance is unknown, but tortoises are commonly affected. Dietary history can be reviewed using Tables 27.1 to 27.3 in Chapter 27 for fiber content of foodstuffs, and routine fecal examination is indicated to exclude parasitic etiology.

Feeding less greens, vegetables, and fruits and more grasses, hays, and commercial diets with good fiber levels are indicated. Prognosis is excellent with dietary changes.

Perinatology

Krista A. Keller

In human medicine, perinatology is a branch of obstetric medicine encompassing the period of time surrounding childbirth. In reptile medicine, perinatology is the time period surrounding hatching for oviparous species, or immediately after birth for viviparous species. For the purposes of this chapter, the term perinatology will include relevant information regarding the egg, incubation period, and hatching (relevant for oviparous species), as well as hatchling and neonatal care and medicine. An understanding of reptile perinatology is important in the management of captive rearing programs within the pet trade, industry, research, or to bolster free-ranging populations. For instance, conservation efforts for Blanding's turtles (*Emydoidea blandingii*) in the United States include "head start" programs, allowing artificial incubation of eggs collected from the wild. Veterinarians aiding in these projects may be involved in diagnostic procedures involving eggs, investigation into causes of hatching failure, and evaluation and treatment of the sick hatchling.

THE REPTILIAN EGG

Oviparous species lay eggs in the environment that hatchlings emerge from. Viviparous species do not lay eggs but instead birth neonates. Ovoviparous species develop eggs, but the juvenile hatches from the egg while within the oviduct or very shortly after oviposition. The discussion of the reptile egg anatomy and physiology is relevant to oviparous and ovoviparous species. A full discussion of reproductive strategies can be found in Chapter 80.

The reptilian egg at oviposition is composed of the eggshell, extra-embryonic membranes, albumen (or whites), and the yolk (Fig. 85.1). Each structure is involved in some support mechanism for the developing embryo. The shell of the reptilian egg can be categorized as being inflexible and hard or flexible and soft (leathery).[1] The structure of the eggshell is correlated with the environment where the eggs will incubate naturally; in general, hard-shelled eggs are laid by species that nest in

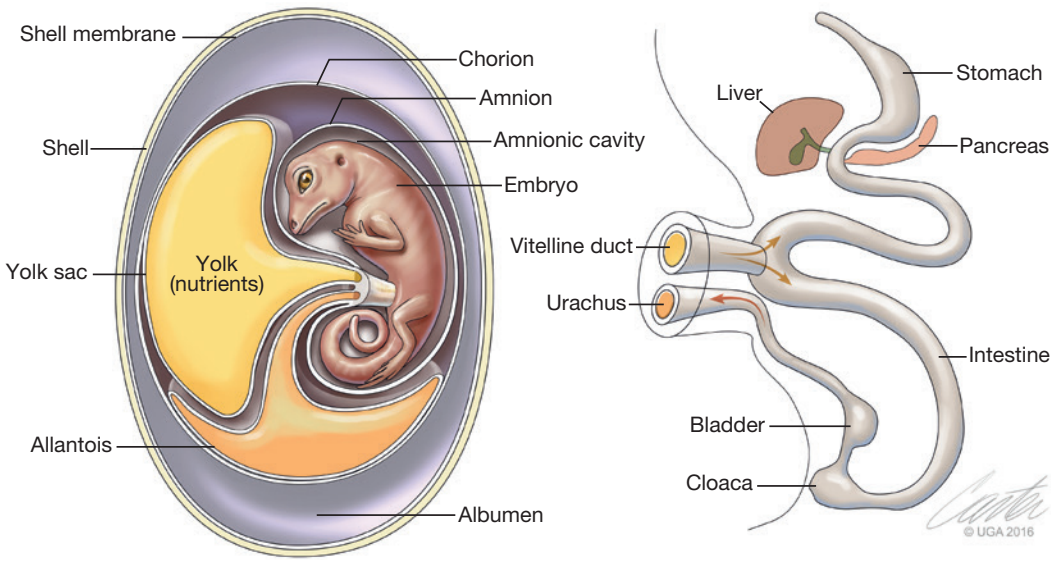

FIG 85.1 The image on the left depicts the diagrammatic appearance of a reptilian egg several weeks after embryonic and extraembryonic membrane development. Note the relationships of the amnion, allantois, chorion, yolk, and associated yolk sac with the embryo. The diagram on the right shows a magnified view of the body stalk, including the flow of yolk through the vitelline duct to the embryonic intestines for nutrient transfer and the flow of urine and urates through the urachus to the allantoic cavity for excretion. arid and semiarid environments while soft-shelled eggs are laid by species that nest in moist environments.[1]

Physiologically, the eggshell functions as the boundary between the embryonic and external environments and provides calcium for embryonic development. Regardless of shell structure (hard or soft-shelled), the porous nature of the shell allows for gas and water exchange.[1,2] Softer-shelled eggs have a higher rate of oxygen exchange when compared to more solid-shelled eggs; however, this has no effect on the metabolism of the developing embryo, and mechanisms of how this is possible are unknown at this time.[2] Reptile embryos derive 20% to 25% of their calcium from the eggshell.[3]

The albumen is a viscous clear to slightly opaque proteinaceous material. Albumen, derived from specialized oviductal glands, has a high water content, although a variety of proteins are present.[4] In the leatherback turtle (*Dermochelys coriacea*), albumen makes up the largest mass component of the egg, whereas in the American alligator (*Alligator mississippiensis*), the mass is divided equally between the yolk and albumen.[4,5] Physiologically, the albumen layer provides the embryo with physical support and assists in water storage.[1] A class of antimicrobial peptides limited to bird and reptile species is secreted by the oviduct into the albumen layer and likely protects the developing embryo from infection.[6]

The extra embryonic membranes are composed of the amnion, allantois, and chorion (see Fig. 85.1). The amnion is the membrane that directly surrounds the embryo. Contraction of specialized amniotic smooth muscles at initiation of hatching causes retraction of the amnion and is ultimately responsible for the internalization of the yolk.[7,8] The allantois originates at the body stalk (paired with the vitelline duct and associated vessels) and is a continuation of the urachus external to the embryo. The allantoic cavity is the major storage site for protein catabolism excretion products, including urea and uric acid.[9] The chorion is the outermost membrane that encloses the embryo, amnion, allantois, yolk, and yolk sacs.

The yolk and its surrounding membrane, the yolk sac, are attached to the developing embryo at the body stalk via the vitelline duct (also referred to as the omphalomesenteric duct) (see Fig. 85.1). The vitelline duct is continuous with the embryonic intestines, allowing direct transfer of nutrients from the yolk. During incubation and embryonic development, as the yolk contents traverse the vitelline duct, the yolk size decreases while the embryo size increases.[9] Whereas avian yolks are liquid in composition, in corn snakes (*Pantherophis guttatus*), the yolk is solid for the last third of incubation due to the proliferation and invasion of endodermal cells and blood vessels from the yolk sac.[10]

Physiologically, the yolk is the primary energy source for the developing embryo and the hatchling.[1] The embryo obtains retinal (storage form of retinoids in reptiles), hormones, fatty acids, proteins, and minerals such as calcium, phosphorus, and magnesium from the yolk.[11–13] Maternal diet influences yolk fatty acid content and yolk size, thus affecting offspring nutrition. This should be considered when evaluating the hatchlings from a female with poor nutrition and captive care.[14–15] In addition, yolk can serve as maternal transfer of toxins (heavy metals, selenium, persistent organic pollutants) and antibodies as reported with *Mycoplasma agassizii* in desert tortoises (*Gopherus agasizzi*).[16–19] There is evidence for vertical transmission of sunshine virus, a neurorespiratory paramyxovirus of pythons, and *Hepatozoon* spp. in garter snakes (*Thamnophis elegans*).[20–21] Countless other pathogens likely have vertical transmission but have not been evaluated.

INCUBATION CONDITIONS

Natural incubation strategies among reptile species are extremely varied. For instance, the northern snake-necked turtle (*Chelodina rugose*) exhibits a post-ovipositional developmental arrest; eggs are laid at the bottom of flooded wetlands and the embryos will not develop until after floodwaters subside. Consequently, these eggs require aquatic submergence prior to incubation for successful development.[1] In addition, many species of python and skinks exhibit egg-brooding behavior.[22,23] Understanding species-specific incubation conditions will improve hatching success in artificial conditions.

Outside of species-specific requirements, it is important to understand the basic conditions of incubation and how they can affect the egg and developing embryo to ultimately achieve successful hatching. The basic conditions of incubation include moisture and temperature.

Humidity

Hard- and soft-shelled eggs will respond differently to moisture in their environment. Soft-shelled eggs are more porous and are expected to enlarge and gain mass during incubation due to diffusion of water into the egg, as seen in the green iguana (*Iguana iguana*) egg that doubles in weight due to water absorption.[9] Hard-shelled eggs do not allow such impressive water diffusion; however, lack of moisture during incubation has been shown to influence hatchling size and performance.[24,25]

If conditions are too dry, soft-shelled eggs will lose water mass to the environment and begin to crinkle or collapse. Intervention with additional moisture at this stage may correct the dehydration; however, further dehydration may cause nonviability of the egg. This has been postulated to be secondary to buildup of toxic levels of nitrogenous wastes in the allantoic cavity.[1,9] At the other extreme, if the egg is surrounded by too much water, oxygen diffusion may cease, leading to hypoxia and death.[1]

Temperature

Species-specific incubation temperatures should be followed whenever available (Table 85.1). Studies show that abnormal incubation temperatures lead to hatchling performance deficits and reduced growth and immunity, and even latent effects on growth after hatching.[24,26–28] Specific syndromes, such as "failure to thrive syndrome," occurs in hatchling crocodilians and is 2.5 times more likely to occur in clutches that are incubated at lower air temperatures.[29] When kept within the species-specific temperature ranges, an inverse relationship exists between temperature and incubation length. For example, in the common wall lizard (*Podarcis muralis*) eggs incubated at a higher temperature (32°C) hatched more than 5 weeks earlier than eggs incubated at a lower temperature (24°C).[30]

Outside of appropriate embryonic development, temperature can be used to manipulate the sex of the developing embryo(s). Many reptiles exhibit temperature-based sex determination (TSD). Unlike genotypic sex determination (GSD), where sex phenotype is determined secondary to genes passed from the parents, in TSD gender phenotype is determined by specific temperature ranges during incubation.[31] Specific patterns of TSD exhibited by different taxon are presented in Table 85.2. Most chelonian species studied exhibit TSD, notable exceptions include the family Chelidae (Pleurodira).[32] Lizards exhibit mixed patterns of sex determination, even within taxonomic families. The leopard gecko (*Eublepharis macularius*) is a classically described TSD species, while other Eublepharid lizards are GSD. Another popular species in the pet trade, the bearded dragon (*Pogona vitticeps*), exhibits GSD.[33] Of the crocodilian and sphenodontia species studied to date, all follow a TSD pattern.[34,35]

While GSD and TSD are the classically discussed mechanisms for sex determination in reptiles, some species have been shown to exhibit multifactorial sex determination that include factors unrelated to temperature, such as yolk size, presence of exogenous hormones, and water availability.[36–38] Interestingly, a single species, the montane lizard

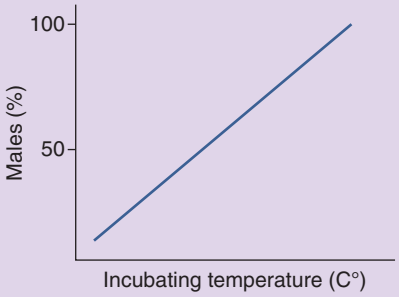
(*Bassiana duperreyi*), exhibits both TSD and GSD.[39] These examples highlight that the traditional categorization of a species as exhibiting either TSD or GSD is likely oversimplified.

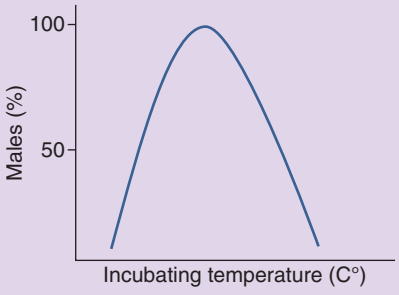
Keeping in mind that many reptile species exhibit TSD, the effect of the warming climate on sex ratios, and ultimately population health, is of concern. Effects of global warming could lead to skewing of the sex ratio, causing catastrophic population declines. For instance, in chelonian species that have more females created at higher temperatures, global warming conditions would create a lower percentage of males.[31] In contrast, with warmer ambient temperatures, the tuatara (*Sphenodon* spp.) would be expected to create more male offspring.[40] Outside of changing sex ratios, climate temperatures above the highest recommended incubation temperatures for a species may lead to reduced hatchling survivability.[26,28]

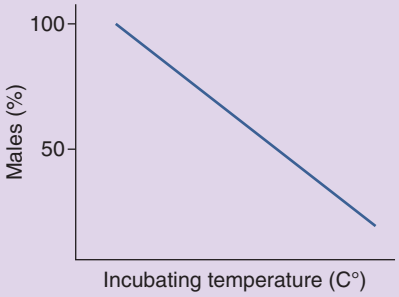
ARTIFICIAL INCUBATION

Incubators can either be constructed or purchased. Commercially available reptile incubators and chick incubators have been used successfully. Most incubators are designed with a double-chamber principle (Fig. 85.2). The inner chamber houses the eggs and substrate and is then suspended within a larger chamber. Either air or water can be present between the two chambers; when water is used, evaporation helps maintain the necessary high humidity. Separation of the inner chamber from the heat source and buffering the heat through the air or water medium has the advantage of creating a more homogenous temperature zone without associated "hot spots." When constructing an incubator, a waterproof container such as a plastic storage bin will work well for the inner chamber, while a larger plastic or Styrofoam ice chest would be appropriate for the outer chamber, with modifications for air flow.

Within the inner chamber, various substrates have been used with success. These include vermiculite, perlite, sterilized potting soil, sand, sphagnum moss, shredded paper, or a combination of the above. Substrates are recommended to be moist but not soaking wet. Concern with chlorine, chloramine, and other potential toxins have prompted many individuals to use bottled water in lieu of tap water. Other toxins that may be present in particulate substrates, particularly pesticides, may cause reduced hatchability or hatchling abnormalities.[41,42] Use of purchased and packaged substrate will remove the likelihood of pesticide exposure. Prior to incubation, discussion with an experienced individual (breeder, zookeeper) will enable more precise information regarding successful substrate types used for the species in question. Typically, the eggs are half buried in the substrate (Fig. 85.3).







Various heat sources have been utilized to maintain incubator temperatures. Heating coils, strips, pads, and submersible aquarium heaters are available. Ideally, heaters with adjustable capacities should be used to maintain accurate temperatures within the inner chamber. Reliable thermometers, ideally digital, should be used that allow external evaluation of the temperature in the inner chamber, as repeated opening of the incubator will allow loss of heat and moisture. Fluctuating temperatures, as would be expected with frequent opening of an incubator, have been shown to delay hatching and affect hatchling body size in the smooth soft-shelled turtle (*Apalone mutica*), signifying the importance of consistent temperatures.[43] Daily monitoring and temperature recording is recommended. Successful species-specific incubation temperature ranges are reported in Table 85.1.

Moisture sources for the humidity required during incubation should come from the substrate and from the water bath used between the inner and outer chamber, depending on incubation design. Daily misting of the substrate may help increase humidity levels but requires opening the incubator, which leads to loss of heat and moisture; thus self-regulation of humidity with a closed incubator design is preferable. If misting is to be done, the misting bottle should be kept at the same ambient temperature as the internal incubation temperatures. Reliable hygrometers should be utilized that allow external evaluation of humidity of the inner chamber and daily monitoring of humidity concentrations. Although a closed system, it is crucial that incubators have appropriate air flow and ventilation. Hypoxia from a completely closed system would be a cause of embryonic death, either in the shell or soon after emergence from the shell. Successful species-specific incubator humidity concentrations are reported in Table 85.2.

The incubator, whether purchased or constructed, should be set up and operational several days before the expected arrival of the eggs to allow for equilibration of the temperature and humidity within the system. A window in the top of the incubator, which is standard in most commercial incubators, allows for observation during incubation and hatching.

During egg collection, care should be taken not to change the spatial orientation of the egg during transport or when placed into the substrate of the incubator. Although a previously controversial topic, it is now supported by a study in the water snake (*Natrix maura*) that showed

TABLE 85.2 Temperature-Based Sex Determination (TSD) Patterns that Are Exhibited by Different Reptile Taxa

that turning the eggs early in embryo development significantly increased post-hatching mortality.[44] In crocodilians, it has been shown that turning the eggs prior to embryo attachment (occurs within 24 hours of oviposition) has no effect on hatchability; however, rotation after this point will cause embryo death.[45] Because the effects of turning and the exact times of embryo attachment post-oviposition have not been elucidated for all species, the author recommends not changing the spatial orientation of any egg during transport.

NATURAL INCUBATION

In many situations, it is preferable and appropriate to allow natural incubation to occur. Knowledge of species-specific incubation strategies is important. Several species of python and *Eumeces* skinks are known for egg brooding, for instance.[22,23] Other species may create elaborate nests or excavate nests into substrate. Either in free-ranging or captive settings, if conditions support incubation change, eggs may be collected and moved to an artificial incubator setting. Egg collection should be done with caution in species that are known to guard nest sites such as crocodilians.

EGG DIAGNOSTIC PROCEDURES

There are several ways to evaluate egg viability: evaluation of the external appearance, candling, and noninvasive heart rate monitoring. Daily monitoring of the appearance of the eggs should be performed and recorded. A healthy, viable egg should stay a consistent color, although slight mottling to the surface is often not significant. Marked changes in color or texture, or growth of fuzzy mold usually indicates that the embryo has either died or that the egg was nonfertile (Fig. 85.4). Wrinkling and shrinking of the eggs does not always indicate embryo death, but that moisture levels are too low and the egg is dehydrating. Moistening of the surrounding substrate and checking humidity levels may be effective at rehydrating the egg, although severe dehydration often leads to embryo death. Viable crocodilian eggs will have a distinct band around the pole of the egg that increases in size with the growth of the embryo. This facilitates visual assessment of fertility and determination of the relative age of the embryo and is an important visual tool for viability in these species.[45]

Candling can be performed with a high-intensity light source, such as an ophthalmic transilluminator or a commercially available egg candler. The light should be placed in direct contact with the far side of the egg in a darkened room. Candled viable eggs will have a diffuse developing vascular pattern or the presence of an embryo (Fig. 85.5A). Nonviable eggs lack a vascular pattern and have a homogenous diffuse yellow-white appearance (see Fig. 85.5B). Care should be taken that the candling process is not prolonged, as heat from some light sources can damage the developing embryo and its membranes.

For soft-shelled eggs, a standard high-frequency (7.5–10 MHz) ultrasound transducer can be used to evaluate the heart rate of the developing embryo (Fig. 85.6). Standard water-soluble ultrasound gel can be used as an interface; however, because it may clog pores of the shell and prevent oxygen exchange, minimal gel should be utilized and removed afterward. In addition, a noninvasive commercially available infrared digital heart rate monitor can be used on both hard-shelled and soft-shelled eggs. Because an infrared light is used it can be a source of heat that may cause harm to the developing embryo if used for a prolonged amount of time.[46]

Additional diagnostics of the egg may be beneficial for research applications and investigation of reduced hatchability. A modified yolk biopsy technique has been described that allows for embryo survival.[47] Necropsy of the egg and collection of samples for histopathologic, bacteriologic, and/or toxicologic examinations can be a vital component of developing a successful incubation and hatching program. Assessment of records of daily temperatures and humidity can also be helpful in evaluation of causes of embryo death. Standard avian egg necropsy practices should be followed.

HATCHING AND MANUAL PIPPING

In the natural hatching process, immediately prior to hatching, the yolk sac is internalized into the coelomic cavity of the hatchling by retraction of the amnion. After successful yolk internalization, the body wall closes around the navel. From this point, gas exchange can no longer take place through the membranes, and the embryo must initiate gas exchange

through its lungs. It is hypothesized that hypoxic conditions in the embryo during yolk internalization cause contraction of muscles in the neck of the hatchling, leading to pipping.[7] Pipping occurs when the egg tooth, or caruncle, (Fig. 85.7) is forced through the eggshell. Once the eggshell is broken, the process of emergence of the hatchling from the shell can take 24 to 48 hours.[7]

Hatching is expected to occur based upon calculated species-specific hatch times that are additionally influenced by incubation temperatures (see Table 85.1). In many instances, the specific hatch time will not be known and constant observation should be performed to investigate when the process should be expected. In some species of crocodilians, embryos will begin vocalizing from within the egg prior to pipping.[48] Environmentally cued synchronous hatching occurs in at least 43 species of reptiles and may include physical disturbances such as vibrations or hypoxia. Synchronous hatching may serve to dilute predation risk in natural environments.[49] Regardless of whether environmentally cued synchronic hatching has been documented in a species, most eggs from the same clutch will be expected to hatch within a few days of each other.

Manual pipping and intervention in the natural events of hatching should be reserved for situations where the viability of the embryo is at risk. An example would be if vocalization was previously heard within an egg, as is the case with crocodilian species,[48] and other eggs in the clutch have been pipping, but this particular egg has not yet pipped. Another indication would be if the hatchling has pipped but not progressed to full emergence in the same amount of time as hatch mates or the expected time for that species. It is important to remember that the process of full emergence from the shell takes 24 to 48 hours,[7] and prematurely initiated emergence can lead to rupture of chorioallantoic membranes, bleeding, or incompletely internalized yolk sac, thus placing that hatchling at risk for infection and death.

In cases where manual pipping is indicated, sterile technique should be used with magnification. A small wedge incision is made in the top of the egg with sharp scissors (Fig. 85.8A). Care should be taken to avoid incising any internal vessels of the extraembryonic membranes (see Fig. 85.8B) When performed properly, the extraembryonic membranes are left intact. A blunt probe when placed in contact with the hatchling should cause movement if viable. If the extraembryonic membranes appear dry and tacky, rehydration can be performed with judicious use of a few drops of isotonic saline. After manual pipping is performed, the neonate should be allowed 24 to 48 hours to emerge from the egg on its own.

NEONATAL/HATCHLING CARE AND MEDICINE

The terms neonate and hatchling refer to the same time period but relate to the different reproductive strategies used by reptiles. Viviparous juvenile reptiles would be referred to as neonates, while oviparous juvenile reptiles would be referred to as hatchlings. The veterinary considerations during this time would be the same, whether caring for a hatchling or a neonate, and therefore the terms are often used interchangeably.

Maternal Care

Few reptile species are noted to provide protection and care to the hatchling. Among these species are the crocodilians and some skinks, to name a few.[50,51] The evolutionary advantages of providing maternal care includes protection of the young from predators and providing young with food, thus improving offspring survival. The parental costs of providing this care may include reduction of reproductive capacity due to loss of mating opportunities, lower energy intake, and in some cases reduced survival. A recent study evaluating long-tailed skinks (*Eutropis longicaudata*) found that populations experiencing higher predation pressure on offspring provided maternal care, while other

FIG 85.4 Egg viability should be visually assessed on a daily basis. (A) Collapsed or wrinkled appearance is a sign of dehydration and not necessarily egg death. These eggs can often be salvaged with rehydration of the substrate and increased humidity in the incubator. (B) Mottling or partial discoloration, although appearing lethal, can be normal in many cases. (C) Waxy yellow "slugs" may be passed from either viviparous or oviparous animals and represent unfertilized ova. (D) Mold on the surface of the egg is usually a sign of egg death. Nonviable eggs should be removed from the incubator immediately.

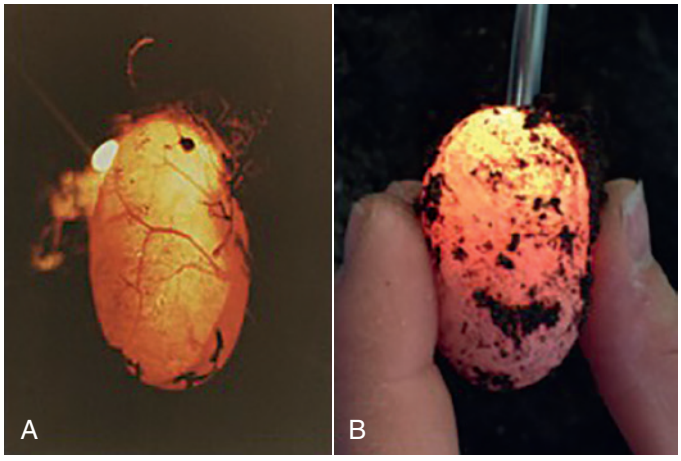

FIG 85.5 Egg viability can be evaluated by candling with a high-intensity light source. (A) Viable eggs readily show developing vasculature. As the embryo develops in later stages, movement can be seen within the egg (not shown). (B) Nonviable eggs lack developing vasculature and appear as homogenous yellow-white egg contents.

populations did not.[52] In the captive setting, the advantages of housing neonates with the parent of a species known to exhibit maternal care should be balanced with the disadvantages of group housing (conspecific predation, trampling, access to appropriate food sources, etc).

Husbandry

Reptile neonates are born precocious and find food, feed themselves, and perform normal functions as an adult. The housing and husbandry requirements of neonates will mirror those of adults, although temperature and humidity requirements tend to be higher. Neonatal growth rates are strongly affected by environmental temperatures.[53] Most breeders keep neonates in the incubator for the first few days of life at the incubation temperatures with a humidity of 90% to 100%, as neonates have a higher total body water loss rate than adults.[54] Neonates will do well on a simple substrate of moistened paper towels that are easy to monitor and clean fecal and urinary outputs. Group housing should only be pursued if appropriate for the species, and care should be taken to ensure that all individuals are eating. Cannibalism can be prevented by reducing stocking density and ensuring that neonates housed together are of similar size.

It is common for a neonatal reptile to not eat for the first few days to weeks of life. During this time period, the internalized yolk is providing

nutrition. The time period that the yolk can sustain the neonate is species specific; in the Mitchell's water monitor (*Varanus mitchelli*), neonates eat after first ecdysis at 4 to 10 days post-hatching, while in the Lake Erie water snake (*Nerodia sipedon insularum*), the first meal may be delayed until after hibernation.[55,56] Inappropriately intervening with nutritional support during this physiological period of fasting is unnecessary and stressful.

In general, the neonate should be fed items that mirror what the adult would eat although in smaller sizes. Smaller versions of the adult diet should be offered, which may require insect breeding to obtain the smallest size for insectivores or finely chopped vegetation in the case of herbivorous species. There are some exceptions to this rule with species that exhibit ontogenetic diet shifts or changing dietary preferences with maturity. In the bearded dragon, adults ingest a diet of 90% plant matter and 10% animal matter, while juveniles consume 50% plant matter and 50% animal matter.[57] Other examples of species that exhibit ontogenetic dietary shifts include the yellow-bellied slider (*Trachemys scripta*), Australian eastern bearded dragon (*Pogona barbata*), green lizard (*Lacerta bilineata*), and the green turtle (*Chelonia mydas*) among others.[58–61]

FIG 85.7 Most oviparous species, including this hatchling red-footed tortoise (*Chelonoidis carbonaria*), have a caruncle (arrow), or egg tooth, that is used to pip through the egg during hatching. This structure is not present in adult specimens and is lost after the first shed or within a couple weeks of hatching.

Because neonates are fast growing and have high nutrient demands, supplementation of foods with additional calcium and a reptile-specific multivitamin, whether dusted, gut loaded, or both, is recommended. In addition, as hind gut–fermenting herbivores, green iguanas (*Iguana iguana*) require a complex population of large intestinal microbes. These microbes are shown to be transferred from the adult to the neonate in the wild, and this should be replicated in captivity by allowing access to fresh feces from a healthy adult.[62]

Techniques for stimulating "slow to eat" neonates are species or diet specific. For carnivorous and insectivorous neonates, visual cues, including prey motion, have significant effects on feeding in hatchling Komodo dragons (*Varanus komodensis*), and live prey should be offered whenever legally possible to resistant feeders.[63] Live prey left with small reptiles can easily harm the neonate, so care should be taken in these situations. The same study in komodo dragons also found that chemical cues were important to the feeding behavior of hatchlings.[63] For species that have feeding preferences that are difficult to recreate in captivity, such as certain frog-eating snakes, scenting easier to obtain food items (e.g., rodents) with the scent from the preferred food item may aid in prey acceptance. Other appetite-inducing techniques may include "slap feeding" in snakes, warming of food items, or placing food in the neonates' mouth. In cases where true assist- or force-feeding must be performed, care should be taken to carefully calculate stomach volume (typically 1%–3% of body weight) and to gently use a soft pliable tube with lubrication so as not to harm delicate tissues.

NEONATE DIAGNOSTIC PROCEDURES

In many cases, diagnostic techniques utilized for adults can be similarly used in the neonatal patient. Complete blood count and plasma biochemical reference intervals for neonates have not been evaluated for any species known to the author, although studies are available that have evaluated limited analytes.[64,65] Additionally, most neonates are of a size that precludes venipuncture or severely limits the amount of blood that can be collected. Radiography may be utilized, and dentistry radiographic units may be most appropriate given the small size of hatchlings. Sex identification of hatchlings is an important topic, and there are many techniques utilized including endoscopic methods in a variety of chelonian species.[66,67] See Chapter 80 for a detailed discussion on sex identification. Necropsy of deceased neonates is advisable, and standard techniques similar to those used for adults are recommended.

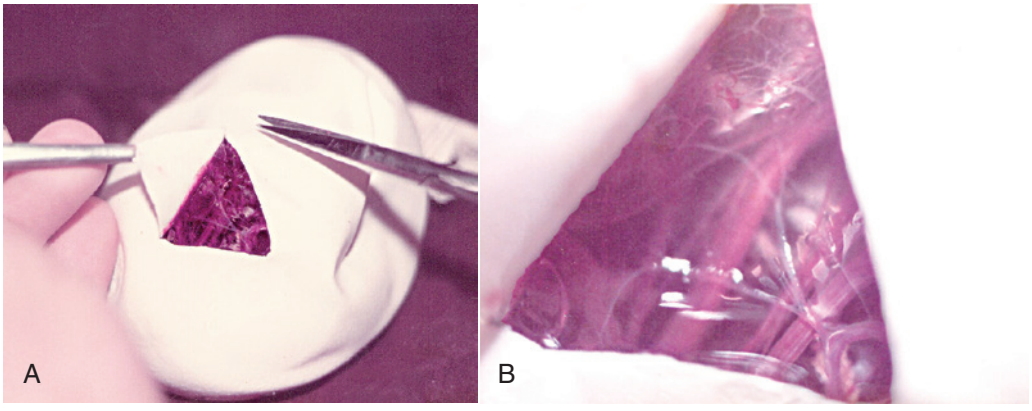

FIG 85.8 Occasionally, artificial pipping of the egg becomes necessary. (A) Using sterile technique and magnification, a triangular wedge is cut into the egg. (B) Extreme care is taken to avoid cutting or damaging the vessels of the extraembryonic membranes.

TABLE 85.3 Common Infectious Diseases and Associated Clinical Signs in Neonatal and Hatchling Reptiles

Etiological Agent	Species	Clinical Signs
Cryptosporidium saurophilum	Any lizard species, especially prevalent in the leopard gecko (*Eublepharis macularius*)	Poor body condition score, diarrhea, anorexia, failure to thrive
Agamid adenovirus 1	Bearded dragon (*Pogona vitticeps*)	Diarrhea, weight loss, anorexia, central nervous system dysfunction
Nannizziopsis sp.	Most lizard species	Crusting/ulcerative dermatological lesions; lesions often yellow in color in bearded dragons
Mycoplasma sp.	Chelonians	Conjunctivitis and ocular discharge, nasal discharge/bubbling, choanal inflammation
Ophionyssus spp.	Snakes and lizards	Increased shedding frequency, visible ectoparasites, increased soaking, anorexia, anemia
Testudid herpesvirus	Chelonians, especially Russian tortoises (*Agrionemys horsfieldii*)	Oronasal discharge, ocular discharge, fibrinous/necrotizing stomatitis

DISEASES

Yolk Sac Diseases

In most cases, the yolk sac has been absorbed into the coelomic cavity before hatching.[7] If this sac is not internalized at emergence, the neonate is at risk for yolk sac rupture and/or infection. If the internalization process has progressed to an advanced state, the natural progression of internalization may progress on its own if the neonate is closely monitored and maintained on a clean damp surface, such as a moistened paper towel. In cases where the umbilicus is pendulously attached to the neonate through the umbilicus, it is advisable to ligate and transect the yolk sac as proximal to the neonate as possible to reduce incidence of infection and allow the neonate to ambulate unencumbered. After transection, if the body wall is open, surgical closure should be performed. A strangulating umbilical cord that has not internalized the yolk must be addressed immediately.

Yolk sac infection may occur even if the yolk was internalized prior to emergence. The yolk may be infected prior to envelopment into the coelom, through an incompletely closed umbilicus and ascension from omphalitis, or it may become infected through ascension of intestinal bacteria from the vitelline duct. Infection of the yolk sac causes closure of the vitelline duct cutting off nutritional sources to the neonate, and the infected yolk and yolk sac may lead to generalized coelomitis. Affected neonates may have a palpable structure in the coelom and will show clinical signs of lethargy, anorexia, and general malaise. Exploratory coeliotomy with collection of bacteriologic samples after surgical removal of the yolk sac is indicated. Post-operatively, antibiotics, modified on culture and sensitivity results, should be administered.

Infectious Diseases

In general, any infectious disease that can affect the adult can also affect the neonate, although with their small size and incomplete immune function, neonates have a higher morbidity and mortality when exposed to these same pathogens. For example, the common snake mite (*Ophionyssus natricis*) may cause subclinical infections in adults, but this hematophagous mite can overwhelm and exsanguinate neonates in a short amount of time. Some classic species-specific pathogens in neonatal and juvenile reptiles are listed in Table 85.3.

The topic of salmonellosis should be discussed in more detail, because it is a common zoonosis (see Chapter 174). Despite a long-standing federal ban in the United States on the sale of turtles with a carapace length of less than 4 inches, continued multistate outbreaks of turtle-associated salmonellosis occur.[68] Although most reptile-associated salmonellosis in humans is linked with turtle contact, a variety of species have been implicated in infections, including bearded dragons, corn snakes (*Patherophis guttatus*), veiled chameleons (*Chamaeleo calyptratus*), and a variety of *Python* spp., among others.[68–70] Infection of the reptile neonate has been shown to occur transovarially and from salmonella-contaminated environments.[71] As it is considered a commensal in most reptiles, *Salmonella* spp. may or may not cause clinical illness in reptile neonates, the former being highlighted in a reported outbreak of salmonellosis in hatchling Nile crocodiles (*Crocodylus niloticus*) that was successfully controlled through supportive care, environmental decontamination, and systemic antibiotics.[72] Basic hygiene and awareness when dealing with neonatal reptiles is appropriate to reduce chances of outbreaks in reptile and human patients.

Husbandry-Associated Diseases

In general, any husbandry-related disease that can affect the adult can also affect the neonate; although, with rapid metabolism and growth, neonates have a higher morbidity and mortality when husbandry deficiencies are present. The most readily noted is nutritional secondary hyperparathyroidism (see Chapters 27 and 84) and is typically related to inadequate dietary intake of calcium and vitamin D3 (or lack of appropriate UVB lighting). Other common husbandry-associated diseases include sand/substrate impaction and predation by prey items and predation from cage mates due to inappropriate pairings or high stocking densities. See Section 3 for more details.

Congenital Diseases

Many congenital diseases have been reported in neonatal reptiles and may have a genetic or inappropriate incubation root cause. In the recent literature, two ball pythons were reported to have bifid ventricles secondary to an abnormally small-sized muscular ridge, and a patent urachus was diagnosed in a hatchling prehensile-tailed skink (*Corucia zebrata*) that was surgically corrected.[73,74] Diagnosis of a congenital lesion should prompt evaluation of the breeding stock and artificial incubation parameters.

TREATMENT CONSIDERATIONS

In general, the sick neonate should be afforded the same treatments as a similarly ill adult. This includes administration of appropriate analgesic and other medications, as well as nutritional, thermal, and fluid support. Due to the small size of neonates, medication administration can be challenging. Dosages for neonates that take into consideration differences that may exist in pharmacokinetics are lacking, and judicial use of dosages used in adults are often utilized. Concentrations of medications

may not be amenable to dosing and may require dilution. Consultation with a veterinary pharmacist may aid in developing medication-specific dilutions that are safe and efficacious. For instance, at least one injectable form of ivermectin (Ivomec 1% sterile solution, Merck & Co., Inc.) is suspended in a lipid carrier. Consequently, dilution with saline or sterile water may lead to nonhomogeneous distribution of the precipitated drug and potential patient overdose or underdose.

Injectable or oral administration of medications can be safely performed using the same guidelines as would be used in adults but with smaller instrumentation and greater care to prevent trauma. Injections can be given using insulin syringes that are available to measure to the nearest 0.005 mL (half unit on a U-100 syringe) (Fig. 85.9). These syringes have the added benefit of having small needle sizes to reduce tissue trauma. Oral medications can be given using insulin syringes after the needle is removed. A guitar pick can be an excellent tool to open small mouths.

Geriatric Medicine

Paul Raiti

The aging process (senescence) is defined as "a persistent decline in age-specific fitness components of an organism due to internal physiological deterioration."[1] Three patterns of senescence have been described for reptiles: rapid, gradual, and negligible.[2] An example of rapid senescence is observed in the African skink (*Trachylepsis buettneri*), which has an average longevity of 1 to 2 years. The majority of lizards and snakes undergo gradual senescence similar to most vertebrates. Chelonians and crocodilians are characterized by negligible senescence.[2] Reptiles have the record of the highest longevity among vertebrates (Table 86.1).[2] Growth rate of most reptiles declines with age. Age-related loss of organ weight and thymus atrophy have been considered secondary indications of senescence.[2] Most reptiles replace their teeth (polyphyodonty) throughout life, presumably to reflect the need for new sets of slightly larger teeth during the continuous growth of their jaws throughout their lifespan.[2] In most lizards and snakes, there is no evidence that tooth replacement ceases or slows down at advanced age, but in crocodiles the replacement rhythm becomes irregular and slower with increasing age. Decreased reproductive capability and the decline in capacity for regeneration are examples of morphogenetic senescence. Long-lived species live longer than short-lived counterparts, whether in natural surroundings or in captivity. Senescence occurs earlier in females with a high reproductive effort early in life compared to those with reproductive effort later in life; hence, there is a trade-off between early reproductive performance and longevity in reptiles.[3] Many reptile species exhibit increasing fecundity with advancing age through a direct physiological effect with increasing body size.[4] In addition to indeterminate growth, reptiles have the ability to shut down their metabolism for long periods of time.

Two theories have been used to characterize senescence. The first is the "oxidative stress" theory, whereby there is an age-related accumulation of cellular damage, and the second is the chromosomal "telomere attrition" theory, which accounts for the loss of DNA replication.[5] The oxidative stress theory of aging hypothesizes that senescence and death result from the accumulation of damaged biomolecules (free radicals) due to a declining ability to repair cellular damage with age.[5] Free radicals oxidatively damage the cellular components: DNA, protein, and lipid.[6] The damaging forces can be such stressors as UV radiation, heat, starvation, xenobiotics, pollution, pesticides, ozone, hyperoxia, etc.[6] Ascorbic acid and catalase have protective effects against lipid peroxidation and oxidative damage.[7] Telomeres are chromosome fragments that possess polarity, which prevents their reunion with any fragment after a chromosome has been broken; hence, they stabilize mitosis and meiosis.[8] Behavior is also an important aspect to consider in aging variation, as it relates to mating strategy,[9] mate choice,[10] and offspring dispersal.[11]

There are several hypotheses regarding the evolution of longevity. The relative reproductive rate hypothesis predicts traits that increase the reproductive output or survival rates of older compared to younger individuals, whereas the senescence hypothesis predicts a reduction in reproductive output or survival in older versus younger individuals.[12] Three traits—increased clutch size, reproductive frequency, and survivorship of individuals in the older age groups—support the relative reproductive rate hypothesis for evolution of longevity. Increases in survival and reproductive output are associated with larger body sizes of older individuals.[13] In many turtle species, increased reproductive output is associated with increased body size of females, because larger females produce larger eggs or larger clutches of eggs.[4] For example,

female Blanding's turtles postpone maturity to 14 to 21 years of age and produce a maximum of one clutch of 3 to 19 eggs annually.[4] Annual survivorship of adult females exceeds 93%, and some individuals can live in excess of 75 years.[4] Faster metabolic rates have been implicated with faster biochemical activity and a faster aging process.[14] The maximum amount of time a mammal can expect to live after maturity, even in captivity, is typically proportional to the amount of time it took that animal to reach maturity.[14] Species with low rates of mortality from extrinsic sources, such as predation, senesce more slowly and have longer maximum life spans than related species with higher rates of predation.[14] Studies of anurans and urodeles (salamanders, newts) have revealed that maximum body size is positively correlated with maximum life span in captivity.[15] Amphibians of northern regions (hibernation) have a longer life span than those of southern regions.[15] Chemically protected species (venomous or poisonous) generally live longer than their nonchemically protected counterparts of similar body sizes, and larger species are less likely to be chemically protected than smaller species.[16]

Morphometric criteria or growth curves/charts established for wild individuals may be skewed in captivity, as growth can be significantly affected by feeding regimen and husbandry.[17] Deficiencies lead to stunting whereas overfeeding, or power-feeding, accelerates growth.[17] Age determination is estimated by sclerochronology and skeletochronology using natural growth rings in epidermal scutes and bone, respectively. Counting growth rings through skeletochronological techniques involves harvesting bone from a live animal (distal phalange or tail) and using histology to estimate age. In a field study involving desert monitor lizards (*Varanus griseus*), it was determined that age could be estimated in adult specimens with an accuracy of ±2 years.[18] It should be noted that sclerochronology and skeletochronology reflect seasonal periodicity of growth and not necessarily yearly time sequences (Fig. 86.1). Under natural conditions, sclerochronological evaluation of geriatric tortoises can be problematic due to seasonal changes in growth, injuries, and abrasive forces associated with foraging, burrowing, etc., which tend to wear away growth rings. Additionally, some species of turtles lose the previous year's scute (*Chrysemys picta*), which affects reliability of growth ring counting. Under captive conditions, irregular growth rates associated with inappropriate diets, lack of ultraviolet B, inadequate hydration, lack of basking areas for semiaquatic turtles, etc., can distort and obscure growth rings. Rattlesnakes (*Crotalus* and *Sistrurus*) add a segment to their rattle with each ecdysis so that a crude age may be estimated by counting segments, but shedding in snakes is irregular, may occur 2 to 3 times each year, and the rattle often breaks as it gains in length.[17] Captive-born reptiles are generally longer-lived than their wild counterparts, because captivity shields reptiles from adverse climatic pressures, starvation, and predation. Captivity can affect longevity negatively if husbandry parameters are inappropriate. As a rule, captive-born animals are better acclimated to captivity and handling, are better feeders, and do not come with the heavy parasitic burden that wild-caught reptiles often bear.[17]

Unlike many mammals, which clearly show the aging process, senescent reptiles and amphibians often show few signs—and even these are subtle—until their death from natural causes.[17] There may be pigmentary changes, decreased mobility, and slowing of actions and reactions (Fig. 86.2). Ecdysis is usually less frequent in older squamates due to decreased growth rate but may also be more frequent with disease. Dysecdysis, hyperkeratosis, cutaneous growths and excrescences, broken tails and regrowths, missing toes and/or nails, and overgrown beaks are more common in senescent animals (Fig. 86.3A–C).[17] Constipation is common and may be caused by dehydration, diminished mobility, and renomegaly/urinary calculi. Degenerative bone and articular changes may also be encountered in geriatric reptiles (Fig. 86.4). Spondylopathies are prevalent in green iguanas, Komodo dragons, and snakes.[19] Symptoms can include reduced mobility, scoliosis, kyphosis, and paraparesis. Articular gout causes painful swelling of the limbs (Fig. 86.5). Diagnosis is by radiography and arthrocentesis (Figs. 86.6 and 86.7). Visceral gout, insidious and difficult to diagnose, may cause death with no premonitory signs or may cause various degrees of lethargy, anorexia, and other nonspecific signs.[17] Tachypnea, bradypnea, and dyspnea may indicate pulmonary disease or may reflect pain or metabolic disturbances. Atherosclerosis and vascular mineralization are common in older squamates and chelonians (Figs. 86.8).[17] What constitutes "geriatric" for a reptile or amphibian varies dramatically by species. (See Table 86.1 for longevities of assorted reptiles and amphibians[20]). Diminished appetite, weight loss, and cachexia commonly accompany significantly advanced age. Geriatric reptiles may bask more, possess sunken eyes, be less active, ambulate in a plantigrade stance, and appear

malnourished.[17] Breeding and reproduction usually decrease with advancing age. There may be fewer eggs or young and a diminished viability of those that are produced. Follicular stasis and egg retention can be problematic in geriatric reptiles (Fig. 86.9). Larger geriatric lizards such as green iguanas are more apt to sustain injuries associated with dyskinesia and/or fractures when they drop from their perches or accidentally fall while held (Fig. 86.10).

VETERINARY CARE OF THE GERIATRIC PATIENT

Geriatrics is defined as the branch of medicine that treats problems peculiar to old age and the aging, including the clinical symptoms of senescence and senility. Signs of senescence can mimic disease and should be distinguished with appropriate diagnostics such as hematology/plasma biochemical analysis and diagnostic imaging. Differentiating senescent-induced morbidity from active disease is not always a straightforward endeavor. Senescence itself is not a disease; however, there are diseases commonly associated with the aging process. Diagnosing age-related pathologies allows the clinician to suggest treatments and alternative husbandry methods that may improve the quality of life for aged reptiles. (See Table 86.2 for a list of common diseases of geriatric reptiles and amphibians).

External features or lesions suggestive of senescence in reptiles may be more a function of prior disease or trauma or may reflect inadequate or substandard husbandry.[17] Serial clinicopathology and radiographs establish baselines for each individual reptile and can be repeated every second year, yearly, or even more often, as the patient ages. Hematocrit, white blood cell count, hepatic and renal function, cholesterol, calcium/phosphorus, uric acid, T_4, and glucose are blood parameters that may change with age. Annual radiographs can optimize the odds of detecting bone and soft tissue changes in an individual reptile. In older females, egg-yolk coelomitis and ovarian neoplasia sometimes occur.

Fluid therapy and diuresis, xanthine oxidase inhibitors, dietary adjustments, and pain management are used to aid reptiles afflicted with articular gout. Infection or impaction of the femoral and perianal pores and hemipenal sulci in lizards, and scent glands and hemipenal sulci and hemipenes in snakes, tend to be seen more often in older individuals[17] (see Chapter 171). Tremors and fasciculations in geriatric reptiles are usually related to hypocalcemia secondary to renal secondary hyperparathyroidism (RSHP). Xanthomas (cholesterol granulomas) have been reported in the central nervous systems and coelomic cavities of geriatric reptiles, including geckos, green water dragons (*Physignathus cocincinus*), and snakes (Fig. 86.11).[21–23] Affected animals are usually sexually mature females. Xanthomas in the brains have been associated with various degrees of hydrocephalus; neurologic symptoms consist of opisthotonos, horizontal head bobbing, and incoordination.[21–23] A case of cerebral xanthomatosis was reported in a 13-year-old female long-nosed snake (*Rhinocheilus lecontei*) that presented for pronounced lethargy, anorexia, and diminished righting reflex.[21] Neoplasia, particularly lymphoproliferative disorders, is seen with increased frequency in older reptiles, especially chelonians and snakes. Neoplasia causes clinical symptoms that may be very slow to progress and vary according to the affected organ systems.[17] Lipid keratopathy (corneal lipidosis) occurs in some agamids and iguanids and has been seen in older green water dragons, plumed basilisks (*Basiliscus plumifrons*), and anurans.[17] This condition is usually associated with a high-fat diet. Ophthalmic age-related changes such as cataracts are similarly seen in reptiles as in other vertebrates (Figure 86.12). Additional diagnostic modalities, such as magnetic resonance imaging, bone scintigraphy, and endoscopy require immobilization to further define lesions or assess progression of disease in the older patient.[17] Short-acting or reversible drug combinations offer the widest safety margins for these geriatric reptiles. Tracheal intubation, placement of an intravenous or intraosseous access line, and the use of monitoring devices will help detect a complication and allow for early intervention.[17]

A literature search reveals a paucity of peer-reviewed sources addressing reptile geriatrics. One report describes cervical subluxation and compressive myelopathy resulting in nerve root and/or spinal cord

compression in four captive geriatric Komodo dragons.[24] Three were presumptively induced by trauma, and one had an unknown inciting cause. Two Komodo dragons had exhibited signs of chronic cervical instability. Clinical symptoms included ataxia; ambulatory paraparesis or tetraparesis to tetraplegia; depression to stupor, cervical scoliosis, and anorexia. Treatment ranged from supportive care to attempted surgical decompression. All dragons died or were euthanatized, at 4 days to 12 months postpresentation. The authors proposed that geriatric Komodo dragons may be anatomically predisposed, pathogenically predisposed, or both to cervical subluxation.[24] Arthritic animals may benefit from rearrangement of the enclosure/cage furniture, weight management, and judicious use of nonsteroidal antiinflammatory drugs.[17] Adjunctive techniques such as acupuncture, low-level therapeutic laser (photobiomodulation), massage, and physical therapy have been used in reptiles where improving blood flow aids healing.[25] Another report describes physical therapy, specifically the Wolf-Kinetic technique (WKT), as adjunctive therapy in the treatment of severe osteoarthritis in a 20-year-old Komodo dragon (*Varanus komodoensis*).[19]

The WKT is a gentle manual technique that is performed with the intent of changing movement patterns in a way that spreads out the work load of the body when the patient performs functional activities. The technique operates under the premise that the performance of the spine and core dictates the movement patterns of the extremities and that the spine and core must move normally for the extremities to move normally. This particular Komodo dragon had been managed with oral analgesics (meloxicam, tramadol, gabapentin, and chondroitin-glucosamine) for 3 years with fair to minimal response over time. Due to worsening of lameness and mobility, physical therapy was initiated. Ten treatment sessions were administered at 1-week intervals. Within 1 month the Komodo dragon exhibited marked improvement in gait and function, increased responsiveness to his environment, and increased mobility that continued to improve over the subsequent sessions. Physical therapy frequency was then reduced to every other week with no appreciable worsening of the animal's condition. By manually performing micromovements that harmonize with the patient's habitual movement patterns, the practitioner attempts to spread the workload throughout the body so that there is an appropriate, proportional amount of work being done as the body moves in functional patterns. Neural plasticity is the mechanism by which the damaged CNS relearns lost behavior in response to rehabilitation and includes the capacity of neurons to change their structure and function in support of normal development and learning, as well as in response to injury or disease.[19,26] After spinal cord injury, plastic changes occur at all levels of the CNS, including the cortex, other areas of the brain, and the spinal cord.[26] At the spinal cord level, there may be normalization of reflexes and strengthening of motor-evoked potentials. Neuroanatomically, axonal and dendritic sprouting and even neurogenesis have been observed. Other causes of morbidity and mortality in captive geriatric Komodo dragons over the past 20 years have included vascular mineralization and follicle rupture in females; renal disease, gout, or both; generalized infection; gastroenteritis; paralytic ileus; and neurologic disorders.[19]

Pain scales are commonly used for human pain assessment, but their use in animals relies on interpretation by the observer and is subject to variability.[26] Because not all animals outwardly respond the same to painful stimuli, recognition and assessment of the level of pain in each individual animal requires skilled observation by the veterinarian and the keeper or caregiver.[26] Some of the pharmaceutical advances in human and companion animal medicine have been adapted for zoological patients.[17] These include major and minor tranquilizers; some in longer-acting formulations; nonsteroidal antiinflammatories; serotonin reuptake inhibitors; better formulations of narcotics, including fentanyl patches; and other drugs.[17] Gabapentin and tramadol are labeled for use in humans but have shown positive results when used for pain control in animals. Zoo and companion animal veterinarians may use multimodal drug strategies and creative dosing regimens for end-of-life comfort and pain control. Most medications used in pain modulation for animals are considered "off label."[27] Routine measures to prevent illness, minimize stress or boredom-associated health problems, and enhance the quality of life for captive individual wild animals and small zoo populations are widely utilized.[27]

The Farm Animal Welfare Council has proposed that an animal's welfare be evaluated in terms of "five freedoms": freedom from hunger and thirst; freedom from discomfort; freedom from pain, injury, or disease; freedom to express normal behavior; and freedom from fear and distress.[27] The following issues should be addressed on a case-by-case basis. To what extent is a disease process affecting normal behavior such as food consumption, mobility, excretion habits, sleeping habits, and presence of pain? Geriatric reptiles may require daily assistance to ensure adequate hydration, thermoregulation, and nutrition as they face the challenges of old age. Daily prolonged observance of the pet, maintenance of a weekly log, and provision of humane captive conditions can significantly reduce morbidity and mortality.[28] To accommodate an aging arboreal lizard (iguana, basilisk, chameleon, etc.), an elevated basking area of easier access can be provided. Branches provided for climbing and basking can be replaced with flat, ridged boards several inches wider than the lizard's body. Geriatric semiaquatic turtles can be provided with readily accessed flat-ridged boards on which they can easily leave the water. Reduction of stressful circumstances is also important. Agonistic displays are intended to intimidate conspecific males. Even when kept in separate terraria across a room, a geriatric male will be unnecessarily stressed if he can view ongoing territorial displays by younger males. Altering dietary needs for aging reptiles and amphibians may also have to be considered. For example, digesting large prey items may become difficult for geriatric snakes, especially if cage temperatures are not ideal and stable.[28] Be certain that cage temperatures are appropriate and give the snake smaller-sized prey. The vitamin and mineral requirements of reptiles, particularly lizards and chelonians, may have to be increased with advancing age. Geriatric heliothermic (sun-basking) species often bask for longer periods and may preferentially choose temperatures a little warmer than normal.[28] By learning to read and interpret "normal" behavior, the caretaker will

be able to provide the reptile or amphibian with the best conditions possible throughout its life.[28]

PALLIATIVE AND HOSPICE VETERINARY CARE

Veterinary assessment combined with observations by the caregiver or owner should guide decisions about when declining quality of life may dictate euthanasia.[26,27] Increasingly, hospice services, palliative care, and grief and bereavement support are becoming incorporated into veterinary medical care.[27] The World Health Organization defines palliative care as "an approach that improves quality of life of patients and their families facing problems associated with life-threatening illness through the prevention and relief of suffering by early identification, impeccable assessment and treatment of pain and other problems, and physical, psycho-social and spiritual care."[29] For companion animals (including reptiles and amphibians), end-of-life issues, as interpreted from their owners' perspective, include addressing pain and symptom control, relationships with family and other animals, providing support and information for caregivers, and assisting with preparation for death and/or euthanasia.[27] These same issues also are applicable for captive wildlife in a zoological park setting. Those reptiles with hierarchical social structure and hospice patients may need to be removed from the group to reduce potential for injury because of aggression, or aggressive individuals may need to be removed from the group with a hospice patient.[27] The transition from curative medical intervention to palliative care should occur on a natural gradient; however, controversy exists regarding prolongation of life and "suffering."[27] In the zoo setting, a recognized hospice program can formalize who will be the animal's advocate and could even set up "advanced directives," such as no resuscitation. If worked out ahead of time, this can reduce the burden of decision making of others who may not be as able or as responsible from attempting to take on that role.[27] Primary concerns at the end of life include the following: adequate pain and symptom control, avoidance of inappropriate prolongation of dying, and ultimately achieving a good death.[29] Most of these goals are applicable and attainable for veterinary patients, including reptiles and amphibians.

The hospice movement is rooted in the centuries-old tradition of offering a place of shelter and rest or hospitality to the weary or sick traveler on a long journey.[30] Veterinary hospice is based on the same basic tenets as human hospice, which was developed during the late 1960s in the United Kingdom and during the early 1970s in the United States as an alternative to aggressive treatment or nontreatment of terminally ill people.[30] Central principles of hospice and palliative care emphasize comfort, relief of pain and anxiety, maintenance of the quality of life, and respect for the patient's needs and wishes.[27] In human medicine, hospice care most often is initiated when the physician believes that the patient is unlikely to live for more than 6 months; further curative medical treatment is unlikely to prolong the patient's life or would be so burdensome as to greatly reduce quality of life; or when the patient refuses such treatment and requests hospice care.[27,28]

For humans and animals, the most common condition necessitating hospice care is cancer. One key difference between humans and animals with regard to hospice care options is the availability of euthanasia for animals.[30] Veterinary hospice care includes 24-hour availability of the primary veterinarian, extended appointments involving supported decision-making and counseling, in-home care, and a wide variety of palliative and euthanasia options tailored to the needs of the client.[29] At-home hospice care gives family members more time to spend with the animal and may increase the animal's comfort and reduce any anxiety associated with being in the hospital. The AVMA Guidelines for Veterinary Hospice Care state, "Euthanasia service should be available if the client and veterinarian at any time believe this service is appropriate."[30] Most veterinarians consider timely euthanasia a part of hospice care. Euthanasia, derived from the Greek, "euthantos," literally means good or pleasant end of life. For reptiles and amphibians, the animal's caregivers, keepers, members of the public, and veterinarians and their staff must deal with the fact that euthanasia is an act intended to end life.[30]

Because the term hospice encompasses an increasing variety of end-of-life care philosophies and protocols, some veterinarians may find certain aspects of it controversial or problematic.[29] Some individuals and groups in the hospice movement believe that animals should not be euthanized or should be euthanized very rarely and will actively support a choice to not euthanize an animal if the client wishes. Thus veterinarians and clients must reach a shared understanding beforehand about the use of euthanasia.[30] When establishing a hospice program, legal advice should be sought regarding risk factors and insurance coverage for staff members, particularly staff members who travel to clients' homes.[30,31] Currently, many veterinarians are perceived as unfamiliar with hospice as a concept or practice, and the variety of uses of this word may compound this misapprehension.[30,31] Veterinarians and their support staff should be able to discuss hospice in such a way that they come to understand their clients' wishes.[28]

In recent years, two international symposia on veterinary hospice care organized by the Nikki Hospice Foundation for Pets and the Assisi International Animal Institute have begun to galvanize the veterinary profession on this issue.[30,31] By embracing hospice concepts and end-of-life care, veterinary practitioners can benefit from personal growth. It can help make one a better and more complete veterinarian, as well as improve relationships with animal care staff and strengthen our institutions.[31] Beyond providing pain relief and compassion, the formal recognition of hospice allows time for grieving, for celebration, and for saying goodbye.[30] With early recognition, the chances of treatment and/or attenuation of geriatric medical conditions increase dramatically. Factors such as genetic background, environment, nutritional history, and veterinary history influence the emergence of age-related conditions.[27,30,31] It has been stated that the quality of life in people and pets is a careful balance between pleasant and unpleasant feelings.[31] A number of progressive small animal veterinary practices, particularly those centered on oncology, have embraced hospice and make it a featured part of their practice.[27] It is only logical that in time reptiles and amphibians, particularly those maintained as companion animals, will become included in the practice of palliative and hospice veterinary care.

Emergency and Critical Care

Olivia A. Petritz and Tolina Tina Son

Do reptile emergencies actually exist? Yes, they most definitely do. However, reptiles are also presented on emergency for acute exacerbation of chronic diseases, seemingly more often than mammals. This, in combination with their slow metabolism, may present challenges for veterinarians and veterinary staff. Adequate staff training on the basics of triage (both on the phone and in person) is imperative. For example, prolonged anorexia in certain reptile species—for example, snakes—may not be a cause for an emergency presentation, which is the opposite for most mammalian species. Owners should also be instructed over the phone to secure their reptile in an escape-proof, ventilated container prior to transport. Ideally, the exact species should be determined prior to the animal's arrival. If the exact species is not known, at least an approximate weight, age, and taxa should be obtained, as some species' (chelonians especially) weights can vary greatly. Any reptile displaying one of the following clinical signs should be seen on an emergency basis: hemorrhage, seizures/tremors, moribund or unresponsive, organ prolapse, and dyspnea or open-mouth breathing. Emergencies should also include animals thought to be in pain or if a reptile experienced trauma, which would be considered painful in a mammal. And finally, regardless of the patient's condition, if an owner or caretaker is concerned about the animal's well-being and wishes it to be seen on an emergency basis, they should not be turned away.

