b) For compromised animals: Premedicate with xylazine 0.22 – 0.44 mg/kg IV (or 100 – 200 mg/450 kg [992 lb] horse [NOT mg/kg]), depending on the status and demeanor of the animal, to minimize cardiovascular effects in compromised animals. Slow IV administration of guaifenesin 5% solution can be used initially to gradually achieve the desired level of sedation. It is still important to allow adequate time for centralization of cardiac output to progress sufficiently prior to initiating the rapid phase of guaifenesin administration. Guaifenesin has a slow onset of action when used to augment the level of pre-induction sedation, and it is important to control drug administration rate to avoid creating an overly weak and ataxic patient while waiting for centralization to progress sufficiently. Guaifenesin is then rapidly infused using pressurization until marked sedation and muscle relaxation is achieved, generally a total dose of 30 – 50 mg/kg IV. To induce anesthesia, decrease the ketamine dose as the degree of compromise increases: ketamine 1.34 – 1.55 mg/kg (or 600 – 700 mg/450 kg [992 lb] horse [NOT mg/kg]) IV for extremely compromised animals at a point that allows slow onset to occur without the animal becoming excessively weak and collapsing from the growing effects of guaifenesin. Experience may be required to get the timing right. Recumbency takes longer (up to a couple minutes) when the ketamine dose is reduced in compromised patients.[9]

Total IV anesthesia:

a) **Guaifenesin/ketamine/xylazine (GKX) | "triple-drip"** (extra-label): Guaifenesin 50 mg/mL, ketamine 1 – 2 mg/mL (2 mg/mL concentration used for more painful or noxious procedures), and xylazine 0.5 mg/mL. To prepare this mixture, add ketamine 10 mL (100 mg/mL) for 1 mg/mL (add 20 mL ketamine for 2 mg/mL) and xylazine 5 mL (100 mg/mL) to a 1000 mL bag of guaifenesin 5%. Most clinicians prefer to induce with xylazine/ketamine or xylazine/midazolam/ketamine and then use GKX for maintenance. Use GKX 1.5 – 2.2 mL/kg/hour IV CRI, depending on the procedure, animal response, and ketamine concentration.

b) **Guaifenesin/ketamine/detomidine (GKD)**: In ponies sedated with detomidine 0.02 mg/kg IM and induced with ketamine 2 mg/kg IV: Guaifenesin 100 mg/mL, ketamine 4 mg/mL, and detomidine 0.04 mg/mL at 0.8 mL/kg/hour IV CRI for the first

hour and 0.6 mL/kg/hour IV CRI for the final 30 minutes.[10,11] To prepare this mixture, add ketamine 40 mL (100 mg/mL) and detomidine 4 mL (10 mg/mL) to a 1000 mL bag of guaifenesin 10%.

Muscle relaxant as part of a general anesthesia after induction (extra-label): **NOTE**: When used as part of total IV anesthetic protocols, guaifenesin is used in triple-drip ("GKX") mixtures that also contain an alpha-agonist (eg, xylazine, detomidine, romifidine) and ketamine. These mixtures can be particularly useful for field use with short procedures (up to 60 minutes). Additional information can be found in anesthesia references.[8,12] The following is an example of a dosage recommendation:

Augmentation of muscle relaxation in horses that are too light or too tense after alpha-2 agonist + ketamine ± benzodiazepine induction, and do not respond sufficiently to additional increments of alpha-2 agonist or ketamine: Guaifenesin 5% dosed at ≈25 – 50 mg/kg (250 – 500 mL) IV

SHEEP, GOATS:

General anesthesia (extra-label):

a) **Using "GK" (or "double-drip") for induction and maintenance**: Add ketamine 1000 mg to 1000 mL of guaifenesin 5% (50 mg/mL). Induce with this combination 1.7 – 2.2 mL/kg IV. Maintain with ≈ 2.6 mL/kg/hour IV CRI (adjust rate as needed).[13]

b) **Using "GKX" for induction and maintenance**:

1. Mix 1000 mL of guaifenesin 5% (50 mg/mL) with ketamine 1000 mg and xylazine 0 – 100 mg. Induce with 2.2 mL/kg IV (calculate dose carefully to avoid an overdose). Maintain with ≈2.2 mL/kg/hour IV CRI (adjust rate as needed).[14]
2. To a 500 mL bag of guaifenesin 5%, add xylazine 50 mg and ketamine 500 mg. Administer at a rate of 2 – 4 mL/kg IV. It is given rapidly until animal is recumbent and then slowed to maintain desired anesthesia plane.[15]
3. To a 500 mL bag of guaifenesin 5%, add xylazine 50 mg and ketamine 500 mg. Induce at a rate of 1 – 1.5 mL/kg IV; in small ruminants, administer via syringe to minimize risk for overdose. Maintain anesthesia at 2.6 mL/kg/hour IV CRI.[13]

CAMELIDS:

General anesthesia using "GKX" for induction/maintenance (extra-label): Mix 1000 mL of guaifenesin 5% (50 mg/mL) with ketamine 1000 mg ± xylazine 200 mg. Induce with 2.2 mL/kg IV (calculate dose carefully to avoid an overdose). Maintain with ≈2.2 mL/kg/hour IV CRI (adjust rate as needed).[14]

Monitoring

Monitoring patients during general anesthesia is vital, and guaifenesin-based injectable anesthesia can affect multiple systems. Monitoring depth of anesthesia, muscle relaxation, respiratory rates/oxygenation, heart rate, and blood pressure are all warranted.

Refer to specific anesthesia references for more information.

Client Information

Injectable guaifenesin must be given by your veterinarian.

Chemistry/Synonyms

Formerly known as glyceryl guaiacolate, guaifenesin occurs as a white to slightly gray, crystalline powder that may have a characteristic odor. It is nonhygroscopic and melts between 78°C to 82°C (172.4°F-179.6°F). One gram is soluble in 50 mL water at room temperature, but it is much more soluble in hot water; it is soluble in alcohol, propylene glycol, and glycerin.

Guaifenesin may also be known as GG, glyceryl guaiacolate, glycerylguayacolum, guaiacol glycerol ether, guaiacyl glyceryl ether, guaifenesina, guaifenesinum, guaiphenesin, and guajacolum glycerolatum; many trade names are available.

Storage/Stability

Guaifenesin is stable in light and heat (less than melting point). Parenteral guaifenesin prepared by compounding pharmacies should be stored as specified on the product label.

When guaifenesin is dissolved into aqueous solutions, it may slightly precipitate out of solution when the temperature is less than 22°C (72°F). Slight warming and agitation generally resolubilizes the drug. A microwave oven has been suggested for heating and dissolving the drug. It is recommended that the solution be prepared freshly before use, but a 10% solution (in sterile water) may apparently be stored safely at room temperature for up to one week with only slight precipitation occurring.

Compatibility/Compounding Considerations

Guaifenesin is physically **compatible** with sterile water or D_5W. It is also reportedly **compatible** with ketamine, pentobarbital, thiamylal, thiopental, and xylazine.

"Triple drip" and similar mixtures should be prepared at the time of administration and promptly discarded after discontinuation.

As there are no commercially available formulations being marketed in the US, compounding an injection product from a USP grade powder may be the only way to obtain a parenteral dosage form. Compounding pharmacies with appropriate facilities, equipment, and procedures may be able to prepare a sterile product. The commercially available products contained per mL: Guaifenesin 50 mg, dextrose (anhydrous) 50 mg, propylene glycol 20 mg, dimethyl acetamide 50 mg, edetate disodium 0.75 mg, water for injection *qs*. For stability, it is highly recommended that the compounding pharmacy use this or another validated formula.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Guaifenesin Injection: 50 mg/mL in 500 mL and 1000 mL. There are several guaifenesin 5% injection products still listed as FDA-approved in the FDA Green Book, but there are no products presently being marketed. Compounding pharmacies may be available to provide (see ***Compatibility/Compounding Considerations*** above).

Guaifenesin is available in oral formulations labeled for use as an expectorant in horses.

The Association of Racing Commissioners International (ARCI) has designated guaifenesin as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

No parenteral preparations are FDA-approved. There are many OTC oral expectorant/cough preparations on the market. Many of these contain additional active ingredients that are not appropriate for use in dogs or cats.

Hemoglobin Glutamer-200 (Bovine)

(hee-moe-***gloe***-bin ***gloo***-ta-mer) *Oxyglobin®*

Semi-Synthetic Hemoglobin Replacer; Colloid

Prescriber Highlights

- ► Polymerized hemoglobin product of bovine origin that is FDA-approved for the treatment of anemia in dogs
- ► Typing and crossmatching not required prior to use
- ► Contraindications include advanced cardiac disease and renal impairment with oliguria or anuria.
- ► Many potential adverse effects, including discoloration of mucous membranes and skin, arrhythmias, bradycardia, vomiting and diarrhea, dyspnea, pulmonary edema, pleural effusion, and peripheral edema
- ► Carefully monitor for volume overload
- ► Many drug-laboratory effects
- ► Not available in the United States

Uses/Indications

Hemoglobin glutamer-200 (HG-200) is FDA-approved for the treatment of anemia in dogs, regardless of the cause of anemia (eg, hemolysis, blood loss, or ineffective erythropoiesis). HG-200 increases systemic oxygen content and improves clinical signs associated with anemia for at least 24 hours.[1] It is likely more valuable in dogs with regenerative anemias than those with nonregenerative anemias. It has also been used as a colloid for treating hypotension in dogs and cats.

Its primary benefit is for the patient that is anemic and difficult to transfuse due to unavailability of blood, or when no suitable donors are identified on crossmatch.[2]

Dogs with gastric dilatation-volvulus resuscitated with HG-200 reached resuscitation end points more rapidly and required significantly smaller volumes of crystalloids and colloids than those resuscitated with hetastarch 6%.[3]

Pharmacology/Actions

Hemoglobin glutamer-200 (HG-200) is a plasma volume expander with colloidal properties similar to dextran 70 and hetastarch. It is a bovine hemoglobin-based oxygen-carrying fluid that increases arterial oxygen content. The bovine hemoglobin in the product is polymerized into larger molecules to increase safety, efficacy, and intravascular persistence; it is shipped in a deoxygenated state and becomes oxygenated once circulated through the lungs. HG-200 does not contain red blood cells (RBCs) and is stroma free. HG-200 releases oxygen to tissue in a mechanism similar to endogenous hemoglobin, thereby increasing plasma and total hemoglobin concentrations and systemic oxygen carrying capacity. Because of its small size in comparison to normal RBCs, it may better deliver oxygen to cells supplied by severely constricted arteries. HG-200 shifts the oxygen dissociation curve to the right, so oxygen is transferred to tissues more easily.

Pharmacokinetics

In dogs receiving hemoglobin glutamer-200 (HG-200) at a dose of 15 mL/kg, peak hemoglobin concentrations increased by ≈2.5 g/dL; at a dose of 30 mL/kg, concentrations increased by ≈4 g/dL. Duration of effect continues for at least 24 hours. The half-life in dogs at labeled dosages is ≈18 to 43 hours, and HG-200 can be detected in plasma for 5 to 7 days after a single dose.

As with endogenous hemoglobin, HG-200 is metabolized and eliminated by the reticuloendothelial system. Small amounts of destabilized hemoglobin (less than 5%) may be excreted through the kidneys, causing a red discoloration of the urine.

Contraindications/Precautions/Warnings

Hemoglobin glutamer-200 (HG-200) is labeled as a single-dose treatment and should not be used in patients that have previously been treated with it. Administration of any foreign protein has the potential to cause immunologic reactions. Although low concentrations of IgG antibodies have been detected after administration of multiple doses, only rare, anecdotal reports of anaphylactic reactions have been reported. Plasma expanders such as HG-200 are generally contraindicated in dogs with advanced cardiac disease (ie, congestive heart failure) or renal impairment with oliguria or anuria. Safety and efficacy have not been evaluated in dogs with disseminated intravascular coagulation, thrombocytopenia with active bleeding, hemoglobinemia, hemoglobinuria, or autoagglutination.

HG-200 is a potent colloid and can cause vasoconstriction. In experimentally induced hypovolemic shock in dogs, HG-200 caused severe vasoconstriction and decreased cardiac output.[4] Because of its vasoconstrictive properties, the amount of HG-200 required for fluid resuscitation in trauma patients is ≈⅓ that of hetastarch.[5] Exercise caution to prevent volume-overloading patients when giving this drug, as hydrostatic pressures may be increased and cause pulmonary overload (eg, pleural effusion, pulmonary edema). Cats are particularly vulnerable to fluid overload, and slower infusion rates are recommended.

If an acute hypersensitivity reaction occurs, immediately discontinue the infusion and administer appropriate treatment. If a delayed hypersensitivity reaction occurs, immunosuppressant therapy is recommended.

Oxidative damage to HG-200 occurs after removal from the foil wrapper, leading to formation of methemoglobin. Toxic concentrations of methemoglobin can occur.[6] Therefore, HG-200 should be discarded 24 hours after removing from the foil wrapper.[7]

Adverse Effects

Adverse effects that occur in more than 4% of dogs treated with HG-200 include discoloration of mucous membranes, sclera (yellow, red, brown), urine (orange, red, brown), and skin (yellow); increased central venous pressure; ventricular arrhythmias (eg, AV block, tachycardia, premature ventricular contractions); ecchymoses/petechiae; bradycardia; vomiting; diarrhea; anorexia; tachypnea; dyspnea; pulmonary edema; harsh lung sounds/crackles; pleural effusion; fever; peripheral edema; hemoglobinuria; dehydration; and death.

Coughing, disseminated intravascular coagulopathy, melena, nasal discharge/crusts (red), peritoneal effusion, respiratory arrest, and weight loss (5% to 7% body weight) have been reported in ≈4% of dogs treated with HG-200.

Adverse effects occurring in less than 2% of dogs treated with HG-200 include abdominal discomfort on palpation, acidosis, cardiac arrest, cardiovascular volume overload (by echocardiography), collapse, cystitis, dark stool, discolored soft stool (red-brown) and tongue (purple), focal hyperemic areas on gums, forelimb cellulitis/lameness, hematemesis or hemoptysis (unable to differentiate), hypernatremia, hypotension, hypoxemia, lack of neurologic responses, left forebrain signs, nystagmus, pancreatitis, pendulous abdomen, polyuria, pulmonary thromboembolism, ptosis, reddened pinnae with papules/head shaking, reduction in heart rate, worsening thrombocytopenia, and venous thrombosis.

Increases in AST and ALT (not associated with histopathologic changes in the liver), increase in serum total protein, and hemoglobinuria may also be seen.

Following infusion, small amounts of unstabilized hemoglobin (less than 5%) may be excreted through the kidneys, resulting in transient red discoloration of the urine. This urine discoloration should not be interpreted as being caused by intravascular hemolysis and has no effect on renal function.

Cats are particularly susceptible to pulmonary edema and pleural effusion; rapid infusion and larger doses increase this risk. A retrospective study using low doses in 44 cats with hypotension reported respiratory changes (8), vomiting (2), and pigmented serum (30).[8] Most adverse effects were not considered to be clinically significant.

Reproductive/Nursing Safety

Safe use in breeding dogs and pregnant or lactating bitches has not been determined.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In healthy dogs given 2 doses of hemoglobin glutamer-200 (HG-200) up to 90 mL/kg (3 times the recommended dose) 3 days apart, clinical signs included yellow-orange discoloration of skin, ear canals, pinnae, mucous membranes, and sclera, red-dark-green-black discoloration of feces, brown-black discoloration of urine, red spotting of skin and/or lips (less common), decreased appetite and thirst, vomiting, diarrhea, and decreased skin elasticity. The frequency and/or intensity of these signs increased with repeated and increasing doses. All dogs survived.

Overdoses or rapid infusions (ie, more than 10 mL/kg/hour) may result in circulatory overload.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

No specific drug interactions have been noted. See ***Compatibility/Compounding Considerations***.

Laboratory Considerations

- Hemoglobin-based oxygen carriers (HBOCs) can impact several laboratory tests.
- The presence of hemoglobin glutamer-200 (HG-200) in serum may cause artifactual increases or decreases in the results of **serum chemistry tests**, depending on the type of analyzer and reagents used. May cause false increases in AST or creatinine. May cause false decreases in LDH. May cause unacceptable interference with GGT, albumin, or bilirubin
- There is reportedly no interference with directly measured hemoglobin tests, but due to the dilutional effects of HG-200, PCV and RBC count are not accurate measures of the degree of anemia for 24 hours following administration. **Prothrombin time** (PT) and **activated partial thromboplastin time** (aPTT) determined using methods that are mechanical, magnetic, and light scattering are accurate, but optical methods are not reliable while HG-200 is present.
- **Urine dipstick** measurements (eg, pH, glucose, ketones, protein) are inaccurate while urine is grossly discolored.

Dosages

DOGS:

Anemia, regardless of the cause (hemolysis, blood loss, or ineffective erythropoiesis) (label dosage; FDA-approved): One-time dose of 10 – 30 mL/kg IV at a rate of up to 10 mL/kg/hour.[9] Administer using aseptic technique via a dedicated standard IV infusion set and catheter through a central or peripheral vein. May be warmed to 37°C (98.6°F) prior to administration. Blood transfusions are not contraindicated in dogs that receive HG-200, nor is HG-200 contraindicated in dogs that have previously received a blood transfusion. Typing or crossmatching is not required prior to use.

Providing oxygen-carrying capacity until immunosuppressive drugs take effect in dogs with IMHA after a blood transfusion reaction (extra-label): 7 – 10 mL/kg IV every 12 hours can maintain hemoglobin concentrations above 3.5 g/dL; higher doses of 30 mL/kg may provide oxygen-carrying support for 48 to 72 hours.[10]

Trauma/resuscitation (extra-label):

a) Resuscitation of trauma patients in shock, with or without hemorrhage: Empirically, 3 – 5 mL/kg IV with concurrent crystalloid at ½ to 2 times maintenance fluid rate.[11] See ***Compatibility/Compounding Considerations***.

b) Provide oxygen-carrying capacity in the trauma patient: 10 – 15 mL/kg IV given over several hours. Care must be taken not to cause fluid overload.[12]

c) As a vasopressor once there is adequate intravascular volume in trauma patients: 3 – 5 mL/kg IV[5]

CATS:

Hypotension (extra-label): From a retrospective study of 44 cases, the average IV bolus dose and administration time was 3.1 mL/kg and 25 minutes.[8] Mean increase of systemic arterial pressure more than 20 mm Hg after the bolus. Most patients also received CRIs after bolus with a mean volume administered of 0.8 ± 0.5 mL/kg/hour. Mean SAP during CRI was 92 ± 18 mm Hg.

Provide oxygen-carrying capacity in the trauma patient (extra-label): 5 – 10 mL/kg IV given over several hours. Care must be taken not to cause fluid overload.[12] Rates of 0.5 to 2 mL/kg/hour have been recommended.[6]

Monitoring

- Hemoglobin
- Clinical signs of adequate tissue oxygenation
- Respiratory rate and character; thoracic auscultation
- Physical examination to check for adverse effects[6]
- Attitude and demeanor[6]
- Central venous pressure

Client Information

- This medicine is used to treat anemia. It is expensive and has many potential side effects. Your veterinarian will go over the cost and risks versus benefits for this agent before use.
- This medicine must be administered by your veterinarian.

Chemistry/Synonyms

Hemoglobin glutamer-200 ((HG-200; bovine) is a sterile, clear, dark purple solution containing 13 g/dL purified, polymerized hemoglobin of bovine origin in a modified lactated Ringer's solution. It has an osmolality of 300 mOsm/kg and a pH of 7.8. Less than 5% of the hemoglobin are unstabilized tetramers, and ≈50% have a molecular weight between 65 and 130 kD, with no more than 10% having a molecular weight more than 500 kD. The product contains less than the detectable concentration of 3.5 µg/mL free-glutaraldehyde and 0.05 EU/mL endotoxin.

Hemoglobin glutamer-200 (bovine) may also be known as HBOC-301, HB-200, HG-200, or *Oxyglobin®*.

Storage/Stability

The product remains stable at room temperature or refrigerated (2°C-30°C [36°F-86°F]) for up to 3 years; expiration date is printed on the bag. Do not freeze. It must remain in its overwrap during storage. Use the product within 24 hours of removing the overwrap. The foil overwrap serves as an oxygen barrier, protecting the hemoglobin from conversion to methemoglobin.

Compatibility/Compounding Considerations

Hemoglobin glutamer-200 should not be mixed with other solu-

tions or medications in the bag. Other IV solutions and medications should be administered via a separate site and line. Do not combine the contents of more than one bag.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:
Hemoglobin Glutamer-200 (bovine) in 60 mL and 125 mL ready-to-use infusion bags; *Oxyglobin*®; (Rx). FDA-approved for use in dogs. Not currently available in the United States; may be available in Europe

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions, and it is prohibited to be at racing premises. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS: NONE

Heparin

Unfractionated Heparin (UFH)

(***hep***-ah-rin)
Anticoagulant

Prescriber Highlights

- ► Parenteral anticoagulant used for thromboprophylaxis in dogs, cats, and horses as adjunctive treatment for thromboembolic disease
- ► Contraindications include known hypersensitivity, severe thrombocytopenia, or uncontrollable bleeding.
- ► The most common adverse effect is bleeding.
- ► Protamine may be used to reverse effects.
- ► Monitoring is necessary; however, specific guidelines are not yet clear for veterinary patients. Anti-Xa monitoring has been recommended during heparin treatment in dogs.

Uses/Indications

Heparin is primarily used for thromboprophylaxis in the adjunctive treatment for immune-mediated hemolytic anemia (IMHA), pulmonary thromboembolism, and other thromboembolic diseases. Prophylactic heparin can reduce the incidence of developing macrovascular thromboembolism in high-risk patients.

Thromboprophylaxis is recommended for all dogs with IMHA, except those with severe thrombocytopenia (ie, less than 30,000 platelets/μL).[1] Although heparin, aspirin, and clopidogrel have been used for thromboprophylaxis in dogs with IMHA, lack of validated therapeutic endpoints and lack of controlled studies make it difficult to determine the efficacy of one drug over another or effect on survival.[2]

Heparin use in patients with disseminated intravascular coagulation (DIC) is controversial. Heparin may be indicated in patients to prevent the formation of microthrombi during the hypercoagulable phase, in patients with evidence of arterial or venous thromboembolic disease, or in patients that do not have signs of hemorrhage but are judged to be at risk for thromboembolism due to severe systemic inflammation.[3]

In horses, heparin has been used in the treatment of jugular vein thrombophlebitis, DIC, and to prevent development of laminitis; however, there are no controlled, prospective studies that demonstrate efficacy for these indications. Heparin has also been administered systemically or as part of a lavage solution administered intraperitoneally to prevent intra-abdominal adhesion formation after surgery, but its efficacy is uncertain.[4–8] Heparin may prevent equine herpesvirus myeloencephalopathy during an equine herpesvirus-1 outbreak.[9]

The use of heparin to prevent clotting in peripheral IV catheters in human medicine has largely been replaced by flushing fluid lines with 0.9% sodium chloride. A study in dogs concluded that over 48 hours, peripheral catheter maintenance with 0.9% saline was equally effective as flushing with heparinized saline.[10] Heparin lock solution, which contains high concentrations of heparin, has been used as a dwell solution to prevent clot formation in long-term central venous catheters such as those used for hemodialysis. When these solutions are used, the catheter should be clearly labeled, and the dwell solution aspirated and discarded prior to catheter use. See ***Laboratory Considerations***.

Pharmacology/Actions

Heparin binds to antithrombin (AT), causing a conformational change that accelerates the binding of AT to several activated clotting factors, particularly factor Xa and factor IIa (thrombin). This binding inactivates their procoagulant activity in the clotting cascade.[11] Heparin also inhibits the activation of factor XIII (fibrin stabilizing factor), preventing the formation of stable fibrin clots. Heparin does not have fibrinolytic activity and will not lyse existing clots.

Heparin causes increased release of lipoprotein lipase, thereby increasing the clearance of circulating lipids and boosting plasma concentrations of free fatty acids.

Pharmacokinetics

Anticoagulant activity begins immediately after direct IV bolus injection but may take up to 1 hour after SC injection. When heparin is given by IV CRI, an initial bolus can be administered to rapidly achieve full anticoagulant activity. Even though heparin is not systemically absorbed when given orally, an anticoagulant effect is possible after oral administration.[12] Preliminary work with inhaled heparin in dogs has been unsuccessful.[13]

In healthy dogs, bioavailability after SC injection is ≈50%. Heparin is extensively protein bound, primarily to fibrinogen, low-density lipoproteins, and globulins. It does not appreciably cross the placenta or enter milk.

The metabolism of heparin is not completely understood. The drug is apparently partially metabolized by the liver and also inactivated by the reticuloendothelial system. Peak anti-factor Xa activity and anticoagulant effects are seen in healthy dogs 2 to 3 hours after a single dose of 300 units/kg SC.[14] In these dogs, plasma heparin concentrations were in the therapeutic range between 1 and 6 hours after administration.[15] In healthy cats, a dose of 250 units/kg SC achieved a target anti-Xa activity 4 hours following injection, and had sustained anti-Xa activity at trough time points.[16,17]

Contraindications/Precautions/Warnings

Heparin is contraindicated in patients that are hypersensitive to it and in patients with severe thrombocytopenia or coagulopathy.[3,11] Because heparin is derived from bovine or porcine tissues, hypersensitivity reactions may be possible.

Individual anticoagulant response to a given dose of heparin may vary based on antithrombin concentrations and severity of underlying condition being treated; monitoring is recommended. Use with caution in patients at an increased risk for hemorrhage.

Do not administer heparin IM, as it may cause hematoma formation. Hematomas, pain, and irritation may occur after SC dosing.

In humans, resistance to heparin is possible in patients with fever, thrombosis, thrombophlebitis, cancer, antithrombin deficiency, and in postsurgical patients.[11]

Medication errors can be fatal. Medication errors have occurred due to use of incorrect heparin sodium strength when preparing pa-

tient doses. Confirm correct product prior to preparation and administration. The word "unit" should be written out on all doses to avoid errors, as a "U"may easily be mistaken for a zero.

Adverse Effects

Bleeding is the most common adverse effect associated with heparin and can result in anemia and thrombocytopenia. Patients with hypertension, GI ulcers, hepatic disease, thrombocytopenia, and older patients may be at an increased risk for hemorrhage.[11] Pain at injection site is also possible.

In humans, additional adverse effects reported include elevated AST and ALT; cutaneous necrosis; rebound hyperlipidemia; hyperkalemia; delayed, transient alopecia; suppressed aldosterone synthesis; injection site reactions; pain on injection; and priapism.[11,18] Osteoporosis has been reported after long-term, high-dose administration, and vasospastic reactions several days after initiation of therapy have rarely been reported.

In humans, heparin-induced thrombocytopenia (HIT) is a serious antibody-mediated reaction that can occur with heparin treatment.[11] HIT has not yet been reported in animals.

Reproductive/Nursing Safety

Although heparin does not cross the placenta and is generally the anticoagulant of choice during pregnancy, its safe use in pregnancy has not been firmly established.[11] Heparin is unlikely to be excreted into milk because of its large molecular weight and negative charge[11,19]; however, preservative-free heparin is recommended for use during lactation, as the benzyl alcohol preservative may enter the milk.[11]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Bleeding is the primary effect of a heparin overdose. Hematuria, tarry stools, petechiae, and bruising may be seen before frank bleeding occurs. Protamine can reverse the effects of heparin; see ***Protamine*** for more information.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretically possible in humans or animals receiving heparin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aspirin**: May increase the risk for hemorrhage
- **Clopidogrel**: May increase the risk for hemorrhage
- **Dextran or Hetastarch**: May increase the risk for hemorrhage
- **Nonsteroidal Anti-Inflammatory Drugs**: May increase the risk for hemorrhage
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, sertraline**): May increase the risk for hemorrhage
- **Warfarin**: May increase the risk for hemorrhage

The following drugs may partially counteract heparin's anticoagulant effects:

- **Antihistamines**
- **Nitroglycerin** (IV)
- **Propylene Glycol**
- **Digoxin**
- **Tetracyclines**

Laboratory Considerations

- The presence of heparin in samples obtained from indwelling catheters can alter the results of coagulation tests such as prothrombin time (PT) and activated partial thromboplastin time (aPTT). To avoid sample contamination in patients receiving a continuous infusion of heparin, a dedicated IV catheter should be used or a large presample should be removed prior to sampling.
- When heparin is used as an anticoagulant in vitro (eg, in **blood collection containers**), white cell counts should be performed within 2 hours of collection. Do not use heparinized blood for platelet counts, erythrocyte sedimentation rates, erythrocyte fragmentation tests, or for any tests involving complement or isoagglutinins. Errors in blood gas determinations for CO_2 pressure, bicarbonate concentration, or base excess may occur if heparin encompasses 10% or more of the blood sample.
- Heparin can interfere with the results of the **BSP** (sulfobromophthalein, bromosulfophthalein) test by changing the color intensity of the dye and shifting the absorption peak from 580 nm to 595 nm.
- Heparin can cause falsely elevated values of serum **thyroxine** if using competitive protein binding methods of determination. Radioimmunoassay (RIA) and protein bound iodine methods are apparently unaffected by heparin.
- Heparin may cause increases in **AST** and **ALT**. It is unclear if this is due to interference with the laboratory test or to hepatotoxicity.

Dosages

DOGS:

NOTE: In critically ill animals, an IV CRI is more likely to result in consistent anticoagulation effects and prolongation of aPTT.

Thromboprophylaxis in patients with immune-mediated hemolytic anemia (IMHA) (extra-label):

a) 150 – 300 units/kg SC every 6 hours.[1,2] Individual responses are highly variable; in one study, dosages ranging from 150 – 566 units/kg SC every 6 hours were required to reach target anti-factor Xa activity.[20]

b) 100 units/kg IV bolus, then 900 units/kg/day IV CRI[1]

c) Loading dose of 100 units/kg IV followed by 20 – 50 units per kg/hour IV CRI.[21] In critically ill animals, an IV CRI is more likely to result in consistent anticoagulation and prolongation of aPTT. Small dose changes can result in large changes in aPTT; starting at a low dose and slowly titrating in increments of 5 units/kg/hour is recommended. When discontinuing, taper the dose gradually (eg, decrease by 50 units/kg/day over 3 to 4 days) to help prevent rebound hypercoagulability.[22]

Thromboprophylaxis (extra-label):

a) 100 units/kg IV bolus, then 480 – 900 units/kg/day IV CRI[23]

b) 150 – 300 units/kg SC every 6 hours[23]

Arterial thromboembolic disease (extra-label): 200 – 300 units/kg IV initially followed by 200 – 250 units/kg SC every 6 to 8 hours[24]

Disseminated intravascular coagulopathy (extra-label): 75 – 100 units/kg SC every 8 hours; however, use is controversial and optimal dosing regimens are unknown.[25]

CATS:

Thromboprophylaxis for feline arterial thromboembolism (FATE) (extra-label): No outcome-based studies have evaluated any heparin dose for FATE, and dosage recommendations are highly variable. **NOTE**: Only the SC route has been studied in cats.

a) 50 – 100 units/kg (low-dose) or 200 – 300 units/kg (high-dose)

SC every 6 to 8 hours.[26,27] There is wide individual variation in heparin pharmacokinetics with FATE, and some cats may require doses up to 475 units/kg.[28]

b) 250 – 375 units/kg IV initially followed by 150 – 250 units/kg SC every 6 to 8 hours[24]

Thromboprophylaxis (extra-label): 250 units/kg SC every 6 hours[23]

HORSES:

Thromboprophylaxis (extra-label): 40 – 100 units/kg SC or IV every 6 hours have been noted[29,30] but are not well established and recommendations range widely.

Prevention of abdominal adhesions (extra-label): 30,000 – 50,000 units of heparin in 10 L of lavage fluid (warm LRS) administered intraperitoneally via a 32 French fenestrated trocar catheter placed in the right ventral abdomen at the time of surgery. Lavage should be performed at 12, 18, 36, and 48 hours post-surgery and allowed to drain through a Heimlich valve. Remove drain after final lavage to prevent occlusion.[4]

Monitoring

NOTE: Appropriate monitoring in veterinary patients receiving heparin is controversial; no outcome-based guidelines have been accepted. Anti-factor Xa activity, activated clotting time (ACT), prothrombin time (PT), and activated partial thromboplastin times (aPTT) may all be used to monitor therapy.

- Anti-factor Xa activity: Target of 0.35 – 0.7 units/mL in dogs.[23] Although there is insufficient evidence for a strong target recommendation in cats, 0.35 – 0.7 units/mL may be reasonable until more evidence is available.[31] The suggested thromboprophylactic range for horses is 0.1 – 0.2 units/mL. Anti-Xa activity may be more reliable than aPTT and may improve survival during heparin treatment for IMHA.[20,32] It may be particularly useful if bleeding occurs or for patients with renal dysfunction.
- Activated partial thromboplastin time (aPTT): Monitoring parameter most often recommended for dogs; less reliable monitoring parameter for cats but may still be recommended.[33] Target is prolongation of aPTT by 1.5 to 2 times baseline value (1.3 – 1.5 sometimes used); however, aPTT may not correlate with anti-Xa activity in dogs, especially those with inflammatory diseases.
- Thromboelastography (TEG): Modified thromboelastography has been significantly correlated to both anti-activated factor X activity and aPTT and could potentially be used to monitor dogs treated with heparin; however, this test is often not readily available.[34]
- Baseline and periodic CBC with platelet counts as needed based on clinical condition
- Baseline and periodic physical examinations to check for signs of bleeding (eg, hematuria, hematochezia, melena, epistaxis, bleeding from the gums)

Client Information

- This medicine must be injected under the skin (subcutaneously). Be sure you understand how to correctly give the injection. Several injections may be required each day.
- Watch for signs of bleeding, such as blood in the urine or stool or bleeding from the nose or gums. If you see any signs of bleeding, contact your veterinarian immediately.
- If your animal is listless (lacking energy or interest in things), appears to be having trouble breathing, has trouble walking, or loses the use of its rear legs, contact your veterinarian immediately.