PHYSIOLOGY AND OSMOLARITY OF BODY FLUIDS

In mammals, approximately 60% of an animal's body weight is water while 40% of the body weight is within the intracellular fluid compartment and 20% is within the extracellular fluid compartment.[1] In reptiles, excluding chelonians, approximately 71% to 75% of the body weight is fluid, with an equal distribution between the intracellular and extracellular fluid compartments.[2] The carapace and plastron of chelonians reduces their distribution of total body water closer to that of mammals, approximately 66%. The osmolal gradient maintains the fluid balance between the intracellular and extracellular spaces. An increase in extracellular fluid plasma osmolality will result in fluid shifting out of cells causing cellular dehydration. A decrease in extracellular plasma osmolality will cause fluid to shift into cells, resulting in cellular swelling. Rapid fluid shifts in either direction can have detrimental consequences.[1,2]

Osmolality refers to the number of osmoles per kilogram of solvent (expressed as milliosmoles per kilogram, mOm/kg), and osmolarity refers to the number of osmoles per liter of solution (expressed as milliosmoles per liter, mOm/L).[3] In biological fluids, the difference in osmolality and osmolarity is negligible, and the terms are often used interchangeably.[3,4] In clinical medicine, the term osmolarity is more commonly used and essentially refers to the concentration of osmotically active particles in a solution and is not related to the molecular weight, size, shape, or charge. Knowledge of the patient's normal osmolarity, as well as their osmolarity on emergency presentation, would be helpful for determining appropriate fluid therapy and minimizing detrimental fluid shifts. Most of the intravenous fluid products readily available on the market are formulated based on the plasma osmolarity of humans. Selection of the appropriate crystalloid solution for reptiles is confounded by a paucity of information about species-specific plasma osmolarity. Documented plasma osmolality and osmolarity in reptile species is reported to have a wide range.[5,6] Commercially available electrolyte solutions isotonic with mammalian blood have been recommended for terrestrial and marine chelonian species, as they may tolerate a wide range of osmolarity without adverse effects.[5,7]

Most of the documented normal osmolality ranges in reptiles have been similar to mammalian osmolality. For example, the mean measured plasma osmolality in 11 healthy adult male bearded dragons (*Pogona vitticeps*) was 295.4 ± 9.35 mOsm/kg, which is similar to normal osmolality ranges reported in dogs, cats, and other desert lizards.[8] Documented normal canine osmolality is 290 to 310 mOsm/kg, and reported normal feline osmolality is 290 to 330 mOsm/kg.[4] Plasma osmolarities of green iguanas (*Iguana iguana*) are reported to be 327 ± 3.3 mOsm/L and 300 mOsm/L.[6,9] Reported plasma osmolality of the desert-dwelling squamates, the Gila monster (*Heloderma suspectum*), is 292 mOsm/kg (range 284–298 mOsm/kg),[10] and osmolarity of the desert iguana (*Dipsosaurus dorsalis*) is 300 mOsm/L.[11] The mean measured plasma osmolality in a study of American alligators (*Alligator mississippiensis*) was 269.3 mOsm/kg.[7] This value was within the range reported in two previous studies, one in American alligators[12] and another in Nile crocodiles (*Crocodylus niloticus*).[13] The study in the American alligators evaluated the effects of chronic salt exposure and found the mean plasma osmolality ranged between 253.5 to 291.1 mOsm/kg.[12] In the study on Nile crocodiles, the mean plasma osmolality of animals in freshwater ranged from 258 to 319 mOsm/kg.[14] Plasma osmolality in adult corn snakes (*Pantherophis guttata*) ranged from 304.5 to 373.0 mOsm/kg, with a mean value of 344.5 mOsm/kg.[13] These values are higher than those of commercially available fluids (see Fluid Therapy later in this chapter). This difference should be considered when administration of large volumes of fluids are needed to avoid rapid and large shifts in the patient's plasma osmolarity. Ideally the use of crystalloid solutions that are significantly hypo-osmolar or hyper-osmolar to normal osmolarity should be avoided.

Determination of plasma osmolality can be performed either by direct measurement with an osmometer or by calculation based on formulas utilizing biochemistry values. Studies have shown that directly measured plasma osmolality in reptiles such as the American alligator had poor agreement with calculated values.[7] The authors of that study do not recommend calculating plasma osmolality using previously reported formulas. There was also poor agreement between measured and initially calculated osmolalities in bearded dragons until a new

formula was proposed to account for the differences in primary cations and anions in reptile plasma.[8] The authors of that study concluded that calculated values were not an accurate measure of the reptile patient's osmolality and recommend using those values with caution when administering fluids to a dehydrated or debilitated bearded dragon.

TRIAGE AND INITIAL ASSESSMENT

Emergency Anamnesis

A complete recount of the animal's history, including diet and husbandry, may seem impractical on an emergency basis. However, this information is vital to help determine the health status of the patient and can occur while general emergency support (e.g., oxygen, warm incubator) is being given. As previously stated, many emergency presentations are actually the result of chronic disease, with inappropriate husbandry still a large contributing factor. Therefore it is extremely important to ask detailed questions and critically evaluate the animal's diet, environmental temperature, humidity, cage setup, lighting, etc. Owners may even try to resolve any husbandry or dietary deficits just before the initial presentation, and as such, their answers to these questions may seem appropriate for the species, even though the animal still suffers from chronic disease resulting from poor husbandry. Additional standard historical information is also important to obtain, including duration and progression of any current abnormal clinical signs, recent additions or new exposure to another species, toxin exposure, previous medical/surgical problems, and a list of all current medications (including all supplements).

Temperature, Pulse, and Respiration (TPR)

Reptiles are ectothermic, and their body temperature varies with changes in the ambient environment. Each species has its own preferred optimal temperature zone (POTZ)—a temperature range in which all aspects of their metabolism and immune function are ideal. POTZ values for commonly seen reptile species have been published previously.[15] Medications should not be administered until a reptile has reached its POTZ, as their efficacy will be greatly diminished. Drugs administered during CPCR (cardiopulmonary-cerebral resuscitation) are an exception. Warming most reptiles to their POTZ should be achieved slowly over 4 to 6 hours and can be completed with various exogenous heating devices, including heated air blankets, warming blankets, incubators, and heat lamps. Larger reptiles, such as sea turtles, are typically warmed more slowly at approximately 1°C (1.8°F) per hour. The use of recirculating hot water blankets and warm water bottles should be used with caution due to risk of iatrogenic thermal burns. Reptiles should be housed in an appropriate thermal gradient, whether at home or in a hospital environment. Ill reptiles reportedly seek temperatures at the high end of their POTZ, and digital thermometers should be placed in multiple locations throughout the hospital enclosure.[16,17] Moribund animals unable to move and thermoregulate should be maintained at the upper end of their POTZ. A temperature range of 75°F to 85°F (24°C–29°C) is a good starting point for most reptile species if the POTZ is unknown (see Chapter 46).[17]

Respiratory rates can be obtained through visualization before handling, bearing in mind that they are usually much slower and may be intermittent. If no respirations are noted, a heart rate should be verified immediately and CPCR may be indicated. Opening of the mouth with each respiration is abnormal, and as in mammals, the clinician should determine whether the upper or lower (or both) respiratory tracts are affected. Dyspnea in chelonians may also manifest with extension of the head, neck, and forelimbs with each respiration. This should be differentiated from straining (to urinate, defecate, or pass an egg).

Auscultation with a stethoscope is challenging if not impossible in most reptiles, but their heart rate can be easily obtained with an ultrasonic Doppler probe directly over their heart or major artery. Distal arteries in extremities can also be used to assess pulse quality and rate, but flow may not always be detected, even in healthy, well-perfused reptiles.[17] In lizards, the probe is placed ventrally between their shoulder blades, or in larger species, in their axillary region. The hearts of varanids are more caudal than other lizards, and this affects Doppler probe placement. Thickened skin or osteoderms of larger lizards and crocodilians may inhibit standard ultrasonic Doppler use altogether, and then an ultrasound probe is required. In chelonians, a pencil ultrasonographic Doppler probe is recommended and can be placed in either axillocervical (cervicobrachial) area, directed ventrocaudally toward the heart (Fig. 87.1).

Confirmation of Death

Some reptiles presented for emergency evaluation may have already experienced respiratory or cardiac arrest, unbeknownst to the owners. According to the AVMA Guidelines for the Euthanasia of Animals, it is "difficult to confirm" death in reptiles and amphibians.[18] Certain reptiles, especially freshwater turtles, can tolerate prolonged periods of anoxia and corresponding severe bradycardia.[19] Corneal reflexes are difficult to assess in reptiles that lack eyelids, such as snakes and some geckos. Every reptile, even if unresponsive and in respiratory arrest, should be checked for a heartbeat using the methods described above. However, the presence of a heartbeat is not synonymous with "life," as reptile and amphibian hearts can and will continue to beat for hours after brain death.[18] An electroencephalogram (EEG) can determine brain activity in unconscious reptile patients that still maintain a heartbeat[20]; however, this test is not practical in most clinical settings. The reader is referred to Chapter 47 in this text for additional information on euthanasia.

DIAGNOSTICS AND MONITORING

Mucus Membrane Color, Capillary Refill Time, Blood Pressure

Routine physical exam assessments commonly used in mammals, such as mucous membrane color and capillary refill time, are not accurate reflections of perfusion in reptiles.[21] The most accurate and consistent assessment of a reptile's cardiovascular status is determination of the heart rate.[21] Because the heart rate is closely related to body temperature in reptiles, baseline heart rates should be recorded with temperature

VetBooks.ir

and while the patient is warmed to the POTZ. Noninvasive, indirect blood pressure measurement can be taken in reptiles using a sphygmomanometer and Doppler probe or oscillometric monitor, but readings are often inconsistent and inaccurate.[22,23] The most accurate assessment for arterial blood pressure measurement is the direct method, which is invasive and not practical for clinical use.

Blood Collection

Chapter 43 in this text reviews venipuncture techniques in all of the common reptile groups. Ethylenediaminetetraacetic acid (EDTA) is the anticoagulant of choice for hematologic studies, but it may cause lysis in certain species, especially chelonians. Blood volumes in reptiles vary from 4% to 8% of total body weight. Of this amount, up to 10% of this volume in a healthy patient can be safely collected for analysis.[16] As a rough approximation, the sample size should never be larger than 0.8% of the animal's total body weight. Estimation of blood loss through hemorrhage should be considered before taking blood from small animals. Pre-heparinizing needles and syringes before blood collection has been shown to cause significant and unpredictable hemodilution in packed cell volume and total solids and cannot be recommended.[24]

Assessment of Dehydration, Acid-Base, Electrolytes, and Perfusion

The severity of dehydration should be assessed to guide the fluid therapy plan. Subjective assessment of hydration should include evaluation of the eyelid turgor, skin turgor and elasticity, appearance of the eyes (sunken vs bright), mucous membrane tackiness, and saliva thickness. Mildly dehydrated reptiles may have dull skin with decreased skin turgor from loss of elasticity. Severely dehydrated reptiles (≥10%) may have sunken eyes, thick durable strands of saliva, durable skin wrinkles, dry mucous membranes, and a doughy abdomen (Fig. 87.2).[17] Sunken eyes can also be seen in severely emaciated animals. If the patient's healthy weight was known prior to becoming ill, the degree and rapidity of weight loss may also primarily reflect fluid loss.

Blood, if available, is preferred for an objective evaluation of dehydration. Evaluation of packed cell volume (a direct measurement and therefore preferred over a calculated hematocrit), total protein/solids, blood urea nitrogen (especially chelonians and crocodilians), uric acid (especially lizards and snakes), plasma sodium, and plasma chloride are helpful, and values should be correlated to the normal range for the given species, or indeed the same individual when healthy.[2] Urine-specific gravity is not as useful for assessment of prerenal dehydration as it is in mammals. Reptiles normally have hypo- to isosthenuric urine, and the urine-specific gravity does not increase above plasma osmolality during dehydration.[25] Also, significant post-renal modification of urine can occur across the bladder or cloacocolonic membranes. Perfusion is more challenging to assess in reptiles compared to mammals. Non-invasive blood pressure methods that are commonly used in mammals, such as a Doppler probe with a sphygmomanometer and oscillometric monitors, are often difficult or impossible to obtain with consistent accuracy in reptiles.[22,23]

The pH of reptile blood is variable and has been shown to be inversely related to environmental temperature.[26] General anesthesia can also lead to increases in blood pH. At temperatures between 23°C to 25°C, the normal blood pH of most reptiles ranges between 7.5–7.7.[27] It is postulated that the buffering systems of reptiles are similar to mammals, which would make the bicarbonate-carbonic acid buffer system the most important. Normal total CO_2 values for most reptiles are thought to be 20–30 mmol/L.[28] The most common causes for metabolic acidosis include renal failure, hypovolemia, and diarrhea.[29] A postprandial decrease of chloride and increase of bicarbonate has been reported in alligators, which will lead to a marked physiological metabolic alkalosis—this may also be true of other species.[28] Additional information regarding acid-base of reptiles in general can be found in Chapter 34 of this text, and acid-base parameters specifically related to rehabilitation of sea turtles can be found in Chapter 176.

Diagnostic Imaging

Radiography (including CT), ultrasonography, and other imaging modalities are important for emergency evaluation. Just as in mammalian patients, it is imperative that orthogonal radiographic views are obtained. This includes dorsoventral and horizontal-beam lateral views for lizards, snakes, and crocodilians (vertical-beam lateral is acceptable for crocodilians due to their unique compartmentalized coelomic anatomy), and dorsoventral, horizontal-beam lateral, and horizontal-beam craniocaudal views for chelonians. Single-view dorsoventral radiographs may be utilized as a screening tool for the presence of shelled eggs, metallic foreign bodies, and uroliths; however, a full image series complete with orthogonal views should always be obtained as part of a minimum database (Fig. 87.3). Larger reptilian species, especially large chelonians, may exceed the capacity of small animal radiographic machines, and a large-animal radiographic unit or computed tomography (CT) may be required. The use of abbreviated ultrasonography, such as *abdominal focused assessment with sonography for trauma* (AFAST),[30–32] is used extensively for emergency evaluation of canine and feline patients in emergency hospitals. There is no published equivalent for this in reptiles; however, ultrasonography still has a purpose for emergency evaluation, including determination of coelomic or pericardial effusions (see Chapters 53 through 59).

Electrocardiography

Electrocardiography (ECG) is not recommended in cold reptiles because of the challenge of identifying ECG wave boundaries.[33] The snake's heart is located in the upper third of the body, and ECG leads can be attached about two heart lengths cranially and caudally to the heart with self-adhering cutaneous skin electrodes.[17] In varanids, such as monitors and tegus, the ECG electrodes should be placed either on the limbs or torso. In other lizards, the cranial ECG electrodes should be placed in the cervical regions (as the heart is located at the level of the front limbs). In chelonians, the ECG leads can be placed on the limbs,

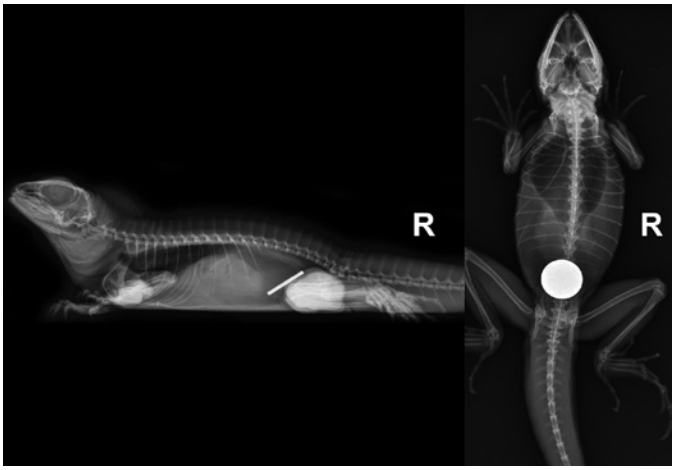

FIG 87.3 Right horizontal beam lateral and dorsoventral whole body radiographs of an adult Chinese water dragon (*Physignathus cocincinus*) that ingested a metallic foreign body (coin). (Courtesy of Karen Schachterle, ACCESS Specialty Animal Hospital.)

although placement of the cranial leads on the skin lateral to the neck and medial to the forelimbs may yield better readings.[17] In smaller species, the alligator clips from the ECG leads can be attached to hypodermic needles that are placed through the skin. See Chapter 68 for more details.

Pulse Oximetry

Pulse oximetry is a modality that is commonly used in emergency medicine for mammals but has limited use in reptiles. It has been shown to underestimate arterial oxygen saturation in green iguanas.[34] In reptiles, pulse oximetry accuracy is influenced by poor tissue perfusion, skin pigmentation, higher levels of methemoglobin, and significant taxa differences in respiratory physiology.[21] Current pulse oximeters are also calibrated to the human oxygen hemoglobin dissociation curve from which the SpO_2 values are calculated, which differs significantly from reptilian oxygen hemoglobin dissociation curves.[21] Therefore pulse oximetry may be used to monitor trends in reptilian species, but specific values should be interpreted with caution.

THERAPY AND INTERVENTION

Oxygen Therapy

In mammals, high carbon dioxide concentrations stimulate respiration; however, in reptiles, respiration is controlled by hypoxia, hypercapnia, and environmental temperature.[35] Many species differences exist, especially between aquatic and terrestrial reptiles. In most species, low oxygen concentrations increase respiration rate, and hypercapnia increases tidal volume. These tenants have been applied to recovery from general anesthesia, and, in a study in green iguanas, prolonged recovery from anesthesia was noted in patients that received 100% oxygen versus room air. This is in contrast to two recent studies in bearded dragons[36] and Dumeril's monitors,[37] both of which found minimal if no statistical difference between animals recovered in room air (approximately 21% oxygen) and 100% oxygen. In cases of true hypoxemia, supplemental oxygen therapy, via facemask or endotracheal tube, is recommended.[17] In fact, it has previously been shown that administration of 100% inspired oxygen resulted in a significant increase in PaO_2 in conscious green iguanas, with no changes in respiratory rate.[34]

Cardiopulmonary Cerebral Resuscitation

Cardiopulmonary arrest is defined as the abrupt cessation of spontaneous and effective ventilation and systemic perfusion. Cardiopulmonary cerebral resuscitation (CPCR) provides artificial ventilation and circulation until advanced life support can be provided and spontaneous circulation and ventilation restored. Basic life support is the cornerstone of CPCR and includes airway management, ventilation, and circulation with external or internal chest compressions. Advanced life support provides more specific interventions based on circumstances of the arrest. The American Heart Association (AHA) publishes updated human guidelines for CPCR, which are often extrapolated for veterinary medicine. There are no established standard guidelines for CPCR in reptiles as there are in humans (AHA) and dogs and cats (RECOVER).[38] Although many of the basic principles of CPCR are applicable, physiological differences among reptile species must be considered.

Airway stabilization via tracheal intubation should be performed with positive pressure ventilation at 6 to 8 breaths per minute and peak positive pressure not to exceed 8 cm water.[17,39] Positive pressure ventilation can be provided via an Ambu bag (Ridge Medical, Lombard, IL) or anesthetic machine. Given that temperature and partial pressure of oxygen are primary stimulators for ventilation in reptiles, in theory, oxygen supplementation may decrease the reptile's own stimulus to breathe. No studies have been performed to assess the role of oxygen therapy in reptile CPCR. Therefore it may be reasonable to initiate CPCR with 100% oxygen when the degree of hypoxemia is unknown, then potentially wean the inspired oxygen gradually to room air to encourage spontaneous breathing.

Cardiovascular monitoring with Doppler scanning and ECG should be performed. If no heart beat is detected, IV or IO epinephrine should be administered at 0.5 mL/kg of the 1:1000 epinephrine concentration.[17] If IV and IO routes are not possible, then the epinephrine should be administered via a catheter through the endotracheal tube at twice the IV dose and diluted with sterile saline at 1 mL/100 g of body weight.[17] Cardiac compressions should be performed when direct cardiac compressions are possible. Atropine can be administered at 0.01 to 0.04 mg/kg IV, IO, or IM, or at 0.2 mg/kg SC or IM.[17] Normal heartbeats can vary from 30 to 100 beats per minute, and IV or IO fluids should be administered to address hypovolemia (see recommendations below). Additional supportive care such as thermal support, blood transfusions, and concurrent treatment for the underlying disease should be provided.

Doxapram has previously been used in cases of severe respiratory distress or cardiopulmonary arrest, but its effect in reptiles has not been as thoroughly evaluated as it has in humans and other mammals.[40] Doxapram is a central nervous system stimulant with various uses in veterinary medicine, such as stimulating respiration in newborns, hastening the awakening from anesthesia, treating respiratory depression, and assisting in diagnosis of laryngeal paralysis in dogs. The use of doxapram is not currently recommended during CPCR in humans, dogs, and cats for reasons such as reducing the cerebral blood flow while increasing myocardial oxygen requirements, resulting in cerebral and myocardial hypoxia.[41,42] Doxapram can also cause transient hypotension before its stimulatory effects.[43] To the authors' knowledge, the effects of doxapram in reptiles during cardiopulmonary arrest have not been studied.

Fluid Therapy

Early goal-directed therapy has demonstrated benefits in outcome in human patients with septic shock and likely increased survival advantage in other patient populations.[44] This treatment strategy has been recommended in veterinary patients as well.[11] This goal-directed strategy directs resuscitation efforts toward restoration of an effective circulating

VetBooks.ir

blood volume and adequate end-organ perfusion.[11] The first line of perfusion restoration, and a fundamental component of early goal-directed therapy, is expansion of the intravascular space with fluid therapy. Due to limited veterinary studies, veterinary recommendations have mostly been extrapolated from human studies. The optimal fluid resuscitation plan remains controversial and is still subject to debate.[11,45] Goal-directed therapy in reptiles would also be beneficial, and applicable guidelines should be extrapolated in light of the significant differences and limitations in monitoring and assessing reptiles compared to mammals.

Maintenance fluid rates range from 10 to 15 mL/kg per day in most reptilian patients.[46] The fluid therapy plan should include calculating the patient's maintenance fluid requirements plus dehydration deficits. The fluid deficit volume should be replaced at a rate related to how long the patient may have suffered the fluid loss. Acute fluid losses may be replaced more rapidly than chronic losses. A fluid deficit replacement rate over 72 to 96 hours has been suggested to avoid interstitial overhydration secondary to overly rapid fluid therapy.[47,48] Boluses of crystalloids (5–10 mL/kg) and colloids (3–5 mL/kg) can be given to address perfusion deficits.[17]

Routes for fluid therapy in reptiles include enteral (oral and cloacal), intracoelomic, subcutaneous, intravenous, and intraosseous. Similar to mammals, intravenous or intraosseous fluid therapy is preferred for the critical patient. However, access to these sites are often more challenging in reptilian patients (see Chapter 44). Additional fluid administration routes include subcutaneous and intracoelomic. The authors advise against intracoelomic fluid administration in reptiles due to reduction of space for lung expansion; potential for perforation of lung, intestine, or urinary bladder; and slower rate of absorption.[49] Depending on the species, provision of high environmental humidity can help minimize insensible fluid losses.

Monitoring and reassessment of the patient should be performed regularly during fluid resuscitation. Animals receiving IV or IO fluid therapy should not be left unmonitored over night. Clinical signs of improvement in hydration and perfusion include improvement in mucous membrane moisture and color, skin turgidity, eye position, and mental state. The heart rate, if at their optimal temperature, should also improve. Rechecking blood results can also be performed to monitor progression. Accurate body weight is a useful parameter to monitor in patients receiving fluid therapy, because the amount of weight gain will reflect the amount of fluid gain and correction of the estimated dehydration. Monitoring urination may be useful but one should be aware of the species differences in urination habits. Well-hydrated chelonians should urinate approximately every other day, and the urine volume can range from 0.5% to 3.0% of body weight.[50]

The only visible peripheral vessel in reptile patients is the dorsal buccal vein in snakes, and, due to its location inside the oral cavity, it is not a practical location for indwelling catheter placement in the conscious patient but may be appropriate for a moribund animal.[2] For placement of most intravenous (IV) catheters in reptiles, a cut-down technique is required. In lizards, the cephalic vein can be accessed via cut-down technique, and it is located in a similar location as in mammals, traversing across the antebrachium. The ventral coccygeal vein has also been used for IV catheter placement in lizards (Fig. 87.4). It is accessed blindly, in a similar fashion to venipuncture of this vessel. There have been several reported cases of distal tail necrosis secondary to intravenous placement in this location in several lizard species, and this should be considered. Intraosseous catheters can be used as a substitute for intravenous access, especially in cases of hypovolemia and/or hypotension. The most common placement sites in lizards include the femur, humerus, or tibia (Fig. 87.5). However, possible complications and considerations for this method are leakage, pain and discomfort, and possible osteomyelitis. Additionally, in reptiles that have nutritional or renal secondary hyperparathyroidism, their compromised bone structure may not support an intraosseous catheter. In snakes, the jugular vein is the most readily accessible, and the right is usually larger than the left. For visualization, a right lateral incision is created 4 to 7 scutes cranial to the heart, at the junction of the ventral scutes and first lateral scale row, or between the first and second lateral scale rows.[17]

The jugular vein of chelonians is the most readily accessible peripheral vessel for IV catheter placement. Long-term jugular catheter placement through a modified Seldinger technique has also been described in chelonians (Fig. 87.6).[51] Intraosseous catheters can be placed in chelonians—the humerus, femur, gular region of the plastron, and the plastrocarapacial junction (bridge) have been described. The humerus and femur are reportedly the most effective in the desert tortoise (*Gopherus agassizii*) when compared with an intravenous jugular catheter.[52] Additionally, a high failure rate for intraosseous fluid administration into the carapacial bridge in the yellow-footed tortoise (*Chelonoidis denticulata*) has been described, and this site was not recommended in this species when they are greater than 3 kg in weight.[53] See Chapter 44 for more details.

Crystalloid Fluids. Crystalloid fluids contain small solutes, mostly electrolytes, that are capable of entering all body fluid compartments and primarily exert their effects on the interstitial and intracellular compartments. Crystalloids have insignificant oncotic (colloidal osmotic) pressure. After infusion of crystalloids, rapid distribution into the

VetBooks.ir

extracellular space occurs with 60% to 80% of the administered volume redistributed out of the vascular space and into the interstitium within 30 to 60 minutes in mammals.[45] Only 25% of the infused crystalloid remains in the intravascular space after 30 minutes in mammals.[45] Compared with colloid solutions, larger amounts of crystalloid solutions are required to expand the intravascular space and restore perfusion.

The osmolarity of the commonly available isotonic parenteral crystalloid fluids include Plasma-Lyte A (294 mOsmol/L; Baxter Healthcare, Deerfield, IL), Normosol-R (294 mOsmol/L; Abbott Laboratories, Chicago, IL), lactated Ringer's solution (273 mOsmol/L; LRS; Abbott Laboratories), 5% dextrose (253 mOsmol/L; D_5W), and 0.9% NaCl (308 mOsmol/L) (Table 87.1). Combination fluids can also be made to tailor to a patient's specific needs. Various osmolarity studies in reptiles have shown reptilian osmolarity to be more similar to mammalian osmolarity than previously thought. Further support for the use of the readily available standard crystalloid solutions is given by studies that have shown that reptiles can tolerate severe dehydration as well as a wide range of plasma osmolarity (250 to 400 mOsm/L) and electrolyte concentrations.[46,48]

FIG 87.6 An adult leopard tortoise (*Stigmochelys pardalis*) with a central line catheter in the jugular vein, an esophagostomy tube for nutritional support, and an indwelling urinary catheter. (Courtesy of Stephen J. Divers.)

Diluted crystalloid fluids such as half-strength LRS/$D_{2.5}W$ (262 mOsm/L) or 0.45% NaCl/$D_{2.5}W$ (280 Osmol/L) should be used at the discretion of the clinician. Normal saline is isotonic but is not a physiological buffered solution. It contains a higher concentration of sodium and chloride than other commercially available isotonic fluids and also has a higher osmolarity of 308 mOsm/L. Use of normal saline could be considered for patients with severe hyperkalemia, hypercalcemia, or hypochloremic metabolic alkalosis. Use of large volumes of saline could result in hypernatremia, hyperchloremia, and hyperchloremic metabolic acidosis.[45] Given the potential adverse effects of saline, isotonic crystalloids such as Lactated Ringer's and Normosol-R have been more widely recommended. These solutions are more physiological than saline, contain electrolytes, and contain a buffer such as lactate or acetate.[45] Crystalloid solutions can be classified as "replacement" (e.g., lactated Ringer's, Normosol-R, Plasmalyte 148) or "maintenance" solutions (e.g., Normosol-M, Plasmalyte 56).[54] The composition of replacement fluids resembles that of extracellular fluid and has a similar osmolarity to mammalian plasma (290 to 310 mOsm/L).[54] Maintenance fluids contain less sodium (40 to 60 mEq/L) and more potassium (15 to 30 mEq/L) than replacement fluids and are therefore hypotonic to plasma. Maintenance fluids should never be given as a rapid bolus due to the risk of cerebral edema.[54,55]

Concerns that the use of lactated crystalloids may be harmful to reptiles have not been validated. Reptiles produce lactate and use anaerobic metabolism during shock. Reptiles have been shown to tolerate high blood lactate levels such as 20 mmol/L, most likely making the amount of lactate in commercially available crystalloids clinically irrelevant.[56] Lactate is rapidly converted to bicarbonate by the liver, and use of lactate-containing fluids is not contraindicated

unless there is concern for hepatic dysfunction.[55] Complications of crystalloid therapy, especially with high volumes, include interstitial fluid gain and expansion of the extracellular space, causing damage to the endothelial surface and impaired capillary exchange. Clinical signs can include interstitial edema, pulmonary edema, cerebral edema, and other organ dysfunction.[45,55] Anemia, hypoproteinemia, electrolyte abnormalities, and hypocoagulability can also occur with large volume crystalloid administration due to hemodilution.[55]

Hypotonic fluids have an osmolarity and sodium concentration much lower than plasma osmolality. Examples of hypotonic fluids include 0.45% saline (154 mOsm/L) and 5% dextrose in free water. Although the 5% dextrose in free water is an isosmotic solution (252 mOsm/L), it has hypotonic effects because the dextrose is rapidly metabolized, leaving behind free water (0 mOsm/L). Hypotonic fluids can be used judiciously to replace free water deficits and treat patients with hypernatremia secondary to hypotonic fluid loss and may also be a safer choice for treating patients with a decreased ability to excrete excess sodium (e.g., renal disease) or decreased tolerance to increased intravascular volume (e.g., heart disease).[57] Hypotonic fluids should never be given as a bolus for intravascular volume resuscitation as they are ineffective at expanding intravascular volume and may also cause life-threatening cerebral and cellular edema.[57] Sterile water (0 mOsml/L) should never be administered intravenously due to the risk of intravascular hemolysis and endothelial damage.[57]

Hypertonic fluid solutions, such as 3% to 7.5% saline, have a higher osmolarity and sodium concentration compared to the patient. Administration of hypertonic solutions causes an osmotic shift of free water from the intracellular space to the extracellular space and can expand the extracellular fluid volume by 3 to 5 times the volume administered.[57] Hypertonic saline may be useful for treatment of hypovolemic shock, intracranial hypertension, and severe hyponatremia (especially given the relatively higher intracellular water content of reptiles). A dose of 3 to 5 ml/kg can be administered as a slow bolus and should be followed with isotonic crystalloids or colloids. Hyperosmotic solutions can cause hemolysis and phlebitis, especially if given repeatedly or through small peripheral veins.[57]

Colloids. Colloid solutions contain larger molecules (>10,000 Da) that tend to remain in the intravascular space after intravenous administration. Natural colloids include whole blood, plasma (fresh, frozen, and thawed), and albumin. Natural colloids such as serum albumin have had controversial effects in dogs, but its use has not been reported in reptiles. To the authors' knowledge, use of plasma administration has also not been reported in reptiles.

Polymerized bovine hemoglobin (Oxyglobin, Biopure, Cambridge, MA) had been commonly used but is currently unavailable. Commonly used synthetic colloid solutions include hydroxyethyl starches such as hetastarch and tetrastarch products. Colloid fluid therapy should be considered in patients that would benefit from intravascular volume resuscitation. Such patients may have severe hypoalbuminemia, hypovolemia, decreased vascular perfusion, or increased capillary permeability. Colloid solutions can be given to reptiles as a 3- to 5-mL/kg bolus over 30 to 60 minutes, and the patient should ideally be reassessed during and after fluid bolus.

Hydroxylethyl starch (HES) solutions are a widely available, cost-effective treatment option for rapid volume expansion. HES solutions are mostly available as an isooncotic 6% formulation. In mammals, synthetic colloidal solutions have been recently associated with adverse effects, including acute kidney injury, coagulopathies, pathologic tissue uptake, pruritus, reticuloendothelial dysfunction, hepatopathies, and anaphylactoid reactions.[45] The coagulopathic effects of HES solutions in mammals are dose dependent.[45] There is much debate on the safety of HES solutions, and they were recently banned in Europe. Coagulopathic effects have been documented in veterinary medicine, as well as human medicine, although the other adverse effects such acute kidney injury have not been scientifically documented in veterinary medicine at this time. Use in reptiles has not yet been investigated.

Whole Blood. Whole blood transfusions are recommended in cases of acute severe hemorrhage and life-threatening anemia. Ideally a whole blood donor of the same species from the same collection is utilized. Given the thousands of different reptile species, finding a conspecific donor may not always be possible. Heterologous blood transfusions from a different species may be necessary and may still be beneficial (Fig. 87.7). Whole blood transfusion doses of 10 to 15 mL/kg every 24 hours at a rate of 5 to 10 mL/kg per hour has been recommended.[29] The whole blood should be kept cool and warmed to 25° to 30°C prior to administration; the blood should be given within 6 hours of collection.[29] Aseptic technique in collection and handling should always be maintained. Anticoagulants that can be used for blood collection include citrate-phosphate-dextrose adenine (CPDA) in a ratio of 1:9 (CPDA to blood) or heparin at a dose of 5 to 10 units per 1 mL of blood.[29]

Incompatibility reactions such as red blood cell agglutination between both homologous and heterologous donor-recipient pairs have been anecdotally reported; therefore it is advised to perform crossmatches whenever possible. Up to 10% of the total blood volume can safely be removed from a healthy reptile donor.[58] At least 4 weeks should be allowed between blood donations from a given donor.[29] Several case reports have described the successful use of homologous and heterologous blood transfusions.[59] Potential complications of blood transfusions have been infrequently reported. Orange urine post-transfusion in a Hispaniolan slider (*Trachemys decorata*) was noted but was not confirmed to be due to the blood transfusion, because oxyglobin had also been administered.[59] The slider recovered well with no other noted abnormalities. An increased leukocyte response was seen after rapid heterologous blood transfusions in a diamond python (*Morelia spilota*) and a bearded

dragon; this leukocyte response was suspected to reflect a possible destructive immune reaction, although no clinical recognizable signs of reactions were observed (McCracken, personal observation).

The use of a blood filter such as the Hemo-Nate18-μ filter (Utah Medical Products, Ltd., Midvale, UT) is standard of care during a blood transfusion to prevent clots and particles from being transferred to the recipient. The 18-μ Hemo-Nate filter resulted in no hemolysis or significant decreases in the packed cell volume in American alligators (*Alligator mississippiensis*) and is recommended for whole blood administration to reptiles.[60]

Analgesics

Many emergency presentations in veterinary medicine involve a pain response, and analgesics are one of the tenants of therapy—reptiles are no exception. Unfortunately, pain has often not been recognized or treated appropriately in reptiles by owners and veterinarians alike. There have been significant advances in the field of reptilian analgesia in the last decade, and any clinician who treats reptiles on a routine or emergency basis should become familiar with these protocols. Although butorphanol used to be the most common analgesic administered to reptiles, it has since been proven to have no analgesic efficacy (determined by use of a thermal noxious stimulus) for a variety of doses in red-eared sliders (*Trachemys scripta elegans*),[61] bearded dragons,[62] and green iguanas.[63] The data on butorphanol usage in snakes is conflicting, with variable analgesic efficacy at high doses in corn snakes[62] but no efficacy on physiological variables in ball pythons when administered at 5 mg/kg IM.[64] Similarly, buprenorphine did not show any analgesic efficacy in green iguanas exposed to an electrical stimulus,[65] nor in red-eared sliders exposed to a noxious thermal stimulus.[66]

Morphine sulfate has been proven to be an effective analgesic in bearded dragons[62] and in turtles.[61,67,68] Significant respiratory depression has occurred at high doses of morphine in certain species, and administration of >5 mg/kg is not recommended.[69] Regardless of the dose, it is recommended to monitor respiratory rates, especially debilitated patients, after parenteral use of μ-opioids. Hydromorphone provided thermal antinociception to healthy red-eared sliders at a dose of 0.5 mg/kg subcutaneously for up to 24 hours, with significantly less respiratory depression.[66] Tramadol, a weak μ-agonist, also has shown analgesic efficacy in red-eared sliders at a dose of 5 to 10 mg/kg[70] and is available for oral administration.

Limited data are available on the use of nonsteroidal antiinflammatory drugs (NSAIDs) in reptiles—particularly their analgesic efficacy and potential negative side effects. No physiological changes indicative of analgesia were noted in ball pythons administered meloxicam at 0.3 mg/kg before a surgical procedure.[64] Pharmacokinetics after intramuscular administration (0.2 mg/kg) of meloxicam has been evaluated in green iguanas,[71] yellow-bellied sliders (*Trachemys scripta scripta*),[72] and red-eared sliders.[73] No significant side effects were noted after these single-dose studies, but clinical efficacy was not assessed. In addition to parenteral administration of meloxicam in yellow-bellied sliders, oral administration was also evaluated, which revealed very low plasma concentrations. Therefore oral administration of this dose could not be recommended in this species. Similar to mammals, the use of NSAIDs in dehydrated patients or those with renal or gastrointestinal disease should be undertaken with caution. For more details on analgesia in reptiles, the reader is referred to Chapter 50.

Antibiotics

Broad-spectrum antibiotic therapy has frequently been recommended in cases of severe integumental (e.g., burns) or gastrointestinal (e.g., intestinal breach and gut-origin sepsis) compromise. However, a systematic review and meta-analysis in human burn victims concluded that antibiotic prophylaxis had no impact on patient survival.[74] In addition, strict criteria and recommendations exist for antibiotic use in cases of gut-origin sepsis.[75] Therefore, given antimicrobial resistance concerns, the essential need for the reptile to be normothermic and hydrated, and the time taken for these drugs to have an appreciable effect, broad spectrum antibiotics are rarely indicated in the reptile emergency room. Specifically, the routine use of advanced cephalosporins and fluoroquinolones should be discouraged, while an antibiotic policy that advocates first-line drugs should be created.[76]

Antibiotic selection would be made based on results of culture and sensitivity testing; however, empirical antibiotic selection may be required before these results are available. In-house cytology and gram stains of potentially infectious exudate may offer some initial direction for antimicrobial therapy. Nevertheless, antibiotics should only be administered after samples have been submitted for microbiological (bacterial and/or fungal) culture, and the patient hydrated with an appropriate body temperature.[76] For a more in-depth review of antibiotic therapy in reptiles, the reader is referred to Chapter 116 in this text.

Other Therapeutics

Reptiles in an acute hypocalcemic crisis will have signs of muscle tremors or seizures, usually as a result of nutritional secondary hyperparathyroidism. Phosphorus, as well as total and ionized calcium, should be evaluated prior to treatment because parenteral calcium may not be required if ionized calcium is acceptable. Calcium gluconate (50–100 mg/kg) should be administered by subcutaneous, intramuscular, or intravenous administration.[77] While calcium chloride contains more elemental calcium in each milliliter of solution, it is extremely irritating to tissues and should only be given intravenously. As in mammals, intravenous administration of calcium should be given slowly, and the heart rate and rhythm should be monitored with an ECG. In cases of concurrent hyperphosphatemia, parenteral calcium supplementation may significantly elevate the solubility index and lead to soft tissue mineralization; therefore phosphate binders and diuresis may be required, along with carefully titrated IV calcium therapy and regular monitoring.

The goal for calcium supplementation, especially in the critical patient, is to alleviate the clinical signs of hypocalcemia rather than to achieve normal plasma calcium concentrations.[78] When the signs of hypocalcemia have resolved, oral calcium supplementation should be initiated with calcium glubionate or calcium carbonate. Severe, chronic hypocalcemia can progress to grand mal seizures, which often require use of midazolam or diazepam in addition to parenteral calcium.[79] Additional information can be found on seizures and nutritional secondary hyperparathyroidism in this text in Chapters 77 and 84, respectively.

Severe hyperuricemia (>25 mg/dL, >1480 μmol/L) can quickly lead to visceral gout and a grave prognosis; therefore administration of allopurinol (25 mg/kg/day) should be considered.[80] Additional information can be found in Chapter 66.

COMMON REPTILE EMERGENCIES

Traumatic Emergencies

As with all species, traumatic injuries often requires emergency evaluation and management. The most common cause of trauma in the authors' practice is predator (another house pet or cagemate) or prey bite wounds (Fig. 87.8). Additionally, hit-by-car injuries, most often in chelonians resulting in shell fractures, are also common emergency presentations. Some owners remain unaware of the severity of the injuries sustained and present the animal for evaluation hours to days after the traumatic event. Specific triage parameters for chelonian shell injuries have been previously published[81] and are discussed in Chapters 113 and 130.

FIG 87.9 A 13-year-old male green iguana (*Iguana iguana*) with a recently prolapsed left hemipenis. (Courtesy of Olivia A. Petritz, NCSU.)

Thermal burns, which may not manifest for several days after injury, should also be addressed as quickly as possible so the appropriate analgesics and fluids can be prescribed (see Chapters 69, 70, and 130). Iatrogenic traumatic injuries inadvertently caused by owners have also been reported, including drill-bit trauma in a blood python.[82] Long bone fractures are another cause for emergency presentation, and methods of external coaptation and surgical fixation are described in Chapters 108 and 109. In brief, the initial management of open fractures is very similar to small mammals, and the same principles should be followed.

Respiratory/Cardiac Emergencies

Acute respiratory emergencies are uncommon, and most are a severe manifestation of chronic disease. Accurate localization of the disease to the upper or lower airways is imperative and follows the same principles from domestic mammal emergency medicine. Common causes of respiratory distress in reptiles include obstructions within the oropharynx or trachea (granuloma, foreign body, neoplasia [tracheal chondroma in ball pythons[83]]), pneumonia, and drowning.[35] Coelomic distension secondary to ascites or organomegaly can also lead to respiratory compromise due to the lack of a diaphragm. Trauma, such as hit-by-car injuries in chelonians, may involve the lungs and present with respiratory distress. Drowning is most commonly seen in chelonians, but any reptilian species is susceptible if given access to deep enough water. These animals may be comatose with no deep pain or corneal reflex on presentation.[17] Despite this seemingly grim prognosis, CPCR is recommended, and successful recovery is possible. Intubation and suctioning of the trachea should be performed in cases of respiratory arrest, as well as placing the chelonian in a head-down position to allow for drainage of fluid. Intermittent positive pressure ventilation and maintaining the animal in its POTZ are usually beneficial.

The most common cardiovascular emergency is severe hemorrhage,[17] and the same principles of hemostasis known in mammals also apply to reptiles. Expedited and effective hemostasis is of utmost importance, as reptile erythrocytes have lower total counts, longer life spans, and slower turnover rate when compared with mammals.[84] Another acute presentation for cardiac emergencies is exposure to cardiac glycosides from the ingestion of fireflies and certain butterfly species in bearded dragons. Shortly after ingestion, dragons exhibit gaping behavior, black beard (gular skin pigmentation) lethargy, depression, and death. Treatment is nonspecific and supportive and often not successful (see Chapter 88). Other cardiac diseases (congestive heart failure, endocarditis, pericardial effusion) usually have a slower onset of clinical signs and are uncommonly presented on an emergency basis (see Chapter 68).

Urogenital Emergencies

A cloacal prolapse can involve one (or more) of the three systems that all terminate at the cloaca: the reproductive, urinary, and gastrointestinal tracts. The clinician should determine whether the prolapsed tissue is viable and which structures are involved. The oviduct and gastrointestinal tracts are both tubular structures with a lumen—longitudinal striations can help differentiate the oviduct from other tissues. The bladder, if present, is a thin-walled, fluid-filled structure that is easily ruptured if exposed for prolonged periods. The phallus and hemipenes terminate in a mushroomlike structure, which helps distinguish these male reproductive organs from other possible prolapsed tissues (Fig. 87.9). Regardless of the origin, it is imperative that any viable prolapsed tissue be addressed as soon as possible to prevent devitalization and further compromise. Following replacement, diagnostics should be performed to determine the cause of prolapse. See Chapters 75 and 106 for additional details.

Dystocia (egg binding) is often a result of improper husbandry, including inappropriate temperature, humidity, and lack of proper nesting areas. Reproductive inertia can be divided into preovulatory (unshelled ova) versus postovulatory (shelled eggs or feti), as well as obstructive (an anatomic inability to pass one or more eggs or fetuses) versus nonobstructive dystocia.[85] The clinician must also differentiate between normal gravid and dystocic females—which can be challenging and is often based on historical information (e.g., laid or gave birth to partial clutch/litter), physical examination, and presence of abnormal clinical signs (i.e., tenesmus). Unlike mammals, dystocia in reptiles rarely requires emergency medical or surgical intervention, and medical management is often pursued initially.[17] See Chapters 80 and 105 for more details.

Neurologic Emergencies

Seizures and muscle fasiculations are cause for emergency presentation, and the same differential diagnosis should be considered as in mammalian patients. These include infectious, inflammatory, toxic, neoplastic, traumatic, and metabolic causes.[79] The latter, specifically hypocalcemia due to nutritional secondary hyperparathyroidism, is the most common cause for seizures and tremors. Total and ionized calcium and phosphorus should be determined and a complete neurologic examination

undertaken, with additional diagnostics pursued as required for definitive diagnosis (see Chapters 77 and 84). The second most common cause of neurologic presentation includes exposure to toxins such as organophosphates from acariasis treatment or ingestion of heavy metal, and these should be excluded. Vertebral fractures or luxations due to trauma or pathological causes (e.g., nutritional secondary hyperparathyroidism, osteomyelitis) can also result in hind limb paresis or paralysis (Fig. 87.10). Orthogonal views of the skeleton are recommended for assessment of bone quality, fractures, and luxations. Severe nephropathy (uremia and uricemia) and hepatic encephalopathy can also result in neurologic depression (see Chapters 66 and 67).

Gastrointestinal Emergencies

Gastrointestinal foreign bodies, usually secondary to lithophagy or pica, are often a result of a mineral-deficient diet (Fig. 87.11). Animals may present with nonspecific signs, such as anorexia and lethargy, but regurgitation or vomiting is sometimes seen. Depending on the stability of the patient and the size of the foreign object, medical management may be attempted in cases of partial obstructions with laxatives (e.g., mineral oil), fluid therapy, and assist feeding.[17] Cases of obvious complete obstruction, or those where medical management fails, are candidates for surgical intervention. Depending on the size of the patient and the foreign body, gastroscopy may be preferred as a less invasive option. Other differentials

for regurgitation or vomiting in reptiles include inappropriate diet size/amount, postprandial handling, gastroenteritis (parasitic, viral, bacterial, fungal), gastrointestinal stasis, and rarely, secondary to metabolic disease. For additional information on regurgitation, vomiting, and gastrointestinal diseases, the reader is referred to Chapters 73 and 74. Ingestion of certain toxins can also be a considered a gastrointestinal emergency, and the reader is referred to Chapter 88 for additional information on common toxicities and their treatments.

Toxicology

Kevin T. Fitzgerald and Albert Martínez-Silvestre

Each year, novel industrial molecules, new herbicides and pesticides, over-the-counter and prescription drugs, and even human diets generate a constantly expanding number of potentially toxic substances. Not just humans, but wild species, domestic livestock, companion species, and animals kept in zoological collections are all susceptible to this increasing body of hazardous molecules.

In the last two decades, increasing numbers of more nontraditional "exotic" species have become popular worldwide as household pets. This phenomenon is particularly apparent in the widening number of reptile species being presented to veterinary hospitals. A large and growing number of poisons have been found to be toxic to lizards, snakes, turtles, and crocodilians. Our knowledge of intoxication in reptiles, once an almost anecdotal domain, has grown tremendously in recent years due to more published accounts of reptilian poisonings and more in-depth pharmacologic studies. Thousands of different molecules are capable of poisoning living reptiles. Practitioners cannot be expected to be familiar with every hazardous substance or new poison, but clinicians must understand that toxicology is an essential part of emergency medicine, and they must recognize the most commonly presented toxidromes (toxic syndromes) in exotic species. It is a privilege to practice veterinary medicine, and practitioners must remain duty-bound to keep current both about new species and new toxins. This index of poisons, though not complete, focuses on the most common poisonings of reptiles, their mechanism of action, and potential treatments.

EMERGENCY TREATMENT

Many reptile owners know little about the exotic animals they keep. Coupling this with many veterinarians being unfamiliar with the anatomy, physiology, natural history, and vital signs of captive reptile species creates a recipe for potential disaster. The problem is further compounded since, like many wild species, captive reptiles tend to mask outward signs of disease. As a result, emergencies in reptiles are not always obvious to veterinarians and certainly not to the average reptile owner. Clinicians must remember that the basic tenets of emergency medicine remain the same regardless of species.

Veterinarians can do much to set themselves up for success when dealing with poisoned reptiles. To maximize treatment success, cases of intoxication must be managed swiftly and intensively. Early, aggressive therapy becomes critical in the management of poisoning. For many cases, the telephone is the first line of defense. Often overlooked, receptionists, technicians, and hospital phone staff must be trained in dealing with toxicologic emergencies. Teaching staff to recognize what is deadly and what is harmless can be the difference between life and death.

Emergency care of reptiles begins with a sound history. Often embarrassed by how their animal was housed, how haphazardly toxins were stored, and how long the illness has been going on, owners may be purposely evasive and not give a true history. Nevertheless, treatment starts with a thorough history and husbandry review (see Section 3 for more information).

Required questions in taking a thorough history from a reptile owner include:

- What is the origin of the animal?
- How long has it been with the owner?
- What type of cage setup is employed?
- How long a photoperiod?
- What type of heating system and what are the temperature ranges?
- What food source and how often fed?
- Are cage mates present?

Many reptile emergencies are secondary to inappropriate husbandry, poor diet, and owner inexperience. It is important to obtain information on the diet and how often an animal is being fed and watered, as well as how frequently and with what products are the cage and environment being cleaned. Establishing a consistent and formal pattern of questioning can help reptile clinicians focus on the cause of the problem. Also, species-specific susceptibility to certain poisons must be remembered. Substances that are toxic to birds and mammals may not be toxic to reptiles. Conversely, molecules extremely hazardous to reptiles may not affect birds and mammals.

A complete physical examination is always required. Heart rate, respiration, hydration, neurologic status, and mentation are all critical cues both for diagnosis and for eventual prognosis. In addition to the history, physical examination, vital and clinical signs, and laboratory findings can also help to determine necessary treatment choices. Practitioners must be mindful of the animal's overall condition and treat the patient *not* the poison. Likewise, laboratory results may take days or weeks to return, so one must treat the patient *not* the lab information. Obtaining a diagnosis and patient information through imaging (radiographs, ultrasonography), clinicopathology, biopsy, and gastric lavage are similar in approach to those utilized with small animals. However, since we are limited by the challenges involved in making reptiles vomit, endoscopy may need to be used to obtain stomach samples or to retrieve toxic objects or remove ingested tablets, capsules, pills, or other substances.

Owing to a variety of constraints, intravenous therapy is not always practical for many reptiles. Nevertheless, several viable alternative routes for fluid administration are available. Many desert reptilian species can tolerate remarkable degrees of dehydration, and chelonians, lizards, snakes, and crocodilians can display varying signs of dehydration; however, for most reptiles, sunken eyes, hanging skin, and dry mouths are consistent changes. If intravenous pathways are not practical, intraosseous, intracoelemic, subcutaneous, and enteral routes of fluid administration may be legitimate alternatives depending on the critical nature of the patient. See Chapters 44-46 for guidelines.

VetBooks.ir

Reptilian species have specific preferred body temperatures and optimal thermal zones. For most temperate species, a range of 72°F to 82°F is safe. Caution must be employed since debilitated reptiles may be too weak to thermoregulate. Rigorous, intensive nursing care can do much to help and revive even severely poisoned reptiles. Diets, dietary supplements, and feeding techniques are available to support animals as they are recovering. (See Chapters 44–46 and 87.)

Next follows a discussion, by no means complete, focusing on the most common poisonings of reptiles, their mechanism of actions, and any potential treatments.

PARENTERAL ANTIPARASITIC DRUGS

Ivermectin

Ivermectin is an antiparasitic from a family of chemicals called avermectins. These are marocylic lactones made from fermentation broth of the fungus *Streptomyces avermitilis*.[1] The macrolide ivermectin is available as an injectable, a spray, and an oral formulation. It has activity against a variety of parasites, including nematodes, arthropods, and arachnids.

Avermectins work by potentiating the effects of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA).[1] They stimulate release of GABA by presynaptic sites and increase GABA binding to postsynaptic receptors, which causes neuromuscular blockage. Avermectins also open chloride channels in membranes of the nervous system and further depress neuronal function. These actions cause paralysis and death of susceptible parasites. Ivermectin is absorbed systemically by host tissues. When parasites bite the host, they then absorb the ivermectin. Ivermectin is active against intestinal parasites, mites, microfilariae, and developing larvae.[1] Concurrent treatment with diazepam, which also works through GABA potentiation, may heighten deleterious effects.

Ivermectin can cause depression, paralysis, coma, and death in chelonians.[2] Species susceptible to ivermectin toxicosis may have a blood-brain barrier more permeable than nonsensitive species. This greater permeability may be the result of p-glycoprotein mutation in membranes of the central nervous system (CNS). Another, currently unproven, theory postulates the existence of a specific protein only present in the brains of ivermectin-sensitive species. Ivermectin toxicity has also been reported in several species of lizards and snakes.[3,4] Toxic reaction has been described in terrestrial tortoises, Central American skinks (genus *Mabuya*), Parson's chameleons (*Calumma parsonii*), Panther chameleons (*Furcifer pardalis*), Solomon island skinks (*Corucia zebrata*), and Nile crocodiles (*Crocodylus niloticus*) (Dumonceaux et al, Proc ARAV, 2004, pp 155-157).[5] In the authors' experience, coma and death occurred after 3 days in young Nile crocodiles (*Crocodylus niloticus)* with a single subcutaneous injection.

For many snakes such as common garter snakes (*Thamnophis sirtalis*) or Boelen's python (*Python boeleni*), ivermectin seems to have no adverse effects. However, ball pythons (*Python regius*) in particular may occasionally show mild neurologic signs when treated (Baier, Proc ARAV, 2004, pp 125-127).

Although reported to be safely used in the treatment of *Foleyella* in chameleons (*Furcifer pardalis*) and internal parasites in monitors (*Varanus exanthematicus*) and green iguanas (*Iguana iguana*), ivermectin should always be used with caution.[8–11]

Diagnosis is confirmed by a history of ivermectin exposure and clinical signs. For postmortem testing, samples recommended for submission include frozen brain, liver, and fat. Ivermectin can also be detected in serum.[2] No known antidote or physiological antagonist exists for ivermectin. Treatment is supportive and should include decontamination of any topical sprays with soap and water, fluid therapy, nutritional support, monitoring of electrolytes, and respiratory (ventilator) support. Recovery may take days to weeks. In the authors' experience, two box turtles (*Terrapene* sp.) and one Hermann's tortoise (*Testudo hermanni*) completely recovered after 4 weeks, and another debilitated box turtle recovered in 6 weeks.

Ivermectin should never be given to chelonians, gravid animals, or neonates. Also, for particularly small species, other therapies should be considered. If any question exists about potential toxicity, ivermectin should only be used topically. The aqueous dilution of ivermectin for injection is problematic. The ivermectin precipitates, thereby making dosing erratic. Alternatively, the mixture of imidacloprid with moxidectin seems to have better tolerance in reptiles.[12]

Fenbendazole

Fenbendazole is a benzimidazole type of antiparasiticide.[12,13] It is safe and effective against many helminth parasites in animals. Fenbendazole and its metabolite, oxfendazole, inhibits glucose uptake in parasites.[12,13] Because of its wide range of activity, its high degree of efficacy, and its broad margin of safety, this antihelminthic is frequently prescribed. Fenbendazole has a high margin of safety and has been reported to be well tolerated even at six times the recommended dosage and three times the recommended duration.[13] Fenbendazole is the drug of choice for treating nematode infections in reptiles. It can be administered orally or per cloaca as a liquid, or the powdered form can be placed on food.

It has been extensively used as an anthelminthic in reptiles at 50 to 100 mg/kg orally (PO) once (repeated in 2 weeks) or 50 mg/kg PO every 24 hours for 3 to 5 days.[14,15] Toxic effects have been reported in birds, rats, cats, and dogs.[16–20] Recently, evidence of fenbendazole overdose has been reported in individuals of a small species of snake given exceedingly large doses of the drug (Alvardo et al, Proc ARAV, 1997, pp 35-36.). Four adult Fea's vipers (*Azemiops feae*) died after administration of single dosages of fenbendazole ranging from 428 mg/kg to 1064 mg/kg. Necropsy findings were suggestive of intestinal changes consistent with fenbendazole toxicity. This study documents adverse effects at doses higher than what is recommended. In Hermann's tortoises (*Testudo hermanni*), fenbendazole has been described as possibly causing heteropenia, leucopenia, and generalized lymphopenia, as well as increases in uric acid, phosphorus, and total proteins or decreased glucose with intensive regimes.[22] Fenbendazole and mebendazole have been shown to cause agranulocytosis in mammals in extremely high dosages and also have been implicated in liver toxicities.[17,20,22] Bone marrow toxicity has also been documented with fenbendazole administration.[23-26]

No antidote exists for this poisoning and treatment is supportive and symptomatic. In long-term treatment, the use of fenbendazole is best indicated in combination with frequent blood tests and vigilant health status evaluation. Additional investigation is needed to determine the effects of antiparasitics such as fipronil and neonicotinoids.

Metronidazole

Metronidazole is used as an antibacterial, antiprotozoal, and appetite stimulant in reptiles. It is formulated as a suspension, as an injectable, and as a tablet. Strict attention must be paid to the dosage, the frequency, and the size of the animal.

The activity of metronidazole is specific for anaerobic bacteria and protozoa.[27] It is specific particularly for *Giardia* and other protozoal organisms. Metronidazole disrupts DNA in target microbes through reaction with intracellular metabolites.

The most severe side effect of metronidazole is dose-related CNS toxicity. Moreover, this drug is hepatotoxic and carcinogenic. High dosages can cause ataxia, inability to walk, nystagmus, opisthotonos,

tremors of the lumbar muscles and hind limbs, seizures, and death.[28–30]

Treatment is symptomatic and supportive and involves administration of fluids and both thermal and respiratory support. With supportive care, most patients recover. In severe cases, the patient may need to be placed on a ventilator. Recovery time is dependent on the extent of the toxicity, taking anywhere from 1 to several days.

PARENTERAL ANTIMICROBIAL DRUGS

Antifungal Toxicity

A variety of fungal infections have been documented in reptiles. Ranging from dermatophytes to systemic mycotic infections, these conditions are treated with a variety of antifungal medications. Based on the often small size of the reptilian patient, the mechanism of action of these drugs, and the idiosyncrasies of reptilian physiology, improper dosing can lead to serious intoxications.

Amphotericin B. Amphotericin B is a macrolide class of antimicrobial that inhibits ergosterol synthesis.[31] Ergosterol is a component of the cell membrane unique to fungal organisms. Amphotericin is a potent nephrotoxin. It produces signs of renal toxicity in 80% of patients that receive it intravenously.[31] Its action causes renal vasoconstriction, reduces glomerular filtration rate, and has direct toxic effects on the membranes of the renal tubule cells.[32] Through these mechanisms, amphotericin B causes acute tubular necrosis. Almost 35% of human patients treated with systemic amphotericin develop hypokalemia sufficient to warrant potassium supplementation.[31]

Clinical signs mimic acute renal failure, anorexia, lethargy, weight loss, etc. Elevated blood urea nitrogen (BUN) and creatinine levels, with decreased potassium and sodium levels, are commonly seen in mammals.[33] In reptiles, uric acid and/or BUN and electrolytes should be monitored. Renal function tests including glomerular filtration rate (GFR) determination by iohexol excretion should be considered.[34]

Treatment includes discontinuation of the drug, aggressive fluid therapy to prevent further kidney damage, and diminishment of renal effects with sodium chloride-containing fluids. Treatment with mannitol may help increase the elimination of amphotericin B.[33]

Prognosis after amphotericin B toxicity depends on the severity of the renal damage. Amphotericin B is still listed as a treatment for aspergillosis in reptiles (1 mg/kg intracoelomically once daily for 2 to 4 weeks).[35] Safer medical and surgical options are available. A less toxic, new formulation of amphotericin B is available for humans and may soon be available for veterinary use. Amphotericin B should not be used for animals with preexisting renal disease.

Griseofulvin. This antifungal works by inhibiting fungal spindle activity and leads to distorted weakened fungal hyphae.[34,36] It has also been shown to cause bone marrow suppression in mammals, although the mechanism of action is unknown.[36]

Anorexia, lethargy, diarrhea, and anemia have been reported with intoxication.[33] Griseofulvin has been shown to be teratogenic in pregnant animals of many species.[37,38] In reptiles, the recommended dosage for fungal dermatitis is 20 to 48 mg/kg PO every third day for five treatments.[38] It is available as a tablet and a topical ointment.

Treatment includes discontinuation of the drug and symptomatic support. No specific antidote exists. Topical treatments can be removed with tepid water and gentle hand soap. Antifungal overdoses can be best avoided by prevention of fungal infection through good husbandry.

Imidazoles (Ketoconazole) and Triazoles (Fluconazole and Itraconazole). These antifungal drugs inhibit fungal replication by interfering with ergosterol synthesis. Ketoconazole also has direct effects on the fungal membrane.[38] These fungistatic drugs are metabolized by the liver. Itraconazole is more potent than ketoconazole and is better tolerated with less hepatotoxicity. Clinical signs of intoxication include anorexia, lethargy, weight loss, and diarrhea. Elevated liver enzymes may be present in intoxicated animals.[39] Dosages recommended for reptiles include 2 to 5 mg/kg PO daily for 5 days for fluconazole, 25 mg/kg PO daily for 3 weeks for ketoconazole, and 23.5 mg/kg PO once daily for itraconazole.[38] Minimal side effects seem to occur when using miconazole preparation applied topically. No specific antidote exists for toxicity by these antifungals. Treatment involves stopping the drug, decontaminating any topicals, and supportive therapy (fluids, warmth). For ketoconazole, treatment includes countering hepatotoxicity. Mild intoxications usually improve with simple cessation of the drug.

The safest and most effective drug should be selected for use in the treatment of fungal infections in reptiles. Considerations include the severity of the infection, the size of the animal, and the condition of the animal before treatment. Dosages must be meticulously checked, particularly for systemics and dips to be used on reptiles. Voriconazol has been tested in slider turtles (*Trachemys scripta*) and in bearded dragons (*Pogona vitticeps*) with "yellow fungal disease" or *Nannizziopsis* spp. This drug may be more effective, safer, and less toxic, but requires a longer duration of treatment.[40,41] (See Chapter 117.) Many treatments are best administered by veterinarians and not clients. Finally, reptiles must never be left alone in any bath or medicated dip.

Antibiotic Toxicity

Selection of antibiotics should be made judiciously. Selection depends on experience of the clinician, empirical considerations, the type of infection present based on culture and sensitivity and Gram stains, and most importantly, the size, age, species, and condition of the reptilian patient. No antibiotic can be relied on to be effective for all situations. Many antibiotics have hepatotoxic or nephrotoxic effects. They can prevent or decrease the expected effects of drugs normally used in reptiles such as ketamine, tiletamine, halothane, acepromazine, or pentoxifylline. In addition, antibiotics are no substitute for good wound management, nursing care, nutrition, or husbandry. Ceftazidine causes the least kidney damage and, if indicated by sensitivity testing, is recommended in cases where kidney disease is present.[42]

Gentamicin. Gentamicin is an aminoglycoside antibiotic. Other aminoglycosides include amikacin, tobramycin, neomycin, streptomycin, and kanamycin. Gentamicin is bacteriocidal and is broad spectrum, except for streptococci and anaerobic bacteria.[42] Its mechanism of action inhibits bacterial protein synthesis by binding to 30S ribosomes. Historically, gentamicin has been used for acute serious infection, such as those caused by gram-negative bacteria. Nephrotoxicity and ototoxicity of gentamicin in reptiles is well documented.[42–45] Recommended dosing for gentamicin varies from 1.5 to 2.5 mg/kg given no sooner than every third day.[46]

Amikacin. Amikacin is also an aminoglycoside, is bacteriocidal, is broad spectrum in activity, and has the same mechanism of action on bacteria as gentamicin.[47,48] It is indicated particularly against gram-negative organisms, where it may have greater activity than gentamicin.[48,49]

Like gentamicin, nephrotoxicity is the primary toxic effect of amikacin. Patients must remain hydrated during therapy. Ototoxicity has also been reported. If used together with anesthetic agents, aminoglycosides may show neuromuscular blockade in mammals.[47] Dosages for amikacin vary. (See Chapters 116, 127, and 128 for drug dosages).

Chloramphenicol. Chloramphenicol is an antibacterial with a broad spectrum of activity against gram-positive bacteria, gram-negative bacteria, and Rickettsia. Its mechanism of action is by inhibition of bacterial protein synthesis by binding with ribosomes.[50]

The major toxicity of chloramphenicol is hemorrhage.[49,51] In all vertebrates studied, toxicity produces direct, dose-dependent bone marrow suppression that results in reduction in red blood cells, white blood cells, and platelets in mammals.[51] This manifestation is aggravated by inappropriate dosages, extended treatments, and repeated use of the drug. Treatment of chloramphenicol intoxication is supportive and may require blood transfusions. The drug has also been reported to be appetite suppressive. Like gentamicin, chloramphenicol is used less frequently as safer antibiotics appear.[46] The recommended dosage for chloramphenicol is 50 mg/kg administered once daily or every other day.[46]

Enrofloxacin. Enrofloxacin is a fluoroquinolone antibacterial drug. It is bacteriocidal with a broad spectrum of activity. Its mechanism of action inhibits DNA gyrase, thus inhibiting both DNA and RNA synthesis. Sensitive bacteria include *Staphylococcus*, *Escherichia coli*, *Proteus*, *Klebsiella*, and *Pasteurella*.[52] *Pseudomonas* is moderately susceptible but requires higher dosages. In some species, enrofloxacin doses range from 2.5 to 5 mg/kg.[46] Enrofloxacin can cause severe muscle and skin necrosis if administered SC or IM (Fig. 88.1). Only a single IM injection is recommended, followed by oral therapy. Necrosis is caused by its high pH, and dilution is ineffective for practical applications. At a pH of 10 it would be necessary to dilute 1 mL of Baytril with 1000 mL to get close to a pH of 7.

MISCELLANEOUS DRUGS AND PRODUCTS

Chlorhexidine Versus Iodine Toxicity

Chlorhexidine and iodine are antiseptic antibacterial agents used as skin cleansing and wound care agents. Chlorhexidine solution is not impaired by organic material, has broad-spectrum activity with minimal systemic absorption, and maintains residual activity up to 2 days after application. Povidone iodine has broad-spectrum activity against bacteria, fungi, viruses, and yeast but is inactivated by the presence of organic material and has little residual activity.

FIG 88.1 Black pigmented scar and skin necrosis following intramuscular administration of several doses of enrofloxacin in an olive Burmese python *(Python bivittatus)*. (Courtesy of Albert Martínez-Silvestre.)

In both cases, caution should be observed with more concentrated formulations, as they are cytotoxic, may slow granulation tissue formation, and ultimately impair or delay wound healing.[53]

Soaking living animals in any solution can be potentially life threatening. Recently, turtles soaked for 1 hour in chlorhexidine scrub have been shown to become intoxicated.[54] Cutaneous absorption of the solution and possible oral and cloacal ingestion of the soaks has been postulated as the cause of the problem. Before any substances are used as a soak, the literature should be checked for preferred usage, dosage, and duration of the soak. Affected animals should be removed from the soak, rinsed, and supported with warmth and fluids. Remember to never leave any reptile unattended in a bath. Animals can drown much faster than anticipated. Also, particular attention must be paid to the depth of fluids in which reptiles are bathed and soaked.

Bleach

Various hypochlorite bleach solutions can be found in most households. Typically, these are 3% to 6% hypochlorite solutions in water.[31,55] Bleaches are moderately irritating. If contact with skin is prolonged, the damage is worsened. Bleaches can be effective in treatment of cage parasites of reptiles but should *never* be applied to live animals. Bleach can cause alkali-type burns if splashed in the eyes of lizards and turtles. Immediate and copious irrigation of the eye minimizes damage. Skin exposed to bleach should be washed with a mild soap and lukewarm water. Animals should be kept out of recently bleached cages for a minimum of 24 hours to prevent respiratory tract irritation. In addition, residual disinfectant can be removed by wiping with a clean cloth or towel and exposing the area to direct sunlight for a few hours.

Dioctyl Sodium Sulfosuccinate (DSS)

DSS is an anionic surfactant substance that traditionally has been recommended as a laxative and stool softener for a variety of vertebrates ranging from humans to rodents.[56] Likewise, DSS has been advocated for the same use in reptiles.[57]

It is generally regarded as a relatively safe pharmaceutical agent with a low toxicity. However, reports of toxic effects exist in the literature for horses, dogs, monkeys, rats, rabbits, guinea pigs, and mice after both oral and topical administration.[58–64] Furthermore, fatalities in reptiles after oral use of DSS have been reported (Paul-Murphy et al, Proc 1st Conference of Zoological and Avian Medicine, 1987). One study documents severe changes in gastric and esophageal mucosa in gopher snakes (*Pituophis melanoleucus*) given oral DSS at a dosage of 250 mg/kg.

A specific dose of DSS has not been established for reptiles, but dosages for other species range from 15 to 40 mg/kg for dogs and cats to 200 mg/kg for horses.[56,63] Concentrations (dilutions) of 1:30 have been recommended for reptiles.[57]

The study in gopher snakes and reports in other species indicate that DSS may not be as innocuous as once believed. These studies demonstrate that DSS can have adverse effects, and, in reptiles, levels greater than 250 mg/kg can result in caustic changes to epithelial surfaces. Additionally, the potential for overzealous oral administration of DSS with resulting aspiration pneumonia exists. Care must be employed if DSS and other laxatives, stool softeners, and enhancers of gastric motility should be considered.

Vitamin Toxicity

For water-soluble vitamins, in which excesses can be excreted into the urine, the margin of safety is large. For fat-soluble vitamins like A and D, this is not the case. Owners, breeders, and veterinarians often oversupplement captive reptiles with these fat-soluble vitamins with deleterious results.

VetBooks.ir

Vitamin A Toxicity. Vitamin A is necessary for normal skin and periocular tissue health, particularly in chelonians and saurians. Turtles and lizards with hypovitaminosis A typically show ocular discharge, palpebral edema, blindness, hyperkeratosis of skin and mouthparts, and aural abscesses. Patients can be treated with oral vitamin A supplementation (2000 IU/kg every 7 days) and an improved diet.[66]

Unfortunately, excessive iatrogenic administration of vitamin A can cause its own issues, including inappetence, full-thickness skin sloughing, secondary bacterial infection, discoloration of the skin, and extreme lethargy. These results usually happen at dosages of 10,000 IU/kg or higher given IM as a single injection.[67] Treatment involves ceasing vitamin A administration, fluid therapy, and nutritional support. The skin lesions may heal slowly, but animals managed supportively can completely recover. Prognosis varies depending on the severity of the lesions.

Vitamin D Toxicity. Dosages of 50 to 1000 times the minimum daily requirement of vitamin D are often given for weeks to months. The use of commercial oral D_3 supplements (Solar Drops Liquid UVB, T-Rex) to avoid the expense and/or substitute for broad-spectrum (UVB) lighting should be actively discouraged. Intoxication can be insidious; particularly when the minimum daily requirement of most mammalian vertebrates for vitamin D is only 10 to 20 IU/kg body weight.[68] Minimum daily requirements have not been established for reptiles. Sometimes a corrective but miscalculated treatment for secondary nutritional hyperparathyroidism may cause iatrogenic vitamin D overdosing. The mechanism of action for toxicity of vitamin D is related to hypercalcemia. This prolonged hypercalcemia causes dystrophic calcification of the gastrointestinal, renal, pulmonary, cardiovascular, and synovial tissues (Fig. 88.2). Definitive and accurate diagnosis is possible by submission of blood for 25(OH)D_3 levels measured by high-performance liquid chromatography or liquid chromatography–mass spectrometry (e.g., Heartland Assays, Ames, IA).[69] Complete removal of vitamin D–containing supplements, diuresis, and cortisone may help control hypercalcemia, but resolution of soft-tissue calcification may not be successful.[69] Calcitonin has historically been recommended for the treatment of vitamin D–induced hypercalcemia, although controlled studies on the efficacy of calcitonin in vitamin D toxicosis are lacking.[69] Pamidronate disodium (a bisphosphonate [Aredia]) has been recommended in dogs to counter hypercalcemia, with 1 to 2 mg/kg given slowly over 2 hours.

In light of the inherent calcium metabolism problems of captive reptiles, veterinarians must counsel clients about proper husbandry, nutrition, and dietary requirements and ensure that no supplements are given to animals without veterinary approval. (See Chapters 27, 84, and 122.)

Organophosphates and Carbamates

Organophosphates are the most commonly used insecticides worldwide.[70] They are the active ingredient in a long list of products. For animal use as insecticides, they are formulated as dips, sprays, topical medications, systemic antiparasitic agents, and flea collars. This group of insecticides includes chlorpyrifos (Dursban), dichlorvos, diazinon, cythioate (Proban), fenthion (ProSpot), malathion, ronnel, parathion, trichlorfon, and vaponna. Their cousins the carbamates include carbaryl (Sevin), bendiocarb, methiocarb, propoxur, and cabofuran. As newer, safer insecticides are marketed, this group is involved in fewer accidental poisonings but still accounts for a large number of intoxications.

Their toxicity in reptiles is well known and even some pesticides are used regularly in different parts of the world to control unwanted populations of iguanas, snakes, and geckos. High concentrations of organochlorine have been proposed as adjuvants to the occurrence of ophthalmic and otic pathologies in the box turtle (*Terrapene carolina*).[71]

Organophosphates and carbamates interfere with metabolism and breakdown of acetylcholine at synaptic junctions.[72] Acetylcholinesterase is the enzyme responsible for breaking down the neurotransmitter at these sites. Acetylcholinesterase is inhibited by organophosphates and carbamates at these cholinergic sites. As a result, acetylcholine accumulates at the synapses, which at first excites and then paralyzes transmission in these synapses, giving it the characteristic "nerve gas" signs associated with organophosphate toxicity. This inhibition of the synapse is irreversible with organophosphates and reversible with carbamates. Organophosphates are readily absorbed by all routes—dermal, respiratory, gastrointestinal, and conjunctival. Overdose with organophosphates may happen more readily if given together with imidothiazoles, such as levamisole.

Clinical signs seen in reptiles include salivation, ataxia, muscle fasciculations, inability to right themselves, coma, and respiratory arrest.[73] Death results from massive respiratory secretions, bronchiolar constriction, and effects on respiratory centers in the medulla, leading to the cessation of breathing.

Blood levels of acetylcholinesterase are variable and poorly diagnostic unless paired. Brain acetylcholinesterase levels are considered definitive. Animals with dermal exposure should be washed with a mild dishwashing detergent and copious amounts of water. Animals should be dried after rinsing to prevent further uptake of the insecticide. The need for fluid therapy to counter dehydration and electrolyte imbalances should be considered. The specific physiological antidote, the muscarinic antagonist atropine, should be given (0.4 mg/kg intramuscularly [IM]) and may help displace the toxin from receptors; however, the more modern poisons tend to bind irreversibly. Atropine should help with salivation, bronchospasm, and dyspnea. Diazepam may be given as needed for seizures. Use of antihistamines as a treatment for insecticide poisonings is controversial and most likely not effective. Prognosis is dependent on dosage, duration of exposure, and size of the animal. It should be noted that, to promote slow absorption and avoid direct contact with

reptile skin, some insecticides can be applied to a piece of tape and adhered to the scales for 2 to 3 days (personal observation).

Therapies both effective and safer than organophosphates exist for treatment of parasites in captive reptiles. (See Chapter 120.)

Pyrethrins and Pyrethroids

Pyrethrin is the oldest used botanic insecticide. It is made from the dried and ground flowers of *Chrysanthemum cineriifolium*.[74] Pyrethroids are synthetic derivatives of pyrethrin and are widely available. Pyrethroid insecticides have enhanced stability, potency, and half-life compared with the parent molecule. A variety of dilute pyrethrin-containing and pyrethroid-containing sprays have been recommended for reptiles.[75,76] In fact, the only licensed product for use in reptile parasites is a pyrethroid (Permethrin – Provent-a-mite; ProProducts, Mahopec, NY).[77,78]

These molecules affect parasites by altering the activity of the sodium ion channels of nerves. These poisons prolong the period of sodium conductance and increase the length of the depolarizing action potential.[74] This results in repetitive nerve firing and death. With the right conditions or at higher dosages, these compounds can intoxicate host animals. Because of the potential for transcutaneous absorption, pyrethrin and pyrethroid sprays must be used with caution. As with ivermectin, organophosphates, carbamates, pyrethrin, and pyrethroids should never be given concurrently with other cholinesterase-inhibiting compounds.

Clinical signs have been reported for pyrethrins and pyrethroids, particularly if sprays used also contain insect growth regulators (suc as methoprene). Animals can have signs develop within 15 minutes of application. Signs include salivation, ataxia, inability to right themselves, and muscle fasiculations.[74] Idiosyncratic reactions to pyrethrins can happen at much lower doses than expected. A small percentage of animals appear to be extremely sensitive to pyrethrins and pyrethroids.

No known antidote exists for these molecules. If caught early enough, treatment for pyrethrin/pyrethroid toxicity involves dermal decontamination, isotonic fluids, atropine, and diazepam for seizures. No good antemortem test exists for detection and pyrethrins and pyrethroids produce no identifiable lesions postmortem.[74] Care must be taken to keep pyrethrin/pyrethroid sprays away from reptiles' eyes and mouth to prevent intoxication. Prognosis depends on the strength of the agent used, the duration of the exposure, and the size of the animal involved.

Rodenticides

Each year, rodents destroy crops in the field, eat and contaminate food in storage, serve as vectors for human diseases, bite people, and cause material damage by gnawing. As a result, a variety of rodenticides are ubiquitously used in an attempt to control populations of these animals. These substances prove to be nearly as dangerous to humans and nontarget animals as they are to rodents. Rodenticide intoxication has been documented in a variety of species, including reptiles.[79,80] The original container housing the poison should be provided on presentation so that active ingredients can be positively identified and appropriate treatment initiated. Reptile clinicians are often presented with tortoises that are attacked by rats. Owners often put out rodenticides to control rodents. Great care must be taken to avoid tortoises coming in contact with rodenticide bait.

Anticoagulants. The long-acting anticoagulants are responsible for 80% of rodenticide poisoning in humans and animals in the United States.[81] These long-acting agents have the same action as warfarin; however, they are more potent and their half-life is longer. They are effective after single or limited feedings when compared with other rodenticides. They act by decreasing the activity of the vitamin K–dependent blood-clotting factors (II, VII, IX, X). When clotting factors are sufficiently reduced, bleeding occurs. Currently in the United States, the anticoagulant rodenticides have been taken off the market due to a dramatic increase in children and nontarget species intoxication, and the only rodenticides available to consumers are bromethalin and cholocalciferol. The most common and most toxic second-generation anticoagulants in use were brodifacoum and bromadilone.

Clinical signs depend on the site and extent of hemorrhage. Most intoxicated animals show anorexia, weakness, and lethargy. The most common clinical sign is dyspnea.[79] Typically, animals bleed into body cavities, abdomen, thorax, joints, and so on. Most of these poisons are packaged as molasses-soaked grain laced with the anticoagulant. These various plant materials can attract herbivorous or omnivorous reptiles. Newer formulations of these baits are dyed turquoise.

Reptiles ingesting toxic levels of anticoagulant rodenticides do not always display hemorrhagic signs. Although hemorrhage was not observed, lethal effects of warfarin and difenacoum after oral ingestion has been demonstrated in brown tree snakes (*Boiga irregularis*).[82] Round Island (Mauritius) was exposed to large amounts of brodifacoum released into the environment (500 kg/ha).[83] Skinks observed eating pellets softened by rain died with high levels of brodifacoum. None showed internal bleeding, and it was postulated the poison interfered with the animals' thermoregulation, causing overheating. Despite these findings, other studies examining lacertids found no evidence of mortality after exposure to brodifacoum at 50 ppm. Balearic lizards (*Podarcis lifordi*), known to be generalist feeders, have demonstrated avoidance of cereal paraffin baits mixed with 50 ppm of difenacoum.[84] Nevertheless, the big-scaled least gecko of Puerto Rico (*Sphaerodactylus macrolepis*) in one experiment showed mortality rates of 15% when exposed to pelleted grains mixed with brodifacoum (50 ppm).[84] Reptiles appear to have a varied response to the effects of anticoagulant rodenticides.

The authors have seen one green iguana (*Iguana iguana*) and two box turtles intoxicated by anticoagulant bait ingestion. Baseline determinations of one-stage prothrombin time (PT) are helpful in animals suspected of consuming anticoagulant poisons in mammals. Comparison PT can be measured in known healthy animals or reptiles. The antidote for anticoagulant poisoning, vitamin K_1, should be administered in animals if PT is increased. Daily dosage recommendations in mammals for vitamin K_1 are 2.5 mg/kg.[79] Therapy with this antidote must be maintained until toxic amounts of the poison are no longer present in the animal. Length of treatment depends on the dose and type of anticoagulant ingested but may be up to 3 to 4 weeks. A PT test should be run 48 hours after cessation of vitamin K_1 treatment. If clotting time is normal, therapy is discontinued. If clotting time is increased, therapy is continued for another week. Vitamin K_1 treatment can be given with subcutaneous injection or orally. Intravenous injections have a high incidence of anaphylactic reaction in mammals.[79] This has not been reported in reptiles. Treatment includes vitamin K_1 and possible oxygen support and plasma transfusion.

Bromethalin. Bromethalin is one of the newer rodenticides that has not been reported to cause poisoning in reptiles, but, because of increasing use, the possibility for intoxication exists. It is formulated in baits of pelleted grain and dyed green or turquoise. Bromethalin is a neurotoxin, but because of its name, it can be confused with the long-acting anticoagulants bromadilone and brodifacoum. Again, one should encourage clients to bring in original containers to obtain valuable label information concerning ingredients.

The mechanism of action of bromethalin is to uncouple oxidative phosphorylation. The brain is the primary target for bromethalin because of its unique dependence on oxidative phosphorylation. The drug causes brain electrolyte disturbances and results in the development of cerebral edema.[81]

Clinical signs include hind limb paralysis, abnormal postures, fine muscle tremors, and seizures. Severely poisoned animals are comatose. Clinical signs are usually seen within 24 hours of ingestion.[85]

VetBooks.ir

Bromethalin is a nonselective vertebrate poison. Antemortem diagnosis of bromethalin poisoning depends on exposure history and subsequent development of appropriate clinical signs. Postmortem diagnosis can be confirmed by the presence of bromethalin residues in frozen fat, liver, kidney, and brain tissues.[81] No antidote exists, and treatment is initially directed at reducing gastrointestinal absorption and providing symptomatic and supportive care. Treatment must also aim at control of cerebral edema seen in severe poisonings. Administration of dexamethasone and mannitol have been recommended to control bromethalin-induced cerebral edema in mammals.[85] Unfortunately, the efficacy of these diuretic agents in controlling bromethalin-poisoned animals is rarely successful. Animals with severe signs such as seizures, paralysis, or coma generally have a grave prognosis.

Cholecalciferol. Cholecalciferol (vitamin D_3), a newer rodenticide, exploits the fact that rodents are extremely sensitive to small percentage changes in the calcium balance in their blood. Cholecalciferol causes hypercalcemia through mobilization of the body stores of calcium predominantly found in bone.[81] This dystrophic hypercalcemia results in calcification of blood vessels, organs, and soft tissues. It leads to nerve and muscle dysfunction and cardiac arrythmias.[69,86] Diagnosis is possible by submission of serum for $25(OH)D_3$ levels measured by chromatography (Heartland Assays, Ames, IA). Prednisone (6 mg/kg) and furosemide (1 to 4 mg/kg) have been recommended in intoxicated mammals.[69] Favorable results have been obtained in several species using these drugs.[69,86,87] Supportive fluids are essential. Calcitonin therapy has been recommended (1.5 UI/kg SID 7 d), but its efficacy is questionable. Pamidronate disodium (Aredia), a biphosphate, has been recommended in dogs, with 1 to 2 mg/kg given slowly over 2 hours.[69,87] Prognosis is poor in animals in which dystrophic mineralization has already occurred.

Metaldehyde. Metaldehyde is the active ingredient in most slug and snail baits.[88] It is formulated in granules, powder, pellets, and liquid. Protein-rich material such as bran or grain is usually added to the bait to make it more attractive to snails. Unfortunately, other animals find it more palatable as well. Metaldehyde poisoning has been reported in a wide range of species, from dogs to livestock.[88] This is not a common intoxication for reptiles; however, the authors did observe one captive tortoise fatality after the poison was encountered in a household backyard garden.

The mechanism of action of metaldehyde poisoning was once thought to be a result of the degradation of the compound to acetaldehyde. Recent studies suggest metaldehyde itself may be the agent that affects the CNS.[89] GABA levels are decreased by metaldehyde, and this decrease can lead to depression, seizures, and coma.

Clinical signs include ataxia, incoordination and locomotor signs, muscle spasms, abnormal postures, and convulsions.[88] The tortoise seen by the author was comatose and nonresponsive and had its head and legs rigidly extended. Clinical signs develop within a few hours of ingestion. Chemical analysis for metaldehyde confirmation is best obtained from antemortem specimens of stomach contents, serum, and urine, and postmortem from frozen liver samples. Bait material can also be tested.

No specific antidote exists for metaldehyde poisoning. Instead, animals are treated supportively. Fluids should be given and oxygen administered to counter respiratory depression. Mammals display the "shake and bake" syndrome and are treated with diazepam or other appropriate anticonvulsants, and steps are taken to counter the hyperthermia. Prognosis is generally better if the animal survives the first 36 hours.[88] The public is strangely unaware of the hazards of this potent poison.

Repticides

Repticides are products used in some parts of the world exclusively to control reptiles as pests.

Alpha-Chloralose. Alpha-chloralose is a humane poison that produces a hypnotic effect by interfering with the body temperature control mechanism of the reptile.[90] Chloralose is both an avicide and a rodenticide used to kill mice at temperatures below 15°C, but its toxic effects also have been widely demonstrated in reptiles. It is part of the composition of a commercial repticide used in Africa, Madagascar, and along the Indian Ocean (Margoillator, Kit Antilezard, La Reunion). The toxic component is mixed with strawberries and dyed pink to attract geckos and other reptiles. It has also been investigated in neuroscience and veterinary medicine for use as an anesthetic and sedative. Affected reptiles become stunned within a few minutes after ingestion and do not move more than 2 m away from the initial feeding point (Fig. 88.3).

Acetaminophen. Acetaminophen (also known as the generic form of *paracetamol*) is a medication used to treat pain and fever. It is typically used for mild to moderate pain in human medicine. Although there is little risk of accidental ingestion in reptiles, it should be avoided as an analgesic by well-intentioned reptile keepers. In fact, this drug is very toxic to reptiles and is even used to control herpetologic pests in different parts of the world. Acetaminophen was registered for use to control brown tree snakes in Guam by the U.S. Environmental Protection Agency.

The acetaminophen dose of 40 mg and 80 mg results in total or near-total lethality for monitors, pythons, and tree snakes. Its toxicity has been described in the Nile monitor (*Varanus niloticus*) and Burmese python (*Python bivittatus*). It has been used as a poison in invasive reptile eradication projects like the lizard *Ctenasaurus similis* and the brown tree snake (*Boiga irregularis*) in Guam.[91–94] In these projects, mice previously injected with acetaminophen are provided to the wild snakes. Snakes die within 48 hours of consumption of poisoned bait.

VetBooks.ir

The mechanism of acetaminophen toxicity in reptiles is not known, although it may be due to liver and kidney toxicity, possibly via glutathione depletion, which can lead to hepatic necrosis. Another possibility is the occurrence of methemoglobinemia, which has been observed in cats.[95] Acetaminophen-treated brown tree snakes also displayed severe methemoglobinemia.

Affected animals display no apparent signs of suffering, distress, or discomfort. Only emesis was reported in both monitor lizards and brown tree snakes given the described doses.

Heavy Metal Toxicosis

The risks of heavy metal exposures, such as lead and zinc, is high in free-roaming pets and zoologic collections with public access. However, the occurrence of heavy metal toxicosis among reptiles is not well documented.[96–101] One reason for this is the lack of information regarding reference blood and tissue levels of heavy metals in reptiles. Normal reference ranges have been suggested as a guide to aid in the diagnosis of lead or zinc exposure or toxicity in live iguanas: whole blood lead levels at, 0.06 ± 0.06 mg/mL, and plasma zinc levels at, 2.68 ± 1.66 mg/mL.[102]

Zinc Toxicosis. Zinc is an essential trace element. It is necessary for the synthesis of more than 200 enzymes required for cell division, growth, and gene expression (Cook et al, Proc AAZV, 1989, p 151).[103] Chronic zinc deficiency from improper diet is more commonly seen than acute zinc poisoning from excessive zinc intake. Zinc toxicosis may result from overzealous administration of supplements, ingestion of galvanized metal objects, zinc oxide ointment, or ingestion of pennies. Before 1982, U.S. pennies were more than 90% copper; since that time, they have been 97% zinc (Fig. 88.4). We have seen two iguanas and one snake with gastrointestinal tracts full of pennies that showed signs of zinc toxicity. A suspected zinc toxicosis was reported in a Cuban crocodile (*Crocodylus rhombifer*) with a serum zinc concentration of 45.3 ppm (Cook et al, Proc AAZV, 1989, p 151).

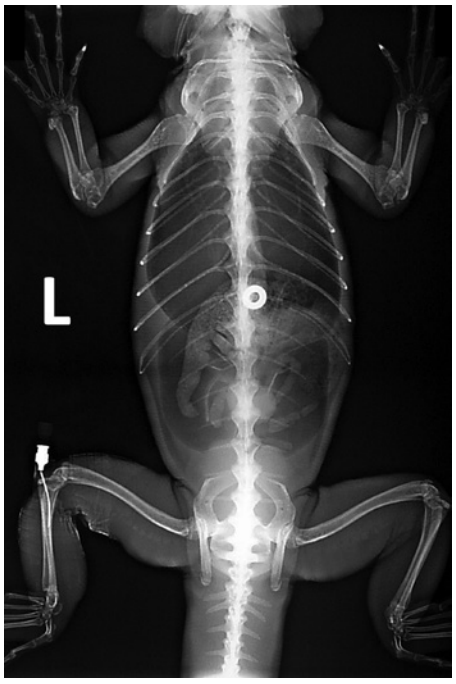

FIG 88.4 Radiographic demonstration of an ingested zinc washer in an iguana that presented with anorexia and lethargy. Plasma zinc levels were significantly elevated confirming the toxicosis. The animal responded to chelation therapy while the washer passed uneventfully. (Courtesy of Stephen J. Divers.)

The precise mechanism of action of zinc toxicosis is not known. However, the red blood cells, kidneys, pancreas, and liver are most affected. Intravascular hemolysis is the most consistent abnormality seen. Zinc is thought to cause oxidative mechanisms that lyse the red blood cell membrane, leading to anemia.[105]

Clinical signs of zinc toxicosis depend on the amount and form of the zinc ingested. Signs are delayed if coins are the source of the zinc. As few as one or two pennies can cause toxicity. First, the animal may be anorectic and lethargic, and the zinc ingestion may mimic gastrointestinal enteritis. This is followed by intravascular hemolysis, hemoglobinemia, yellow discoloration of the skin and mucous membranes, and weight loss.

Palpation may be positive for coins, but in larger animals, radiographs may be necessary to reveal the pennies (see Fig. 88.4). Elevated zinc levels can be confirmed on a serum/plasma sample antemortem, and in liver, kidney, and pancreas samples postmortem. Treatment consists of removal of the zinc-containing foreign object by endoscopy or surgery. Additional supportive therapy involves fluid treatment to maintain hydration, possible blood transfusion to control anemia, and in severe cases, use of a zinc chelator. However, chelators such as D-penicillamine and calcium-EDTA have been shown to be of questionable value once the source of the exposure has been removed. At our hospital, coins in all three reptiles were successfully removed endoscopically.

Lead Toxicosis. With the prohibition of lead-based paints, lead toxicity is seen less frequently but may still occur. Lead interferes with multiple processes in the body. It affects various cell types, enzymes, tissues, and organ systems. Lead competes with calcium ions, thereby substituting for calcium in bone. Lead mimics and inhibits many cellular actions of calcium and alters calcium flux across membranes.[106] This ultimately increases levels of cytoplasmic calcium in many cell types. Acute calcium-mediated cell death, chronic impairment of neuronal function, diminished energy metabolism by mitochondria result from lead toxicosis, all resulting in apoptosis.

More than 90% of absorbed lead is bound to red blood cells.[101] Lead can be detected antemortem in blood and postmortem in the liver and/or kidney. Care should be taken because blood concentrations do not always correlate with either occurrence or severity of signs.

Clinical signs are similar to those described for zinc, with the addition of neuromuscular dysfunction.[102] In the case of oral ingestion, radiography may show multiple metallic densities in the stomach. Confirmation must be obtained by blood chemical analysis. Published cases of suspected heavy metal toxicosis in reptiles report lead concentrations of 14.7 µg/ml (0.71 µmol/L in a false gharial (*Tomistoma schlegelii*), 3.6 µg/ml (0.17 µmol/L) in a snapping turtle (*Chelydra serpentina*), 4.8 µg/ml (0.23 µmol/L) in a green iguana (*Iguana iguana*), and 8.51 µg/ml (0.41 µmol/L) in a red-eared slider (*Trachemys scripta*) (Cook et al, Proc AAZV, 1989, p 151).[103,107,108] Intestinal perforation has been described in a snapping turtle with lead intoxication (Cook et al, Proc AAZV, 1989, p 151).[104,107,108] In south Spain, high levels of lead were detected in eggs of chameleons (*Chamaelo chamaeleon*), with an associated higher risk of complication of normal incubation or resorption.[109] One case of lead poisoning was cited in a red-eared slider after ingestion of a thermometer containing lead pellets.[108] The main problem is determining if the detected values are greater than the reference ranges of the species.[102]

It is interesting to note that crocodilians are more susceptible to lead poisoning than other reptiles due to the presence of stones in their stomachs. These stones help wear down and dissolve ingested metallic pieces (like saturnism in birds), and liberated lead can then enter the blood stream during digestion.[107,110,111]

VetBooks.ir

Chelation therapy can be started with CaEDTA 30 mg/kg IM SID for 5 days, off for 4 days, and repeated for 5 days.[112] In case of accidental ingestion, prokinetics have been shown to have little effect in lead evacuation.[113]

Successful treatment of zinc/lead toxicity involves removal of the metal-containing objects through surgery or endoscopy and supportive care. Prognosis depends on the amount of metal ingested, the duration of the toxic exposure, and the severity of the resulting anemia. Reptiles must be kept in environments free of potential sources of heavy metal ingestion.

VENOMOUS AND POISONOUS ANIMALS

Snake Envenomations

Snake venoms are complex mixtures of enzymatic and nonenzymatic proteins.[114,115]Derived from modified salivary glands, snake venoms immobilize prey and begin to predigest their tissues (Table 88.1). Hyaluronidase is present in most snake venom and works by catalyzing the cleavage of internal glycosides bonds and mucopolysaccharides.[114,115] This action potentiates the activity of many of the other toxic agents. Phospholipase A_2, which causes hydrolytic breakdown of membrane phospholipids, is common to many snake venoms. This molecule displays cytotoxic, anticoagulant (prevents activation of clotting factors), and neurotoxic activities.[114,115] Collagenase is also found in snake venom and leads to the digestion of collagen and breaking down of connective tissue.

Snake venoms are approximately 90% water and, in addition to enzymatic and nonenzymatic proteins, can contain lipids, carbohydrates, and biogenic amines.[114,115,116] The actual toxins that compose the "killing fraction" are referred to as venins. The entire mixture is called venom. Not only does much variability exist in venom composition among snake species, tremendous variability is also seen in susceptibility to different snake venoms by potential prey species.

Venomous snakes do appear to be relatively more resistant to their own venom (Fig. 88.5).[114] Neutralizing antibodies have been documented in the serum of many snakes to the toxins of their own venom.[116,117] In our experience, twice in prairie rattlesnakes (*Crotalus viridus*) and once in western diamondback rattlesnakes (*Crotalus atrox*), snakes were seen to die after being bitten by a conspecific. The severity of the response appears to be dependent on the location of the bite, the volume of venom injected, and the size of the recipient. We have also seen bites between conspecifics and self-inflicted bites that were nonfatal.

Certain nonvenomous snake species that prey on other snakes (including venomous ones), such as the king snake (*Lampropeltis getulus*), also appear to have some resistance to venom.[118] Despite evidence that this venom resistance exists, variability in the venom-neutralizing properties of serum of snakes within genus *Lampropeltis* is also apparent and not always protective. Sometimes when these nonvenomous colubrids are bitten by venomous species, they die.[119]

Beginning in the 1930s, resistance to venoms among both conspecifics and congenerics was observed and theorized. For example, in rattlesnakes, bites between conspecifics, bites between congenetic species, and an individual's bite on itself were documented and observed to be nonlethal.[120] Some species of Australian elapids are not only immune to their own venom but also immune to venom of conspecifics and congenerics of the same continent. In contrast, several authors found examples in other venomous snake species where no such immunity was present, where bites between individuals of the same genus or same species has fatal consequences.[121] In these cases, the bitten snakes displayed clear symptoms of envenomation before death. In captivity, most cases between reptiles of the same species occur during feeding or courtship. In the king cobra (*Ophyophagus hannah*), mating season is a particularly delicate period because males have been seen to bite females. It is noted that in most cases, aside from some tissue damage, the bite is nonlethal.[122,123] In the venomous snake *Bothriopsis taeniata*, death of specimens has been observed in conspecific bites. In the author's experience, we have also witnessed a bite of a male *Agkistrodon contortrix* on a same species cage-mate to be nonfatal, only causing inflammation in the region. Another conspecific bite was observed during copulation from a female upon a male *Trimerisurus trigonocephalus*, with almost no effect apart from a small wound. Also, a female prairie rattlesnake (*Crotalus viridus*) found badly tangled in a ball of masking tape was seen to bite itself multiple times while the tape was removed. Despite numerous bites, the snake showed no ill effects and was successfully released 1 week later.

Humans repeatedly bitten by venomous snakes have claimed immunity to their bite. Satisfactory serologic evidence for these claims has not been established. Effective antivenins exist for many venomous snake bites. A vaccine against rattlesnake bites (Rattlesnake Vaccine, Red Rock Biologics, Woodland, CA, http://www.redrockbiologics.com) has recently been marketed for dogs. However, its overall effectiveness has not been determined.

Lizard Envenomations

Of the approximately 3000 species of lizards, only two known poisonous species exist. The Gila monster, *Heloderma suspectum* (with two subspecies), and the Mexican beaded lizard, *H. horridum* (with three subspecies), comprise the venomous lizards and are found only in the Americas. Their venom is only used in defense.[124]

The venom of these lizards is antigenically unrelated to snake venom.[125] The venom glands are in the lower jaw, and the venom is delivered to the gums at the base of the teeth. Delivery of the venom is dependent on intense chewing action.

Heloderma venom consists of multiple enzymatic proteins, including hyaluronidase, phospholipase, arginine hydrolase, and kallikrein-like

enzymes.[124] Other proteins have been identified in this venom, including gilatoxin and helothermine.

Hyaluronidase acts as a spreading factor, decreases the viscosity of connective tissue, and catalyzes the cleavage of acid mucoglycosides.[114,115] Arginine hydrolase causes hydrolysis of peptide linkages, and the kallikrein-like enzymes cause vasodilation, increase capillary permeability, lead to edema, and affect the contraction or relaxation of extravascular smooth muscle. Gilatoxin is a neurotoxic protein.[126] Helothermine has been shown to depress the body temperature in mice subjected to this poison.[127] Bites of these lizards to people have been reported as very painful. Currently, no specific antivenom is available for venomous lizard bites, and treatment is supportive. Gila monsters appear to be relatively resistant to the effects of their own venom. The evolution of the venom in these lizards and their primitive delivery system appears to be for defense, for it is not used in the apprehension of prey. This sets it apart from snake and spider venoms, which are used in defense but are primarily designed for immobilization and predigestion of prey.

In lizards, Heloderma bites are common between partners in the same terrarium, either by territoriality, character, or during the breeding season; however, the authors have witnessed no deaths. Conspecific immunity may be because of osteoderms present in their skin that act as a "protective layer," their specific method of envenomation, gender, or a particular immunity to their own venom.[128,129]

Amphibian Toxins

Certain amphibians are poisonous and can cause intoxications. In the United States, two toad species (genus *Bufo*) are the source of most toad poisonings.

The cane or marine toad (*Rhinella* [*Bufo*] *marinus*) and the Colorado River toad (*B. alvarius*) are the two species most implicated.[130]

All *Bufo* species of toads have parotid glands that release toxic substances when the animals are threatened. These are biologically active compounds such as dopamine, norepinephrine, epinephrine, serotonin, bufotenine, bufagenin, bufotoxins, and indolealkylamines.[131] Severe toxicosis has been seen in small animals that bite, masticate, or hold these toads in their mouths. The active compounds secreted from the toad parotid gland are rapidly absorbed by the mucous membranes of the predator and enter the systemic circulation.

Once these compounds have entered the circulation, the greatest effects are seen on the peripheral vascular system, the CNS, and the heart. Bufotenine has pressor effects on blood vessels but may act as a hallucinogen as well.[131] Bufagenin has digitalis-like effects causing alterations in heart rate and rhythm.[130–132] Bufotoxins are vasoconstrictors and add to pressor effects.[131] Indolealkylamines have activity similar to the hallucinogen lysergic acid diethylamide.[126]

Dogs are most commonly affected by amphibian parotid toxins. However, adverse reactions have also been reported in cats and ferrets. Exposure in reptiles has not been documented but anecdotal reports of poisonings do exist. Therefore the assumption is logical that predatory reptiles that include amphibians in their diet might encounter and ingest poisonous toads. No specific antidote is available and treatment is supportive. Therapy includes thorough flushing of the oral cavity. Severely affected animals may need medications to stabilize heart rhythms and control seizures. Supportive care involving fluids may be necessary. Many other toxicoses and conditions can lead to neuropathies, and cardiac arrhythmias can present with signs similar to those of toad poisonings. Differential diagnosis must always be considered and explored.

Fire Ants

In the early 1900s, the imported fire ant reached the United States from South America. The black fire ant (*Solenopsis richteri*) has remained in a small area of central Alabama and Mississippi. The red imported fire ant (*Solenopsis invicta*) has now reached 13 southern states from Texas to North Carolina.[133] In some areas, as many as 60% of local humans report being stung at least once annually.[134] For humans, 1% of stings result in hypersensitivity reactions.[134,135]

These fire ants bite and sting. First, the ant uses powerful mandibles to bite and anchor itself to the skin of the victim, then it uses its abdominal stinger to inject venom in a series of stings rotating in a circle around the head. Unlike the venom of most stinging insects, ant venom is composed primarily of alkaloids, particularly piperadine. Ant venoms have local necrotic and hemolytic effects.[133,134,135]

The authors have seen several small reptiles victimized by these predatory ants in Louisiana and Florida. Neonatal reptiles are especially vulnerable to these aggressive insects.

No antidote therapy exists; however, the use of antihistamines, topical steroid ointments (1% hydrocortisone), topical alcohol, and warm water baths may provide symptomatic relief.

Fire ants generally build mounds in warm sunny areas, places where reptiles typically bask. We can expect more reptile species to fall victim to the bites of these ants as these predatory insects continue to expand their range. Efforts to control the spread of these ants so far have not been effective.

Firefly Toxicosis

Reptile caretakers often supplement the diet of captive animals with freshly caught insects. Fireflies of the genus *Photinus* have been shown to contain steroidal pyrones (lucibufagins) that are poisonous.[136] These pyrones are structurally similar to cardenolides of plants and bufodienolides of toads, both of which are well-studied toxins.[136,137,138] These two compounds cause nausea and vomiting at low concentrations and can be potentially cardiotoxic at higher dosages. If extrapolations from mammals are correct, less than one half of a firefly could be lethal to a 100-g lizard.

Bearded dragons (*Pogona vitticeps*) have shown fatal intoxication after ingestion of fireflies.[139] In both cases documented, the lizards showed signs 30 to 60 minutes after ingestion. Clinical signs included pronounced oral gaping, intense color change in the neck area, and dyspnea. Both animals died within 90 minutes of eating the fireflies. At present, no effective therapy is known.

Lucibufigins protect fireflies from predators. Spiders, birds, and several species of lizard have been shown to avoid fireflies.[140–142] Like many lizards, bearded dragons show indiscriminate eating strategies and may ingest toxic substances. Furthermore, the bearded dragon, an Australian native, has no natural contact with *Photinus* species of fireflies and thus may exhibit no self-protective behavior.

Other lizard species have been shown to eat fireflies without lethal results. In one study, both fence lizards (*Sceloporus undulatus*) and skinks (*Eumeces laticeps*) were fed fireflies.[143] Both species readily attacked and ate the insects but immediately spit them out, wiping their mouths and rubbing their faces on the ground. When offered fireflies a second time (even days later) they refused to eat them and exhibited the same mouth wiping that they displayed after tasting the insects. Next, the authors stuffed five to seven fireflies into live crickets. Both types of lizards ate the crickets but subsequently regurgitated all the crickets they had eaten. No deaths of either species occurred. This study concluded that fireflies were distasteful and could cause regurgitation and vomiting. The conclusion was that the ingestion of fireflies was not always lethal to all lizard species.

Keepers must be advised to feed only safe food items. Any questions should be referred to a veterinarian. Fireflies should not be fed to reptiles nor any insects that sequester cardenolides, such as monarch butterflies (*Donaeus plexxipus*), queen butterflies (*Donaeus gillipus*), and lygaeid bugs (*Oncopeltus fasciatus*).[139] Other lizard species and other captive

reptiles may be susceptible to intoxication after firefly ingestion, and they should not be offered as food.

SMOKE INHALATION

Dangerous fires are still a daily occurrence in the new millennium. In the continental United States alone, every 17 seconds a fire department responds to a fire call.[144] Depending on the source, it is estimated that 50% to 80% of fire deaths are the direct result of smoke inhalation rather than injuries from burns or trauma.

When compared to the rest of the world, the United States has one of the highest death rates caused by fire. This may be attributable to wider use of synthetic materials for building and furnishings. These synthetic substances generally produce much more toxic combustion substances. In addition, the nature of our buildings, and the presence of more high rises, skyscrapers, and multifloor dwellings make it much more difficult to escape from the effects of a disastrous fire and much harder to stop the fires once started.

In European countries, forest fires affect mainly Hermann's tortoise (*Testudo hermanni*). If they are not initially killed outright from the fire and burns, they subsequently will succumb to smoke inhalation. In Africa, the species most affected by smoke inhalation due to forest fires are the threatened Malagasy tortoises (*Astrochelys radiata* or *Astrochelys yniphora*). Some species such as gopher tortoises (*Gopherus agasizii*) are said to be more likely to survive fires. This may be a function of their natural history, such as digging burrows or using rabbit burrows as dens.

The pathophysiology of smoke inhalation is complex. Generally, a toxic combustion product (i.e., smoke) exerts its poisonous effects by filling enclosed vital airways with gases other than oxygen and by inducing local chemical reactions in the respiratory tract; chemical asphyxiates elicit toxic changes in tissue distant from the lung.[145] Water solubility of toxic inhalants is the most important factor in determining the level of injury. Injury from water-soluble molecules occurs in the upper airways. Chemical toxicants with low water solubility reach the lungs, where they then exert their damaging effects. In addition, duration of exposure, concentration of the combustion products, and toxin particle size all contribute to the overall severity of the injury. Pathologic changes in the lungs and respiratory tissues may progress over hours to days. Inhalation of super-heated particulate matter in smoke can lead to extensive tissue damage.

In our practice, several captive reptiles have been presented after being exposed to the damaging smoke of house fires. Two young ball pythons arrived after a particularly aggressive apartment fire. Direct laryngoscopy of the animals revealed the accumulation of soot and carbonaceous debris, copious secretions, and edematous laryngeal tissue. Both snakes were in severe respiratory compromise. Their breathing was weak and rapid, and the airways became increasingly edematous. The animals were treated by intubating and administering 100% oxygen and supportive fluids. Despite our aggressive efforts, the smaller snake continued to deteriorate and died. After 2 days of therapy, the larger snake survived. A box turtle presented after a residential fire. The reptile displayed no burns, was nonresponsive, and never regained consciousness despite our efforts, which included supplemental oxygen, fluid therapy, antibiotics, and suctioning the airways. The turtle died roughly 2 hours after exposure. Effective management of smoke inhalation must include establishing airway patency, administration of supplemental oxygen, frequent airway suctioning and removal of both debris and secretions, and cardiovascular support. Early intubation is often more beneficial than waiting for the animal to decompensate. Radiographic evidence of lung damage due to smoke inhalation may not be evident for several hours.

TABLE 88.2 Factors That Affect the Potential Toxicity of Poisonous Plants

Geographic and Seasonal Variables

Plants poisonous in one part of the world may not be as toxic in other areas.

Season.

Plant Part Ingested

Not all parts of poisonous plants are always toxic.

Example: tomato; very edible fruit; stems and leaves contain toxic alkaloids.

Example: apples, peaches, apricots; have cyanide-containing seeds; fruit is edible.

Absorbability of Toxins

Apples, peaches, apricots: cyanide not released unless seeds are broken

Castor bean: poison (ricin) not released unless seeds are chewed

Species That Ingest the Plant

Poisonous plant intoxication often depends directly on the species involved.

Smoke inhalation patients are labor intensive to manage but may result in successful outcomes if animals are treated early and aggressively. Often intoxication from smoke inhalation is seen in wild chelonians after forest fires. It is not uncommon in animals living in areas susceptible to fire. In reptiles, pulmonary edema and congestion is often observed in the respiratory tree during necropsy.[145]

POISONOUS PLANTS

Some plants produce very powerful poisons. For many years, veterinary toxicology largely dealt with livestock suffering from plant poisonings. The last 20 years have seen tremendous growth in our understanding of small and zoologic animal intoxications.

Because many reptiles are either partially or entirely herbivorous, the potential for the accidental ingestion of toxic plants is real (Table 88.2). Although consideration of all plants potentially toxic to reptiles is beyond our present discussion, this section examines the more frequently encountered plant poisonings and those commonly reported in the literature. See Table 88.3 for a list of the most common toxic plants for reptiles.

Heaths (Family: Ericaceae)

The heath family plants (laurel [*Laurus nobilis*], rhodendrons [*Rhododendron*], azaleas [*Rhododendron penthatera* sp., *Rhododendron tusutsusi* sp]) are commonly planted in the United States as ornamental shrubbery. These plants contain grayanotoxins (diterpenoids) that interfere with membrane-based sodium channels.[146,147] The toxin is found in the stem, leaves, flowers, and nectar.[148] Ingestion can lead to bradycardia, gastrointestinal signs, depression, ataxia, and convulsions.[148] No antidote exists; treatment is supportive. We have seen two iguanas poisoned after eating azalea plants, one of which died. Both lizards were recumbent and nonresponsive a few hours after ingestion. Toxic levels in dogs begin at 7 mg/kg.[146,147] The one lizard died shortly after presentation.

Yews (Family: Taxaceae)

Ground hemlock (*Taxus canadensis*), Florida yew (*Taxus floridana*), English yew (*Taxus bacatta*), Pacific yew (*Taxus brevifolia*), and Japanese yew (*Taxus cuspidata*) are all members of a group that contains taxine, a cardiotoxic alkaloid.[146,147] This substance is a sodium channel blocker

Plant names can vary depending on the source and region. Consult a veterinarian with concerns about plants before feeding them to your reptile or using them in your home or yard.

VetBooks.ir

that can cause both cardiac and neurologic toxicity.[147] The bark, leaves, and seeds are poisonous but not the red fruit surrounding the seeds of these ornamental shrubs.[146,147] Wild birds spread the seeds by eating the fruit (nontoxic) and then excreting the seeds (toxic, but the bird does not chew them). No antidote exists. Poisonings have been reported in livestock, dogs, and caged birds.[149]

Lilies (Family: Liliaceae, Xanthorrhoeaceae, Asparagaceae)

Easter lily (*Lilium longiflorum*), tiger lily (*Lilium lancifolium*), day lily (*Hemerocallis* sp.), Japanese showy lily (*Lilium speciosum*), and Asiatic lily (*Lilium asiàtica*) are known to be poisonous to cats by causing renal toxicosis.[147] All parts of the plant are poisonous.[147] In addition, lily of the valley (*Convallaria majalis*) contains a potent cardiac glycoside.[150] Asparagus contains excess proteins, so as a consequence of it metabolism, excessive uric acid may be produced and the reptile can suffer gout. In our experience, toxic plant ingestion by reptiles is likely possible; captivity exposes animals to all sorts of novel plant exposures. We have administered activated charcoal to an iguana that ingested Easter lilies. The animal survived with supportive therapy, including fluids, warmth, and oxygen.

Fruit Seeds

The seeds of apples, apricots, cherries, peaches, plums, and the jetberry bush contain cyanogenic glycosides.[151] The seeds are dangerous if the seed capsule is broken. In humans, as few as 5 to 25 broken seeds can cause cyanide toxicosis.[152] Cyanide disrupts the ability of cells to use oxidative phosphorylation by poisoning mitochondria. The net effect is tissue hypoxia. The onset of clinical signs may be very rapid, and death can occur suddenly. Treatment for cyanide toxicosis is often not successful but does include 100% oxygen administration, supplemental fluids, and perhaps sodium nitrate or sodium thiosulfate. Attention must be given to what captive reptiles are eating, being fed, or are coming into contact with.

Avocado

Avocado (*Persea americana*) has been shown to be toxic to rabbits, mice, and caged birds.[147,153] All above-ground parts of the plant are toxic.[147] Persin, a compound isolated from the leaves, is believed to be the toxin responsible for avocado toxicity.[153] Intoxicated mammals display cardiac arrhythmias, necrosis of the myocardium, and acute death.[153] Caged birds show respiratory distress.[147,153]

Douglas Mader (personal communication) reports observing green iguanas in the wild eating avocados that have fallen on the ground. However, with all the toxicity reports in other species regarding the ingestion of avocados, they should be avoided in reptile diets.

Ricins (*Ricinus communis*)

Castor bean plants contain ricins, a potent toxin that stops protein synthesis. The poison, present in the whole plant, is most concentrated in seeds.[147] Chewing or breaking of the seed coat is necessary before intoxication can take place. For mice, rats, rabbits, and dogs, one seed can be fatal. In dogs, clinical signs involve the gastrointestinal tract but can include kidney failure and convulsions.[154] No known antidote is available. All ingestions of castor beans should be taken seriously because of the high toxicity. However, seed coats are not always chewed or broken when animals ingest seeds. Often the seeds pass undigested, and animals show no clinical signs.[154]

Cycad (Sago) Palms (*Cycas revoluta*)

These palms are used as house/garden plants and are naturally occurring in tropical and subtropical regions. All parts of the plant are toxic.[147] The nuts (seeds) are most toxic and only produced by female plants.[147] Toxins induce gastrointestinal, hepatic signs (cycasin), and neurologic signs (B-methylamino-L-alanine).[155] Gastrointestinal signs generally appear within 24 hours of ingestion.[155] No antidote exists; treatment is supportive. Clients should be encouraged to bring in the chewed plant to help identify the species.

Holly (*Ilex* spp.), Mistletoe (*Viscum* spp.), and Poinsettia (*Euphorbia pulcherrima*)

During the holiday season (usually Christmas in the Northern Hemisphere), several potentially toxic plants are often brought into the home.

Mistletoe are evergreen parasitic plants that grow on trees. Human exposures usually involve the berries either eaten by small children or brewed into tea.[156] Attempts to reproduce clinical signs in animals have been unsuccessful. In humans, the most common clinical signs are gastrointestinal. No antidote is available, and treatment is supportive. In children and mammalian companion animals, this intoxication is not lethal.

Holly includes English or Christmas holly (*Ilex aquifolium*), American or white holly (*Ilex opaca*), and winterberry (*Ilex verticillata*). Berries contain the sapponin ilicin, which is a potent gastrointestinal irritant.[147,156] In humans and companion mammalian species, the most common sign is digestive upset. No antidote exists, and treatment is symptomatic. These types of poisonings are not lethal.

Poinsettia (*Euphorbia pulcherrima*) possesses a milky sap rich in diterpenoids.[156] These molecules are fairly irritating to the skin, mucous membranes, and gastrointestinal tract. Reports of toxicity stem from a single account.[157] Poisoning is rare, and treatment is supportive.

Plants Containing Cardiac Glycosides

Several plants contain cardiac glycosides, including oleander (*Nerium oleander*), foxglove (*Digitalis purpurea*), and lily of the valley (*Convallaria majalis*).[147] For oleander, all parts of the leaf are poisonous; a single leaf well-chewed has been reported to be lethal.[158] Foxglove leaves and seeds are toxic. Lily of the valley poisoning comes from leaves, flowers, and roots. The cardiac glycosides are gastrointestinal irritants, may be responsible for a variety of cardiac arrhythmias (irregular pulse, bradycardia, rapid thready pulse, ventricular fibrillation), and can be fatal.

Ivy (*Hedera* spp.)

Ivy is used in greenhouses, as a houseplant, and as a ground cover. English ivy (*Hedera helix*), Atlantic or Irish ivy (*Hederix hibernica*), Persian ivy (*Hedera colchica*), etc., are all potentially toxic.[147] These plants, particularly the berries, contain terpenoids.[147] These molecules can cause salivation, gastrointestinal irritation, and diarrhea. Most ingestions are not serious, and treatment is supportive.

Plants Containing Nicotine

Tobacco products, including pipe tobacco, cigarettes, cigars, chewing tobacco, and snuff, contain the alkaloid nicotine. Nicotine is a stimulant of the CNS and cardiovascular system. It stimulates sympathetic ganglia and increases heart rate and blood pressure. High-dose exposures can cause paralysis of chest muscles and lead to respiratory compromise and cardiac arrest.[159] Cigarettes average from 15 to 25 mg of nicotine depending on the brand. Cigars have four to five times the nicotine of cigarettes. Chewing tobacco is even more palatable to animals because of flavors added (e.g., honey, sugar, molasses, cinnamon, licorice, and various syrups). Aids to stop smoking can also be a source of accidental nicotine ingestion. Nicotine patches usually contain between 7 and 25 mg, and nicotine gum contains 2 to 4 mg per piece. Some garden spray insecticides contain 40% nicotine (Black Leaf 40).

VetBooks.ir

As few as two cigarettes have been shown to cause lethal poisonings in puppies.[159] No data exists for secondary smoke intoxication, but an association between chronic respiratory conditions in captive reptiles and households with one or more smokers have long been suspected by the authors (personal observation). Clinical signs of high-dose nicotine intoxication include excitement followed by depression, diarrhea, seizures, coma, and respiratory or cardiac arrest.[160] No known antidote exists. Treatment includes frequent monitoring of heart rate, and animals may benefit from fluid therapy and oxygen administration. Prognosis is poor for high-dose intoxication.

Captive reptiles may ingest cigar and cigarette butts, pipe tobacco, chewing tobacco, or nicotine patches and gums. We have seen death in one African spurred tortoise (*Centrochelys sulcata*) and one green iguana after eating several cigarette butts.

Treatment includes fluid therapy and oxygen administration. Prognosis is poor for long exposure intoxications. No intoxications have been seen by ingestion of "e-cigarettes" or their nicotine-containing fillers, but the potential for this type of poisoning exists.

Oak (*Quercus* spp.)

Oak trees are found almost worldwide. Acorns, buds, twigs, and leaves have been implicated, but most intoxications involve either immature leaves or freshly fallen acorns in the spring.[161]

Oaks are heterophile plants (leaves of differing ages on the same plant). In several species, the younger trees have leaves that are more pointed than in adult plants and have a different composition, making them less palatable to leaf-eating animals. This may confer a protective advantage to young plants, allowing them to grow and survive.

Toxicosis from oak is produced by high concentrations of tannic acid and its metabolites, gallic acid and pyrogallol. Ingestion of toxic amounts of oak have been shown to cause ulcerative lesions in the upper and lower gastrointestinal tract, liver lesions, and necrosis of renal epithelial cells in the proximal tubules.[147]

A fatal episode of oak intoxication has been reported in a tortoise.[162] An African spurred tortoise was found dead in an outdoor enclosure where numerous oak trees hung over and into the area. On necropsy, the stomach of the tortoise was markedly distended with partially digested oak leaves. Extensive necrosis was found in the oral cavity, esophagus, stomach, and kidneys. The proximal renal tubules showed 45% necrosis.

Reports of this type show the importance for both caretakers and veterinarians to be aware of the potential for toxicity of any plant material ingested either in browsing or as an intentional part of the captive diet. Nutrition of captive reptiles must be carefully considered and continually monitored.