Chemistry/Synonyms

Heparin is an anionic, heterogeneous sulfated glycosaminoglycan molecule with an average molecular weight of 12,000 daltons that is found naturally in mast cells. It is available commercially as the sodium salt and is obtained from either porcine intestinal mucosa or bovine lung tissue (sodium salt only). Heparin sodium occurs as a white, amorphous, hygroscopic powder having a faint odor. It is soluble in water and practically insoluble in alcohol; the commercial injections have a pH of 5 to 7.5. Heparin potency is expressed in terms of USP heparin units, and values are obtained by comparing against a standard reference from the USP. The USP requires that potencies be not less than 180 units/mg on a dried basis for heparin derived from lung tissue, and 140 units/mg when derived from all other tissue sources.

Heparin sodium may also be known as heparinum natricum, sodium heparin, and soluble heparin; many trade names are available.

Storage/Stability

Heparin solutions should be stored at room temperature (15°C-30°C [59°F-86°F]) and not frozen. Avoid excessive exposure to heat.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Heparin sodium is reportedly physically **compatible** with the following IV solutions and drugs: amino acids 4.25%-dextrose 25%, dextrose-Ringer's combinations, dextrose-lactated Ringer's solutions, fat emulsion 10%, Ringer's injection, *Normosol®-R*, aminophylline, amphotericin B lipid complex, ascorbic acid injection, bleomycin sulfate, buprenorphine HCl, butorphanol tartrate, calcium gluconate, cefazolin sodium, chloramphenicol sodium succinate, clindamycin phosphate, dimenhydrinate, dexamethasone sodium phosphate, dexmedetomidine, dopamine HCl, erythromycin gluceptate, famotidine, fentanyl citrate, isoproterenol HCl, lidocaine HCl, magnesium sulfate, metoclopramide, metronidazole with sodium succinate, norepinephrine bitartrate, potassium chloride, prednisolone sodium succinate, propofol, ranitidine HCl, sodium bicarbonate, verapamil HCl, and vitamin B-complex with or without vitamin C.

Heparin **compatibility information conflicts** or is dependent on diluent or concentration factors with the following drugs or solutions: dextrose-saline combinations, dextrose in water, lactated Ringer's injection, saline solutions, ampicillin sodium, amphotericin B (conventional), atracurium besylate, diltiazem HCl, diphenhydramine HCl, dobutamine HCl, hydrocortisone sodium succinate, methylprednisolone sodium succinate, midazolam HCl, oxytetracycline HCl, penicillin G sodium/potassium, pantoprazole sodium, and tetracycline HCl.

Heparin sodium is reported physically **incompatible** when mixed with the following solutions or drugs: sodium lactate 1/6 M, amikacin sulfate, chlorpromazine HCl, ciprofloxacin, codeine phosphate, cytarabine, daunorubicin HCl, diazepam, dolasetron HCl, doxorubicin HCl, doxycycline hyclate, erythromycin lactobionate, gentamicin sulfate, hyaluronidase, hydroxyzine HCl, hydromorphone HCl, ketamine HCl, levorphanol bitartrate, meperidine HCl, methadone HCl, mitoxantrone, morphine sulfate, pentazocine lactate, phenytoin sodium, polymyxin B sulfate, and vancomycin HCl.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

NOTE: To minimize risk for medication errors, product labels for heparin sodium list the strength of the entire container followed closely by the strength per mL (eg, heparin 10,000 USP units/10 mL, 1000 USP units/mL). Always read product labels carefully.

Heparin Sodium Injection: 1000 units/mL, 5000 units/mL, 10,000 units/mL, and 20,000 units/mL in 0.5 mL, 1 mL, 2 mL, 4 mL, 5 mL, 10 mL, and 30 mL vials; generic; (Rx)

Heparin Unit-Dose Sodium Injection: 1000 units/dose, 2500 units/dose, 5000 units/dose, 10,000 units/dose and 20,000 units/dose in 0.5 mL and 1 mL single-dose vials; *Tubex®*, *Carpuject®*; generic; (Rx)

Heparin Sodium and 0.9% Sodium Chloride Injection: 250 units in 250 mL; 1000 units in 500 mL; 2000 units, 4000 units, 5000 units, 10,000 units and 30,000 units in 1000 mL; generic; (Rx)

Heparin Sodium and 0.45% Sodium Chloride Injection: 2500 units in 250 mL; 4000 units in 1000 mL; 12,500 in 250 mL and 25,000 units in 250 mL and 500 mL, respectively; 25,000 units in 250 mL and 500 mL; generic; (Rx)

Heparin Sodium and 5% Dextrose Injection: 2500 units in 250 mL; 20,000 units in 500 mL; 12,500 units in 250 mL and 25,000 units in 500 mL; 10,000 units in 100 mL and 25,000 units in 250 mL; generic; (Rx)

Heparin Sodium Lock Flush (IV use) Injection: 10 units/mL in 5 mL prefilled syringes; 100 units/mL in 3 mL and 5 mL prefilled syringes; generic; (Rx)

Hyaluronate

Hyaluronan

(hy-al-yoo-***ron***-nate) *Hyalovet®, Hyvisc®, Legend®*

Mucopolysaccharide

Prescriber Highlights

- ► Parenteral, high-viscosity mucopolysaccharide used for synovitis
- ► No contraindications listed on the product label
- ► Adverse effects vary by route of administration
- ► Different products have different dosages; check label before using.

Uses/Indications

Hyaluronate is useful in the treatment of synovitis not associated with severe degenerative joint disease. It may be helpful for treatment of secondary synovitis in conditions where full-thickness cartilage loss exists.

The choice of a high molecular weight product (molecular weight more than $1x10^6$) versus a low molecular weight one is controversial. One author states *…low molecular weight products (which tend to be less expensive) can be equally efficacious in ameliorating signs of joint disease. When synovial adhesions and pannus are to be avoided (as in most surgeries for carpal and fetlock fracture fragment removal), higher molecular weight preparations are recommended because they inhibit proliferation of synovial fibroblasts.*[1] However, there are no controlled studies directly comparing the various products for treating joint disease and product choice is primarily a result of a clinician's personal preference.

There is considerable interest in oral hyaluronate administration for treatment of equine joint disease. One blinded, controlled study found that the use of an oral gel nutraceutical significantly reduced synovial effusion in tarsocrural joints postarthroscopic surgery for osteochondritis dissecans (OCD).[2]

In dogs, one study looked at using an oral supplement (*Hyaloral®*) containing hyaluronic acid, hydrolyzed collagen, glucosamine, chondroitin sulfate, and gamma oryzanol to prevent elbow dysplasia. The number of dogs (Labradors) developing elbow dysplasia was significantly lower in the treated group compared to the control, but the study had several limitations, including lack of blinding, radiographic evaluation (not CT or MRI) only, and using a fixed dose combination product where determining which components were responsible for the effect was not possible.[3]

Pharmacology/Actions

Hyaluronate is found naturally in the connective tissue of both humans and animals and is chemically identical regardless of species. Highest concentrations are found in the synovial fluid, vitreous of the eye, and umbilical cord. Surfaces of articular cartilage are covered with a thin layer of a protein-hyaluronate complex; hyaluronate is also found in synovial fluid and the cartilage matrix. The net effects in joints include a cushioning effect, reduction of protein and cellular influx into the joint, and lubrication. Hyaluronate has a direct anti-inflammatory effect in joints by scavenging free radicals and suppressing prostaglandins.

Pharmacokinetics

In the equine joint, the half-life of hyaluronate has been reported to be 96 hours.[4]

Contraindications/Precautions/Warnings

No contraindications to the use of hyaluronate are noted on the product labels. Hyaluronate should not be used as a substitute for adequate diagnosis; radiographic examinations should be performed to rule out severe fractures. Do not perform intra-articular injections through skin that has recently been fired or blistered, or that has excessive scurf and counterirritants on it. Administer hyaluronate only by routes listed on the product label.

Adverse Effects

The following adverse effects are based on voluntary post-approval reporting. IV administration: occasional depression, lethargy, and fever. Intra-articular administration: transient lameness, joint effusion, joint or injection-site swelling, joint pain, and synovial sepsis.[5] Effects generally subside within 24 to 48 hours; some animals may require up to 96 hours for resolution. No treatments for these effects are recommended. When used in combination with other drugs, incidence of flares may be higher. No systemic adverse effects have been noted.

Reproductive/Nursing Safety

Although hyaluronate is unlikely to cause problems, safe use in breeding animals has not been established and most manufacturers caution against its use in these animals.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute toxicology studies performed in horses have demonstrated no systemic toxicity associated with overdoses.

Drug Interactions

- None were noted.

Laboratory Considerations

- None were noted.

Dosages

HORSES:

Joint dysfunction of the carpus or fetlock due to noninfectious synovitis associated with osteoarthritis (label dosage; FDA-approved):

NOTE: Because of the differences in the commercially available products, see each individual product's label for specific dosing information.

- *Hyvisc®*: 22 mg/joint (NOT mg/kg) IA in small or medium joints (eg, carpal, fetlock), 44 mg/joint IA in larger joints (eg, hock); treatment may be repeated weekly for a total of 3 treatments

- *Hyalovet*®: 20 mg/joint (NOT mg/kg) IA in small or medium joints (eg, carpal, fetlock); more than 1 joint may be treated at the same time. Treatment may be repeated after 1 or more weeks, but do not exceed 2 injections each week for a total of 4 weeks.
- *Legend*®:
  a) 20 mg IA in the carpus or fetlock. Treatment may be repeated weekly for a total of 3 treatments.
  b) 40 mg IV slowly into the jugular vein. Treatment may be repeated weekly for a total of 3 treatments.
- *NexHA*®: 40 mg IV slowly into the jugular vein at weekly intervals for a total of 3 treatments

Reducing joint effusion postarthroscopic surgery for osteochondritis dissecans (OCD) (extra-label): 100 mg/horse (NOT mg/kg) PO (as an oral gel [*Conquer*®]) once daily for 30 days[2]

DOGS:

Adjunctive treatment of synovitis not associated with damaged articular cartilage (extra-label): Using a high molecular weight compound: 5 – 15 mg/joint (NOT mg/kg) IA once,[6–8] or 5 mg/joint (NOT mg/kg) IA weekly for 3 to 5 weeks[8]

Monitoring

- Efficacy
- Adverse effects

Client Information

- Hyaluronate should only be administered by your veterinarian.

Chemistry/Synonyms

Hyaluronate sodium (HS) is the sodium salt of hyaluronic acid, which is a naturally occurring high-viscosity mucopolysaccharide. Many of the commercially available hyaluronic acid products are derived from the combs of roosters.

Hyaluronate sodium may also be known as HA, sodium hyaluronate, hyaluronan, hyaluronic acid, and natrii hyaluronas; many trade names are available.

Storage/Stability

Store at room temperature or refrigerate depending on the product label. Do not freeze. Protect from light. Discard unused portion.

Compatibility/Compounding Considerations

Do not mix with other drugs unless the product's label states otherwise.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Hyaluronate Sodium: 10 mg/mL or 11 mg/mL in 2 mL vials or prefilled syringes; *Hyalovet*®, *Hyvisc*®; (Rx) FDA-approved for IA use in horses not intended for food.

Hyaluronate Sodium: 10 mg/mL in 2 mL or 4 mL single-dose vials and 20 mL multi-dose vials; *Legend*®; (Rx). FDA approved for IV or intra-articular administration for use in horses not intended for food.

Hyaluronate Sodium: 10 mg/mL in 4 mL single-dose vials; *NexHA*®; (Rx). FDA-approved for IV use only for use in horses not intended for food.

There may also be other hyaluronate products marketed as topical solutions, semen extenders, and oral supplements. These products are not necessarily approved by the FDA. Products that are approved as devices (ie, semen extenders, wound management products) should not be used in place of FDA-approved drug products.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Hydralazine

(hye-***dral***-a-zeen) *Apresoline*®

Vasodilator

Prescriber Highlights

- ► Vasodilator drug used primarily for systemic hypertension or adjunctive treatment of congestive heart failure
- ► Contraindications include known hypersensitivity, hypovolemia, or pre-existing hypotension.
- ► Use caution in patients with severe renal disease, intracranial bleeding, or pre-existing autoimmune diseases.
- ► Adverse effects include hypotension, reflex tachycardia, sodium/water retention, or GI distress (eg, vomiting, diarrhea).

Uses/Indications

The primary uses of hydralazine in veterinary medicine have been as an afterload reducer in patients with congestive heart failure (CHF) or aortic valve disease. By reducing peripheral vascular resistance, hydralazine promotes forward left ventricular stroke volume and reduces the mitral regurgitant fraction. Hydralazine is not particularly useful in treating heart failure when myocardial disease is present. Additionally, it may be useful in dogs and cats with large septal defects or severe aortic regurgitation. When used to treat systemic hypertension, hydralazine may be used in combination with other drugs (eg, beta-blockers) to offset hydralazine's tendency to cause reflex tachycardia and fluid retention.

Pharmacology/Actions

Hydralazine is a direct systemic arterial vasodilator, which acts upon vascular smooth muscle and reduces peripheral resistance and blood pressure (BP). Hydralazine is a semicarbazide-sensitive amine oxidase (SSAO) inhibitor. It is believed that hydralazine alters cellular calcium metabolism in smooth muscle, thereby interfering with calcium movements and preventing the initiation and maintenance of the contractile state. Hydralazine has more effect on arterioles than on veins.

In patients with congestive heart failure (CHF), hydralazine significantly increases cardiac output and decreases systemic vascular resistance. Cardiac rate may be slightly increased or unchanged, while BP, pulmonary venous pressure, and right atrial pressure may be decreased or unchanged.

When hydralazine is used to treat primary or secondary systemic hypertension, increased heart rate, cardiac output, and stroke volume can be noted. Hydralazine may activate the renin-angiotensin system, and in humans, the drug has been documented to increase sodium and water retention if not given with diuretics. Sodium and water retention has not been documented in veterinary medicine, but careful monitoring is recommended.

Parenteral hydralazine administration can cause respiratory stimulation.

Pharmacokinetics

Specific pharmacokinetic parameters for this drug in veterinary species are limited, but in dogs, hydralazine is rapidly absorbed after oral administration with an onset of action within 1 hour and peak effects at 3 hours.[1] Food decreases oral bioavailability in dogs by about 63%.[2] At lower doses, there is a relatively high first-pass effect, but this is apparently a saturable process as bioavailability increases with the dose.[2] Duration of action of hydralazine in dogs after oral administration is reportedly 11 to 13 hours. N-acetylation is a primary enzymatic pathway for hydralazine metabolism, and this pathway is mostly absent in dogs, leading to concerns for increased risks for toxicity.

Hydralazine is widely distributed in body tissues. In humans,

≈85% of the drug in the blood is bound to plasma proteins. Hydralazine crosses the placenta, and small amounts are excreted into the milk. Hydralazine is extensively metabolized in the liver, and ≈15% is excreted unchanged in the urine. The half-life in humans is usually 2 to 4 hours but may be as long as 8 hours.

Contraindications/Precautions/Warnings

Hydralazine is contraindicated in patients that are hypersensitive to it. The drug is listed as contraindicated in human patients with mitral valvular rheumatic disease, but it has been recommended for use in small animal patients with myxomatous mitral valve disease. It is not recommended to use the drug in patients with hypovolemia or pre-existing hypotension.

Hydralazine doses need to be titrated upwards carefully, as severe hypotension can result.

Hydralazine should be used with caution in patients with renal disease. Secondary to reduced renal blood flow, hydralazine can activate the renin-angiotensin-aldosterone system (RAAS) and exacerbate renal injury.

In humans, a syndrome resembling systemic lupus erythematosus has been documented after hydralazine use. Although this syndrome has not been documented in veterinary patients, the drug should be used with caution in patients with pre-existing autoimmune diseases.

Do not confuse hydrALAzine with hydrOXYzine.

Adverse Effects

The most prevalent adverse effects seen in small animals are hypotension, weakness, lethargy, and syncope, particularly when doses are increased too fast. Reflex tachycardia, sodium and water retention, and GI distress (eg, vomiting, diarrhea) can also occur. Reflex sinus tachycardia may be treated with beta-blockers; however, caution must be exercised due to the risk for reduced cardiac performance. Hydralazine can increase creatinine levels due to decreased renal perfusion. Other adverse effects documented in humans that could occur include systemic lupus erythematosus-like syndrome, lacrimation, conjunctivitis, blood dyscrasias, urinary retention, constipation, and hypersensitivity reactions. Peripheral neuritis may occur and appears to be due to hydralazine-induced pyridoxine deficiency.[3]

Reproductive/Nursing Safety

Hydralazine crosses the placenta and teratogenic effects (eg, cleft palate, facial and cranial bone malformations) have been noted in mice.

Hydralazine is excreted in milk. According to the American Academy of Pediatrics, hydralazine is compatible with breastfeeding, but exercise caution.[4]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose /Acute Toxicity

Overdoses may be characterized by severe hypotension, tachycardia or other arrhythmias, skin flushing, and myocardial ischemia. Cardiovascular system support is the primary treatment modality. Evacuate gastric contents and administer activated charcoal using standard precautionary measures if the ingestion was recent and cardiovascular status has been stabilized. Treat shock using volume expanders without using pressor agents if possible. If a pressor agent is required to maintain blood pressure (BP), the use of a minimally arrhythmogenic agent (eg, phenylephrine) is recommended. Monitor BP and renal function diligently.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydralazine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **enalapril**): May cause an additive hypotensive effect; may be used for therapeutic advantage
- **Diazoxide**: May cause profound hypotension
- **Diuretics**: May cause an additive hypotensive effect; usually used for therapeutic advantage
- **Furosemide**: Hydralazine may increase furosemide's renal effects.
- **monoamine oxidase Inhibitors** (MAOIs; eg, **amitraz, linezolid, selegiline**): May cause an additive hypotensive effect
- **Propranolol**: Concurrent use may increase the risk for propranolol adverse effects, such as bradycardia, fatigue, and bronchospasm. With concomitant oral administration, hydralazine increased propranolol bioavailability, peak concentration, and AUC.[5]
- **Sildenafil**: May cause an additive hypotensive effect
- **Sympathomimetics** (eg, **epinephrine**): Hydralazine may cause decreased pressor effect and additive tachycardia.

Laboratory Considerations

- None were noted.

Dosages

Because of the sodium and water retention associated with this drug, it is often used concurrently with a diuretic when used for adjunctive treatment of heart failure. When used to treat systemic hypertension, a diuretic may not be required.

DOGS:

Adjunctive therapy in the treatment of heart failure secondary to valve disease (extra-label): Published high-level evidence is not available to support any dosage, but many cardiologists believe the drug may be useful in certain circumstances, particularly in dogs with refractory CHF. The following dosage regimen is one example:

The effective dose is 0.5 – 3 mg/kg PO every 12 hours. The dose must be titrated, starting with a low dose and titrating upwards in 0.5 mg/kg increments.

In dogs that are not receiving ACE inhibitors: Establish initial baseline parameters (eg, mucous membrane color, capillary refill time, murmur intensity, cardiac size on radiographs, and severity of pulmonary edema). Starting dose is 1 mg/kg PO every 12 hours, and repeat assessments are made in 12 to 48 hours. If no response is identified, increase the dosage to 2 mg/kg every 12 hours. Repeat assessments as above and increase to 3 mg/kg PO every 12 hours if there is no response. Hydralazine can be titrated with or without blood pressure (BP) monitoring. If BP cannot be monitored, titration is performed more slowly while clinical and radiographic signs are monitored.

If BP measurement is available, dosage titration can be made more rapidly than above. Measure baseline BP. Administer the drug 1 mg/kg PO. Repeat BP measurement in 1 to 2 hours, and if BP has decreased by at least 15 mm Hg, administer every 12 hours from then on. If the response is inadequate, give another 1 mg/kg dose and repeat BP measurement in 1 to 2 hours. This may be repeated until a cumulative dose of 3 mg/kg has been given within a 12-hour period. The resulting cumulative dose becomes the

dosage to be given every 12 hours.

In dogs that are receiving ACE inhibitors: Give hydralazine with caution as severe hypotension may occur if the dosage is not titrated carefully. Begin dosing at 0.5 mg/kg PO every 12 hours with BP monitoring and increase in 0.5 mg/kg increments until a response is identified to a maximum of 3 mg/kg within a 12-hour period. Consider referral to a board-certified cardiologist.

For dogs with acute, fulminant heart failure due to severe mitral regurgitation and not receiving ACE inhibitors: 2 mg/kg PO every 12 hours along with IV furosemide. Monitor BP closely.[6,7]

Systemic hypertension (extra-label): For severe, acute hypertension, hydralazine can be considered as an alternative to nitroprusside. Parenteral doses of 0.5 – 3 mg/kg IV every 12 hours or a 0.1 mg/kg IV loading dose, followed by 1.5 – 5 µg/kg/minute IV CRI, have been noted.[8] Oral dosages of 0.5 – 3 mg/kg PO every 12 hours to effect have also been reported and are commonly used. For long-term use, 0.5 – 2 mg/kg PO every 12 hours[9]

CATS:

Adjunctive therapy in the treatment of heart failure (extra-label): See the dog dosage above for heart failure but start titration at 2.5 mg/cat (NOT mg/kg), and, if necessary, increase up to 10 mg/cat (NOT mg/kg).[10]

Systemic hypertension (extra-label): For severe, acute hypertension: Parenteral doses of 1 – 2.5 mg/cat (NOT mg/kg) SC; may be repeated in 15 to 30 minutes if systolic BP has not decreased; or 0.1 mg/kg IV loading dose, followed by 1.5 – 5 µg/kg/minute IV CRI, have been noted.[9] Oral dosages of 2.5 mg/cat PO every 12 hours to effect have also been recommended. For long-term treatment of hypertension in cats, hydralazine is usually considered as a third- or fourth-step drug after amlodipine, ACE inhibitors, and possibly spironolactone. Hydralazine is usually dosed at 2.5 mg/cat (NOT mg/kg) PO every 12 to 24 hours.[9]

HORSES:

Adjunctive therapy in the treatment of heart failure (afterload reducer); (extra-label): Not commonly used in horses. One dosage recommendation is 0.5 mg/kg IV; for long-term therapy, use 0.5 – 1.5 mg/kg PO every 12 hours.[11]

Monitoring

- Baseline thoracic radiographs
- Clinical signs of CHF (eg, exercise intolerance, cough, increased resting respiratory rate and effort, mucous membrane color)
- Hydration status, urine output
- Serum electrolytes
- If possible, arterial blood pressure and venous PO_2. A mean arterial pressure (MAP) of between 60 and 80 mm Hg has been recommended when used in dogs for the short-term treatment of CHF secondary to valve disease.[12]
- Because blood dyscrasias have been noted in humans, consider monitoring CBC.

Client Information

- Give this medication with food.
- When starting your animal on this medication, your veterinarian may start with a low dose and gradually increase it over time. Be sure you are giving your animal the right dose.
- If the initial dose is too large, hydralazine may cause low blood pressure (BP) and cause your animal's condition to worsen. Loss of appetite, depression, lack of energy, or muscle weakness can indicate that BP is too low.

Chemistry/Synonyms

Hydralazine HCl, a phthalazine-derivative antihypertensive and vasodilating agent, occurs as an odorless, white to off-white crystalline powder with a melting point between 270°C and 280°C (518°F-536°F) and a pK_a of 7.3. One gram is soluble in ≈25 mL of water or 500 mL of alcohol. The commercially available injection has a pH of 3.4 to 4.

Hydralazine may also be known as apressinum, hydralazini, hydrallazine, idralazina, *or Apresoline®*.

Storage/Stability

Store the hydralazine tablets in tight, light-resistant containers at room temperature. Store the injectable product at room temperature; avoid refrigeration or freezing.

When hydralazine is mixed with most infusion solutions, a color change can occur, which does not necessarily indicate a loss in potency (if occurred over 8 to 12 hours).

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Hydralazine is reported to be physically **compatible** with the following infusion solutions and drugs: dextrose-Ringer's combinations, dextrose-saline combinations, Ringer's injection, lactated Ringer's injection, sodium chloride solutions, and dobutamine HCl.

Hydralazine is reported to be physically **incompatible** when mixed with 10% dextrose or fructose and is reported to be physically **incompatible** when mixed with the following drugs: aminophylline, ampicillin sodium, chlorothiazide sodium, edetate calcium disodium, hydrocortisone sodium succinate, phenobarbital sodium, and verapamil HCl.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Hydralazine HCl Oral Tablets: 10 mg, 25 mg, 50 mg, and 100 mg; generic; (Rx)

Hydralazine Injection: 20 mg/mL in 1 mL vials; generic; (Rx)

Hydrochlorothiazide

(hye-***droe***-klor-oh-***thye***-a-zide) *HydroDIURIL®, Microzide®*

Thiazide Diuretic

Prescriber Highlights

- ► Thiazide diuretic used for nephrogenic diabetes insipidus, hypertension, calcium oxalate urolith prevention, hypoglycemia, and as a diuretic for heart failure
- ► Contraindications include hypersensitivity, anuria, and pregnancy (relative contraindication).
- ► Use extreme caution in patients with severe renal disease, pre-existing electrolyte and water imbalances, concurrent high-dose administration of loop diuretics, impaired hepatic function, hyperuricemia, SLE, and diabetes mellitus.
- ► Adverse effects include hypokalemia, hypochloremic metabolic alkalosis, other electrolyte imbalances, hyperuricemia, and GI effects.
- ► Many possible drug interactions and laboratory test interactions

Uses/Indications

In veterinary medicine, furosemide has largely supplanted the use of thiazides as a general diuretic. Thiazides are still used for the treatment of ascites, hypermagnesemia, nephrogenic diabetes insipidus, to help prevent recurrence of calcium oxalate uroliths in dogs (potentially also in cats), and as adjunctive therapy (eg, in combination with a loop diuretic[1]) in advanced cases of congestive heart failure. Thiazides are also a diuretic choice in avian species with cavitary effusion or heart failure. In horses, hydrochlorothiazide may be used as an alternative to acetazolamide for hyperkalemic periodic paralysis (HyPP) when dietary therapy alone does not control episodes.

Pharmacology/Actions

Thiazide diuretics act by interfering with the transport of sodium ions across renal tubular epithelium, possibly by altering the metabolism of tubular cells. The principal site of action is at the cortical diluting segment of the nephron. This results in enhanced excretion of sodium, chloride, and water. Thiazides increase the excretion of potassium, magnesium, phosphate, iodide, and bromide and decrease the glomerular filtration rate (GFR). Plasma renin and resulting aldosterone levels are increased, which contribute to the hypokalemic effects of thiazides. Bicarbonate excretion is increased, but effects on urine pH are usually minimal. Thiazides initially have a hypercalciuric effect, although with continued treatment, calcium excretion is significantly decreased. Uric acid excretion is decreased by thiazides. Thiazides can cause or exacerbate hyperglycemia in diabetic patients or induce diabetes mellitus in prediabetic patients.

In nephrogenic diabetes insipidus, the administration of a thiazide diuretic can result in a paradoxical decrease in urine output. The proposed mechanism for this effect is related to sodium reduction. Thiazide diuretics reduce the reabsorption of sodium and chloride in the distal tubule of the nephron, initially resulting in sodium loss and extracellular volume contraction. Over time, this results in increased reabsorption of sodium and water in the proximal tubule, then less filtrate is presented to the distal nephron, collecting duct, and subsequently excreted as urine.[2]

The antihypertensive effects of thiazides are well known, and these agents are used extensively in human medicine for treating essential hypertension. The exact mechanism for this effect has not been established.

Pharmacokinetics

The pharmacokinetics of thiazides have apparently not been studied in domestic animals. In humans, hydrochlorothiazide is ≈65% to 75% absorbed after oral administration. The onset of diuretic activity occurs 2 hours after administration and peaks at 4 to 6 hours. The serum half-life is ≈5.6 to 14.8 hours, and the duration of activity is 6 to 12 hours. The drug is not metabolized and is excreted unchanged in the urine. Like all thiazides, the antihypertensive effects of hydrochlorothiazide may take several days to occur.

Contraindications/Precautions/Warnings

Hydrochlorothiazide is contraindicated in patients with anuria or in patients that are hypersensitive to any thiazide. Although many sources state that thiazides are contraindicated in patients that are hypersensitive to sulfonamides, clear evidence for cross-reactivity has not been established in humans or animals.[3] In humans, use is inappropriate during pregnancy in women who are otherwise healthy and have only mild edema.

Do not use hydrochlorothiazide in dogs with absorptive (intestinal) hypercalciuria, as hypercalcemia may result.

Thiazides should be used with extreme caution, if at all, in patients with severe renal disease (may worsen azotemia) or with a pre-existing electrolyte (including hypercalcemia) or water imbalance, impaired hepatic function (may precipitate hepatic coma), hyperuricemia, lupus (SLE), or diabetes mellitus. Patients with conditions that may lead to an electrolyte or water imbalance (eg, vomiting, diarrhea) should be monitored carefully.

Do not confuse hydroCHLOROthiazide with hydrocortisONE, hydrALAZIne, or hydrOXYzine.

Adverse Effects

Hydrochlorothiazide may cause electrolyes disturbances, including hypokalemia, dilutional hyponatremia, and hypomagnesemia. Hypochloremic metabolic alkalosis (with hypokalemia) may develop, especially if there are other causes of potassium and chloride loss (eg, vomiting, diarrhea, potassium-losing nephropathies, concurrent use of loop diuretics) or the patient has cirrhotic liver disease. Hyperuricemia can occur but is usually subclinical. Hyperparathyroid-like effects of hypercalcemia and hypophosphatemia have been reported in humans, but have not led to effects such as nephrolithiasis, bone resorption, or peptic ulceration. GI effects (eg, vomiting, diarrhea) are possible and may be more prevalent in animals with mild azotemia. Other possible adverse effects include hypersensitivity and dermatologic reactions, GU reactions (polyuria), hematologic toxicity, hyperglycemia, hyperlipidemias, and orthostatic hypotension.

Reproductive/Nursing Safety

Hydrochlorothiazide crosses the placenta; no evidence of fetal harm occurred when it was administered to pregnant mice or rats during periods of organogenesis.[4]

Thiazides enter human breastmilk,[4] but hydrochlorothiazide is considered compatible with breastfeeding in humans.[5]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute overdose may cause an electrolyte and water imbalance, CNS effects (lethargy to coma and seizures), and GI effects (eg, hypermotility, GI distress). Transient increases in BUN have been reported.

Treatment consists of GI decontamination after recent oral ingestion using standard protocols. Avoid giving concomitant cathartics, as they may exacerbate the fluid and electrolyte imbalances that may ensue. Monitor and treat electrolyte and water imbalances supportively. Additionally, monitor respiratory, CNS, and cardiovascular status; treat signs supportively if required.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information

is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydrochlorothiazide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Use with thiazides can lead to an increased risk for severe hypokalemia.
- **Bromides**: May enhance the excretion of bromides, thereby affecting seizure control and dosage requirements
- **Calcium-Containing Products**: Hypercalcemia may be exacerbated if thiazides are concurrently administered.
- **Cholestyramine**: May reduce hydrochlorothiazide absorption
- **Corticosteroids, Corticotropin**: Use with thiazides can lead to an increased risk for severe hypokalemia.
- **Diazoxide**: Increased risk for hyperglycemia, hyperuricemia, and hypotension
- **Digoxin**: Thiazide-induced hypokalemia, hypomagnesemia, and/or hypercalcemia may increase the likelihood of digitalis toxicity.
- **Hypotensive Agents** (eg, **amlodipine, enalapril, telmisartan**): May have additive hypotensive effects
- **Insulin**: Thiazides may increase insulin requirements.
- **Loop Diuretics** (eg, **furosemide, torsemide**): May have additive hypotensive, hypovolemic, and electrolyte effects. Concurrent use may be considered in cases of advanced heart failure.[1]
- **Methenamine**: Thiazides can alkalinize urine and reduce methenamine effectiveness.
- **Myelosuppressive Agents** (eg, **cyclophosphamide, methotrexate**): May increase exposure and enhance myelosuppression
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs;** eg, **carprofen, meloxicam, robenacoxib**): Thiazides may increase risk for renal toxicity, and NSAIDs may reduce diuretic actions of thiazides.
- **Neuromuscular Blocking Agents**: May increase the response or duration of effect of tubocurarine or other nondepolarizing neuromuscular blocking agents
- **Probenecid**: Blocks thiazide-induced uric acid retention (used to therapeutic advantage)
- **Quinidine**: Half-life may be prolonged by thiazides (thiazides can alkalinize the urine).
- **Vitamin D**: Hypercalcemia may be exacerbated if thiazides are concurrently administered.

Laboratory Considerations

- **Acetaminophen**: May falsely increase acetaminophen levels
- **Amylase**: Thiazides can increase serum amylase values in subclinical patients and those in the developmental stages of acute pancreatitis (humans).
- **Cortisol**: Thiazides can decrease the renal excretion of cortisol.
- **Estrogen, urinary**: Hydrochlorothiazide may falsely decrease total urinary estrogen when using a spectrophotometric assay.
- **Histamine**: Thiazides may cause false negative results when testing for pheochromocytoma.
- **Hydroxycorticosteroids**: Thiazides may decrease urinary corticosteroid values by interfering in vitro with the absorbance in the modified Glenn-Nelson technique for urinary 17-hydroxycorticosteroids.
- **Parathyroid-function tests**: Thiazides may elevate serum calcium; it is recommended to discontinue thiazides prior to testing.
- **Phenolsulfonphthalein (PSP)**: Thiazides can compete for secretion at proximal renal tubules.
- **Phentolamine test**: Thiazides may give false negative results.
- **Protein-bound iodine**: Thiazides may decrease values.
- **Triiodothyronine resin uptake test**: Thiazides may slightly reduce uptake.
- **Tyramine**: Thaizides can cause false negative results when testing for pheochromocytoma.