Marijuana (*Cannabis sativa*)

Marijuana continues to be the most used illicit drug in the United States.[163] Due to recent legislation, medical and recreational marijuana has been legalized in some U.S. states. As a result, the potential for companion animals to be exposed to varying forms of marijuana has greatly increased. *Cannabis sativa* has been used for centuries for its hemp fiber, as rope, and for its psychoactive resins. Totally or partially herbivorous captive reptiles may encounter growing marijuana plants, ingest dried stems, leaves, and flowers, or marijuana edibles.

The main active ingredient of marijuana is tetrahydrocannibinol (THC). The highest concentration of this psychoactive constituent is found in the leaves and the flowering tops of plants.[163–165] Hashish is the dried resin of flower tops. The precise mechanism of action of THC is unknown, but the psychoactive effects of this drug are thought to stem from a number of sites within the CNS, including cholinergic, dopaminergic, serotonergic, noradrenergic, and GABA receptors.[163–165] Ingested marijuana shows effects much more slowly than the results of the inhaled smoke; however, the effects of ingested THC last much longer.

Clinical signs after ingestion of marijuana include mydriasis, weakness, ataxia, bradycardia, hypothermia, and stupor.[163] The extent of clinical signs after marijuana ingestion is almost totally dose related.

Treatment for marijuana ingestion is primarily supportive and symptomatic. Marijuana intoxications are rarely fatal because of the wide margin of safety of THC. Activated charcoal administration is recommended to decrease enterohepatic recirculation. For most vertebrates, minimum lethal oral dosage for THC is greater than 3 g/kg.[163] Despite its relative safety margin, recovery after ingestion may be prolonged and take up to 3 to 4 days. Fluids and monitoring of body temperature may be beneficial.

We have treated two reptiles for having ingested large amounts of marijuana. A 4-kg (10 lb) African spurred tortoise showed no effects after eating four marijuana cigarettes. However, a 3-kg (6 lb) male green iguana was stuporous after eating into a "baggie" of marijuana and needed support. Both animals recovered completely. The potential exists for captive reptiles to ingest a variety of illicit drugs. Cannabis intoxication has also been reported in green iguanas.[166]

The herbivorous Steppe or Russian tortoise (*Agryonemis horsfieldii*) has a curious selective diet in the wild. They avoid some plants such as grasses that represent an important component of the plant community. Surprisingly, their preferred food items are the papaveraceae flowers (Opium plants), highly toxic for herbivorous mammals.[167] The tortoise seems resistant to the high concentrations of papaverine. This is an adaptive ecology that avoids sharing the same source of food between different species of herbivorous animals in a harsh environment.

Mushrooms

Confirmed mushroom toxicities are relatively rare, but the potential for such poisonings remain. For humans poisoned by mushrooms in the United States, the exact species is never identified in 95% of cases.[168] Furthermore, for humans known to have ingested toxic mushrooms, the individuals show no symptoms in 50% of the cases. Far and away the most toxic North American mushrooms are members of the *Amanita* species. The next most dangerous are hallucinogenic mushrooms.

The rarity of mushroom poisoning, lack of serious effects, and the inability of most physicians and veterinarians to correctly identify mushroom species involved all contribute to complicating the diagnosis. Nevertheless, a deliberate strategy and treatment plan for suspected mushroom poisoning is necessary. Veterinarians must strive to learn the toxic varieties of mushrooms in their region and their general incidence. Successful diagnosis includes gross identification of the mushroom specimen and a microscopic spore assessment ("spore-prints") by trained mycologists. The authors use mycologists from the Rocky Mountain Poison and Drug Center for mushroom identification in suspected mushroom poisonings. Investigation and confirmation of species by such collaboration is crucial to distinguishing toxic mushrooms from those mistakenly believed to be edible. Veterinarians must establish solid contacts with other local health professionals, such as human toxicologists, university mycologists, and laboratories well versed in toxicologic analysis.

Captive reptiles can be exposed to mushrooms in yards and greenhouses, in household terrariums, and as additives to their diet. Owners witnessing potential toxic mushroom ingestions should present the culprit mushroom for identification. *A. pantherina* occur throughout the United States and usually exists singly.[169] It has a brilliant red cap and is often photographed by naturalists because of its dramatic appearance. These mushrooms contain ibotenic acid and muscicol, its

VetBooks.ir

decarboxylated metabolite. Ibotenic acid is related structurally to the stimulatory transmitter agent, glutamic acid. Muscimol is very similar to the neurotransmitter, GABA, and acts as a GABA agonist with typical GABA signs and manifestations. Treatment is supportive. Most GABA manifestations respond solely to supportive care, and the animals completely recover. Benzodiazepines, such as diazepam, may be required for the management of seizures.

We have seen one case where a pet iguana ingested *Amanita pantherina* in a backyard. Within 30 minutes of ingestions, the approximately 1-kg lizard became lethargic and ataxic. The owners brought parts of the remaining mushrooms along with the lizard to facilitate identification and diagnosis. The iguana responded within a few hours to fluids, warmth, and support. No long-lasting effects were noted, and the animal was released after 24 hours. Some tortoises, such as box turtles, have been described as immune to certain toxic mushrooms.[170] Some species of mushrooms eaten by box turtles are quite poisonous to humans. There are cases of nonlethal human poisoning from eating a box turtle.[170]

DIETS TO AVOID

Although some foods may be relished by reptiles, nevertheless, many of these same foods have potentially toxic components and should only be fed in small quantities. Spinach, rhubarb, and beets contain the chelating agent oxalic acid, which binds with calcium ions in the blood to form calcium oxalate crystals. This can lead to a decrease in calcium levels and predispose to bladder stones.[171]

Broccoli, brussels sprouts, and cabbage contain mustard oil glycosides, which have been shown to contribute to the formation of goiter.[171] Fagopyrine found in buckwheat can cause photosensitivity. Iguanas fed buckwheat may develop blepharitis and conjunctivitis when exposed to sunlight. This condition is self-limiting and can be remedied without treatment if animals are kept in the dark and out of the sun for 48 hours.[171]

CONCLUSION

The keeping of any animal is not an inalienable right. Anyone keeping animals is accountable for their well-being and responsible for their treatment. There are 10 million other forms of life on this planet besides human beings. They all share the same life force that we do, thus they deserve our consideration, our respect, and our kindness. Toxins are just one hazard faced by captive reptiles. Exotic animal clinicians must keep current on the ever-expanding number of hazardous molecules that can lead to intoxication in their reptile patients.

Amphibian Medicine

Brent R. Whitaker and Kevin M. Wright[†]

Our world is changing and so too are our global amphibian populations. In some cases, these changes are in direct response to human activity, such as the development of land for commercial or residential use and the associated creation of transit corridors, all resulting in destruction of habitat and pollution. Similarly, the transition of land to agricultural use has resulted in increased pollution and habitat destruction, which has directly affected terrestrial and aquatic habitats. Other activities, including energy and mining, deforestation, hunting and collecting, and the introduction of invasive species, have all had a significant impact.[1] In other cases, changing climate patterns are known to affect amphibian populations. For example, with the increased frequency of El Nino years resulting in less precipitation in the Cascade Mountains, the western toad has been forced to lay eggs in shallower lakes and pools than they would normally. The lack of depth has increased exposure to ultraviolet light (UVB), causing the eggs to be more susceptible to *Saprolegnia ferax* infection resulting in a greater than 50% mortality.[2]

The emergence of infectious diseases and subsequent extinction of select species will continue, as our environments change along with the biodiversity of organisms that live within them. Amphibian populations exemplify this changing relationship between host and organism (e.g., viruses, bacteria, and parasites). Today we recognize organisms, such as iridoviruses and chytridiomycosis, as pathogens responsible for the global decline of amphibian populations. Veterinarians with a thorough understanding of amphibian medicine are needed to contribute to the care and ultimately to the conservation of these incredible animals.

To accomplish this, the veterinarian must have a thorough understanding of the biology and captive husbandry of amphibians. Amphibians are a unique class of vertebrates that appear in the fossil record during the Upper Mississippian era, more than 300 million years ago. Amphibians were the first vertebrates capable of exploiting terrestrial habitats on a long-term basis, although they still relied on aquatic environments for breeding and the development of young. This class of vertebrates is named Amphibia because of the double life (*amphibios* in Greek) that is characteristic of many of its members: an aquatic larval stage followed by a terrestrial adult stage. The modern-day amphibians have been categorized in three orders: Gymnophiona, the caecilians; Urodela, the salamanders and newts; and Anura, the frogs and toads. (Throughout this chapter the word "salamander" is used to refer collectively to salamanders and newts and the word "anuran" is used to refer to frogs and toads.)

EXAMINATION AND PHYSICAL RESTRAINT

The amphibian examination should be performed in a room that is between 70° and 75°F (21° to 24°C) or is in keeping with the patients preferred body temperature. Rooms suited for housing reptiles kept between 82° and 85°F (27° to 30°C) are unsuitably warm for most amphibians. Unbleached paper towels wetted with chlorine-free water may be used on the examination table. A humidifier in the room may be necessary, especially if the ambient humidity is below 50%. A bottle of clean, dechlorinated water should be in the room to wet down the amphibian as needed. With these precautions, an amphibian may be examined without risking dehydration.

The amphibian's skin is very sensitive to human handling. Soaps, lotions, natural oils, etc. can all irritate or damage the skin. The use of disposable gloves is protective to the animal and to the clinician. It also prevents the spread of pathogens, and for these reasons the authors recommend using them when handling amphibian patients. Several publications, however, caution of potential toxic effects of latex, vinyl, and nitrile gloves when working with amphibian larvae.[3–5] Reactions appear to be species specific. Thoroughly rinsing gloves in fresh water before use with adult or larval amphibians to remove talcum and reduce potential toxins is recommended.

Avoid clutter in the examination room because many amphibians are small and can disappear with surprising alacrity into the instruments and other accoutrements of the typical veterinary practice. For this same reason, close the door to the examination room whenever the amphibian is out of its carrying case.

When setting up the appointment, ask the owner to bring several photographs taken from multiple angles of the animal's normal enclosure, a water sample in a clean container for analysis, and any written records that he or she might have. Upon arrival, peruse the information that the owner has brought as part of the anamnesis. Learn as much about the microhabitat (the vivarium) and the macrohabitat (the environment within which the vivarium is housed) as possible, then proceed with the physical examination of the amphibian patient in a stepwise routine manner to ensure that nothing of importance is overlooked. First, observe the amphibian without handling or removal from its carrying case. Note body stance, responsiveness, and general demeanor, as well as respiratory movements, including gular movements and pulmonary respirations (Figs. 89.1 and 89.2). Body condition, including texture of skin and estimates of hydration status, can often be assessed during this hands-off examination (Fig. 89.3). The nares should be clean and free of debris, and the oropharynx should have no visible lesions. Excessive saliva or the presence of bubbles suggests respiratory complications.

The corneas should be clear, and a blink reflex should be initiated if the ocular globe is approached. Failure to blink mandates further investigation of the eye to determine whether the animal has vision. Slit lamp observation of the cornea and ocular fundus is warranted in any case.[6] Check pupillary reflexes. Note any cutaneous lesions. Erythema may be in response to handling or may signal a more serious underlying cause such as septicemia.

FIG 89.1 The clinician must consider the life stage of the animal being examined. This healthy larval form of the Arizona salamander (*Ambystoma mavortium nebulosum*) will soon absorb the fins on its tail and its gills as it makes its transition to land. Its legs will also become muscular and its broad head will become sleeker, developing eyes that protrude and have eyelids. (Courtesy of Brianna Whitaker.)

FIG 89.2 This red-eyed leaf frog (*Agalychnis callidryas*) shows the typical body form and posture of a healthy adult anuran: four limbs and a reduced or absent tail. No external neck exists, so the head and body appear unbroken. (Courtesy of National Aquarium.)

As part of the actual physical examination, coelomic palpation should be attempted, but in some species, this is not practical because many amphibians inflate themselves as a defensive maneuver. This defensive bloat appears when the amphibian is upset and can be distinguished from true bloat that remains once the animal has become calm. Edema may also extend down over the legs, especially in anurans. Edema has been associated with renal disease,[7] skin disease, gastrointestinal disease, microbial and parasitic infections, improper environmental conditions, toxins, cardiovascular and lymphatic disease, metabolic imbalances, and liver disease. The stomach may be palpable in recently fed amphibians. Ingested stones and other foreign bodies may be palpated too, as well as the presence of cystic uroliths.

Oral examination is facilitated with the use of a speculum. Use waterproof paper or thin strips of firm plastic, such as a guitar pick, are often used to open the mouth of the anuran. Inserting the paper at the tip of the snout works in some specimens, and inserting at the corner of the mouth works best in others. Large specimens may require a small spatula or thicker piece of plastic, such as a credit card, to pry open the mouth. Care must be taken not to put too much torque on the mouth, because the bones are thin and can easily be fractured if excess force is used. Test and note the withdrawal reflex of the limbs and righting reflex. Auscultation of the pulmonic fields is rarely practical because of the small size of many amphibians.

Proper manual restraint is essential to conduct a safe and informative physical examination, perform clinical diagnostics, and ultimately administer treatment to the amphibian patient. Some species produce toxic secretions, and some, such as the bicolored poison dart frog (*Phyllobates bicolor*), even produce toxins of a potentially lethal nature to humans. Other species (e.g., toads, *Bufo* spp.) produce toxins that irritate mucous membranes and may have lethal effects when absorbed by a human. Some amphibians defend themselves by producing mucilaginous secretions (e.g., slimy salamanders, *Plethodon glutinosis* complex). Wear protective gloves when handling amphibians to eliminate contact with these secretions and take special care not to rub your eyes or nose. Before handling the patient, rinse the gloves under distilled water to remove any talcum powder, which can irritate the amphibian and thereby cause the production of even more defensive secretions. Wearing eye protection is recommended, especially with larger amphibians. When pressure is applied to the parotid gland of a neotropical giant toad (*Bufo marinus*), the gland's secretion may spurt several feet into the air, with unfortunate consequences to the intercepting human.

The bulk of the amphibian's body needs to be supported during manual restraint. Grasp large anurans behind the forelegs.[8,] Often the anuran gives a release call, a signal to other anurans that it is either not sexually receptive or is of the wrong sex to be amplexed. The release call may sound similar to a distress call, a vocalization emitted by an anuran in response to predation, but either call may serve to startle a clinician momentarily, resulting in escape.

Many amphibians bite. Some, such as the Argentine horned frog (*Ceratophrys ornata*) (Fig. 89.4), can inflict severe wounds on the human handler. Large anurans often kick violently when first captured, so the handler must be ready to grasp in front of the hind legs immediately after picking up the animal behind the forelegs. Smaller anurans can be encircled with the thumb and index finger, or the hind legs gripped in a firm fist during the examination. For a thorough physical examination, place medium to small specimens inside clear plastic delicatessen cups, or small glass jars, for an unobstructed view of the entire body, including the ventrum.

Grasp medium to large salamanders behind the head and in front of the forelegs and again immediately in front of the back legs. Some salamanders have tail autotomy, so the handler should avoid placing any pressure on the tail. Occasionally, despite the gentlest efforts of the handler, a specimen may drop its tail anyway, so the client should be forewarned that this is a possibility. Small specimens may be examined more closely in a cup or jar as mentioned for anurans. Aquatic salamanders should not be removed from the water except for clinical diagnostics, such as collecting a skin scraping or obtaining the weight, and should be returned to the water as quickly as possible to minimize damage to the skin. Many of the larger salamanders (e.g., Hellbender, *Cryptobranchus alleganiensis*) can inflict painful bites that bleed profusely, so the handler is forewarned to maintain a firm grip when restraining these amphibians and to have owners keep their distance.

Caecilians and some salamanders (e.g., Amphiuma, *Amphiuma* sp.) are somewhat problematic to restrain for examination. An appropriately sized clear plastic tube, such as used for aquarium filtration equipment, or a clear glass jar or clear plastic cup is the most practical way to observe these elongated amphibians. However, to restrain the caecilian for diagnostics such as a skin scrape, without damaging the skin on the rest of the body, can be difficult because many specimens writhe violently when pressure is applied to the body. A soft foam rubber sponge moistened with chlorine-free water can be used to pin the caecilian, and the desired portion of the body can be cautiously exposed for

closer examination. Soft damp flannel may also be used. Precoating the "squeeze cage" with water-soluble gel (e.g., K-Y jelly) may be of benefit.

ANESTHESIA AND CHEMICAL RESTRAINT

Physical restraint alone may not yield a thorough examination of certain amphibian patients or may be impractical for other reasons. Chemical restraint is often needed for a thorough evaluation of the amphibian patient. Although familiar veterinary drugs such as sevoflurane, isoflurane, and ketamine hydrochloride may be used for chemical restraint, other drugs, such as tricaine methanesulfonate, isoeugenol, and benzocaine, are the anesthetics of choice for amphibians in most cases. Apnea and cardiac depression are common effects of many anesthetics used in amphibians. Heart rate can be monitored using an ultrasonic Doppler,

and gular movements can be visualized to determine apnea in many species.[9]

Immersion anesthetics prepared using water of a neutral pH, and free of ammonia, nitrite, nitrate, chlorine and chloramine, and other contaminants is most effective for amphibian anesthesia. Care must be taken to prevent drowning by keeping the solution below the humeroscapula joint[10] and carefully monitoring the patient.

Tricaine methanesulfonate (e.g., Tricaine-S (MS 222), Syndel USA [formerly Western Chemical], Ferndale, WA) is a water-soluble white powder derivative of benzocaine that can be added to water with the resultant solution used to titrate to the desired anesthetic effect.[11] Because tricaine methanesulfonate is very acidic, buffering the solution using a 1:1 ratio (dry weight) of sodium bicarbonate is recommended in order to reduce the risk of acidosis while increasing the absorbability of the drug. A 0.05% solution of tricaine methanesulfonate (0.5 g/L = 0.5 mg/mL) serves to anesthetize tadpoles and other amphibian larva. A range from 0.1% to 0.2% solution (1 g/L to 2 g/L) is needed for induction of surgical level anesthesia in most frogs and salamanders, but a 0.3% solution (3 g/L) is needed for many toads (*Bufo* spp.). Because the anesthesia is titrated, the final concentration of solution does not have to be precise to be useful; a slightly more dilute or stronger concentration simply increases or decreases the time to induction of the desired plane of anesthesia.

Tricaine solution may be managed simply with premeasured amounts of drugs in a container of known volume. For example, 1 gram of tricaine methanesulfonate in a 2-liter plastic soda bottle yields a 0.05% solution when 2000 mL of water is added. A 0.1% solution requires 2 g of tricaine methanesulfonate in the 2-liter soda bottle, 0.2% requires 4 g, and 0.3% requires 6 g. The concentration does not have to be exact to be effective, as the solution is administered to effect. Precision is only necessary for a controlled study.

A clear plastic bag is an ideal induction chamber for many specimens. Large specimens need correspondingly larger chambers. Plastic sweater boxes and lock-top plastic tubs are inexpensive options. In the case of flighty anurans, the induction tub should be lined with a plastic bag. The loose-fitting plastic serves to cushion the jumps during the excitatory phase of induction. Have readily available a copious supply of well-oxygenated chlorine-free water for the recovery period. If the anesthetic solution is too deep and covers the nostrils, many amphibians drown. This is less important for lungless amphibians and gilled forms that can survive total submergence for varying lengths of time. Nevertheless, using the shallowest depth of anesthetic solution possible is best to avoid accidents.

Tricaine methanesulfonate may be administered intracoelomically.[12] Aseptic technique must be used to prepare an injection quality solution. Intracoelomic dosages range from 50 to 300 mg/kg.

A surgical plane of anesthesia typically is induced within 20 minutes of immersion into the tricaine solution. Respiratory efforts slow down, and may stop, during tricaine anesthesia, but the cardiac rate is unaffected or even slightly increased except at very deep levels of anesthesia. Renal circulation may become reduced at high concentrations of tricaine methanesulfonate.

Erythema of the ventral skin or other light-colored skin is the first sign of anesthetic induction with tricaine methanesulfonate. The amphibian may appear agitated, and anurans often attempt escape leaps. As mentioned previously, induction of an amphibian inside a plastic bag minimizes the trauma associated with these attempts.

A light plane of anesthesia from tricaine methanesulfonate is characterized by the loss of the righting reflex and corneal reflex, but the withdrawal reflex (deep pain), spontaneous movement, gular respiration, and the cardiac impulse (visible heartbeat) are retained. A deep plane of anesthesia is the stage when only the cardiac impulse is present. The withdrawal reflex is the last reflex to go. An overdose is indicated when the cardiac impulse slows or becomes difficult to detect. Once an amphibian is in a deep plane of anesthesia, place it in tricaine-free water and titrate the level of anesthesia by trickling additional anesthetic solution over the amphibian's body periodically. Once the procedure is complete, anesthesia can be reversed with rinsing the body in well-oxygenated water.

Clove oil (which contains eugenol as its active anesthetic ingredient) and the commercially available pharmaceutical (Aqui-S, http://www.aqui-s.com/) has been used as an anesthetic in adult and larval amphibians.[13–15] One study showed that immersing *Xenopus laevis* in a bath of 350 mg/L of Aqui-S for 15 minutes to be effective in producing short-term surgical anesthesia.[13] Another study concluded that Aqui-S could safely be used to anesthetize southern brown tree frog (*Litoria ewingii*) tadpoles.[15] Researchers implanting passive integrated transponder (PIT) tags found immersing the three-toed amphiuma (*Amphiuma* tridactylum) in diluted clove oil (2 mL/4 L of water) for 5 minutes to be safe and effective whereas surgical implantation of transmitters required at least 10 minutes in the anesthetic.[16]

Propofol has been documented as an anesthetic with intracoelomic injection or intravenous injection in frogs. Intracoelomic injection of 9 to 30 mg/kg resulted in deep anesthesia in White's tree frogs (*Pelodryas caerulea*); a higher dosage was lethal in one specimen.[17] Intravenous injection (10 mg/kg) resulted in sedation or light sedation, but this may reflect perivascular deposition of some of the dose. Topical propofol (100–150 mg/kg) sedated maroon-eyed tree frogs (*Agalychnis litodryas*) of less than 20 g body weight, with the frog rinsed in fresh water once it was sedated (Wright, unpublished data). However, topical or intracoelomic propofol is inconsistent with time of induction, depth of anesthesia, and time to recovery and offers no advantages over topical tricaine methanesulfonate.

Ketamine hydrochloride may be used to immobilize amphibians, but it is less satisfactory than tricaine methanesulfonate or isoeugenol in that a comparatively large volume of drug may be needed, the induction time is extremely variable, the level of anesthesia achieved may vary greatly between species (in fact, many amphibians continue to show spontaneous movement even after the withdrawal reflex is lost), and the recovery time is variable.[18,19] Ketamine may be administered intramuscularly, intravenously, lymphatically via the dorsal lymph sacs in anurans (Fig. 89.5), or subcutaneously, depending on the size of the specimen and the needs of the clinician.

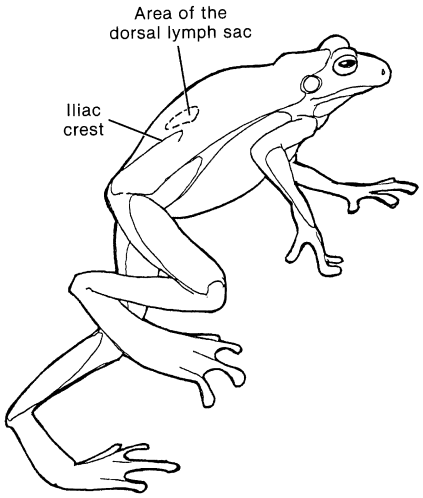

FIG 89.5 In some anurans, a pair of dorsal lymph sacs lies immediately lateral to the base of the sacrum.

Dosages for ketamine are between 75 and 100 mg/kg body weight for most species, although some amphibians may prove extremely sensitive or resistant to ketamine and dosages must be adjusted accordingly. A minimum of 30 minutes should be allowed to pass before the anesthetic stage is evaluated. If a satisfactory level is not achieved, a supplementary dose of ketamine may be administered. If adequate anesthesia is still not achieved, one should consider delaying the effort for 24 hours and starting at a much higher initial dosage. As with tricaine methanesulfonate, anesthetic deaths are rare except in debilitated specimens or through dosage errors of several orders of magnitude. Ketamine (200 mg/kg) combined with diazepam (0.2 mg/kg) administered IM to anesthetize cane toads (*Rhinella marina*) showed minimal activation of the hypothalamic-pituitary-adrenal axis as did tricaine methanesulfonate; however, ketamine-diazepam induction and recovery times were significantly prolonged.[20]

Alfaxalone, a neuroactive steroid and general anesthetic, has recently been made available in the United States and could provide the clinician an alternative option. Although not used extensively, one study using a 5 mg/L immersion bath was successful in anesthetizing a Mexican axolotl undergoing the surgical removal of two gastric foreign bodies.[21] Alfaxalone administered IM to Australian green tree frogs (*Litoria caerulea*) (30 mg/kg) and green and golden bell frogs (*Litoria aurea*) (20 mg/kg) provided sedation within 10 minutes. It also produced a light plane of anesthesia in booroolong frogs (*Litoria booroolongensis*) (20 mg/kg). All doses in this study were insufficient for painful procedures.[22] More work is needed to confirm the benefits and safety of this drug when used in amphibians.

Sevoflurane and isoflurane are inhalant anesthetics that may be used topically in amphibians. Several formulas may be used; a useful ratio is 1 mL isoflurane, 1 mL water, and 3 mL water-soluble gel, stirred to form a viscous liquid. This isoflurane solution is then smeared to the amphibian's ventral surface and rinsed away with fresh water once the animal is in a deep plane of anesthesia. The use of sevoflurane may be preferred. American green tree frogs (*Hyla cinerea*) anesthetized with a mixture of 1.5 parts distilled water, 3.5 parts spermicidal jelly, and 3 parts seroflurane recovered 4.5 times quicker and did not develop the skin lesions that isoflurane-treated animals did.[23] Some amphibians, such as the neotropical giant toad (*Bufo marinus*) or Argentine horned frog, may be anesthetized with directly dripping halothane or isoflurane onto the skin. The problem with either topical technique using inhalant anesthetics is that the induction should be performed under a fume hood or other system for scavenging waste anesthetic gases as the agent outgases from the solution.

If inhalant anesthetics are used in an induction chamber, a saturation level of 2.5% to 3% is recommended for methoxyflurane,[27] halothane, and isoflurane. The amphibian should be kept in the chamber for 5 to 10 minutes after voluntary movement ceases. A deep plane of anesthesia from a chamber induction usually lasts for 10 to 30 minutes. The chamber should be moistened with fresh water for the amphibian patient's comfort. If an amphibian appears particularly irritated during the process, stop the flow of anesthetic gas and remove the animal from the chamber. Some specimens do not tolerate the volatile anesthetics; epidermal damage may occur if kept in contact with halothane or isoflurane for a prolonged period of time. Large amphibians may be intubated and maintained on gaseous anesthetics, but because of alternate respiratory patterns (e.g., cutaneous, buccopharyngeal routes), maintenance of a steady level of anesthesia via this technique is difficult. An uncuffed endotracheal tube is recommended to avoid damage to the tracheal tissue.

Analgesia should be provided to amphibian patients undergoing potentially painful procedures. The opioid buprenorphine injected into the dorsal lymph sac (37.6 mg/kg) may provide significant analgesia to a common laboratory test of pain and last for up to 4 hours; the alpha-adrenergic agonist dexmedetomidine injected into the dorsal lymph sac (40–120 mg/kg) may provide analgesia up to 8 hours.[25] Alpha-adrenergic agonists appear to be effective in producing analgesia in amphibians. Northern leopard frogs (*Rana pipiens*) administered dexmedetomidine (0.1–3 nmol/g), clonidine (100–1000 nmol/g), epinephrine (1–30 nmol/kg), and norepinephrine (10–300 nmol/g) showed dose-dependent analgesic effects compared with those pretreated with selective alpha-2 receptor antagonists.[26] Meloxicam, a nonsteroidal antiinflammatory drug, has also been used as an antiinflammatory and analgesic in amphibians with apparent success. North American bullfrogs receiving a 4-mm punch biopsy and treated with 0.1 mg/ kg IM meloxicam showed a significant decrease in serum PGE2, suggesting that a daily dose of 0.1 mg/kg does provide analgesia.[27] This author has used doses of 0.1 to 0.2 mg/kg SID on a variety of amphibian species. The characteristics of opioid, nonopioid, and partial opioid drugs following systemic administration to *Rana pipiens* in behavioral studies are available[28] and may provide the clinician with alternative options to consider. Further work, however, is needed.

EUTHANASIA

Two agents are noted as methods of sedation and anesthesia in many research articles that are not recommended for the amphibian patient except for euthanasia purposes: ethanol and pentobarbital. An amphibian immersed in 10% ethanol enters a deep plane of anesthesia within 15 minutes. Increasing the concentration of ethanol to 70% kills the animal. An overdose of pentobarbital (>100 mg/kg) can be administered via intracardiac or intracoelomic injection. Evidence exists that amphibians may still feel pain after decapitation for several minutes. If decapitation is necessary for specific reasons, it should follow the induction of deep anesthesia. Other methods of euthanasia have been used, such as immersing small amphibians (<4 g) in liquid nitrogen, but the authors do not consider these to be practical in a clinical setting.

CLINICAL TECHNIQUES

Parasitological diagnostics are similar to those reported for other orders of animals. Direct examinations and flotation concentrations are recommended for detection of most protozoal and helminth parasites. Acid-fast stains of the feces should reveal *Cryptosporidium* spp. if present.

Hematology is an underused tool in the diagnosis and treatment of disease in amphibians. Historically, part of the problem is that large volumes of blood were required to perform relatively simple tests such as hemoglobin analysis. Another problem is that most of the techniques described for amphibian blood collection in the literature were non-survival methods such as decapitation. Thus, most of the data was collected strictly for physiological investigations, and scant attention was paid to the health or survival of the specimens.

Blood collection is relatively simple for total white blood cell counts (WBC), packed cell volume (PCV), total solids (TS), leukocyte differentials, and one or two chemistries on medium-sized amphibians (40–80 g); in larger specimens, one can run complete blood counts and plasma chemistry panels because of the larger volume of sample that can be obtained. Ideally, creating blood smears and evaluating the packed cell volume and total solids is done immediately upon collecting blood from an amphibian. The pretreatment of the syringe and storage of blood using lithium heparin could lead to lower and inconsistent values as observed in one study of blood collected from American alligators.[29] Lithium heparin is the anticoagulant of choice for blood because it does not affect the values of plasma calcium, sodium, or ammonia. One should avoid the use of ammonium heparin when obtaining a sample that is to be analyzed for NH_3 levels or else a falsely elevated reading results. Sodium heparin should be avoided when electrolyte values are desired. Ethylenediamine tetraacetic acid (EDTA) may lyse the erythrocytes of some species of amphibians and is not recommended as an anticoagulant for amphibian blood.

Several options are available for obtaining blood from a frog. A relatively simple procedure is to bleed from the lingual venous plexus that lies immediately beneath the tongue.[30] The authors have used this method on frogs as small as 25 g. Care must be taken to gently pry open the mouth to avoid breaking the thin mandibular bones. A small firm rubber spatula works well, or even a cotton minitip applicator can be used as a mouth speculum. In some animals, working from the lateral edge of the oral commissure is easier, and in other animals, insertion of the speculum into the philtrum, a small divot found just beneath the tip of the nose, is easiest. Once the mouth is opened, a cotton-tipped applicator is used to draw the tongue forward, as if the tongue were flipping out to catch a prey item (Fig. 89.6A). The lingual venous plexus is then visible on the underside of the tongue and the buccal floor. Most frogs have pale-colored tongues, so the purple to red network of veins is readily apparent. One large vein can then be punctured with a 26-gauge or 25-gauge needle, and a heparinized microhematocrit tube can be used to collect the blood that oozes from the vein. Once an adequate sample of blood is obtained, release the tongue. In most cases, this serves to put enough pressure on the vein that it stops bleeding. Occasionally, direct pressure on the venipuncture site with a cotton-tipped applicator is necessary to achieve hemostasis. The disadvantage to this technique is that the samples can be contaminated with saliva and mucus, but this can be minimalized if care is taken to swab the surface of the plexus thoroughly before venipuncture. In the case of a fractious animal, blood collection can be facilitated with sedation or anesthesia.

Large frogs and toads can be bled quite easily from the midline ventral vein on the ventral surface (see Figs. 89–6B and 89–6C). A 26-gauge or 27-gauge needle can be carefully inserted in a craniodorsal direction into this vein and gentle pressure applied to withdraw blood into the syringe. A good insertion site is the point midway between the sternum and the pelvis. Unfortunately, the passage through the bore of these small-gauge needles does tend to distort some blood cells, but a risk of lacerating the midline ventral vein is found with larger-gauge needles.

Salamanders may also be bled from the anterior abdominal vein in the manner described previously, but identification of the venipuncture site in these amphibians is more difficult. An additional site for venipuncture is the ventral caudal vein, also called the tail vein, which runs immediately ventral to the vertebral bodies. In salamanders weighing less than 80 g, a 27-gauge needle is the most practical choice for venipuncture attempts, but a 26-gauge or 25-gauge needle may be used for larger animals. Some salamanders and newts can perform tail autotomy, and in these species, one should not attempt this method with a conscious animal because it could result in the loss of the specimen's tail during the venipuncture endeavor.

A final choice for the collection of hematologic samples is cardiocentesis. This works equally well for anurans, most salamanders, and even caecilians. If the animal is difficult to restrain, it should be sedated or anesthetized to reduce the risk of pericardial, ventricular, or atrial laceration. Place the amphibian in dorsal recumbency to locate its cardiac impulse (heartbeat). The location of the heart may be quickly determined with a Doppler probe; once located with Doppler, the cardiac impulse is easy to track visually. Once the cardiac impulse is noted, a 25- to 27-gauge needle may be inserted into the central part of the impulse to penetrate the apex of the ventricle. Gentle pressure is applied, and the needle is slowly advanced or withdrawn until a flash of blood is visible in the hub of the syringe. If a clear yellow fluid appears instead, the needle should be withdrawn because the sample is most likely fluid from the pericardial sac. If sufficient pericardial fluid was obtained, it can be submitted for culture (if no anticoagulant was used), have cytological specimens prepared from it, or be analyzed for biochemical parameters. Even a small quantity can be prepared for either wet mount examination or stained slides to determine whether inflammatory cells or other abnormal items are present. A new needle and syringe should be used for a second attempt, but an increased risk exists of a problem arising with each subsequent puncture of pericardial or cardiac tissue.

(B) The lingual venous plexus is a prominent network of superficial veins that can serve as a phlebotomy site in many anurans. If a blood flash is detected, pressure should be let off the syringe. A cycle of gentle pressure and release coaxes blood into the syringe with each ventricular beat. Once an adequate sample is obtained, pressure is released, and the needle is withdrawn from the ventricular chamber.

Complete blood counts may be performed in the same manner as described for avian and reptilian species.[31–33] Natt & Herrick's solution allows one to make a direct count of WBCs and red blood cells (RBCs) from the same sample with a hemocytometer. Another option is to use the eosinophil indirect method, such as the Avian Leukopette (VetLab, Palmetto Bay, FL), to count granulocytes and calculate the total WBC/μL by the formula that uses the percent heterophils and eosinophils from the leukocyte differential to correct for the cells not counted in the hemocytometer. Although the eosinophil method may not work in all amphibian species, in the author's experience, it has worked well in axolotls (*Ambystoma mexicanum*), marine toads, smokey jungle frogs (*Leptodactylus pentadactylus*), hellbenders (*Cryptobranchus alleganiensis*), and sirens (*Siren intermedia*) and may be applicable to a wide variety of amphibians.

For each species encountered, the eosinophil technique is not recommended for use until it is verified for that species. This may be done by established guidelines for calculating the allowable total error for the two methods. If the calculated error is ≤ the allowable total error, then the two methods may be considered interchangeable.[34] An advantage to the eosinophil method is that it is much easier to count the stained granulocytes than it is to distinguish leukocytes from similarly sized thrombocytes in the Natt & Herrick's solution. However, the Natt & Herrick's solution allows an accurate WBC independent of the leukocyte differential count. This is important because in amphibians the granulocytes have been poorly described and may vary tremendously in staining characteristics and gross morphology between species.[35–38] Considerable expertise is needed for an accurate leukocyte differential count and interpretation.

Wright-Giemsa solution enhances the detail of the cell's internal morphology and provides consistently richer colors compared with other commonly available stains. It is important to remember that currently granulocytes are described on the basis of their staining characteristics and that the classes of granulocytes generally are not proven to be fully homologous nor analogous to the mammalian granulocytes with similar staining characteristics.[36] Documentation of the disease accompanying the differential leukogram is important to elucidate the role of the various leukocytes seen in amphibians. Few studies report normal blood values for amphibians[32] (e.g., for the American Bullfrog [*Rana catesbeiana*]). (See Chapter 35 for additional hematology and biochemistry values.)

Whenever an amphibian is manually restrained, some damage occurs to the thin epidermis. For this reason, moistened gloves should be worn by the handler to ameliorate the cutaneous injury to the patient. Although the humoral and cell-mediated immunological response in amphibians is poorly delineated, macrophages are responsible for phagocytic removal of cellular debris and bacteria.[36,39] Because of the presence of injured epithelial cells after handling, an amphibian's monocyte count may show a relative and absolute increase on subsequent leukocyte profiles.

Rickettsiae, parasites, and inclusions caused by viruses may be detected on appropriately stained blood smears.[40,41] Trypanosomes and microfilariae are extraerythrocytic parasites. Hemogregarine parasites are common intraerythrocytic inclusions in amphibians. The relative percentage of erythrocytes afflicted with inclusions may be important clinical prognostic indicators. Low levels are probably unimportant or may only be a minor contributing factor to the amphibian's signs. High levels of inclusions may be significant, especially if coupled with signs of anemia such as low PCV or RBC, polychromatic erythrocytes, microcytosis, or hypohemoglobinemia.

With the advent of small inexpensive dry film analyzers (e.g., Heska Element DC, Heska, Loveland, CO; VetScan VS2, VetScan HM5, VetScan I-Stat, Abaxis, Union City, CA; Catalyst Dx Chemistry Analyzer, Catalyst One Chemistry Analyzer, IDEXX Westbrook, ME), plasma chemistry tests on amphibians are now practical to obtain. The small volume of sample needed for analysis by these machines allows even a 0.5 mL sample to yield important results such as total protein/albumin, aspartate aminotransferase (AST, also known as serum glutamic-oxaloacetic transaminase or SGOT), alanine transaminase (ALT, also known as serum glutamate pyruvate transaminase or SGPT), blood urea nitrogen (BUN), ammonia (NH_3), glucose, and electrolytes. For serum samples, the blood should be allowed to clot for a minimum of 20 minutes before centrifugation to minimize the chance of sample coagulation after separation. Plasma samples may be spun down immediately, and then the plasma may be decanted from the cellular component.

Unfortunately, given the paucity of clinicopathologic information about amphibians, even with plasma chemistry data and hematologic values, it is still more of an art than a science to interpret those values in the context of the clinical picture. Interpretation is made more complicated by the fact that normal values may be influenced by environmental conditions, life cycle stage, nutrition, and other variables that directly affect amphibians. Reference values are best generated for a specific species by sampling as many healthy individuals from the population as possible (ideally 60 or more individuals) and analyzing those samples in the same laboratory.[42] If a consistent systematic approach is maintained with evaluation of an amphibian (as is done with evaluation of a domesticated mammal), then each practitioner has the potential to contribute to the development of this field of veterinary medicine.

Coeliocentesis may be performed via the paralumbar region or just off the ventral midline. Obtained fluid should be analyzed for protein content (generally <2 g/dL or <20 g/L), cytological characteristics, and biochemistries and submitted for microbial cultures.

Amphibian bacteria should be cultured at 98°F (35°C) and room temperature. However, most amphibian bacterial isolates can be recovered at 98°F. Although standardized kits may yield useful information as to the identity of the bacterial isolate, more elaborate techniques are often needed to confirm the etiological agent. The laboratory used should be competent in isolating and identifying specimens from other ectotherms (i.e., reptiles and fish), because many human-oriented microbiology laboratories do not have the expertise to identify amphibian pathogens.

Cutaneous lesions should be examined with direct observation of a wet mount, stained samples, biopsy, and microbial culturing. A skin scrape of the lesion may be obtained with the blunt edge of a scalpel blade or a dulled scalpel blade. The scraping should be viewed as a wet mount to determine the presence of fungi and protozoa. A gram stain should be made from the scraping if fungi or bacteria are the suspected etiological agents. A biopsy can be made of epidermal tissue with tenting the skin and removing a small oval of tissue. Tissue glue can be used to oppose the epidermal flaps. Cultures and histopathology of any samples obtained should be submitted if deemed appropriate.

NUTRITIONAL DISEASES

Amphibian nutrition has been a poorly understood aspect of captive husbandry; however, a recent publication on amphibian nutrition and the nutritive value of common feeder insects adds significant information and is recommended reading.[43] Anuran larval forms may be herbivorous, omnivorous, or carnivorous, and caecilian and salamander larvae are entirely carnivorous. Adult amphibians are entirely carnivorous, with the exception of one tree frog (*Hyla truncata*) that includes fruit of the coca tree in its diet.[24] The marine toad has been observed to consume vegetable matter in Florida, but no observations of this are reported

VetBooks.ir

in its natural range. Although starvation/emaciation is the most commonly reported nutritional disease, at least two major nutritional diseases are the result of the poor nutritional value of domestically produced insects, primarily crickets and mealworms, which do not provide the proper levels of calcium, phosphorus, vitamin D_3, and vitamin A required. These diseases are preventable in most cases. Vitamin and mineral supplementation through gut-loading or dusting of feeder insects can be effective in correcting the inverse Ca:P ratio and can bring vitamins A and D_3 to appropriate levels.

Nutritional Secondary Hyperparathyroidism (NSHP)

Nutritional secondary hyperparathyroidism (NSHP) is the most common form of metabolic bone disease (MBD) in captive amphibians and is the second most commonly reported nutritional disease in a survey of captive amphibian pathology. An absolute or relative calcium deficiency is likely the underlying cause of most cases of NSPH in amphibians because most of the commonly fed prey items have an inverse calcium-to-phosphorus ratio and a low total calcium. At this point, no descriptions of other forms of MBD have been found in amphibians.

One of the first clinical signs of NSHP in adult anurans is spastic tetany after strenuous movement (e.g., leaping) that subsides during rest. As the disease progresses, swimming may appear uncoordinated, with a lack of direction. Hypocalcemia results in coelomic distension from gastrointestinal stasis and gas buildup, and this may be seen with or without accompanying tetany. With chronic NSHP, amphibians develop spinal deformities, angulation of the long bones, and bowed mandibles that readily bend when manipulated (commonly called "rubber jaw" by herpetologists) (Fig. 89.7).

The clinician may appreciate misalignment of the long bones visually or by gentle palpation. High-resolution radiographs may confirm decreasing bone density in affected individuals and the presence of pathological fractures. The lateral processes of the vertebrae and urostyle become radiolucent early in the course of NSHP in anurans. The long bones typically become radiolucent after the "ghosting" of the lateral processes of the vertebrae and urostyle. If an apparently healthy member of the same species is available, including the healthy animal in the same exposure as the ill animal will assist the clinician in evaluating the skeletal structure. (Be wary in interpretation because the "healthy" animal may simply have subclinical NSHP.) The clinician may wish to retain the humerus, femur, vertebrae, and urostyle of a healthy necropsy specimen to have comparative elements for radiographic studies, in the event that a healthy specimen is not immediately available.

The authors believe that different species of anurans have different calcium and vitamin needs, because one species may develop signs of NSHP when fed the identical diet used to successfully maintain another species. The intake of calcium during the larval stage is especially critical for normal skeletal development and calcium homeostasis of the adult. Calcium absorption is dependent on available UVB, dietary vitamin D_3, and calcium, as well as a healthy gastrointestinal tract, kidneys, integument, and musculoskeletal system.[43] A calcium source such as cuttlebone should be available for the tadpoles of many species; Ramsey Canyon leopard frog (*Rana subaquavocalis*) tadpoles that did not have access to a calcium block developed NSHP as froglets despite being fed a diet used successfully in many other ranid species (Wright, Proc ARAV, 2001, pp 41–42). Thus, any case of NSHP should elicit a thorough dietary review with an examination of the vitamin and mineral supplements administered. Consultation with others who have kept this species may provide essential tips to correct the contributing husbandry (including dietary) problems involved with NSHP.

Amphibians presenting with tetany, spastic movement, muscle fasciculation, bloat, limb paralysis, or rigidity are considered a medical emergency and should be treated immediately for hypocalcemia using

FIG 89.7 Mandibular, skull, and limb deformities as a result of metabolic bone disease of nutritional origin (NSHP) in a New Granada cross-banded frog (*Smiliscus phaeota*). (Courtesy of National Aquarium.)

100 mg/kg calcium gluconate intracoelomically, IM, IV, or SC. Administer treatment a minimum of 1 to 2 times daily (or more frequently if needed) until presenting signs of hypocalcemia resolve. Continue with weekly injections of calcium gluconate until eating, then switch to heavy daily supplementation with calcium carbonate; oral or injectable vitamin D_3 supplements may be required to facilitate calcium utilization. Providing daily baths in 2% to 5% calcium gluconate and 2 to 3 IU/mL vitamin D_3 may allow uptake of the calcium ion in many species but should be used as a supplementary aid and not the single course of corrective efforts. Amphibians with NSHP require several months of treatment for resolution of radiographic lesions and improvement of other abnormalities.

Oral supplementation with Feline Clinical Care Liquid (Pet-Ag, Elgin, IL), Carnivore Care (Oxbow Animal Health, Murdock, NE), or Emeraid Intensive Care (Lafeber, Cornell, IL) may be beneficial. The diet should be corrected so that the amounts of calcium, phosphorus, and vitamin D_3 are balanced. In some instances, the level of calcium may need to be increased over what is considered "normal" for other species—this is especially true for those amphibians that come from hard alkaline environments and those from peat bogs and other weakly acidic environments. Many amphibians are presented too late in the disease to ever regain normal health. Even if calcium homeostasis and normal bone density are achieved, amphibians with deformities of the skull and hyoid bones may not be able to feed on their own. Calcitonin therapy described for reptiles has not proven effective in amphibians because of the major structural differences between amphibian calcitonin and the salmon calcitonin used for the treatment of human osteoporosis.[45]

Hypovitaminosis A

Hypovitaminosis A is a significant disease of captive amphibians, as they are unable to synthesize carotenoids, which includes vitamin A, leading to vision loss, epithelial hyperplasia, squamous metaplasia, and keratinization of mucosal epithelium.[43] This nutritional disorder was first recognized in captive Wyoming toads (*Bufo baxteri*), an endangered species that is the subject of an intense captive propagation program to produce specimens for reintroduction to the wild. An afflicted toad sights and targets a moving cricket and then rocks forward and flicks its tongue out to capture that prey. Often the cricket walks away from this attack, seemingly missed by the tongue flick. Within the Wyoming toad species survival program (SSP), this syndrome became known as

VetBooks.ir

"short tongue syndrome" because it looked like the toads were undershooting their targeted prey, as if their tongues were shorter than they should be. The condition appeared to be acquired, with clinical signs usually occurring in subadult to adult animals and slowly worsening over time. Affected toads eventually require assist-feeding as they become completely unable to capture prey.

Pessier determined that the underlying cause of short tongue syndrome was squamous metaplasia of the mucous glands of the tongue rather than an actual shortening of the tongue.[46] These lingual mucous glands were not able to produce mucus. A healthy toad tongue is coated with a sticky layer of mucus that serves to "glue" a prey item to the tongue and hold the prey as the tongue is retracted into the mouth. An afflicted toad was indeed hitting a cricket with its tongue flick, but the tongue lacked the gluey coating necessary to hold the cricket. Squamous metaplasia of the mucous glands is a lesion consistent with hypovitaminosis A in other vertebrates. Since the documentation of this lesion in Wyoming toads, several other amphibians have been reported with lingual squamous metaplasia. Squamous metaplasia has also been noted in the urinary bladder and kidney and may be an underlying etiology for hydrocoelom. Afflicted toads had mean liver retinol levels of 105 ug/kg (range, 44–164 ug/g), whereas the toads with short tongue syndrome had a mean of 1.5 ug/g (range, undetectable to 7.3 ug/g).[46] This finding supported the diagnosis of hypovitaminosis A. Some frogs with conjunctival swellings that were nonresponsive to antibiotic treatments did have resolution after supplementation with vitamin A either orally or topically (Fig. 89.8).

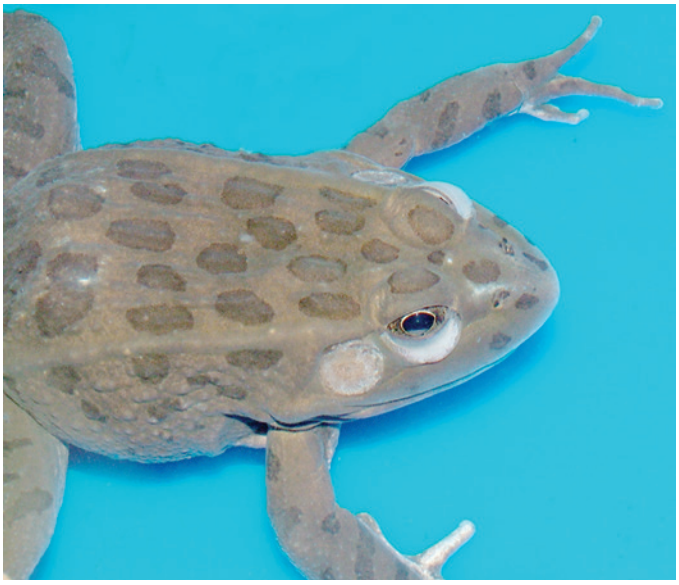

FIG 89.8 An anuran with bilateral conjunctival swelling typical of hypovitaminosis A.

Hypovitaminosis A is associated with an impaired immune system and secondary infections in other vertebrates. It is not clear if hypovitaminosis A impacts the secretions of glands involved in producing and maintaining the cutaneous slime layer, but it does seem likely that at least the mucus production is impaired. This may enhance colonization of the skin by various pathogens and predispose to infection by *Batrachochytrium dendrobatidis*, a fungus that feeds on keratin.

Insects are typically low in vitamin A, so domestic crickets are a poor source of vitamin A, yet crickets are a mainstay of the diets for captive amphibians. One popular commercial supplement lacks vitamin A but has beta-carotene. Frogs that received only this supplement developed conjunctival lesions. Even multivitamin supplements with sufficient vitamin A at the time the container is opened lose their potency if the supplement is stored in areas that have high humidity, warm temperatures, or both. A multivitamin supplement should be used within 6 months of opening the container.

Consideration of vitamin A supplementation in any clinically ill amphibian is reasonable, particularly one with signs similar to short tongue syndrome, swollen eyelids, evidence of infectious dermatitis, hydrocoelom, or simple failure to thrive. Commercially available vitamin A injectable solutions are too concentrated to use in all but the largest amphibians. If a sufficiently low concentration can be made at a compounding pharmacy, an intramuscular dose of 2 IU/g every 72 hours until clinical signs resolve is possible. Another possible treatment route is oral administration at a dose not to exceed 1 IU/g orally daily for 2 weeks or until clinical signs resolve. The oral vitamin A can be expressed from a human-grade vitamin A supplement (liquid gel cap) and diluted with propylene glycol to an appropriate concentration. Propylene glycol may cause irritation in some amphibians, so the client should be advised of possible adverse reactions. Topical treatment with vitamin D_3 is effective in amphibians, so topical administration of vitamin A may be effective.

During a necropsy, the whole tongue should be submitted to rule out hypovitaminosis A. Because the affected glands are more prominent at the rostral tip of the tongue early in the disease, a longitudinal section of the tongue should be examined rather than a cross section. In addition, other sensitive structures, such as the bladder, kidneys, and eyelids, should be assessed histologically for evidence of squamous metaplasia. A frozen section of the liver can be submitted for vitamin A analysis. If the levels are below 40 ug/g, and histological evidence of squamous metaplasia is seen in any of the high-risk organs, a diagnosis of hypovitaminosis A is reasonable.

Obesity

Obesity is also a common nutritional disease in captive amphibians, especially in animals that are regularly offered rodents. Some horned frogs (*Ceratophrys* spp.) may reach astounding proportions if fed to satiation on a regular basis. Most of an amphibian's stored fat is in the form of coelomic fat pads; thus, the obese amphibian generally has a grossly distended abdomen and normal-appearing limbs and tail (if present). Although investigations into the long-term effects of obesity in captive amphibians are lacking, obesity in amphibians undoubtedly has a major impact on health. Decreased longevity and poor reproductive performance may be associated with obesity in amphibians.

Gastric Overload or Impaction

Another common syndrome in captive amphibians is gastric overload or impaction (GOI). This potentially lethal condition is generally the result of eating a single overly large prey or consuming too many prey items in a short period of time. South American horned frogs and African bullfrogs (*Pyxicephalus adspersus*) are most likely to be presented with this condition, because many owners take inordinate pride in the gustatory capabilities of their animal. The owner may attempt to see how many prey items (e.g., mice) the anuran can eat in a single setting, unaware of the deleterious consequences this may have. An amphibian is often stimulated to feed when it sees movement. This may cause an amphibian to ingest a smaller cage mate, which is another cause of GOI in captive amphibians. Rocks and other foreign bodies may be ingested incidental to prey capture and swallowing, although pica has been noted in some anurans and aquatic salamanders. Some anurans retch and expel foreign bodies and large meals, but this is not often the case.

Swallowing an overly large meal can decrease respiratory ability. The lung is a simple saclike structure dorsal to the stomach, and when

VetBooks.ir

the stomach is distended, the tidal volume and total lung capacity are correspondingly decreased. Another complicating factor is that bacterial decay may outpace enzymatic digestive processes, leading to gastric bloat and endotoxemia. Because the prey often still moves after being swallowed, a distended stomach is prone to perforation, with subsequent contamination of the coelomic cavity with gastric contents. In the case of furred prey, the accumulated mass of undigested hair and bones may cause gastric or intestinal impaction. Gastric washes with hypotonic saline solution may remove ingesta in cases of acute gastric impaction, or if gastric bloating from fermentation is noted. Endoscopic retrieval of items via the esophagus may be possible in some cases. In most cases of GOI, a gastroenterotomy to remove the items is recommended. Pre- and intraoperative antibiotics and fluid therapy are recommended for an amphibian with GOI. The surgeon must determine whether postoperative treatment is needed based on the environment into which the animal will be placed during recovery. The benefit of mucosal protectants such as sucralfate is unknown. If an intestinal impaction from a trichobezoar is suspected, medical therapy (e.g., mineral oil) may be attempted.

Nutritional Support

Liquid formulas designed for the nutritional support of obligate carnivores are generally useful for amphibians, including Feline Clinical Care Liquid (Abbott Laboratory, Chicago, IL), Hill's A/D (Topeka, KS), Waltham Feline Concentration (Leicestershire, UK), Carnivore Care (Oxbow Animal Health, Murdock, NE), Emeraid Intensive Care Carnivore (Lafeber Co, Cornell, IL), or a ReptoMin slurry (Tetra, Blacksburg, VA).

A puree of cricket or mealworm abdomens, earthworms, or pinkie mice supplemented with vitamins and minerals may also serve as a tube-feeding formula, but this may need to be enzymatically digested with pancreatic enzymes to reduce its viscosity enough to flow through small-diameter tubes. Exoskeleton and skin are not digested well by pancreatic enzymes and need to be screened out of the formula to prevent clogs.

A red rubber catheter, polypropylene intravenous catheter, stainless steel gavage tube, or soft silastic tubing may be used as a feeding tube, the choice depending on the size of the amphibian's mouth. Care should be taken to avoid injuring the esophagus or stomach with injudicious use and placement of the tube. The tube only needs to be inserted one-third of the amphibian's snout-vent length to be in the stomach. Begin by diluting the supplement 50/50 with chlorine-free water and giving 1% of the animal's weight daily. This is slowly increased to 2% over a course of days.[47]

Hand-feeding (assist-feeding) may be possible for some debilitated amphibians such as the tiger salamander (*Ambystoma tigrinum*) or the dumpy tree frog (*Pelodryas caerulea*). Even debilitated specimens often swallow a piece of food (e.g., a headless cricket) that is placed in the mouth. Removing the head of the cricket exposes the viscera of the cricket and speeds its digestion. This option is preferred to oral tubing when possible.

INFECTIOUS DISEASES

Viral Diseases

The longest-studied amphibian virus is the herpesvirus, which causes renal adenocarcinomas in the northern leopard frog (*Rana pipiens*).[48] Lucke's renal tumor or ranid herpesvirus (RaHV-)-1 is one of the better-described viral-associated tumors, and its life cycle is generally predictable. Renal tumors grow rapidly during the warm months of the year. Virus replication is greatest at lower temperatures, with viral production occurring in the fall after the tumor has reached maximal size.[49] Viral shedding occurs the following spring, during spawning, thereby ensuring the infection of the offspring and perpetuation of the disease. Affected frogs become extremely thin and generally die in the months after spawning. Hydrocoelom and hydrops may be noted in the latter stages of renal failure, and coeliocentesis may yield neoplastic cells. At necropsy, either or both of the kidneys may be affected, with a histopathologic diagnosis of papillary adenocarcinoma. Eosinophilic intranuclear inclusions may be detected in the kidneys of infected frogs during the winter months. In many ponds, the entire population of leopard frogs may be infected. A second herpesvirus, frog virus 4 or (RaHV-)-2, has been isolated from the urine of a leopard frog with adenocarcinoma, but the importance of this virus is unclear.[49]

Iridoviruses are DNA-based viruses in the genus Ranavirus that have been associated with die-offs in wild populations of frogs and tiger salamanders (*Ambystoma tigrinum* spp.) globally. A number of factors including persistence in the environment, direct and indirect transmission, the presence of reservoir species including fish and turtles, and changing environmental conditions contribute to the impact of ranaviruses. Ranavirus type III is the iridovirus responsible for tadpole edema syndrome, a disease that is fatal to the tadpole, with adult anurans as asymptomatic carriers.[50,51] Infected tadpoles and metamorphosing froglets have edema and subcutaneous hemorrhage, which may be secondarily contaminated with bacteria. Grossly, the lesions appear consistent with bacterial dermatosepticemia ("red leg disease"). Histopathology reveals intranuclear inclusions within the erythrocyte; a recent finding is that basophilic intracytoplasmic inclusions may also be seen within the glandular cells of the stomach.[52] Bohle iridovirus, implicated in declines of Australian anurans, is closely related to ranavirus III.[53,54] An iridovirus has been associated with mortalities of wild populations of the European common frog (*Rana temporaria*).[55] Gross lesions include erythema, petechiae, ecchymoses, and skin ulcers. Histologically, basophilic and acidophilic intracytoplasmic inclusions may be found within hepatocytes. Secondary bacterial infections are often noted. Frog erythrocytic virus (FEV) appears iridovirus-like and has been found in the erythrocytes of several species of frogs and toads, although the clinical significance of this infection is not known.[49] Ranaviruses can live in aquatic environments for several weeks without a host, emphasizing the need for biosecurity when accepting new amphibians into existing collections. Bleach (3%) and chlorhexidine (0.75%) for 1 minute of contact time are effective disinfectants. In 2016 ranavirus infection in amphibians became a disease listed by the World Organization for Animal Health (OIE) (http://www.oie.int/animal-health-in-the-world/oie-listed-diseases-2017/).

Other viruses have been described from amphibians (e.g., calicivirus, herpesvirus), as have suspected viral-induced lesions, but little effort has gone into the elucidation of disease states associated with viral agents, a fact hampered by the overall paucity of information on normal histology of amphibians. In fact, "poxvirus" lesions originally described from the European common frog (*Rana temporaria*)[56] actually turned out to be normal melanosomes when reviewed with transmission electron microscopy.[55] Nevertheless, viral diseases seem likely to continue to be recognized as a significant source of disease and mortality in captive and wild amphibians.

Bacterial Diseases

Gram-negative bacteria such as *Aeromonas, Pseudomonas, Proteus,* and *Escherichia coli* are part of the bacterial flora that may be routinely cultured from otherwise healthy captive amphibians. Poor husbandry (as exemplified by crowding, poor water quality, inappropriate cage design, spoiled food, exposure to toxins such as pesticides, etc.) may cause immunosupression and allow any one of these organisms to cause disease. Other pathogens, such as iridovirus or *Batrachochytrium dendrobatidis,* may be the primary etiology of disease in many amphibians diagnosed

VetBooks.ir

with bacterial infections; the original pathogen may be difficult to detect by the time the amphibian shows clinical signs of illness such as ventral erythema. This clinical sign gave rise to the term "red leg disease" or "red leg syndrome" in early reports of amphibian disease. When this clinical sign is caused by a bacterial pathogen, a more appropriate term for the disease is bacterial dermatosepticemia (Fig. 89.9).

Aeromonas is the most common genus isolated in published cases of clinical bacterial disease in amphibians. *Aeromonas hydrophila,* a common contaminant of water, has historically been associated with bacterial dermatosepticemia.[57–60] However, several other aeromonads and other gram-negative bacteria have been implicated in amphibian disease in addition to *A. hydrophila.* The following discussion is based on what is currently known about bacterial dermatosepticemia in amphibians, with the caveat that appropriate antibacterial therapy ultimately depends on the exact pathogen that has been cultured and definitively identified from the clinical case in question.

Clinical signs of bacterial dermatosepticemia may be brief and extremely rapid in chronology. Dilation of the surface capillaries and petechiation are common clinical signs and cause an erythema that is readily visible against white or pale-colored skin (Fig. 89.10). This condition may progress into ecchymosis and large subcutaneous hemorrhages several hours before death; at this point, the underlying pathogenesis is similar to disseminated intravascular coagulation in mammals. Typically, ecchymosis appears immediately before or during the agonal convulsions.

Bloating from intestinal gas, hydrocoelom, hydrops (Fig. 89.11), anorexia, and lethargy may be noted shortly before the onset of convulsions and sudden death. More than one animal in an enclosure is typically affected as a rule. Postmortem lesions are consistent with disseminated septic thrombi and may also include splenic congestion and areas of hepatic necrosis. Culture of the blood and internal organs of the dead amphibians is recommended to determine the underlying pathogen, and a blood or coelomic fluid (Fig. 89.12) culture of apparently healthy amphibians within the same enclosure is suggested to determine the likelihood of further outbreaks. Some bacteria, such as *Flavobacterium* spp., have as high an epizootic potential as the classic *Aeromonas* spp.[60,61]

Because amphibians commonly have mixed infections by the time they present for clinical examination, the initial therapy for an amphibian with signs of septicemia should target gram-negative bacteria and *Batrachochytrium dendrobatidis.* The patient should be treated immediately with aminoglycosides (5–10 mg/kg intramuscularly [IM] or intracoelomically [ICe] every 48 hours) and then soaked for 10 minutes in 0.01% itraconazole solution or other topical imidazole solutions. Be sure to use solutions that are alcohol-free; note that many of the solutions do not carry this note on the bottle's label and the manufacturer must be contacted to determine whether alcohol is in the solution. If the history suggests possible exposure to sources of *Chlamydophila psittaci,* doxycycline or tetracycline therapy should also be initiated immediately. Immediate evaluation of the husbandry should be performed with the intent of eliminating contributing factors. If possible, isolate, individually monitor, and treat on a case-by-case basis affected and suspect amphibians. Broad-spectrum antibiotics with anaerobic activity (e.g., metronidazole, penicillins) may be warranted, as anaerobic bacteria may be isolated from ill amphibians. Even with appropriate treatment, morbidity and mortality in an outbreak are likely to be high, especially if secondary infections are noted. Soaking the patient in amphibian Ringer's solution, 0.5% to 0.6% sodium chloride, or other electrolyte solution isotonic to amphibian plasma helps combat the metabolic derangement caused by the associated skin pathology.

Chlamydophila species have been reported to cause disease in a number of amphibians.[62] Symptoms may be similar to those observed in animals with dermatosepticemia. Differentiation of this syndrome

from classical bacterial dermatosepticemia relies on the absence of bacteria in the cultures obtained and detection of *Chlamydophila* inclusions in the spleen or liver. Distinguishing between chlamydial diseases and rickettsial diseases may be difficult unless antigen or polymerase chain reaction (PCR) tests are used.[63] Doxycycline is the drug of choice for chlamydophilosis,[64] although tetracycline also may be effective.

Chronic bacterial infections are uncommon. Typical presentations include cutaneous ulcers, abscesses, or an amphibian with prolonged lethargy and a poor feeding response. Skin scrapings or cultures of any lesions should be obtained to rule out mycobacterial or fungal involvement. Cutaneous ulcers and abscesses respond quite well to debridement and appropriate antibiotic therapy, both topical and parenteral. The underweight and depressed amphibian likely has internal abscesses or a granulomatous disorder. Internal abscesses are poorly responsive to treatment unless they can be surgically removed. If a granulomatous disease is confirmed, such as mycobacteriosis or chromomycosis (see subsequent), immediate euthanasia is recommended because treatment is ineffective, and the diseases are likely to be zoonotic. A husbandry review is suggested to determine whether any contributing factors are present (e.g., abrasive surfaces, previous occupants that died).

Mycobacterium spp. can cause lesions in amphibians, and the species associated with amphibians are generally waterborne species or those that are soil saprophytes (e.g., *Mycobacterium marinum*, *M. chelonea*, *M. ulcerans*, *M. liflandii*, *M. ranae*, *M. xenopi*). Mycobacteria are ubiquitous in the aquatic environment, being found typically in the biofilms coating the animal's aquatic habitat. Infection occurs through direct contact with infected cohorts, consumption of infected organisms, or exposure to contaminated water. Immunologically competent amphibians will remain subclinical for long periods of time, whereas stressed animals typically develop acute and severe disease.[65] Mycobacteriosis must be considered in amphibian colonies, especially those on recirculating systems that are experiencing chronic illness and mortalities. In contrast to the more typical bacterial infections, amphibians with mycobacterial infections generally display weight loss early on despite a good appetite (Fig. 89.13). Clinical signs are typically nonspecific and include weight loss, dermal ulcerations, anorexia, and bloating. If any cutaneous lesions are present, diagnostics should include examination of an aspirate, scraping, or biopsy to determine whether acid-fast bacteria are present. If acid-fast bacteria are detected, samples should be submitted for culture or PCR and identification. The identification of the mycobacterial species does not alter the patient's prognosis but is important because some species have a higher zoonotic potential than others. If no cutaneous lesions are found, exploratory coelioscopy or coeliotomy may detect internal granulomas consistent with mycobacteriosis. Finding such lesions warrants immediate euthanasia of the amphibian and counseling the client of the zoonotic potential of amphibian *Mycobacterium* spp. In closed, recirculating systems mycobacteriosis can be spread rapidly and infect many of the animals within the colony. Because there is no effective treatment at this time, removal and euthanasia of infected individuals is required to control the spread throughout the colony and prevent the infection of the human handlers.

Fungal and Algal Diseases

Most fungal and algal species that are involved in infectious diseases of amphibians are opportunistic invaders that invade injured or otherwise immunocompromised animals. An important exception is amphibian chytridiomycosis. The causative agent, *Batrachochytrium dendrobatidis* (Bd), was first described in captive amphibians but has since been identified in free-ranging populations and has been implicated in the decline of frogs, toads, salamanders, and newts in seemingly pristine environments.[66] Recently, a second, highly divergent, chytrid pathogen, *Batrachochytrium salamandrivorans* (Bs), has been implicated in the near-extinction of the fire salamander, *Salamandra salamandra*, in the Netherlands.[67]

Chytridiomycosis is typically associated with moist environments where motile zoospores can swim and infect cohorts. Because Bd feeds on keratin, postmetamorphic anurans with keratinized skin are usually affected more than tadpoles, which have only keratinized mouthparts and are usually subclinical. Clinical signs associated with Bd may vary from sudden death with no obvious external signs to progressive lethargy, excessive skin shedding, ventral erythema and petechiation (Fig. 89.14), deformities of the keratin beaks in tadpoles, and cutaneous lesions on the tips of the toes. In contrast, salamanders infected with Bs show multifocal skin erosions all over their body, become ataxic, anorectic, and die within 7 days of being infected.[67] Diagnosis of Bd relies on identification of the agent in skin scrapings or other tissue samples.[68] Biopsies of the drink patch or toe tips are often productive. A commercially available polymerase chain reaction (PCR) test may be used to identify chytrid DNA from skin scrapings and is even more sensitive than histopathology or wet mount examinations (Pisces Molecular, Boulder, CO). Diagnosis of Bs is confirmed using a newly developed PCR. Bd responds to treatment using itraconazole at 0.01% in 0.6%

saline in a 5-minute bath for 11 consecutive days.[69,70] Spraying animals daily with vorticonazole at 125 mg/L for 7 days may also be effective and much less labor intensive.[71] Elevating environmental temperature to 25°C for 10 days has been effective for Bs.[72] Unfortunately, the fungus appears to persist in wild habitats and may continue to be a proximate cause of the decline of some free-ranging amphibian populations. As of 2016, *Batrachochytrium dendrobatidis* and *Batrachochytrium salamandrivorans* infections in amphibians are diseases listed by the World Organization for Animal Health (OIE) (http://www.oie.int/animal-health-in-the-world/oie-listed-diseases-2017/).

Other than chytridiomycosis, fungal infections are rarely encountered if an amphibian's husbandry is appropriate. Many of these fungi are ubiquitous in aquatic and moist terrestrial environments. An amphibian's covering layer of mucus and other glandular secretions provide protection from invaders, but damage to the slime layer or the epidermis allows fungi to colonize. Cage furnishings may be the source of the amphibian's injury; thus care should be taken to select decorations with nonabrasive surfaces and rounded edges.

Cage-mate aggression may be the source of the traumatic injury, especially if the vivarium is overcrowded. During the breeding season, the vivarium may become functionally smaller, as the inhabitants are more aware of each other and more prone to aggressive displays. In the wild, the subordinate amphibian is able to flee and avoid serious injury, but within the enclosed setting of a vivarium, little chance exists for escape. Reproductive and territorial disputes may culminate in bite wounds. Other sources of cutaneous injury are the nylon nets that are used to transfer fish and amphibians from tank to tank. Care should be taken to use soft netting or a plastic bag when capturing an amphibian to minimize the disruption afforded to the protective slime layer.

Amphibians stressed by other inappropriate husbandry techniques are especially prone to fungal infections. Proper nutrition, sanitation, and water quality are recognized as key elements in prevention of fungal disease in amphibians.

Saprolegniasis is primarily an infection of aquatic amphibians that can be caused by more than 20 different species of aquatic fungi. The characteristic sign of this fungal disease is the presence of a cottonlike material on the surface of the amphibian's skin or gills (Fig. 89.15) or in the oral cavity.[73] This filamentous growth covers an underlying cutaneous ulcer. The fungal mat's color can help the clinician determine the chronicity of the lesion. Acute infections are characterized by a light-colored fungal mat, and more chronic infections often turn green with algae or brown as debris is trapped in the fungal strands. If left unchecked, secondary bacterial infection may occur. A tadpole affected by saprolegniasis may starve as a result of infection of the keratin beak and ulceration of the mouth.[73] Temperature is an important factor in the progress of saprolegniasis, as its incidence rate markedly decreases at water temperatures over 68°F (19°C). Wet mounts of the cottony mat reveal the characteristic fungal hyphae and confirm the lesion as saprolegniasis. Because most cases of diffuse saprolegniasis are eliminated with appropriate use of salt, itraconazole, or benzalkonium baths, it is not necessary to speciate the etiological agent any further. Isolated lesions respond to topical miconazole, dilute benzalkonium chloride, or malachite green.

Chromomycosis is a disease of anurans that is caused by several taxa of pigmented fungi.[74] Cutaneous lesions are usually light-tan or gray to dark raised nodules, and the anuran may show signs of debilitation and weight loss. Presumptive diagnosis is based on finding pigmented fungi in wet mounts of scrapings from a lesion. Etiological diagnosis requires histopathology and fungal isolation. Chromomycosis has a tendency to become systemic, unlike saprolegniasis, which is normally a cutaneous infection, and chromomycotic granulomatous lesions may spread throughout the viscera. The course of this disease may be quite slow, and therapy is usually unrewarding. Cryosurgery may be effective in eliminating individual lesions, but the commonly available antifungal agents and topical antiseptics appear to have little effect on the course of chromomycosis in amphibians. Euthanasia is recommended for infected amphibians due to the zoonotic potential of many of the fungi and the lack of viable treatment modalities to date.

Amphibian eggs often mold if kept in an inappropriate hydric environment. Dendrobatid frog eggs typically need little free water if the humidity is high and the incubation temperature is correct. Salamander eggs often mold if the water is too warm or if the dissolved oxygen is too low. The mold may not kill the embryo but may affect the yolk and kill the tadpole within 48 hours of hatching.

Treatment of fungal disease should be aimed at correcting the underlying cause, so a diagnosis of fungal disease always requires a thorough husbandry review to improve the captive environment of the amphibians.

Mesomycetozoans

Mesomycetozoans are a clade of eukaryotic protists that phylogenetically exist near the animal–fungal boundary. Those known to infect amphibians include *Amyphibiocystidim*, *Amphibiothecu*, and *Ichthyophonus.* Previously reported as *Dermocystidium*, *Dermosporidium*, and *Dermomycoides* ssp., the Dermocystids that infect amphibians are now recognized as two distinct genera, *Amphibiothecum* (previously *Dermosporidium*)[75,76] and *Amphibiocystidium.* Continued molecular characterization of these organisms will likely result in nomenclature changes and taxonomic reorganization. The Dermocystids are spore-forming organisms that appear to be nonlethal, although severe infections may lead to generalized infection and mortality. Infected animals have multifocal nodules and pustules, usually on the ventrum, that resolve in 4 to 8 weeks.

The mesomycetozoan order Ichthyophonida includes the genus *Ichthyophonus,* whose species are pathogenic, causing myositis in pre- and postmetamorphic stages of salamanders and frogs. Clinically, animals

show muscle swelling in the thigh, rump, and tail and may appear nodular, especially in tadpoles. Although it may be considered an incidental finding, as in one study that looked at wild amphibians in Quebec, Canada,[77] debilitation may lead to mortality, especially in adults. A similar organism was found infecting the central nervous system of the southern toad (*Anaxyrus terrestris*) in Florida.[78] Diagnosis is based on histopathology or finding characteristic spores in skeletal muscle through microscopic examination of material from the lesions.[79] There is no treatment other than supportive care at this time.

PROTOZOAL DISEASES

Amoebiasis

Entamoeba ranarum is frequently found and has been implicated as a cause of amoebiasis in amphibians. Whether amphibians can recover spontaneously from this disease is questionable. Transmission is accomplished with ingestion of the cysts. The direct life cycle can lead to rapid spread within a collection. Cysts are relatively durable in the environment, and once ingested, the trophozoite stage excysts to mature in the colon. Pathogenic amoebae are most likely to directly attack the colonic mucosa, but the liver and kidneys can also be infected.[80] Certain conditions, such as inappropriate food items, lack of ingesta, or concomitant bacterial or parasitic infections, may predispose amphibians to amoebiasis.

Clinical signs are limited in the early stages of amoebiasis. Anorexia, dehydration, and wasting are common signs of intestinal amoebiasis. Stools change in consistency, becoming liquid and tinged with blood. Failure to pass any stool, as well as regurgitation, may be noted at this point. Hydrocoelom and hydrops may accompany renal or hepatic disease in amphibians. Dehydration is usually associated with renal disease in terrestrial amphibians.

Antemortem diagnosis relies on a combination of clinical signs and accurate identification of the cyst or trophozoite from a fecal sample or a colonic wash. Trophozoites are typical amoeboid forms, generally with a diameter between 16 and 18 µm. Cysts are multinucleate and are between 12 and 20 µm. Direct fecal examination of feces diluted with saline solution reveals the active trophozoite. Cysts are found either with direct smears or with flotation. Detection of the cyst may be enhanced with the use of Lugol's iodine. *Entamoeba ranarum* has very similar morphological characteristics to the familiar mammalian *E. histolytica* but generally has 4 to 16 nuclei. Pathogenic forms are difficult to distinguish from commensal amoebae, but a preponderance of trophozoites and cysts in the presence of clinical signs such as gastroenteritis, hydrocoelom, hydrops, or dehydration lends support to a clinical diagnosis of amoebiasis. Other stressors are likely present in most cases.

Metronidazole may be used to treat amoebiasis in amphibians, and the preferred dosage and route are 50 mg/kg orally (PO) every 14 days. Aquatic amphibians tolerate a 15-minute to 30-minute bath in metronidazole (500 mg/L), but an oral dose is preferred when practical. If severe signs of intestinal amoebiasis exist, metronidazole may be given at 50 mg/kg PO daily for 3 to 5 days. Fluid therapy may be necessary. If an animal displays signs of neurological disease (e.g., listing, spasticity, lethargy), the dosage of metronidazole should be decreased.

Ciliated Protozoa

Ciliated protozoa are reported from many families of amphibians. At present, ciliated protozoa in the gastrointestinal tract are not clearly shown to have pathogenic effects on the host.[81] Ciliated protozoa are also found in the urinary bladders of some amphibians without apparent pathogenicity.

Finding ciliated protozoa in a gastric wash, colonic wash, or the feces of an amphibian is not unusual. If all other causes for an amphibian's unthriftiness have been ruled out, but a high density of ciliated protozoa is voided in the feces or urine, treatment with metronidazole, tetracyclines, or paromomycin may be warranted. Gastric wash, colonic wash, and fecal parasite examinations usually reveal ciliated protozoa during the direct observation of a sample. Cysts may be found on direct examination and after concentration with flotation. Ciliated protozoa often are found in the lumen of the gastrointestinal tract at necropsy. The absence of signs of an inflammatory process such as heterophilic infiltrates supports the supposition that the ciliated protozoa are commensals. With signs of inflammation, care must be taken to exclude other etiological agents, such as amoebae, coccidia, and bacteria.

Cloudy patches of skin, ulcers, and reddened gills may be related to ciliated protozoal infections in aquatic amphibians. It is most likely to be a problem if water filtration and sanitation are poor and lead to high concentrations of organic debris. Skin scraping and direct observation with a wet-mounted sample usually reveal ciliated protozoa causing cutaneous lesions.

Oral tetracyclines and paromomycin sulfate may be warranted in an ill amphibian (with or without overt gastrointestinal disease) that has a high density of ciliated protozoa in its feces or gastric wash. Dosage is empirical, but a starting level of 10 mg/kg PO once daily (SID) for metronidazole, 50 mg/kg PO twice daily (BID) for tetracycline, or 50 to 75 mg/kg PO SID for paromomycin is suggested. Frequent water changes and improved sanitation and filtration usually eliminate ciliated protozoa in aquatic amphibians. Baths with acriflavin, salt (10–25 g/L), or benzalkonium chloride may be useful in some cases.

Miscellaneous Protozoa

A variety of hemoparasites are found in amphibians, and the description and nomenclature of this group of parasites are beyond the scope of this article. A common finding in amphibian blood films is the presence of trypanosomes. Many trypanosome infections are subclinical and apparently have little effect on the captive amphibian. However, quinidine therapy may be warranted for an amphibian with signs of anemia or debilitation and concomitant trypanosomes. A suggested regimen for quinidine may begin with the method recommended for tropical fish, a 1 hour bath of quinine sulfate (30 mg/L).[82]

Sudden death may occur in amphibians with trypanosome infections. Splenomegaly is a common postmortem finding in these amphibians, and the trypanosome may often be seen in impression smears made

VetBooks.ir

of the spleen. Malarial parasites have been found to exert an influence on the performance and reproductive success of certain lizards, and a similar situation likely occurs with amphibians and their trypanosomes.

The introduction of various pathogenic protozoa can occur via feeder fish and via other live aquatic foods (e.g., Tubifex worms) or live aquatic plants placed within a vivarium. A protocol for screening live foods and decorative plants is suggested to minimize the accidental introduction of pathogens into a collection. Dipping the food items and live plants in a hypertonic salt bath (<5 minutes), and following that with chlorinated tap water (<30 minutes) or an acriflavin bath (1–2 hours), helps reduce the possibility of introducing unwanted organisms into the amphibian's enclosure.

METAZOAL DISEASES

Nematodes

Amphibians are host to a staggering variety of nematodes, only a few of which have received intensive study.[83] *Rhabdias* spp. are the best-known lungworms in anurans. Infective larvae penetrate the skin and migrate, with the final molt occurring in the lungs. Little damage may be noted on histopathologic examination of the lungs of an anuran with one or two adult *Rhabdias* present, but heavy infections can result in damage to the pulmonary tissue with associated inflammation and secondary infections. Diagnosis is through fecal parasite or oropharyngeal mucus examination, and the characteristic rhabditiform larvae may be seen. Embryonated ova may be detected in the feces (Fig. 89.16). Some frogs (e.g., glass frogs [*Centrolenella* spp.]) can be transilluminated and thereby reveal large adult worms in the lungs, but this is generally a postmortem finding. Because of the direct life cycle, infected amphibians should be isolated and strict hygiene practiced, preventing spread to other amphibians or superinfection of the original animal.

Strongyloides sp. also have a direct life cycle and may cause severe intestinal lesions. Severe strongyloidiasis may be debilitating and contribute to protein-losing enteropathy and generalized malnutrition.[84] Treatment with anthelmintics may need to be prolonged to eliminate *Strongyloides* sp., as with *Rhabdias* infections, and scrupulous attention to cage sanitation is required. Baths with ivermectin (10 mg/L) or levamisole (100–300 mg/L for 24 hours) weekly for 12 weeks or more may be needed to reduce or eliminate *Rhabdias* spp. Oral fenbendazole (crushed and coated onto crickets for 3 consecutive days) and levamisole (6.5–13.5 mg/kg), applied to the pelvic patch of Houston toads (*Bufo [Anaxyrus] houstonensis*), has been used to effectively decrease the nematode burden of both *Strongyloides* and *Rhabdias* and may offer a practical solution to managing these infections in captive environments.[85]

Filarid nematodes are frequently found free within the coelomic cavity, vasculature, or encysted within various organs.[86] Microfilaria may be noted in some infections, and the presence of microfilaria in the blood of debilitated amphibians does suggest a causal relationship. Treatment with ivermectin may be attempted, but the inflammation associated with the death of the nematode can severely compromise the amphibian.

Some nematodes may cause signs of cutaneous hemorrhage and exfoliation. *Pseudocapillaroides xenopi* has been the causative agent of these signs in the aquatic African clawed frog (*Xenopus laevis*).[87,88] The nematodes and ova can be found in both the mucus and skin scrapings from the lesions. Thiabendazole (50–100 mg/kg PO) and levamisole (5 mg/kg subcutaneously [SQ] followed by 10 mg/kg SQ at day 10 and day 20) was reported as efficacious in eliminating the parasite. Ivermectin baths (10 mg/L) or levamisole baths (100–300 mg/L) for 1 hour weekly are also effective in eliminating cutaneous nematodes.

Signs of gastrointestinal distress may accompany intestinal nematodiasis. Demonstration of parasite ova in feces warrants anthelmintic treatment. Oxfendazole (25 mg/kg PO), fenbendazole (100 mg/kg PO), oxfendazole (5 mg/kg PO), or ivermectin (0.2–0.4 mg/kg PO) is a recommended choice for intestinal nematodiasis. Multiple weekly treatments may be needed to reduce or eliminate some nematodes.

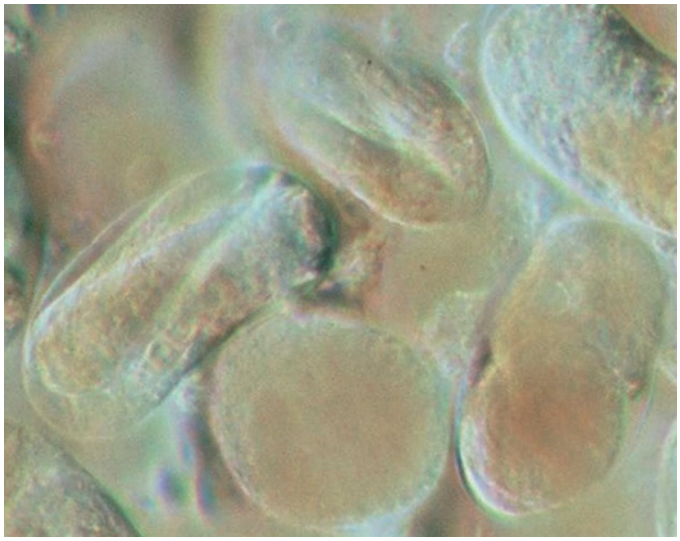

FIG 89.16 Larvated eggs from the lungworm, *Rhabdias*, found in the feces can be difficult to differentiate from other nematode ova. (Courtesy of Sarah Poynton, Johns Hopkins University.)

Trematodes and Cestodes

Amphibians may be host to a variety of both trematodes and cestodes, and this situation is further complicated in that the amphibian may serve as the parasite's primary, secondary, or tertiary host, or even as a paratenic host. Larval forms are often found within an amphibian's body with a minimum of associated pathological effects once encysted. However, significant pathology may be associated with migration of the larval forms.[89] Adult trematodes are commonly found in the lung, urinary bladder, kidney, gastrointestinal tract, and skin. One trematode *Ribeiroia ondatrae* has been linked with development of supernumerary limbs in a bufonid *Bufo boreas* and other limb abnormalities.[90]

Antemortem detection is rare unless the trematode is visible, as may be the case for cutaneous infections, or if the trematode is shedding ova in a way that can be detected with routine parasite examinations (e.g., gastrointestinal or urinary tract trematodes). The same may be said for cestodes. The adult cestodes may occasionally reach high enough numbers to cause wasting and anorexia by themselves or in part from obstruction of the gastrointestinal lumen. Therapeutics of trematodiasis and cestodiasis are relatively unexplored. Praziquantel has been used in a number of species of amphibians without ill effect and with some efficacy in eliminating adult and larval trematodes and cestodes.

Other Metazoan Parasites

Microsporidial septicemia with ulcerative dermatitis has been described in the giant tree frog (*Phyllomedusa bicolor*).[91] Microsporidial spores were detected in impression smears from the cutaneous ulcers. Chloramphenicol sodium succinate (5–10 mg/kg ICe) in combination with topical oxytetracycline hydrochloride and polymyxin B sulfate appeared to be an effective treatment.

Myxosporeans are intracellular, obligate parasites that have been found in the gonads, oviducts, kidneys, urinary bladder, ureter, gallbladder, and liver of amphibians.[92] Fatal renal myxosporean infection in Asian horned frogs (*Megophrys nasuta*) has been reported.[93]

VetBooks.ir

Chloramphenicol (70 mg/kg IM every 24 hours) and trimethoprim sulfadiazine (30 mg/kg IM every 24 hours) were not effective.[93] Medicated feed containing 0.1% fumagillin DCH has been helpful in managing *Myxobolus cerebralis* infection in fish.[94] In 2012, the myxozoan parasite *Cystodiscus axonis* was extracted from brain tissue of the critically endangered captive Australian yellow-spotted bell frogs (*Litoria castanea*). Clinical findings included subcutaneous edema, intracoelomic fluid, and swollen kidneys with pale foci. Histological evaluation showed sever tubulonehphropathy and acute encelphalomalacia.[95] *Cystodiscus* was first recognized in 1966.

Acanthocephalans are common gastrointestinal parasites. The ova may be detected on fecal parasite examination. Infection is usually without overt clinical signs, but if the acanthocephalan penetrates the intestinal wall, coelomitis may occur with rapid deterioration of the amphibian's condition. Acanthocephalans require an arthropod host, so the infection is self-limiting within the collection unless the arthropod food supply is contaminated or the amphibian's enclosure is contaminated with ova and suitable arthropods are introduced as prey species and can thereby acquire the parasite before consumption. Treatment is generally unrewarding, although high-dose ivermectin (>0.4 mg/kg ICe) may kill the acanthocephalan.

Leeches are rarely a problem of the established amphibian but may sometimes be seen in freshly imported or otherwise wild-caught specimens. Most leeches are ectoparasites, but one species actually resides within the lymphatic system of anurans. Ectoparasitic leeches are more commonly a problem of aquatic amphibians but have been noted in many nonaquatic species as well. Direct removal is necessary and may be facilitated with exposing the leech to a hypertonic salt bath.

Copepods are occasionally noted on the epidermis of aquatic amphibians. The arthropod can be diagnosed when placed in a wet mount and examined with light microscopy. Antiparasitic hypertonic salt baths as recommended for tropical fish are the suggested therapy for copepod infestation (10–25 g NaCl/L for 5–30 minutes), although ivermectin baths (10 mg/L for 60 minutes) also seem to be effective.

Trombiculid mites are occasionally encountered in terrestrial anurans and salamanders.[96] The suggestive clinical sign is the presence of erythematous vesicles in the amphibian's skin. Scrapings or biopsies of the lesions show the presence of the mites. Topical ivermectin is a suggested therapy in these cases, but hypertonic salt baths may have some effect. Antibiotic therapy may be required in amphibians with extensive cutaneous involvement and secondary bacterial infection. Prevention of this disease in a captive collection is established by heat-treating the soil and leaf litter used in an enclosure before its use.

An uncommonly seen but devastating parasite of terrestrial anurans is the toad fly (*Bufolucilia* spp.). The larvae infest the nasal passage of the anuran and literally eat the host until it can no longer function. Levamisole or ivermectin flushes of the nares and oropharynx may have some efficacy in killing small larvae, and brief exposure (<1 hour) to organophosphates (e.g., no-pest strips) may have some merit. More typical cutaneous and superficial bots may be manually removed.[97] Allergic reactions accompanying the removal of the bot are rare in amphibians. Flushing the wound with an antibiotic solution (e.g., gentamicin in saline solution) and concurrent administration of parenteral antibiotics is recommended in cases of secondary bacterial infection.

TOXICITIES

Amphibians are exquisitely sensitive to many toxins at levels that are tolerated without ill effects by reptiles, birds, and mammals. In part, this is the result of the permeable nature of the amphibian skin, the associated vascular network in those amphibians that rely heavily on it as a respiratory organ, and the high surface area to volume ratio of these generally small animals, all of which enhance the cutaneous absorption and assimilation of many compounds. Clinical signs of toxicosis may be quite vague, and considerable detective sleuthing is necessary to uncover the underlying offending agent. For example, the improper curing of polyvinyl glues used in plumbing vivariums results in the release of methyl-ethyl ketones and tetrahyrofurans, which can be toxic to amphibians, causing the animals to actively try to escape their environment (Whitaker, unpublished data). In some cases, the toxin may be detected with tissue assays of dead amphibians, but the small body size of many amphibians precludes exhaustive analysis in a toxicology laboratory—simply not enough tissue is available for analysis. Environmental samples (e.g., water, soil, food sources) should be obtained for analysis in addition to the samples taken from the amphibian.

A general recommendation for the veterinary clinic is to have a supply of well-aerated chlorine-free water and several clean glass or plastic containers for the treatment of intoxicated amphibians. A gallon of spring water that is aerated using an air pump and stone is an easy and inexpensive solution for clinics seeing the occasional amphibian. Tap water can also be used but may require pretreatment to remove chlorine or chloramine, if present. Chlorine (Cl_2) is easily removed using sodium thiosulfate, sodium hydroxymethanesulfonate (AmQuel, Kordon LLC, Hayward, CA), and/or a carbon filter. Chloramine (NH_2Cl), a combination of chlorine and ammonia, is more difficult to remove. Sodium thiosulfate can be used to break apart the chlorine and ammonia and remove the chlorine, but the ammonia remains at toxic levels and must be removed using zeolite or a biological filter. Sodium hydroxymethanesulfonate, however, effectively splits the chlorine-ammonia bond and neutralizes the resulting ammonia. The chloraminated water is recommended to be adequately aerated for 24 to 48 hours before use. Alternatively, there are water filtration systems now available that use catalytic carbon made from coconut shell to remove chlorine and chloramines that may be effective.

Avoid use of plastic containers that have held anything other than water to minimize the chance that toxic compounds are present (see subsequent iodine toxicity discussion). Rinsing the amphibian with clean water often helps remove some of the more common toxins (e.g., ammonia).

Clinical signs of toxicosis include erythema, petechia, increased mucus production, irritability, agitation, lethargy, dyspnea, convulsions, flaccid paralysis, regurgitation, and diarrhea. Many of the common disinfectants are toxic to amphibians: povidone iodine, chlorhexidine, quaternary ammonium compounds, chlorine, and ammonia. Iodine-based compounds and disinfectants that contain colorizers or perfumes are not recommended for cleaning amphibian enclosures, because the plastic and organic material within the enclosure may retain these compounds and serve as a leach source that subsequently contaminates the captive environment.[98] Stoskopf originally reported an incident of iodine intoxication of poison dart frogs that resulted in agitation and abnormal posturing before death. It was suspected that toxic levels of iodine diffused out of the plastic despite prior rinsing of the enclosure (Proc AAZV 1985, pp 86–88).

Treatment for disinfectant-associated toxicities is aimed at removing the source of the toxin and providing support to the amphibian patient. Rinsing with clean water, parenteral fluids, and nutritional support is indicated. If detected early, most amphibians recover from mild exposure. However, the long-term effects of the exposure may include immunosuppression and resultant secondary infections and other physiological impairments.

High levels of chlorine and ammonia are commonly implicated in the deaths of amphibians. Signs of ammonia toxicity include sudden death, gaping, reddened skin, excess mucus, bright-red gills, disorientation, seizures, failure to gain weight, and dull colors. Diagnosis is difficult, but ammonia intoxication should be suspected if the amphibian has been kept in a vivarium with biologic filtration of the water, and the

VetBooks.ir

system has been restarted or otherwise manipulated (e.g., major water change has occurred within the past 2 weeks; antibiotics have been added to tank water). A level above 0.2 parts per million is suspicious for a diagnosis of ammonia toxicosis, and a level above 1 part per million should be considered verification of ammonia as one etiology for the clinical signs. A complete water change is the best therapy for ammonia intoxication. Sodium hydroxymethanesulfonate (e.g., AmQuel) may be used to temporarily bind the ammonia if a water change is not immediately practical. In the event this agent is used, a water change should be done at the earliest opportunity.

Chlorine intoxication is likely if a major water change has occurred within the past 24 hours. Test the source water using a reliable system (e.g., total chlorine checker colorimeter; Hanna Instruments, Woonsocket, RI) to determine whether chlorine is at a dangerous level (i.e., 0.5 parts per million or higher). The affected amphibian should be placed in clean oxygenated water. A bath of 100 mg/mL sodium thiosulfate can be used to manage confirmed chlorine toxicosis. Sodium thiosulfate neutralizes the free chlorine by eliminating its oxidizing properties. After at least 30 minutes in the sodium thiosulfate solution, the amphibian should be placed in well-oxygenated, chlorine-free water.

Heavy metals are often overlooked as a killer of many captive amphibians. Plumbing generally contains copper, lead, or zinc; if tap water is used, the faucet should be allowed to run several minutes before the water is collected. In facilities with galvanized ventilation ducts, zinc toxicosis can occur due to the falling of condensate into the vivarium. Heavy metal toxicoses are far more difficult to diagnose than chlorine or ammonia toxicity unless the clinician is specifically considering it. An amphibian with a heavy metal toxicosis is often beyond the point of effective therapy. The use of chelating agents (calcium versenate, calcium disodium EDTA, dimercaprol) have not been documented but may be of use in managing metallotoxicoses in amphibians.

Salt toxicosis is rare and is generally associated with a marine aquarium near the amphibian enclosure. Amphibian enclosures should be kept well away from a marine tank, and water containers for the marine aquarium should be distinctly labeled to avoid confusion. If the possibility exists within the home, a hydrometer should be used to check the salinity of the enclosure water. Increasing the salinity of the aquarium water has been recommended to prevent ammonia buildup in unfiltered tanks. If significant evaporation occurs, the salinity may reach inappropriately high levels. Therapy for salt intoxication includes the use of hypotonic intracoelomic fluids (see Dehydration section) and rinsing in freshwater baths.

Pesticides are ubiquitous. The amphibian is exposed to these compounds in the wild and within the home. The effects of these compounds in amphibians include immunosuppression, reproductive failure, hepatic disorders, renal disorders, neurological disorders, and developmental abnormalities of larvae. Even a small exposure can have long-term effects in an amphibian—just remember the devastating ecologic effects of the "safe" pesticide, dichloro-diphenyl-trichloroethane (DDT)—and pesticides do not have to be evaluated with regard to their effects on amphibians to be declared safe for the environment. Do not use pesticides around amphibians. If pesticides are used, insect growth regulators are preferred over toxicants. Secondhand tobacco smoke appears to be irritating to amphibians. Amphibia vivaria should be kept in smoke-free rooms.

ENVIRONMENTAL CONDITIONS

Dehydration

Dehydration can quickly progress to desiccation for an amphibian without access to standing water in the absence of appropriately high humidity. Some species (e.g., *Bufo* spp.) are much more tolerant of low humidity than the average amphibian because of their decreased reliance on ammonia as an excretory product. Other amphibians (e.g., *Hyla* spp.) are able to tolerate low humidity by altering body posture to reduce surface area or by excreting protective substances on the epidermal surface. Nevertheless, all species of amphibians are susceptible to dehydration. When water loss exceeds a certain percentage of body weight (dependent on the species, as some species can tolerate over a 30% water loss without lasting ill effect), the excretory system may be irreversibly damaged. Thus, the amphibian may initially respond to therapy, but hydrocoelom and edema may develop within days to weeks due to renal failure.

The severely dehydrated amphibian often has sunken eye sockets, wrinkled and discolored skin, and feels tacky to the touch. Excessive tackiness of the slime coat of an amphibian may be the only sign of mild dehydration. Escapes are not uncommon; placing a shallow water dish on the ground can help support an escaped amphibian until it can be returned to the enclosure.

Rehydration is typically accomplished by placing the dehydrated amphibian in a shallow layer of well-oxygenated, chlorine-free water that is at the species-specific preferred body temperature. Intracoelomic fluids may be necessary and two solutions useful for rehydrating amphibians may be made from intravenous fluids commonly available to the clinician. One solution consists of one part saline (0.9% NaCl) to two Parts 5% dextrose (314 mOsm/L). The second solution consists of seven parts saline to one part sterile water (270 mOsm/L). Do not exceed 25 mL/kg body weight for an initial dose. Avoid use of potassium-containing fluids in the initial therapy, unless hypokalemia has been confirmed. Supplemental doses may be empirically derived based on response to the freshwater baths.

Abrasions

Abrasions are an important route of invasion for secondary pathogens. The environment should be free of coarse-grained woods, sharp rocks, or any other cage furniture that is rough and likely to cause injury to a delicate epidermis. Harsh nylon fishnets are a potential source of injury for aquatic species, so the softer fine-weave nets are preferred. Human hands can be abrasive to some amphibians, so gloves rinsed with aged water should be used when handling smooth-skinned amphibians. Abrasions may require treatment with topicals (e.g., benzalkonium chloride, gentamicin ophthalmic solution) if the wounds appear to be increasing in size, become erythematous, or have an opaque or serosanguineous discharge.

Water Quality

Certain parameters of water quality can cause problems if not within a narrow range: dissolved oxygen, nitrite/nitrate, ammonia, pH, hardness, and turbidity/bacterial blooms. Other parameters, such as tannin concentration, may be important to the animal but difficult to analyze. A sample of the amphibian's tank water should accompany any physical examination for illness, especially if the amphibian is entirely aquatic. Appropriate diagnostic tests should be administered to a sample of the tank water to determine whether any parameters could be contributing to the clinical signs seen. Therapy is aimed at correcting the underlying problem and restoring the tank water to appropriate parameters.

Ammonia and chlorine toxicity can be treated with sodium thiosulfate baths followed with well-oxygenated fresh water, whereas nitrite/nitrate intoxication may respond to treatment with methylene blue baths. Amphibians that have been exposed to a bacterial bloom are at risk of ocular and epidermal infections and systemic disease.

Trauma

Cage-mate aggression is responsible for many of the traumatic injuries in captive amphibians. Some anurans have tusks and sharp dental

VetBooks.ir

projections that may be used in territorial battles and may inflict severe lacerations in a fight. Amphibians that lack such armament may still cause injury by badgering the less dominant animals and holding them at bay from food, water, and appropriate niches within the vivarium.

Dendrobatid frogs may drown if maneuvered into deep water by cage mates. Amphibians may try to ingest one another, especially if the group experiences a "feeding frenzy" as has been noted in some anurans and salamanders. This can prove fatal to both animals involved, as frequently the ingested animal is too large (see gastrointestinal overload and impaction). Some larvae are carnivorous and may eat other tankmates. If cage-mate trauma is the suspected source of any injuries, animals may need to be isolated or set up in a new vivarium with more space and hiding spots. Injuries may necessitate treatment with topical or parenteral antibiotics. Fluid therapy and other therapies may be needed to treat shock in severely injured amphibians.

Clear-sided enclosures are another source of traumatic injury, especially to the rostrum, for many amphibians (Fig. 89.17). This is especially true in active saltatorial anurans that do not recognize the glass as a barrier and may crash into the glass when startled. The clear sides may be covered with an opaque material until an amphibian has grown accustomed to its vivarium. Sudden movements and loud noises startle many amphibians, so a vivarium with these species should be kept in a quiet room with little human or pet traffic.

In addition to acting as a source of heavy metal contamination, metal screen tops can be a source of traumatic injury in anurans and should not be used. Plastic screening or drilled plastic is a preferred ventilation option for the amphibian enclosure.

Hyperthermia

Aquatic amphibians are especially susceptible to hyperthermia. Temperatures should not exceed 80°F to 85°F (27°C–29°C). Hyperthermia typically occurs as seasons change. In the fall, the vivarium that was placed either adjacent to or on the radiator when the heat first comes on can overheat. In the spring and summer, hyperthermia may occur as the vivarium receives more sunlight as the sun shifts in the sky. Malfunctioning thermostats are another source of hyperthermia. For these reasons, questioning the owner about location of the vivarium in the home is essential.

Signs of hyperthermia include frenzied swimming, uncoordinated jumping or walking, lethargy, and death. Autolysis is extremely rapid. If the autolysis is not advanced, histopathology reveals congestion of the cutaneous tissues and gill vasculature. Confirmation of hyperthermia requires skilled anamnesis in the absence of observed temperatures within the enclosure. Therapy is aimed at returning the amphibian's body temperature to normal levels rapidly and can be accomplished with bathing in freshwater ice baths and administering cool intracoelomic fluid therapy. Corticosteroid therapy may be helpful in some cases. If scalding has occurred, parenteral and topical antibiotics may be necessary, especially if there is any tissue manipulation or debridement. Unfortunately, amphibians with even minor burns have a poor prognosis because of the importance of the skin in maintaining water and electrolyte homeostasis. The amphibian may be placed into a continuous bath of full-strength amphibian Ringer's solution to combat fluid and electrolyte imbalances.

Hypothermia

Hypothermia is rarely life threatening in amphibians unless a rapid temperature drop of greater than 15°F (10°C) occurs or the absolute temperature drops below 45°F (5°C). The main clinical sign is lethargy or immobility, although regurgitation of a recently eaten meal or abdominal bloating may be noted. The hypothermic patient should be returned to its preferred body over the course of 12 to 24 hours. Some amphibians are immunosuppressed after hypothermia, so the affected animal should be closely monitored for signs of infection over the next 4 to 6 weeks. Antibiotics are warranted if secondary bacterial infection occurs.

Noise and Vibration

Excessive noise and vibration from construction, pumps, and filters can cause stress and resulting health issues in amphibians. In one case, all 175 Xenopus frogs exposed to construction-related vibrations showed excessive gulping at the surface, skin sloughing, and abnormal buoyancy resulting in bloating and the death of seven animals.[99] Whenever possible, relocating animals during construction—creating noise, vibration, or dust—is recommended.

SYNDROMES OF UNCERTAIN ETIOLOGY

Spindly Leg

Spindly leg refers to a group of limb deformities that are associated with metamorphosing tadpoles. The classical sign is a tadpole that starts to develop hind legs normally, but the hind legs do not complete development and are noticeably thin and may show varus or valgus deformation at the time the forelegs emerge (Fig. 89.18). The deformities are not correctable, and the affected animal generally dies. Euthanasia of affected individuals is recommended. This condition has been attributed to various influences: genetic or hereditary, malnutrition, water quality, and enclosure temperature, among others.

Some dendrobatid frog enthusiasts believe the disease is due to improper nutrition of either the mother frog or the tadpoles and have recommended various dietary supplements for the parents and the tadpoles. Iodine solution has been recommended as an addition to the water to prevent development of this syndrome but has been refuted by other hobbyists. The use of water conditioners designed for tropical freshwater fish has been advocated by some. B-vitamin deficiencies and calcium deficiencies have been associated with causing abnormal metamorphosis of amphibian larvae; ensuring larval amphibians have B-vitamin and calcium in their diet or water is recommended. Several factors likely can be involved in the clinical condition called spindly leg. Careful histopathologic analysis of the affected tadpoles and concomitant standardization of the husbandry of the tadpoles and adults may well help elucidate the etiology and pathogenesis of spindly leg and indeed may recategorize this broad syndrome into a number of different diseases. A classification scale has been developed for *Mantella*

aurantiaca tadpoles and metamorphs (Fig. 89.19A and B).[100] This scheme can be used by the clinician to document and gain a better understanding of the various manifestations of this disease in other species.

Corneal Lipidosis (Lipid Keratosis)

Some anurans have white corneal opacities develop (Fig. 89.20). In many cases, histopathologic analysis of the corneal tissue suggests the presence of cholesterol clefts; this condition is referred to as corneal lipidosis or lipid keratopathy.[101] The actual site of development of the lipid deposits may vary somewhat. It may originate from the scleral margins and advance toward the central cornea, or it may be present as a vertical line across the cornea. The opacities may remain flat or may develop into raised irregular lesions. Most affected anurans have a demonstrable hypercholesterolemia. Typically, the disease is systemic, with cholesterol clefts and inflammation detected in multiple tissues besides the corneas at the time of death.

The diets offered to captive anurans typically consist of pinkie mice and cultured crickets, which have different fatty acid profiles than their wild prey. In a controlled study, corneal lipid deposition was more prevalent in frogs fed a high-cholesterol diet than those receiving a regular diet; however, both groups had higher serum cholesterol than wild frogs.[101] Treatment of corneal lipidosis is generally unrewarding and consists of debulking the lesions and dietary manipulation. Unfortunately, debulking may actually exacerbate the lesion. Dietary management is aimed at the use of wild-caught insects instead of the commonly available monoculture crickets and feeding small amphibians or reptiles in place of mice. Alternatively, sparingly feed high-protein, low-fat foods (e.g., lean chicken heart dusted with vitamins and minerals, earthworms, and crickets that have not fed for 24 hours). The interested clinician may wish to investigate the potential therapeutic use of cholesterol-blocking agents in affected anurans.

Many of the species commonly reported with corneal lipidosis, such as the White's tree frog (*Pelodryas caerulea*), often bask and elevate their temperatures well above 100°F (39°C) in the wild. The opportunity to have these regular high body temperatures is seldom provided to captive specimens. These peak body temperatures may be important for normal fat metabolism. Basking spots should be offered to any amphibian with corneal lipidosis and is an important part of providing proper husbandry to all amphibians.

Gout

Gout has been reported in some anurans. Precipitating causes in amphibians are unknown but probably include dehydration, renal failure, inappropriate diet, and toxicities. Gout is most likely to occur in those amphibians that commonly excrete a portion of their nitrogenous wastes as uric acid. Waxy tree frogs (*Phyllomedusa sauvagii*) are a commonly kept species that have gout and develop cystic calculi composed of ammonium urate.[102] This is likely due to a number of factors, including the feeding of a high-protein diet together with uricotelism and dehydration. Cystotomy to remove the stones may be required and is readily performed (see Chapter 107).

Gastric and Cloacal Prolapse

Many anurans may evert their stomach and wipe its mucosa clean with their hands. This may help rid the stomach of undigestible or otherwise unpalatable materials. It has also been seen as a sign of toxicosis, anesthesia with clove oil, hypocalcemia, and various other metabolic disorders. It is a nonspecific sign in anurans and may be benign and self-correcting. It usually indicates a serious disorder when noted in salamanders.

Cloacal prolapse is commonly seen. Predisposing conditions include dehydration, hypocalcemia, hypoglycemia, and malnutrition; gastrointestinal foreign bodies; cystic calculi; gastroenteritis; hyperthermia; trauma; and parasitism (Fig. 89.21). Treating an animal with a cloacal prolapse as quickly as possible will improve the likelihood of success. This includes keeping the prolapsed tissue moist and protected before gently massaging it back into place (see Chapter 107). It is important to maintain hydration of the animal, administer antimicrobials if tissue necrosis and infection has occurred, and correct the underlying cause of the prolapse.

NEOPLASTIC DISEASE

Renal, integumentary, hepatic, and gonadal neoplasms are among the most commonly reported tumors of amphibians. Although some anurans appear to have anticancer secretory products and cytoprotective devices, and the urodeles are hypothesized to have reduced tumor susceptibility due to their regenerative capability, neoplasia due to cellular neoplastic transformation occurs. Etiologies may include viral infection, exposure to pollutants, or genetic predisposition.[103] Clinically, examination may reveal the presence of internal or external masses or simply the presence of hydrocoelom and hydrops. Celiocentesis may yield cells with mytotic figures, high nucleus to cytoplasm ratios, and other histopathologic indications of neoplasia. Metastasis appears to be uncommon. Diagnosis of any of these tumors carries a grave prognosis, although some cases may be amenable to surgery (see Chapter 107, Fig. 107.2D).

Fibromas and papillomas are common types of benign tumors encountered. Management attempts may include surgical excision or debulking. Where possible, a surgical margin of at least 0.2 to 1.0 cm is recommended.[103]

A comprehensive review of the literature on amphibian neoplasia that included cases filed in the Registry of Tumors in Lower Animals and a comprehensive overview of amphibian oncology have been published.[103,104]

MEDICAL TREATMENTS

Relatively few studies support the extralabel use of drugs in amphibian species. The formulary in Chapter 128 consists of a variety of drugs that have been published or that the authors have used without ill effect in a variety of amphibian species. So many variables, including environmental temperature, water quality parameters, diet, and health status, affect the absorption and utilization of drugs. Thus no claim can be made to the actual efficacy of a drug for the treatment of a given set of clinical conditions. This formulary is intended solely as a guide for

the clinician. Whenever possible, we suggest that referenced papers be reviewed before administering medications to amphibians.

Routes of Delivery

Drug pharmacokinetics are influenced by many factors, including the route of administration. Transcutaneous administration of drugs in the form of a dip, prolonged bath, or topical application is quite effective for cutaneous diseases, such as fungal and protozoal infections. Given the extensive ventral vascularization and thickness of the skin of amphibians, sufficient uptake of the drug may occur to achieve therapeutic levels in the blood and internal organs, and thus antibacterial baths and topical treatments have been successfully used. Other factors that are likely to affect percutaneous absorption include damage and disease to the barrier properties of the skin, appendage density and size, exocrine secretions that coat the skin, and the physiochemical properties of the chemical and its formulation.[105]

Oxytetracycline baths have been advocated in the treatment of aeromoniasis in aquatic larval tanks and adult breeding tanks. Given that many aeromonads are resistant to tetracyclines, the clinician often must use other antibiotics, and many of these antibiotics are not useful for "bath therapy." Gentamicin baths have been an option for management of septicemia, but the drug concentration must exceed 1 mg/mL solution to reach effective blood levels in *Rana pipiens*.[106] Ciprofloxacin 10 mg/L in a 6 to 8 hr bath has been effective in treating many bacterial infections but should be reserved for cases with resistance to more basic drugs.

Ivermectin (0.2–0.4 mg/kg)[107] and praziquantel (8–24 mg/kg) solutions have been applied topically to anurans with subsequent reduction in the numbers of parasitic ova shed via the feces. Given the small body size of many amphibians, such as dendobatid frogs, administration of drugs via oral or parenteral routes may be impractical. When practical, oral or parenteral routes of administration are preferred to ensure adequate uptake and distribution of any given drug. Microliter syringes and pipettes greatly improve accuracy when administering small doses of drugs.

Intracoelomic, subcutaneous, and intramuscular injections are the most common routes of drug delivery used in the treatment of amphibians of sufficient body size. Intracoelomic injections may be given in the paralumbar fossa or just off the ventral midline. The skin over the dorsum, shoulder, or pelvis is usually loose enough to allow tenting of the skin for subcutaneous injections. The epaxial musculature is a useful site for the injection of intramuscular medications in salamanders and caecilians. The maximum drug volume given per site is dependent on the body size/mass of the animal, muscle condition, and irritation/pain associated with the medication administered. The forelimbs are a preferred site for anurans. The ability of the amphibian mesonephric kidney to excrete many of the commonly used drugs and drug metabolites is poorly documented.

Amphibians with hydrocoelom or subcutaneous edema may require baths in electrolyte solutions to reduce fluid volume and correct plasma electrolyte abnormalities. Amphibian Ringer's solution is isotonic to typical amphibian plasma (~230 mOsm/L) and can be created by dissolving 6.6 g NaCl, 0.15 g KCl, 0.15 g $CaCl_2$, and 0.2 g $NaHCO_3$ in 1.0 liter of distilled water (see Chapter 128). A continuous bath in amphibian Ringer's solution is a suggested supplemental therapy for any amphibian with a bacterial or fungal infection. If amphibian Ringer's solution is not available, 0.5% to 0.6% saline solution is an alternative but lacks critical electrolytes. Hypertonic solutions may be needed when the amphibian patient appears grossly distended or edematous from fluid overload. Simple hypertonic solutions are 0.8% to 0.9% saline or the compounds for amphibian Ringer's solution dissolved in 900 mL or less of distilled water. Dextrose (5% or higher concentration) and hetastarch solutions may also be used as short-term hypertonic baths. Monitor the amphibian while it is in the hypertonic solution and remove it if it appears distressed or when it is within 25% of its normal weight. If the amphibian starts to regain fluid when returned to normal water, it should be returned to isotonic or hypertonic solutions for additional therapy. Some amphibians may need to be maintained in isotonic solutions for several days to weeks after recovery from a severe infection.

The intravenous route is largely unused in amphibians, although euthanasia solution may be administered via cardiocentesis.

The oral route is historically how tetracycline has been administered during *Aeromonas* outbreaks. Anthelmintics and nutritional support may be given via this route. An appropriately sized over-the-cuff intravenous catheter is a useful feeding tube for small amphibians. Waterproof paper or a thin wedge of plastic can function as a mouth

speculum. Stainless steel rodent feeding tubes work well with larger amphibians.

AKNOWLEDGMENTS

On September 26, 2013, we lost Dr. Kevin Wright, our colleague, our collaborator, and my close friend. Whitaker and Wright were two dreamers alphabetically sitting side-by-side through veterinary school who shared a common interest in everything unusual and who wanted to make an important contribution of some kind. Our original *Amphibian Medicine and Captive Husbandry* book was the result of a mutual interest in these incredible creatures and our ability to study them in our day jobs. This chapter, on amphibian medicine, is likely one of the last works that Dr. Wright and I will write together—at least in this world. Although much of this chapter remains unchanged from that published in Mader's second edition of *Reptile Medicine and Surgery,* new information, illustrations, and references have been added.

To you, the reader, enjoy and discover.

To you, Kevin, farewell my friend. You truly have changed the world. We loved what we did, and we did what we loved. I will carry the bucket with you always.

Surgical Equipment, Instrumentation, and General Principles

Stephen J. Divers

In general, performing surgery on a reptile patient should be approached in a similar way to domestic animals, and general surgical principles should not be violated.[1] However, there are some specific anatomical considerations, as well as unique aspects of patient preparation, positioning, and equipment, with which the reptile clinician should be familiar.

WOUND HEALING

Wound healing in reptiles occurs through phases similar to those observed in mammalian species. Initially, proteinaceous fluid and fibrin fill the defect to form a scab. A single layer of epithelial cells migrates beneath the scab. This single layer then proliferates to restore the thickness of the normal epithelium.[2] In addition, macrophages and heterophils migrate into the tissue below the scab to clean up bacteria and debris. A transversely arranged fibrous scar is produced by fibroblasts that migrate into the area. Heterophils are present within the scar tissue matrix until maturation has occurred. This is a slow process in reptiles. Consequently, suture removal is generally recommended 4 to 8 weeks after placement. The activity of the dermis and epidermis during ecdysis appears to promote healing.[2] If suture removal can be delayed until the subsequent ecdysis, wound strength is likely to be better. Peripherally placed sutures may slough off during the first postoperative ecdysis.

Environmental temperature has an effect on wound healing.[2] Maintenance of the patient in the upper end of its optimum range has been shown to promote healing. The orientation of the wound also influences the rate of healing, with cranial- to caudal-oriented wounds healing faster than transverse wounds. With treatment of open wounds, such as those that occur from burns, good environmental hygiene is important. These wounds heal well by second intention with a relatively low incidence of secondary infections.

SURGICAL EQUIPMENT AND SUPPLIES

Instrumentation

Table 90.1 lists some useful manufacturers and distributers of surgical supplies. It can be challenging to maintain a prepackaged "reptile surgery pack" that is applicable for a wide variety of species and procedures (Table 90.2). For truly giant reptiles, including giant tortoises and crocodilians, the use of stronger large-animal instruments is required, but for reptiles between 5 kg and 50 kg, most small-animal instruments are appropriate. However, most patients are less than 5 kg in size, and indeed the majority are typically <500 grams, and for these animals, small and even microsurgical instruments are often required (see Table 90.2).

Microsurgery instruments are not merely miniaturized versions of standard instruments but rather balanced instruments with fine small tips, which are often the optimal instrumentation for small reptiles (Fig. 90.1). Since microinstruments can be costly, other viable options include ophthalmological instruments, and many practices probably have an "ophtho pack" in their inventory. Standard iris scissors, tenotomy scissors, Castroviejo needle holders, and Colibri forceps can be very useful. Organization of the instrument table is important and aids efficient instrument selection (Fig. 90.2).

One of the most important considerations in surgery is exposure. Plastic self-retaining retractors (e.g., the Lone Star retractor) are sterilizable (by autoclave, gas, or cold immersion), and can be adjusted to fit different sizes and conformations of surgical approaches. These ring-style retractors are lightweight, do not compromise ventilation, and occupy minimal space in the often-limited surgical field (Fig. 90.3). Smaller versions of standard abdominal retractors, such as pediatric Balfour retractors, Haight baby rib spreaders, and so on, can also be utilized but are significantly heavier and more obtrusive. Eyelid retractors can be useful for retracting coelomic incisions in small lizards and snakes.

A variety of surgical drills and saws should also be available. Autoclavable or gas-sterilizable models are preferred. For general orthopedic work of normal bones (which admittedly is rare), the Stryker drill offers excellent control and versatility, even for the smallest of patients (Fig. 90.4A). The oscillating sagittal saw attachment to the air-powered 3M mini-driver provides fine control and reduced tissue trauma compared with rotating saws (see Fig. 90.4B). The VI MiniDriver and MaxiDriver systems appear to be comparable and offer a sagittal saw as well as pin-and-wire driver attachments. A handheld power tool (e.g., Dremel 4000 High Performance Rotary Tool) offers a budget alternative to a dedicated surgical device, and various cutting discs are available (e.g., 22 mm Dremel 545 diamond wheel, 38 mm EZ545 1.5" diamond wheel). Small versions of suction tips, rongeurs, elevators, and bone-holding clamps are also useful.

Epoxy resins (e.g., Enviroset 5-minute epoxy, Environmental Technologies Inc., Fields Landing, CA) or low-temperature veterinary acrylics (e.g., Technovite 8100 MG kit, APEF acrylic packs) may be used for chelonian plastron closures and shell repairs. A two-polymer orthopedic putty is also a very useful aid to external fixation. A selection of intramedullary pins, miniature fixator pins, aluminum/carbon fiber clamps, and titanium/carbon fiber support rods (IMEX Veterinary Inc., Longview, TX) can be used to repair traumatic (nonpathological)

fractures in larger reptiles (Fig. 90.5A). A lightweight tubular fixation system, FESSA (Fixateur Externe du Service de Santé des Armées), is small and lightweight and incorporates a pin-clamping mechanism that is preferred for external fixation in smaller animals. The system, available from major distributors, is available in 6- and 8-mm tube diameters, with ranges in length from 31 mm (3.0 g) to 97 mm (12.2 g), and permits the placement of multiple miniature fixator pins close together in small fragments (see Fig. 90.5B). For internal fixation, small locking compression plates are preferred because they facilitate fixed-angle constructs and do not rely on plate-bone compression for stability, which is a frequent cause of cortical fractures when using conventional plates and screws (see Fig. 90.5C).

Lighting and Magnification

Proper lighting is an obvious requirement for surgery. However, it becomes even more important in small patients, and surgical lights should be focused with variable power settings. Modern LED lighting systems are more expensive initially but last longer, are cheaper to run, and produce less heat.