Dosages

DOGS:

Prevention of recurrent calcium oxalate uroliths with renal hypercalcuria (extra-label): Usually added when dietary treatment does not adequately control calcium oxalate crystalluria. Most clinicians recommend 2 – 2.2 mg/kg PO twice daily.[6]

Diuretic agent (extra-label):

a) Adjunctive treatment of heart failure when patients become refractory to loop diuretics alone: 0.2 – 0.84 mg/kg PO daily.[1] Other dosage regimens have recommended 0.5 to 4 mg/kg PO once or twice daily.[7] For dogs already on loop diuretic therapy to achieve sequential nephron blockade, low starting doses should be selected with frequent monitoring of renal values and electrolytes as the dose is escalated pending clinical response. The fixed-dose (1:1) combination with spironolactone (*Aldactazide*®) can be considered for dogs already receiving spironolactone.

b) Ascites in patients with liver disease using the fixed-dose (1:1) combination with spironolactone (*Aldactazide*®): Dosed empirically based on the spironolactone content at 0.5 – 1 mg/kg PO twice daily[8]

Systemic hypertension (extra-label): 2 – 4 mg/kg PO once or twice daily as an alternate agent to calcium channel blockers or renin-angiotensin-aldosterone blocking drugs.[9] Other reports suggest 1 mg/kg PO once to twice daily that may be combined with spironolactone 1 – 2 mg/kg PO twice daily to reduce potassium loss.[10]

Nephrogenic diabetes insipidus (extra-label):

a) 2 mg/kg PO twice daily with a low sodium diet[11]

b) 2.5 – 5 mg/kg PO twice daily[12]

Hypoglycemia secondary to insulinoma (extra-label): 1 – 2 mg/kg PO twice daily in conjunction with diazoxide if diazoxide alone does not adequately increase blood glucose.[13]

CATS:

Diuretic agent (extra-label):

a) For heart failure in combination with furosemide in patients that have become refractory to furosemide alone: 1 – 2 mg/kg PO twice daily.[14,15] As in dogs, low starting doses should be selected with frequent monitoring of renal values and electrolytes as the dose is escalated pending clinical response. The fixed-dose (1:1) combination with spironolactone (*Aldactazide*®) can be considered for cats already receiving spironolactone.

b) For ascites in patients with liver disease using the fixed-dose (1:1) combination with spironolactone (*Aldactazide*®): Dosed empirically based on the spironolactone content at 0.5 – 1 mg/kg PO twice daily[8]

Reduce calcium oxalate saturation in urine (extra-label): 1 mg/kg PO twice daily.[16] **NOTE**: Study was done in healthy cats; it is unknown what effect hydrochlorothiazide will have in cats with spontaneously occurring calcium oxalate urolithiasis.

Nephrogenic diabetes insipidus (extra-label): 2.5 – 5 mg/kg PO twice daily[12]

Central diabetes insipidus (extra-label): 12.5 mg/cat (NOT mg/kg) PO twice daily[17,18]

HORSES:

Adjunctive therapy of hyperkalemic periodic paralysis (HyPP) (extra-label): 0.5 – 1 mg/kg PO every 12 hours when diet adjustment does not control episodes[19]

BIRDS:

Diuretic agent for heart failure treatment, using the fixed-dose (1:1) combination with spironolactone (*Aldactazide*®) (extra-label): Hydrochlorothiazide 1 mg/kg PO twice daily[20]

Monitoring

- Serum electrolytes, BUN, creatinine, glucose
- Hydration status
- Blood pressure, if indicated
- CBCs, if indicated

Client Information

- When beginning this medicine, your animal may urinate more often than normal.
- This medicine may be given with or without food. Allow access to water at all times and encourage normal food intake. If your animal vomits or acts sick after getting the medicine on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Because this drug can change electrolytes (salts) in the blood, your veterinarian will recommend more frequent monitoring.
- Contact your veterinarian immediately if excessive thirst, muscle weakness, collapsing or fainting, head tilt, lack of urination, or a racing heartbeat is noticed.

Chemistry/Synonyms

Hydrochlorothiazide occurs as a practically odorless, slightly bitter, white or practically white crystalline powder with pK_as of 7.9 and 9.2. It is slightly soluble in water and soluble in alcohol.

Hydrochlorothiazide may also be known as HCTZ, hidroclorotiazida, or hydrochlorothiazidum; many trade names are available.

Storage/Stability

Hydrochlorothiazide capsules and tablets should be stored at room temperature (20°C-25°C [68°F-77°F]) in tight, light-resistant containers.

Compatibility/Compounding Considerations

Compounded preparation stability: A method for compounding a spironolactone/hydrochlorothiazide oral suspension from commercially available tablets has been published.[21] Triturate 24 spironolactone/hydrochlorothiazide 25/25 mg tablets with 60 mL of *Ora-Plus*® and make up to 120 mL with *Ora-Sweet*® (or *Ora-Sweet*® *SF*). This yields a 5 mg/mL suspension of both spironolactone and hydrochlorothiazide that retains more than 90% potency for 60 days stored at both 5°C (41°F) and 25°C (77°F). Compounded preparations of hydrochlorothiazide should be protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Hydrochlorothiazide Oral Tablets: 12.5 mg, 25 mg, and 50 mg; generic; (Rx)

Hydrochlorothiazide Oral Capsules: 12.5 mg; *Microzide*® *Capsules*; generic; (Rx)

Spironolactone/Hydrochlorothiazide Oral Tablets: 25 mg/25 mg and 50 mg/50 mg; *Aldactazide*®; generic; (Rx)

There are other fixed-dose combinations with hydrochlorothiazide, including (partial list) with: amlodipine, benazepril, candesartan, enalapril, irbesartan, lisinopril, losartan, metoprolol, telmisartan, and triamterene.

References

Hydrocodone Combinations

(hye-droe-***koe***-done) *Hycodan*®, *Vicodin*®

Opioid Agonist; Anti-tussive Agent

Prescriber Highlights

- ► Immediate-release product available in combination with homatropine or acetaminophen, or ibuprofen
- ► Prescriptions must specify which combination is to be dispensed.
- ► Used primarily as an antitussive in dogs; efficacy as an oral analgesic for moderate pain in dogs has been disappointing.
- ► Contraindicated in patients with hypersensitivity to narcotic analgesics, receiving monoamine oxidase inhibitors (MAOIs), or presented with diarrhea due to toxic ingestion. Any combination with acetaminophen should **NOT** be used in cats or ferrets.
- ► Additional monitoring may be required in patients with hypothyroidism, severe renal or hepatic insufficiency, hypoadrenocorticism, head injuries or increased intracranial pressure, and acute abdominal conditions, as well as in geriatric or severely debilitated patients. Extreme caution should be exercised in patients with increased respiratory secretions or with nebulized treatments.
- ► Potential adverse effects include sedation, constipation (with long-term therapy), vomiting, other GI disturbances (eg, gastroesophageal reflux, regurgitation), and respiratory depression.
- ► May mask the clinical signs of respiratory disease (eg, cough)
- ► All products are DEA Schedule II (C-II) controlled substances

Uses/Indications

Hydrocodone is used principally in dogs as an antitussive for cough secondary to conditions such as collapsing trachea, bronchitis, or canine infectious respiratory disease complex (CIRDC; also known as kennel cough, canine infectious tracheobronchitis). Hydrocodone use is generally reserved for harsh, dry, nonproductive coughs.

Hydrocodone is more potent than codeine, and commercially available dosage forms of hydrocodone are combined with homatropine to prevent abuse, which is why many clinicians prefer a combination hydrocodone/homatropine versus codeine for use as an antitussive in dogs.

Hydrocodone has not proved to be a useful analgesic. Neither extended-release hydrocodone tablets (single agent)[1] nor a combination product containing hydrocodone and acetaminophen[2] provided acceptable postoperative analgesia in dogs following tibial plateau leveling osteotomy (TPLO).

Pharmacology/Actions

Opioid receptors are found in high concentrations in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain. The GI tract, urinary tract, and other smooth muscle tissues also contain opiate receptors. Hydrocodone has primary activity at mu receptors, with some activity at kappa and delta receptors at higher doses, and binding at these CNS receptors results in reduced neuronal excitability.

Primary pharmacologic effects of opioids include analgesia, antitussive activity, respiratory depression, sedation, and GI effects (eg, vomiting, constipation).

Secondary pharmacologic effects include CNS: sedation, excitatory effects (disinhibition); cardiovascular: bradycardia due to central vagal stimulation, syncope, decreased peripheral resistance, and baroreceptor inhibition; urinary: increased bladder sphincter tone can induce urinary retention; endocrine: inhibited secretion of glucagon, insulin, somatostatin, and vasopressin.

Although hydrocodone exhibits the characteristics of other opioid agonists, it tends to have a slightly greater antitussive effect than codeine (on a weight basis) because of direct suppression of the cough reflex in the medullary cough center. Hydrocodone tends to have a drying effect on respiratory mucosa, and the viscosity of respiratory secretions may be increased; the addition of homatropine methylbromide (in *Hycodan*® and others) may enhance this effect.

Pharmacokinetics

Hydrocodone oral bioavailability is ≈40% in dogs.[3] In healthy greyhounds ($n = 6$), oral doses of ≈0.5 mg/kg hydrocodone bitartrate (in combination with acetaminophen) produced peak concentrations of hydrocodone in ≈45 minutes and hydromorphone, the active metabolite, in ≈1.5 hours. Plasma concentrations of hydromorphone remained greater than 1.6 ng/mL through the 8 hours of the study; this value is greater than the concentration thought to be antinociceptive. Mean elimination half-life (t½) of hydrocodone was 1.6 to 1.8 hours.[4,5] In a study of postoperative client-owned dogs,[6] time to hydrocodone peak concentration and elimination half-life was 3.5 hours and 16 hours, respectively. The hydrocodone data in this study could not be fit into a pharmacokinetic model, and the 16-hour value for t½ (which exceeds the 8-hour study interval) was not robust. The authors speculate that reduced GI transit due to anesthesia or preoperative morphine may have altered drug absorption. In addition, hydromorphone was isolated in only 3 of 24 dogs. Dogs hepatically metabolize hydrocodone via *N*- and *O*-demethylation pathways, and hydromorphone is an active metabolite.[4,7,8]

The antitussive and analgesic actions of hydrocodone are thought to persist for 6 to 12 hours, but pharmacokinetic/pharmacodynamic studies correlating oral hydrocodone's antinociceptive effects in dogs are not currently available. Extrapolating data from hydromorphone, drug concentration did not correlate with analgesic activity in cats[9] and horses.[10,11]

In humans, hydrocodone is well absorbed after oral administration, and absorption is not affected by food. The drug is hepatically metabolized by several pathways, including *N*- and *O*-demethylation and glucuronidation and has a serum half-life of ≈3.8 hours. The antitussive effect usually lasts 4 to 6 hours in adults.

Information regarding the pharmacokinetics of the extended-release (ER) formulation of hydrocodone in veterinary patients is not available.

Contraindications/Precautions/Warnings

Hydrocodone is contraindicated in patients hypersensitive to it or with marked respiratory depression, GI obstruction, or diarrhea caused by a toxic ingestion (until the toxin is eliminated from the GI tract). Because opioids may impact the CNS, cardiac, respiratory, and GI systems, animals with underlying conditions affecting these systems (eg, hypothyroidism, severe renal or hepatic insufficiency, seizure disorders, hypoadrenocorticism, GI obstruction or reduced motility, geriatric or severely debilitated) should be monitored closely for adverse effects related to these systems.[12,13]

Commercially marketed hydrocodone products in the United States are available only as extended-release or combination products. Combinations containing acetaminophen (eg, *Vicodin*®) should **NOT** be used in cats or ferrets, and products containing ibuprofen should not be used in dogs or cats. Because of available dosage form concerns and lack of evidence supporting hydrocodone use in cats for any purpose, it cannot be recommended for feline patients.

Because hydrocodone may obscure the diagnosis or clinical course, this drug should be used with caution in patients with head injuries or increased intracranial pressure and acute abdominal conditions. The drug should be used with extreme caution in patients with respiratory disease, with increased respiratory secretions, or nebulized treatments.

Hydrocodone may impair the performance of service or working dogs.

Hydrocodone products have a high abuse potential in humans, and diversion from its intended use is possible.

Do not confuse hydroCODone, hydroMORPHone, and hydroCORTisone.

Adverse Effects

Adverse effects in dogs include sedation, constipation (with long-term therapy), vomiting, or other GI disturbances. Hydrocodone may mask the clinical signs (eg, cough) of respiratory disease and should not replace appropriate specific treatments for the underlying cause of cough.

Long-term opioid use has been associated with dysfunction of the hypothalamic-pituitary-adrenal axis in humans.[14]

Reproductive/Nursing Safety

Skeletal malformations and reductions in fetal weight, survival rate, and litter size occurred following hydrocodone exposure to pregnant laboratory animals, usually at higher doses (2 to 15 times the recommended dose).[14] Long-term opioid use may cause reduced fertility in both male and females.[14]

Hydrocodone and its hydromorphone metabolite enter breast milk in humans.

Because safety has not been established in animal species, this drug should only be used when the maternal benefits outweigh the potential fetal risks.

Overdose/Acute Toxicity

The initial concern with a hydrocodone overdose is CNS, cardiovascular, and respiratory depression secondary to opioid effects. Common clinical signs associated with overdose may include lethargy/sedation, vocalizing, hyperactivity, ataxia, and vomiting.

If ingestion was within 2 to 3 hours of presentation, gastric decontamination using standard protocols should be performed, and treatment with naloxone instituted as necessary. The homatropine ingredient may give rise to anticholinergic effects that can complicate the clinical picture, but its relatively low toxicity may not require treatment. For further information on handling opioid or anticholinergic overdoses, see ***Meperidine*** and ***Atropine***, respectively. Refer to ***Acetaminophen*** for toxicosis associated with acetaminophen combination products.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have been reported or are theoretical in humans or animals receiving hydrocodone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Drugs** (eg, **atropine, glycopyrrolate**): May cause additive anticholinergic effects and increased risk for urinary retention, constipation, or paralytic ileus; risk is likely greater with hydrocodone/homatropine combinations
- **Benzodiazepines** (eg, **alprazolam**, **diazepam, midazolam**): May result in additive CNS and respiratory depressant effects
- **Clopidogrel**: May reduce the efficacy of clopidogrel in humans
- **CNS Depressants, Other** (eg, **anesthetic agents, antihistamines, phenothiazines**): May cause increased CNS or respiratory depression
- **Desmopressin**: May result in increased risk for hyponatremia
- **Diuretics** (eg, **furosemide**): May decrease diuretic efficacy because opioids can induce antidiuretic hormone (ADH) secretion
- **GI Agents, Prokinetic** (eg, **cisapride**, **metoclopramide**): May antagonize the GI motility effects of these agents
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May increase serum hydrocodone concentration and risk for toxicity
- **Monoamine Oxidase Inhibitors (MAOIs;** eg, **amitraz, selegiline**): May potentiate CNS and respiratory adverse effects; not recommended (in humans) with concurrent MAOI use, or if MAOI has been used within 14 days
- **Ondansetron**: May increase risk for serotonin syndrome
- **Naloxone**: Antagonizes opioid effects. **NOTE**: This action is an expected outcome when naloxone is used as a reversal agent.
- **Opioid Mixed Agonists/Antagonists** (eg, **butorphanol, buprenorphine**): May reduce the efficacy of hydrocodone
- **Rifampin**: May induce hydrocodone metabolism and decrease hydrocodone serum concentration
- **Phenobarbital/Primidone**: May increase risk for CNS and respiratory depression; may induce hydrocodone metabolism and decrease hydrocodone serum concentration
- **Quinidine**: May result in reduced analgesic and antitussive effects
- **Serotonin Modulators** (eg, **fluoxetine, mirtazapine, trazodone**): May result in psychomotor impairment and increase risk for serotonin syndrome
- **Skeletal Muscle Relaxants** (eg, **dantrolene, methocarbamol**): May enhance CNS depressant effects
- **Tricyclic Antidepressants**(eg, **amitriptyline, clomipramine**): May have additive CNS depressant and anticholinergic effects

Laboratory Considerations

- Opioids may increase pressure on the biliary tract, leading to increased plasma **lipase** and **amylase** activity for up to 24 hours following opioid administration.

Dosages

NOTE: All prescriptions for hydrocodone combinations must specify the strength of both hydrocodone and the combination drug (eg, hydrocodone 5 mg/homatropine 1.5 mg tablet).

DOGS:

Antitussive (extra-label): 0.2 – 0.5 mg/kg PO every 6 to 12 hours is usually recommended, but doses up to 1 mg/kg PO every 6 hours have been noted. The goal of therapy is to suppress cough without excessive sedation.[15]

Analgesic (extra-label): Pharmacokinetic studies[4,6] suggest hydrocodone may be an effective analgesic for mild to moderate pain in dogs, but clinical trials do not support analgesic efficacy following orthopedic surgery.[1,2] If using the combination product that contains hydrocodone with acetaminophen, calculate the dose to provide **hydrocodone** 0.5 – 0.6 mg/kg and **acetaminophen** 15 mg/kg PO every 8 hours.[2,16] Fixed-dose combinations of hydrocodone and acetaminophen make it difficult to administer less than 15 mg/kg of the acetaminophen component every 8 hours.

Monitoring

- Adverse effects (eg, vomiting, constipation, excessive sedation)
- Clinical efficacy for condition being treated (eg, improved cough suppression, improved analgesia)

Client Information

- Any product that also contains acetaminophen (eg, *Tylenol*®, APAP, *Vicodin*®) should **NEVER** be used in cats or ferrets. If you are unsure whether a product containing hydrocodone is safe for use in your animal, ask your veterinarian.
- This medicine can be given with or without food. If your animal vomits or acts sick after receiving hydrocodone on an empty stomach, give with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Sedation (ie, sleepiness, fatigue) and constipation are the most likely side effects. Watch for side effects and contact your veterinarian immediately if your animal stops eating, if the whites of the eyes become yellowish, if the animal continues to vomit or has diarrhea, or if blood is seen in vomit or stool.
- Contact your veterinarian if you are concerned that your animal's condition is not improving on this medication.
- Do **NOT** give more to your animal than your veterinarian prescribes. Unless your veterinarian instructs, do **NOT** give other pain, cough, or fever medication at the same time as using hydrocodone.
- Hydrocodone in combination with acetaminophen or homatropine is a controlled substance in the United States and requires a new written prescription for refills. Use of this medication in animals or humans other than those for whom they were prescribed is illegal.

Chemistry/Synonyms

Hydrocodone, a phenanthrene-derivative opiate agonist, is a hydrogenated ketone derivative of codeine. Hydrocodone bitartrate occurs as fine, white crystals or crystalline powder. It is susceptible to photodegradation. One gram is soluble in ≈16 mL of water; it is slightly soluble in alcohol.

Hydrocodone bitartrate may also be known as hydrocodone tartrate, dihydrocodeinone acid tartrate, hydrocodone acid tartrate, or hydrocodoni bitartras.

Storage/Stability

Products should be protected from light and stored at room temperature (20°C-25°C [68°F-77°F]); excursions from 15°C to 30°C (59°F-86°F) may be permitted for some products.

Hydrocodone is a Schedule II controlled substance. In accordance with DEA regulations, it must be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs. Report dispensing to state monitoring programs where required.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 1 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regula-

tions before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:
Hydrocodone Bitartrate Oral Tablets: 5 mg with Homatropine MBr 1.5 mg; *Tussigon®*, *Hycodan®*, generic; (Rx, C-II)

Hydrocodone Bitartrate Oral Syrup: 5 mg with Homatropine MBr 1.5 mg (per 5 mL) in 473 mL; *Hydromet®* Syrup, *Hycodan®* Syrup, generic (Rx, C-II). Hydrocodone 1 mg/mL syrup is available in Canada; Narcotic (CDSA I)

Hydrocodone Bitartrate Extended-Release Oral Tablets: 10 mg, 15 mg, 20 mg, 30 mg, 40 mg, 50 mg, 60 mg, 80 mg, 100 mg, and 120 mg; *Hysingla ER®*, *Zohydro ER®*; (Rx, C-II)

The following products are representative oral dosage forms containing hydrocodone and acetaminophen and include those most likely to be of benefit (higher ratios of hydrocodone to acetaminophen) in treating dogs and that are usually stocked at human pharmacies. **WARNING**: These products should **NOT** be used in cats or ferrets.

Hydrocodone/Acetaminophen Oral Tablets: 5 mg/300 mg, 5 mg/325 mg, 7.5 mg/300 mg, 7.5 mg/325 mg, 10 mg/300 mg, and 10 mg/325 mg. A commonly used trade name is *Vicodin®*; generic; (Rx, C-II)

Hydrocodone/Acetaminophen Oral Solution: Hydrocodone 2.5 mg/5 mL (0.67 mg/mL) in combination with acetaminophen 100 mg/5 mL (20 mg/mL). generic; (Rx, C-II)

Combination products with hydrocodone/ibuprofen are also available: 5 mg/200 mg, 7.5 mg/200 mg, and 10 mg/200 mg under the commonly used trade name *Vicoprofen®* and generics; (Rx, C-II). **NOTE**: This product is not recommended for use in dogs or cats.

Oral liquids with hydrocodone are also available in combination with chlorpheniramine and/or pseudoephedrine. Some of these products have 2 or more active ingredients; (Rx, C-II)

Report dispensing to state monitoring programs where required.

Hydrocortisone

Hydrocortisone Sodium Succinate

(hye-droe-***kor***-ti-zone) *Cortef®, Solu-Cortef®*
Glucocorticoid

Prescriber Highlights

- ► Benchmark injectable, oral, and topical glucocorticoid. The IV form (sodium succinate salt) is most commonly used when immediate glucocorticoid and mineralocorticoid activity is desired (eg, Addisonian crisis, critical illness-related corticosteroid insufficiency [CIRCI]).
- ► Contraindications include systemic fungal infections and idiopathic thrombocytopenia (IM use).
- ► Primary adverse effects occur with sustained use and include clinical signs of hyperadrenocorticism.
- ► Tapering required after chronic use
- ► Many potential drug interactions and laboratory interactions

Uses/Indications

Hydrocortisone is used in dogs and cats for acute treatment of hypoadrenocorticism (Addisonian crisis) and for long-term maintenance therapy for hypoadrenocorticism. Because of its rapid effect and relatively high mineralocorticoid effect, IV hydrocortisone sodium succinate is the most commonly used form of this medication when an acute glucocorticoid/mineralocorticoid effect is desired (eg, acute adrenal insufficiency; critical illness-related corticosteroid insufficiency [CIRCI]). While oral forms are available, they are not routinely used in veterinary patients.

Pharmacology/Actions

Glucocorticoids have effects on virtually every cell type and system in mammals. See the ***Glucocorticoid Agents, General Information*** monograph for more information.

Pharmacokinetics

In humans, hydrocortisone is readily absorbed after oral administration, and hydrocortisone sodium succinate is rapidly absorbed after IM administration. Duration of activity is 8 to 12 hours.

Contraindications/Precautions/Warnings

Hydrocortisone products are contraindicated in patients with known hypersensitivity to those particular products or their constituents. Glucocorticoid agents used systemically are generally considered contraindicated in systemic fungal infections (unless used for replacement therapy in patients with Addison's disease). IM administration is contraindicated in patients with idiopathic thrombocytopenia. Intrathecal administration is contraindicated.[1] In humans, epidural administration of glucocorticoids has resulted in serious neurologic events including spinal cord infarction, cortical blindness, and death.

Some formulations contain benzyl alcohol and are contraindicated in neonatal patients.[1]

Patients that have received the drug chronically should be tapered off slowly until normal adrenal and pituitary function resume, as endogenous ACTH and corticosteroid function may return slowly. If the animal undergoes a stressful event (eg, surgery, trauma, illness) during the tapering process, additional glucocorticoids should be administered.

Do not confuse hydroCORTIsone with hydroCODONE, hydroCHLOROthiazide, or hydroxyCHLOROquine. Do not confuse Solu-CORTEF with SOLU-Medrol. Consider writing part of the drug's name in uppercase letters (tall-man designations) on prescriptions/orders to reduce the risk of errors.

Adverse Effects

Adverse effects are generally associated with long-term administration of glucocorticoids, especially if given at high dosages or on a daily basis. Effects generally manifest as clinical signs of hyperadrenocorticism. Glucocorticoids can delay growth when administered to young, growing animals. A complete list of potential adverse effects is provided in ***Glucocorticoid Agents, General Information.***

The adverse effect profile for IV hydrocortisone in dogs and cats for acute hypoadrenocorticism or CIRCI is not well described. In humans in the ICU setting (CIRCI), potential important adverse effects include immune suppression with increased risk for infection, impaired wound healing, hyperglycemia, myopathy, hypokalemic metabolic acidosis, psychosis, and HPA axis and glucocorticoid receptor suppression.[2]

Reproductive/Nursing Safety

Excessive glucocorticoid doses early in pregnancy may lead to teratogenic effects. When administered in the latter stages of pregnancy, exogenous steroids may induce parturition, including premature parturition followed by dystocia, fetal death retained placenta and metritis. Cleft palate, foreleg deformities, phocomelia, and anasarca have occurred in offspring of dogs that received corticosteroids during pregnancy.[3] In horses and ruminants, exogenous steroid administration may induce parturition when administered in the latter stages of pregnancy.

Glucocorticoids not bound to plasma proteins will enter milk.

High doses or prolonged administration to mothers may potentially inhibit the growth of nursing newborns.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Glucocorticoids, when given short-term, are unlikely to cause harmful effects, even in massive doses. One incidence of a dog developing acute CNS effects after accidental ingestion of glucocorticoids has been reported. If clinical signs occur, use supportive treatment as necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydrocortisone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Administered concomitantly with glucocorticoids may cause hypokalemia; in humans, there have been cases of CHF and cardiac enlargement reported after using hydrocortisone to treat amphotericin B adverse effects.
- **Anticholinesterase Agents** (eg, **neostigmine, pyridostigmine**): In patients with myasthenia gravis, concomitant glucocorticoid and anticholinesterase agent administration may lead to profound muscle weakness. If possible, discontinue anticholinesterase medication at least 24 hours prior to hydrocortisone administration.
- **Aspirin**: Glucocorticoids may reduce salicylate blood levels and increase the risk for GI ulceration/bleeding.
- **Azole Antifungals** (eg, **ketoconazole**): May decrease the metabolism of glucocorticoids and increase hydrocortisone blood levels; ketoconazole may induce adrenal insufficiency when glucocorticoids are withdrawn by inhibiting adrenal corticosteroid synthesis.
- **Barbiturates** (eg, **phenobarbital**): May increase the metabolism of glucocorticoids and decrease hydrocortisone blood levels
- **Cyclophosphamide**: Glucocorticoids may inhibit the hepatic metabolism of cyclophosphamide; dosage adjustments may be required.
- **Cyclosporine**: Concomitant administration of glucocorticoids and cyclosporine may increase the blood levels of both drugs by mutually inhibiting the hepatic metabolism of each other; the clinical significance of this interaction is not clear.
- **Diuretics, Potassium-Depleting** (eg, **furosemide, thiazides**): When administered concomitantly with glucocorticoids, may cause hypokalemia
- **Ephedrine**: May reduce hydrocortisone blood levels
- **Estrogens**: The effects of hydrocortisone and, possibly, other glucocorticoids may be potentiated by concomitant administration with estrogens.
- **Insulin**: Insulin requirements may increase in patients receiving glucocorticoids.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May decrease the metabolism of glucocorticoids and increase hydrocortisone blood levels
- **Mitotane**: May alter the metabolism of steroids; higher than usual doses of steroids may be necessary to treat mitotane-induced adrenal insufficiency.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam**): Administration of ulcerogenic drugs with glucocorticoids may increase the risk for GI ulceration.
- **Rifampin**: May increase the metabolism of glucocorticoids and decrease hydrocortisone blood levels
- **Vaccines**: Patients receiving corticosteroids at immunosuppressive dosages should generally not receive live attenuated-virus vaccines as virus replication may be augmented; a diminished immune response may occur after the vaccine, toxoid, or bacterin administration in patients receiving glucocorticoids.
- **Warfarin**: Hydrocortisone may affect coagulation status; monitor

Laboratory Considerations

- Hydrocortisone can cross-react with **cortisol** in the ACTH response test. This test must be performed before hydrocortisone is administered or 24 hours after the last dose of hydrocortisone. **NOTE**: Dexamethasone does not cross-react.
- Glucocorticoids may increase **serum cholesterol.**
- Glucocorticoids may increase **urine glucose** levels.
- Glucocorticoids may decrease **serum potassium.**
- Glucocorticoids can suppress the release of thyroid-stimulating hormone (TSH) and reduce **T_3 and T_4** values. Thyroid gland atrophy has been reported after chronic glucocorticoid administration. The uptake of **I^{131}** by the thyroid may be decreased by glucocorticoids.
- Reactions to **skin tests** may be suppressed by glucocorticoids.
- False-negative results of the **nitroblue tetrazolium** test for systemic bacterial infections may be induced by glucocorticoids.
- Glucocorticoids may cause **neutrophilia** within 4 to 8 hours after dosing and return to baseline within 24 to 48 hours after drug discontinuation.
- Glucocorticoids can cause **lymphopenia** that can persist for weeks after drug discontinuation in dogs.
- Glucocorticoids can cause elevations in **ALT, ALP, and GGT** in dogs.

Dosages

DOGS/CATS:

Adjunctive therapy for acute adrenocortical insufficiency (extra-label): After completion of the ACTH stimulation test, most recommendations are hydrocortisone sodium succinate 0.3 – 0.5 mg/kg/hour IV CRI or 2 – 4 mg/kg IV every 6 to 8 hours. Once GI function has returned and the patient is eating and drinking normally, therapy can be changed to oral steroid supplementation.

Long-term treatment of hypoadrenocorticism (extra-label): In the changeover period, as animals recover from an acute crisis and start to eat and drink, glucocorticoid supplementation is changed from parenteral to an oral dosage form. Traditionally, treatment is initially started with a mineralocorticoid (fludrocortisone or DOCP) combined with a glucocorticoid (eg, cortisone acetate, hydrocortisone, or prednisolone). The mineralocorticoid can be discontinued in some patients after 1 to 2 months. When using oral hydrocortisone tablets, most dogs are started on an anecdotal dose of 0.4 – 0.8 mg/kg PO once to twice a day. Once stable, generally, a dose of hydrocortisone 0.4 mg/kg PO once to twice a day provides adequate additional glucocorticoid supplementation.

Relative adrenal insufficiency (RAI); critical illness-related corticosteroid insufficiency (CIRCI); (extra-label): At present, there is no strong evidence for the use of any corticosteroid in

veterinary patients for these indications, and no consensus guidelines have been published; however, based upon research done in critically ill humans, it is reasonable to consider hydrocortisone. One recommended dosage is hydrocortisone sodium succinate 1 – 4.3 mg/kg/day divided into 4 equal doses and given IV every 6 hours or as a CRI. Because the HPA dysfunction in CIRCI is thought to be transient, lifelong therapy with corticosteroids is not required, and dosage is tapered by 25% each day after resolution of critical illness. An ACTH stimulation test should be repeated to confirm the return of normal adrenocortical function following the resolution of critical illness and discontinuation of corticosteroid supplementation.[4] Human data suggest that CRIs may provide better glycemic control but may cause greater HPA axis suppression than when given episodically.

Post-CPR resuscitation (extra-label): Routine administration of corticosteroids is not recommended. Use may be considered in patients that remain hemodynamically unstable despite administration of fluids and positive inotropes and vasopressors. Hydrocortisone sodium succinate 1 mg/kg IV, followed by either 1 mg/kg every 6 hours IV or 0.15 mg/kg/hour IV CRI, then tapered as the patient's condition allows.[5]

Monitoring

Monitoring of glucocorticoid therapy is dependent on its reason for use, dosage, dosage schedule (daily versus alternate day therapy), duration of therapy, and the animal's age and condition. The following list may not be appropriate or complete for all animals; use clinical assessment and judgment when adverse effects occur.

- Body weight, appetite, signs of edema
- Serum and/or urine electrolytes
- Total plasma proteins and albumin
- Blood glucose
- Urine culture

Client Information

- If using oral tablets at home, carefully follow the dosage instructions and do not discontinue the medicine abruptly without consulting with your veterinarian beforehand.
- Give oral tablets with food to help prevent stomach upset.

Chemistry/Synonyms

Hydrocortisone, also known as compound F or cortisol, is secreted by the adrenal gland. Hydrocortisone occurs as an odorless, white to practically white, crystalline powder. It is very slightly soluble in water and sparingly soluble in alcohol. Hydrocortisone is administered orally.

Hydrocortisone sodium succinate occurs as an odorless, white to nearly white, hygroscopic, amorphous solid. It is very soluble in both water and alcohol. Hydrocortisone sodium succinate injection is administered via IM or IV routes.

Hydrocortisone may also be known as an anti-inflammatory hormone, compound F, cortisol, hydrocortisonum, 17-hydroxycorticosterone, and NSC-10483; many trade names are available.

Storage/Stability

Store hydrocortisone sodium succinate in intact containers at controlled room temperatures of 20°C to 25°C (68°F-77°F). After reconstitution, solutions are stable if protected from light and kept at or below controlled room temperature. Use the solution only if it is clear; discard unused solutions after 3 days. Hydrocortisone sodium succinate is heat labile and cannot be autoclaved. Reconstituted HSS 500 mg/4 mL solution kept frozen for 4 weeks showed no loss of potency.

Store hydrocortisone tablets in well-closed containers at room temperature (15°C to 30°C [59°F-86°F]).

Compatibility/Compounding Considerations

Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Hydrocortisone sodium succinate is reportedly physically **compatible** with the following solutions and drugs: dextrose-Ringer's injection combinations, dextrose-Ringer's lactate injection combinations, dextrose-saline combinations, dextrose injections, Ringer's injection, lactated Ringer's injection, sodium chloride injections, amikacin sulfate, aminophylline, amphotericin B (limited quantities), calcium chloride/gluconate, chloramphenicol sodium succinate, clindamycin phosphate, corticotropin, daunorubicin HCl, dopamine HCl, erythromycin gluceptate, erythromycin lactobionate, lidocaine HCl, mephentermine sulfate, metronidazole with sodium bicarbonate, penicillin G potassium/sodium, piperacillin sodium, polymyxin B sulfate, potassium chloride, prochlorperazine edisylate, sodium bicarbonate, vancomycin HCl, verapamil HCl, and vitamin B-complex with C.

Hydrocortisone sodium succinate is reportedly physically **incompatible** when mixed with the following solutions and drugs: ampicillin sodium, bleomycin sulfate, dimenhydrinate, diphenhydramine HCl, doxorubicin HCl, ephedrine sulfate, heparin sodium, hydralazine HCl, oxytetracycline HCl, pentobarbital sodium, phenobarbital sodium, promethazine HCl, and tetracycline HCl.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

There are no products containing hydrocortisone (or its salts) known for systemic use. There are a variety of hydrocortisone veterinary products for topical use. A 10 ppb tolerance has been established for hydrocortisone (as the succinate or acetate) in milk.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance.