Some degree of magnification is often beneficial if not essential. There are a variety of magnification systems available. Table-mounted operating microscopes are very stable but must be properly positioned to avoid strain and fatigue (Fig. 90.6). Headband- or frame-mounted operating loupes (2× to 4× magnification) with a dedicated LED light source are affordable, versatile, comfortable, and, unlike table-mounted microscopes, have the advantage of allowing the surgeon to adjust surgical perspective (Surgitel, General Scientific Corporation Ann Arbor, MI, USA) (Fig. 90.7). The VITOM (video telescope operating monitor; Karl Storz Veterinary Endoscopy, 1 S Los Carneros Rd, Goleta, CA 93117) system allows practitioners to use their rigid endoscopy tower for operating microscopy.[3] The basic system involves a mechanical arm to hold an exoscope (so called because it is used externally), which is positioned above the surgical field, with the image relayed to the endoscopy monitor (Fig. 90.8). An 11-cm, 0-degree exoscope at 25 cm from the surgical site provides a 7 to 10 cm field of view at 4× to 8× magnification. The standard 2.7-mm telescope (commonly used in exotic animal practice) can also be used in a similar fashion.

Hemostasis

A healthy reptile, depending on species, can generally tolerate between 0.4 and 0.8 ml of blood loss per 100 g body weight. Patients in need of surgery are often compromised, and diagnostic blood samples may have been collected prior to surgery. Therefore the amount of intraoperative blood loss that the patient can tolerate may be considerably less. Careful consideration must therefore be given to evaluating, documenting, and reducing hemorrhage intraoperatively.

To allow the surgeon to apply localized pressure to a small vessel and keep track of blood loss, cotton-tipped spears, or applicators, are less traumatic and more manageable in small confined spaces than standard gauze squares. A blood-soaked cotton-tipped applicator typically holds about 0.3 ml of blood. Used applicators should not be discarded out of view but their number recorded to track blood loss.

Vascular clips (e.g., Hemoclips, Weck Closure Systems, Teleflex, Morrisville, NC; Ligaclips, Ethicon Inc., Somerville, NJ) are a convenient and effective way to clamp vessels, which are widely available from distributors (Fig. 90.9). Autoclavable applicators and clips are available in a variety of sizes. Applicators come in a variety of lengths and conformations (straight, angled), and clips come in 10- or 25-clip cartridges. The application of vascular clips is faster than standard suture ligatures, and therefore their use significantly decreases operating time. Any incompletely used cartridge can be cleaned, autoclaved, and reused until empty.

Surgical Lasers and Radiosurgery

A variety of surgical devices are available and most represent major capital investments that warrant careful consideration. A variety of comparative studies have been published and should, in conjunction with a hands-on trial (at a wetlab or in-practice demonstration), help form the basis of an informed purchase decision (Table 90.3).[4–9]

The most commonly used surgical laser (light amplification by the stimulated emission of radiation) in veterinary medicine is probably the CO_2 laser (10,600 nm), although diode devices and Holmium:YAG lasers are also in use and vary in wavelength and tissue absorption characteristics (Fig. 90.10).[10,11] CO_2 lasers offer bloodless dissection comparable to radiosurgery. In contrast, the diode lasers produce more collateral damage but consequently can seal larger vessels, up to 2 mm in diameter. Surgical lasers require enhanced human safety precautions, including a sealed, windowless surgery room and the use of protective glasses specific for the wavelength of lasers being used. Lasers and radiosurgery cause varying degrees of carbonization and produce smoke (which contains DNA, bacteria, and viruses) that should be evacuated with a filtered vacuum (see Fig. 90.10).

CO_2 Laser. There are several companies that sell CO_2 lasers. The CO_2 laser comes in a variety of sizes and power capacities from 2 to 45 W, and all are class IV (Fig. 90.11A). The invisible 10,600 nm beam is beyond the visible wavelength. When laser light is absorbed by a cell, the water within the cell is boiled and the cell essentially explodes. The cell denatures into smoke and the cell remnant, called char (carbonization).

When the laser is used for cutting, cellular destruction is limited to a region only three to four cells away from the target area, thus minimizing tissue devitalization (see Fig. 90.11B). In contrast, tissue destruction can be deliberately maximized for purposes of tissue ablation. Tissue cutting versus ablation can be controlled either by tip size or by "defocusing" the laser's beam. "Focusing" the beam allows the surgeon to use the laser's intensified light beam to "cut" tissue, whereas "defocusing" the beam allows the laser to "ablate" the tissue (Fig. 90.12A). There are three factors that determine the tissue impact of the delivered laser beam: spot size, power, and exposure.

Spot size refers to the diameter of the aperture that contains 86% of the laser's beam. There are several tips that permit precise control of spot (cutting) size (see Fig. 90.12B). The tip sizes range anywhere from 0.25 to 3.0 mm, with the most commonly used tips being 0.25 to 0.8 mm. With focused beam tips, the distance of the tip from the target tissue determines the actual spot size at the target. For most tips the focal distance is typically 1 to 3 mm. Power is measured in watts, which is defined by the amount of energy applied over time (defined as Joules/second). Power is adjusted on the laser by adjusting the wattage. The greater the wattage, the higher the power. Power density is affected by the size of the target area. If the spot size is small, the power is concentrated. If the spot size is large, the power is spread out over a larger area, and the power density is decreased, thus producing a lesser tissue effect. Exposure is also a user-controlled variable and is determined by the duration of the applied laser. The greater the exposure, the greater the tissue impact. Exposure can be delivered as continuous, repeat, or single pulse.

Diode Laser. The most common types used in veterinary medicine are the gallium-aluminum-arsenide 810 to 980 nm diode lasers, which are available in varying powers from 15 to 60 W and are all class IV. The laser beam is transmitted from the base unit to surgical site by a solid quartz-core, fiber-optic cable (Fig. 90.13A). A visible light beam is combined with the invisible laser beam to facilitate aiming. Laser fibers come in a variety of sizes (400–1000 µm) and shapes, including flat, conical, orb tips, and air/water cooled. The fibers may be used through the instrument channel of a variety of rigid and flexible endoscopes or in hand-pieces for open surgical use. Unlike the CO_2 fiber, a damaged diode fiber can be trimmed and reused.

The diode laser can be used in direct contact with tissue (contact mode) or at a distance from tissue (noncontact mode) (see Fig. 90.13B). In contact mode the fiber tip is coated with a thin layer of carbon. This is most easily achieved by lightly burning a sterile wooden tongue depressor with the tip of the laser fiber at 10 W. The carbonized tip absorbs virtually 100% of the laser beam, which causes the tip to instantly heat up to ablative tissue temperatures at relatively low power settings, usually just a few watts. The heated tip can then be used to incise, excise, and coagulate tissue, while a 0.3 to 0.6 mm zone of thermocoagulation provides excellent hemostasis of vessels up to 2 mm in diameter (Fig. 90.14). The advantages of carbonized fiber tips are minimized collateral

damage and reduced tissue penetration (more comparable to those of CO_2 lasers). This is possible because of the dramatic reduction in both laser power and duration required to achieve a given superficial effect.

In noncontact mode the laser is aimed at the tissue from a short distance. The degree of tissue penetration, coagulation, and vaporization depends upon laser type and power setting; duration of exposure; and tissue characteristics, particularly, water content, hemoglobin content, and pigmentation. Generally, diode lasers can penetrate tissue to a greater degree than other lasers (up to 4 mm in nonpigmented tissue) in noncontact mode. Penetration is greatly reduced to around 0.3 mm when carbonized tips are used in contact mode. In practice, contact mode is more accurate and controllable, while noncontact mode is more diffuse with deeper penetration.

For open surgery, the laser fiber is usually housed within a hand-piece that is held much like a pen. The fiber tip is gently stroked across the tissue, either in contact or noncontact modes, until the desired incision or ablative effect is obtained. When used down the operating channel of an endoscope, the fiber is used in contact mode and the entire

scope-fiber unit is moved as one. Gentle stroking movements of the scope-fiber unit are used to produce the desired effect, and always under direct visual control.[10] Additionally the diode laser can be utilized in a fluid medium that increases its utility through the endoscopic operating channel, allowing application in the gastrointestinal tract or urogenital system.

Radiosurgery. Radiosurgery utilizes high-frequency radio waves (3.8–4.0 MHz) to cause vaporization of intracellular water, causing the cell to rupture (in a very similar way to CO_2 lasers). Unlike electrocautery, radiosurgery maintains a cooler electrode and offers superior accuracy and reduced collateral damage, comparable with CO_2 laser incisions, at a significantly reduced cost.[4,12] The 3.8 MHz and 4.0 MHz radiofrequency units (Surgitron, Ellman International Inc. Hicksville, NY) offer monopolar/bipolar applications with foot-pedal/finger-switch control for cut, coagulate, hemostasis, fulgurate, and bipolar modes (Fig. 90.15A).[5,13] Monopolar cutting needles are typically used for dissection, and bipolar forceps for sealing blood vessels (see Fig. 90.15B). A variety of waveforms are possible (Fig. 90.16): (1) A pure filtered waveform utilized for pure microsmooth cutting is used for skin incisions and wire loop excisions, where hemostasis is not expected to be a problem. This waveform gives the least lateral heat and is comparable to focused CO_2 laser incisions (Fig. 90.17A). (2) A fully rectified waveform that blends cutting and coagulation is used where slight bleeding might be expected. It cuts as well as coagulates small blood vessels and gives slight lateral heat to the tissues. (3) A partially rectified waveform is primarily for hemostasis; it cannot be used for cutting but is excellent for coagulation. (4) A fulgurating current that results in spark-gap tissue destruction is very similar to the unipolar diathermy and gives superficial tissue damage by holding the needle electrode close to the tissue and allowing a stream of sparks to burn the tissues. It is suitable for superficial hemostasis and destruction of cysts and superficial neoplasms. (5) Bipolar coagulation allows precise hemostasis obtained by using bipolar forceps (see Fig. 90.17B). Each blade is connected to the radiosurgical unit so that the current passes between the points of the forceps. There are also numerous other radiosurgical attachments for specialized oral, neurological, and endoscopic applications.

(B) A variety of tips can be used with the CO_2 laser. Tip size affects spot size, which affects the laser–tissue interaction and power density. The smaller the tip, the more precise the cut. Cryosurgery

Cryosurgery is the use of extreme cold (typically liquid nitrogen at −196°C [−321°F]) applied to a tissue to cause cellular freezing and necrosis.[14–16] The technique has been commonly used in the treatment of various dermatological and ocular conditions, especially hyperplastic and neoplastic diseases (Fig. 90.18). However, cryosurgery of visceral lesions is also possible following a traditional or endoscopic surgical approach. A number of cryosurgery systems are commercially available.

Intraoperative Fluoroscopy

A fluoroscopy C-arm (e.g., OEC 9800 Plus Mobile C-arm, GE Medical Systems, Covington, GA, USA) is an expensive but useful device that permits interventional radiographic imaging during surgery. It is particularly useful for the intraoperative assessment of orthopedic repairs and the placement of surgical implants.

Intraoperative Temperature Support

Maintaining patient temperature is essential for similar reasons to mammals. In addition, reduced body temperature in reptiles results in

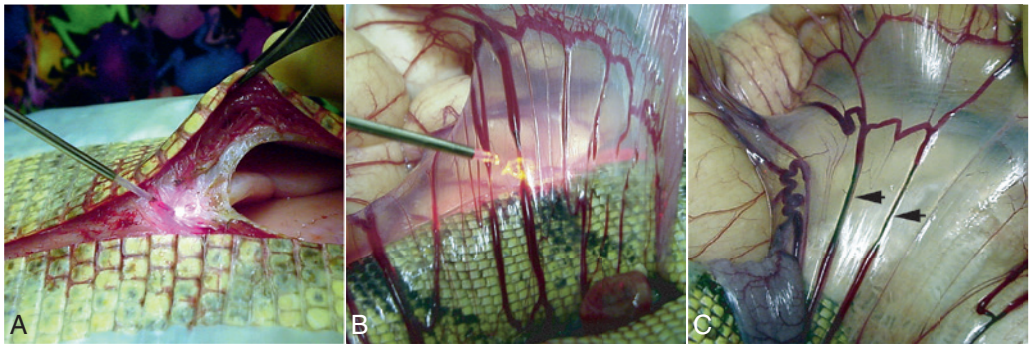

FIG 90.14 (A) 980 nm diode laser incision (contact mode) through the ventral coelomic musculature of a large varanid lizard. (B) Noncontact coagulation of large oviductal vessels in a large iguanid lizard undergoing ovariosalpingectomy. (C) Same iguana demonstrating the ability of the diode to coagulate larger vessels. considerable increases in recovery and healing time. Warm-water-circulating blankets and/or forced warm air devices offer the most effective means of maintaining patient temperature (Fig. 90.19).

Suture Materials

In general, the skin of reptiles is strong and acts as the primary holding layer for maintenance of wound closure. For example, with coelomic surgery, the coelomic membrane and body wall are often thin and weak. The success of wound closure relies on strong, well-placed skin sutures. Because the skin is tough, sutures are unlikely to tear through, although tension typically results in necrosis and subsequent dehiscence. Most reptiles do not traumatize their incisions.

Chromic catgut does not appear to be an appropriate suture for use in the reptile patient. In a rhinoceros viper (*Bitis nasicornis*), the material was still present 12 weeks after placement in both the pleuroperitoneum and the subcutaneous tissues.[17] Other absorbable materials not dependent on proteolysis are recommended for deeper tissue closures. Modern rapidly absorbed suture materials (particularly poliglecaprone 25) are recommended for short-term, internal, soft-tissue applications, and antibiotic-impregnated options are now available. Polyglactin 910 has been associated with greater inflammation and less favored.[18] Polydioxanone lasts for several months, but for permanent internal durability nylon is required. Depending upon the expected rate of healing, monofilament nylon, polydioxanone, or poliglecaprone 25 are often preferred for skin suturing, although wire may be necessary for crocodilians and shell repairs. More recently, knotless suture materials (Quill Knotless Closure System, Surgical Specialties Corp Wyomissing, PA; Strarafix, Ethicon Inc.) have become available. When required, suture removal is generally scheduled 6 to 8 weeks after surgery.

Antibiotics

The routine use of broad-spectrum antibiotics following surgery implies a low level of expertise on the part of the clinician. Excessive use of antibiotics has led to widespread drug resistance and is an ongoing major global health hazard for animals and humans. There should be no need to use postoperative antibiotics if appropriate aseptic techniques are employed. However, when performing clean-contaminated procedures (e.g., enterotomy, cystotomy) or procedures where infection would be disastrous (e.g., orthopedics), short-term pre/perioperative (intravenous or intraosseous) antibiotics have been shown to be more effective than several days of postoperative therapy.[19,20] The author does not use postoperative antibiotics routinely, but, when indicated, frequently uses cefazolin at 20 to 25 mg/kg IV or IO, given before moving into the operating room and repeated every 90 to 120 minutes.

POSITIONING, ERGONOMICS, AND PREPARATION

Patient

Fasting is often a nonissue, as many diseased reptiles present with days to weeks or even months of anorexia. However, if still feeding, it is wise to fast prior to surgery, especially if a gastrointestinal procedure is planned. A useful rule of thumb is to miss a single feeding cycle. Therefore a small lizard fed every day should be fasted for 24 hours, whereas a large constrictor fed every 2 weeks could be fasted for 2 weeks. Fasting for 24 to 96 hours should result in an empty stomach but is unlikely to have a significant effect on the voluminous large intestine of herbivores.

Prior to surgery a preanesthetic evaluation should be completed and followed by appropriate premedication, induction, intubation, catheterization, and application of intraoperative monitoring devices (see Chapters 48 through 52).

Precise patient positioning will depend upon the species and the nature of the surgery, and specific recommendations are provided in each of the following surgery sections. However, some consideration should be given to maximizing desired surgical access while (1) ensuring that head and neck position does not interfere with ventilation; (2) avoiding excessive compression of the head, limbs, or coelom to prevent pressure necrosis, visceral rupture, or hypoventilation of the lungs; (3) avoiding extreme and prolonged hyperextension or hyperflexion of any joint; (4) ensuring the surgical site is easily accessible and does not require a surgeon to adopt a posture that results in fatigue; and (5) using appropriately sized sandbags, vacuum beanbags, foam supports, and adhesive tape to maintain patient position (Fig. 90.20).

FIG 90.21 Sitting is ergonomically preferred for most procedures, especially when using magnification during microsurgery. This often requires placement of the animal toward one end of the operating table so that the surgeons can sit with their legs under the table, unimpeded by the table pedestal. (Courtesy of Stephen J. Divers.)

FIG 90.22 This snake has been positioned on a forced-air heater blanket over a water-circulating blanket, and a sterile adhesive drape has been applied. Note the focused illumination of the surgical site. (Courtesy of Stephen J. Divers.)

Surgeon Ergonomics

Rather than assuming contorting positions, the surgeon must dedicate some time to planning factors such as patient positioning and table height if fatigue and musculoskeletal issues are to be avoided.[21] The ideal posture for the surgeon involves sitting (or standing) with a straight back and a slightly flexed neck (see Fig. 90.6).[22] Surgeon posture becomes even more critical during microsurgery, with the surgeon's wrists resting on a padded support on the surgical table (see Fig. 90.6). In most cases, utilizing sandbags or similar objects to support the wrist allows optimal motor control when using microinstruments. Poor positioning will quickly lead to surgeon fatigue, reduced surgical ability, and increased patient morbidity (Fig. 90.21). During microsurgery, surgeons should follow the 20-20-20 rule to reduce fatigue—every 20 minutes look at something 20 feet away for 20 seconds.

Presurgical Preparation and Draping

Aseptic surgery should be performed in an appropriately clean and sterile operating room by surgeons wearing surgical masks, hats, sterile gloves, and gowns. The (non-ocular) surgical site should be aseptically cleaned using standard 0.05% chlorhexidine or 5% povidone–iodine surgical scrub solutions; however, recent studies have indicated that povidone-iodine-alcohol combinations are superior to chlorhexidine-alcohol solutions.[23] A small brush (e.g., toothbrush) is particularly useful for cleaning scaled skin. Dousing with alcohol is not recommended because of increased evaporative heat loss. However, where a surgical solution devoid of alcohol was used for skin preparation, a final alcohol wipe will help ensure a dry grease-free area to which adhesive drapes will readily adhere.

Traditional cloth drapes can be heavy, hinder animal observation for anesthetic monitoring, and are less effective bacterial barriers compared to plastic adhesive drapes.[24] Transparent adhesive drapes have several advantages, including better visualization and monitoring of the patient, maintenance of a waterproof barrier, ability to be secured without towel clamps, and are lightweight with greater aseptic benefits (Fig. 90.22).

POSTOPERATIVE CARE

The two most important points to address postoperatively are thermal support and pain control (see Chapter 50). No excuse exists for not providing postoperative analgesia to patients. During and after anesthetic recovery, the patient should be maintained in a clean, warm, quiet environment. Unless the wound closure is waterproof, incision immersion should be prevented for a period of 5 to 14 days after surgery to allow a scab to form and desiccate. Prevention of brumation (hibernation) for 3–6 months is best to allow complete healing. The fluid and nutritional needs of the patient must be assessed and maintained (see Chapter 87). Fluid therapy is indicated to maintain the hydration status of the patient. Many patients become anorectic after surgery and need nutritional support (see Chapter 122). In some cases, esophagostomy tubes and central jugular lines may be necessary to provide long-term support (see Chapters 44 and 45). It is wise to schedule postoperative examinations after 7 to 10 days (to check for infection/dehiscence) and 6 to 8 weeks (for suture removal).

Eye

Martin P.C. Lawton

The approach to ophthalmic surgery in reptiles is similar to that used in other species. Many of the techniques utilized for reptiles are modifications of those designed for humans or pet carnivores. An understanding of ophthalmic basics and anatomic differences is essential (see Chapter 71). Most procedures will require general anesthesia. Less often, local anesthesia alone may be adequate, usually with simple procedures, such as a foreign body removal. Sometimes a combination of general anesthesia and either topical, subtenons, or retrobulbar local anesthesia (lidocaine or marcaine) is required.

EQUIPMENT SPECIFIC TO OPHTHALMOLOGIC SURGERY

The size of ocular tissues will make it desirable to use an operating microscope or at the very least a decent loupe system.

Specific ophthalmic instruments should allow atraumatic handling of the delicate tissues. Appropriate suture handling and tying instruments, such as Castroveijos, that will not inadvertently straighten the small swaged on needle or damage the fine suture materials (usually 6/0 to 10/0) should be used. Forceps such as St Martin Forceps (1–2 rat tooth), Bishop Harmans, neurologic forceps, or watchmakers forceps are advantageous.

Aseptic surgery should always be undertaken. Due to the possibility of infection from environmental organisms, it is important to prepare the surgical area with an effective disinfectant/antiseptic, such as 0.5% to 1% chlorhexidine or povidone-iodine (usually diluted 1 : 4) that has been warmed. Alcohol should be avoided to prevent loss of body heat or damage to the exposed cornea (where there is no spectacle).[1]

There are many disposable drape systems for human ophthalmic surgery that are ideal for reptiles. These drapes are adhesive with a central clear window for keeping the drape in position and for isolating tissues not involved in the surgery. Care should be taken on removing such adhesive drapes as the outer layer of skin may be prematurely avulsed if the reptile is nearing ecdysis.

SPECIFIC OPHTHALMOLOGIC PROCEDURES

Eyelid Repair

Most repairs required are the result of traumatic injuries, including fights, resulting in the loss of the normal integrity of the eyelids. Appropriate perioperative antibiotic therapy may be required. Return to normal conformation and function is the desired effect with minimum scarring or distortion. Where there are substantial damage to the eyelids (e.g., heat lamp burns), a blepharoplasty may be required (Fig. 91.1).[2] In all reptiles with functional eyelids, the lower eyelid is the most important for the protection of the eye and should be the priority in any repair.

Often simple repair to return a normal anatomic apposition using a 6/0 or 7/0 "coated braided suture" such as Vicryl is all that is necessary. The leading edge of the eyelid should be inline to prevent kinks or notches that could later potentially cause corneal irritation or damage. Sutures should be either buried or on the outside of the skin and not on the bulbar conjunctival surface of the eyelid.

Sliding grafts are more difficult to undertake in reptiles than in mammals, but gentle dissection may be able to free up skin for advancement grafts to close any defects.

Spectacle Debridement and Spectaculectomy

The spectacle, being skin, is an ideal area for surgical approaches, such as surgical debridement, repair, or removal of substrate under the surface layer of the spectacle. Any debridement is best performed with the aid of an operating microscope to allow reliable removal of all the foreign material, especially when organic, to prevent the possibility of foreign body reaction or granuloma formation. If the development of scarring should occur during the healing stage, this will usually disappear after

the next or subsequent slough. Rarely does damage or treatment of abrasions result in permanent opacity to the spectacle.

Treatment and obtaining material for cytology or culture is the ideal approach in dealing with and resolving a subspectacle abscess. The approach requires making a small wedge resection of the spectacle (spectaculotomy), usually at the lateral quadrant. Up to 25% to 30% of the spectacle can be removed by this approach but greater than this could result in excessive loss of the tear film and desiccation of the cornea.[3] If a larger incision is required, then a flap with a temporary suture placement to allow reopening is required. On opening the subspectacular space, a swab should first be taken of any material and submitted for culture and sensitivity; a stained smear may be useful in confirming a bacterial infection. The spectaculotomy wound is left open so that the subspectacular space can be repeatedly flushed out with balanced salt solution (or another suitable solution) (Fig. 91.2) and an appropriate ophthalmic antibiotic solution such as ciprofloxacin or gentamicin once or twice a day. Antibiotics are required if infection is present but are not essential for healing once infection has resolved.[3,4]

Following experimental spectaculectomy in ball pythons, engorgement of the spectacular vessels with edema adjacent to the wound edges is common for several weeks. An amorphous plaque of homogenous proteinaceous material fills the defect and allows reestablishment of the subspectacular space and normal wetting of the corneal surface within 1 week. A variable degree of inflammatory cell infiltration occurs immediately postoperatively and subsides over 4 weeks. Normal wound healing results in regeneration of normal spectacle morphology by 3 months postoperatively. Experimental pythons were not at risk for a higher incidence of ocular or subspectacular infections as a direct result of partial spectaculectomy.[3]

Pseudobuphthalmos

Pseudobuphthalmos is the distension of the subspectacle space with fluid, usually because of a blockage to the normal drainage of the tear film into the mouth (see Chapter 71) (Fig. 91.3). A temporary fistula is required to allow drainage of the fluid and resolution of the distension. There have been descriptions of treating this condition with a small wedge-shaped incision in the ventral spectacle,[5] but recurrence can occur if the wedge is too small.[6] Even with a 30-degree wedge section removed from the inferior quadrant, recurrence was noted and eventually led to the rupture of the lacrimal duct and fluid draining down the face.[7] This author considers that irrespective of the size of the wedge removed, a high risk of recurrence always exists, and, if too big a wedge is removed,

problems can develop from exposure keratitis or secondary infection. The critical and essential part of the treatment is to either treat the blocked nasolacrimal duct or create a new drainage canal.[4] A new drainage canal (conjunctivoralostomy) should be formed between the medial aspect of the inferior fornix of the subspectacular space and the mouth, emerging between the palatine and maxillary teeth. This is performed with a 22- to 18-gauge needle (Fig. 91.4); the conjunctivoralostomy should be prevented from closing by placing a 0.625-mm Silastic/silicon tube, sutured in place on the periorbital scales and left in situ for up to 6 weeks.[4,7,8] Any fluid removed from the subspectacular space should always be examined under the microscope (fresh and stained), because flagellates have been found in subspectacular exudates.[7]

Spectacle Avulsion

The total loss of the spectacle will lead to loss of the tear film, desiccation of the cornea, eventual loss of the sight in that eye, and even the loss of the eye. Protection of the cornea is essential by covering the defect until new skin can grow across the defect. This is best done by using mucosal graft, Biosist graft (bovine collagen), or commercially available amniotic membrane.[9] The graft material should be sutured to any

remnants of the spectacle edge with fine sutures (6/0 to 8/0) to act as a scaffold for the growth of new skin. The transparency of the spectacle is unlikely to be fully regained, and some degree of opacity should be expected.

Gecko Retained "Eye Caps"

This is not a true spectacle condition but a unique syndrome in gecko species with eyelids.[10] A solid mass forms within the palpebral fissure from the retention conjunctival lining and debris under the eyelids, usually with associated secondary infection (Fig. 91.5). Hypovitaminosis A is considered to be a predisposing factor related to this problem, as is low environmental humidity. This procedure may be performed under topical local (proxymetacaine or marcain) or general anesthesia. Magnification is essential to allow removal of all the matter without damaging the cornea (Fig. 91.6). Removal of the retained material is carefully undertaken with forceps or absorbent dental paper points. Lubrication (using balanced salt solution or a viscous tear solution) may be required to soften the material. Repeat surgical intervention, topical antibiotics, and lubrication (e.g., Gentacin – Clincagel, Ceva), and vitamin A supplementation may be required.

Corneal Repair

Superficial corneal damage can typically be treated topically, but deep corneal ulcers should be treated surgically[11] in order to prevent rupture and facilitate healing. A corneal laceration with no loss of tissue can be repaired with simple interrupted sutures of 8/0 or 10/0[12] or the use of a surgical cynoacrylic adhesive (Steribond or Vetbond). Where there is loss of corneal tissue that will not allow direct apposition, the use of a surgical "bandage" is preferred by transposition of a prepared pedicle or bridging graft of conjunctiva that is sutured over the ulcer bed to the edges of healthy cornea with 10/0 Vicryl sutures.

Severe ulcerations in Chelonia and lizards may be treated by performing a third eyelid flap (Fig. 91.7), although Millichamp[11] does not like this approach because it applies pressure to the globe that could potentiate corneal rupture. The placement of the third eyelid flap also has the disadvantage of preventing further examination of the cornea during the healing process.

Corneal Plaque (Keratitis) Removal

Treatment of this condition requires the removal of the plaque from the cornea and appropriate topical antibiotic therapy (Figs. 91.8 and

91.9). The technique requires the controlled use of a 27-gauge needle to gently lift the mass off the cornea. The plaque can be pretreated with topical antibiotics, often resulting in the mass becoming firmer, which aids removal. Where the mass is very adherent to the damaged corneal surface, superficial keratectomy is performed, and the resulting corneal ulcer treated with appropriate protective products (e.g., hyaluronic drops) and topical antibiotics.

Cataract Surgery

Cataract surgery is indicated in patients whose quality of life is impacted by vision loss. However, the small size of the patient's globe and requirement for specialist equipment (phacoemulsification) renders most reptiles as poor surgical candidates for this procedure.[10]

Cataract surgery in reptiles can be performed in a similar manner to that described for birds. The lens is soft,[13] which means less ultrasound (phacoemulsification) and more irrigation/aspiration is required during removal of the lens nucleus and cortex. Repair of the cornea does not always have to be undertaken, even in aquatic species.[13] Suture materials such as vicryl in the cornea have been reported to cause focal abscesses, which resolved only after the suture was removed.[13] Cataract surgery in reptiles with spectacles is more difficult. Initially the surgeon must incise and flap the spectacle to allow exposure of the cornea before incising into the anterior chamber to deal with the abnormal lens. Visual results can be good, often with reptiles regaining the ability to feed themselves, allowing rehabilitation and a possible return to the wild.[13]

Enucleation

When there is severe infection, inflammation, or trauma of the globe with little chance of recovery, enucleation can be performed. Glaucomatous eyes are particularly good candidates for enucleation,[11] because the prognosis is otherwise poor.

In species with nonfused eyelids, the approach is similar to that described for mammals. Utilizing a lateral canthotomy, the palpebral fissure is enlarged for easier removal of the globe, followed by removal of the eyelid margins and sutured closure to form a permanent tarsorrhaphy (Fig. 91.10). In snakes, the whole of the spectacle and the globe should be removed, the optic blood vessels sealed with hemostatic pressure, and the wound allowed to granulate over a period of 4 weeks.[14]

Ear

Michelle Kischinovsky and Stephen J. Divers

Generally, the reptilian (and amphibian) ear is not prone to disease requiring major surgical intervention. As with other body systems, the ear can be a site for trauma, dermatologic, and parasitologic insults; however, many are managed medically and supportively. Polyps, neoplasia, abscesses, and other protruding or obstructive growths are likely to need surgical excision to achieve resolution.

Malignant and benign tumors, including nonneoplastic polyps, may develop in or around the aural cavity of the reptilian ear.[1–3] Thorough presurgical assessment of diseased tissue and margin-determination aids in surgical planning and accurate prognosis. This may be done through impression smears, fine-needle aspiration, and/or tissue biopsy. Because the deeper aural regions are difficult to assess, radiography, CT, or MRI may be required.[4] The surgical approach and technique depend on the associated pathology and vascularity of the structure. Conventional surgical techniques can be used, although radiosurgery, laser, or cryosurgery may be favored for speed and improved hemostasis. Magnification (such as operating loupes or microscopy) can be invaluable.

AURAL ABSCESS

Following intubation and the establishment of surgical anesthesia, the oral cavity is packed with moistened gauze to prevent aspiration from eustachian tube lavage during surgery. The animal can be positioned in sternal or lateral recumbency, with the head and neck rotated to position the tympanic area toward the surgeon. Given the close proximity to the ocular structures, aseptic preparation of the tympanic region is best undertaken using dilute povidone-iodine rather than chlorhexidine, and alcohol should be avoided.

A variety of surgical approaches are possible, ranging from a single horizontal incision, cross incisions, partial, and, in severe cases, complete excision of the entire tympanum. For most abscesses, a full-thickness incision made through the tympanum along its ventral border from the 9 o'clock to the 3 o'clock positions and connected horizontally to facilitate removal of the ventral portion (Fig. 92.1). In some cases, it may be necessary to remove the entire tympanic membrane. Inflammatory debris is extracted with small ear loops or curettes, and it is often possible to remove a single caseous plug. Surgical debridement of inflammatory tissue may be required, but care must be taken not to damage the columella during surgery (Figs. 9.21A and 9.22). Because a variety of gram-positive and gram-negative bacteria have been isolated from these lesions, specimens for in-house cytology, Gram stains, culture, and sensitivity should be collected at this time.[5] In addition, acid-fast stains or PCR should be considered if *Cryptospordium* is suspected, and histopathology should be considered if there is granulomatous or other abnormal tissue.[1,2]

Note the extent of the middle ear cavity demarcated by the dashed line (B) Right lateral view of an African spurred tortoise (*Centrochelys sulcata*) demonstrating the ventral and horizontal tympanic incisions between the 9- and 3-o'clock positions. The larynx (1), endotracheal tube (2), and tongue (3) are also visible. (C) Postoperative view of the same leopard tortoise (cranial to right). The tympanic membrane has been marsupialized to the skin to delay healing until the infection has resolved. A red rubber catheter has been sutured into the tympanic cavity to facilitate flushing and topical therapy in this uncooperative animal. The opening to the eustachian tube is indicated (*arrow*). (Courtesy of Stephen J. Divers.)

The caudomedial aspects of the tympanic cavity are inspected to ensure complete debridement, and patency of the eustachian tube is evaluated (Fig. 92.3A and B). After debridement, the tympanic cavity and eustachian tube are liberally lavaged with sterile saline (with or without an appropriate antimicrobial agent). Indwelling aural irrigation catheters can be used to facilitate twice-daily flushing and topical treatment for uncooperative chelonians (see Fig. 92.3C).

Antibiotics are seldom required following complete surgical removal; however, their use should be governed by established antibiotic policy (i.e., selection of a first-line drug based upon examination of cytology and gram-stained smears, modified by culture and sensitivity results, and preference for local topical therapy over systemic administration). First-line aural antibiotics include trimethoprim-sulfa, amoxicillin, and first- and second-generation cephalosporins. Aminoglycosides should

VetBooks.ir

be used with caution given the proximity of neural tissues. Anticoccidial drugs are indicated in cases of cryptosporidiosis. Depending on the degree of surgical manipulation, the routine use of postoperative analgesics for 1 to 3 days is appropriate, with meloxicam and opiates favored by the authors. Aquatic species should be dry-docked for 24 hours and then maintained in shallow water that does not cover the surgical site for the first 10 to 14 days.

Additional support measures including assist feeding may be required based on individual patient response; however, most reptiles recover quickly and are discharged the following day. Clients are instructed to continue daily sterile saline lavage until the wound is closed (often 2–4 weeks) and to make necessary improvements in husbandry (including hygiene) and nutrition (e.g., vitamin A supplementation).[6,7] Reexamination at 1 and 6 to 8 weeks postoperatively is advised to evaluate for infection, assess healing, and remove any sutures.

Rhinarium

Michelle Kischinovsky and Stephen J. Divers

The rhinarium includes the nostrils, nasal passages, and choana, which open into the oral cavity. The nostrils are often a site of self-induced trauma in captive reptiles, and abscesses involving the maxilla may involve the rhinarium; however, currently there appear to be few indications for rhinotomy.

TRAUMA, ABSCESS, AND OSTEOMYELITIS

Captive reptiles and amphibians are prone to self-trauma from excessive rubbing or striking against enclosure sides. Injuries span from superficial self-limiting abrasions to severe rostral trauma requiring extensive wound management and repeated debridement.

Damage to the rostral area often leads to disruption of air movement through the nares, which results in open-mouth breathing. In turn, this may dry out the oral mucosa, leading to secondary oral and/or respiratory disease as the normal movement of air through the respiratory tract is disrupted. Therefore repairing rhinarial tissue to allow patency of the nares is critical to long-term success. Husbandry scenarios that result in this damage must also be addressed and resolved for surgical repair, manipulation, or treatment to ultimately be successful.

In severe cases, tissues become secondarily infected, leading to stomatitis, osteomyelitis, or even fractures (Fig. 93.1).[1] If any concerns for bone involvement exist, imaging including radiology, CT, and MRI may be useful in determining a surgical plan and prognosis. Aggressive surgical debridement is usually necessary to remove infected soft tissue and bone to minimize recurrence. Deep, uncontaminated samples should be collected initially for in-house cytology and gram stains, and, if indicated, bacterial and fungal cultures, as well as samples for infectious disease PCR submission (e.g., chlamydia, mycoplasma, ranavirus, herpesvirus, nidovirus) (see Section 4 for more information).

Due to the vascularity of the area, hemorrhage can be a concern because a laryngeal obstruction can result in dyspnea. Use of radiosurgery or laser modalities for hemostasis may be of value when manipulating these vascular tissues. Attention should be paid to protection of the

VetBooks.ir

larynx itself, especially in procedures where the nares or choana are being flushed, because tissue damage or aspiration can result.

Performing corrective surgery to close wound deficits is difficult, and bandaging any of these areas is generally not possible. Daily or twice-daily flushing using topical antiseptics is essential (e.g., dilute chlorhexidine or betadine, or saline-containing antimicrobials). However, stress to the herptile must be considered when determining frequency of these treatments. In addition, topical treatments may be considered (e.g., manuka honey, silver sulfadiazine, antibiotic ointments). In severe cases where infection is confirmed but topical treatment is ineffective or may require adjunct therapy, systemic antimicrobials are indicated; however, they are no substitute for surgical debridement. Some affected animals may become anorectic, presumably due to interference with olfaction and may need nutritional support (see Chapters 45 and 122). The wounds should be monitored through all phases of second intention healing.

Due to the anatomy and delicate structure of the the rhinarium, and the safety of the surgeon, patients who are fractious or require special attention to internal structures will likely require chemical restraint (see Chapters 48 through 52). To allow safe access to the choana and internal nares, the use of oral speculums, a soft tape roll or other improvised mouth gag device is invaluable. To debride or surgically correct difficult-to-reach areas of the rhinarium, the aid of small and purpose-made (uniquely angled and sized) dental or ophthalmic surgical instruments is useful. Additionally, magnification or video endoscopy, is especially valuable to evaluate the choana and internal nares.

FOREIGN BODIES AND RHINOLITHS

Being an orifice, any foreign object small enough could potentially lodge itself in the cavity. Sea turtles have been described with both a plastic straw and a fork occupying this space.[2,3] In both cases, the object was removed in situ with pliers using forceful retraction and cleaned with a betadine solution before immediate release. In the latter case, it is believed that attempts at regurgitation following ingestion resulted in the foreign body entering the choana and lodging within the nasal turbinates. This highlights the importance of a thorough clinical examination and the use of appropriate imaging modalities (radiography, MRI, CT). It is also a site for fish hook trauma in aquatic and semiaquatic species. Endoscopic evaluation and retrieval may be useful in larger reptiles.

Rhinoliths are seen infrequently, even in burrowing species where dirt could be an obvious nidus. Because the diameter and the angle of the nostrils in most reptilian species usually does not allow great visibility within the nasal cavity, rhinoscopy may aid investigation and removal.

Oral Cavity, Mandible, Maxilla, and Beak

Michelle Kischinovsky and Stephen J. Divers

This chapter discusses surgical aspects of the oral cavity (teeth, tongue, mucosa), hard palate, mandible, maxilla, and beak (rhamphothecae). Oral cavity pathology requiring surgery is usually the result of trauma. Predisposing conditions and circumstances resulting in injury, such as poor enclosure design and other husbandry-related issues, including nutritional deficiencies, are often contributing factors. A thorough history, clinical assessment, and diagnostic investigation will help to differentiate between a primary injury and one caused by an underlying disease process, and it will help determine a management plan and prognosis.

Neoplastic processes and other growths have been described and are managed similarly to other species with regard to malignancy determination, chemotherapy, radiation therapy, or surgical decisions.[1] Care should be taken when examining the oral cavity to prevent iatrogenic trauma to bone and teeth, as well as soft tissues. Venomous species require particular care and should be examined under general anesthesia (see Chapter 22).

GLOSSITIS AND GLOSSAL PROLAPSE

It is not uncommon for chameleons to prolapse and, in some cases, subsequently "swallow" their tongue. The condition should be treated as an emergency. A full clinical assessment should be made before advising surgical solutions, as the condition is often related to nutritional deficiencies (especially nutritional secondary hyperparathyroidism), and the patient may need stabilization before anesthesia and surgical intervention. In more severe cases where there are concerns related to sepsis, multiple disease processes, and client compliance, euthanasia should be considered. The tissues should be evaluated for viability. A prolapsed or "swallowed" tongue can be replaced to its normal anatomic position using an atraumatic spay hook or similar. If necrosis is evident, then amputation is advised. Bacterial and fungal glossal infections occur in snakes, lizards, and chelonians. Such processes may be diffuse (often acute) or well demarcated (often more chronic). Given the critical roles that the tongue can play in olfaction (snakes and lizards), food prehension (anurans, chameleons), and swallowing (lizards and chelonians), complete amputation can lead to significant postsurgical feeding problems. Although permanent hand feeding is rare, a protracted postoperative recovery period necessitating nutritional support may be required. In general, attempts should be made to retain as much glossal anatomy and function as possible.

Glossal Repair

A novel alternative surgical technique to amputation has been suggested where tissues are viable. In one case involving a Malagasy giant chameleon (*Furcifer oustaleti*), the tongue was brought back into its normal anatomic position after swallowing, then sutured in place with modified cruciate sutures on both sides of the tongue (K. Mathes, personal communication, 2018). Sutures were removed after 5 days, and the patient regained full tongue functionality. Hand feeding was necessary for 3 weeks.

Partial and Complete Glossectomy

The patient is given appropriate preemptive analgesia, induced, intubated, and maintained at a surgical plane of anesthesia. Positioning in sternal or lateral recumbency with the head and neck extended, and rostrally facing the surgeon, is appropriate. Mouth gags can help maintain visualization. Aseptic preparation should be attempted using povidone-iodine rather than chlorhexidine, though with caution because tissues may easily slough. The oropharynx can be gently packed with cotton-tipped applicators or gauze to reduce the chances of aspiration.

In cases of focal, well-encapsulated, or demarcated disease, often involving the fleshy chelonian tongue, gentle dissection along a plane of healthy tissue may enable an abscess or granuloma to be removed (Fig. 94.1). Hemorrhage often occurs, and the judicious use of radiosurgery, pressure, local epinephrine, and hemostatic sponges are effective. Careful consideration should be given to closure because there can be no tension on the glossal epithelium. Fine (4/0–5/0), monofilament, absorbable suture should be used in a simple interrupted pattern, and antibiotic-impregnated poliglecaprone 25 (Monocryl-Plus, Ethicon, Athens, GA) is preferred.

For complete glossectomy in lizards and snakes with a long narrow tongue, a transfixing circumferential ligature is placed on healthy tissue a few millimeters from the nonviable border, and the proximal tissues are amputated using a scalpel, scissors, or radiosurgery (Fig. 94.2). In chelonians and lizards with larger fleshy tongues, multiple mattress sutures may be required. Care should be taken to ligate veins and to avoid damage to the entoglossal process of chameleons, which should be adequately covered by epithelium. Minimal bleeding is expected. Any suture ends should be as short as possible as not to provoke the oral mucosa, although proximal glossectomy usually results in the surgical site retracted within the lingual sheath (see Fig. 94.2C) in species with this structure. The needs, duration, and practicality of nutritional support are important, and placement of an esophagostomy tube should be considered. (See Chapter 45.)

Healing should be monitored closely but is usually rapid for oral tissues, with the patient reevaluated at 1 and 4 weeks postoperatively to assess for possible infection and healing. Prolonged hand feeding may be required, potentially lifelong; however, most patients eventually adapt.

ORAL MASSES AND STOMATITIS

Stomatitis can present as localized or diffuse inflammation and/or infection. In addition, soft tissue swellings or projections may represent abscesses, cysts, papillomas, granulomas, and neoplastic or benign growths

(Fig. 94.3). Temporal glands, located at the commissures of the mouth in some old-world chameleons, often present swollen and may be asymmetrical and filled with inspissated material. This is particularly common in Jackson's chameleons (*Trioceros jacksonii*), where green exudate often cultures *Pseudomonas* (see Fig. 94.3).[1] Superficial cytology may be useful but is often poorly diagnostic due to chronicity and oral contamination. Radiography and CT are useful for determining whether there is boney involvement and to plan surgical approaches. Surgical biopsy is often required for a histologic and microbiologic diagnosis to direct treatment. As with the treatment of other abscesses in reptiles these affected glands need to be surgically explored and marsupialized to allow flushing and topical treatment. If bone is involved debridement may be necessary. For such invasive procedures (e.g., debulking, debriding) involving the small and complex nature of most oral structures, magnification, microsurgery, and radiosurgery are often beneficial (Fig. 94.4A).

FACIAL MASSES AND OSTEOMYELITIS

Facial abscesses and granulomas, like their intraoral counterparts, rarely if ever resolve after mere lancing and flushing. Typically, surgical removal *in toto* is required; however, unlike other areas of the body, there is rarely sufficient skin and subcutaneous tissue to ensure closure, and marsupialization or grafting techniques may be required. Although most discrete facial swellings are infectious, aspiration cytology and gram staining can help identify neoplastic or inflammatory masses that may need biopsy for a histologic diagnosis and treatment plan (Fig. 94.4B). Bilateral mandibular swellings, typically due to nutritional secondary hyperparathyroidism, are especially common in lizards and represent a medical, not surgical, condition. Additionally, periodontal disease is a significant cause of oral pathology in captive lizards and is caused by bacterial or fungal invasion of the unique periodontal tissues of lizard species with acrodont dentition, including agamids (e.g., bearded dragons,

Pogona vitticeps, and Asian water dragons, *Physignathus cocincinus*) and old-world chameleons.[2] These lizards typically present with asymmetrical swellings and discoloration along mandibular and maxillary bones and improper closure of the mouth. Often osteomyelitis is associated with these lesions, and aggressive therapy to identify and surgically explore these lesions is indicated (Fig. 94.5). (See Chapters 73 and 161.)

Asymmetrical swellings in the region of the maxillae or mandibles should be evaluated radiographically because osteomyelitis is common and does not respond well to medical therapy alone (Fig. 94.6). Typically, surgical exposure, thorough debridement, and marsupialization are required with prolonged antimicrobial therapy, based on culture and sensitivity testing, for 6 weeks or more. Radiographic reevaluation is recommended because disease progression is common.

OVERGROWN BEAK (RHAMPHOTHECA)

Beak disorders are commonly encountered in chelonians. A thorough history and physical examination should be performed, because this is often a multifactorial issue that can be associated with husbandry, nutrition, trauma, infection, and congenital deformity.

Overgrowth of the keratin rhamphotheca (rhinotheca of the maxilla and gnathotheca of the mandible) is especially common and has been controversially associated with nutritional secondary hyperparathyroidism, elevated dietary protein, and soft, easily prehended food items (Fig. 94.7). In severe cases the upper beak becomes compressed, resulting in the rhinarium tissues and the outer nares becoming occluded. Depending on the strength and tenacity of the patient, sedation or anesthesia may be required, and the head and neck are extended and held in place using two fingers behind the jaw. A dremel with a small rounded head is used to correct minor abnormalities, but a cutting disc may be necessary if there are large overgrown sections to remove. Care should be taken as friction heat is created; intermittent tool use and cold saline-soaked gauze or cotton-tipped applicators can be used for cooling. Corrective treatment may only provide temporary relief, as the beak is likely to continue abnormal growth unless underlying causes are identified and corrected.

FRACTURES (BEAK, MAXILLA, AND MANDIBLE)

Fractures of the keratinized beak are not uncommon after severe trauma, especially in free-ranging chelonians. The fractures may be superficial and only include the keratinized structures, or they may involve the underlying maxilla and mandibular bones. Multiple radiographic planes are typically required, although CT is often preferred for identifying skull fractures (Fig. 94.8).[3,4] It is important to appreciate normal radiographic anatomy because the temporomandibular joint is relatively ventral and should not be mistaken for a fracture. If there is no instability or displacement, then preventing beak use by esophagostomy feeding should be sufficient. Distracted or unstable fractures should be reduced and anchored. A variety of techniques can be used as long as the basic principles of fracture stabilization are maintained. Unless the fracture

is <12 hours old, the wound edges should be freshened with a scalpel blade before reduction. Internal fixator pins, tension band wires, and external fixators are commonly used, often in combination with polymethylmethacrylate to provide greater protection and support (Figs. 94.9 and 94.10).[2–5] External fixator pins should not enter the oral cavity, because contamination and infection of the pin sites becomes likely. Any exposed pin entry sites should be cleaned twice daily. Chronic fractures often become infected, requiring more aggressive debridement and second intention healing (see Fig. 93.1). Implants should not be placed into an infected site or to reduce a pathologic fracture (e.g., in

animals with nutritional secondary hyperparathyroidism). Postoperative complications include trauma to any external fixator, pin loosening, and infection. Placement of an esophagostomy tube is recommended to reduce pressures being applied to the beak during prehension. Radiographs should be repeated, often at 4 and 12 weeks, to monitor healing and evaluate for any signs of osteolysis that might indicate infection. Fracture implants are typically left in place for 12 weeks, although radiographic evidence of complete healing is often delayed and can take 12 to 28 weeks.[3–5] However, external fixator removal should not be solely based on radiographic evaluation, but also on clinical evaluation and palpation because a persistent radiolucent line may persist for many months if not years.

A novel, nonsurgical technique has been described in a blue-tongued skink (*Tiliqua scincoides*) that utilized an intraoral plate (U-shaped plastic, 2 mm thick), which was secured in position using a tape muzzle (Köchli et al, ExoticDVM, 2008, 10:25–28). An esophagostomy tube was placed for nutritional support. The plate was removed after 36 days because of damage and loss of teeth, but the lizard resumed eating by day 44 and made a complete recovery.

Venomoid Surgery

Richard S. Funk

Venomoid surgery is a surgical technique developed to render a venomous snake or lizard nonvenomous by altering the venom production and delivery systems. In some countries, such a procedure is considered a mutilation and is not legally permitted. Additionally, veterinarians who legally perform this procedure should be aware of the liability associated with subsequent envenomation from an imperfect surgery. In the author's experience, an important indication for this procedure is to reduce risk for less-experienced keepers/curators in zoological collections. Additionally, the procedure has been performed on reptiles used in "sting" operations to reduce the risks to all handlers, including the would-be poachers. This procedure is not recommended for those that simply have a desire to keep a venomous reptile.

SNAKES

An early (1937) description of this surgery discussed a crude intraoral approach without surgical hemostasis and "closure" utilizing rubber bands around the patients' heads (excluding lower jaws) for 10 to 48 hours.[1] Another technique utilized in the 1970s involved an approach to the venom apparatus via an incision on the side of the snake's head. Double ligation and transection of a segment of the venom duct was then performed and the venom gland was left intact.[2] A lateral approach for venom duct ligation and resection results in a facial scar on each side, which owners may find cosmetically unappealing, and some snakes (especially elapids) developed a granulomatous response at the surgical site, resulting in a disfiguring swelling. A further modification of this lateral approach was to remove the venom gland and its duct, but a facial scar may still persist. A recent study involving venom duct ligation and resection in four venomous snakes (puff adder [*Bitis arietans*], western diamondback rattlesnake [*Crotalus atrox*], painted saw-scaled viper [*Echis coloratus*], and red spitting cobra [*Naja pallida*]) concluded that scars were virtually invisible after the second postoperative skin shed.[3]

In the 1980s the author developed an intraoral technique that leaves no visible scars and involves the complete removal of the venom gland and the venom duct. Following induction of general anesthesia, the snake is surgically prepped in dorsal recumbency with the mouth opened widely to give full exposure to the buccal surfaces of the maxillae. Care is taken to avoid envenomation of the surgeon. The oral mucosa of the maxillary areas are aseptically prepared. An incision is then made between the palatine-fang axis and the lip margin with radiosurgery, a CO_2 laser, or a no. 15 scalpel blade. Careful dissection with small (preferably ophthalmic) instruments exposes the venom gland and its duct. The venom duct in elapids may be thicker and more difficult to handle. Several small vessels are associated with the gland and the duct, with the largest being encountered dorsomedially; these can be cauterized with the laser or with radiosurgery or, in the case of larger snakes, ligated with absorbable suture and then transected. Good hemostasis is important.

The venom duct is transected at its entrance into the base of the maxillary bone, and the entire duct and venom gland are then elevated and dissected out of the incision as a unit and safely discarded (Fig. 95.1A). To help preserve the cosmetic postoperative appearance of the head, a sterilized silicone prosthesis is cut to a size approximating the

(A) The right venom gland has been elevated through an intraoral incision, but the venom duct is still attached to the base of the right maxillary fang. The duct will be separated at its attachment, and the venom gland and duct will thereby be removed. (B) The venom gland and its duct have been removed; a silicone prosthesis has been placed into the space formerly occupied by the gland, and the incision has been closed with absorbable monofilament suture in a simple continuous pattern.

size of the gland that was removed, and then placed into the surgical site from which the gland was removed (Silicone Elastomer Block, Implantable Restoration Material, Soft White; McGhan Medical Corp., Santa Barbara, CA). To facilitate future identification, a segment of surgical stainless steel suture may be placed within the silicone prosthesis so that it is visible radiographically, or better still, a microchip transponder may be placed into the prosthesis. The mucosal incision is closed with absorbable monofilament suture in a simple continuous pattern (see Fig. 95.1B). Follow-up suture removal is therefore unnecessary. A broad-spectrum antibiotic is administered perioperatively (e.g., IV cephalosporins).

Following surgery, the snake is not fed for 2 to 3 weeks to help facilitate the healing process and minimize the chances of infection from the oral cavity or from prey abrading the surgical site. The cage is kept clean, and the drinking water is changed daily. Thereafter the snake should be fed only dead prey. No complications have been noted from the uses of these prostheses.

Snakes that this author has rendered venomoid have lived well and even bred subsequently (unpublished data). Legally, most jurisdictions still classify a snake from which the venom glands and ducts have been removed as a venomous species even though it is functionally no longer venomous. In two adult *Crotalus,* one *atrox* and one *pyrrhus,* that underwent this surgery, the snakes were surgically reinvestigated 12 and 14 months later (respectively), and the previous surgical sites from which the venom glands were removed were explored. No trace of gland or duct regeneration was found. Subsequently, test prey envenomation was negative for both snakes (unpublished observations).

GILA MONSTER VENOMOID SURGERY

Venomoid surgery for heloderms, Gila monsters (*Heloderma suspectum*) and beaded lizards (*Heloderma horridum*), is performed differently than venomous snakes because of the anatomic location of the venom glands in the ventrolateral regions on the lower jaws. The location of each gland is indicated by a prominent swelling or bulge along the anterior and middle region of each lower jaw laterally (Fig. 95.2). Under general anesthesia, the skin at the surgical site is aseptically prepared, and a ventrolateral skin incision is made with a scalpel blade, CO_2 laser, or radiosurgery. The helodermid venom gland differs from snakes in that a single duct is lacking; instead, a number of tiny ducts lead from the lobulated gland to the bases of several teeth. The lightly pinkish venom gland is carefully elevated from the mandible and removed by a combination of sharp and blunt dissection. Hemorrhage is typically minimal. No prosthesis is placed into the venom gland site. The skin is closed with a nonabsorbable monofilament suture in a simple interrupted (noneverting) pattern. Feeding may be resumed in 7 to 10 days. Sutures are removed in 5 to 6 weeks.

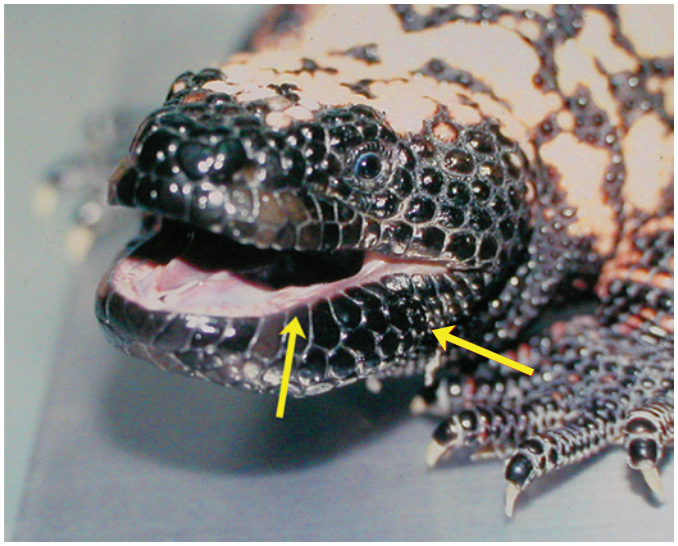

FIG 95.2 The location of the venom gland in the Gila monster (*Heloderma suspectum*) can be noted as swelling or bulge along the anterior and middle portions of the lower jaw (arrows). The gland on each side has a series of tiny ducts leading to the oral cavity.

Integument

T. Franciscus Scheelings and Tom Hellebuyck

Surgery of the reptilian integument is frequently warranted for management of wounds, collection of skin biopsies for disease characterization, removal of abscesses and neoplasms, and as a first step in many invasive surgical procedures. Depending on the nature of the pathology and the temperament of the patient, these procedures can either be performed under general anesthesia or by using a combination of sedation and local nerve blocks. Other chapters within this text cover the principles of anesthesia, analgesia, and administration of other therapeutics such as antimicrobials and fluids.

SURGICAL SITE PREPARATION

Established aseptic surgical techniques should be followed for reptile patients. The intended surgical site should be prepared using chlorhexidine or povidone iodine. A sterile toothbrush or a hand brush may be beneficial when trying to adequately scrub uneven, scaled skin. Excessive use of alcohol may lead to patient hypothermia due to evaporative heat loss,[1] but a light, final wipe with alcohol-moistened gauze is still recommended and helps with plastic drape adhesion. There are a range of options available for veterinarians to create a sterile surgical field. Clear, adhesive plastic drapes are particularly useful because they allow for better visualization of the patient, are waterproof, and do not require the use of towel clamps.[1] These are preferred in small to medium-sized animals. For larger reptiles, traditional cloth or paper drapes may be required.

SKIN INCISIONS AND WOUND CLOSURE

Reptilian skin is often heavily keratinized and may be difficult to incise. In addition, many species have enlarged scales or osteoderms, which need to be avoided. Similar to small-animal surgery, the clinician should consider tension lines and incision orientation when planning their approach. To make the initial incision, it is sometimes helpful to tent the skin with a pair of toothed forceps and then stab into the skin with a small scalpel blade. A pair of sharp scissors or a guarded, upturned scalpel can then be used to extend the incision. Radiosurgery and laser units can also be used to make skin incisions in reptiles, although their use should be avoided if histological evaluation of skin margins is required.[2–5] No matter the technique used, the surgeon should avoid cutting directly into scales, which means that many incisions will require a scalloped technique, especially in snakes.

Incised reptile skin tends to invert, therefore an everting suture pattern (e.g., horizontal mattress) is often preferred over simple interrupted patterns for primary closure (Fig. 96.1).[1,6,7] A number of materials are suitable for closing surgical wounds in reptiles, including nonabsorbable (e.g., monofilament nylon, Ethilon; Ethicon, Inc., Piscataway, New Jersey) or absorbable suture (e.g., poliglecaprone 25, Monocryl, Piscataway, NJ).[8] However, braided materials that allow wicking or chromic catgut that causes intense inflammation should not be used.[8] Suture removal is generally 6 to 8 weeks postoperatively, but ecdysis during this time may lead to premature loss of sutures placed too close to incision margins. Clients should be advised that some degree of dysecdysis may be experienced at the site of the wound, necessitating minor management, but this usually resolves after 1 to 3 shedding cycles (Fig. 96.2). Alternatives to

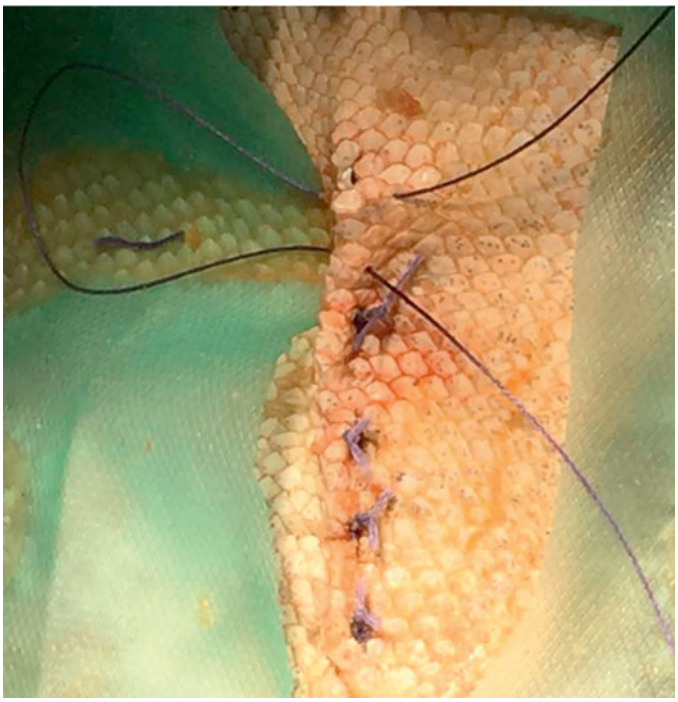

FIG 96.1 Incised reptile skin has a tendency to invert, so an everting pattern should be used. (Courtesy of Tom Hellebuyck.)

suture material that can be used to close wounds include skin stables, or, in small incisions, cyanoacrylic tissue adhesives (Nexaband Veterinary Products Laboratories, Phoenix, Arizona).