See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Hydrocortisone Oral Tablets: 5 mg, 10 mg, and 20 mg; *Cortef*®, generic; (Rx)

Hydrocortisone Oral Sprinkle: 0.5 mg, 1 mg, 2 mg, and 5 mg; *Alkindi Sprinkle*®; (Rx)

Hydrocortisone Sodium Succinate Injection: 100 mg/vial, 250 mg/vial, 500 mg/vial, and 1000 mg/vial; *Solu-Cortef*®, *A-Hydrocort*®; (Rx)

There are many OTC and Rx topical and anorectal products are available in a variety of dosage forms.

Hydrogen Peroxide 3% (Oral)

(***hye***-droe-jen per-***oks***-ide)

Oral Emetic

NOTE: Also refer to the ***Overdose and Toxin Exposure Decontamination Guidelines*** in the ***Appendix***

Prescriber Highlights

- ► Topical antiseptic that is used orally as a home-administered emetic in dogs when clients cannot transport the patient to a veterinary hospital in a timely manner or when other emetics have failed or are unavailable.
- ► Can cause esophageal irritation or other gastric effects; aspiration is possible
- ► Not recommended for use in cats
- ► Many contraindications for use as an emetic
- ► Do not use hydrogen peroxide solutions greater than 3%; solution should not be expired

Uses/Indications

Hydrogen peroxide 3% solution can be used as an orally administered emetic in dogs, pigs, and ferrets. It is reserved primarily for those cases when animals cannot be transported to a veterinary hospital promptly and immediate emesis is required; it may also be used in a clinic setting when other emetics have failed or are unavailable. A prospective observational study found that hydrogen peroxide 3% solution successfully induced emesis in 90% of treated dogs and was equally as effective as apomorphine at 94%.[1]

Hydrogen peroxide is not recommended in cats because of its unreliability as an emetic and because of potentially life-threatening adverse effects (eg, hemorrhagic gastritis,[2] acute respiratory failure[3, 4]).

Apomorphine or ropinirole for dogs and alpha-adrenergic agonists (eg, dexmedetomidine) or hydromorphone for cats are preferred emetic agents for administration in a veterinary clinic.

Pharmacology/Actions

Orally administered hydrogen peroxide 3% solution induces a vomiting reflex via direct irritant effects of the oropharynx and gastric lining. Emesis typically ensues within 10 to 15 minutes following oral administration to dogs.[1,5] It is estimated that an average ≈50% of ingested contents are recovered after inducing emesis with either apomorphine or hydrogen peroxide.[1]

Pharmacokinetics

No pharmacokinetic information located. Emetic effects may persist up to ≈2 hours after administering PO to dogs.[1]

Contraindications/Precautions/Warnings

Emesis with hydrogen peroxide should only be considered if preferred methods (eg, apomorphine, ropinirole) are not available and the benefits of decontamination outweigh the risks of its use.[2] Before inducing emesis, obtain a complete history of the ingestion and ensure that vital signs are stable.

If home administration of hydrogen peroxide is necessary, be sure that clients use only the 3% medical-grade solution and not another, more concentrated hydrogen peroxide product. Do not induce emesis with solutions that contain greater than 3% hydrogen peroxide, or that contain other active ingredients (eg, "accelerated" solutions, teat dips).

Emetics can be an important aspect in the treatment of orally ingested toxins, but they must be used judiciously. Most emetics are effective only if given within 2 hours of ingestion. Emetics should not be used in horses, rodents, or rabbits because these patients are either unable to vomit or do not have stomach walls strong enough to tolerate emesis. Emetics are also contraindicated in patients that are hypoxic, have evidence of cardiovascular shock or respiratory distress, are actively having seizures, and/or lack normal pharyngeal reflexes (ie, laryngeal paralysis). The risks and benefits of administering an emetic should also be considered for animals with a recurrent history of aspiration pneumonia or with recent abdominal surgery, seizures, coma, severe CNS depression or deteriorating CNS function, or extreme physical weakness. Emetics should also be withheld in patients that have previously vomited repeatedly. Because of the risk for additional esophageal or gastric injury with emesis, emetics are contraindicated in patients that have ingested a sharp object, strong acids, alkalis, or other caustic agents. Because of the risk for aspiration, emetics are usually contraindicated after petroleum distillate ingestion but may be employed when the risk for toxicity of the compound is greater than the risk for aspiration. Use of emetics after ingestion of strychnine or other CNS stimulants may precipitate seizures.

Emetics generally do not remove more than 80% of the material in the stomach (usually 40% to 60%) and significant quantities of the ingested drug/toxin may remain or may have already been absorbed. Successful induction of emesis does not signal the end of appropriate monitoring or therapy.

Because aspiration and/or bradycardia are possible, animals should be closely observed after administration. Suctioning, respiratory support, and cardiovascular support (eg, atropine) should be available. Do not allow animal to re-ingest vomitus.

Adverse Effects

In dogs, diarrhea, lethargy, and protracted nausea and vomiting are possible[1]; antiemetic agents administered after desired emesis occurs may alleviate nausea and vomiting in severely affected dogs. Hydrogen peroxide solution may be aspirated during administration or after inducing emesis. In an experimental study, significant visual and histopathologic gastric lesions occurred following administration of hydrogen peroxide 3% solution to dogs; less severe duodenal lesions were seen.[2] Gastric ulcers and gastric degeneration and necrosis were evident at 4 and 24 hours. Most gastroduodenal lesions were present for up to 1 week and resolved by 2 weeks. Gastric dilatation-volvulus in dogs has been reported following hydrogen peroxide administration.

Cats can be particularly susceptible to hemorrhagic gastritis or esophagitis.[6] Aspiration with life-threatening lung injury and acute respiratory failure has also been reported in a cat.[4]

Reproductive/Nursing Safety

No specific information was located. Although orally administered hydrogen peroxide 3% solution is unlikely to cause reproductive harm, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Hydrogen peroxide 3% solution can cause significant injury to the GI tract (see ***Adverse Effects***) after oral ingestion. Hydrogen peroxide in concentrations of 10% or greater can be very corrosive (causing severe burns to oral/gastric mucosa) and in humans, can induce oxygen emboli after oral ingestion.[7]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydrogen peroxide and may be of significance in veterinary patients. Unless otherwise noted, use

together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetylcysteine, Oral**: Hydrogen peroxide can oxidize acetylcysteine in the GI tract and, although clinical significance is unclear, alternative emetics (eg, apomorphine, hydromorphone, xylazine) are preferred to induce emesis in patients with acetaminophen overdoses.[8]
- **Antiemetics** (eg, **maropitant, ondansetron**): Pre-administration or ingestion of these products may negate the emetic effects of hydrogen peroxide.

Laboratory Considerations

- No specific concerns were noted.

Dosages

NOTE: All dosages use hydrogen peroxide 3% solution. The solution should not be expired.

DOGS:

Emetic (extra-label): 1 – 2.2 mL/kg PO (recommended maximum 50 mL/dog [NOT mL/kg][9]) once; a subsequent dose may be given after 10 to 15 minutes if emesis is not achieved.[1,10] Results are improved if there is a small amount of food in the stomach.[5,11]

POT-BELLIED PIGS:

Emetic (extra-label): 1 – 2 mL/kg PO not to exceed 50 mL/pig (NOT mL/pig). Mix with a small amount of milk to encourage voluntary ingestion.[12]

FERRETS:

Emetic (extra-label): 0.45 – 1.4 mL/kg PO, which can be repeated once if necessary. Results are improved if there is food in the stomach.[13,14]

Monitoring

- Efficacy (ie, emesis)
- Adverse effects (eg, prolonged nausea or vomiting, respiratory distress)
- Heart rate and respiratory rate/character, including thoracic auscultation after emesis
- Clinical signs associated with toxicity of the substance ingested
- Blood toxicant concentrations if applicable

Client Information

- Use only under the direct instructions of your veterinarian or an animal poison control center.
- Only use hydrogen peroxide 3% solution; stronger concentrations can be very toxic. Do not use expired solutions.
- Do not shake bottle. Carefully administer to avoid your animal unintentionally inhaling the liquid.
- Monitor your animal after giving hydrogen peroxide. Do not allow your animal to re-ingest the vomited material.
- Save all vomited fluid and material for your veterinarian to examine.
- Your animal should be seen by your veterinarian as soon as possible.

Chemistry/Synonyms

Hydrogen peroxide 3% solution is a clear, colorless liquid containing 2.5% to 3.5% w/v hydrogen peroxide. Up to 0.05% of the liquid may contain preservatives.

Hydrogen peroxide 3% solution may also be known as dilute hydrogen peroxide solution, hydrogen peroxide solution 10-volume (**NOTE**: **NOT** 10%), or hydrogen peroxide topical solution.

Storage/Stability

Store hydrogen peroxide 3% solutions in airtight containers at controlled room temperature between 15°C to 30°C (59°F-86°F) and protected from light. If hydrogen peroxide is allowed to become alkaline or it comes into contact with oxidizable organic matter, it will decompose. Do not shake bottle.

Hydrogen peroxide 3% solution can deteriorate with time; outdated or improperly stored products may not be effective as an emetic.

Compatibility/Compounding Considerations

No specific information noted. Any compounded emetic for home use should be made from hydrogen peroxide 3% solution and not stronger concentrations.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Hydrogen peroxide 3% solution in 473 mL bottles and 3.8 L (1 gallon) jugs; generic; (OTC). Not reviewed or approved by the FDA

HUMAN-LABELED PRODUCTS:

Hydrogen peroxide 3% solution is readily available OTC from a variety of manufacturers. Not reviewed or approved by the FDA. It is usually sold in pint bottles.

For the complete list of references, see **wiley.com/go/budde/plumb**

Hydromorphone

(hye-droe-***mor***-fone) *Dilaudid®*

Opioid Agonist

Prescriber Highlights

- ► Injectable opioid used as a sedative/restraining agent, analgesic, and preanesthetic agent. May be used as an emetic
- ► Adverse effects in dogs include nausea, vomiting, defecation, panting, vocalization, and sedation. CNS depression, respiratory depression, and bradycardia are possible; decreased GI motility with resultant constipation may occur with chronic use.
- ► Nausea is a common adverse effect in cats. Ataxia, hyperesthesia, hyperthermia, and behavior changes (without concomitant tranquilization) are also possible.
- ► Many drug interactions are possible.
- ► DEA Schedule II controlled substance

Uses/Indications

Hydromorphone is used in dogs and cats as a sedative/restraining agent, analgesic, and preanesthetic agent. Hydromorphone may be useful as an analgesic in horses and other species. In dogs, equipotent doses of hydromorphone and morphine cause similar degrees of sedation.[1] In dogs and cats, hydromorphone usually causes minimal histamine release after IV administration, and rarely causes vasodilation or hypotension. Hydromorphone may be useful as an emetic, but this effect may be more reliable in cats than in dogs.[2]

Pharmacology/Actions

Opioid receptors are found in high concentrations in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain. The GI tract, urinary tract, and other smooth muscle tissue also contain opioid receptors.

Hydromorphone is ≈5 times more potent an analgesic on a per weight basis as compared with morphine and similar in potency as compared with oxymorphone. Morphine-like agonists (eg, morphine, meperidine, fentanyl, oxymorphone, hydromorphone) have primary activity at mu receptors and some activity at delta receptors. The precise mechanism of action is unknown but appears to reduce neuronal excitability in the CNS.

Primary pharmacologic effects include analgesia, antitussive activity, respiratory depression, sedation, physical dependence, and

intestinal effects (eg, emesis, constipation/defecation, reduced secretions). Analgesic effects in dogs and cats begin ≈1 to 5 minutes after IV injection and usually persist for 2 to 4 hours, depending on dose and pain severity. Duration of analgesia has not been shown to correlate with plasma hydromorphone concentration in cats[3] or horses.[4]

Secondary pharmacologic effects include:

CNS: Euphoria, sedation, and confusion; excitatory effects (ie, disinhibition) can occur, possibly through reduction in the release of inhibitory neurotransmitters (eg, gamma-aminobutyric acid [GABA]), and may be mediated by a glucuronide metabolite.

Cardiovascular: Bradycardia due to central vagal stimulation, peripheral vasodilation from depressed alpha-adrenergic receptors but not histamine release,[5] decreased peripheral resistance, and baroreceptor inhibition. Orthostatic hypotension and syncope may occur.

Urinary: Increased bladder sphincter tone can induce urinary retention.

Endocrine: Inhibited secretion of glucagon, insulin, somatostatin, and vasopressin. Hydromorphone administered to healthy dogs after mask induction reduced isoflurane minimum alveolar concentration (MAC) by 33% to 50% for up to 4.5 hours after administration.[6]

Various species may exhibit contradictory effects from hydromorphone. For example, horses, cattle, swine, and cats may develop excitement, and dogs may defecate after hydromorphone injections. These effects are in contrast to the expected effects of sedation and constipation. Dogs and humans may develop miosis, and other species, particularly cats, may develop mydriasis.

Hydromorphone-associated sedation in dogs is often reported as an attribute/adverse effect (see ***Adverse Effects***). A prospective, randomized, blinded, controlled trial found that clinically normal dogs receiving hydromorphone (alone) 0.1 mg/kg IM did not have significantly higher sedation scores as compared with placebo, whereas acepromazine (alone) and acepromazine/hydromorphone caused significant levels of sedation.[7]

Respiratory depression can occur, especially in debilitated, neonatal, or geriatric patients. Bradycardia, slight decrease in cardiac contractility, and/or decrease in blood pressure may occur. Like oxymorphone, hydromorphone initially increases respiratory rates (panting in dogs), and oxygenation may decrease and blood CO_2 concentrations may increase by 10 mm Hg or more. Gut motility decreases with resultant increases in gastric emptying times. Unlike morphine or meperidine, IV hydromorphone rarely causes mild histamine release in dogs or cats. Unlike morphine and fentanyl, hydromorphone does not appear to affect the immune system or stimulate the hypothalamic-pituitary-adrenal (HPA) axis or cortisol release.[8]

Horses have marked variation in response. Opioids can induce eating behavior at low doses and dose-dependent locomotor activity with incoordination at high doses.[9]

Pharmacokinetics

Hydromorphone is absorbed via IM, SC, and rectal routes. It is rapidly absorbed following oral administration, but extensive first-pass metabolism limits bioavailability. Peak concentrations occur 10 to 30 minutes after SC administration in dogs. The volume of distribution in dogs is high (more than 4 L/kg) with IV and SC administration.[1] In a study of cats, bioavailability was 22% following buccal (OTM) administration.[10] Protein binding is negligible.

Hydromorphone is metabolized in the liver by glucuronidation. The terminal half-life is short and appears to be route- and dose-dependent; half-life in dogs receiving 0.1 mg/kg IV is ≈30 to 50 minutes and ≈60 to 80 minutes at higher doses (0.2 – 0.5 mg/kg IV)[1,11], and SC dosing extends half-life ≈10% to 15%.[11] In a study of cats, elimination half-life was 99 minutes,[3] possibly due to reduced capacity for glucuronidation. The glucuronidated metabolite is excreted by the kidneys.

After IM administration (0.04 mg/kg) in horses, bioavailability was high.[12] Volume of distribution is 1.1 – 2.2 L/kg, and clearance is 66-92 mL/minute/kg.[4,12] In horses receiving IV hydromorphone, elimination half-life appeared to be dose-dependent: 0.01 mg/kg, 18.1 minutes; 0.04 mg/kg, 34 minutes; 0.08 mg/kg, 41 minutes.[4] After IM administration (0.04 mg/kg), elimination half-life was 27 minutes.[12]

Contraindications/Precautions/Warnings

Hydromorphone is contraindicated in patients hypersensitive to it or other narcotic analgesics and in patients that have significant respiratory depression, asthma, or other airway hyperresponsiveness. Due to the adverse effect of vomiting, hydromorphone as a preanesthetic medication in animals with suspected gastric dilatation volvulus, ileus, or intestinal obstruction is usually considered contraindicated. Opioid analgesics are contraindicated in patients that have been stung by the scorpion species *Centruroides sculpturatus Ewing* or *C gertschi Stahnke*, as they may potentiate the scorpion's venom.[13] Hydromorphone is generally considered contraindicated in humans if a monoamine oxidase inhibitor (MAOI; eg, selegiline) has been used in the past 14 days due to unpredictable CNS effects with concurrent therapy.

Hydromorphone should be used with extreme caution in patients with head injuries, increased intracranial and ocular pressure, or deep corneal ulcers, as reduced respiration and resulting CO_2 retention may exacerbate the underlying conditions. Hydromorphone should also be used with extreme caution in patients suffering from respiratory disease or acute respiratory dysfunction (eg, pulmonary edema secondary to smoke inhalation). However, opioids may be used in animals that are anesthetized and ventilated. Consider having a narcotic antagonist (eg, naloxone) readily available if use of hydromorphone in high-risk patients cannot be avoided. Use with caution in animals with acute abdominal conditions (eg, colic), as it may obscure the diagnosis or clinical course of these conditions.

Opioids should be used with caution in patients with hypothyroidism, seizure disorders, hypotension, and/or hypoadrenocorticism (Addison's disease). Opioids should also be used with caution in patients with moderate to severe hepatic or renal insufficiency, and a dose reduction of 25% to 50% is recommended in humans with hepatic or renal impairment. All opioids should be avoided in patients with diarrhea caused by a toxic ingestion until the toxin is eliminated from the GI tract.

Hydromorphone can cause bradycardia and therefore should be used cautiously in patients with pre-existing bradyarrhythmias. Hypotension resulting in decreased cardiac output can occur with hydromorphone.

Neonatal, debilitated, or geriatric patients may be more susceptible to the effects of hydromorphone and may require lower dosages.

Hyperthermia has been reported in cats with hydromorphone use, and some recommend avoiding use in cats.[14–16] If hydromorphone is used in cats at high dosages, it has been recommended to give concurrently with a tranquilizing agent (eg, acepromazine), as hydromorphone can produce unpredictable behavior changes in this species.

For humans, there is an FDA black-box warning to emphasize the risk for respiratory depression, abuse, and medication errors associated with prescribing hydromorphone.

Hydromorphone may impair the performance of service or working dogs.

Adverse Effects

Hydromorphone has an adverse effect profile that is similar to oxy-

morphone and morphine in dogs and cats. In dogs, vomiting, sedation, panting, whining/vocalization, and defecation can be noted. Studies in dogs have concluded that hydromorphone-induced vomiting can be prevented by maropitant (SC given 15 to 45 minutes prior or PO given at least 2 hours prior to hydromorphone).[17–21] Vomiting, nausea, and defecation may occur more frequently after SC administration as compared with IV administration. CNS depression may be greater than desired, particularly when treating moderate to severe pain. In dogs, CRIs administered at greater than 0.05 mg/kg/hour IV for more than 12 hours may cause sedation and adverse effects severe enough to require reducing the rate.[14] In a study, acupuncture at pericardium 6 reduced the incidence of vomiting in dogs receiving hydromorphone.[22]

Dose-related respiratory depression is possible and more likely to occur with general anesthesia. Panting may occur more often with hydromorphone than with oxymorphone. Cough suppression can occur and may be a benefit of therapy.

Hydromorphone can cause bradycardia secondary to enhanced vagal tone to the same degree as with morphine, and can be treated with an anticholinergic (eg, atropine, glycopyrrolate). QT interval prolongation has been documented in dogs.[23]

Hydromorphone may cause histamine release that may be significant in critically ill animals, although this is generally significantly less than what is seen with morphine and usually clinically insignificant.[5]

Constipation is possible with prolonged administration.

In cats, hydromorphone may increase body temperature following anesthesia.[15,24] One study in 8 cats showed that hydromorphone, morphine, butorphanol, and buprenorphine all similarly cause an equivalent increase in body temperature.[24,25] The increased body temperature in all of the experimental treatments was self-limiting, and most returned to normal within 5 hours. No apparent morbidity or mortality was noted. Administration of ketamine or isoflurane in addition to hydromorphone did not produce a clinically relevant increase in body temperature as compared with hydromorphone alone.[25] Naloxone can be used to reverse hydromorphone to rapidly reduce body temperature in cats if hyperthermia occurs. As an alternative, if analgesia is still required, low doses of dexmedetomidine can be administered. One study documented dysphoria in 2 of 6 cats.[16]

Increased heart rate, respiratory rate, and body temperature have been noted in healthy horses given hydromorphone under experimental conditions.[4] Hydromorphone does not appear to increase the incidence of postanesthesia signs of colic in horses.[26]

Reproductive/Nursing Safety

Following hydromorphone exposure in pregnant laboratory animals, reduced postnatal survival, neural tube defects, and skeletal and soft tissue abnormalities were noted.[27] Reduced fertility (both male and female) has been noted in laboratory animals. Hypogonadism has occurred in humans.

Hydromorphone is excreted in breastmilk but minimal effects in the nursing offspring would be expected as oral hydromorphone is poorly bioavailable.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Massive overdoses may produce profound respiratory and/or CNS depression in most species. Other effects may include cardiovascular collapse, hypothermia, and skeletal muscle hypotonia. Mania may be seen in cats. Naloxone is the agent of choice in the treatment of respiratory or circulatory depression. In overdoses, naloxone doses may need to be repeated and animals observed closely, as naloxone's effects can diminish before subtoxic concentrations of hydromorphone are attained. Mechanical ventilatory support should be considered in cases of severe respiratory depression.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydromorphone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Anticholinergic Agents** (eg, **atropine, glycopyrrolate**): Medications with anticholinergic properties may increase the risk for urinary retention and constipation when combined with opioids.
- **Antihistamines** (eg, **diphenhydramine, hydroxyzine**): Additive CNS depressant effects possible
- **Benzodiazepines** (eg, **alprazolam**, **diazepam, midazolam**): Additive CNS and respiratory depressant effects are possible.
- **Buprenorphine**: Concurrent high-concentration buprenorphine and hydromorphone did not provide additive antinociception, and the combination had a shorter duration of effect as compared with high-concentration buprenorphine used alone.[28]
- **Butorphanol**: Butorphanol has been shown to decrease the duration of analgesia in dogs and cats and may be considered a partial antagonist.[29,30]
- **Clopidogrel**: Opioid use may delay and reduce formation of the clopidogrel active metabolite and the drug's antiplatelet effect, possibly by reducing GI motility and drug absorption.
- **Desmopressin**: Opioids may increase the risk for water intoxication or hyponatremia when combined.
- **Diuretics** (eg, **furosemide**): Opioids may decrease efficacy in heart failure patients.
- **Gabapentin**: Additive CNS depressant effects possible
- **Gastrointestinal Agents, Prokinetic** (eg, **metoclopramide, cisapride**): Opioids may antagonize the GI motility effects of these agents.
- **Local Anesthetic Agents** (eg, **bupivacaine, lidocaine, ropivacaine**): Additive cardiorespiratory depressant effects possible
- **Magnesium Sulfate**: The CNS effects of hydromorphone may be increased, more likely with higher magnesium doses or IV magnesium therapy.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): Severe and unpredictable opioid potentiation may be seen; not recommended in humans if MAOIs have been given within 14 days.
- **Ondansetron**: Increased risk for serotonin syndrome
- **Phenobarbital**: Additive CNS depressant effects possible
- **Phenothiazines** (eg, **acepromazine**): Some phenothiazines may antagonize analgesic effects and increase the risk for hypotension.
- **Serotonin Modulators** (eg, **fluoxetine, mirtazapine, trazodone**): CNS depression may occur when combined with hydromorphone and increase the risk for serotonin syndrome.
- **Sevoflurane**: Sevoflurane enhanced hydromorphone-induced QT prolongation in dogs.[23]
- **Skeletal Muscle Relaxants** (eg, **dantrolene, methocarbamol**): Hydromorphone may enhance CNS depressant effects.

- **Succinylcholine**: Opioids combined with succinylcholine may enhance the bradycardic effects of opioids.
- **Trazodone**: Additive CNS depressant effects possible
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Hydromorphone may exacerbate the effects of tricyclic antidepressants.

Laboratory Considerations

- Opioids may increase biliary tract pressure, resulting in increased plasma **amylase** and **lipase** values up to 24 hours following their administration.

Dosages

DOGS:

Analgesic (extra-label): Recommendations vary but are generally 0.05 – 0.2 mg/kg IV, IM, or SC every 2 to 4 hours. May be given as a CRI with an initial dose of 0.025 – 0.05 mg/kg IV followed by 0.03 mg/kg/hour IV CRI[31]

Sedative or premedication prior to painful procedures (extra-label): Used in combination with another agent:

Young, healthy patients:

a) Hydromorphone 0.1 mg/kg in combination with acepromazine 0.02 – 0.05 mg/kg and administered IM, although acepromazine has been used at higher (0.1 mg/kg)[7] and lower doses (0.005 mg/kg).[32]
b) Hydromorphone 0.1 mg/kg IM combined with dexmedetomidine 3.5 µg/kg IM. Injection into the semimembranosus and cervical muscle sites had a faster onset of sedation compared to gluteal and lumbar sites.[33]

Sedative/restraint agent for fractious or aggressive dogs: Hydromorphone 0.1 – 0.2 mg/kg combined with acepromazine 0.05 mg/kg and administered IM. Maximal effect usually reached in ≈15 minutes but waiting another 15 minutes may be necessary in some dogs.

Alternative induction method (especially in critical patients): Hydromorphone 0.05 – 0.2 mg/kg IV slowly to effect, followed by diazepam 0.02 mg/kg IV (do NOT mix together). Endotracheal intubation may be possible after administration; if not, use an induction agent (eg, propofol [IV]; ketamine or alfaxalone [IV or IM]). Controlled ventilation will likely be necessary.[34]

Anesthesia (extra-label):

a) During surgical sterilization: Hydromorphone 0.09 mg/kg combined with medetomidine 40 µg/kg and ketamine 4.5 mg/kg and administered IM.[35]
b) Hydromorphone 0.1 mg/kg IV bolus followed by 0.02 – 0.1 mg/kg/hour IV CRI with isoflurane.[36]

Emetic (extra-label): 0.1 mg/kg IM. Apomorphine and ropinirole may be more reliable emetics in dogs.

CATS:

Analgesic (extra-label): Recommendations vary but are generally 0.05 – 0.1 mg/kg IV, IM, or SC every 2 to 6 hours. May be given as an IV CRI with an initial dose of 0.025 mg/kg IV followed by 0.01 – 0.05 mg/kg/hour IV CRI (starting at low end of range).

Sedation (extra-label): Hydromorphone 0.1 mg/kg combined with alfaxalone 1.5 mg/kg and midazolam 0.2 mg/kg and administered IM.[37]

Premedication prior to moderately painful procedures (extra-label):

Young, healthy patients: Hydromorphone 0.1 mg/kg combined with acepromazine 0.05 – 0.2 mg/kg and administered IM

Alternative induction method (especially in critical patients): Hydromorphone 0.05 – 0.2 mg/kg IV slowly to effect, followed by diazepam 0.02 mg/kg IV (do not mix together). Endotracheal intubation may be possible after administration; if not, delivery of an inhalant by facemask will give a greater depth of anesthesia. Positive pressure ventilation will likely be necessary.[34]

Anesthesia (extra-label): Hydromorphone 0.05 – 0.1 mg/kg combined with dexmedetomidine 15 – 20 µg/kg, and ketamine 5 – 8 mg/kg and administered IM.[38,39] Doses at the high end of these ranges have been used for female cats being sterilized.[38] Once intubated, alfaxalone or inhalant anesthesia can be added to maintain general anesthesia as needed for longer procedures.

Epidural (extra-label): 0.05 mg/kg provided analgesia for up to 3 hours in healthy cats without causing hyperthermia.[40]

Emetic (extra-label): 0.1 mg/kg SC; hydromorphone causes less sedation as compared with dexmedetomidine when used as an emetic.[2]

HORSES:

Analgesia (extra-label): 0.04 mg/kg IV or IM.[4,12,41] Analgesia and an increase in thermal threshold persisted for 8 to 12 hours in healthy horses under experimental conditions.[4,12]

Epidural (extra-label): 0.04 mg/kg administered epidurally increased avoidance threshold to noxious stimuli for 250 minutes after administration to 6 healthy horses.[42]

FERRETS:

Analgesic (extra-label):

a) 0.05 – 0.2 mg/kg IV, IM, or SC every 6 to 8 hours[43]
b) 0.05 mg/kg IV loading dose, followed by 0.05 – 0.1 mg/kg per hour IV CRI[43]

SMALL MAMMALS:

Analgesia for moderate to severe pain (extra-label): 0.05 – 0.2 mg/kg SC or IM every 6 to 8 hours[43]

Chinchillas (extra-label): 2 mg/kg SC was effective for short-term analgesia but caused transient decreases in food intake and fecal output.[44]

Rabbits (extra-label): Hydromorphone 0.1 mg/kg combined in the same syringe with dexmedetomidine 5 µg/kg and alfaxalone 5 – 7 mg/kg and administered IM facilitated orotracheal intubation.[45]

REPTILES:

Analgesic (extra-label): Most clinicians recommended dosages are 0.5 – 1 mg/kg SC or IM every 24 hours.

Monitoring

- Respiratory rate and depth, $ETCO_2$, pulse oximetry (SpO_2)
- Heart rate
- CNS level of depression/excitation
- Blood pressure (especially with IV use)
- Analgesic efficacy
- Body temperature

Client Information

- Use injectable hydromorphone in an in-patient setting or with direct veterinary professional supervision.
- Hydromorphone is classified as a schedule II (C-II) controlled drug by the federal Drug Enforcement Agency (DEA). Use of this medication in animals or humans other than those for whom they are prescribed is illegal.

Chemistry/Synonyms

Hydromorphone HCl, a semisynthetic phenanthrene-derivative opioid related to morphine, occurs as a white to off-white, fine, crystalline powder. It is freely soluble in water and very slightly soluble in

ethanol. The commercial injection has a pH of 3.5 to 5.5.

Hydromorphone may also be known as dihydromorphinone hydrochloride. *Dilaudid*® is a common trade name.

Storage/Stability

The injection should be stored protected from light at room temperature (20°C-25°C [68°F-77°F]); excursions are permitted between 15°C and 30°C (59°F-86°F). A slight yellowish tint to the solution for injection may occur but does not indicate loss of potency. The injection remains stable for at least 24 hours when mixed with commonly used IV fluids if protected from light.

Hydromorphone tablets should be stored at room temperature (20°C-25°C [68°F-77°F]) in tight, light-resistant containers. Refrigerate suppositories and protect from light.

Hydromorphone is a DEA Schedule II-controlled substance that should be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Hydromorphone injection is **compatible** with commonly used IV fluids (for 24 hours when protected from light at 25°C [77°F]) and with atracurium, atropine, dexmedetomidine, glycopyrrolate, mannitol, metoclopramide, midazolam, ondansetron, potassium chloride, and propofol. Hydromorphone injection mixed in the same syringe with atropine and medetomidine for use as a preoperative agent in dogs prior to sevoflurane or propofol anesthesia has been described.[46]

Hydromorphone is **incompatible** with ampicillin, cefazolin, dantrolene, diazepam, ketamine, pantoprazole, phenobarbital, sodium bicarbonate, and thiopental.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Hydromorphone HCl Injection: 1 mg/mL in 0.5 mL syringes; 1 mg/mL in 1 mL ampules and syringes; 2 mg/mL in 1 mL vials, ampules, and syringes; 2 mg/mL in 20 mL vials; 4 mg/mL in 1 mL ampules and syringes; 10 mg/mL in 1 mL and 5 mL ampules and syringes; and 10 mg/mL in 50 mL vials; *Dilaudid*®, generic; (Rx, C-II). Preservative-free formulations available

Hydromorphone HCl Oral Tablets: 2 mg, 4 mg, and 8 mg; generic; (Rx, C-II)

Hydromorphone HCl Oral Tablets (extended-release): 8 mg, 12 mg, 16 mg, and 32 mg; generic; (Rx, C-II)

Hydromorphone HCl Oral Liquid: 1 mg/1 mL in 473 mL bottle (may contain sodium metabisulfite); *Dilaudid*®, generic; (Rx, C-II)

Hydromorphone Suppositories: 3 mg; generic; (Rx, C-II)

Report dispensing to state monitoring programs where required.

Hydroxychloroquine

(hye-***drox***-ee-***klor***-oh-kwin) *Plaquenil*®

Antimalarial; Immunomodulator

Prescriber Highlights

- ► Oral antimalarial and immunomodulating drug with potential to treat variants of canine lupus erythematosus
- ► Contraindications include hypersensitivity to it or other 4-aminoquinolones.
- ► Adverse effect profile is not well established because of lack of experience in veterinary medicine, but may include lethargy, vomiting, diarrhea, and sensitivity to the sun.
- ► Little clinical experience or published evidence for veterinary use; use with caution

Uses/Indications

There is limited information available on the safety and efficacy of this agent in dogs, but case reports suggest hydroxychloroquine may be useful for treating variants of canine exfoliative cutaneous lupus erythematosus[1,2] and generalized discoid lupus erythematosus.[3] Only a few case reports have been published to date, and while the drug may prove beneficial, its use at present must be considered experimental.

Pharmacology/Actions

Hydroxychloroquine is an orally administered aminoquinoline with antimalarial and immunomodulatory properties. The exact immunomodulatory mechanism is unknown, but it is thought to inhibit neutrophil phagocytosis and superoxide production, chemotaxis, and toll-like receptor (TLR)-9 stimulation. Other actions that may contribute to its effects for treating lupus erythematosus include decreasing ultraviolet light sensitivity, and antiplatelet and antihyperlipidemic effects.

Hydroxychloroquine is active against the erythrocytic forms of chloroquine-sensitive strains of *Plasmodium* spp, but not against exoerythrocytic forms and gametocytes. The drug appears to concentrate in parasite digestive vacuoles; antimalarial activity may result from impairment of the parasite's ability to metabolize and utilize erythrocyte hemoglobin.

Pharmacokinetics

No information was located for dogs. In humans, hydroxychloroquine has an oral bioavailability of 74%. It is extensively metabolized by the liver. Elimination half-life is very long (40 days).

Contraindications/Precautions/Warnings

Hydroxychloroquine is contraindicated in patients hypersensitive to the drug or to other 4-aminoquinoline compounds (eg, amodiaquine, chloroquine). In humans, it is recommended to use hydroxychloroquine with caution in pediatric patients and in patients with pre-existing cardiac abnormalities (eg, cardiomyopathy, rhythm disturbances), psoriasis or other dermatoses, porphyria, myopathy, neuropathy, and renal or hepatic disease. Application of this information to animals is unknown.

Avoid excessive sun exposure in dogs with thin hair coats.