SUBCUTANEOUS MASSES (ABSCESSES, PARASITIC CYSTS, AND NEOPLASMS)

Subcutaneous abscesses are frequently encountered (Fig. 96.3A). They may present as either single or multiple disseminated firm masses entrenched within the skin. Reptile abscesses are typically hard and rarely liquid, so they must be removed completely; lancing and drainage are rarely, if ever, effective. If the surgeon is confident that all the abscess material has been completely removed, then the wound can be closed as previously described. Where there is any suspicion that some contamination may remain, the affected site should be managed as an open wound and allowed to heal by second intention (see Fig. 96.3B). Antibiotics are rarely indicated following abscess removal but, if required, should be based upon fungal and bacterial culture of a portion of the capsule. Differential diagnoses for cutaneous masses include neoplasia and parasitic granulomas, and thus it may be prudent to submit samples of excised tissue for histopathological examination.

OPEN WOUND MANAGEMENT

In some instances, primary closure of wounds is not possible, necessitating second intention healing and delayed closure. Fortunately, reptiles tolerate this well, and it is particularly useful for contaminated wounds or where large deficits exist. Most importantly, the wound needs to be thoroughly debrided and lavaged so that only a healthy bed of granulation tissue remains. Sterile saline is best for wound irrigation, as the addition of antiseptics has not been shown to be beneficial.[9] Furthermore, these compounds can be cytotoxic and may inhibit wound healing. Surgical debridement may be preferred when anesthesia can be performed. Mechanical debridement (wet-to-dry bandages) is less selective.[10] If clinicians deem mechanical debridement important to wound healing, then it should only be performed during the initial inflammatory phase and should be preceded by administration of adequate analgesia.[10]

Once the wound has been debrided and lavaged, it needs to be covered to prevent it from desiccating and to promote healing. Topical wound coverings such as hydroscopic gels, antibiotic ointments, silver cream, and honey can be utilized to promote wound healing and decrease the risks of post-debridement infection. These, in turn, should be covered by a layer of bandage to provide further protection from mechanical damage. The choice of bandage material used is dependent on the nature of the wound. Products commonly used for small animals translate well to herpetologic medicine. An important sequela of second intention healing is the possibility of significant scar formation and future dysecdysis (see Chapters 69 and 130 for more details). A useful adjunct treatment in managing open wounds is application of low-level laser therapy (biophotomodulation). This can be helpful in the resolution of intractable wounds that are unresponsive to other modalities of treatment (see Chapter 129). The exact method by which lasers promote wound healing is not yet well understood, but they seem to act at molecular, cellular, and tissue levels to promote ingression of inflammatory cells, modulate cytokines, growth factors, and inflammatory mediators, as well as increasing tissue oxygenation.[11]

Snake Coeliotomy

Richard S. Funk and Rodney W. Schnellbacher

Coeliotomy in snakes is relatively easy for an experienced surgeon to perform. The body cavity is linear, and so the surgical approach involves a linear incision generally over the organ or structure being addressed. But unlike lizards, one short incision will not expose the contents of the entire coelomic cavity. The basic principles of anesthesia and surgical preparation of the patient apply. If possible, try to avoid incising snake skin when the patient is nearing a shed cycle, because the skin is softer and more difficult to handle surgically. Fasting is also recommended to minimize the diameter of the gastrointestinal tract.

When the surgical area is localized, place the anesthetized snake in lateral recumbency and mark the exact surgical site (Fig. 97.1). It is advisable to prep a larger area of the body than originally intended in case it proves necessary to either lengthen the incision or make an additional incision. (Fig. 97.2). The patient may be draped with paper or cloth drapes and affixed with towel clamps, but the authors prefer sterile transparent plastic drapes that adhere to the patient for all but the largest snakes.

An incision should be made, not through the ventral scales, but laterally between the first two or the second and third rows of dorsal scales. If possible, these scale rows are gently spread and the skin incised linearly between the scale rows, trying not to incise any scales (Fig. 97.3A). Make the incision long enough to provide good exposure. Longer incisions take more time to close and may result in a larger scar but may be unavoidable to ensure adequate exposure. After incising the skin, the subcutaneous tissue is incised, exposing the ventral portions of the rib cage (see Figs. 97.3B and 97.4). Hemorrhage is generally minimal and can typically be controlled with gentle pressure, ligation, or with radiosurgery. Continue the incision deeper, just ventral to the rib cage border, incising fascial planes and muscle, and enter the body cavity. Sharp or blunt dissection, radiosurgery, or CO_2 laser may be

used in the subcutaneous tissues and muscular layer. To enter the body cavity, gently pick up and tent the coelomic membrane near the ventrolateral body wall with atraumatic forceps and incise it with the scalpel blade's cutting edge facing the surgeon, then advance the incision carefully. This technique will help to avoid cutting any internal structures.

Alternatively, scissors, radiosurgery, or a CO_2 laser can be used based on the surgeon's preference. Authors frequently utilize radiosurgery. The coelomic membranes are thin and tend to be relatively transparent. After transecting these membranes, stay sutures can be utilized to help the surgeon find these delicate tissues at closure. There generally is a midline ventral abdominal vein that should be avoided (Fig. 97.5). The fat bodies (one row on each side within the body cavity) will need to be moved aside to explore the body cavity further; this can be more time-consuming and difficult in very large or obese snakes. At this point the surgeon will locate the structure of interest and follow applicable internal soft tissue surgery principles detailed elsewhere in this volume.

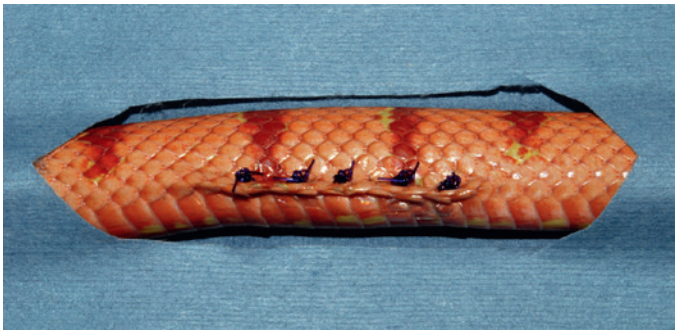

FIG 97.7 The skin incision is closed with a nonabsorbable monofilament suture in a horizontal mattress pattern, with the knots facing dorsally. (Courtesy of Richard S. Funk.)

With gastrointestinal foreign body surgery and an enterotomy, it is usually possible to exteriorize that portion of the intestinal tract, which will help to minimize the chances of contamination. With dystocias, an incision at the center of the group of eggs or fetuses often allows you to move the anterior eggs or fetuses caudally into that incision and move the more posterior ones anteriorly, one at a time, for removal. But if these cannot safely be moved, it will be necessary to either extend the incision or create a second or third one. Appropriately sized retractors (e.g., Lone Star retractor) may be useful in providing suitable exposure to the coelomic cavity in larger snakes (see Fig. 97.4). If surgical contamination is suspected, coelomic cavity should be flushed appropriately with sterile fluids before closure (see Fig. 97.5).

During closure, it may be difficult to suture the coelomic membrane, which often doesn't hold sutures well. If the membrane can be closed, it is recommended to do so, using a simple continuous suture of absorbable monofilament material. The body wall is closed with a simple continuous monofilament absorbable suture (Fig. 97.6). The skin is closed using an everting pattern with horizontal mattress sutures of a nonabsorbable monofilament suture. An everting pattern is recommended due to the keratinized skin's tendency to invert, resulting in reduced contact of cut surfaces resulting in poor healing. It is best to orient the knots dorsally to help minimize the adhesion of substrate debris to the knots (Fig. 97.7). In general, and specifically in aquatic species, no or limited access to complete submersion of the incision in water is recommended for 14 days postsurgery. The use of tissue glue around the incision site may also reduce contamination during the healing process in aquatic species. In most cases sutures are removed in about 6 weeks.

Surgery may accelerate a shed cycle, and a snake may shed the sutures intact while shedding its skin. Postoperative management may include appropriate antibiotics if infection is present, or other medications depending on the case. Postoperative pain management should be routinely considered with injectable NSAID medications and/or opioids (see Chapter 50). Changes in husbandry, such as use of a paper substrate to increase cleanliness, postoperative fasting, or a reduction in prey size to reduce the incidence of dehiscence, and increases in temperature within the animal's preferred optimal temperature zone to accelerate healing are recommended.

Lizard Coeliotomy

Scott J. Stahl

Surgical coeliotomy in lizards provides important access to most major organs of the coelom and can be an effective diagnostic tool, allowing organ evaluation and potential biopsy. Once the coelom is entered, soft-tissue surgeries, including reproductive procedures, gastrotomy, enterotomy, cystotomy, and other procedures, are performed similar to mammals. However, there are important and unique anatomical considerations that surgeons must appreciate to operate safely. Fasting is recommended to minimize the size of the gastrointestinal tract (especially in species such as monitors that eat large prey items) at surgery. Generally, there are two basic approaches to the coelom in lizards. The most common is the ventral coeliotomy (midline and paramedian) and is the preferred approach for most species. The second approach is a lateral (flank) coeliotomy and is used primarily for laterally compressed lizards such as old-world chameleons.

POSITIONING AND PREPARATION

For ventral coeliotomy the lizard is positioned in standard dorsal recumbency and, for the lateral approach, contralateral recumbency. For ventral and lateral positioning the use of tape, bean-bag supports, or rolled towels is helpful (Fig. 98.1). Standard aseptic preparation is performed before draping, and adhesive clear plastic drapes are generally preferred for better contour and visibility of the patient (Fig. 98.2). One important consideration when using clear plastic drapes involves the adhesive portion, which, when removed after the procedure, can damage the fragile skin of some gecko species such as leopard geckos (*Eublepharis macularius*), African fat-tailed geckos (*Hemitheconyx caudicinctus*), and crested geckos (*Correlophus ciliatus*). Using the nonadhesive portions of the drape or applying a small amount of mineral oil to gently release the adhesive from the skin postoperatively is useful.

VENTRAL COELIOTOMY

There are two different techniques to a ventral coeliotomy, a paramedian and a midline approach. The paramedian approach has been used for many years and involves making a surgical incision in the skin, parallel and lateral to the midline (Fig. 98.3).[1] Following skin incision the thin coelomic musculature is bluntly dissected to avoid hemorrhage (Fig. 98.4). This traditional technique is utilized to completely avoid the ventral abdominal vein (VAV) on approach and allows the surgeon to safely identify the vessel early in the coelomic approach. This procedure is preferred by the author and has been used to safely enter the coelom, avoiding the VAV, in hundreds of lizards of many different species.[2,3] This is the recommended approach for the novice surgeon.

Mader et al. have described a midline coeliotomy technique that also allows safe entry into the coelom by avoiding the VAV.[4] Following an initial ventral midline skin incision, the linea alba is sharply dissected,

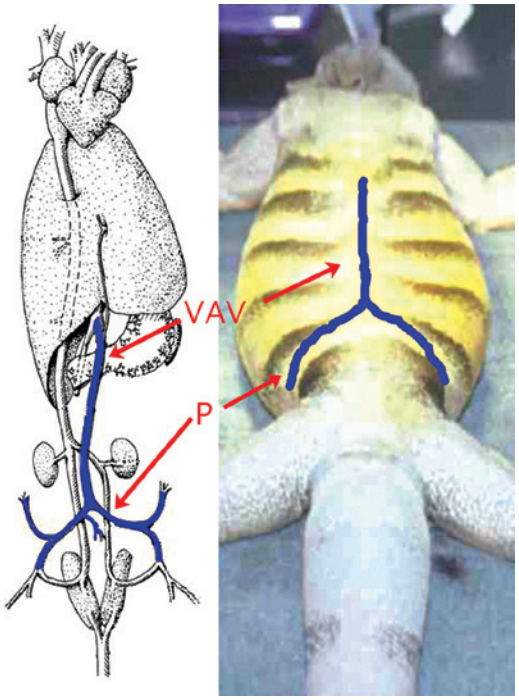

FIG 98.5 The ventral abdominal vein (VAV) is a confluence of the bilateral pelvic veins (P) that are joined bilaterally by the hypogastric veins and the single ventral pubic vein and can be found along the ventral midline, deep to the abdominal muscles. (Courtesy of Douglas R. Mader.)

being careful to avoid the vein. The main advantage of this technique is the presumed reduction in pain associated with an incision through the linea alba (as in most mammals), instead of through the thin coelomic muscles. Regardless of which coeliotomy procedure utilized, a good understanding of the anatomy of the VAV will reduce the likelihood of damage and serious hemorrhage, which if it occurs requires prompt ligation.

The VAV is a confluence of the bilateral pelvic veins, which are joined bilaterally by the hypogastric veins and the single ventral pubic vein. It is located along the ventral midline of the patient, just axial to the abdominal muscles (Fig. 98.5).[4,5] The distance from the pubis to the caudal origin of the abdominal vein varies by species and patient size but is approximately one-fourth the distance between the cranial pubic bone and the umbilicus.[4]

The abdominal vein then courses along the inside of the coelomic wall until it reaches the level of the umbilicus, where it turns dorsad and joins the hepatic vein. Thus the region between the cranial margin of the pubis and extending one-fourth of the distance toward the umbilicus, and the region cranial to the umbilicus progressing to the xiphoid, will have no significant ventral vessels present.[4]

With this anatomical knowledge, the initial surgical incision can occur in either of these anatomical locations without contact with the VAV (Fig. 98.6A and B).[4] As the surgeon proceeds with the incision, the VAV can be gently moved to avoid damage.

Another surgical consideration for the VAV is its variable location within the mesovasorum, which is actually an extension of the ventral coelomic membrane. The mesovasorum varies in size from a couple of millimeters to nearly 1 cm in larger specimens.[4] Although the origin of the mesovasorum is from the ventral midline, the actual location of the vein at surgery depends on the animal's state of repletion and other space-occupying coelomic structures (e.g., bladder calculi, eggs).[4] Thus the vessel may lie on the centerline, or it may be several millimeters off center in either direction (Fig. 98.7). Therefore the surgeon must use caution even when making a paramedian incision as the vessel may be off center.

However, if the VAV is accidently cut and quickly ligated, it is unlikely to be life threatening, as blood will be redirected back through the pelvic veins, into the bilateral renal veins, and directly into the vena cava.[4]

Once exposure is adequate, the linea alba or coelomic aponeurosis (formed by the external abdominal oblique muscle) is gently lifted with forceps to elevate it away from any underlying coelomic structures and carefully incised with a scalpel blade or radiosurgery (Fig. 98.8). After the initial incision, whether using a paramedian or midline approach, the VAV is identified and avoided as the incision is extended to provide adequate exposure for the intended coelomic procedure (Fig. 98.9A–D).

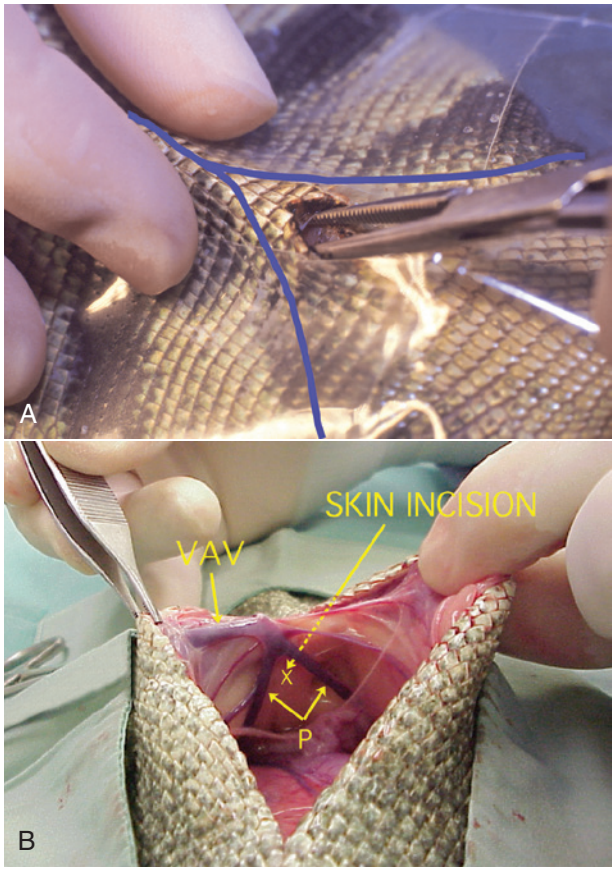

FIG 98.6 (A) The initial surgical stab incision is made between the pubis and the umbilical scar (x) to avoid the ventral abdominal vein (VAV) in lizards. (B) By starting the incision in this location, the blade will not contact the VAV. P, Pelvic veins. (Courtesy of Douglas R. Mader.)

FIG 98.7 The ventral abdominal vein (VAV) of a green iguana undergoing a coeliotomy. The VAV is identified early in the coeliotomy approach to avoid any damage to the vessel. (Courtesy of Stephen J. Divers.)

Caudally the presence of the paired ventral coelomic fat bodies may inhibit the ability to extend the coelomic wall incision to the pubis (Fig. 98.10). These structures are quite vascular and potentially friable, and the surgeon must be careful handling them. If the fat bodies are large they may need to be gently exteriorized (depending on the procedure and species) to allow access to deeper structures. While out of the

coelom, they must be protected with moistened lap sponges or gauze. A small amount of "clear" free fluid is not uncommon in healthy lizards. Larger amounts of discolored or flocculent fluid is abnormal and likely an indication of ascites or coelomitis. The use of retractors such as the Lone Star retractor (Fig. 98.11) for larger, deep-bodied lizards or ophthalmic retractors and magnification for smaller lizards can be helpful to allow better coelomic visibility. At this point the surgeon will locate the structure of interest and follow applicable internal soft-tissue surgery principles detailed elsewhere in Section 10.

LATERAL (FLANK) COELIOTOMY

This approach is primarily used for old-world chameleons because of their laterally compressed bodies. The ventral coeliotomy procedure (midline or paramedian) can be used in these species, but the ribs extend caudally and ventrally to the midline, and several ribs may have to be transected to allow access to the coelom (see Fig. 98.9A–D). The paramedian coeliotomy approach is still the author's preferred technique

in chameleons, because it allows greater access to explore the entire coelom. Additionally, compared with the lateral approach, the incision and subsequent scar are not readily visible once healed. Transected ribs heal readily, and complications after paramedian coeliotomy in chameleons are rare. The lateral approach, however, is an effective approach for reproductive procedures such as ovariosalpingectomy, ovariectomy, salpingotomy, and castration.[6] Both sides of the reproductive tract can usually be accessed from a unilateral approach. The incision is made below the lumbar spine in the paralumbar space, often at an angle (caudal to or between the last ribs) to allow the largest possible incision without involving ribs (Fig. 98.12A and B). Unlike the ventral coeliotomy approach there are no major vessels on entry into the coelom. The initial skin incision is made with a scalpel and carefully extended with iris scissors or a scalpel blade, and the coelomic aponeurosis is incised with iris scissors or radiosurgery to avoid damage to coelomic organs (see Fig. 98.12C). Besides the advantages of avoiding ribs and the VAV, this

technique also reduces interference by the paired coelomic fat bodies. One other consideration during old-world chameleon coeliotomy (whether ventral or flank approach) is the presence of air-sac–like extensions of the lungs, which appear as clear finger-like projections often present in the surgical field (Fig. 98.13). These delicate structures must be kept moistened and protected during the coeliotomy procedure.

Before closing the coelom, warm (27°C–29°C, 80°F–85°F) sterile saline irrigation and gentle suction should be performed, especially in cases of coelomitis or following clean-contaminated procedures (e.g., enterotomy, cystotomy). Coeliotomy closure in lizards involves gentle apposition of the coelomic aponeurosis. The muscle and linea tissues are quite fragile and can easily tear with rough manipulation or tension. The goal is to gently bring the wound edges together to create a coelomic "seal," because this closure is not considered a holding layer as in mammals. Absorbable monofilament suture in 3.0 to 5.0 size depending on the patient size, in a simple continuous pattern with minimal tension, is recommended (Fig. 98.14). One exception to this simple continuous closure exists with some gecko species (such as leopard geckos, African fat-tailed geckos, and crested geckos). In these species, the skin is delicate and fragile and does not have the same "holding" strength that more typical keratinized lizard skin does. In these species a simple interrupted suture pattern is recommended to close the coelomic wall, followed by a typical horizontal mattress suture pattern in the skin to increase the strength and integrity of closure (Fig. 98.15).[2,3]

The skin in lizards is closed routinely using nylon (or absorbable monofilament suture if suture removal is unlikely to be possible) with a horizontal mattress suture pattern (Fig. 98.16). An everting pattern

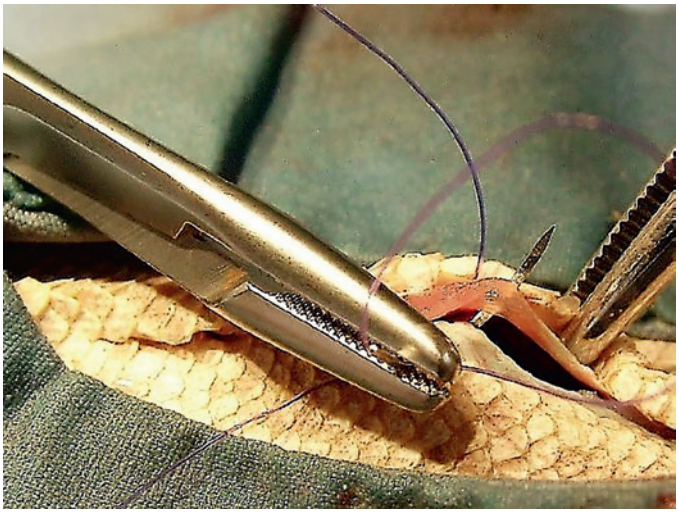

FIG 98.14 The first layer of the coeliotomy closure in lizards involves apposition of the coelomic aponeurosis. The goal is to gently bring the wound edges together to create a coelomic "seal" as this closure is not considered a holding layer (except geckos). A simple continuous pattern with minimal tension is recommended, as utilized here closing the coelomic wall in this bearded dragon (*Pogona vitticeps*). (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

FIG 98.15 A leopard gecko (*Eublepharis macularius*) recovering from a coeliotomy to remove an ovarian neoplasm (present at the top of the figure). The skin is closed with nylon in a horizontal mattress (everting) pattern. In this species (and other geckos) the skin is fragile and does not have the "holding" strength typical for keratinized lizard skin. Therefore, in these species, a simple interrupted suture pattern, instead of continuous (as in Fig. 98.14), is used to close the coelom followed by a horizontal mattress skin closure to increase the strength of the coeliotomy closure. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

is necessary because of the keratinized skin's tendency to invert, resulting in reduced contact of cut surfaces and poor healing (Figs. 98.12D, 98.15, and 98.17). Surgery may accelerate ecdysis, and sutures placed too close to the wound edges may be prematurely shed.

Tissue adhesive can also be placed along the incision line to help with waterproofing and protection. However, when possible, complete submersion of the incision in water is not recommended for 10 to 14 days postsurgery. Lizards that are routinely soaked can be misted or sprayed to encourage drinking and hydration during this period. Postoperative management may include appropriate antibiotics if

infection is present and pain management with injectable nonsteroidal autoinflammatory drugs and/or opioids (see Chapter 50). Changes in husbandry, such as using a paper substrate for cleanliness, a short period of postoperative fasting or a reduction in food size or quantity, and increasing temperature to the higher end of the preferred optimal temperature zone (POTZ) to accelerate healing are recommended. In most cases sutures are removed (if still present) 6 to 8 weeks postoperatively (Fig. 98.18).

Chelonian Prefemoral Coeliotomy

Elisa Wüst and Stephen J. Divers

Surgical coeliotomy provides access to most of the major internal organs of chelonians and thus is useful for a range of surgical procedures, including exploration and biopsy. However, because of the variable anatomy and boney makeup of the chelonian shell, surgical access to the coelom is often challenging. Depending on the species and the surgical site or organ of interest, there are two major approaches to the coelom of chelonians: transplastron and prefemoral. The traditional transplastron coeliotomy approach requires a temporary osteotomy through the plastron, whereas the prefemoral approach is a soft-tissue technique that involves entry into the coelom in front of a pelvic limb (Table 99.1).

Approaching the coelom through the prefemoral fossa is less invasive and can provide unilateral surgical access to the caudal lung, liver, small and large intestine, reproductive tract, kidney, and bladder.[1] This approach is most commonly used for surgery involving the reproductive tract.[1–9] In some species (especially aquatic chelonians such as red-eared sliders, *Trachemys scripta elegans*), it is possible to perform bilateral reproductive surgery with a unilateral approach.[3] In others (including terrestrial tortoises like the Hermann's tortoise, *Testudo hermanni,* and desert tortoise, *Gopherus agassizii*), the suspensory ligaments may be short, the bladder large and obstructive, and/or the prefemoral window small. These factors can complicate access and necessitate a bilateral approach.[2,9] The prefemoral access to the coelom can also be used for organ biopsies, coelomic and gastrointestinal foreign body removal, and urinary bladder stone removal.[10,11] However, when dealing with large cystic calculi or masses, transplastron access to the coelom may be preferable.[12,13]

PATIENT POSITIONING AND PREPARATION

The patient is usually positioned in lateral recumbency, although dorsal recumbency can be more practical for some procedures. Unless anatomic asymmetry or diagnostic imaging dictate otherwise, a left prefemoral approach is often preferred by right-handed surgeons (with a right approach easier for those who are left-handed). Positioning can be achieved using troughs, tape, bean-bag supports, or rolled towels (Fig. 99.1). Tilting the animal into a 30- to 40-degree

head-down position can also be helpful.[3] To gain access to the prefemoral fossa, the ipsilateral pelvic limb is maximally extended and secured caudad often by taping to the other pelvic limb, caudal shell, or table. Standard aseptic preparation precedes draping, and adhesive plastic drapes are preferred and can be better contoured to the fossa (Fig. 99.2).

SURGICAL TECHNIQUE

The skin incision is made cranial to the extended limb and in a cranial-to-caudal direction, in the middle of the prefemoral fossa, starting close to the skin insertion at the plastrocarapacial (bridge) junction and ending just cranial to the musculature of the limb (Fig. 99.3A). Blunt dissection cranial to the sartorius and ventral to the iliacus muscles exposes the pale coelomic aponeurosis formed by the external abdominal oblique muscle (see Fig. 99.3B). Gentle perforation of this aponeurosis can then be extended with forceps, scissors, or radiosurgery to gain access to the coelom. Stay sutures or a ring retractor and a focused light source provide significant improvements in visualization (Fig. 99.4). Endoscope-assisted procedures are common and are detailed in Chapter 65.[3–5]

Following clean-contaminated procedures involving the bladder, intestinal tract, or other non-sterile sites, the coelom should be thoroughly lavaged prior to closure. The coelomic membrane, musculature,

and, if necessary, the subcutaneous tissues are closed with a simple continuous pattern using absorbable sutures (e.g., poliglecaprone 25, polyglyconate, or polydioxanone) (Fig. 99.5A). The skin is closed routinely using nylon or polydioxanone and simple, horizontal mattress sutures, which should be removed (if still present) 8 weeks postoperatively (see Fig. 99.5B and C).

Chelonian Transplastron Coeliotomy

Stephen J. Divers and Elisa Wüst

For decades this approach has been the traditional coeliotomy technique used in chelonians. However, concerns regarding increased surgical trauma, pain and discomfort, and prolonged bone healing have resulted in a shift in preference to the prefemoral approach (with or without endoscope assistance) whenever possible (see Table 99.1). Nevertheless, when extensive exposure (e.g., for large cystic calculus, foreign body, or mass removal) or exploration is required, the transplastron may be preferable, especially in patients with small prefemoral fossae.[1–6]

PATIENT POSITIONING AND PREPARATION

The chelonian is supported in dorsal recumbency using beanbags, towels, and tape, taking care to support the head, neck, and anesthetic attachments. Following aseptic preparation of the ventral plastron (using a brush to remove all debris from the scute interfaces and any plastron hinges), a sterile, adhesive, transparent drape is applied (Fig. 100.1).

SURGICAL TECHNIQUE

Surgical planning must take into account the primary organ/area of interest, the size of any structure(s) to be removed, location of any plastron hinge, shell thickness, and regional subplastron anatomy. Therefore the locations of the heart (usually at the midline intersection of the pectoral and abdominal scutes), paired abdominal veins (running caudocranially within the ventral abdominal musculature), hinges (e.g., between the abdominal and femoral scutes in *Testudo*, and between the pectoral and abdominal scutes in *Terrapene*), and plastron thickness (including its expansion toward the plastrocarapacial bridge) have to be considered before surgery (Fig. 100.2). Careful consideration must also be given to the degree of access required to perform the procedure (e.g., cystic calculus, mass, or foreign body removal), and, because access cannot be easily enlarged, ensure that the initial cuts are sufficient.

In neonates and young juveniles with poorly mineralized shells, a scalpel blade can be used to incise the plastron (Fig. 100.3A). In most cases, an oscillating sagittal saw couples accuracy with reduced collateral damage and minimal soft-tissue trauma (see Fig. 100.3B), whereas thinner incisions can often be obtained using a fine blade rotary saw (e.g., Dremel) (see Fig. 100.3C). However, rotating saws are less forgiving on soft tissues, and over-scoring at the corners occurs with larger-blade diameters. The saw is held at 45 to 60 degrees to bevel the lateral shell incisions, which are made first (Fig. 100.4A). A fine hypodermic needle or scalpel blade can be used to gauge depth and ensure that the cuts are full-shell thickness (see Fig. 100.4B). The caudal cut and, finally, the cranial cut are made in a similar fashion, but bevelling is not necessary. Penetration of the shell over the heart is generally made last. The caudal or cranial cut can be incomplete, with a few millimeters bone thickness left. While lifting the segment using a periosteal elevator or scalpel handle, the thin bone breaks that will later help to stabilize the loose bone fragment during closure. In addition, blood supply may be maintained, increasing the chances of primary healing. While elevating the cranial or caudal margin of the bony segment, the soft tissues are bluntly dissected free, staying as close to the shell as possible (Fig. 100.5). The paired abdominal veins are closely associated with the plastron. The soft-tissue attachments at the fractured bone line can also be left intact, because the plastron flap is reflected caudal and covered with moistened, sterile gauze. Alternatively, the plastron flap can be reflected cranial, leaving the cranial attachments intact.

Depending on circumstances, several variations are possible regarding entry into the coelom, including (1) midline incision, between the abdominal veins, through the poorly defined linea alba; (2) unilateral or bilateral paramedian incision(s) lateral to the abdominal veins; and (3) even ligation and transection of one abdominal vein to permit an L-shaped flap for removing large structures (Fig. 100.6). Ligation of both abdominal veins is not recommended, because severe circulatory disturbance would likely ensue. An elastic ring retractor often improves exposure (Fig. 100.7A).

Following clean-contaminated procedures, thorough lavage of the coelom should be performed before a routine two-layer closure (see Fig. 100.7B). The coelomic membrane is closed in a simple continuous pattern using absorbable suture material (Fig. 100.8A). Poliglecaprone 25 or polyglyconate can be used for closure of paramedian incisions, but polydioxanone is preferred for the linea alba. Three or four stabilizing sutures (usually polydioxanone, but wire can be used for large species) can be placed through drilled holes to anchor the bony section to the plastron (see Fig. 100.8B and C). The shell incision line can be filled with sterile antibiotic, absorbable bone wax, or absorbable collagen (Fig. 100.9). The closure is completed using epoxy resin or acrylic (e.g., polymethylmethacrylate), either at four

points or around the entire bony incision. In aquatic species it can be helpful to score or roughen the shell to improve adhesion. The shell is carefully cleaned with an alcohol swab to remove any debris, before epoxy resin or an acrylic is applied (Fig. 100.10A). Temporary masking tape can be used to protect adjacent areas, particularly hinges, before applying the repair material. Any excess, uncured material can then be easily removed along with the tape, thereby creating a clean finish (see Fig. 100.10B). Exothermic materials can cause thermal necrosis, and cold saline drips or cold saline-soaked gauze should be used to control heating.

The healing process depends directly on the size of the bony gap and the quality of the repair. Maintenance of soft-tissue attachments, accurate reduction and immobility of the bony section, aseptic technique, and attention to postoperative hygiene to prevent infection will improve the chances of first or second intention healing. However, it is common for the plastron flap to become a sequestrum that provides temporary protection for new bone growth beneath (Fig. 100.11A). The plastron typically heals within 12 weeks but can take longer, and therefore the covering is usually left in place for 6 to 12 months. Radiography is seldom helpful in the assessment of healing because radiolucent lines tend to persist long after healing is complete (see Fig. 100.11B). However, osteolysis may suggest osteomyelitis, which warrants surgical investigation, debridement and samples for histopathology, and cultures (aerobic, anaerobic, and fungal).

Crocodilian Coeliotomy

Javier G. Nevarez

Some indications for coelomic surgery in crocodilians may include gastrotomy for removal of foreign body after unsuccessful gastroscopy, enterotomy, follicular stasis, organ or tissue biopsy, and exploratory coeliotomy. However, unlike snakes and lizards, coelomic surgery in crocodilians is far more challenging due to their anatomy, which must be appreciated for successful surgery. There is a limited window for accessing the coelomic cavity. The ventral skin is thicker than on the flanks and can be quite challenging to suture together, especially in older animals and those that have ventral osteoderms (e.g., caiman). Good apposition of the ventral skin is often not possible, leading to delayed healing, and, because of low skin elasticity in this area, stainless steel sutures may be required. For these reasons, a lateral flank approach may be preferred. Nonetheless, some have successfully performed coeliotomy via a ventral midline or paramedian incision.

Within the ventral body wall are free-floating ribs called gastralia, which are found immediately caudal to the sternum (Fig. 101.1). The right and left gastralia are joined by a cartilage at midline. An incision into the ventral coelom requires cutting through the gastralia, which may become more fibrotic or calcified as the animal ages. Though seemingly invasive, cutting through the gastralia generally has no detrimental impact on the animal. The coelomic cavity of crocodilians has two grossly distinct features from other reptile taxa, the presence of a diaphragmaticus muscle (Fig. 101.2) and a distinct mesentery surrounding the intestines (Fig. 101.3). In addition there are eight serosal cavities. The diaphragmaticus muscle originates from the ischia and last gastralia and inserts on connective tissue on the caudal aspect of the liver (see Fig. 101.2).[1] It is incomplete and more horizontally oriented, so it does not create a true separation of the cavity. This thin muscle is thought to

They lie caudal to the sternum (S) and cranial to the pubic bones (P). As crocodilians age, these become fibrotic and may calcify. Cranial is to the left of the image. (Courtesy of Javier G. Nevarez.)

The diaphragmaticus muscle (*DM*) originates from the ischia and last gastralia (dotted arrow) and inserts on connective tissue on the caudal aspect of the liver (solid arrows). In this image, part of the diaphragmaticus has been transected where the gastralia were incised. H, Heart; LL, left liver lobe; P, pubic bones; RL, right liver lobe; S, stomach. assist with respiration but more likely plays an active role in buoyancy.[1,2] Uriona et al. revealed that transection of the diaphragmaticus muscle can lead to decreased submersion times in *Alligator mississipiensis*.[3] Therefore care must be taken to not transect this muscle during surgery. Crocodilians have a rather unique mesentery that encloses the majority of the small intestine and all of the large intestine, essentially creating a mesenteric "sac" (see Fig. 101.3). This arrangement creates a true separation between the intestines and the rest of the viscera, preventing any direct contact with the stomach, duodenum, liver, lungs, or heart. The duodenum lies in close association with the stomach, right liver lobe, and the gallbladder. To access the spleen, gonads, adrenals, and small and large intestines, an incision has to be made through this mesenteric sac (Figs. 101.4 and 101.5). Suturing this mesentery is challenging, and herniation of the intestines through the incision is a possible complication. The clinical effects of this are unknown. This also makes coelioscopy of crocodilians quite challenging.

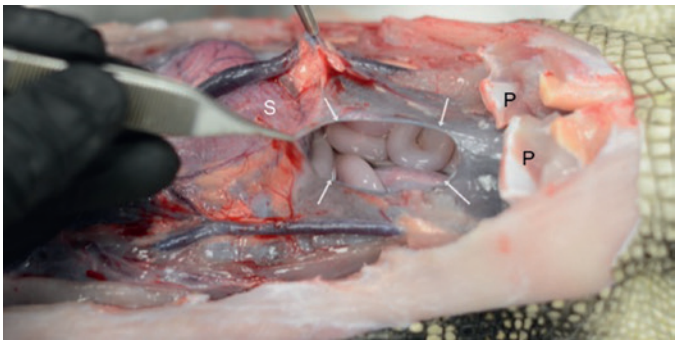

FIG 101.4 An incision through the mesenteric "sac" (arrows) of an American alligator (*Alligator mississippiensis*) reveals the small intestines. The mesentery must be incised to access the intestines and other organs. P, Pubic bones; S, stomach. Cranial is to the left of the image. (Courtesy of Javier G. Nevarez.)

Unlike lizards, crocodilians do not have a centrally located ventral abdominal vein but rather two lateral abdominal veins (see Fig. 101.3). These are usually large in size and found deeper within the cavity, dorsal to the diaphragmaticus muscle. On the caudoventral aspect of the coelom, crocodilians have prominent pubic bones that extend ventrocranially from the pelvis and have articulation with the ischium (see Figs. 101.2 and 101.6). The pubic bones obscure visualization of the mesenteric "sac" (see Fig. 101.2) and must be transected to access the small and large intestines (see Figs. 101.3 and 101.4); therefore, incision over this area is not recommended.

An additional consideration before performing a ventral coelomic incision in crocodilians is the postoperative care. Animals will have to be maintained dry to semidry for at least 10 days or until the incision has sealed. The use of a liquid bandage material may help provide additional protection. When maintained outside of water, the weight of their bodies and viscera will place additional strain on the ventral skin incision, affecting its integrity and cleanliness. This could lead to dehiscence and infection of the site. If stainless steel suture was utilized, it will need to be removed once healing is complete.

The numerous, aforementioned issues regarding a ventral incision suggest that a lateral incision through the flank is a better approach to the coelomic cavity (Figs. 101.7 and 101.8). The skin on the lateral aspect of the body is thinner and more pliable and will hold sutures better. There is also less pressure from the body weight and viscera, and the suture line can be maintained dry if the animal is kept in shallow water. In the craniolateral aspect there are still ribs that have to be incised to access the stomach and liver. However, in larger crocodilians these organs may be accessed caudal to the ribs. A flank incision can be made caudal to the last rib and cranial to the pelvis (see Fig. 101.7). The muscle layers must then be incised before entering the coelomic cavity (see Fig. 101.7). Upon entering the cavity, the mesenteric sac can be visualized and must be incised before the intestines can be accessed (see Fig. 101.8). The mesentery sac can be maintained in a taut position by use of a retractor (see Fig. 101.8). Via this approach, most of the small intestines can be exteriorized. It also allows access to the cranial colon (see Fig. 101.8). The caudal aspect of the stomach is

Fat (F) and the mesenteric sac (MS) can be visualized in the coelomic cavity. The mesenteric sac must be incised to gain access to the intestines (B). The edges of the mesenteric sac (MS) can be pulled apart with the retractor to allow visualization of the caudal aspect of the stomach (S) and small intestines (SI) (C). Most of the small intestine can be exteriorized (D). This allows easy access all the way from the jejunum (J) to the colon (C and D). also accessible, but the duodenum remains fixed inside the coelomic cavity. Access to other organs is limited and may require the aid of an endoscope for visualization.

Based on all these factors, coeliotomy should be considered a last resort in crocodilians. It is certainly possible that a skilled surgeon may successfully perform a specific coelomic surgery. However, the postoperative management of these patients is difficult and results in a more guarded prognosis for successful healing and recovery.

Lower Respiratory Tract

Stephen J. Divers

By definition the lower respiratory tract encompasses the larynx, trachea, bronchi, and lungs, while the upper respiratory tract is covered in Chapter 93. Primary indications for surgical intervention include surgical or endoscopic biopsy, lung mass removal, and tracheal resection. Endoscopic techniques are covered in Chapters 64 and 65.

There are no specific equipment or instrument items required that are not covered in Chapter 90. However, it is worth noting that it is especially important to appreciate regional anatomy of the neck and coelomic inlet and be particularly diligent regarding vessels, nerves, and other critical structures.

TRACHEAL RESECTION

Tracheal chondroma and lymphoma have been reported in boid snakes, and the author has additionally seen mycotic granulomas in a tortoise (Fig. 102.1). Tracheal resection has been successful in some cases.[1–3] Radiography but especially computed tomography (CT) are required to determine the nature and extent of the tracheal pathology (Fig. 102.2). Before considering resection, endoscopic evaluation and biopsy for definitive diagnosis is important and may dictate the need for nonsurgical therapy (e.g., radiation, chemotherapy, antimicrobials) (see Fig. 102.1A–C). Endoscope-assisted debulking and clinical resolution of a chondroma in a ball python (*Python regius*) utilizing a diode laser has been successful (Stahl S, personal communication, 2018)

Snakes often present with respiratory distress that can be temporarily alleviated by placement of a saccular lung cannula until surgery can be undertaken (Fig. 102.3).[3,4] The temporary cannula should be surgically placed approx. 55% to 70% snout-to-vent to avoid the vascular lung. Maximal ventilation of the anesthetized snake can help identify the caudal lung entry site. A small, lateral coeliotomy incision and intercostal entry

into the coelom permits the placement of a sterile endotracheal tube of equal or greater diameter to that used for tracheal intubation. A cuffed tube is often more secure, but a Chinese finger trap suture is still required, and skin closure can also help maintain tube security. The cannula can be used to maintain anesthesia during tracheal surgery, but a filter should be placed at the entrance of the cannula when not in use to reduce contamination. Nonetheless, a saccular lung cannula should be considered temporary, with removal recommended within 48 hours of placement.

After induction, the anesthetic circuit should be connected to the saccular lung cannula and the trachea occluded using a moistened cotton-tipped applicator or similar. The snake should be positioned in lateral recumbency to afford the best approach to the affected portion of the trachea. The serpentine trachea is often located to the right of midline, making left lateral recumbency preferred and a right approach preferable. After aseptic preparation, a standard craniocaudal coeliotomy skin incision is performed between the first and second or second and third lateral rows of scales. Meticulous dissection and hemostasis is required to avoid the right carotid artery, jugular vein, and smaller vascular supplies to the trachea. The left jugular, left carotid, and esophagus should be deep to the area of interest, but placement of an esophageal catheter may be helpful to aid identification and preservation. If the resection involves the caudal trachea, then appreciation of the thymus and great vessels is required. Placement of stay sutures to elevate the trachea facilitates resection. The tracheal anastomosis is performed using full-thickness, simple interrupted sutures of 4-0 to 5-0 antibiotic-impregnated polydioxanone (PDS-Plus, Ethicon) tied extraluminally. Additional extraluminal tension-relieving sutures on each lateral side encompassing two to three tracheal rings cranial and caudal to the anastomosis site can be considered. The stay sutures are removed and the surgical site carefully inspected for any hemorrhage or esophageal trauma. The subcutaneous tissues are then apposed with a simple continuous suture pattern using 4 to 0 poliglecaprone 25 (Monocryl, Ethicon), followed by routine skin closure. Tracheoscopy 6 to 8 weeks after surgery can confirm healing.

LUNG BIOPSY

There are occasions when a more invasive surgical approach to a lung is required for the purposes of biopsy because appropriate endoscopy equipment is not available, the site of interest is inaccessible (walled off by fibrosis), or small endoscopic biopsies were inconclusive.

Pre- and postcontrast CT images are preferred, but radiography may be acceptable for lesion identification and planning a surgical approach. After aseptic preparation, a 1- to 4-cm craniocaudal skin incision is followed by a 0.5- to 2-cm dorsoventral intercostal approach. Dissection between the ribs is usually blunt or accomplished using radiosurgery to reduce hemorrhage. A ring or eyelid retractor increases intercostal distraction and access to the craniodorsal coelom. An endoscope is valuable for identifying and grasping the affected lung, which can then be exteriorized through the intercostal space. If endoscopy is not available, then holding at maximal inspiration will often facilitate grasping the inflated lung. Abnormal tissue can be sampled or resected. Suturing the lung is problematic, and it is generally more effective to place a transfixing circumferential suture of 4/0 antibiotic impregnated poliglecaprone-25 (Monocryl Plus Antibacterial, Ethicon, Athens, GA, USA) to isolate a small section of lung before sharp distal resection. The lung is replaced and observed for leakage during maximal ventilation. The retractor is removed, and the intercostal incision is closed by placing simple interrupted 4/0 polydioxanone sutures around the adjacent ribs. Skin closure is routine.

In chelonians, a similar lung biopsy procedure as described previously can be used via the prefemoral fossa but is restricted to the caudolateral

aspect of the lung. A 2- to 5-cm craniodorsal prefemoral incision is made, followed by blunt entry into the coelom. An alternative, carapacial approach has also been described (Fig. 102.4).[5] Diagnostic imaging is used to pinpoint a 5-mm drill access hole through the carapace, directly over the pulmonary lesion. While temporarily maintaining maximal inspiration, small hemostats perforate the pleuroperitoneum to allow access for needle biopsy (e.g., Tru-Cut). It is not necessary to close the pleuroperitoneum, but the small osteotomy is closed using epoxy or acrylic. An intrapulmonary catheter can be temporarily secured through the osteotomy to facilitate intrapulmonary therapy.[5]

MASS/ABSCESS/GRANULOMA REMOVAL

When a discrete lung mass (neoplasm, abscess, granuloma) has been identified, a similar, but more extensive, surgical approach to that described previously can be used. In lizards and snakes, a standard ventrolateral coeliotomy provides greater exposure than the intercostal approach. In chelonians, a larger dorsal carapacial flap can be created (Fig. 102.5). Again, the use of a transfixing circumferential suture to isolate the diseased area is often preferred because of the difficulty of suturing lung. This may result in significant loss of pulmonary tissue, which, although well tolerated and unlikely to result in clinically significant respiratory compromise, may result in long-term asymmetrical swimming in aquatic chelonians.

Gastrointestinal Tract

Ryan De Voe

Surgery of the gastrointestinal tract, including the liver and pancreas, is frequently indicated in reptilian patients. Many of the same procedures that veterinarians are called on to perform in domestic animals can be necessary in reptiles. Indications for performing surgery on the gastrointestinal tract include gastrointestinal foreign bodies, intraluminal impactions, neoplasia, abscesses or granulomas, and intussusceptions, volvulus, or strictures.[1,2] Biopsies of various segments of the gastrointestinal tract and associated organs are often indicated to obtain a diagnosis in disease states or to provide samples for infectious disease screening.[3]

PRINCIPLES OF GASTROINTESTINAL SURGERY IN REPTILES

The same principles of antisepsis and tissue handling used in domestic animal medicine are appropriate for reptiles. A review of literature regarding surgical procedures of the gastrointestinal tract in reptiles does not reveal any unique techniques or procedures that would be unfamiliar to most surgically competent veterinarians.[2,4,5] However, magnification is often beneficial for small species (Fig. 103.1). The phases of wound healing take longer in reptiles but otherwise mirror what is observed in mammals.[1] Longer tissue-healing times may influence decisions regarding antimicrobial, antiinflammatory, and analgesic therapy, as well as nutritional support. It is often beneficial, and indeed is standard practice, to provide intraoperative (IV or IO) antimicrobials prior to entering the nonsterile gastrointestinal tract.[6] Intraoperative antibiotics have been shown to be equal, if not more effective, at reducing postsurgical complications and reducing antibiotic resistance when compared with postoperative therapy.

Prior to entering the gastrointestinal tract of a reptile, the segment of gut should be carefully isolated with saline-soaked gauze or sponges to limit contamination of the coelom. Following closure of the gut, the site should be thoroughly irrigated before removal of the gauze or sponges. With the structures back in normal anatomic position, the coelom should be irrigated thoroughly and then gloves and instruments changed prior to closure.

Surgical incisions into the stomach should be closed in two layers. An initial, full-thickness closure utilizing a simple continuous or simple interrupted pattern followed by an inverting pattern (Cushing or Connell pattern) is preferred. Antemesenteric, longitudinal intestinal incisions closed end to end result in a larger diameter and reduced constriction. Colotomy incisions should also be closed in two layers. The first layer can be appositional or inverting and the second layer inverting. Intestinal closures are often challenging due to the relatively thin wall and small luminal diameter of the intestines of many reptiles. A single layer of accurately placed simple interrupted sutures is usually sufficient to form an adequate seal and encourage normal healing (Fig. 103.2). In all cases, selection of an appropriate suture material and needle is critical for success. Monofilament absorbable suture material, such as polydoxanone or poliglecaprone 25, should be utilized. Those impregnated with antimicrobials (e.g., Monocryl Plus containing triclosan) have been shown to significantly reduce bacterial colonization of suture tracts and reduce infection rates, making them ideally suited for intestinal closure.[7] Fine suture with a tapered, swaged needle is usually indicated,

especially when closing intestinal enterotomies. Even very small cutting needles can create unacceptable trauma in the thin-walled intestines of some species. Gastrotomy incisions in larger species with muscular stomachs may require cutting needles for easy closure. Suturing the serosal surface of an adjacent segment of bowel to the enterotomy site may provide insurance against leakage and dehiscence with questionable closures.[1]

Resection and anastomosis of various segments of the gastrointestinal tract may be indicated due to devitalization of tissue or neoplasia. The technique utilized for anastomosis should be based on size of patient and the segment of gut. Typically, a simple interrupted, appositional pattern is preferred to promote maintenance of luminal patency. Initial placement of sutures at the mesenteric and antimesenteric aspects and closure of the walls in between usually facilitates accurate apposition of tissues and effective anastomosis. Magnification is often required for this procedure when working with smaller species. The prognosis following resection and anastomosis is usually guarded, particularly when resection is necessary due to the presence of abscesses, granulomas, or segments of grossly necrotic gut and/or large lengths of the gastrointestinal tract require resection.

Enterostomy of the lower gastrointestinal tract is possible when the condition of the bowel does not allow for anastomosis following resection of the diseased segment. Enterostomy carries a guarded long-term prognosis[8] Careful case selection is necessary, as aftercare is intensive, both in the immediate postoperative healing and maintenance phases.

PERIOPERATIVE CARE

Due to the slower healing times of reptiles and the potential for contamination, especially with surgeries involving the lower gastrointestinal tract, perioperative antimicrobial therapy is often indicated. IV or IO broad-spectrum antimicrobials (e.g., cefazolin) prior to incision negate the need for postoperative therapy in clean-contaminated procedures, and reduces the chances of favoring antimicrobial resistance.[6] Obviously, if infection is suspected at the time of surgery, samples should be submitted for culture prior to starting therapy, and continued postoperatively.

In most reptile species, postoperative resumption of feeding should not occur for a minimum of 3 to 7 days and even for several weeks in snakes. When feeding is resumed, the composition and volume of the diet should be managed to ensure maximum digestibility and minimize distention of the gastrointestinal tract (and body wall and skin of snakes). The diet should be increased gradually over a period of 3 to 6 feedings until normal intake is resumed.

BIOPSY OF THE GASTROINTESTINAL TRACT

Mucosal biopsies of the esophagus, stomach, and colon may be obtained in most larger species via endoscopic methods. If full-thickness biopsies are required for a diagnosis, celiotomy is necessary. The same techniques that are used in mammals are appropriate in reptiles. Full-thickness wedges of gastric, intestinal, or colonic wall may be collected following isolation of the section of gut with saline-soaked gauze or sponges. Closure of the resultant defect is similar to the technique described following gastrotomy, enterotomy, or colostomy above.

HEPATIC BIOPSY/PARTIAL HEPATECTOMY

Hepatic disease is frequently encountered in reptilian patients and hepatic biopsy may be required to reach a definitive diagnosis. Partial hepatectomy may be indicated to resect hepatic abscesses, granulomas, and parasitic or neoplastic masses. Collection of liver tissue may also be indicated to screen for certain infectious diseases as part of a preventative medicine program. The same methods that are employed in avian and mammalian practice are typically suitable for reptiles. Laparoscopic or percutaneous ultrasound-guided hepatic biopsy is often possible, though the size of the biopsy can limit histologic evaluation depending on available equipment and size of the patient, and gastric perforation and fatal hemorrhage have been reported.[9,10] Laparotomy can facilitate acquisition of larger biopsies via a variety of methods. Intraoperative utilization of various biopsy forceps can be effective. Kevorkian biopsy forceps enable the clinician to obtain relatively small tissue samples without inducing crushing artifact that may inhibit histological evaluation. Skin-punch biopsy tools can also be used intraoperatively with good success. Hemorrhage is the most likely adverse consequence of hepatic biopsy or partial hepatectomy and can result in mortality if not controlled. Hemostasis can be accomplished via strategic application of stainless steel hemostatic clips, sutures, cellulose-based hemostatic agents, or other methods typically employed in avian and mammalian medicine.

Surgery of the biliary system is uncommon in reptiles but occasionally necessary (Fig. 103.3). Surgical removal of choleliths is reported anecdotally in reptiles. There are no special techniques involved in surgery of

VetBooks.ir

the reptile biliary system, though taxa-specific knowledge of anatomy is necessary.

PANCREATIC BIOPSY

Pancreatic biopsies are likely underutilized as a diagnostic measure in reptile patients. Derangements of glucose metabolism are frequently encountered in lizards, neoplastic disease of the pancreas is reported and the pancreas may be involved with a variety of infectious diseases. Many of the same methods that are employed with hepatic biopsies can be used to collect pancreatic tissue. There is variation in pancreatic anatomy between reptilian taxa, but the pancreas is typically found adjacent to the duodenum. In some species of snakes (such as members of the family Boidae), the pancreatic tissue contacts the caudal aspect of the spleen forming what can appear to be a single organ referred to as the splenopancreas.[11] This is not the condition in all snakes, however, so normal anatomy should be investigated prior to pursuing a pancreatic biopsy in an unfamiliar species. When performing pancreatic biopsies, care should be taken to avoid causing undue damage to the remaining tissue as iatrogenic exocrine pancreatic insufficiency and diabetes mellitus following resection of masses affecting the organ are reported.[12]

Urinary Tract

Stephen J. Divers

The urinary system includes the kidneys, ureters, urodeum, and, if present, the urethra and bladder. Surgery of the cloaca is covered elsewhere (see Chapter 106). Following the investigation of urinary tract disease, surgical biopsy or correction may be required (see Chapter 66). The most common urologic surgeries include cystotomy (for the removal of calculi or eggs) and renal biopsy; however, cystectomy and nephrectomy are also possible.[1] Surgical techniques are mirrored from small animal surgery, with adjustments for reptile anatomy and physiology.[2] In many situations, minimally invasive endoscopic options are replacing the more traditional and invasive coeliotomy approaches (see Chapters 64, Diagnostic Endoscopy, and 65, Endosurgery).

CYSTOTOMY AND CYSTECTOMY

Indications for cystotomy include removal of calculi, repair of bladder trauma, biopsy or resection of bladder masses, and biopsy and culture of the bladder wall in cases of severe cystitis. Indications for partial or complete cystectomy include bladder necrosis, neoplasia, or possible management of recurring calculi in some lizard species.[3]

While performing a surgical approach to the coelom, it is important to be cautious of the often full, voluminous, and thinly walled (often transparent) bladder, especially as cystitis and disease may have resulted in greater fragility and tendency to rupture (Fig. 104.1). Bladder (like intestinal) contents should be considered contaminated, non-sterile sites, and great effort should be made to prevent coelomic contamination and subsequent septic coelomitis. Given the clean-contaminated nature of the surgery intraoperative IV or IO antibiotics should be considered (e.g., cefazolin 20–25 mg/kg IV started 30 minutes prior to first incision and repeated every 90 minutes until closure). However, if bacterial disease (rather than just contamination) is considered likely, then antibiotics should not be started until after the collection of samples for cultures and sensitivity testing.

For lizards, ventral coeliotomy approach is standard; however, for chelonians, a ventral transplastron or prefemoral approach may be used. The decision will depend upon the size, shape, and location of the calculus, and the species of chelonian (because this determines the conformation of the prefemoral fossa). The prefemoral approach is less traumatic but provides reduced surgical access in most terrestrial species. Radiographic evaluation and prefemoral measurements will enable an objective decision to be made regarding preferred approach.

Ideally, the bladder should be gently exteriorized through the coeliotomy incision because this greatly reduces the chances of coelomic contamination (see Fig. 104.1). When this is not possible, the coelomic muscle and skin incisions should be retracted to provide greater exposure and the coelom packed with moistened sterile gauze (Fig. 104.2). The cystotomy incision is made through a less vascular area of the ventral bladder wall (or lateral bladder wall in the case of a prefemoral approach),

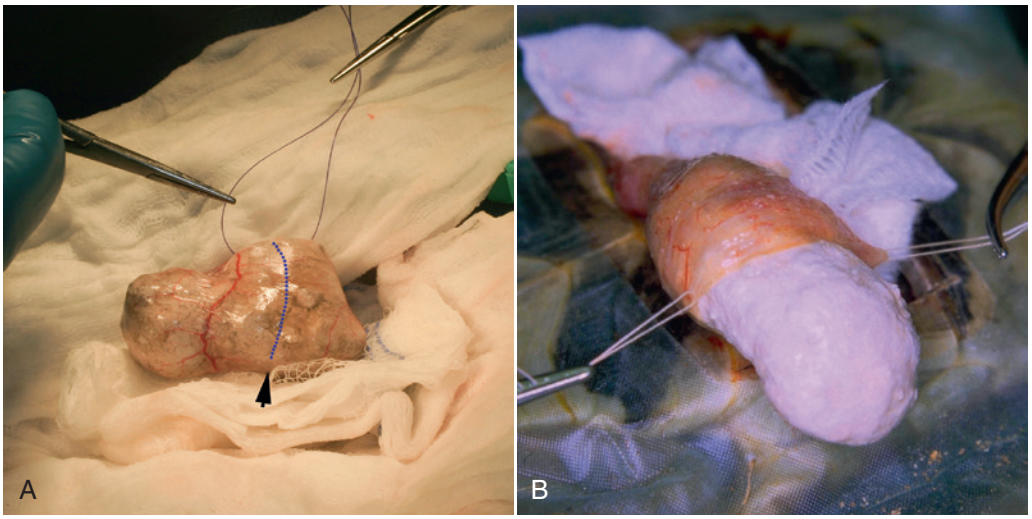

FIG 104.3 (A) The first stay suture has been placed and the position of the second is indicated (*arrow*). The proposed incision is indicated as a dotted blue line. (B) Following incision between the stay sutures, the bladder wall recedes, and the calculus can be removed. Care is required to suction any fluid and prevent contamination of the coelom. (Courtesy of Stephen J. Divers.)

taking care to use suction to remove any fluid from within the bladder (Fig. 104.3A). Stay sutures should be placed and held by hemostats. This will help keep the incision elevated, thereby preventing leakage, and will also maintain incision orientation during suturing (see Fig. 104.3B). When performing a prefemoral cystotomy a lateral incision in the bladder is made, and it is wise to marsupialize the bladder wall to the prefemoral skin incision by using a Lone Star retractor or suture to prevent contamination (Fig. 104.4A). If the bladder wall is abnormal then biopsies should be collected for histopathology and cultures. The easiest place to excise a full-thickness biopsy is along the lateral edge of the cystotomy incision.

Small calculi and eggs can usually be removed with the aid of an angled spoon. It can be difficult to manipulate a large calculus through the incision, and in some cases breaking the calculus in situ may be required; however, excessive fragmentation can create considerable debris and should be avoided (see Fig. 104.4B). One successful technique to aid in large calculus manipulation and removal is to use large, autoclaved, hardware wood screws (Michael Kiedrowski, personal communication, 2014). Most calculi are relatively soft, and one or two 5-to-8-cm (2″–3″) screws can be placed into the calculus (Fig. 104.5A and B). On rare occasions, when the stone is too hard, a pilot hole may be required. The screws provide greater leverage to facilitate elevation and removal (see Fig. 104.5C). Applying compressive or distractive force between the screws often breaks the stone into two pieces, each with a screw attached for simple removal (see Fig. 104.5D).

Following removal of the calculus or egg(s), the bladder should be inspected, copiously flushed and irrigated with sterile saline, and checked for integrity. Necrotic bladder wall should be debrided and removed. In severe cases of bladder necrosis or neoplasia, most, if not all, of the bladder can be resected without interfering with urine flow; however,

such reptiles will be less tolerant of drought, and therefore wild animals should not be released, although captive reptiles can be adequately managed and thrive.

The bladder wall is closed with fine absorbable monofilament suture, and triclosan-coated poliglecaprone 25 (Monocryl Plus Antibacterial, Ethicon, Athens, GA) is preferred.[4,5] Although a single continuous closure has been shown to be effective with only minimal urine leakage, given the chances of bacterial contamination, a second inverting layer should be routinely performed for added security in reptiles.