In humans, irreversible retinopathy has been noted, particularly in association with higher dosages, duration of treatment greater than 5 years, concurrent macular disease, and reduced renal function.

Do not confuse hydroxyCHLORoquine with hydroxyUREA or hydroCORTisone.

Adverse Effects

There is not enough clinical experience of this drug's use in dogs to fully characterize an adverse effect profile. In the limited numbers of dogs treated, it generally has been tolerated well. Lethargy and GI

effects (eg, vomiting, diarrhea) have been noted.[5]

In humans, common adverse effects include ocular effects (eg, retinal damage), myopathy or neuromyopathy, GI effects (eg, anorexia, diarrhea, nausea, abdominal cramps, vomiting), CNS effects (eg, headache, dizziness, decreased seizure threshold), dermatologic effects, and hypoglycemia. Children appear especially prone to adverse effects. The risk for retinal changes in humans is low when dosages are 6.5 mg/kg per day or less.

Reproductive/Nursing Safety

Hydroxychloroquine readily crosses the placenta. Embryonic death and fetal ophthalmic toxicity (eg, anophthalmia, microphthalmia) have been demonstrated in mice. In humans, when used at antimalarial dosages, the CDC considers the drug safe for use during pregnancy, but it is unknown if it is safe at higher doses. Manufacturers state its use during pregnancy should be avoided except in the suppression or treatment of malaria.

Hydroxychloroquine is excreted into milk. While one source considers the drug compatible with nursing,[6] use cautiously during nursing as pediatric patients appear particularly sensitive to the effects of hydroxychloroquine.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses can be very serious and toxic quinidine-like effects can be noted within 30 minutes of ingestion. Signs of overdose and toxicity in humans include headache, drowsiness, visual disturbances, seizures, severe hypokalemia, rhythm, and conduction disorders (eg, QT prolongation, torsades de pointes, ventricular tachycardia, ventricular fibrillation) followed by sudden, potentially fatal, respiratory and cardiac arrest.

For patients in which the potential hydroxychloroquine overdose is large, consider GI decontamination. Acidification of the urine may increase urinary excretion.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydroxychloroquine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antacids** (eg, **aluminum hydroxide, calcium carbonate, magnesium hydroxide**): Reduced hydroxychloroquine absorption may occur; separate dosing by 4 hours.
- **Cimetidine**: Potentially increases pharmacological effects of hydroxychloroquine; dosage adjustment may be required.
- **Cyclosporine**: Increased serum levels of cyclosporine possible
- **Dapsone**: Combination may increase risk for hematologic toxicity
- **Digoxin**: Increased digoxin levels and effects possible
- **Hepatotoxic Drugs**: (eg, **androgens, azole antifungals [fluconazole, itraconazole, ketoconazole], estrogens, NSAIDs**): Increased risk for hepatotoxicity
- **Hypoglycemic Agents** (eg, **glipizide, insulin**): Enhanced glucose-lowering effects may occur.
- **Kaolin**: May reduce hydroxychloroquine absorption; separate dosages by at least 4 hours.
- **Metoprolol**: Hydroxychloroquine may increase effects.
- **Praziquantel**: Reduced praziquantel absorption may occur.
- **QT Prolonging Drugs** (eg, **amiodarone, cisapride, sotalol**): May increase risk for QT prolongation
- **Rabies Vaccine**: In human patients, hydroxychloroquine may decrease immune response. Veterinary significance is not known.

Laboratory Considerations

- No specific information noted

Dosages

DOGS:

Adjunctive treatment of canine exfoliative cutaneous lupus erythematosus (extra-label): There is little information available on doses, efficacy, or adverse effects. The following is derived from two case reports of 4 dogs total (German shorthaired pointers [$n = 3$], Chinese crested dog [$n = 1$]): 5 – 10 mg/kg PO once daily.[1,2]

Adjunctive treatment of canine generalized discoid lupus erythematosus (extra-label): From a report on the treatment of 3 dogs that received 5 mg/kg PO once daily along with topical tacrolimus 0.1% ointment applied twice daily, 2 dogs experienced complete remission; the third dog had 75% partial remission.[3]

Monitoring

- Efficacy
- Because there is little information on the safety of this drug in dogs, consider regular monitoring with eye examinations, CBC, serum chemistry profiles (including creatine kinase [CK]).
- Consider ECG and cardiac examinations in dogs with pre-existing cardiac abnormalities.
- Adverse effects include lethargy, GI disturbance, muscle pain, weakness.

Client Information

- Give this medicine with food.
- Not much experience when used in animals, report any side effects to your veterinarian.
- Keep away from children and other animals; overdoses can be very serious.
- While your animal is taking this medication, it is important to return to your veterinarian for examinations and lab work. Do not miss these important follow-up visits.

Chemistry/Synonyms

Hydroxychloroquine is a 4-aminoquinoline antimalarial agent that occurs as a white or practically white, odorless, crystalline powder. It exists in 2 forms: one form (usually used as the pharmaceutical) melts at about 240°C (464°F) and the other form melts at about 198°C (388.4°F). It is freely soluble in water and practically insoluble in alcohol, chloroform, and ether. Solutions in water have a pH of about 4.5. Hydroxychloroquine sulfate is a colorless crystalline solid, soluble in water to at least 20%. Hydroxychloroquine sulfate 200 mg is equivalent to 155 mg hydroxychloroquine.

Hydroxychloroquine sulfate may also be known as WIN-1258-2. A common trade name is *Plaquenil®*.

Storage/Stability

Hydroxychloroquine tablets can be stored at room temperature between 20°C and 25°C (68°F-77°F) in light-resistant containers with child-resistant closures. Medication should be stored out of reach of children and pets.

Compatibility/Compounding Considerations

Tablets may be split. Dogs weighing less than 5 kg (11 lb) require the dosage form to be compounded for accurate dosing (¼ tablet is

≈50 mg; upper end of suggested dosage is 10 mg/kg).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Hydroxychloroquine Sulfate Oral Tablets: 200 mg; *Plaquenil®*, generic; (Rx). Dosages for animals may need to be compounded.

Hydroxyethyl Starch (HES) Colloids

Hetastarch
Pentastarch
Tetrastarch

(***hye***-drox-ee ***eth***-il starch) *Hespan®, Vetstarch®*

Colloid Volume Expander

Prescriber Highlights

- ► Used to treat hypovolemia when colloidal therapy is required
- ► Contraindicated in patients with heart failure, pulmonary edema, intracranial bleeding, severe bleeding disorders, severe hypernatremia or hyperchloremia, and/or oliguric or anuric renal failure. Caution recommended in patients with thrombocytopenia or severe liver disease and patients undergoing CNS surgery
- ► May cause volume overload; use with caution in patients with cardiac or renal dysfunction.
- ► Adverse effects include the following: coagulopathies possible; rapid administration to small animal species (especially cats) may cause nausea and/or vomiting; hypersensitivity reactions are possible but very rare.
- ► Available hydroxyethyl starch (HES) colloids differ in their molecular weight (MW), degree of substitution, and concentration; nomenclature for these products can be confusing.

Uses/Indications

Hydroxyethyl starch (HES) colloids are used in the adjunctive treatment of hypovolemia and states of low oncotic pressure (ie, hypoalbuminemia) in small and large animal species.[1] They can be used to increase and support colloid osmotic pressure (COP). HES therapy can be considered when crystalloid therapy is not sufficiently improving or maintaining blood volume, when there is a need to prolong the duration of fluid resuscitation effects, or if crystalloids cannot be delivered fast enough to resuscitate a patient. They may also be chosen if edema develops during fluid resuscitation, when hypovolemia is due to blood loss but blood products are not deemed necessary, or to provide oncotic support in patients with decreased oncotic pressure (ie, total protein is less than 3.5 g/dL or albumin is less than 1.5 g/dL) where crystalloid therapy will cause hemodilution and promote further drops in oncotic pressure.[2]

Colloids (in combination with crystalloids) may also be considered in patients with traumatic brain injury.[3,4]

In experimental isoflurane-induced hypotension in dogs, hetastarch administration was found to be superior to lactated Ringer's solution (LRS) for restoration of blood pressure.[5]

In horses, hetastarch may be useful in increasing plasma oncotic pressure and volume expansion in hypoproteinemic conditions (eg, acute colitis); however, it has been shown that plasma may be superior to treat horses with enterocolitis when compared with hetastarch.[6] A study in anesthetized horses found that administration of hetastarch 6% at 2.5 mL/kg IV over 1 hour in combination with LRS failed to attenuate the decrease in COP typically seen during anesthesia with crystalloid administration alone.[7] Hetastarch 10 mL/kg and plasma 10 mL/kg both comparatively increased plasma COP in healthy horses for up to 48 hours.[8]

Pharmacology/Actions

Hydroxyethyl starch (HES) colloid acts as a plasma volume expander by increasing the oncotic pressure within the intravascular space similarly to either dextran or albumin. Maximum volume expansion occurs within a few minutes of the completion of infusion.

Duration of effect is variable but may persist for 24 hours or more for hetastarch (HES 450/0.7)[9] and ≈12 hours for tetrastarch (HES 130/0.4).

Pharmacokinetics

Lower molecular weight (MW) molecules (less than 50 kDa) are rapidly excreted by the kidneys; larger molecules are slowly degraded enzymatically to a size where they then can be excreted.[9] In a human pharmacokinetic study, 33% of a single 500 mL dose of 6% hydroxyethyl starch (HES) colloids 450/0.7 was excreted in the first 24 hours after infusion and after 2 weeks, more than 90% of the drug was excreted. In hypoproteinemic horses, colloidal pressure may be increased up to 24 hours after dosing. A study in healthy llamas found that administration of 15 mL/kg of HES 450/0.7 during a 60-minute IV infusion significantly increased plasma COP for 96 hours.[10]

Contraindications/Precautions/Warnings

The veterinary-labeled product (6% hydroxyethyl starch [HES] colloid 130/0.4) lists the following contraindications: known hypersensitivity to hydroxyethyl starch, fluid overload (eg, pulmonary edema, congestive heart failure), renal failure with oliguria or anuria not related to hypovolemia, patients receiving dialysis treatment, severe hypernatremia or hyperchloremia, or intracranial bleeding.[1] In severely dehydrated patients a crystalloid solution should be given prior to HES administration.[1]

Because of the danger of volume overload, use of HES for the treatment of shock that is not accompanied by hypovolemia or in the face of renal dysfunction or cardiac insufficiency may be hazardous. Additionally, administration of HES to animals with sepsis, systemic inflammatory response syndrome (SIRS), or severe trauma may cause extravasation of fluids into the lungs to cause or worsen pulmonary edema. See ***Monitoring.***

It is believed that significant bleeding can occur if HES colloids are used in animals with compromised coagulation systems (eg, von Willebrand disease, severe liver disease, thrombocytopenia), and therefore should be used with caution in these patients.[1,11,12] Because of their effect on platelets, HES should also be used with extreme caution in patients undergoing CNS surgery.

As they have no oxygen carrying capacity, HESs are not a replacement for whole blood or red blood cells.

In humans, there is a risk for acute kidney injury (AKI) with HES, particularly in acute sepsis patients.[9,13] The risk for AKI in animals remains under investigation.[14–17]

Nomenclature for these products can be confusing. Be certain when using HES products that you are familiar with the specific product and its respective cautions and uses. See ***Chemistry/Synonyms***.

Adverse Effects

Hydroxyethyl starch (HES) colloids can affect platelet function and coagulation times and alter factor VIII and von Willebrand factor. At recommended dosages, HES may cause changes in clotting times and platelet counts due to direct (precipitation of factor VIII) and dilutional causes.[1,9] A retrospective study in dogs showed that he-

tastarch can significantly increase PTT, but did not affect patient survival rates.[18] Tetrastarch did not impair primary hemostasis and induced transient dilutional coagulopathy comparable with lactated Ringer's solution in hemorrhaged dogs.[19] Clinically, all these effects may be insignificant, but patients with pre-existing coagulopathies or severe liver disease may be predisposed to further bleeding. Dosages of HES 450/0.7 exceeding 20 mL/kg/day are more likely to cause coagulation abnormalities.[11,20] Potentially, tetrastarch (HES 130/0.4) may have less effect on coagulation than hetastarch (HES 450/0.7 or HES 670/0.75). One in vitro study found that HES 130/0.4 affected canine platelet function, but the authors concluded that the clinical relevance of these in vitro findings is not obvious.[21] Another study found that HES 200/0.5, but not HES 130/0.4, significantly increased platelet closure time beyond the dilutional effect.[22] An in vivo study in dogs found that HES 670/0.75 at clinically relevant dosages prolonged closure time for up to 24 hours.[23]

HESs are less antigenic than dextrans, but they can cause sensitivity reactions and interfere with antigen-antibody testing. Anaphylactic reactions and severe coagulopathies can occur.[1] Pruritus has been observed in dogs.

When it is given via rapid infusion to cats, hetastarch may cause signs of nausea and vomiting[24]; if administered over 15 to 30 minutes, these signs are eliminated.

Circulatory overload leading to pulmonary edema is possible, particularly when large doses are administered to patients with diminished cardiac or renal function.[1] Do not give HES intramuscularly, as bleeding, bruising, or hematomas may occur.

When HES infusions are stopped, colloid that has leaked into interstitial spaces can pull additional fluid from the intravascular space.[25]

Administration of HES can cause hemodilution with resulting decreases in hematocrit and plasma protein concentration.[1]

Reproductive/Nursing Safety

Hydroxyethyl starch colloid (HES) 130/0.4 was not teratogenic in rabbits or rats, but embryolethality and fetal retardation have been observed.[1] It is not known whether HES are excreted in milk.[9]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

An overdose could result in volume overload (eg, pulmonary edema) in susceptible patients. Monitor fluid status carefully. In case of volume overload, the infusion should be stopped immediately and, if necessary, a diuretic should be administered.[1]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving HES colloids and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticoagulants** (eg, **heparins, rivaroxaban, warfarin**): High doses of hydroxyethyl starch colloid (HES) may increase risk for bleeding; use together with caution
- **Anti-Platelet Agents** (eg, **aspirin, clopidogrel**): High doses of HES may increase risk for bleeding; use together with caution
- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **enalapril**): Potential for increased serum potassium if used with HES in lactated electrolytes; increased monitoring warranted
- **Angiotensin Receptor Blockers** (**ARBs**; eg, **irbesartan, telmisartan**): Potential for increased serum potassium if used with HES in lactated electrolytes; increased monitoring warranted
- **Potassium-Sparing Diuretics** (eg, **spironolactone**): Potential for increased serum potassium if used with HES in lactated electrolytes; increased monitoring warranted
- **Ceftriaxone**: In human neonates, use with calcium-containing IV fluids (eg, HES in lactated Ringer's solution) is contraindicated.

Laboratory Considerations

- Administration of 6% hydroxyethyl starch colloid (HES) 130/0.4 in dogs has been found to cause an overestimation of total plasma protein when assessed via refractometry for at least 3 hours after treatment.[26]
- HES can falsely elevate **urine specific gravity** in dogs.[27]
- In humans, **serum amylase** concentrations may be increased for 3 to 5 days and interfere with pancreatitis diagnosis.[9]
- Increased **indirect bilirubin** concentration has been observed in humans for up to 96 hours following infusion of HES 450/0.7.
- At high doses, the dilutional effects may result in decreased concentrations of **coagulation factors**, other **plasma proteins,** and a decrease in **hematocrit.**[1,9]

Dosages

NOTE: Rate of administration is determined by individual patient requirements (ie, blood volume, indication, and patient response); adequate monitoring for successful treatment of shock is mandatory. The initial 10 – 20 mL should be infused slowly, keeping the patient under close observation due to possible anaphylactic-like reactions.[1] See ***Monitoring***. The following dosages should be used as general guidelines for treatment.

DOGS/CATS:

Plasma volume substitute: The daily dose and rate of infusion depend on the patient's blood loss, on the maintenance or restoration of hemodynamics, and on the hemodilution (dilution effect); can be administered repetitively over several days. The following dosages should be used as general guidelines for treatment.

a) **Using 6% HES 130/0.4 | *Vetstarch*®** (label dosage; not FDA-approved): As a general recommendation, up to 20 mL/kg/day in small animal patients[1]

b) **Using 6% HES 450/0.7 | *Hespan*®** (extra-label): Recommenations vary somewhat. In general, shock bolus (resuscitation): 10 – 20 mL/kg in dogs and 5 – 10 mL/kg in cats IV usually over 15 to 30 minutes. A CRI can follow at 1 – 2 mL/kg/hour IV; not to exceed 20 mL/kg/day (some clinicians recommend not exceeding 10 mL/kg/day in cats).

HORSES:

Plasma volume substitute (extra-label):

Adult horses:

a) 3 – 10 mL/kg IV bolus using hetastarch or tetrastarch. Total daily doses of 10 mL/kg should not be exceeded due to risk for coagulopathies.[28]

b) 10 mL/kg/hour IV bolus OR 8 – 10 mL/kg/day IV; maximum of 10 mL/kg/day[29]

c) 0.5 – 1 mL/kg/hour IV CRI; maximum of 10 mL/kg/day[29]

Neonatal foals: From a study using healthy foals, tetrastarch 20 mL/kg IV increased colloid osmotic pressure for up to 3 hours post-infusion.[30]

CAMELIDS:

Plasma volume substitute (extra-label): A study done in healthy llamas showed that 15 mL/kg IV significantly increased colloid

oncotic pressure for up to 96 hours. Transient, mild hemodilution, and mild increases in PT and PTT were noted.[10]

BIRDS:

Plasma volume substitute (extra-label): 10 – 15 mL/kg IV over 20 to 40 minutes, up to 4 times daily, OR 10 – 15 mL/kg bolus over 20 to 40 minutes followed by 1 – 2 mL/kg/hour IV CRI. Recommended maximum dosage is 20 mL/kg/day, but the author notes that she has exceeded this dosage with no adverse effects noted.[31]

Small volume replacement/CPCR resuscitation (extra-label): For debilitated patients in shock, administer hypertonic saline 3 – 5 mL/kg IV over 5 minutes, followed by hetastarch 3 – 5 mL/kg IV over 5 minutes. Follow with small boluses of crystalloid fluids (eg, lactated Ringer's solution, *Plasma-Lyte*® 15 – 20 mL/kg IV) in combination with hetastarch 3 – 5 mL/kg IV over 15 minutes and reassess the bird every 15 minutes. The crystalloids and hetastarch can be combined in the same syringe or fluid bag. This process is repeated every 15 to 20 minutes until temperature normalizes and blood pressure is over 120 mm Hg.[31]

Monitoring

- Hydration status and signs of fluid overload (eg, increased respiratory rate and effort, pulmonary edema)[1]
- Clinical signs of anaphylactic-like reactions, including worsening signs of shock and pruritus
- Renal chemistry panel and urine output[1]
- Serum electrolytes, acid-base balance[1]
- Colloid oncotic pressure
- Blood pressure, central venous pressure
- Coagulation parameters particularly in high-risk patients or when using high doses of hydroxyethyl starch colloid (HES)[1]

Client Information

- As these fluids are used in an inpatient setting only, factors to consider when communicating with owners are the drug's cost, the reasons for using colloid therapy, and potential adverse effects of therapy.

Chemistry/Synonyms

A synthetic polymer derived from a waxy starch, hydroxyethyl starch colloid (HES) is composed primarily of amylopectin. Hetastarch occurs as a white powder. It is very soluble in water and insoluble in alcohol.

To avoid degradation by serum amylase, hydroxyethyl ether groups are added to the glucose units. Commercially available HES solutions are classified by their mean molecular weight (MW) and degree of substitution (DS). The DS refers to the average number of hydroxyethyl groups per glucose unit within the branched-chain polymer.

A commonly used HES solution is 6% HES 450/0.7 in 0.9% sodium chloride (*Hespan*®), which has an average MW of 450 kD and a DS of 0.75. Although the average MW is 450 kD, commercial HES solutions contain a wide variation in molecule sizes, ranging from a few thousand to a few million Daltons distributed in a concentration/size ratio that is more or less a bell-shaped curve. The commercially available colloidal solution appears as a clear, pale yellow to amber solution. The 500 mL-commercial preparation (containing 6% HES 450/0.7 and 0.9% sodium chloride) contains sodium 77 mEq and chloride 77 mEq with an osmolality of 310 mOsm/L and a pH of ≈5.5.

The high-MW product 6% HES 670/0.75 in lactated electrolyte solution (*Hextend*®) contains sodium 143 mEq/L, chloride 124 mEq/L, lactate 28 mEq/L, calcium 5 mEq/L, potassium 3 mEq/L, magnesium 0.9 mEq/L, and dextrose 0.99 g/L. These values approximate what is found in human plasma.

The low-MW product 6% HES 130/0.4 in 0.9% sodium chloride (*Vetstarch*®, *Voluven*®) has an average MW of 130 kD, a DS of 0.4 (range 0.38-0.45), and a pH of 4 to 5.5. Each 500 mL bag contains sodium 77 mEq and chloride 77 mEq. Calculated osmolarity is 308.

Pentastarch 10% in 0.9% sodium chloride (*Pentaspan*®) MW ranges from 200 to 300 kD, has a DS range of 0.4 to 0.5, and a pH of ≈5. Calculated osmolarity is 326.

Hetastarch may also be known by the following synonyms: etherified starches, synthetic colloid, HES, and hydroxyethyl starch; many trade names are available.

Storage/Stability

Hetastarch 6% in 0.9% sodium chloride or lactated electrolyte should be stored at room temperature (15°C-25°C [59°F-77°F]); freezing and excessive heat should be avoided. Exposure to temperature extremes may result in formation of a crystalline precipitate or a color change to a turbid deep brown; do not use this product if this occurs.[9]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The following drugs are reported **compatible** at Y-sites with hetastarch (6% HES 450/0.7 in 0.9% sodium chloride): cimetidine, diltiazem, enalaprilat, and ertapenem. For *Hextend*®: Do not administer this product simultaneously with blood products through the same administration set, as there is a risk for coagulation.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated plasma expanders including hydroxyethyl starch colloid (HES) as class 3 substances with no legitimate use in racehorses. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

Tetrastarch Injection: 6% (6 g/100 mL) HES 130/0.4 in 0.9% sodium chloride injection in 250 mL and 500 mL polyolefin bags; *Vetstarch*®[1]; (Rx). This product is not FDA-approved for use in animals, but the label information has been approved by FDA.

HUMAN-LABELED PRODUCTS:

Hetastarch Injection 6% (6 g/100 mL) HES 450/0.7 in 0.9% sodium chloride in 500 mL IV infusion bottles, polyolefin bags, and single-dose containers; *Hespan*®; generic; (Rx)

Hetastarch Injection 6% (6 g/100 mL) HES 670/0.75 in lactated electrolyte in 500 mL IV infusion single-dose containers; *Hextend*®, generic; (Rx)

Tetrastarch Injection: 6% (6 g/100 mL) HES 130/0.4 in 0.9% sodium chloride in 500 mL polyolefin bags; *Voluven*®; (Rx). In some countries (not in the United States): Pentastarch 10% in 0.9% sodium chloride in 250 mL and 500 mL plastic bags; *Pentaspan*®; (Rx)

Hydroxyurea

(hye-***drox***-ee-yor-***ee***-a) *Hydrea®, Droxia®, Mylocel®*

Antineoplastic

Prescriber Highlights

- ► Used for the treatment of polycythemia vera, mast cell tumor, meningioma, and leukemias in dogs and cats
- ► Use with caution in patients that have anemia, myelosuppression, history of urate stones, infection, impaired renal function, or in patients receiving other chemotherapy or radiotherapy.
- ► Adverse effects include myelosuppression, GI-related (eg, anorexia, vomiting, diarrhea), stomatitis, sloughing of nails, alopecia, and dysuria.
- ► Proven teratogen; the National Institute for Occupational Safety and Health (NIOSH) classifies hydroxyurea as a hazardous drug; use appropriate precautions when handling it.

Uses/Indications

Hydroxyurea may be useful in the treatment of polycythemia vera, mast cell tumors, meningioma (as a single agent or combined with radiation therapy),[1,2] and leukemias in dogs and cats. A prospective, open-label study in dogs with mast cell tumors found an overall response rate of 28%.[3] It has also been used to treat dogs with chronic myelogenous leukemia that is no longer responsive to busulfan, and for the adjunctive medical treatment (to reduce hematocrit) of right to left shunting patent ductus arteriosus or tetralogy of Fallot. Hydroxyurea may also be of benefit in the treatment of feline hypereosinophilic syndrome.[4]

Pharmacology/Actions

Although the exact mechanism of action for hydroxyurea has not been determined, it appears to interfere with DNA synthesis without interfering with RNA or protein synthesis. Hydroxyurea apparently inhibits thymidine incorporation into DNA and may directly damage DNA. It is an S-phase inhibitor but may also arrest cells at the G_1-S border.

Hydroxyurea inhibits urease but is less potent than acetohydroxamic acid. Hydroxyurea can stimulate the production of fetal hemoglobin.

Pharmacokinetics

In humans, hydroxyurea is well absorbed after oral administration, reaching C_{max} in 1 to 4 hours. It crosses the blood–brain barrier and has a volume of distribution similar to total body water. Approximately 50% of an absorbed dose is excreted unchanged in the urine, and about 50% is metabolized in the liver and then excreted in the urine.

Contraindications/Precautions/Warnings

Risk versus benefit should be considered before using hydroxyurea in patients with the following conditions: anemia, bone marrow depression, history of urate stones, current infection, impaired renal function, or in patients that have received previous chemotherapy or radiotherapy (resulting in bone marrow dysfunction).

The National Institute for Occupational Safety and Health (NIOSH) classifies hydroxyurea as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Do not confuse hydroxyUREA with hydroxyZINE, hydroxychloroquine, or hydrochlorothiazide.

Adverse Effects

Potential adverse effects include GI effects (eg, anorexia, vomiting, diarrhea), stomatitis, sloughing of nails,[5] alopecia, and dysuria. Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant alopecia. Although hydroxyurea can cause vomiting, it is usually not severe. In humans, the most serious adverse effects associated with hydroxyurea are myelosuppression (eg, anemia, thrombocytopenia, leukopenia) and pulmonary fibrosis. If myelotoxicity occurs, it is recommended to halt therapy until values return to normal.

Macrocytosis has been reported in a dog receiving hydroxyurea therapy.[6]

In a case series of cats treated for primary erythrocytosis, 3 of 10 cats that were treated with hydroxyurea developed methemoglobinemia.[7] These cats had received hydroxyurea at greater than 100 mg/kg per dose, with clinical signs (eg, dyspnea, tachypnea, and cyanosis) seen after administration of the first dose.

Reproductive/Nursing Safety

Hydroxyurea is a teratogen. Use only during pregnancy when the benefits to the mother outweigh the risks to the offspring. Hydroxyurea can suppress gonadal function; the arrest of spermatogenesis has been noted in dogs. For sexually intact patients, verify pregnancy status prior to administration.

Hydroxyurea is distributed into milk, and nursing puppies or kittens should receive milk replacer when the dam is receiving hydroxyurea.

Overdose/Acute Toxicity

The reported LD_{50} in dogs following PO and IV administration was greater than 2 g/kg and greater than 1 g/kg, respectively. Cats given hydroxyurea in doses greater than 500 mg (total) may develop methemoglobinemia.

The most common clinical signs associated with an overdose include vomiting, ataxia, methemoglobinemia, tachycardia, lethargy, and hypothermia.

Because of the potential toxicity of the drug, overdoses should be treated aggressively with GI decontamination protocols employed when possible. Acetylcysteine or methylene blue (not for cats) has been suggested for treating methemoglobinemia.[8] For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydroxyurea and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Immunosuppressive Agents** (eg, **glucocorticoids, leflunomide**): Additive immunosuppressant effects may increase the risk for infection.
- **Myelosuppressive Agents** (eg, **other antineoplastics, chloramphenicol, iron chelators**): Concurrent use with other myelosuppressive medications may result in additive myelosuppression; avoid combination when possible.
- **Vaccines** (live and inactivated): Hydroxyurea may diminish vaccine efficacy and enhance adverse effects of vaccines.

Laboratory Considerations

- Hydroxyurea may raise serum **uric acid** concentrations; drugs such as allopurinol may be required to control hyperuricemia.

Dosages

NOTE: Hydroxyurea is not commonly used in veterinary med-

icine, and published dosage recommendations can vary widely. Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and because chemotherapy indications, treatment protocols, monitoring, and safety guidelines often change, the following dosages should be used only as a general guide.[9]

DOGS:

Polycythemia vera (PV) | Chronic myelogenous leukemia | mast cell tumors (extra-label): Dosage recommendations vary considerably. Generally, initial dosages of 30 – 60 mg/kg PO once daily (or divided twice daily) for 1 to 2 weeks (for PV, until hematocrit is below 60%) and then every other day (for PV, taper to lowest effective dosing frequency).[10]

Meningioma (extra-label): 50 mg/kg PO every 48 to 72 hours[1,2,11]

CATS:

PV | Chronic myelogenous leukemia (extra-label): Dosage recommendations vary considerably. Generally, initial dosages of 30 mg/kg PO once daily or 10 – 15 mg/kg PO twice daily for 1 to 2 weeks (for PV, until hematocrit is below 60%) and then every other day (for PV, taper to lowest effective dosing frequency). In one report, the median maintenance dosage for treatment of primary erythrocytosis was 22 mg/kg PO every 48 hours.[7]

Monitoring

NOTE: Cats may require more frequent monitoring than dogs.

- Baseline CBC with platelets followed by periodic evaluation at least every 1 to 2 weeks until stable, then every 3 months
- Baseline BUN and creatinine, then every 3 to 4 months
- Monitor for signs of methemoglobinemia (dyspnea, tachypnea, and cyanosis).

Client Information

- Hydroxyurea is a type of chemotherapy (anticancer). This medicine can be hazardous to other animals and people that come in contact with it. On the day your animal gets the medicine, and then for a few days afterward, handle all bodily waste (ie, urine, feces, litter), blood, or vomit only while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in with the regular trash.
- This medicine affects your animal's ability to fight infection. This effect will be greatest within a few weeks after treatment. Your veterinarian will monitor your animal for this problem. Do not miss important recheck appointments.
- Contact your veterinarian immediately if you see bleeding, bruising, fever (indicating an infection), difficulty breathing, or if your animal becomes tired easily.
- Hydroxyurea can be toxic to the gastrointestinal tract, causing vomiting, diarrhea, ulcers, and stomach upset. Giving the medicine to your animal with food may decrease these side effects.
- Hydroxyurea can cause loss of toenails and fur.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Structurally similar to urea and acetohydroxamic acid, hydroxyurea occurs as a white, crystalline powder that is freely soluble in water. It is moisture labile.

Hydroxyurea may also be known as hydroxycarbamide, hydroxycarbamidum, NSC-32065, SQ-1089, WR-83799, *Dacrodil®*, *Droxiurea®*, *Hydrea®*, *Droxia®*, *Hydrine®*, *Litalir®*, *Medroxyurea®*, *Neodrea®*, *Onco-Carbide®*, *Oxeron®*, *Siklos®*, and *Syrea®*.

Storage/Stability

Protect hydroxyurea capsules and tablets from light and store at 20°C to 25°C (68°F-77°F); keep bottle tightly closed.

Compatibility/Compounding Considerations

Because of limited available dosage forms, compounded preparations may be necessary to accurately dose small animals.

Compounded preparation stability:

A 40 mg/mL oral suspension has been prepared with eight 500 mg capsules and a 1:1 mixture of *OraSweet®* and *OraPlus®*, or a 1:1 mixture of methylcellulose 1% and simple syrup NF *qs ad* to 100 mL. Suspension is stable for 14 days at room temperature or refrigerated.[12]

Additionally, triturating ten hydroxyurea 500 mg capsules with room temperature water, stirring, filtering, and bringing to a final volume of 50 mL with *Syrpalta®* yields a 100 mg/mL suspension that retains greater than 95% potency for 180 days when stored at 25°C (77°F).[13]

Suspensions of hydroxyurea heated to 41°C (106°F) result in an immediate 40% loss of drug potency. Compounded preparations of hydroxyurea should be protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Hydroxyurea Oral Capsules: 200 mg, 300 mg, 400 mg, and 500 mg; *Hydrea®*, *Droxia®*, generic (500 mg only); (Rx)

Hydroxyurea Oral Tablets: 100 mg and 1 g; *Siklos®*; (Rx)

Hydroxyzine

Hydroxyzine Hydrochloride

Hydroxyzine Pamoate

(hye-***drox***-i-zeen) *Atarax®, Vistaril®*

Antihistamine, First-Generation

Prescriber Highlights

- ► Used principally for antihistaminic, antipruritic, and sedative or tranquilization qualities; should be given on a regular basis when prescribed for adjunctive therapy of atopic dermatitis
- ► Contraindications include hypersensitivity to hydroxyzine or cetirizine (metabolite of hydroxyzine).
- ► Caution is advised with narrow-angle glaucoma, hypertension, GI or urinary obstruction, hyperthyroidism, seizures, and cardiovascular disease.
- ► Sedation is the most common adverse effect. Tremors and/or seizures can occur in dogs (rare); polydipsia, depression, and/or behavioral changes can occur in cats.

Uses/Indications

Hydroxyzine is a first-generation antihistamine that may be useful in dogs, cats, and horses for the adjunctive treatment of histamine-mediated pruritic and allergic conditions (eg, urticaria, insect bite hypersensitivity) and atopic dermatitis. It also has sedative and tranquilization effects. Guidelines for atopic dermatitis treatment in dogs state that antihistamines have modest efficacy; hydroxyzine should be given continuously (ie, daily) as preventive therapy before an acute flare.[1,2]

The response to hydroxyzine, as with other antihistamines in dogs and cats, is individualized and not predictable. One patient may respond to one antihistamine but not another. Better results might be

obtained if hydroxyzine is combined with chlorpheniramine, as this combination has been reported to be effective in reducing the clinical signs of canine atopic dermatitis in ≈1 of 3 treated dogs,[3] and pruritus improved by more than 25% in 10 of 17 dogs.[4]

This class of drugs may also be used as adjunctive therapy for mast cell tumors and to prevent local histamine release during surgical excision of mast cell tumors.

Because of its CNS depressant effects, hydroxyzine may also be of benefit as a mild sedative in small animal species.

Pharmacology/Actions

H_1-receptor antagonist antihistamines competitively inhibit histamine H_1 receptors; they do not inactivate or prevent the release of histamine but can prevent histamine's action on the cell. In addition to its antihistaminic effects, hydroxyzine has anticholinergic, sedative, tranquilizing, antispasmodic, local anesthetic, mild bronchodilative, and antiemetic effects.