RENAL BIOPSY

Histopathologic and microbiologic evaluations of samples from diseased kidneys may be required to determine the underlying pathology causing renal dysfunction. Indications for renal biopsy include neoplasia, nephrotic syndrome, chronic renal disease, and acute progressive renal failure of undetermined etiology.[2] The benefits of a definitive diagnosis should be weighed against the risks of complications and whether the results will change current treatment. The greatest complication is hemorrhage, and consideration should be given to evaluating clotting times prior to surgery.

Endoscopic renal biopsy is safe, effective, minimally invasive, and preferred over open surgical approaches (see Chapters 64 and 66 for more details).[6–8] The advantage of traditional coeliotomy is the ability to collect larger samples, as well as an improved opportunity to more completely evaluate and sample other visceral structures. Access to the dorsal kidneys can be challenging from a ventral coeliotomy approach, and good retraction and packing are often required. In some cases, a lateral coelomic approach directly over the kidney may be easier. Surgical access to the chelonian and intrapelvic iguanid kidneys can be particularly difficult by traditional coeliotomy, and in all cases increased surgical exposure and duration of anesthesia must be considered. Before embarking on renal biopsy in the snake, it is important to appreciate the precise location of both kidneys.[9]

Surgical biopsies collected using a sharp dissection technique with a scalpel blade results in histologic samples with minimal to no artifacts (Fig. 104.6A). However, hemorrhage is often encountered and must be addressed using radiosurgery, laser, or hemostatic materials (e.g., Gelfoam Pfizer, NY). Vascular clips can be used to isolate a small section of kidney prior to sharp dissection, although small biopsy forceps or needle biopsy devices can also be used and typically result in less hemorrhage but greater crush artifact (see Figs. 104.6B and 104.7A). Radiosurgical and laser devices should be avoided when collecting tissue biopsies because they cause significant thermal and histologic artifacts.

A relatively simple technique to biopsy the intrapelvic kidneys of iguanids requires a cranial tail cut-down procedure under local or, more commonly, short-term general anesthesia. A small longitudinal incision is made in the lateral midline just below the lateral processes of the coccygeal vertebrae at the tail base. The incision extends for 1 to 3 cm caudad, starting just behind the hind limb. Blunt dissection between the dorsal and ventral coccygeal muscles permits exposure of the caudolateral aspect of the kidney that can then be sampled (see Fig. 104.7B). This technique is particularly valuable when the kidneys are not enlarged, a surgical approach to the intrapelvic kidneys is difficult, and endoscopy is not available. It is limited to unilateral biopsy unless bilateral cut-down procedures are undertaken. Furthermore, because only a small area of the caudal kidney can be visualized and sampled, this technique is best reserved for diffuse diseases involving the caudal kidney.

NEPHRECTOMY

Indications for nephrectomy include irreparable trauma, persistent infection, renomegaly, obstructive urolithiasis with hydronephrosis, and renal or perirenal masses (due to abscess, granuloma, gout, or neoplasia).[2] Nephrectomy has been performed in a number of colubrids and boids (Divers and Stahl, unpublished data), two cape coral snakes (*Aspidelaps lubricus*), and a monocellate cobra (*Naja kaouthia*).[10,11] Renal neoplasia and localized renal gout were the primary indications. It is critical to evaluate the unaffected kidney and ensure sufficient renal function before considering unilateral nephrectomy. Diagnostic imaging and routine plasma biochemistry, including (depending upon taxa) ammonia, urea, and uric acid, should give some confidence that sufficient renal function remains; however, an iohexol excretion study to measure GFR would be most definitive. Nephrectomy would be more challenging in most lizards and most difficult in iguanids and chelonians.

Prior to serpentine nephrectomy, it is important to appreciate the position and entire length of the affected kidney, as well as the vascular supplies (Fig. 104.8).[9] There are several fascial membranes, including a retroperitoneal membrane, that require transection to expose the kidney (Fig. 104.9A). Once exteriorized, the renal vasculature can be appreciated and ligated using vascular clips or radiosurgery/laser. Starting from the caudal pole of the kidney, the renal portal vein(s) arising from the caudal vein are ligated (see Fig. 104.9B). It is also wise to ligate the

ureter to avoid the retrograde flow and coelomic contamination of urine stored in the terminal ureters. The kidney is then gently dissected free in a cranial direction, taking care to ligate the numerous small renal arteries that arise from the dorsal aorta and enter the dorsal aspect of the kidney (see Fig. 104.9C). The efferent renal veins are then ligated at the cranial margin of the kidney. Care should be taken to avoid damaging the closely associated aorta and vena cava. In males of breeding value, consideration should be given to preserving the closely associated vas deferens; however, in most cases it is easier to perform a unilateral vasectomy (see Fig. 104.9D). Following nephrectomy, the surgical site should be thoroughly irrigated with sterile saline before routine coeliotomy closure.

Reproductive Tract

Scott J. Stahl

The reproductive system of reptiles includes the ovaries, testes, salpinges (oviducts), epididymides, vasa deferentia, phallus, and clitoris in chelonians and crocodilians, and hemipenes and hemiclitores in squamates.[1] The urodeum contains the openings of the oviducts and genital papillae (vas deferens termination). A sexual segment of the kidney in squamates is considered part of the reproductive tract.[1] Renal surgery is covered in Chapter 104, and surgical management of the urodeum and cloaca is discussed in Chapter 106. Following a diagnosis of reproductive disease or complication, surgical investigation (including biopsy) or reproductive sterilization may be indicated. Ovariectomy (oophorectomy), ovariosalpingectomy, salpingotomy, orchiectomy, and phallectomy are commonly performed surgical procedures in reptiles. Surgery is often indicated with reproductive disease such as oophoritis, orchitis, salpingitis, paraphimosis, and neoplasia.[2,3] For breeding reptiles, sample collection including surgical biopsies may be performed intraoperatively. Complications from reproductive activity in females (with or without the presence of a mate), including preovulatory follicular stasis, dystocia (postovulatory egg stasis), ectopic eggs, or yolk coelomitis, are common indications for surgery.[2,3] Preventative health measures and behavior management of pet or display reptiles may include elective gonadectomy to eliminate high-risk complications of reproduction in females or to reduce aggression in males.[2–6] When preserving future reproductive capabilities is important, salpingotomy and unilateral ovariosalpingectomy may be indicated.[2,3,7]

In chelonians ovariectomy, orchiectomy, and phallectomies have been utilized to manage population issues in conservation projects.[8–10] Vasectomy was successful in two garter snakes[11] and, although an option for male sterilization, is not commonly performed and not discussed further here. Prolapses involving reproductive organs are common in reptiles and are a frequent indication for surgery.[12] The general equipment and instruments required for surgery are covered in Chapter 90. Many reproductive surgical procedures discussed here can be performed using minimally invasive endoscopic approaches, and the reader is directed to Chapters 64 and 65.[13–17] For a thorough discussion of reproductive diseases and indications for reproductive surgery, see Chapter 80.

MALE REPRODUCTIVE SURGERY

Orchiectomy/Orchidectomy

Indications for castration in lizards and chelonians are to reduce intraspecies and interspecies aggression,[5,6] inhibit the ability to reproduce (population control),[8,9] engage in research,[18] and eliminate testicular pathology such as neoplasia or orchitis (abscess, granuloma).[2,19] Indications for orchiectomy in snakes and crocodilians are less common and are primarily to manage pathological change.

Lizards. For castration in most lizards, a ventral (paramedian or midline) coeliotomy approach is recommended. However, with laterally compressed species such as old-world chameleons, a lateral (flank) coeliotomy approach can be utilized.[2,19] For details on these approaches, see Chapter 98. Once the coelom is safely entered, the testes are identified. Generally, the testes are paired (right testis slightly more cranial) and found dorsally in the mid to caudal coelom just cranial to the kidneys. The paired coelomic fat pads, bladder (if present), and portions of the gastrointestinal tract may need to be retracted, exteriorized, protected, and kept moist. Exposure of the testes can be improved with the use of retractors such as the lone star retractor. The testes are encased in a fibrous, mesorchium capsule that provides some stability for manipulation; however, if the capsule ruptures, the testis is friable and difficult to manage. When possible, the testis is gently exteriorized through the incision to visualize vessels for ligation. To facilitate elevation of the testis, a suture can be placed through the top of the capsule and gently retracted, or grasped gently with Allis tissue forceps or hemostats (Fig. 105.1). The mesorchium is often tightly adhered to the dorsal coelomic wall, restricting the ability to exteriorize the testis, and the surgeon may have to work within the coelom.

Surgically important anatomical differences exist between the right and left testes in lizards (Fig. 105.2).[1] The right testis is attached directly to the vena cava with short vessels (1–2 mm), and the right adrenal gland is located on the *opposite* side of the vena cava (see Figs. 105.1A and 105.2). Due to its location, accidental damage or removal of the right adrenal gland is unlikely. However, the left testis has its own distinct testicular artery and vein, and the adrenal gland is located *adjacent* to

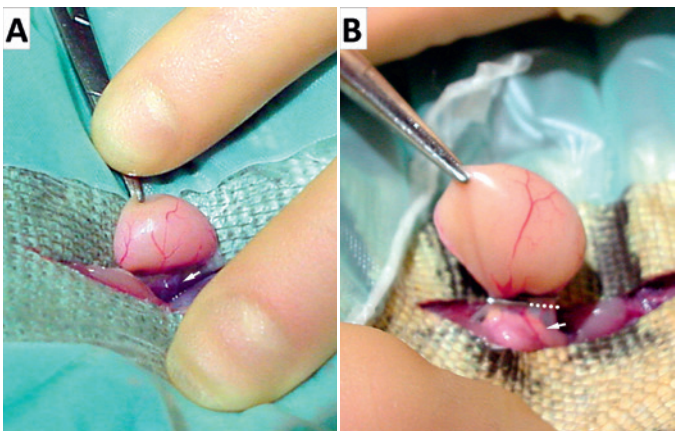

FIG 105.1 Saurian orchiectomy. (A) Hemostats can be used to gently grasp and elevate the testis. The right renal vein (arrow) is located immediately below the testis, and the adrenal gland is below the vein on the right side. (B) A vascular clip has been placed below the left testis and above the left adrenal (arrow); the renal vein is below the adrenal gland on the left side. A second clip is required, as indicated by the dotted line, before the testis can be sharply dissected free. (Courtesy of Stephen J. Divers.)

the left testis utilizing the same vessels. The elongated pink-tan granular adrenal gland should not be accidentally removed or damaged during ligation of the left testis (see Figs. 105.1B and 105.2). Once each testis is isolated, the vascular supply is identified and small windows are made in the mesorchium between the testicular vessels with iris scissors or a scalpel, and the vessels are ligated with vascular clips (Fig. 105.3) or absorbable monofilament suture. In some species (e.g., bearded dragons, *Pogona vitticeps*), the mesorchium is pigmented and the vasculature difficult to visualize. Magnification, focal lighting, and microsurgical instruments can be useful in these situations. After ligation, the mesorchial pedicles are observed for bleeding (Fig. 105.4) before routine closure (see Chapter 98). For laterally compressed lizards such as old world chameleons, a lateral (flank) coeliotomy approach can be utilized. With this lateral coelomic approach the testes are easily identified upon entry, as they are typically positioned close to the entry site. The same careful ligation of the testicular vessels is performed, and both testes can usually be removed from one incision unless there is associated pathology. Castration of lizards can be performed endoscopically (see Chapter 65 for details).

Chelonians. The least invasive and preferred technique for castration in chelonians is the prefemoral coelomic approach instead of the ventral transplastron coelomic approach.[2,5,11,14,16,17] The testes in most chelonians are accessible from a prefemoral approach (especially with endoscopic assistance), and the trauma of cutting through plastron bone is avoided. However, with testicular pathology or neoplasia, or in some chelonian species, a transplastron coeliotomy may be necessary.[2,13,14,16] For chelonian coeliotomy approaches, see Chapters 99 and 100.

VetBooks.ir

Once the coelom is entered, with either approach, the bladder, intestinal tract, and lungs are gently manipulated to allow access to the testes. The testes of chelonians are paired and found dorsally in the caudal coelom cranial to the kidneys. With the prefemoral approach, the use of retractors such as the lone star retractor can help with exposure (Fig. 105.5). The testis is then identified and grasped with forceps or hemostats and gently manipulated to the level of the prefemoral incision to allow visualization of the mesorchium and the testicular vessels (Fig. 105.6A).[2,18] It is difficult, if not impossible, to exteriorize the testes. With the transplastron approach the testis is manipulated up toward the ventral plastronotomy incision, but again, the surgeon will generally have to work within the coelom. When the testis is globoid, a single vascular clip may be sufficient, otherwise windows are made in the mesorchium with iris scissors or a scalpel to allow ligation of vessels with multiple vascular clips, suture, or radiosurgery/laser (see Fig. 105.6B and C). Both testes are accessible from a transplastron coeliotomy. However, with a prefemoral approach, the contralateral testis can be difficult to identify and remove from the ipsilateral approach without endoscopy, and a second prefemoral coeliotomy incision is often necessary. The mesorchial pedicles are evaluated for bleeding before routine closure (see Fig. 105.6D and Chapters 99 and 100). Endoscopic-assisted prefemoral castration in chelonians (see Fig. 105.6 A–D) has been found to be effective, minimally invasive, and a preferred technique,[9,13,14,16,17] and complete endosurgery coelioscopic castration can also be performed in many chelonian species.[13,17] For details on these procedures, see Chapter 65.

(C) After ligation the mesorchium is transected with scissors or radiosurgery. (D) The mesorchium pedicle is observed for bleeding before closure. (Courtesy of Stephen J. Divers.)

Testicular Biopsy

In some situations, the collection of histopathologic and microbiologic samples from testes may be required to determine underlying disease or dysfunction/infertility. Indications for testis biopsy include neoplasia, orchitis (abscess, granuloma), and abnormal sperm production (infertility). In most reptiles, endoscopic testis evaluation and biopsy is effective, minimally invasive, and preferred to open surgical approaches (see Chapter 64). However, an open coeliotomy approach may be necessary if endoscopy equipment is unavailable or when evaluating the testes of snakes, which are inherently more challenging patients for coelioscopy.

Phallectomy and Hemipenal Amputation

Phallectomy has been utilized to control reproduction in chelonian conservation projects[10] and in green iguanas (*Iguana iguana*) (Mader DR, personal communication, 2014). It is a less invasive and safer procedure than castration and allows normal (testosterone-driven) social behaviors without insemination of females. Phallectomy (chelonians) and hemipenal amputation (snakes and lizards) are frequently performed procedures, as prolapses are common.[12] One important, unique consideration with reptile phallus surgery is, unlike mammals, amputation does not affect the urinary system, as these structures do not contain a urethra. Additionally, for squamates, the removal of one hemipenis will still allow copulation with the remaining hemipenis. See Chapters 75, 80, and 106 for medical management and indications for removal of the phallus or hemipenis. The anesthetized patient is usually placed in dorsal recumbency, and the phallus or hemipenis is aseptically prepared. Copulatory organs are vascular and transfixing sutures are required. For hemipenal amputation the hemipenis is clamped close to its base with a hemostat, and one or two absorbable monofilament transfixing sutures are placed proximal to the hemostat depending on the patient size (Fig. 105.7). When possible, the remaining tissue should be short enough to allow the sutured stump to recess into the caudal vent/hemipenal sulcus to avoid postoperative exposure trauma.[7,20] In chelonians, the phallus is retracted caudally and clamped at the base with a hemostat or tissue clamp and a minimum of two absorbable monofilament transfixing and encircling sutures are placed, each approximately halfway across the phallus (Fig. 105.8A).[2,3] In larger chelonians, the blood supply to each distinct longitudinal ridge (basically dividing the phallus in half longitudinally) must be identified and each body (corpus cavernosa) and blood supply individually clamped and double ligated with absorbable monofilament sutures.[2,10] Bleeding can be substantial if a vessel is damaged when placing a transfixing suture, and additional sutures may be required. Sutures should be placed close to the base for a good "hold" (but minimize leaving any functional

phallus) and to ensure any remaining tissue will recess into the cloaca to avoid postoperative exposure trauma (see Fig. 105.8B). The remaining phallus stump can be closed with a simple continuous pattern using absorbable monofilament suture.[2,3,10]

FEMALE REPRODUCTIVE SURGERY

Ovariectomy/Ovariosalpingectomy

The most common indications for ovariectomy and ovariosalpingectomy in lizards, chelonians, and less commonly snakes is to manage reproductive follicular activity and dystocia, although neoplasia is possible.[2,3,14,15,21]

Preventative (elective) ovariectomy can be performed in lizard and chelonian species that are prone to reproductive-related issues.[2,4,5,19]

Lizards

Preventative/Elective and Postovulatory Ovariectomy. For ovariectomy in most lizards, a ventral coeliotomy (midline or paramedian) approach is recommended.[2,19] Once the coelom is entered, the ovaries are identified as paired (right ovary slightly cranial to the left) dorsal structures in the mid to caudal coelom, often just cranial to the kidneys. The paired coelomic fat pads, bladder (if present), and portions of the gastrointestinal tract may need to be retracted, exteriorized, protected, and kept moist. Exposure is improved with the use of retractors such as the lone star retractor. In cases of dystocia, the oviducts are filled with eggs or fetuses and need to be exteriorized and removed first (see Salpingectomy) to allow exposure of the ovaries. With a preventative (immature or seasonally inactive) ovariectomy (Fig. 105.9) or a postovulatory ovariectomy (Fig. 105.10A), the ovaries are generally small and appear as a small cluster of fluid-filled follicles located deep in the coelom. Each ovary is identified and, when possible, gently exteriorized through the incision to visualize the mesovarium and vessels. Often the mesovarium in these inactive ovaries is restrictive, and the ovary is fragile and cannot be exteriorized. The surgeon may have to work within the coelom, and the coeliotomy incision may need to be extended to ensure exposure. Important anatomical differences exist between the right and left ovaries in lizards (see Fig. 105.2).[1] The right ovary is attached directly to the vena cava with short vessels (1–2 mm), and the

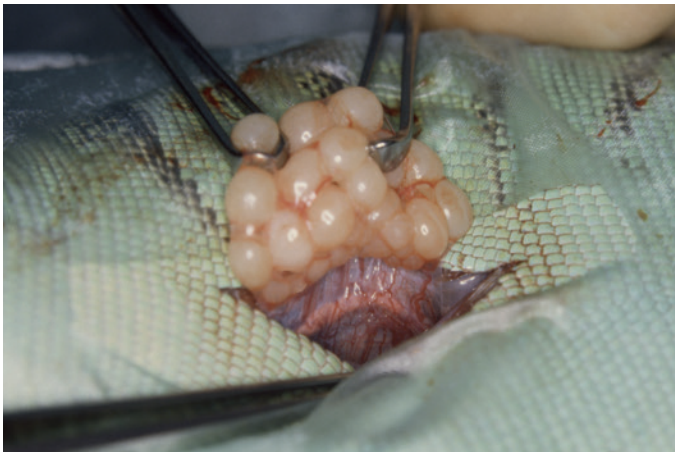

FIG 105.9 A seasonally inactive ovary in a green iguana (*Iguana iguana*); these ovaries are small, located deep in the coelom, and may be more difficult to exteriorize. This is the left ovary, as the adrenal gland (pink-tan elongated structure) is adjacent to the ovary and shares vascularity. Caution must be taken not to damage or accidently remove the adrenal gland when performing the ovariectomy (see Fig. 105.2). (Courtesy of Stephen J. Divers.)

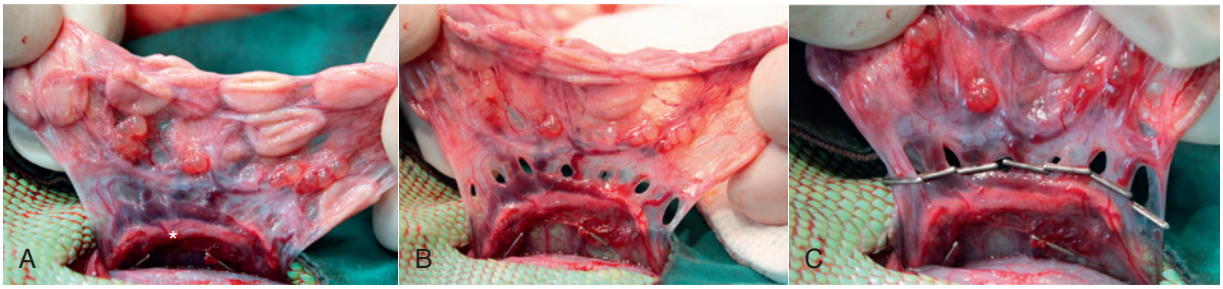

FIG 105.10 A postovulatory right ovary of a green iguana (*Iguana iguana*) exteriorized during ovariosalpingectomy. (A) The adrenal gland (pink-tan elongated structure, indicated by *) is located on the opposite side of the vena cava than the ovary. Note the recent ovulatory change to the ovary and the vascular clips below the adrenal gland, which are ligatures previously placed on the right oviduct vessels, as the oviduct (full of shelled eggs) was removed first to allow access to the ovary. (B) The vascular supply has been identified and small windows are made in the mesovarium between the ovarian vessels with iris scissors. (C) The vessels are ligated with vascular clips, which is easier and preferred; however, absorbable monofilament suture can be used alternatively. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

right adrenal gland is located on the *opposite* side of the vena cava (see Fig. 105.10A) and thus unlikely to be damaged at surgery due to its location. However, the left ovary has its own distinct ovarian artery and vein, and the adrenal gland is located *adjacent* to the left ovary, utilizing the same vessels (Fig. 105.9).[1] The elongated, pink-tan, granular adrenal gland must not be removed or damaged during ligation of the left ovary. Once each ovary is isolated, and proper exposure of the vascular supply is identified, small windows are made in the mesovarium between the ovarian vessels with iris scissors or a scalpel (see Fig. 105.10B), and the vessels are ligated with vascular clips (easier and recommended, see Fig. 105.10C) or absorbable monofilament suture (more difficult).

In some species (e.g., bearded dragons), the mesovarium may be heavily pigmented and the vasculature difficult to visualize for ligation and may obscure the adrenal tissue. Additionally, in bearded dragons the right liver lobe is closely associated with the vasculature of the right ovary, and the surgeon must avoid damaging the liver during ligation of the right ovarian vessels (Fig. 105.11). Magnification and focal lighting, along with microsurgical instruments, can be useful in these situations; however, these anatomical issues make ovariectomy less routine and more challenging in this species. After ligation, the ovarian pedicles are observed for any bleeding before routine closure of the coelom (see Fig. 105.4 and Chapter 98 for details).

For laterally compressed lizards, a lateral (flank) coeliotomy approach can be utilized (see Chapter 98). With this approach the small ovaries are easily identified upon entry, as they are typically positioned near the entry site (Fig. 105.12A and B). However, in cases of dystocia, the oviducts are filled with eggs/fetuses and must first be exteriorized and removed to allow access to the ovaries (see Fig. 105.12E and Salpingectomy). The ovariectomy technique is the same as described previously for the ventral coeliotomy, with careful ligation of the ovarian vessels within the mesovarium (see Fig. 105.12D). Both ovaries can often be removed from a single lateral incision unless there is compounding pathology.[2,19] Preventative ovariectomy (small involuted ovaries) of lizards can be performed endoscopically (see Chapter 65).

Ovariectomy (Preovulatory Follicular Stasis). The same approach is utilized for a preovulatory ovariectomy as described previously, except in these cases large ovulatory follicles are present. Following coelomic entry, the enlarged ovaries, which appear as a "grapelike" cluster of vitellogenic follicles, are obvious (Fig. 105.13A), although in lizards

The mesovarium is often heavily pigmented in this species, and the vasculature difficult to visualize for ligation and may obscure the adrenal tissue. Stahl, Stahl Exotic Animal Veterinary Services.)

such as geckos, which lay two eggs at a time, only a single static follicle may be present on each ovary (see Fig. 105.13B). The mesovarium is more elastic in these cases and will usually stretch to allow manipulation of the entire ovary out of the incision (see Figs. 105.12C and 105.13A and B). However, the ovary is often larger than the incision, and the follicles may be friable and begin to coalesce (especially if diseased) and can rupture with handling. Gentle manipulation and patience are required, and the coeliotomy incision may need to be extended to allow the entire ovary to be safely manipulated out. Once the ovary is isolated (usually one at a time due to the size), the vascular supply is identified and small windows are made in the mesovarium between the ovarian vessels with iris scissors or a scalpel, and the vessels are ligated with vascular clips or absorbable monofilament suture (Fig. 105.14). Particularly large vessels can be double ligated. The ovary is transected from its mesovarial attachments and removed. The process is repeated for the second ovary. If normal in appearance, the oviducts can be left

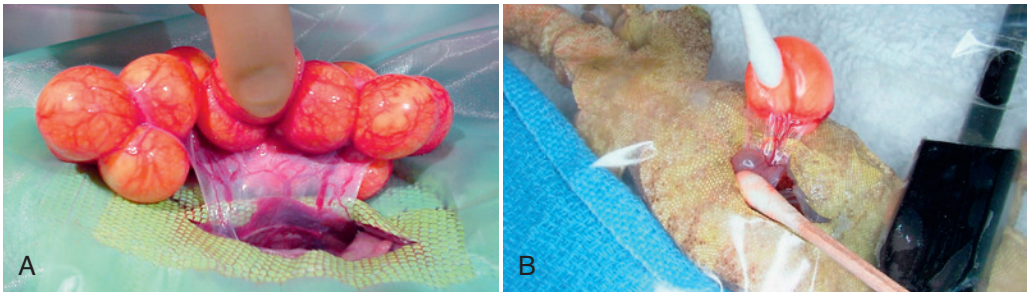

FIG 105.13 A preovulatory ovariectomy involves removing enlarged ovaries with vitellogenic, often static follicles. With this ovarian activity the mesovarium is more elastic and will usually stretch to allow manipulation of the entire ovary out of the incision. in situ. Also, if any ovarian remnant remains, the oviducts can prevent egg yolk coelomitis. This is a legitimate concern, especially in species such as bearded dragons in which the mesovaria are short and pigmented and the liver is closely associated with the right ovarian vasculature. It can be difficult to be certain that all the ovarian tissue is removed in this species, and clients should be warned of this possibility.

Salpingectomy. A salpingectomy is the first procedure performed in cases of surgical dystocia, and upon entry into the coelom the oviducts filled with eggs or fetuses will usually be the first structures identified. The oviducts are paired and found adjacent to the ovaries, and when full of eggs/fetuses, they may occupy most of the saurian coelom. The paired coelomic fat pads, bladder (if present), and portions of the gastrointestinal tract may need to be retracted, exteriorized, protected, and kept moist. Exposure of the oviducts is improved with the use of retractors. Once identified, the oviducts are gently exteriorized from the cranial (fimbria) to caudal (junction with urodeum) to allow visualization of the vascular supply (see Fig. 105.12E).The fimbria is identified, clamped with a hemostat, and ligated with absorbable monofilament suture or vascular clips and transected. In many cases, the fimbria is thin and poorly vascular, and radiosurgical/laser dissection (without ligation) may be all that is required. Starting cranially and

working caudally, small windows are made in the fanned out mesosalpinx to ligate vessels individually or in groups using vascular clips, absorbable monofilament suture, or radiosurgery/laser (Fig. 105.15A). Before ligation of the distal oviduct, the pelvic inlet should be checked to ensure no eggs are present. The distal oviduct is then clamped with a hemostat at its juncture with the urodeum, double-ligated with circumferential and transfixing absorbable monofilament sutures or vascular clips (see Fig. 105.15B), and transected, allowing the entire oviduct and contained structures to be removed en bloc (Fig. 105.16). This procedure is repeated on the opposite oviduct. Following the removal of both oviducts, ovariectomy is performed as described previously (see Fig. 105.16). Failure to completely remove both ovaries will result in fatal yolk coelomitis if the lizard ovulates in the future (see Yolk Coelomitis, Ectopic Follicles/Eggs later in this chapter and chapter 80).

Salpingotomy. If a lizard is presented with a dystocia, and maintaining future breeding capability is important, then salpingotomy is recommended. Following identification and exteriorization of the oviducts, the number and location of the retained eggs/fetuses are evaluated and the site for the initial incision can be determined (Fig. 105.17). To improve future reproductive success, trauma to the oviduct must be minimized, and the initial incision is made longitudinally along the antemesenteric border with a scalpel blade to ensure primary intention healing. The location of the incision should be strategically determined to allow the removal of as many eggs/fetuses as possible through the same incision. Diagnostic samples including oviductal biopsy for histopathology and microbiology can be collected at this time. If necessary, the incision can be extended with a scalpel or iris scissors. Often with dystocia there are fibrin adhesions and secondary inflammation inhibiting the eggs/fetuses from moving freely through the oviduct. If the eggs/fetuses are adhered to the mucosa, the oviduct can be isolated with moistened lap sponges, and warm saline infused into the lumen. The saline, along with gentle manipulation, may allow more eggs/fetuses to be freed and increase the number that can be manipulated out of a single incision.[5] Nevertheless, several incisions may be required to successfully remove all eggs/fetuses. Before closing the oviduct, the pelvic inlet should be checked to ensure no eggs are present. The oviduct incisions are closed with a simple continuous or inverting pattern using fine monofilament absorbable suture. The coelom is lavaged with warm sterile saline and routinely closed (see Chapter 98 for closure).

Snakes

Ovariectomy. Indications for ovariectomy and ovariosalpingectomy are less common in snakes but are often related to damage to the salpinx

via prolapse or an obstructive dystocia.[2,7] In these cases, if the oviduct cannot be repaired, the ipsilateral ovary must be removed along with the diseased or damaged oviduct (see Salpingectomy later in this chapter).

For ovariectomy or ovariosalpingectomy in snakes, a ventrolateral coeliotomy approach is recommended (see Chapter 97). McCracken reported the ovaries in most species of snake to be in the 60% to 80% snout-to-vent (SVL) position.[22] However, variation will occur depending on ovarian activity, with folliculogenesis resulting in a larger ovary. Ultrasonography can be useful in locating the ovaries, as follicles are generally easily identified as anechoic to hypoechoic ovoid structures, and this can help determine the incision site. A single long incision or multiple smaller incisions may be necessary to ensure exposure of both ovaries in snakes. Once the coelom has been entered, the ovaries are identified as elongated structures appearing as a string of ovoid, fluid- or yolk-filled structures (follicles) varying in size and color depending on cycle and species of snake. However, there may be several fascial layers to breach in order to obtain direct access to the ovaries. Stay sutures can be used to help identify the layers for eventual closure of the coelom. The staggered, overlapping ovaries (right cranial to left) are found dorsally, with the most cranial portion of the right ovary starting just distal to the gallbladder and the most caudal portion of the left ovary ending just cranial to the kidneys.[1] Unfortunately, because of this elongated morphology and staggered positioning, the surgical exposure necessary to remove both ovaries is extensive. Also, coelomic organs in snakes are more intimately connected by multiple fascial membranes, making exposure challenging. In addition, the saccular lung (air sac) often extends into the reproductive surgical field. Therefore, given these difficulties, ovariectomy is not considered a routine preventative procedure in snakes.

The use of retractors can help with exposure. The ovary is fragile and must be handled gently; however, the mesovarium will usually stretch and allow exteriorization of the ovary (Fig. 105.18A). Once exteriorized and the vascular supply is exposed, small windows are made in the mesovarium between the ovarian vessels with iris scissors or a scalpel blade (see Fig. 105.18B), and the vessels are ligated with vascular clips or absorbable monofilament suture. If the oviducts are unaffected, they can be left in place (see Fig. 105.18C), and closure is routine (see Fig. 105.18D and Chapter 97).

Salpingectomy. Indications for salpingectomy are often related to damage to the salpinx via prolapse or an obstructive dystocia. In these cases, if the diseased or damaged oviduct cannot be repaired and must be removed (Fig. 105.19 A and B), then the ipsilateral ovary must also be removed to avoid ectopic follicles and yolk coelomitis (see Ovariectomy previously).

The coelomic approach is often clearly dictated by coelomic distention. Upon entry into the coelom (see Chapter 97), the oviduct(s) filled with eggs/fetuses are the first structures identified. However, there may be several fascial layers to navigate before achieving direct access to the oviducts. Stay sutures can be used to help identify the layers for eventual closure of the coelom. The oviducts are paired and found adjacent and caudal to their respective ovaries. The affected oviduct should be exteriorized, utilizing the retained eggs/fetuses as a guide. Retractors such as the lone star can help with exposure. It can be challenging to determine which oviduct is involved upon initial entry, which is critical because the ipsilateral ovary must be removed. To expose the entire "affected" oviduct and its ipsilateral ovary, a long incision or multiple smaller incisions may be necessary. Exposed tissues that are to be retained should be protected with moistened lap sponges. Once identified, the affected oviduct is gently exteriorized from cranial (fimbria) to caudal (junction with urodeum) to allow visualization of the vascular supply (see Fig. 105.19A and B). The fimbria is identified and transected as previously described. Working caudally, the mesosalpinx is exposed, vessels ligated, and the mesosalphinx transected, as previously described. The distal oviduct is then clamped with a hemostat, as close to the urodeum as possible, double ligated, and transected. In the case of a prolapsed portion of oviduct, the prolapse may have to be retracted back into the coelom to allow proper ligation and removal. Following removal of the damaged oviduct, the ipsilateral ovary must be removed as described previously (see Fig. 105.19C). The same procedure is performed on the contralateral oviduct and ovary if necessary and is performed through the same incision, although extension may be required. Follicles, eggs and fetuses may be ectopic, and there may be an associated coelomitis from oviduct damage or prolapse. In such cases, warm saline lavage is required before routine closure (see Chapter 97).

Salpingotomy. If a snake is presented with a dystocia involving eggs/fetuses retained in the oviduct(s), and maintaining its ability to

(B) Once the ovary was exteriorized (in the same snake), small windows were made in the mesovarium between the ovarian vessels with iris scissors, and the vessels were ligated with vascular clips. In this case one entire oviduct had prolapsed and the ipsilateral ovary was removed. (C) The contralateral ovary (at top) and oviduct (above finger) were inspected and left in place to maintain reproductive potential. FIG 105.19 Indications for salpingectomy are often related to damage to the salpinx via prolapse or an obstructive dystocia. (A) A green tree python (*Morelia viridis*) presented for a chronic dystocia, and surgery revealed one oviduct had ruptured and was severely damaged. (B) Unfortunately, oxytocin had been inappropriately used in this case and may have contributed to the oviduct torsion and rupture. A unilateral procedure was performed (the other oviduct was empty and normal) to keep the female reproductive. The damaged oviduct, retained eggs, and ipsilateral ovary were removed. breed in the future is important, salpingotomy is often recommended (Fig. 105.20).

Upon entry into the coelom (see Chapter 97), the oviduct(s) filled with eggs/fetuses are the first structures identified. However, there may be several layers of coelomic membranes to incise to expose the oviduct. Stay sutures can be used to help identify the layers for eventual closure of the coelom. A portion of the oviduct should be exteriorized utilizing the retained eggs/fetuses as a guide to finding the affected section of oviduct (see Fig. 105.20A). The use of retractors such as the lone star retractor can help with exposure. Once the condition of the oviduct and the number and location of the retained eggs/fetuses are evaluated, the location for the initial oviduct incision can be determined. To improve future reproductive success, the surgeon's goal is to minimize trauma to the oviduct.

The initial incision is made in a nonvascular area of the oviduct with a scalpel in a strategic location, which allows the removal of as many eggs/fetuses as possible through the same incision. Diagnostic samples including oviductal biopsy, culture and sensitivity, and PCR swabs can be collected at initial entry. The incision is then extended as necessary with iris scissors or scalpel, and the eggs/fetuses are gently manipulated out of the oviduct (see Fig. 105.20B). Often with dystocia there are fibrin adhesions and secondary inflammation that may inhibit the eggs from moving freely in the oviduct.

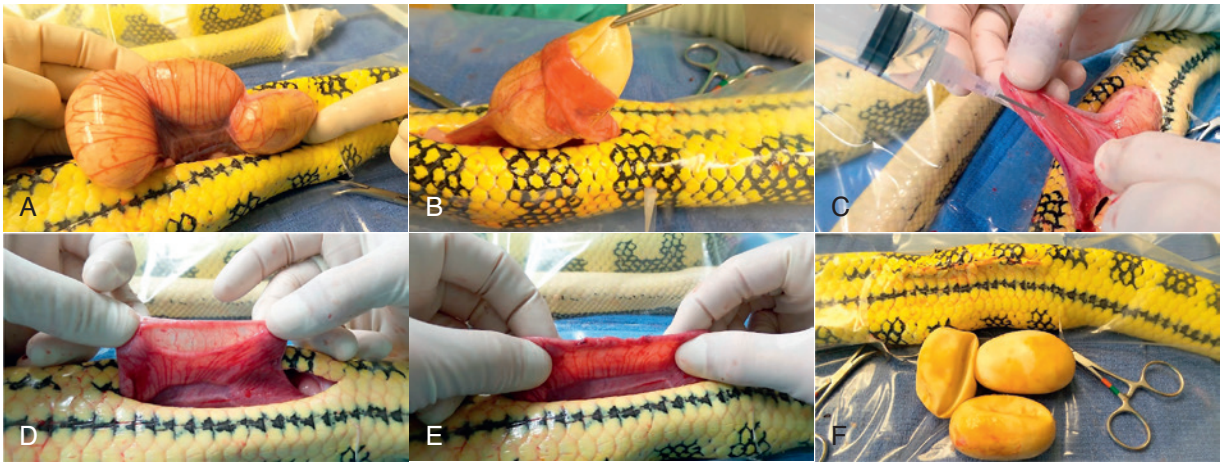

FIG 105.20 If a snake is presented for dystocia, and maintaining its ability to breed in the future is important, salpingotomy is often recommended. A jungle carpet python (*Morelia spilota cheynei*) was presented for dystocia several weeks after laying most of her clutch. (A) Upon surgical entry into the coelom, directed by the presence of retained eggs, one oviduct containing three eggs was identified. (B) The initial incision was made in a nonvascular area of the oviduct, and the first egg was manipulated out. Due to the chronicity of the egg retention, fibrin adhesions were present, and the egg was difficult to detach from the oviduct mucosa (note the thickened, inflamed oviduct). (C) Once the first egg was removed, warm saline was infused into the oviduct lumen, and the saline, along with gentle manipulation, allowed the other two eggs to be manipulated through the same incision. (D) The oviduct after egg removal and (E) after closure with a simple continuous pattern. (F) The coelom was lavaged with warm saline and routinely closed. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

If the eggs/fetuses are adhered to the oviduct mucosa, the oviduct can be isolated with moistened lap sponges and warm saline infused into the lumen (see Fig. 105.20C). The saline, along with gentle manipulation, may allow the eggs/fetuses to move and therefore increase the number that can be manipulated out of the oviduct incision (see Fig. 105.20D).[7] However, often several incisions may need to be made in each oviduct to successfully remove all the eggs/fetuses. The oviduct incisions are closed with a simple continuous or inverting pattern using fine monofilament absorbable suture (see Fig. 105.20E). The coelom is lavaged with warm saline and then routinely closed (see Fig. 105.20F and Chapter 97).

Chelonians

Ovariectomy. The least invasive and thus preferred technique for ovariectomy in chelonians is the prefemoral approach instead of the more traditional ventral transplastron approach.[2,4,8,14–16] The ovaries in most chelonians are accessible from a prefemoral approach (especially with endoscopic assistance), and the trauma of cutting through plastron bone can be avoided. In some species the prefemoral fossa is too restrictive, and there may be situations (such as an obstructive dystocia involving many retained eggs, yolk coelomitis, ovarian neoplasia, cystic calculus) where a transplastron coeliotomy is necessary.[2,3,14] For details on celiotomy approaches in chelonians, see Chapters 99 and 100.

Once the coelom has been safely entered, the bladder, intestinal tract, and lungs may need to be gently manipulated to allow access to the ovaries. The ovaries are paired and found dorsally in the mid to caudal coelom cranial to the kidneys. With the prefemoral approach, the use of retractors such as the lone star retractor can help with exposure (see Fig. 105.5). The ovary is identified, and the interfollicular tissue is grasped with atraumatic forceps and gently manipulated to the prefemoral incision. The ovary is gently teased out of the incision to allow visualization of the mesovarium and ovarian vessels (Fig. 105.21A and B). Vascular clips or absorbable monofilament suture is used to ligate the vessels before transecting distally and removing the ovary. Once the ipsilateral organ has been removed, the contralateral ovary can often be exteriorized through the same incision. However, if this is not possible, a second prefemoral coeliotomy incision (on the contralateral side) will be necessary.[5,8,14–16] With the transplastron approach, the ovary is manipulated up and out of the plastronotomy whenever possible, or the surgeon may have to work within the coelom.[2,3] Both ovaries are accessible from a transplastron coeliotomy, and each ovary is isolated and removed as described previously (Fig. 105.22). The vascular pedicles are evaluated for bleeding before lavage and routine closure of the coelom (see Chapters 99 and 100 on celiotomy closure in chelonians).

Endoscopic-assisted prefemoral ovariectomy in chelonians is effective, minimally invasive and therefore preferred,[10,13–15] and complete endosurgery coelioscopic ovariectomy can also be performed in many species.[13,14] For details on these procedures, see Chapter 65.

Salpingectomy. Indications for salpingectomy in chelonians are often related to damage to the salpinx via prolapse or an obstructive dystocia. Exploratory surgery is indicated with oviductal prolapse. If attempts to replace and repair the oviduct intracoelomically are not possible, the prolapsed portion is no longer viable, or the salpinx has associated pathology (salpingitis or neoplasia), then salpingectomy with ipsilateral ovariectomy are indicated. A transplastron coeliotomy is recommended with an obstructive dystocia involving many eggs, yolk coelomitis, or with other concurrent coelomic issues (e.g., calculus or egg in the bladder), as this approach allows a more thorough evaluation of the coelom.[2,3] Upon entry into the coelom, the oviduct(s) filled with eggs are often obvious; however, the use of retractors can help with exposure. The oviducts are paired and found adjacent to the ovaries. Once identified, the affected oviduct is gently exteriorized from cranial (fimbria) to the caudal (junction with urodeum) to allow visualization of the vascular supply (Fig. 105.23). The fimbria is identified, clamped with a hemostat, and ligated with absorbable monofilament suture or vascular clips, or,

if thin and largely avascular, radiosurgery or laser transection is sufficient. Working caudally, the mesosalpinx is fanned out and windows are made in the mesosalpinx to ligate vessels individually or in groups using vascular clips or absorbable suture (Fig. 105.24). Before ligation of the distal oviduct, the pelvic inlet should be checked to ensure no eggs are present. The more substantive distal oviduct is then clamped with a hemostat at its juncture with the urodeum and double ligated with a circumferential and transfixing absorbable suture before being transected to allow en bloc removal. This procedure can be repeated with the opposite oviduct unless unilateral reproductive function is to be maintained. An ovariectomy must be performed on any side where the oviduct is removed or is no longer functional.

In the case of a prolapsed oviduct, the prolapse may have to be "retracted back" into the coelom to allow proper ligation and removal of the oviduct at the level of the urodeum. Following removal of the damaged oviduct, the ipsilateral ovary is removed as previously described.

Often eggs may be ectopic and there may be an associated coelomitis from oviductal damage or prolapse, and warm saline lavage should be considered before routine closure. An endoscopic-assisted prefemoral coeliotomy could be considered for salpingectomy in chelonians where few or no oviductal eggs are involved or the oviduct has prolapsed, and the goal is to perform an ipsilateral (to the damaged oviduct) or bilateral ovariectomy.[3,14,23] For details on these procedures, see Chapter 65.

Salpingotomy. Salpingotomy procedures are not performed as commonly in chelonians, as unobstructed dystocias are often responsive to medical management with oxytocin.[3] A transplastron coeliotomy is recommended with an obstructive dystocia involving many eggs, yolk coelomitis, ectopic follicles/eggs, or if other concurrent coelomic issues are diagnosed, as this approach allows a more thorough evaluation of the coelom.[2,3]

In addition, unless future reproductive activity is desired, permanent resolution by ovariosalpingectomy is preferred. The coelom is entered, and the oviducts identified and exteriorized as previously described (see Fig. 105.23). Once the condition of the oviduct, and the number and location of the retained eggs have been evaluated, the location for the initial oviduct incision can be determined. To minimize damage and scarring, the initial incision is made longitudinally along the antemesenteric border with a scalpel in a strategic location, which allows the removal of as many eggs as possible through the same incision. Diagnostic samples can be collected, including biopsy following the initial entry. The incision is then extended as necessary with a scalpel or iris scissors (Fig. 105.25), and the eggs are gently manipulated from the oviduct. Often with dystocia there are fibrin adhesions and secondary inflammation inhibiting the eggs from moving freely in the oviduct. If the eggs are adhered to the mucosa, then packing of the oviduct with lap sponges and utilizing saline infusion in the oviduct can help as previously described for lizards and snakes.[7] Nevertheless, several incisions may need to be made in each oviduct to successfully remove all eggs. Before closing the oviduct, the pelvic inlet should be checked to ensure no eggs are present. The oviduct incisions are closed with a simple continuous or inverting pattern using fine monofilament absorbable suture. The coelom should be lavaged with warm saline, and closure is routine (see Chapter 100).

A prefemoral coeliotomy approach (see Chapter 99) could be considered for salpingotomy in chelonians, where just a few eggs are involved (preferably all in one oviduct).[3,13,14,23] This approach may not be possible depending on the female's size and conformation. The use of retractors can help with exposure in the prefemoral area (see Fig. 105.5). An endoscopic-assisted approach is preferred, as the endoscope is used to identify and, with the help of forceps or a spay hook, retrieve the affected oviduct and monitor its manipulation toward the incision. If an endoscope is not available, the use of a spay hook or small spoon in combination with tilting the chelonian patient may allow retrieval of the oviduct.[2,3,23] Once a portion of the oviduct is manipulated out of the incision, it can be used for traction. Stay sutures can be placed in the oviduct, and it is packed off with moistened lap sponges. The portion of the oviduct with retained eggs may be too large to pass through the incision (which is limited by the carapace and plastron).

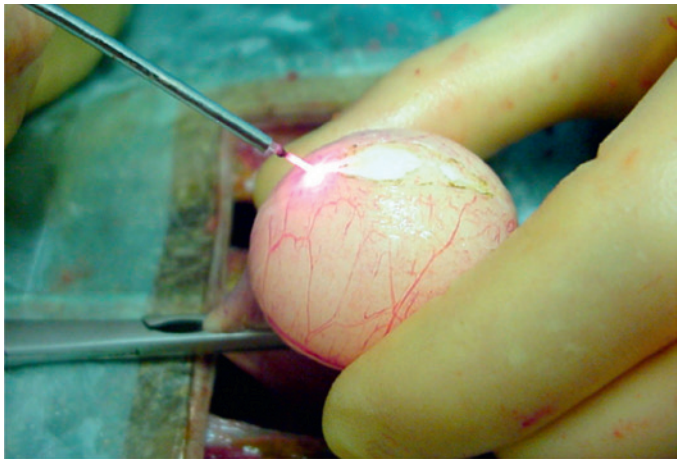

FIG 105.25 Salpingotomy procedures are performed less commonly in chelonians, as dystocias (unobstructed) are often responsive to medical management with oxytocin. After a transplastron coelomic approach in this dystocic tortoise, an incision was made in the oviduct with a diode laser to remove a chronically retained egg. In general, a scalpel salpingotomy incision is preferred over any other surgical device in order to minimize collateral damage and scarring. (Courtesy of Stephen J. Divers.)

(B) A crested gecko (*Correlophus cilliatus*) with yolk coelomitis associated with chronic follicular stasis. This species usually only produces one vitellogenic follicle at a time on each ovary, so the change is quite dramatic. The author has seen this condition in several geriatric female crested geckos, and it may be an age-related condition. (A, Courtesy of Stephen J. Divers; B, courtesy of Scott J. In such cases, the egg(s) can be aspirated and collapsed following oviductal incision. Again, diagnostic samples can be collected at this initial entry. The process is repeated one by one until all the eggs have been removed. Before closing the oviduct, the pelvic inlet should be checked to ensure no eggs are present. The oviduct is then gently flushed and closed with a simple continuous or inverting suture pattern using fine monofilament absorbable suture. The oviduct is lavaged with sterile saline before being gently returned to the coelom. If the dystocia is bilateral, an endoscope can be used to find and attempt to manipulate the contralateral oviduct toward the same prefemoral incision. If the contralateral oviduct cannot be accessed or manipulated, a second prefemoral approach on the opposite side may be required.[2–4,13,14,23] The coelom is checked for any ectopic eggs or yolk leakage, gently lavaged, and closed routinely (see Chapter 99).

Yolk Coelomitis and Ectopic Follicles/Eggs

Yolk coelomitis is not an uncommon sequela to reproductive disease in females (see Chapter 80 for more details). It is important to thoroughly evaluate the coelom during any reproductive procedure to ensure that such pathology is not missed. Diagnostic samples for histopathology (or cytology) and microbiology should be taken before the coelom is copiously and repeatedly lavaged with warm sterile saline to remove as much yolk material as possible (Fig. 105.26A and B).[5] In more chronic cases, a fibrinlike yolk material may be adhered to serosal surfaces and will require gentle debridement. A gram stain can be performed to help direct immediate antimicrobial treatment and subsequently adjusted based on future sensitivity results.

Ovarian Biopsy

In some situations, the collection of histopathologic and microbiologic samples from ovaries may be required to determine underlying disease or dysfunction/infertility. Indications for ovarian biopsy include neoplasia, oophoritis (abscess, granuloma), and infertility. In most reptiles endoscopic ovarian evaluation and biopsy/aspiration is effective, minimally invasive, and preferred to open surgical approaches (see Chapter 64). However, an open coeliotomy approach may be necessary if endoscopy equipment is unavailable or when evaluating the ovaries of snakes, which are inherently more challenging for coelioscopy.

Cloacal Prolapse

Stuart McArthur and Ross A. Machin

Effective treatment of all cloacal prolapses involves a simultaneous balance of medical and surgical interventions. The presentation therefore draws upon many of the techniques described across the clinical disciplines.

Information to assist a clinician faced with a cloacal prolapse in a reptile patient is available in several sections of this book; surgical management is covered here and throughout Section 10. Medical management of a cloacal organ prolapse and associated conditions are also covered in Chapters 75 and 143 and throughout Sections 5 and 9 of this book. We recommend general anesthesia or sedation with additional analgesia, such as opiates and nonsteroidal antiinflammatories, during the surgical resolution of cloacal prolapses, and these techniques and drugs are covered in detail in Chapters 48 through 51 and summarized in Table 75.5 (McArthur S, Machin R, personal observation, 2017).[1–3] See Chapter 16 for further husbandry details and also Chapters 46 and 87.

PHALLUS (CHELONIAN)/HEMIPENIS (SQUAMATE) PROLAPSE

Male reproductive organ prolapse is a common emergency presentation in clinical practice (Figs. 106.1 and 106.2).[4,5] In one UK study that included more than 3000 reptiles, male organ prolapse represented more than 35% of all prolapses and was the most common prolapse type of reptiles and has been reported in chelonians,[4,7–10] lizards,[4,11] snakes,[10,12] and crocodilians.[14] Known causes are covered in more detail in Chapter 75.

Chapter 75 contains a guide to prolapse identification and the conditions predisposing to a prolapse. Prolapse phallus or hemipenis identification is generally straightforward. Only mature male animals will be presented. A phallus prolapse does not contain a lumen and is relatively small and originates within the caudolateral vent in squamates and may be a bilateral presentation as squamates have two (hemipenes). In chelonians, a large single fleshy structure projects out centrally from the cranial cloaca, and this may be a considerable size. In squamates, the main differential diagnoses are hemipenile plugs and infections, which may accompany a hemipenile prolapse. Usually, a reptile can urinate and defecate around this type of prolapse because the male copulatory organ contains no urethra.

A male organ cloacal prolapse can either be reduced or amputated. If a reduction procedure meets significant complications, or is unsuccessful, the clinician can revert to amputation. Amputation affects future reproduction but not the output of the urinary system. In species with hemipenes, the reptile may still be able to successfully copulate and reproduce if only one organ is amputated. Male cloacal organ amputation

carries a favorable prognosis; euthanasia is usually unnecessary. Underlying husbandry and welfare issues must be addressed, as with other presentations.[4–14] Initial stabilization is described in Table 75.3 (see Chapter 75). This includes protection of the prolapsed organ, analgesia, rehydration, and placement in a warm environment.

In an anesthetized reptile with a phallus or hemipenis prolapse, protruding tissue should be assessed for viability, cleaned, lubricated, and gently replaced into the cloaca when possible. A moistened cotton-tipped applicator or tongue depressor may be a helpful tool during prolapse reduction. Application of topical local anesthetic agents (e.g., lidocaine and bupivacaine) mixed with lubricant gels may reduce straining and aid reduction and subsequent retention. Anesthetic agents can be applied topically via infiltration or as an intrathecal block.[1–3] Topical glycerine, dextrose, honey, or concentrated sugar solutions allow osmotic reduction of tissue edema and may be helpful when the organ is profoundly edematous.[21,22] These are often required when managing prolapse of the phallus in chelonians.[8]

Where a prolapse cannot be manually reduced, the vent may be surgically enlarged via a lateral releasing incision, on one or both sides of the vent, with surgical closure after reduction. This allows a swollen prolapse to be reduced and replaced within the cloaca. Once the organ is correctly replaced it rapidly deceases in size. A correctly placed cloacal suture (e.g., 3/0 Polydioxanone), or staples, prevents further prolapse but allows normal urination and defecation.[6,15,16] Sutures or staples are monitored for 1 or 2 days to ensure normal urination and defecation is possible and subsequently removed in 5 to 7 days or longer if necessary to allow a stable reduction to occur.

Where the prolapse is traumatized, severely swollen, or necrotic, amputation is advisable. In both squamates and chelonians, amputation under general anesthesia or sedation is a quick procedure and often simpler than an attempt at reduction. Local anesthetic agents (e.g., lidocaine and bupivacaine) can be infiltrated into tissue at the base of the prolapse, which is then transected distal to a transfixed, circumferential hemostatic suture (e.g., 3/0 Polydioxanone). The amputation stump is replaced within the cloaca where it rapidly reduces in size.

Postoperative complications are unusual and may include hemorrhage or infection. Once the postoperative patient is stable, it can be discharged and managed on an outpatient basis, as long as a suitable recovery environment can be provided. Husbandry should be optimized, and normal perioperative care should be followed, maintaining core body temperature and hydration, and a feeding plan should be established. Provide suitable postoperative analgesia (see Chapter 50) and monitor for urine and fecal production and evidence of straining, discomfort, or pain.[20]

OVIDUCT PROLAPSE

Oviductal prolapses have been reported in female lizards and chelonians (Figs. 106.3 through 106.8). In theory, at least, they may occur in any female reptile. However, reports in snakes appear absent from the literature. In one UK study, only 3% of reptile prolapses were oviducts.[4] Chapter 75 contains information on identification of an oviduct prolapse and conditions predisposing to oviductal prolapse.

Female reptiles with a recent prolapse of an oviduct will present with a tubular prolapsed structure projecting through the vent. The prolapse has a smooth surface with occasional longitudinal striations. A lumen is present. The presence of fecal material is unusual, but surface contamination may occur. Some animals may continue to pass fecal and urinary excretion products around a prolapse. Bilateral prolapses are not reported in the literature and are not known to either the authors or editors. Chronic prolapses quickly become strangulated, necrotic, and traumatized, all of which complicate organ identification.

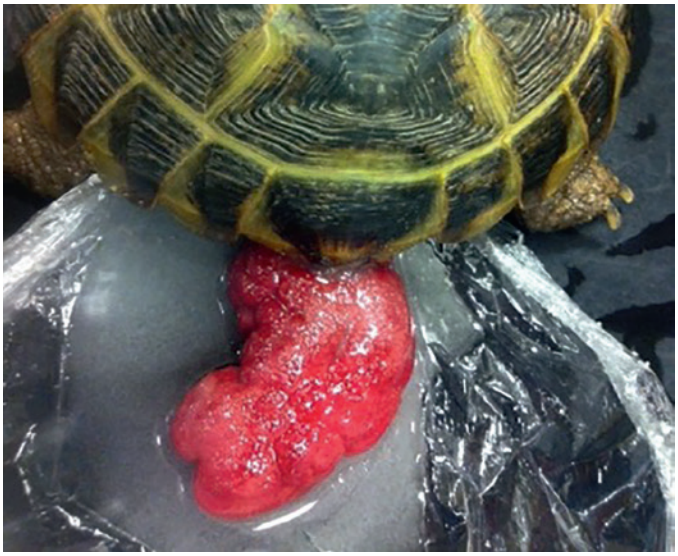

FIG 106.3 Osmotic reduction during stabilization and transportation (*Agrionemys horsfieldii*). An oviduct prolapse is bathed in a concentrated sugar solution and lubricating gel and then wrapped in Clingfilm. This protection is suitable stabilization until a reptile clinician or transportation to a reptile veterinary facility becomes available. (Courtesy of Stuart McArthur.)

FIG 106.4 Osmotic reduction using sugar (*Agrionemys horsfieldii*). Further reduction is possible under general anesthesia. Here sugar solution is applied in the preoperative period after the prolapse has been cleaned with warm fluid flushing. It is rinsed off and then the prolapse can be reduced. In some cases, oxytocin may reduce the prolapse volume. (Courtesy of Stuart McArthur.)

The primary differential diagnosis of an oviductal prolapse is a prolapse of the colon. Examination of the cloaca with an otoscope or endoscope may be useful and may confirm the presence of a patent colon.

Initial stabilization is described in Table 75.3 (see Chapter 75) and includes protection of the prolapsed organ, analgesia, rehydration, and placement in a warm environment. Suitable analgesia protocols are identified in Table 75.4 (see Chapter 75). Local anesthetic agents can be applied topically, via infiltration or as an intrathecal block.

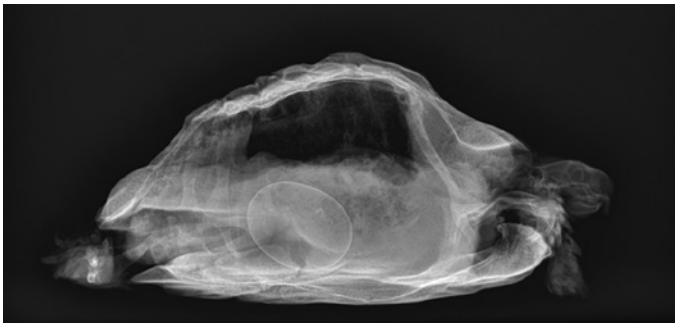

FIG 106.6 Radiographic examination of a reptile with an oviduct prolapse will often reveal a space-occupying mass in the coelom, dystocia (as seen in this *Agrionemys horsfieldii* with a retained egg), or a urolith, or a urolith. A coeliotomy (open reduction) with multimodal analgesia is advised as part of the overall management strategy.[1–3] There may be radiographic evidence of dystocia or urinary calculi, which can also be addressed during the coeliotomy. Surgical entry to the coelomic cavity varies with species and is covered in detail in Chapters 97 through 101.

It is rare for a prolapsed oviduct or shell gland to be preserved during treatment. Amputation is usually necessary. Amputation of the externalized prolapse with stump closure is often performed immediately before any coeliotomy, allowing the remaining issues to be addressed, as this ensures only one surgical site is active at a time. Additional coelomic interventions that may be required should be considered, and risks and costs should be carefully and realistically assessed and discussed with the client. Euthanasia may also be considered in severe presentations (e.g., sepsis and collapse) or where there are economic constraints. Closed reduction of an inverted oviduct and temporary retention using staples or purse string sutures is possible; however, it is unusual to simply reduce an oviduct prolapse (e.g., using hydrostatic warm water local irrigation) without persistence of inversion or recurrence.

Exploratory coeliotomy (open reduction) under general anesthesia allows for a comprehensive assessment of the reproductive tract and appropriate management of any dystocia or urolith. Provided the clinician is confident that a prolapse is oviduct and not the colon, then it is acceptable to amputate the prolapse close to the vent before any coeliotomy, closing the residual stump using circumferential transfixion sutures (e.g., 3/0-5/0 polydioxanone or poliglecaprone with triclosan).[6,15,16] Prolapse amputation removes any need to draw necrotic, infected, friable, or traumatized structures back through the vent and cloaca, into the coelomic cavity, during coeliotomy. Where the prolapse has been amputated before coeliotomy, it is usually straightforward to locate the residual oviduct stump, and the subsequent coeliotomy procedure itself is far more straightforward.

Female reptiles all have a bicornuate reproductive system and two ovaries. Removal of the affected portion of the reproductive tract and its accompanying ovary is recommended in most cases of oviduct prolapse, as few reduced prolapses are likely to continue without complication. At coeliotomy, a unilateral prolapse may recover well with removal of just the affected oviduct and its related ovary, leaving the contralateral tract intact.[19] Surgical entry to the coelomic cavity varies with species and is covered in detail in Chapters 97 to 101. Where future reproduction is not a concern, bilateral ovariohysterectomy is