Pharmacokinetics

In dogs, hydroxyzine (pamoate) has an oral bioavailability of ≈70% but with high interpatient variability. Peak concentrations occur ≈3 hours after administration, and elimination half-life is ≈18 hours. Hydroxyzine is rapidly converted to the active metabolite, cetirizine, which has an elimination half-life of ≈11 hours. Area under the curve (AUC) for cetirizine was ≈10 times that for hydroxyzine.[5]

In a study with 12 horses, peak plasma concentration was reached ≈45 minutes after a single 500 mg oral dose of hydroxyzine hydrochloride was given. Elimination half-life was 7.4 hours. Hydroxyzine AUC was roughly double that of cetirizine.[6]

Contraindications/Precautions/Warnings

Hydroxyzine is contraindicated in patients hypersensitive to it or its active metabolite, cetirizine. Because of its anticholinergic activity, hydroxyzine should be used with caution in patients with prostatic hypertrophy, bladder neck obstruction, severe cardiac failure, angle-closure glaucoma, prolonged QT interval, pulmonary diseases with minimal mucosal secretions, or pyeloduodenal obstruction. Avoid or use with caution in patients with a history of seizures.

Pediatric human patients are more susceptible to the adverse CNS effects of antihistamines; it is recommended to avoid use in neonates.

Hydroxyzine is a vesicant; injections should only be administered IM, preferably into a large muscle. Injection by any other route (eg, IV, SC) is contraindicated in humans.

Do not confuse hydrOXYzine with hydrALAZINE, HYDROmorphone, hydroxychloroquine, or hydroxyurea.

Adverse Effects

The most likely adverse effect associated with hydroxyzine is sedation. In dogs, this is usually mild and transient and may diminish with repeated doses. Antihistamines may cause paradoxical excitement, and fine rapid tremors, whole body tremors, and seizures (rare) are possible in dogs. Anticholinergic effects (eg, dry mouth, urine and fecal retention) are possible.

Local reactions (including significant tissue damage) may occur after administration of hydroxyzine injection. Tissue necrosis and abscesses have occurred after SC injection.

The sedative effects of antihistamines may adversely affect the performance of working dogs and horses.

Reproductive/Nursing Safety

Hydroxyzine crosses the placenta. The drug has been shown to be teratogenic in laboratory animals at doses substantially greater than those used therapeutically.[7] Use during the first trimester of pregnancy is contraindicated in humans.[7]

It is unknown if hydroxyzine enters maternal milk. In breastfeeding women that require an antihistamine, second-generation agents (eg, cetirizine) are preferred.[8]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses would be expected to cause increased sedation and hypotension (possible). Coma and apnea were reported in a dog with a large oral exposure.[9] At high doses, common signs can include lethargy, hyperthermia, tremors, tachycardia, ataxia, and seizures.

Treatment consists of GI decontamination (if ingestion was oral) using standard protocols. Induce emesis if the animal is alert and CNS status is stable. Administration of a saline cathartic and/or activated charcoal may be given after emesis or gastric lavage. Treatment should be performed using supportive therapy based on clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hydroxyzine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetylcholinesterase Inhibitors** (eg, **neostigmine, pyridostigmine**): Hydroxyzine may reduce effects of acetylcholinesterase inhibitors.
- **Anticholinergic Agents** (eg, **atropine, glycopyrrolate, oxybutynin**): Additive anticholinergic effects may occur when hydroxyzine is used concomitantly with other anticholinergic agents.
- **Benzodiazepines** (eg, **alprazolam, diazepam, midazolam**): Additive CNS depression may occur.
- **Cimetidine**: Cimetidine increased hydroxyzine serum concentration and area under the curve (AUC) as well as prolonging the duration of IDT wheal suppression in rabbits.[10]
- **CNS Depressant Drugs, Other** (eg, **acepromazine, ketamine, methocarbamol, mirtazapine, phenobarbital, trazodone**): Additive CNS depression may occur if hydroxyzine is combined with other CNS depressant medications.
- **Epinephrine**: Hydroxyzine may inhibit or reverse the vasopressor effects of epinephrine; use norepinephrine or metaraminol instead.
- **Opioids** (eg, **buprenorphine**, **fentanyl, hydromorphone, methadone, morphine, tramadol**): Additive CNS depression and anticholinergic effects may occur. In humans, hydroxyzine may have an opioid-sparing effect.
- **Potassium Salts, Oral**: Hydroxyzine may reduce GI motility, which can enhance the ulcerogenic effects of oral solid potassium dosage forms.
- **Prokinetic Agents** (eg, **cisapride, erythromycin, metoclopramide**): The anticholinergic effects of hydroxyzine may decrease the effects of prokinetic agents.
- **QT Prolonging Agents** (eg, **amiodarone, cisapride, ondansetron, quinidine, sotalol**): May have additive arrhythmogenic effects
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine, doxepin**): Additive CNS depression and anticholinergic effects may occur.

Laboratory Considerations

- False increases have been reported in **17-hydroxycorticosteroid** urine values after hydroxyzine use.

- **Intradermal allergy testing (IDT)**: Suppression of IDT results may persist for 3 to 5 days after discontinuation of the drug but was as long as 9 days in some dogs.[11] It is recommended to discontinue hydroxyzine at least 1 to 2 weeks prior to testing in dogs[12] and 7 days in horses.[13]

Dosages

DOGS:

Antipruritic/antihistamine (extra-label): Based on a pharmacokinetic study,[5] 2 mg/kg PO every 12 hours. 3 mg/kg PO twice daily has also been used.[11] Data suggest that increasing dose or frequency of administration would not result in greater histamine inhibition. Antihistamines appear to be more useful when used routinely (ie, before a flare) in dogs with mild atopic dermatitis.[1]

CATS:

Antipruritic/antihistamine (extra-label): 5 – 10 mg/cat (NOT mg/kg) PO every 12 hours; 2 mg/kg PO every 12 hours

HORSES:

Antipruritic/antihistamine (extra-label):

a) 0.5 – 1 mg/kg IM or PO twice daily[14]
b) Using the pamoate salt: 500 mg/horse (NOT mg/kg) PO twice daily[13]

BIRDS:

Pruritus associated with allergies, feather-picking, or self-mutilation (extra-label):

a) 2 mg/kg PO every 8 hours PO; adjust dose to minimize drowsiness and maximize effect[15]
b) 1.5 – 2 mg/4 oz (≈120 mL) of drinking water (NOT mg/kg) PO daily; adjust dose to minimize drowsiness and maximize effect.[15]
c) 2 mg/kg PO every 12 hours[16]

FERRETS:

Antipruritic/antihistamine (extra-label): 2 mg/kg PO 2 or 3 times daily[17,18]

RABBITS:

Antipruritic/antihistamine (extra-label): 2 mg/kg PO every 8 to 12 hours[18]

Monitoring

- Clinical efficacy; trial periods to determine an antihistamine's efficacy are usually 1 to 2 weeks long
- Adverse effects

Client Information

- Antihistamines are normally used on a regular, ongoing basis in animals that respond well to them. Antihistamines work better when used before an animal has been exposed to an allergen or before an allergy flare-up occurs.
- The most common side effect is drowsiness/sleepiness, which may be helpful in some animals.
- Dry mouth, decreased gastrointestinal activity (including constipation), and urine retention (less frequent urinations) are possible.
- This medicine may be given with or without food. If your animal drools, vomits, or acts sick after receiving this medicine on an empty stomach, give with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.

Chemistry/Synonyms

Hydroxyzine HCl, a piperazine-derivative antihistamine, occurs as a white, odorless powder. It is very soluble in water and freely soluble in alcohol. Hydroxyzine pamoate occurs as a light yellow, practically odorless powder. It is practically insoluble in water or alcohol. Hydroxyzine oral syrup/solution has a pH of 2.8 to 4.3.

Hydroxyzine may also be known as hydroxyzine embonate, hydroxyzine HCl, hydroxyzine pamoate, hydroxyzini HCl, *Atarax*®, *Hyzine*®, *Masmoran*®, *Neucalm*®, *Vistacot*®, *Vistaril*®, or *Vistazine*®.

Storage/Stability

Hydroxyzine oral products should be stored in tight, light-resistant containers at room temperature 20°C to 25°C (68°F-77°F). Hydroxyzine injection should be stored protected from light at room temperature 20°C to 25°C (68°F-77°F) with excursions permitted to 15°C to 30°C (59°F-86°F). Avoid freezing all liquid products.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Hydroxyzine injection has been reported to be physically **compatible** with the following drugs when mixed in syringes: atropine, buprenorphine, butorphanol, diphenhydramine, doxapram, droperidol, fentanyl, glycopyrrolate, hydromorphone, lidocaine, meperidine, metoclopramide, midazolam, morphine, and oxymorphone.

Hydroxyzine injection has been reported to be physically **incompatible** with cefazolin sodium, clindamycin, furosemide, heparin, pantoprazole, penicillin G potassium, phenobarbital, and sodium bicarbonate.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Hydroxyzine HCl Oral Tablets: 10 mg, 25 mg, and 50 mg; *Atarax*®, generic; (Rx)

Hydroxyzine HCl Oral Syrup/Solution: 10 mg/5 mL (2 mg/mL) in 118 mL and 473 mL bottles (may contain alcohol, propylene glycol, and flavoring); *Atarax*®, generic; (Rx)

Hydroxyzine HCl Injection:25 mg/mL (may contain benzyl alcohol) in 1 mL and 2 mL vials and 50 mg/mL (may contain benzyl alcohol) in 1 mL, 2 mL, and 10 mL vials; generic; (Rx)

Hydroxyzine Pamoate Oral Capsules (equivalent to hydroxyzine HCl): 25 mg, 50 mg, and 100 mg (as pamoate); *Vistaril*®, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Hyoscyamine

(hye-oh-***sye***-ah-meen or hye-***ah***-ska-meen) *Levsin®*

Anticholinergic

Prescriber Highlights

- ► May be useful for treating hypermotile GI conditions such as irritable bowel syndrome, bradycardia, or AV block in dogs
- ► Limited use or experience in veterinary medicine
- ► Based on human data, hyoscyamine is contraindicated in patients with glaucoma, intestinal obstruction, toxic megacolon, intestinal atony, severe ulcerative colitis, obstructive uropathy, or acute hemorrhage.
- ► Use with caution in patients with renal dysfunction, tachyarrhythmias, cardiac valve disease, congestive heart failure, or myasthenia gravis.
- ► Adverse effects may include mydriasis, xerostomia, constipation, urinary retention, and xerophthalmia.

Uses/Indications

Although not commonly used in veterinary medicine, hyoscyamine may be useful in dogs as an alternative to other anticholinergic drugs (eg, glycopyrrolate) for treating bradycardia or AV block that is associated with clinical signs when pacemaker implantation is not possible.[1] In dogs, it may also be useful for short-term treatment of hypermotile GI conditions such as chronic idiopathic large bowel disease.[2] It potentially could be useful for treating hypersalivation, urinary spasms, vomiting, or reducing secretions perioperatively; however, little is known regarding safety and efficacy in animals when used for these conditions.

In humans, hyoscyamine is used primarily for its effects in reducing GI tract motility or to decrease pharyngeal, bronchial, and tracheal secretions.[3] It can also be used for acetylcholinesterase inhibitor poisoning.

Pharmacology/Actions

Hyoscyamine is an anticholinergic agent, and the levo-isomer of atropine. Therefore, it is more potent than atropine in its central and peripheral effects. It inhibits acetylcholine at tissues innervated by postganglionic nerves and on smooth muscles that respond to acetylcholine but do not have cholinergic innervation. It does not have action on autonomic ganglia. Pharmacologic effects include dose-related reductions in secretions, GI and urinary tract motility, mydriasis, and increased heart rate.

Pharmacokinetics

No pharmacokinetic data were located for veterinary species. In humans, hyoscyamine is rapidly and nearly completely absorbed after oral or sublingual administration.[3] Extended-release oral dosage forms may have somewhat reduced oral bioavailability. Hyoscyamine is distributed throughout the body, enters the CNS, and crosses the placenta. Hyoscyamine is partially hydrolyzed in the liver to tropic acid and tropine. The majority of the drug is excreted unchanged in the urine. Elimination half-life is about 3.5 hours; about 7 hours for the sustained-release product (*Levsinex®*). Average duration of action in humans is ≈4 to 6 hours.

Contraindications/Precautions/Warnings

Hyoscyamine is contraindicated in patients hypersensitive to it. Patients sensitive to one belladonna alkaloid or derivative may be sensitive to another. In humans, contraindications include glaucoma (narrow or wide angle), unstable cardiac disease in acute hemorrhage, intestinal obstruction, toxic megacolon, intestinal atony, severe ulcerative colitis, obstructive uropathy, or myasthenia gravis.[3]

Use hyoscyamine with caution in patients with renal dysfunction as hyoscyamine elimination may be reduced. Carefully consider use of anticholinergics in patients with tachyarrhythmias, cardiac valve disease, or congestive heart failure.

Do not confuse hyosCYAmine with hyosCINE.

Adverse Effects

Adverse effects can include mydriasis, xerostomia, constipation, urinary retention, tachycardia, and xerophthalmia. Higher doses may cause CNS depression or excitation.

Reproductive/Nursing Safety

There is limited information available on the drug's use during pregnancy. Although hyoscyamine crosses the placenta, reproductive studies in animals have not been performed. Two limited studies (322 and 281 pregnancies) in humans have been published evaluating hyoscyamine safety during pregnancy. One study showed no increase in congenital malformations, but the other showed a slight increase above normally expected malformations in infants.

Only traces of hyoscyamine are detected in milk. Although no problems have been reported, risk to offspring cannot be ruled out.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The LD_{50} for hyoscyamine in rats is 375 mg/kg.[3] Significant overdoses in animals may be serious and contacting an animal poison control center is advised. Toxicity is exhibited by intensified and prolonged anticholinergic effects including tachycardia, CNS effects (behavior changes, depression, seizures), urinary retention, decreased gut sounds/motility, and mydriasis. Protocols to decrease oral absorption should be considered in acute overdoses. Severe anticholinergic effects can be treated with physostigmine or neostigmine, but it is suggested to do so only under the guidance of an animal poison control center. In humans, delirium or excitement has been treated with small doses of short-acting barbiturates or benzodiazepines. Hyoscyamine can be removed by hemodialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving hyoscyamine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antacids containing magnesium**, **aluminum,** or **calcium salts**: May interfere with hyoscyamine absorption
- **Anticholinergics, Other** (eg, **atropine, glycopyrrolate**): Additive actions and adverse effects can occur.
- **Antihistamines, First Generation** (eg, **diphenhydramine**): Additive actions and adverse effects can occur.
- **Ketoconazole**: Hyoscyamine may decrease serum concentration of ketoconazole; separate administration by at least 2 hours.
- **Potassium Chloride, Potassium Citrate (Oral)**: Anticholinergic agents may enhance ulcerogenic effect of oral potassium chloride or citrate; combination is contraindicated in humans.
- **Prokinetic Agents** (eg, **cisapride**, **metoclopramide**): Hyoscyamine may counteract their prokinetic effects.

Laboratory Considerations

- No specific concerns noted with hyoscyamine

Dosages

DOGS:

NOTE: The following doses are assumed to be for the immediate release oral dosage forms. Extended-release tablets or capsules may be effective and reduce dosing frequency, but no data were located.

Antimuscarinic for irritable bowel syndrome (extra-label): 3 – 6 µg/kg (0.003 – 0.006 mg/kg) PO every 8 to 12 hours[2]

Sinus node dysfunction, atrioventricular block (extra-label): 3 – 6 µg/kg (0.003 – 0.006 mg/kg) PO every 8 hours[4]

Monitoring

- Clinical efficacy (eg, heart rate, syncopal episodes, exercise tolerance, GI signs)
- Adverse effects (eg, tachycardia and bowel or urinary elimination difficulties)

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give it with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Common side effects include dry mouth, dry eyes, constipation, trouble urinating, and faster heartbeat.
- Be sure animal has access to water at all times.
- Contact your veterinarian immediately if seizures (convulsions), collapsing/fainting or large changes in behavior (eg, hyperexcitability (overly excited) or depression) occur.
- If using a sustained-release capsule or tablet, do not split, crush, or allow the animal to chew it.

Chemistry/Synonyms

Hyoscyamine sulfate is a tertiary amine that occurs as white, odorless crystals or crystalline powder. One gram is soluble in 0.5 mL of water or in 1 mL of alcohol. It is practically insoluble in ether.

Hyoscyamine may also be known as daturin, duboisine, tropine-L-tropate. International trade names include: *Egazil Duretter®* and *Neo-Allospasmin®*.

Storage/Stability

Unless otherwise advised by the manufacturer, hyoscyamine sulfate oral products should be stored at room temperature, in tight containers, and protected from light. The injectable product should be stored at room temperature and protected from freezing.

Compatibility/Compounding Considerations

No specific information noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None as single ingredient products

HUMAN-LABELED PRODUCTS:

Hyoscyamine Oral Tablets: 0.125 mg (regular and chewable) and 0.15 mg; many trade names are available including: *Anaspaz®*, *ED-SPAZ®*, *HyoMax®*, *Levsin®*, *Cystospaz®*, generic; (Rx)

Hyoscyamine Orally Disintegrating Tablets: 0.125 mg and 0.25 mg; *Neosol®*, *NuLev®*, *Symax FasTab®*, *Mar-Spas®*; (Rx)

Hyoscyamine Sublingual Oral Tablets: 0.125 mg; *Levsin/SL®*, *Symax-SL®*, generic; (Rx)

Hyoscyamine Extended/Sustained-Release Oral Tablets: 0.25 mg (0.125 mg immediate-release) and 0.375 mg; *Levbid®*, *Symax-SR®* and *Symax Duotab®*, generic; (Rx)

Hyoscyamine Extended/Timed-Release Oral Capsules: 0.375 mg; *Levsinex®*, generic; (Rx)

Hyoscyamine Oral Solution: 0.125 mg/mL in 15 mL; generic; (Rx)

Hyoscyamine Oral Elixir: 0.025 mg/mL (0.125mg/5mL) in pint bottles; generic; (Rx)

Hyoscyamine Oral Spray: 0.125 mg/spray in 30 mL; *IB-Stat®*; (Rx)

Hyoscyamine Injection: 0.05 mg/mL in 1 mL ampules and 10 mL vials; *Levsin®*; (Rx)

References

Hypertonic Saline (7% to 7.5%)

Sodium Chloride 7% to 7.5%

(hye-per-***ton***-ik ***say***-leen)

Prescriber Highlights

- ► Hypertonic saline (HTS) can provide immediate intravascular expansion in hypovolemic shock and reduce intracranial pressure in traumatic brain injury.
- ► Must be administered IV slowly; prolonged infusions are not recommended. Follow with isotonic crystalloids to replenish body water
- ► Contraindicated in patients with hypernatremia, hyperosmolality, hyperchloremia, hypokalemia, or intravascular overload
- ► Use caution in patients that are dehydrated, coagulopathic, thrombocytopenic, or have platelet dysfunction.
- ► Veterinary-labeled product is not an FDA-approved drug. If compounding from concentrated sodium chloride, use extreme caution.

Uses/Indications

Hypertonic saline (HTS) solutions with concentrations of 7% to 7.5% are most commonly used in veterinary medicine. HTS is used as an alternative to isotonic crystalloids for resuscitation in previously normovolemic healthy patients with intravascular hypovolemic shock, and in patients with burns or hypovolemic traumatic brain injury (TBI). HTS is particularly useful in conditions where large fluid volumes of crystalloids can cause interstitial edema (eg, traumatic brain injury, spinal cord trauma, pancreatitis, burns). HTS is also used as a hyperosmolar agent for intracranial pressure reduction after TBI or to reduce spinal edema after spinal cord trauma. In patients with increased intracranial pressure and systemic hypotension, HTS is preferred to mannitol because hypotension after HTS administration is less likely to occur due to sodium redistribution within the body and the diuretic effect.

Use in combination with a synthetic colloid (eg, dextran, hydroxyethyl starch) is somewhat controversial. Duration of extravascular expansion can be significantly prolonged, but in 2 studies of experimental controlled hemorrhagic shock in dogs, HTS-colloid solutions were shown to be inferior for improving systemic and regional tissue oxygenation as compared with either lactated Ringer's or hydroxyethyl starch alone (both given in various ratios with shed blood).[1,2]

A study in horses comparing isotonic saline versus HTS (7.2%) for fluid resuscitation after an endurance ride found that HTS-treated horses had greater decreases in PCV, total protein, albumin and globulin concentrations, and had a shorter time to urination with lower urine specific gravity.[3]

Calves with noninfectious diarrhea and metabolic acidosis treated with HTS (7.5%) and an oral PO isotonic electrolyte solution had faster decreases in hematocrit, total protein and albumin concentrations, BUN, increased plasma volume, and faster increases in blood

pH, bicarbonate concentration, and central venous pressure than calves treated with oral PO isotonic electrolyte solution alone.[4]

Pharmacology/Actions

Small bolus doses of hypertonic saline (HTS) can cause immediate intravascular volume expansion. High sodium concentration increases plasma osmolarity, causing movement of water from the interstitial space into the intravascular space. Intravascular volume expansion can be in excess of the amount of HTS infused. Equilibrium between the intravascular and interstitial spaces is restored by intracellular water moving into the interstitial space.

HTS may have additional benefits when it is used for trauma resuscitation, including positive immunomodulatory effects due to alterations of neutrophil-endothelial interactions, albumin leakage, and endothelial cell swelling reduction, improvement of cardiac function and microcirculation, and reduction of edema formation.

Pharmacokinetics

Volume expansion occurs immediately and is highest at the end of the infusion. Volume expansion effects are relatively transient and may only persist for 30 minutes to 3 hours. Effects may last longer than 3 hours if combined with a colloid (eg, dextran or hydroxyethyl starch).

Contraindications/Precautions/Warnings

Hypertonic saline (HTS) is contraindicated in patients with significant hypernatremia, hyperosmolality, hyperchloremia, hypokalemia, or intravascular overload. It must be used with extreme caution in dehydrated patients, and isotonic crystalloid therapy is required after HTS infusion to replenish interstitial and intracellular water.

Adequate patient monitoring is mandatory as the effects of HTS are transient and critically ill patients can rapidly decompensate.

HTS can improve perfusion, but it is not a replacement for blood products.

Use HTS with caution, especially at higher than recommended dosages in patients with coagulopathies, thrombocytopenia, or platelet dysfunction.[5–7] Until further evaluation, prolonged infusions of HTS are not recommended.[8]

HTS is a high-risk medication, and mistakenly administering HTS instead of isotonic crystalloids can be extremely hazardous. To ensure patient safety in human hospitals, the following controls have been recommended: limiting the available concentrations, standardizing dosing and monitoring, keeping the solution separate from other fluids in controlled-access cabinets, colored labeling, and oversight by pharmacists.[9]

Adverse Effects

When used at dosages less than 5 mL/kg IV and at infusion rates not greater than 1 mL/kg/minute IV, hypertonic saline (HTS) is considered relatively safe in patients where it is not contraindicated. If infused at a higher rate (infusion time less than 1 minute, or infusion rate greater than 1 mL/kg/minute), arteriolar vasodilation with transient reductions in mean arterial pressure and vagally mediated bradycardia can occur.

Fluid and electrolyte disturbances (eg, hypokalemia, hypernatremia, hyperchloremia) are possible, especially when used repeatedly, at high doses, or if adequate fluid replenishment is not administered.

At concentrations less than 10%, infused at recommended rates into peripheral veins, HTS is not likely to cause phlebitis. Consider administering via a central line if available.

In vitro studies have shown that HTS infusions exceeding 5 mL/kg may prolong clotting or cause clinical coagulopathies.[5–7]

Reproductive/Nursing Safety

When used appropriately in critically ill patients, use of hypertonic saline (HTS) in pregnant animals should not be a clinical concern.

Overdose/Acute Toxicity

Inadvertent overdose can cause electrolyte imbalance (eg, hypernatremia, hyperchloremia, hypokalemia), edema, and aggravation of existing acidosis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

- No specific drug interactions were noted.

Laboratory Considerations

- No specific concerns were noted.

Dosages

DOGS/CATS:

NOTE: All dosages are for hypertonic saline (sodium chloride) 7% to 7.5%. Many clinicians use the veterinary labeled 7.2% product, but there is no evidence to suggest that using concentrations from 7% to 7.5% is unacceptable.

Low-volume resuscitation using hypertonic saline (HTS) alone (extra-label): Using HTS 7% to 7.5%, 4 – 6 mL/kg IV infusion at a rate not to exceed 1 mL/kg/minute is recommended; however, dosages ranging from 2 – 8 mL/kg IV have been noted. Some clinicians suggest that cats should receive dosages at the low end of the range. Follow with crystalloid therapy to maintain adequate tissue hydration.

Low-volume resuscitation using HTS with a colloid (extra-label): Mix concentrated sodium chloride 23.4% solution with hetastarch in a 1:2 ratio (1 part sodium chloride 23.4% to 2 parts hetastarch 6%); administer 4 – 5 mL/kg IV over 5 minutes.

Neurologic trauma using HTS alone (extra-label): Dosage recommendations vary but 3 – 5 mL/kg IV over 15 to 20 minutes has been noted.[10] Follow with crystalloids. Do not use in hyponatremic patients and monitor sodium concentrations.

Symptomatic hyponatremia refractory to mannitol and furosemide treatment (extra-label): For patients with plasma sodium of 120 mEq/L or lower, sodium correction should not exceed 2 mEq/L/hour (maximum increase of 15 mEq/L in the first 24 hours). The sodium deficit, which will determine the amount of HTS to be administered, is calculated using the following formula Na^+ deficit = (target Na^+ - patient Na^+) × (0.6 × lean body weight in kg). The target Na^+ should be no higher than 10% to 15% of the current patient's sodium. Administer as a HTS 3% solution.[11]

HORSES:

Small-volume resuscitation (extra-label): In the study (after an endurance ride), treated horses received an initial IV bolus of 2 liters/horse (NOT L/kg) of HTS 7.2% and 5 liters/horse (NOT L/kg) of lactated Ringer's solution (also contained 250 mL of 23% calcium gluconate) followed with additional LRS as deemed necessary by the treating veterinarian.[3]

CATTLE:

Adjunctive treatment of neonatal diarrhea in calves (extra-label): Using HTS 7.2%, 5 mL/kg IV over 3 to 10 minutes along with 60 mL of an isotonic electrolyte solution PO (repeated twice at 8 and 16 hours)[4]

BIRDS:

Small-volume replacement/CPR resuscitation (extra-label): For the shocky debilitated patient, hypertonic saline is administered 3 – 5 mL/kg over 5 minutes, followed by hetastarch 3 – 5 mL/

kg over 5 minutes. This combination prior to crystalloid administration enables fluids to stay within the vascular space. Blood pressure should be monitored closely. Follow with small boluses of crystalloid fluids (LRS, *Plasma-Lyte*® at 15 – 20 mL/kg) along with hetastarch 3 – 5 mL/kg over 15 minutes; reassess the bird every 15 minutes. The crystalloids and hetastarch can be combined in the same syringe or bag. This process is repeated every 15 to 20 minutes until temperature normalizes and blood pressure is over 120 mm Hg.[12]

Monitoring

- Efficacy: blood pressure, central venous pressure (if possible), and clinical parameters (eg, heart rate, pulse quality, mucous membrane color, capillary refill time, mental acuity, body temperature)
- Serum electrolytes (ie, sodium, potassium, chloride), serum osmolality, urine output, hematocrit

Client Information

- Hypertonic saline should only be used in an inpatient setting with appropriate monitoring.

Chemistry/Synonyms

7.2% sodium chloride for injection solution contains 1232 mEq/liter (1.23 mEq/mL) of sodium and 1232 mEq/liter (1.23 mEq/mL) of chloride. Osmolarity is 2464 mOsm/L. Colloid osmotic pressure (COP) is 0.

Storage/Stability

Sodium chloride 7.2% injection should be stored at controlled room temperature between 15°C and 30°C (59°F-86°F). It does not contain a preservative and is appropriate for single use only. Discard any unused solution.

Sodium chloride 14.6% and 23.4% (both for additive use) should be stored at controlled room temperature and protected from excessive heat and freezing.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The veterinary labeled 7.2% product does not contain a preservative and is appropriate for one-time use only.

Concentrated sodium chloride solutions for IV additive use (14.6% and 23.4%) are thought to be compatible with hydroxyethyl starch compounds.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Hypertonic Saline (sodium chloride 7.2%) Injection Solution: in 1000 mL bottles; generic; (Rx). Contains no preservative and is labeled for single use. Labeled (not FDA-approved) for use in horses and cattle.

HUMAN-LABELED PRODUCTS:

Sodium Chloride Solution Concentrate 14.6%, 23.4%; generic; (Rx). For IV additive use only; must be diluted before use.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Ifosfamide

(eye-***foss***-fa-mide) *Ifex*®

Antineoplastic

Prescriber Highlights

- ► Alkylating agent that may be useful in treating lymphomas and sarcomas in dogs and cats
- ► Limited veterinary experience to date
- ► Cat dose is much greater than dog dose
- ► Contraindications include patients with severe myelosuppression, urinary outflow obstruction, active hemorrhagic cystitis, and patients that are hypersensitive to ifosfamide.
- ► Significant toxicities (eg, myelosuppression, nephrotoxicity, bladder toxicity, neurotoxicity, GI toxicity) may occur.
- ► Must be given with saline diuresis and mesna, an injectable bladder-protective agent; do not use in patients that are unable to tolerate forced saline diuresis (eg, severe heart disease)
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies ifosfamide as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

In small animal species, ifosfamide may be beneficial in combination chemotherapy protocols for a variety of neoplasms. Limited efficacy has been demonstrated with ifosfamide in the treatment of lymphomas and soft tissue sarcomas in dogs and cats. It appears to be inferior to single-agent treatment for lymphoma. A phase II study in cats with vaccine-associated sarcoma demonstrated a measurable response in 41% of treated cats.[1]

Ifosfamide has been evaluated in alternating cycles with doxorubicin in dogs with soft tissue sarcomas and hemangiosarcoma. Although ifosfamide was well tolerated, no significant survival advantage was conferred.[2] Minor anti-tumor activity against metastatic canine osteosarcoma has been documented.[3]

In humans, ifosfamide is used in various treatment protocols for neoplasias of the urinary bladder, cervix, ovaries, and some types of lymphomas.

Pharmacology/Actions

Ifosfamide is an alkylating antineoplastic agent. Its chemical reactivity is nonspecific, but the primary cytotoxic effect is thought to be due to alkylation of cancer cell DNA strands resulting in cross-linking and inhibition of tumor growth, DNA replication, RNA transcription, and protein synthesis.

Pharmacokinetics

The pharmacokinetics of ifosfamide are complex. Although ifosfamide is normally given IV, it is well absorbed after SC injection or oral administration; bioavailability via these routes is 90% or greater. Ifosfamide and its metabolites are widely distributed and enter bone and CNS, although not in therapeutic concentrations. Ifosfamide, a prodrug, is metabolized primarily via oxidative pathways found in the liver and, to a smaller extent, in the lungs. It then is catalyzed into the primary active alkylating agent, ifosfamide mustard. In humans, ifosfamide's half-life and excretion is dose dependent, but its metabolites are primarily excreted via the kidney into urine.

Contraindications/Precautions/Warnings

Because of its toxicity, ifosfamide should only be used by clinicians that are experienced with the use of cytotoxic agents and able to adequately monitor the effects of therapy. Ifosfamide is contraindicated in patients with a history of hypersensitivity, severe myelosuppression, urinary outflow obstruction, or active hemorrhagic cystitis. Ifosfamide should be used with extreme caution in patients with impaired renal function. Do not use ifosfamide in patients that are

unable to tolerate forced saline diuresis (eg, severe heart disease).

Ifosfamide must be used in conjunction with mesna, an injectable detoxifying agent, to reduce the risk for hemorrhagic cystitis. If secondary UTIs occur, it has been recommended that ifosfamide (or cyclophosphamide) must not be used again in that patient, even after clinical resolution.

The National Institute for Occupational Safety and Health (NIOSH) classifies ifosfamide as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Dose-related neutropenia generally occurs at 5 to 7 days posttreatment but may be delayed (14 to 21 days), particularly with repeated dosing. Nadirs in cats are seen typically at day 7 or 8. Platelets can also be significantly impacted.

Ifosfamide can damage urinary bladder epithelium and cause nephrotoxicity with resultant electrolyte abnormalities. Renal toxicity is primarily focused on proximal and distal tubular damage, but glomerular effects may occur. To reduce the incidence of nephrotoxicity and urinary bladder toxicity, saline diuresis is required, and mesna is given concomitantly to reduce urinary bladder epithelial toxicity; however, volume overload and pulmonary edema may result, particularly in patients with pre-existing cardiac disease. GI effects including nausea, drooling, and vomiting have been reported, especially during drug administration. Treatment with antiemetics may be required. Other adverse effects may include hypersensitivity reactions, anorexia, neurotoxicity (eg, somnolence to confusion, coma, encephalopathy), alopecia, and increased hepatic enzymes.

In cats, doses of 900 mg/m^2 or less resulted in neutrophil counts less than 1000 cells/µL in ≈33% of treated cats, but no secondary infections were noted. Some cats demonstrated mild, self-limiting GI effects, including lack of appetite, vomiting, and diarrhea. Signs of nausea during IV infusion were seen in ≈⅓ of treated cats. Pulmonary edema and hypersensitivity were each seen in 1 cat, and nephrotoxicity was seen in 2 cats.[1,4]

Administering mesna with ifosfamide significantly reduces the incidence and severity of ifosfamide-induced hemorrhagic cystitis. Mesna interacts with metabolites of ifosfamide that cause this toxicity. Because mesna is hydrophilic, it does not enter most cells and therefore does not appear to significantly reduce the anti-tumor efficacy of ifosfamide. Mesna does not prevent or reduce the incidence of other adverse effects associated with ifosfamide (eg, myelosuppression, GI effects, neurotoxicity, renal toxicity).

Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant alopecia.

Reproductive/Nursing Safety

Teratogenic and fetotoxic effects have been demonstrated at usual dosages in humans and laboratory animals; treatment is not recommended during pregnancy. For sexually intact patients, verify pregnancy status prior to administration.

Ifosfamide is excreted in maternal milk. If this drug is being used in lactating mothers, consider using milk replacer.

Overdose/Acute Toxicity

The lowest reported lethal dose in dogs following IV administration was 66 mg/kg, resulting in acute pulmonary edema and hemorrhage.[5]

The drug is dialyzable, but no data are available regarding use during overdose. No specific antidote is known, and treatment is supportive. Methylene blue (50 mg in a 1%-2% aqueous solution IV over 5 minutes) has been suggested to treat ifosfamide-induced encephalopathy in humans.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ifosfamide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Azole Antifungals** (eg, **ketoconazole**): Concomitant use may decrease metabolism of ifosfamide to its active metabolites, resulting in reduced ifosfamide efficacy.
- **Cisplatin**: Ifosfamide may enhance cisplatin-induced ototoxicity and nephrotoxicity.
- **Maropitant**: In humans, NK1-receptor antagonists similar to maropitant are thought to increase concentrations of toxic metabolites of ifosfamide; monitor for clinical signs of ifosfamide neurotoxicity.
- **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medications may result in additive myelosuppression; avoid combination when possible.
- **Vaccines** (live and inactivated): Ifosfamide may diminish vaccine efficacy and enhance adverse effects of vaccines.

Laboratory Considerations

- None were noted.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and because chemotherapy indications, treatment protocols, monitoring and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[6–10] are strongly recommended.

DOGS:

Adjunctive treatment of lymphomas and sarcomas (extra-label):

a) Saline diuresis is required prior to ifosfamide administration. Administer 0.9% sodium chloride IV at a fluid rate of 6 times the maintenance dose over 30 minutes. Mesna 75 mg/m^2 (NOT mg/kg) should then be administered immediately prior to ifosfamide. Ifosfamide 375 mg/m^2 (NOT mg/kg) should be diluted to 20 mg/mL or less and given IV over 20 minutes, followed by 0.9% sodium chloride IV diuresis at 6 times maintenance over 5 hours. Mesna dose is repeated 2 hours and 5 hours after ifosfamide. This therapy may be repeated on a 21-day basis.[11] **NOTE**: Some sources say treatment can be repeated every 2 to 3 weeks.[12]

b) Administer 0.9% sodium chloride IV at 18.3 mL/kg/hour for 6 hours. After 30 minutes of the saline infusion, administer ifosfamide 350 mg/m^2 (NOT mg/kg) IV over 30 minutes for patients less than 10 kg (22 lb) or 375 mg/m^2 (NOT mg/kg) IV over 30 minutes for patients greater than 10 kg (22 lb). Administer mesna (20% of ifosfamide dose) as an IV bolus at the start of the ifosfamide infusion, and again 2 hours and 5 hours after the ifosfamide infusion is complete. Repeat treatment regimen every 3 weeks.[13] **NOTE**: Some sources say treatment can be repeated every 2 to 3 weeks.

CATS:

Adjunctive treatment of lymphomas and sarcomas (extra-label):

a) Based on a phase I safety study and a phase II trial for vac-

cine-related sarcomas, the authors recommend ifosfamide 900 mg/m^2 (NOT mg/kg) IV every 3 weeks. Before ifosfamide administration, give mesna bolus (20% of ifosfamide dose) and begin diuresis with 0.9% sodium chloride 18.3 mL/kg per hour IV CRI over 30 minutes prior to ifosfamide; continue saline diuresis for 5 hours after completion of ifosfamide administration.[1,4]

b) Administer 0.9% sodium chloride IV at a fluid rate of 6 times the maintenance dose over 30 minutes, then administer ifosfamide 900 mg/m^2 (NOT mg/kg) diluted to 20 mg/mL or less IV over 20 minutes, followed by diuresis with 0.9% sodium chloride at 6 times the maintenance dose over 5 hours. Administer mesna (20% of ifosfamide dose) immediately before ifosfamide administration and repeat 2 hours and 5 hours after ifosfamide. This treatment regimen may be repeated every 21 days.[11]

Monitoring

- Baseline and periodic (ie, before each dose):
  - Complete blood count with platelet count
  - Serum chemistry panel and electrolytes
  - Urinalysis
- Adverse effects: volume overload/pulmonary edema, neurotoxicity, GI toxicity
- Efficacy of therapy

Client Information

- Ifosfamide is a chemotherapy (anticancer) drug. This medicine can be hazardous to other animals and humans that come in contact with it. On the day your animal gets this medicine and then for a few days afterward, all bodily waste (eg, urine, feces, litter), blood, or vomit should only be handled while wearing disposable gloves. Seal the waste in a plastic bag and then place both the bag and gloves in with the regular trash.
- Bone marrow suppression can occur. The greatest effects on bone marrow usually occur within a week or 2 after treatment. Your veterinarian will do blood tests to watch for this problem. Do not miss these important follow-up visits.
- If you see bleeding, bruising, fever (indicating an infection), shortness of breath, or if your animal becomes tired easily, it is important that you contact your veterinarian right away.
- This medicine is considered a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Ifosfamide is an alkylating agent that is structurally related to cyclophosphamide and occurs as a white, crystalline powder with a melting point of 40°C (104°F). It is freely soluble in water and very soluble in alcohol. A 10% solution in water has a pH between 4 and 7.

Ifosfamide may also be known as MJF-9325, NSC-109724, Z-4942, and *Ifex*®.

Storage/Stability

Ifosfamide powder for injection should be stored at 20°C to 25°C (68°F-77°F). It should be protected from temperatures greater than 30°C (86°F), as the drug may liquefy at temperatures greater than 35°C (95°F). Once reconstituted with sterile water for injection or bacteriostatic water for injection, the solution is stable for 24 hours when refrigerated (2°C-8°C [36°F-46°F]).

Compatibility/Compounding Considerations

The reconstituted drug is **compatible** for dilution with 5% dextrose, 0.9% sodium chloride, or lactated Ringer's and is stable for up to 24 hours when refrigerated. Ifosfamide is compatible and stable when mixed with mesna in 5% dextrose or lactated Ringer's.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Ifosfamide Injection: 1 g/20 mL and 3 g/60 mL in single-dose vials; generic; (Rx)

Ifosfamide Powder for injection: 1 g and 3 g in single dose vials; *Ifex*®, generic; (Rx)

Imepitoin

(ih-meh-pi-***toyn***) *Pexion*®

$GABA_A$ receptor partial agonist

Prescriber Highlights

- ► Approved in the United States for the treatment of noise aversion in dogs
- ► Licensed in the United Kingdom and European Union as an anticonvulsant for idiopathic epilepsy in dogs and for the reduction of anxiety and fear associated with noise phobia
- ► Contraindications include hypersensitivity to imepitoin, severely impaired hepatic function, severe renal disease, and severe cardiovascular disorders.
- ► Use imepitoin with caution in animals weighing less than 2 kg (4.4 lb) and in animals less than 5 months of age, as there are limited safety data.
- ► Adverse effects may include ataxia, increased appetite, lethargy, and emesis; hyperactivity also has been observed.
- ► Disinhibition of fear-based behavior may lead to aggression; observe the patient carefully during treatment.

Uses/Indications

Imepitoin is approved in the United States to treat noise aversion in dogs. FDA approval was based on the results of a clinical field trial using New Year's Eve fireworks as the test noise event.[1] Another study found imepitoin to be effective for storm phobia but also showed a high incidence of mild-to-moderate adverse effects.[2]

This drug is also available in the United Kingdom and European Union, where it is indicated in dogs for the reduction of anxiety and fear associated with noise phobia, as well as initial therapy for generalized seizures due to idiopathic epilepsy.[3] The safety or efficacy of imepitoin as an add-on drug is uncertain.

A study comparing imepitoin and phenobarbital efficacy and adverse effects in dogs with idiopathic epilepsy found imepitoin's efficacy comparable with phenobarbital; however, imepitoin had significantly fewer adverse effects (ie, somnolence/sedation, polydipsia, increased appetite).[4] In contrast, another study found that phenobarbital had a significantly higher reduction in seizure frequency. Although this was a smaller cohort study rather than a randomized trial, phenobarbital resulted in a significantly lower seizure frequency than imepitoin and had a similar frequency of persistent adverse effects. After 3 years, 70% of dogs discontinued imepitoin due to poor seizure control or adverse effects, compared with zero in the phenobarbital group.[5] There are also conflicting studies regarding imepitoin's ability to reduce or prevent the development of cluster seizures.[5,6] A clinical consensus statement on seizure management in dogs has identified imepitoin as having Level IA evidence for monotherapy and Level IIIC evidence for add-on treatment.[7]

One small study in cats demonstrated that imepitoin was well tolerated at 30 mg/kg twice daily for 30 days, with no serious adverse effects reported.[8] This study also demonstrated that imepitoin showed

preliminary efficacy for idiopathic epilepsy in cats,[8] but further studies are needed.

Pharmacology/Actions

Imepitoin is a low-affinity partial agonist at benzodiazepine binding sites of the $GABA_A$ receptor. Affinity at the site is ≈600 times less than for diazepam. When compared with full agonists, imepitoin may cause less severe adverse effects and have a lower risk for tolerance and dependence development.[9] $GABA_A$–receptor-mediated inhibitory effects on neurons are potentiated, thereby preventing seizures. In addition, a weak inhibition of neuronal calcium channels may contribute to its anticonvulsant activity. Imepitoin also possesses anxiolytic effects.

Pharmacokinetics

In dogs, imepitoin demonstrates linear kinetics over the therapeutic dosing range. It is slowly but well absorbed after oral administration. Peak concentrations occur ≈2 hours after dosing. The presence of food does not significantly affect peak concentrations or time to peak. Bioavailability under fasting conditions is ≈92%, but administration with food may reduce the total AUC by 20%. The volume of distribution ranges from 0.6 to 1.6 L/kg; protein binding is relatively low (60% to 70%). It is extensively metabolized via oxidative mechanisms in the liver to 4 major inactive metabolites. Clearance ranges from 260 to 570 mL/hour/kg. The elimination half-life is ≈1.5 to 2 hours.[1] The majority of a dose is eliminated via fecal routes. Although imepitoin absorption is greater in a fasted state, clinical field studies support imepitoin efficacy for noise aversion when administered in either a fed or fasted state.[1]

Following rectal administration, imepitoin is slowly and poorly absorbed, and drug delivery by this route is not recommended.[10]

Contraindications/Precautions/Warnings

Imepitoin is contraindicated in patients that are hypersensitive to it, patients that have severely impaired hepatic function, or in patients that have severe renal or cardiovascular disorders. Safety has not been tested in dogs weighing less than 2 kg (4.4 lb); dogs younger than 5 months of age; or in dogs with renal, liver, cardiac, GI, or another disease.[3,11,12]

Imepitoin may lead to disinhibition of fear-based behaviors and may result in a change in aggression level.[1]

In dogs receiving imepitoin for seizures, mild behavioral or muscular signs may be observed upon abrupt termination of treatment. Consider withdrawing the drug gradually if appropriate. One taper schedule reduced the dosage to 20 mg/kg twice daily for 1 month, then 10 mg/kg twice daily for 1 month, then 10 mg/kg once daily for 1 month.[13]

Adverse Effects

Common adverse effects include ataxia, increased appetite, lethargy, emesis, hyperactivity, aggression, somnolence, and hypersalivation.[1] Ataxia has occurred in up to 60% of dogs receiving the drug.[2] Other reported adverse effects include polyphagia (especially at the beginning of treatment), decreased appetite, polyuria, polydipsia, apathy, diarrhea, prolapsed nictitating membrane, and decreased sight and sensitivity to sound.

Mild elevations in plasma creatinine and cholesterol levels were noted but did not exceed normal reference ranges and were not associated with clinically significant observations or events. Elevation of liver enzymes has been noted.[2]

Skin lesions were noted after a dose increase in a dog that had been receiving imepitoin for 5 months.[14]

In cats, emesis, lethargy, and decreased appetite were the most common adverse effects reported. Hypersalivation was common at higher doses.[8]

Reproductive/Nursing Safety

Reproductive safety or safety during nursing is not known; imepitoin is not recommended in male breeding dogs or in female dogs during pregnancy and lactation.[3,11,12] In male dogs receiving 10 times the recommended dosage, diffuse atrophy of seminiferous tubules in the testes and associated decreased sperm counts were observed.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The acute toxicity of imepitoin was assessed in rats and mice after oral administration; no mortality was noted in either species up to 2105 mg/kg.[15] The TD_{50} for motor impairment in the rotarod test was ≈1 g/kg PO in rats.[16]

In dogs receiving repeated overdoses of up to 5 times the highest recommended dose, CNS effects (eg, loss of righting reflex, decreased activity, eyelid closure, lacrimation, dry eye, tremors, nystagmus), GI effects (eg, vomiting, diarrhea, salivation), and reversible prolongation of the QT interval were noted. These effects are not usually life-threatening and generally resolve within 24 hours with supportive and symptomatic treatment. Weight gain was noted and was greater in dogs receiving 3 times the highest recommended dose as compared with the group receiving 5 times the highest recommended dose. Daily administration of the labeled dosage (30 mg/kg PO twice daily) for 6 months was generally well tolerated.[1]

The benzodiazepine antagonist flumazenil could potentially be used to reverse severe CNS effects associated with an overdose and to eliminate the drug's anticonvulsant action.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The United Kingdom product label states, *The product [imepitoin] has been used in combination with phenobarbital in a small number of cases and no harmful clinical interactions were observed.*[11] Imepitoin has a very low drug interaction potential, and interactions with highly protein-bound or enzyme-inducing drugs are not expected.[17] The following drug interactions have either been reported or are theoretical in humans or animals receiving imepitoin and may be of significance in veterinary patients; unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed, and additional monitoring should be performed when appropriate.

- **Flumazenil**: Could antagonize the anxiolytic and anticonvulsant effects of imepitoin[16]

Laboratory Considerations

- No specific laboratory interactions or considerations were noted.

Dosages

DOGS:

Noise aversion (label dosage; FDA-approved): 30 mg/kg PO every 12 hours. Initiate therapy starting 2 days prior to the day of the expected noise event and continue through the noise event.[12]

Storm anxiety (extra-label): 30 mg/kg PO every 12 hours (continuously, not as needed)[2]

Generalized seizures due to idiopathic epilepsy (extra-label): Initially, 10 mg/kg PO twice daily (≈12 hours apart).[3,11] If the frequency of seizures is not adequately reduced following a minimum of 1 week of treatment at the current dose, the dose may be increased in 50% to 100% increments to a maximum of 30 mg/kg twice daily.[11]

CATS:

Idiopathic epilepsy (extra-label): 30 mg/kg PO every 12 hours has been reported in cats and appears well tolerated, but data are limited.[8]

Monitoring

- Clinical efficacy
- Adverse effects including ataxia, change in appetite, polyuria/polydipsia, lethargy, and somnolence
- If imepitoin is being used long term, consider baseline and intermittent renal and hepatic analyte testing.

Client Information

- This medicine is best given on an empty stomach about 12 hours apart; however, if the animal vomits after receiving the drug, try giving it with food.
- To be effective, the drug must be given on a regular basis as instructed by your veterinarian.
- Possible side effects in dogs include abnormal gait, increased appetite and thirst, increased urination, increased drooling, vomiting, and changes in behavior or activity level. Contact your veterinarian if these effects are severe or continue.

Chemistry/Synonyms

Imepitoin, an imidaolinone, occurs as a white to almost-white, solid, nonhygroscopic, odorless, non-bitter–tasting substance. It is practically insoluble in water.

Imepitoin may also be known as AWD 131–138, ELB 138, or 1-(4-chlorophenyl)-4-morpholino-imidazolin-2-one. The canine product trade name is *Pexion*®.

Storage/Stability

Store at 20°C to 25°C (68°F-77°F), excursions are permitted between 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Imepitoin Oral Tablets (scored): 100 mg and 400 mg; *Pexion*®; (Rx). FDA-approved in the United States, but not yet commercially marketed; NADA 141-509. This product is also available in the United Kingdom, Australia, New Zealand, and the European Union.

HUMAN-LABELED PRODUCTS: NONE

Imidacloprid, Systemic

(eye-mi-da-***kloe***-prid) *advantus*®

Oral Insecticide

See also ***Imidacloprid/Imidacloprid Combinations, Topical*** and ***Moxidectin/Moxidectin Combination Products*** for imidacloprid combination products containing moxidectin

Prescriber Highlights

- ► Rapid-acting oral medication used for short-term treatment of acute flea infestations in dogs or puppies 10 weeks of age and older and weighing 1.8 kg (4 lb) or greater; it does not protect against ticks or mosquitoes.
- ► Flea kill begins within 1 hour; 97% of fleas are killed within 4 hours.
- ► **Not for use in cats**
- ► Use with caution in debilitated, aged, pregnant, or nursing animals.
- ► Adverse effects include decreased appetite, vomiting, diarrhea, lethargy, and difficulty walking.
- ► Does not treat the environment; separate environmental treatments are required for treatment of infestations.
- ► All pets in a household must be treated with a flea preventive to help resolve flea infestations.

Indications/Actions

Imidacloprid is indicated for treatment of flea infestations in dogs and puppies 10 weeks of age and older and weighing 1.8 kg (4 lb) or greater.[1] Postadministration, 30% of fleas are killed within 1 hour and 97% within 4 hours. Worldwide, *Ctenocephalides felis* ("cat flea," the most common flea found on dogs) susceptibility to imidacloprid remains high.[2]

Pharmacology/Actions

Imidacloprid acts on nicotinic acetylcholine receptors on the postsynaptic membrane, causing CNS impairment and death. This is a different mechanism of action than other insecticidal agents (eg, organophosphates, pyrethrins, carbamates, insect growth regulators, insect development inhibitors). The nicotinic acetylcholine receptors of insect species have higher affinity for imidacloprid than the receptors of vertebrate species.[3]

Pharmacokinetics

In healthy dogs given imidacloprid soft chewable tablets under laboratory conditions, maximum imidacloprid concentration was reached after 1.3 hours, and terminal half-life was 2.2 hours.[4] Under experimental conditions, imidacloprid given in combination with either methoprene or pyriproxyfen displayed synergistic insecticidal activity against *Ctenocephalides felis* second and third instars.[5]

Contraindications/Precautions/Warnings

Do not use in puppies younger than 10 weeks of age or weighing less than 1.8 kg (4 lb).[1] The manufacturer of topical imidacloprid combination products recommends to use it with caution in sick, debilitated, or underweight animals.[6,7]

Do not confuse imidaCLOPRID with imidoCARB.

Adverse Effects

Adverse effects are unlikely at the label dosage. Vomiting, decreased appetite, decreased energy, soft stools, and difficulty walking have been noted.[1] Imidacloprid may be a contributing or exacerbating factor for gallbladder mucocele formation in Shetland sheepdogs.[8]

Reproductive/Nursing Safety

Oral imidacloprid has not been tested in pregnant or nursing dogs. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdoses/Acute Toxicity

In dogs given 18.7 mg/kg/day (4.5 times the labeled dose), no adverse effects were noted clinically or on laboratory, histology, or necropsy examinations.[4] No adverse effects were observed in dogs that received a single oral dose of 30 mg/kg.[9]

Most adverse effects are seen following oral administration of *topical* imidacloprid products. Signs include hypersalivation and vomiting; oral ulcers have been rarely reported in cats. See ***Imidacloprid/Imidacloprid Combinations, Topical.***

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

Oral imidacloprid chewable tablets may be used together with other products, including heartworm preventives, corticosteroids, antibiotics, vaccines, deworming medications, and shampoos.[1]

Laboratory Considerations

- None noted

Dosages

DOGS:

Flea infestation in dogs or puppies (label dosage; FDA-approved): Administer the appropriate tablet size based on body weight (see table below).[1] Dose may be repeated as often as once daily; do not exceed more than 1 tablet/day. Field studies used a dose range of 0.7 – 4 mg/kg PO once.[4]

Body weight in kg (lb)	Imidacloprid (mg)	Number of tablets
1.8 – 10 (4-22)	7.5	1
10.5 – 50 (23-110)	37.5	1
More than 50 (110)	--	Appropriate combination of tablets

Monitoring

- Clinical efficacy (ie, absence of adult fleas after dosing)
- Adverse effects (eg, vomiting, diarrhea, lethargy, difficulty walking)

Client Information

- This medicine is used to treat flea infestations on dogs only. It does not protect against ticks or mosquitoes.
- Weigh your dog before administration of this medicine to make sure the correct amount is given.
- Make sure your dog swallows the medicine.
- Fleas begin to die within 1 hour of administration, and most fleas die within 4 hours.
- This medicine does not treat fleas living in the environment, and reinfestation is possible if the environment is not treated at the same time.
- All pets in a household must be treated with a flea preventive to help resolve flea infestations.

Chemistry/Synonyms

Imidacloprid occurs as a colorless to beige powder or crystals with a slight characteristic odor. It is freely soluble in water.

Systemic imidacloprid may be known as *advantus*®. Imidacloprid is widely used as a pesticide for agricultural purposes.

Storage/Stability

Imidacloprid soft chews should be stored at temperatures between 20°C to 25°C (68°F-77°F) out of reach of children and pets.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Imidacloprid tablet, chewable: 7.5 mg and 37.5 mg soft chewable tablets in 7- or 30-count bottles; *advantus*®; OTC. NADA #141-435. Chewable tablets do not contain any animal proteins and are suitable for dogs with animal protein food allergies.[10]

Imidacloprid is also available in topical formulations (eg, spot-on, collar) alone or in combination with other antiparasitic agents. See ***Imidacloprid/Imidacloprid Combinations, Topical*** and ***Moxidectin/Moxidectin Combination Products*** for imidacloprid combination products containing moxidectin.

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Imidapril

(ih-***mid***-a-pril) *Prilium*®

Angiotensin-Converting Enzyme (ACE) Inhibitor

Prescriber Highlights

- ► Veterinary ACE inhibitor (not presently available in the United States) labeled in the United Kingdom for dogs to treat moderate to severe heart failure caused by mitral regurgitation or dilated cardiomyopathy.
- ► Contraindications include hypersensitivity to ACE inhibitors, hypotension, acute renal insufficiency, congenital heart disease, obstructive hypertrophic cardiomyopathy, and patients with hemodynamically relevant stenoses (aortic stenosis, mitral valve stenosis, pulmonic stenosis).
- ► Use with caution in patients with renal insufficiency (doses may need to be reduced), patients with hyponatremia, coronary or cerebrovascular insufficiency, pre-existing hematologic abnormalities, or a collagen vascular disease (eg, SLE).
- ► Adverse effects may include GI distress (eg, anorexia, vomiting, diarrhea), and, less commonly, weakness, hypotension, renal dysfunction, and hyperkalemia.

Uses/Indications

Imidapril is labeled in the United Kingdom for use in dogs to treat moderate to severe heart failure by mitral regurgitation or by dilated cardiomyopathy.[1] When compared to other ACE inhibitors in dogs, imidapril has similar clinical efficacy and safety profile in dogs with congestive heart failure.[2,3] Like other ACE inhibitors, it could also be useful for treating dogs with protein-losing nephropathy.

Pharmacology/Actions

Like enalapril, imidapril is a prodrug and is converted in the liver to the active compound imidaprilat. Imidaprilat prevents the formation of angiotensin-II (a potent vasoconstrictor) by competing with angiotensin-I for the enzyme angiotensin-converting enzyme (ACE). ACE has a much higher affinity for imidaprilat than for angiotensin-I. Because angiotensin-II concentrations are decreased, aldosterone secretion is reduced, and plasma renin activity is increased by negative feedback mechanisms.

The cardiovascular effects of ACE inhibitors in patients with CHF include decreased total peripheral resistance, pulmonary vascular resistance, mean arterial and right atrial pressures, and pulmonary capillary wedge pressure; no change or decrease in heart rate; and increased cardiac index and output, stroke volume, and exercise tolerance.

ACE inhibitors increase renal blood flow and decrease glomeru-

lar efferent arteriole resistance. In animals with glomerular disease, ACE inhibitors decrease proteinuria and may help to preserve renal function. Imidapril partially blocks amlodipine's activation of the renin-angiotensin-aldosterone system (RAAS) in dogs.[4]

Pharmacokinetics

Following oral administration in the dog, imidapril is rapidly absorbed, but bioavailability is decreased by the presence of food.[1] Maximum plasma concentration occurs less than one hour after dosing, and elimination half-life is about 2 hours. Imidapril is mainly hydrolyzed in the liver and kidney to its active metabolite, imidaprilat. Peak imidaprilat plasma concentrations occur in about 5 hours; elimination half-life is more than 10 hours. Protein binding of imidapril and imidaprilat is moderate (85% and 53%, respectively). After oral administration of radiolabeled imidapril, about 40% of total radioactivity is excreted in urine and about 60% in feces. After multiple dosing, plasma imidaprilat concentrations are about 3 times higher after the second dose than after the first, but no additional increase is observed with subsequent doses.

Contraindications/Precautions/Warnings

The product label has several contraindications for use in dogs, including hypersensitivity to ACE inhibitors, low blood pressure, acute renal insufficiency, congenital heart disease, obstructive hypertrophic cardiomyopathy, and those with hemodynamically relevant stenoses (aortic stenosis, mitral valve stenosis, pulmonic stenosis).

Use ACE inhibitors with caution in patients with hypovolemia or dehydration, hyponatremia or sodium depletion, coronary or cerebrovascular insufficiency, pre-existing hematologic abnormalities, or a collagen vascular disease (eg, SLE). Patients with severe CHF should be monitored very closely upon initiation of therapy.

Adverse Effects

Imidapril's adverse effect profile in dogs is not well described. The product label states, *Diarrhea, hypotension and related symptoms such as fatigue, dizziness or anorexia can occur in rare cases. Vomiting can also occur in very rare cases. In such cases treatment should be discontinued until the patient's condition has returned to normal. The use of ACE inhibitors in dogs with hypovolemia/dehydration can lead to acute hypotension. In such cases the fluid and electrolyte balance should be restored immediately, and treatment suspended until it has been stabilized. Parameters used for monitoring renal function should be checked at the beginning of the treatment and at regular time intervals thereafter.*

Other ACE inhibitors' primary adverse effect in dogs is GI distress (eg, anorexia, vomiting, diarrhea). Potentially, weakness, hypotension, renal dysfunction, and hyperkalemia could occur. Because it lacks a sulfhydryl group (unlike captopril), there is less likelihood that immune-mediated reactions will occur, but rashes, neutropenia, and agranulocytosis have been reported in humans with other ACE inhibitors. No signs of toxicity were noted in cats receiving 0.5 mg/kg/day PO for 3 months.[5]

Reproductive/Nursing Safety

The product label states, *Laboratory studies in rats and rabbits did not produce any evidence of teratogenic, embryotoxic or maternotoxic effects, or effects on reproductive performances, when imidapril was administered at the therapeutic dose. In the absence of data, do not use in pregnant or lactating bitches or in breeding dogs*. Other ACE Inhibitors cross the placenta and are associated with decreased fetal weights and increases in fetal and maternal death rates. Human product labels contain black box warnings to discontinue ACE inhibitor treatment as soon as possible when pregnancy is detected.

It is not known if imidapril/imidaprilat enters maternal milk. Other ACE Inhibitors are excreted in milk, and safe use of imidapril during nursing cannot be assumed.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In dogs, doses up to 5 mg/kg (20 times label dose) of imidapril PO have been well-tolerated in healthy dogs. Hypotension may occur as a clinical sign of overdose with signs of apathy and ataxia; treatment is symptomatic.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ACE inhibitors and may be of significance in veterinary patients receiving imidapril. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Anesthetic Agents, Inhalant and Injectable** (eg, **alfaxalone, etomidate, isoflurane, propofol**): Concurrent use may increase the risk for hypotension.
- **Antacids, Aluminum-, Calcium-, or Magnesium-Containing**: Reduced oral absorption of ACE inhibitors may occur if given concomitantly with antacids; it is suggested to separate dosing by at least two hours.
- **Angiotensin Receptor Blockers (ARBs;** eg, **telmisartan**): Concurrent use of an ACE inhibitor with an angiotensin II receptor antagonist may cause additive effects on the renin-angiotensin system causing hyperkalemia, hypotension, syncope, and acute kidney injury.
- **Antihypertensive Agents/Vasodilators** (eg, **amlodipine, hydralazine, prazosin, sildenafil**): Concurrent use may increase the risk for hypotension and other adverse effects.
- **Baclofen**: Concurrent administration may increase the risk for hypotension.
- **Buspirone**: Concurrent use may increase the risk for hypotension.
- **Cabergoline**: Concurrent use may lead to additive hypotension.
- **Cimetidine**: Concurrent use with ACE inhibitors has caused neurologic dysfunction in two human patients.
- **Corticosteroids** (eg, **dexamethasone, fludrocortisone, prednis(ol)one**): May decrease the antihypertensive effects of ACE inhibitors
- **Darbepoetin alfa; Epoetin Alfa**: ACE inhibitors may interfere with erythropoiesis.
- **Digoxin**: Levels may increase 15% to 30% when an ACE inhibitor is added; automatic reduction in dosage is not recommended but monitoring of serum digoxin levels should be performed.
- **Diphenhydramine**: Concurrent use may increase the risk for hypotension.
- **Disopyramide**: Hypoglycemic effects may be enhanced.
- **Diuretics** (eg, **furosemide, torsemide**): Concomitant diuretics may cause hypotension if used with ACE inhibitors; titrate dosages carefully.
- **Doxepin**: Concurrent use may increase the risk for hypotension.
- **Glycerin, Oral**: Concurrent use may increase the risk for hypotension.
- **Heparin, Low Molecular Weight Heparins** (eg, **dalteparin, enoxaparin**): Concurrent use may increase the risk for hyperkalemia

- **Nonsteroidal Anti-inflammatory Agents (NSAIDs,** eg, **carprofen, meloxicam, robenacoxib**): May reduce the clinical efficacy of ACE inhibitors when it is being used as an antihypertensive agent
- **Opioids** (eg, **butorphanol, hydrocodone, morphine**): Concurrent use may increase the risk for hypotension.
- **Potassium** or **Potassium Sparing Diuretics** (eg, **spironolactone**): Hyperkalemia may develop.
- **Probenecid**: Can decrease renal excretion of ACE inhibitors and possibly enhance the clinical and toxic effects of the drug

Laboratory Considerations

- When using iodohippurate sodium I^{123}/I^{134} or Technetium Tc^{99} pentetate **renal imaging** in patients with renal artery stenosis, ACE inhibitors may cause a reversible decrease in localization and excretion of these agents in the affected kidney, which may lead to confusion in test interpretation.

Dosages

DOGS:

Adjunctive treatment of moderate to severe heart failure by mitral regurgitation or by dilated cardiomyopathy[1] (extra-label): 0.25 mg/kg PO once daily

Heart failure: 0.25 mg/kg PO once daily; dosage may be increased to 0.25 mg/kg every 12 hours[2]

Monitoring

- Clinical signs of CHF
- Serum electrolytes, creatinine, BUN, urine protein:creatinine ratio
- CBC with differential, periodic
- Blood pressure (if treating hypertension or clinical signs associated with hypotension arise)

Client Information

- Use imidapril to treat heart failure, high blood pressure, and some forms of kidney disease in dogs and cats.
- Usually well tolerated but vomiting and diarrhea can occur. Imidapril is best given on an empty stomach. However, if your animal vomits, stops eating, or acts sick after getting it on an empty stomach, give it with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- If a rash or signs of infection occur (eg, fever), contact your veterinarian immediately.
- Very important to give as prescribed. Do not stop or reduce the dosage without your veterinarian's guidance.
- Your animal will need to have blood pressure and lab tests performed regularly.

Chemistry/Synonyms

Imidapril and imidaprilat, angiotensin-converting enzyme (ACE) inhibitors, are structurally related to captopril. Imidapril is a prodrug and is converted in vivo by the liver to imidaprilat. Imidapril occurs as a fine, white powder. After reconstitution, the resulting solution is clear and colorless.

Imidapril may also be known as imidaprilum. *Tanatril*® and *Prilium*® are two trade names.

Storage/Stability

Before reconstitution, do not store this product above 25°C (77°F). After reconstitution, store at 2°C to 8°C (36°F-46°F; in the refrigerator) for up to 77 days.

Compatibility/Compounding Considerations

Preparation of the oral solution: Remove the nipple and the stopper of the vial containing the powder and fill with tap water up to the 30 mL mark that is indicated by a raised ring around the body of the bottle; place the childproof cap on the bottle and screw on tightly.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None in the United States. In the United Kingdom and some other countries: Imidapril Powder for Oral Solution: 2.5 mg/mL (75 mg per bottle), and 5 mg/mL (150 mg per bottle); *Prilium*®; POM-V (United Kingdom)

HUMAN-LABELED PRODUCTS: NONE

Imidocarb

(i-***mid***-oh-karb) *Imizol*®

Antiprotozoal

Prescriber Highlights

- ► Antiprotozoal with activity for *Babesia* spp and related parasites
- ► Contraindications include patients exposed to cholinesterase-inhibiting drugs (eg, pyridostigmine), pesticides, or chemicals.
- ► Use caution in patients with impaired lung, hepatic, or renal function; safety in puppies, pregnant, lactating, or breeding animals has not been established.
- ► Adverse effects: The most common effects are pain during injection and mild cholinergic signs (eg, salivation, nasal drip, and brief episodes of vomiting); less common effects include panting, diarrhea, injection site inflammation (rarely ulceration), and restlessness. Cholinergic effects may be lessened with antimuscarinic drugs.
- ► Not for IV administration

Uses/Indications

Imidocarb is FDA-approved for use in dogs to treat *Babesia canis* infections (babesiosis), but the drug may also be efficacious against other *Babesia* spp (eg, *Babesia conradae* and North Carolina *Babesia* spp). Imidocarb appears to be more effective against *B canis* than *Babesia gibsoni*.[1] A prospective, unmasked study in dogs with *B gibsoni* comparing atovaquone/azithromycin (AA) with a protocol using clindamycin, diminazene, and imidocarb (CDI) found that CDI had higher recovery and lower relapse rates, albeit longer therapy duration and slower reduction in parasite numbers than AA. The authors concluded that CDI was effective for initial therapy and when the M121I gene in *B gibsoni* had mutated.[2] Imidocarb has been used to treat canine ehrlichiosis (*Ehrlichia canis*), but one study found that, when used alone, it did not clear the organism.[3] Imidocarb appears to be effective in treating hepatozoonosis (*Hepatozoon canis*) in dogs, but without eliminating gamonts.[4] It has also been suggested as a treatment for American canine hepatozoonosis (*Hepatazoon americanum*), but it does not clear the encysted stage.

In cats, imidocarb therapy has been recommended for treating cytauxzoonosis (*Cytauxzoon felis*), but currently AA is the treatment of choice.[5]

In horses, imidocarb dipropionate is considered to be the most effective treatment for piroplasmosis, including *Babesia caballi* and *Theileria equi* (formerly *Babesia equi*), currently causing infections in horses in the United States.[6]

Imidocarb may be of benefit in treating *Babesia* spp and related parasitic diseases in a variety of other domestic and exotic animals.

Pharmacology/Actions

Imidocarb is thought to act by combining with nucleic acids of DNA in susceptible organisms, causing the DNA to unwind and denature. This damage to DNA is believed to inhibit cellular repair and replication. It

also appears to alter the parasite's ability to regulate glucose. Imidocarb has cholinergic properties that contribute to its toxicity profile.

Pharmacokinetics

Imidocarb is poorly absorbed after oral administration. After IM injection of imidocarb dipropionate in horses, imidocarb rapidly distributes and is not detected in plasma 12 hours after dosing. However, urine concentrations are similar to peak plasma concentrations up to 36 hours, and the drug is detectable in feces up to 10 days, suggesting that it is rapidly sequestered into tissues. Imidocarb undergoes little metabolism and is primarily eliminated from the body as an unchanged drug.

Contraindications/Precautions/Warnings

Do not use imidocarb in patients that have been exposed to cholinesterase-inhibiting drugs, pesticides, or chemicals. The manufacturer states to consider risks versus benefits before treating dogs with impaired lung, hepatic, or renal function. Donkeys and mules appear to be more sensitive to the toxic effects of the drug than are horses.

Do **NOT** give imidocarb IV. In cats, puppies, and debilitated dogs, pretreatment with atropine or glycopyrrolate has been advised. See warnings in ***Dosages***.

Do not use imidocarb in horses less than 1 year of age[7] or in horses intended for food. See ***Reproductive/Nursing Safety.***

Imidocarb is not intended for use in humans. In the event of human exposure, it is recommended to immediately contact a local poison control center.

Do not confuse imidocarb with imidacloprid.

Adverse Effects

The most commonly reported adverse effects in dogs include pain during injection and mild cholinergic signs (eg, salivation, nasal drip, and brief episodes of vomiting). Less commonly reported effects include panting, diarrhea, restlessness, and injection site inflammation (more common after the second dose and rarely may ulcerate). Hypoglycemia has been reported. Rarely, severe renal tubular or hepatic necrosis and severe cholinergic signs have occurred. Adverse effects in cats include salivation, lacrimation, vomiting, diarrhea, muscle tremors, restlessness, tachycardia, and dyspnea. Cholinergic adverse effects can be treated with an antimuscarinic (eg, atropine, glycopyrrolate) agent if necessary.

Horses given therapeutic dosages (2.4 mg/kg) can show signs of abdominal pain/colic, diarrhea, lacrimation, sweating, and serous nasal discharge after treatment. Antimuscarinic agents (eg, atropine, glycopyrrolate, or butylscopolamine) have been used to mitigate these effects.

Imidocarb has reportedly caused an increased incidence of tumor formation in rats.

Reproductive/Nursing Safety

Imidocarb can cross the placenta. Safety in puppies, pregnant, lactating, or breeding animals has not been established.[8] Imidocarb should not be used in equids in near-term pregnancies.[7]

Imidocarb is detectable in mare's milk 2 hours after a single dose of 2.4 mg/kg IM. Safety has not been established for nursing foals. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Dogs receiving a dosage of 9.9 mg/kg (1.5 times the labeled dose) showed signs of liver injury (slightly increased liver enzymes), pain and swelling at the injection site, and vomiting.[8] Overdoses or chronic toxicity may present with cholinergic signs (eg, anorexia, vomiting, weakness, lethargy, salivation) or adverse changes in liver, kidney, lung, or intestinal function. Treatment with atropine may be useful to treat cholinergic signs associated with imidocarb.

The LD_{50} in horses is reportedly 16 mg/kg. Deaths in cattle have been reported at 5 times the labeled dose.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The manufacturer warns not to use imidocarb in patients exposed to **cholinesterase-inhibiting drugs** (eg, **neostigmine, pyridostigmine**), **pesticides,** or **chemicals**.

Laboratory Considerations

- Imidocarb IM injections may cause significant increases in **creatine kinase** (**CK**).

Dosages

DOGS:

WARNINGS:

1. Do NOT administer imidocarb by the IV route.
2. Some references recommend using atropine 0.5 mg/kg SC as a pre-medication to mitigate the muscarinic effects of imidocarb in dogs. This is a decimal point error that can lead to tachycardia and other antimuscarinic effects. A more reasonable dose would be 0.02 – 0.05 mg/kg SC.[9–11]

Babesiosis:

Label Dosage (FDA-approved): 6.6 mg/kg IM or SC; repeat dose in 2 weeks[8]

Extra-label Dosages:

a) ***Babesia canis***: Dosage recommendations vary somewhat and range from 5 – 7.5 mg/kg IM or SC; repeat in 2 weeks. Some clinicians will re-treat in 7 days if the dog is doing poorly clinically.

b) ***Babesia gibsoni* when the *M121I* gene has mutated** (extra-label): Based on a prospective, unmasked study, clindamycin 30 mg/kg PO every 12 hours with diminazene aceturate 3.5 mg/kg IM once on the day of presentation and imidocarb dipropionate 6 mg/kg SC once on the day after administration of diminazene[2]

Ehrlichiosis (extra-label): In particularly severe cases, imidocarb 5 mg/kg SC (in a single injection, or 2 injections 15 days apart) in combination with doxycycline 10 mg/kg PO every 24 hours for 28 days.[12] Use is generally reserved for when doxycycline or minocycline are demonstrated to be ineffective. A study has demonstrated that imidocarb alone was not effective in clearing *Ehrlichia canis* from the blood of experimentally infected dogs.[3]

Hepatozoonosis (*Hepatozoon canis*) (extra-label): Most clinicians recommend 5 – 6 mg/kg IM or SC, every 14 days until gamonts clear from blood smears and remain absent for 2 to 3 consecutive months.[13] However, PCR or buffy-coat smears are much more sensitive to detect the presence of parasitemia for *H canis* than blood smears.[14] The prognosis for dogs with low levels of parasitemia is usually good with repeated injections, but the prognosis is guarded in dogs with higher levels of parasitemia.

CATS:

Cytauxzoon felis (extra-label): At present, treatment with atovaquone with azithromycin is considered superior to treatment with imidocarb. If therapy is attempted with imidocarb, 5 mg/kg IM once and repeated in 14 days. Consider pretreatment with atropine or another antimuscarinic agent. Aggressive supportive therapy (eg, IV fluids, prophylactic heparin, nutritional and nursing care, analgesia, and potentially transfusion) is required.[5]

Feline babesiosis (large babesia) (extra-label): Primaquine is usually the drug choice. Imidocarb 2.5 mg/kg IM once alone or with co-administration with doxycycline may be effective for treating *B canis* subsp *presentii* and *Babesia herpailuri*. Does not appear to have efficacy against *Babesia felis*[15]

Feline hemoplasmosis (Nomenclature is in flux: *Haemobartonella felis, Mycoplasma haemofelis*; *Candidatus Mycoplasma, Candidatus Mycoplasma turicensis)* (extra-label): Doxycycline is preferred, but in cats that are intolerant to it, marbofloxacin, enrofloxacin, or orbifloxacin may be effective. Alternatively, imidocarb 5 mg/kg IM every 2 weeks for at least 2 injections was used successfully in the management of 5 naturally infected cats that had failed treatment with other drugs. Blood transfusion should be given if clinically indicated. Most drug protocols have failed to eliminate infection, and so at this time, there is no clinical utility to repeat PCR testing. The owners should be warned that recurrence might occur.[16,17]

EQUIDS (HORSES/ZEBRAS):

Babesia caballi (label dosage; FDA-approved): 2 mg/kg IM, repeating dosage once after 24 hours.[7] Administer IM in the neck region.

Theleria (Babesia) equi (label dosage; FDA-approved): 4 mg/kg IM, repeating dosage 4 times at 72-hour intervals.[7] Administer IM in the neck region.

Equine piroplasmosis | *B caballi; T equi* (extra-label): Reported dosages for alleviation of clinical signs vary; most sources indicate that 2.2 – 4.4 mg/kg given IM once are effective. If necessary, lower dosages can be repeated at 24- to 72-hour intervals for 2 to 3 treatments. In nonendemic areas where chemotherapeutic clearance of the organism is desired, animals infected with *B caballi* or *T equi* can be cleared with a dose of 4.4 mg/kg IM every 72 hours for 4 treatments.[6]

CATTLE:

Treatment bovine babesiosis | *Babesia divergens* (extra-label): 0.85 mg/kg SC once[18]; do not administer IM or IV and do not exceed 10 mL per injection site.

Prevention of bovine babesiosis/*Babesia divergens* (extra-label): 2.125 mg/kg SC once[18]; do not administer IM or IV and do not exceed 10 mL per injection site.

Monitoring

- Efficacy. Usually via blood smear in patients with acute infections; however, PCR tests are more sensitive for detecting the presence of the parasite when organism numbers are low.[19]
- Adverse effect profile
- Baseline and periodic renal and hepatic function tests after treatment until stable

Client Information

Imidocarb should only be administered by your veterinarian. Possible side effects after a dose include:

- Dogs: Common: salivation/drooling, nasal drip, and brief episodes of vomiting. Less common: panting, diarrhea, injection site inflammation (rarely ulceration), and restlessness
- Cats: salivation/drooling, lacrimation, tearing, vomiting, diarrhea, muscle tremors, restlessness, fast heart rate, and difficulty breathing
- Horses: abdominal pain/colic, diarrhea, lacrimation, tearing, sweating, and nasal discharge
- Your veterinarian may give your animal another medicine to counteract some of these side effects if they are severe.

Chemistry/Synonyms

Imidocarb dipropionate is a diamidine of the carbanalide series of antiprotozoal compounds.

Imidocarb may also be known as 4A65 (imidocarb hydrochloride) and *Imizol®*.

Storage/Stability

Store the injection between 2°C and 25°C (36°F-77°F) and protected from light.

Compatibility/Compounding Considerations

Do not mix imidocarb injection with other medications.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Imidocarb Dipropionate for IM or SC Injection: 120 mg/mL in 10 mL multi-dose vials; *Imizol®*; (Rx). FDA-approved for use in dogs. A formulation approved for use in horses and zebras (100 mg/mL, *Imizol® Equine*) is still listed in FDA's Green Book of approved animal drugs but does not appear to be commercially available in the United States. Some countries have a product (85 mg/mL) approved for single-dose use in cattle (check the label or consult FARAD for withdrawal times). Imidocarb should not be used in horses intended for food.

HUMAN-LABELED PRODUCTS: NONE

Imipenem/Cilastatin Sodium

(ih-me-***peh***-nem sye-la-***sta***-tin) *Primaxin®*

Carbapenem Antibiotic

Prescriber Highlights

- ► Parenteral broad-spectrum carbapenem antibiotic and deactivating enzyme inhibitor combination used for serious, multidrugresistant infections
- ► Contraindications/Cautions: Patients hypersensitive to it or other beta-lactams, patients with renal impairment (dosage adjustment may be required), or patients with CNS disorders (eg, seizures, head trauma)
- ► Adverse Effects: GI effects, CNS toxicity (seizures, tremors), hypersensitivity, and infusion reactions (thrombophlebitis)
- ► Rapid IV infusions may cause GI or CNS toxicity.

Uses/Indications

Imipenem may be useful in rare situations in equine or small animal medicine to treat serious infections caused by multidrug-resistant bacteria when lower tier antibiotics are ineffective or have unacceptable adverse effect profiles. The most common uses of carbapenems are for the treatment of extended-spectrum beta-lactamase (ESBL) producing Enterobacterales or *Pseudomonas* spp. However, when a carbapenem is indicated, meropenem is most often used as meropenem is generally more active against gram negatives and is amenable to SC administration. The carbapenems (eg, imipenem, meropenem) can be valuable when treating serious gram-negative infections, particularly when multidrug-resistant bacteria are documented to be susceptible to imipenem. *Because this antibiotic is used for multidrug-resistant infections in humans, its use in veterinary medicine should be reserved for confirmed infections where culture and susceptibility testing demonstrates resistance to all other options, the infection is considered treatable, and consultation with an infectious disease expert has concluded that meropenem is a viable and reasonable treatment.*[1,2]

The World Health Organization classifies carbapenems, including imipenem, as a Critically Important, High Priority antimicrobial for human medicine.[3]

Pharmacology/Actions

This fixed combination of a carbapenem antibiotic (imipenem) and an inhibitor of dehydropeptidase I (DHP I) (cilastatin) has a very broad spectrum of activity. Imipenem is generally considered to be a time-dependent bactericidal agent but may be bacteriostatic against some bacteria. As it is a beta-lactam, it has an affinity for and binds to most penicillin-binding protein sites, thereby inhibiting bacterial cell wall synthesis.

Imipenem has activity against a wide variety of bacteria, including gram-positive aerobic cocci (including some bacteriostatic activity against some enterococci), gram-positive aerobic bacilli (including static activity against *Listeria* spp), gram-negative aerobic bacteria (*Haemophilus* spp, Enterobacterales, many strains of *Pseudomonas aeruginosa*), and anaerobes (including some strains of *Bacteroides* spp). *Enterococcus faecium* has inherent carbapenem resistance. Methicillin-resistant staphylococci are resistant to imipenem. Acquired imipenem resistance is currently rare in animals but has been identified and is an increasingly serious problem in human medicine.

Cilastatin inhibits the metabolism of imipenem by DHP I on the brush borders of renal tubular cells. This serves 2 functions: it allows higher imipenem urine concentrations and may protect against proximal renal tubular necrosis that can occur when the imipenem is used alone.

Pharmacokinetics

Neither drug is absorbed appreciably from the GI tract, and, therefore, they are given parenterally. In dogs, the bioavailability of imipenem after SC injection is complete, and the elimination half-life is about an hour.[4]

In cats, 5 mg/kg (using the IV form) SC and IM bioavailability was high (greater than 90%). The elimination half-life is between 1 and 2 hours after IV, SC, or IM administration.[5]

In horses, the elimination half-life is about 70 minutes. When used for regional limb perfusion, the concentration of imipenem in the synovial fluid remained above the MIC of most susceptible pathogens for ≈6 hours.[6]

Imipenem is distributed widely throughout the body, with the exception of the CSF. When given with cilastatin, imipenem is eliminated by both renal and non-renal mechanisms. ≈75% of a dose is excreted in the urine, and about 25% is excreted by unknown non-renal mechanisms. Half-lives in patients with normal renal function range from 1 to 3 hours on average.

Contraindications/Precautions/Warnings

The potential risks versus benefits should be carefully weighed before using imipenem/cilastatin in patients hypersensitive to it or other beta-lactam antibiotics (eg, penicillins or cephalosporins) as partial cross-reactivity may occur. Patients with impaired renal function may require dose reductions or increased dose intervals, as severe renal impairment can increase the risk for seizures. Caution in patients with CNS disorders (eg, seizures, head trauma), as CNS adverse effects are more likely.

Serious and sometimes fatal hypersensitivity reactions have been reported in humans. Use in the absence of a proven or strongly suspected infection or for a prophylactic indication can increase the risk for bacterial resistance and is not recommended.[7]

Do not give this drug via rapid IV infusion, as seizures are possible. In humans, it is recommended to give doses of 500 mg or less over 20 to 30 minutes and doses over 500 mg over 40 to 60 minutes.

Adverse Effects

Potential adverse effects include GI effects (eg, vomiting, anorexia, diarrhea), CNS toxicity (seizures, tremors), hypersensitivity (pruritus, fever to anaphylaxis), and infusion reactions (thrombophlebitis; too rapid IV infusions may cause GI or CNS toxicity). Rapid IV infusion or multiple high doses to animals with reduced renal function (including neonates and geriatric animals) may increase the risk for seizures.

SC or IM administration may cause severe pain at the injection site and neurovascular damage. There was a separate IM form available, but that product has been discontinued. Rarely, hypotension, tachycardia, or transient increases in renal (BUN or serum creatinine values) function tests and/or hepatic (AST/ALT/ALP) enzymes may be noted.

Reproductive/Nursing Safety

Imipenem crosses the placenta and is distributed into milk. While no teratogenic or reproductive effects have been noted in animal studies, safe use during pregnancy has not been firmly established. While imipenem enters milk, no adverse effects attributable to it have been noted in nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Little information is available. The LD_{50} of imipenem/cilastatin in a 1:1 ratio in mice and rats is ≈1 g/kg/day. At that dosage, ataxia and clonic convulsions and death occurred within 1 hour. Acute overdoses should be handled by halting therapy then treating supportively and symptomatically.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving imipenem/cilastatin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides**: Additive effects or synergy may result when aminoglycosides are added to imipenem/cilastatin therapy, particularly against *Enterococcus* spp, *Staphylococcus aureus*, and *Listeria monocytogenes*. There is apparently neither synergy nor antagonism when used in combination against Enterobacteriaceae or *Pseudomonas aeruginosa*.
- **Beta-Lactam Antibiotics**: Antagonism may occur when used in combination with other beta-lactam antibiotics against several Enterobacteriaceae or *Pseudomonas aeruginosa*. The clinical importance of this interaction is unclear, but at present, it is **not** recommended to use imipenem in conjunction with other beta-lactam antibiotics.
- **Chloramphenicol**: May antagonize the antibacterial effects of imipenem (in vitro evidence)
- **Cyclosporine**: Increased cyclosporine levels and potential for CNS effects
- **Ganciclovir**: Increased risk for seizures
- **Probenecid**: May increase concentrations and the elimination half-life of cilastatin, but not imipenem; concurrent use not recommended.
- **Theophylline**: May result in theophylline toxicity
- **Trimethoprim/Sulfa**: Synergy may occur against *Nocardia*

asteroides when imipenem is used in combination with trimethoprim/sulfa.

Laboratory Considerations

- Imipenem may cause a false-positive **urine glucose** determination when using the cupric sulfate solution test (eg, *Clinitest®*), Benedict's solution, or Fehling's solution. Enzymatic glucose oxidase-based tests are not affected (eg, *Tes-Tape, Clinistix®*).

Dosages

NOTES:

1. Dosages are for imipenem alone, not the combined drugs.
2. Reconstituted imipenem solution should be further diluted in a compatible IV solution and infused over 20 to 60 minutes.

DOGS/CATS:

Susceptible infections (extra-label): 5 – 10 mg/kg IV every 6 to 8 hours

HORSES:

Susceptible infections (extra-label):

Adult horses[8]: 10 – 20 mg/kg via slow IV (over a 10-minute period) every 6 hours; alternatively, 16 µg/kg/minute (0.016 mg/kg per minute) IV CRI should maintain synovial concentrations greater than 1 µg/mL (0.01 mg/mL).[9]

Foals: 10 – 15 mg/kg slow IV every 6 to 12 hours; IM if diluted into lidocaine 1%. May give 0.4 – 0.8 mg/kg/hour IV CRI[10]

Intravenous regional limb perfusion (extra-label): Based on a pharmacokinetic study, 500 mg (diluted in 0.9% sodium chloride to 100 mL total) injected into the cephalic or saphenous vein of standing horses with a 30-minute tourniquet time; concentrations above the MIC of most susceptible pathogens were maintained for ≈6 hours.[6]

Monitoring

- Efficacy
- Adverse effects, including vomiting, diarrhea, anorexia, seizures, tremors, pruritus, and fever
- Renal and liver values in cases of prolonged treatment or pre-existing renal or liver disease

Client Information

- Your veterinarian must administer imipenem/cilastatin in an inpatient setting.

Chemistry/Synonyms

Imipenem monohydrate is a carbapenem antibiotic that occurs as a white or off-white, non-hygroscopic, crystalline compound. At room temperature, 11 mg are soluble in 1 mL of water. Cilastatin sodium, an inhibitor of dehydropeptidase I (DHP I), occurs as an offwhite to yellowish, hygroscopic, amorphous compound. More than 2 g are soluble in 1 mL of water.

The commercially available injections are available in a 1:1 fixed-dose ratio. The solutions are clear to yellowish in color; pH after reconstitution ranges from 6.5 to 7.5. These products have sodium bicarbonate added as a buffer.

Imipenem may also be known as N-formimidoyl thienamycin, imipemide, MK-787, and MK-0787; multi-ingredient preparations: *Imipem®*, *Klonam®*, *Primaxin®*, *Tenacid®*, *Tienam®*, *Tracix®*, and *Zienam®*.

Storage/Stability

Store the commercially available sterile powders for injection at room temperature (less than 25°C [77°F]). After reconstitution, the solution is stable for 4 hours at room temperature; 24 hours when refrigerated. If other diluents are used, stability times may be reduced (see package insert). Do not freeze solutions. The manufacturer does not recommend admixing with other drugs.

Compatibility/Compounding Considerations

Vials should be reconstituted with 10 mL of an appropriate diluent: normal saline, 5% or 10% dextrose, 5% dextrose with 0.9% sodium chloride, 5% dextrose with 0.225% or 0.45% saline, 5% dextrose with 0.15% potassium chloride, and 5% or 10% mannitol. Reconstituted solutions can range from clear to yellow, but the potency is the same within this color range. The solution must be further diluted before administration (see package insert).

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Imipenem is **compatible** with 5% dextrose and 0.9% sodium chloride, depending on concentration. The following drugs are reportedly **compatible** with imipenem/cilastatin for an IV infusion at a Y-site: aztreonam, buprenorphine, butorphanol, cefazolin, cefepime, ceftazidime, clindamycin, dexamethasone HCl and SP, diltiazem, famotidine, furosemide, insulin, metoclopramide, ondansetron, propofol, and voriconazole.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Imipenem/Cilastatin Powder for Injection: imipenem 500 mg equivalent and cilastatin 500 mg equivalent (1.6 mEq sodium); *Primaxin®*, generic; (Rx)

Imipramine

(im-***ip***-ra-meen) *Tofranil®*

Tricyclic Antidepressant

Prescriber Highlights

- ► Used primarily in dogs and cats for urinary incontinence, narcolepsy, and behavior disorders. It may be useful for the adjunctive treatment of chronic pain. In horses, imipramine has been tried for treatment of narcolepsy and ejaculatory dysfunction.
- ► May reduce seizure thresholds in epileptic animals
- ► Can be very toxic in overdoses
- ► May take a few weeks to see clinical effects; taper dose when discontinuing.
- ► Most likely adverse effects include sedation and anticholinergic effects (tachycardia, hyperexcitability, tremors)
- ► Many possible drug interactions

Uses/Indications

In dogs and cats, imipramine has been used for urinary incontinence, narcolepsy, and tricyclic-responsive behavior disorders. Like other tricyclic antidepressant agents, it may be useful for the adjunctive treatment of chronic pain. In horses, imipramine has been used to treat narcolepsy[1] and ejaculatory dysfunction.[2,3]

Pharmacology/Actions

Imipramine and its active metabolite, desipramine, have a complicated pharmacologic profile, including inhibition of serotonin and norepinephrine reuptake at the neuronal membrane, thereby increasing neurotransmitter concentrations; sedation; and central and peripheral anticholinergic activity. Although not completely understood, it is thought that the antienuretic activity of imipramine is related to its anticholinergic effects, but imipramine may also have some alpha-1-adrenergic receptor antagonist activity. Imipramine also antagonizes the histamine H1 receptor. In animals, tricyclic an-

tidepressants have similar pharmacologic actions to the phenothiazines with respect to altering avoidance behaviors.

Pharmacokinetics

Imipramine is rapidly absorbed from both the GI tract and parenteral injection sites. Peak concentrations occur within 1 to 2 hours after oral dosing. Imipramine and desipramine enter the CNS and maternal milk in concentrations equal to that found in maternal serum. The drug is metabolized in the liver to several metabolites, including desipramine, which is active. In humans, the terminal half-life is ≈8-16 hours.

Contraindications/Precautions/Warnings

Imipramine is contraindicated if prior sensitivity has been noted with any other tricyclic antidepressant. Concomitant use (or use within 14 days before or after treatment) with monoamine oxidase inhibitors (MAOIs) is generally contraindicated.[4]

Use with caution in patients with seizure disorders as imipramine may lower the seizure threshold.[4] Because of its anticholinergic effects, use imipramine with caution in animals with decreased GI motility, urinary retention, cardiovascular disease (especially cardiac rhythm disturbances), narrow angle glaucoma, or increased intraocular pressure. Use with caution in patients with thyroid, renal or hepatic disease.

If discontinuing imipramine, the dose should be slowly tapered over 2 to 3 weeks to minimize the risk for signs of withdrawal.

Adverse Effects

The most predominant adverse effects seen with the tricyclic antidepressants are related to their anticholinergic (dry mouth, constipation, tachycardia, hyperexcitability, tremors) and sedative properties. They have been shown to cause CNS stimulation with the potential to lead to seizures. Adverse effects may also affect the following systems: cardiac (dysrhythmias), hematologic (bone marrow suppression), GI (diarrhea, vomiting), endocrine (glycemic changes, hyponatremia), and renal (delayed micturition).

Reproductive/Nursing Safety

Imipramine crosses the placenta. Studies in rats have shown systemic and embryotoxic potential, and isolated reports of limb reduction abnormalities have been noted.[4]

Imipramine is excreted into milk in low concentrations (approximate milk:plasma ratio of 0.4 to 1.5).

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The oral LD_{50} for dogs is 100 – 215 mg/kg.[4] Overdoses of tricyclic antidepressants can be life-threatening (arrhythmias, cardiorespiratory collapse, seizures, CNS depression and coma).

Overdoses should be treated with standard decontamination measures if appropriate for the animal. IV lipid emulsion therapy has been used successfully in humans and may be beneficial in veterinary patients as well.[5]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving imipramine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-2-Adrenergic Agonists** (eg, **clonidine**, **dexmedetomidine, xylazine**): Increased risk for CNS and respiratory depression, hypertension, and bradycardia. Tricyclic antidepressants (TCAs) may interfere with the antihypertensive effects of alpha-2 agonists. Use cautiously in combination
- **Antihypertensive Agents** (eg, **amlodipine, enalapril, telmisartan**): Increased risk for hypotension
- **Albuterol**: Concurrent use may increase risk for cardiotoxicity.
- **Alprazolam**: Concurrent use may result in increased imipramine plasma concentrations.
- **Anticholinergic Agents** (eg, **atropine**, **glycopyrrolate, oxybutynin**): Because of additive effects, use with imipramine cautiously.
- **Antihistamines** (eg, **cetirizine, chlorpheniramine, diphenhydramine, hydroxyzine**): Concurrent use may increase risk for CNS depression and additive anticholinergic effects. Avoid combination or monitor for sedation, tachycardia, ileus, mydriasis, or constipation.
- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): Concurrent use may increase the risk for QT-interval prolongation.
- **Cimetidine**: May inhibit tricyclic antidepressant metabolism and increase the risk for toxicity
- **CNS Depressants** (eg, **cannabidiol**, **diazepam, methocarbamol, pregabalin**): Because of additive effects, use with imipramine cautiously.
- **Cyclobenzaprine**: Concurrent use may result in increased risk for serotonin syndrome.
- **Cyproheptadine**: May antagonize the serotonergic effects of tricyclic antidepressants
- **Dextromethorphan**: Increased risk for serotonin syndrome
- **Flumazenil**: Flumazenil use in animals suspected of TCA overdose may increase the risk for seizures and arrhythmias.[6]
- **Metoclopramide**: Concurrent use may result in an increased risk for extrapyramidal reactions or neuroleptic malignant syndrome. This combination is considered contraindicated in humans.
- **Mirtazapine**: Increased risk for constipation, urinary retention, CNS depression and serotonin syndrome
- **Monoamine Oxidase Inhibitors** (eg, **amitraz**, **linezolid**, and possibly **selegiline**): Concomitant use (within 14 days) with monoamine oxidase inhibitors is generally contraindicated (serotonin syndrome).
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam**): Concurrent use may result in an increased risk for bleeding.
- **Opioids** (eg, **buprenorphine, butorphanol, fentanyl, methadone, morphine, tramadol**): Concurrent use may increase the risk for urinary retention, constipation and paralytic ileus, CNS and respiratory depression, and serotonin syndrome.
- **Phenobarbital**: May decrease tricyclic antidepressant concentrations
- **Phenothiazines** (eg, **acepromazine**): Concurrent use may result in an increased risk for cardiotoxicity.
- **QT Prolonging Agents** (eg, **amiodarone**, **cisapride, procainamide, quinidine, sotalol**): Increased risk for QTc interval prolongation and tricyclic antidepressant adverse effects
- **Rifampin**: May decrease tricyclic antidepressant blood concentrations
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, paroxetine, sertraline**): Increased risk for serotonin syndrome; avoid concurrent use

- **Sympathomimetic Agents** (eg, **epinephrine, phenylpropanolamine**): Use with sympathomimetic agents may increase the risk for cardiac effects (arrhythmias, hypertension) and hyperpyrexia.
- **Thyroid Agents**: May increase risk for cardiac arrhythmias

Laboratory Considerations

- **ECG**: Tricyclic antidepressants can widen QRS complexes, prolong PR intervals, and invert or flatten T-waves on ECG.
- **Glucose, blood**: Tricyclic antidepressants may alter (increase or decrease) blood glucose levels.

Dosages

DOGS:

Urethral incompetence (extra-label): No controlled studies were noted documenting efficacy; most clinicians recommend 5 – 15 mg/dog (NOT mg/kg) PO every 12 hours; some recommend dosages up to 20 mg/dog (NOT mg/kg) twice daily.

Adjunctive therapy for narcolepsy (extra-label):

a) 0.5 – 1 mg/kg PO 2 to 3 times a day (every 8 to 12 hours); titrate dose based on clinical effect.[7]

b) 0.45 – 2.2 mg/kg PO every 8 to 12 hours was used in narcoleptic dogs with cataplexy[8]

Behavior-related conditions (extra-label): Not often recommended as clomipramine (FDA-approved) or amitriptyline are most commonly used when a tricyclic antidepressant is employed. One recommended dosage for adjunctive treatment of separation anxiety or other tricyclic antidepressant-responsive behavior disorders: 2.2 – 4.4 mg/kg PO once to twice daily.[9]

Adjunctive treatment of chronic pain (extra-label): No controlled studies located documenting efficacy. Recommended dosage is 0.5 – 1 mg/kg PO every 8 hours.

CATS:

Urethral incompetence or adjunctive treatment of chronic pain (extra-label): No controlled studies were noted documenting efficacy; most clinicians recommend 2.5 – 5 mg/cat (NOT mg/kg) PO every 12 hours.

HORSES:

NOTE: The injectable product is no longer marketed in the United States. Compounded preparations may be available.

Pharmacologic induced ejaculation (extra-label):

a) 2 mg/kg IV followed 10 minutes later by xylazine 0.3 mg/kg IV[10]

b) 3 mg/kg PO followed 2 hours later by xylazine 0.66 mg/kg IV.[2] Imipramine doses as low as 100 mg/stallion (NOT mg/kg) PO have been noted.[3]

Narcolepsy and cataplexy (extra-label): 0.55 mg/kg IV or 250 – 750 mg/horse (NOT mg/kg) PO.[1] PO administration produces inconsistent results.[11]

Monitoring

- Efficacy
- Adverse effects
- Baseline CBC, serum chemistry profile, urinalysis, and baseline thyroid testing (eg, tT_4, thyroid panel) prior to therapy, 1 month after initial therapy, and yearly, thereafter.
- Baseline ECG is recommended prior to therapy. TCAs can widen QRS complexes, prolong PR intervals, and invert or flatten T-waves on ECG; significance in animals is not fully understood.

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after receiving it on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- It may take several days to weeks to determine if the medicine is working.
- The most common side effects are drowsiness/sleepiness, dry mouth, and constipation. Be sure your animal has access to fresh water at all times.
- Rare side effects that can be serious: abnormal bleeding or fever, seizures, very fast or irregular heartbeat. Contact your veterinarian immediately if you see any of these.
- Overdoses can be very serious. Keep this medicine out of reach of animals and children.
- If your animal has worn a flea and tick collar in the past two weeks, let your veterinarian know. Do not use one of these collars on your animal while it's getting this medicine without first talking to your veterinarian.

Chemistry/Synonyms

A tricyclic antidepressant agent, imipramine is available commercially in either the hydrochloride or pamoate salts. Imipramine HCl occurs as an odorless or practically odorless, white to off-white crystalline powder that is freely soluble in water or alcohol. Imipramine pamoate occurs as a fine yellow powder that is practically insoluble in water, but soluble in alcohol. The HCl injection has a pH of 4 to 5.

Imipramine HCl may also be known as imipramini chloridum, imipramini hydrochloridum, imizine, and *Tofranil®*.

Storage/Stability

Imipramine HCl tablets and the pamoate capsules should be stored in tight, light-resistant containers, preferably at room temperature. The HCl injection should be stored at temperatures less than 40°C (104°F) and freezing should be avoided. Expiration dates for oral HCl products are from 3 to 5 years after manufacture; for the pamoate, 3 years.

Imipramine HCl will turn yellow to reddish on exposure. Slight discoloration will not affect potency but marked changes in color are associated with a loss of potency.

Compatibility/Compounding Considerations

No specific information noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Imipramine HCl Tablets: 10 mg, 25 mg, and 50 mg; *Tofranil®*, generic; (Rx)

Imipramine Pamoate Capsules: 75 mg, 100 mg, 125 mg, and 150 mg; *Tofranil®-PM*, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Immune Globulin (Human), Intravenous

(im-***myoon glob***-yoo-lin) *IGIV, IVIG, hIVIG*

Immune Serum

Prescriber Highlights

- Potentially useful for refractory cases of canine immune-mediated diseases (eg, immune-mediated hemolytic anemia [IMHA], immune-mediated thrombocytopenia [ITP]), and immune-mediated dermatopathies
- Limited experience in veterinary medicine; limited studies to support use
- Hypersensitivity reactions possible. Potentially could increase the risk for thrombosis in dogs with IMHA
- Very expensive. Can be difficult to obtain. May require obtaining from human hospitals

Uses/Indications

Human intravenous immune globulin (IVIG) has been used in veterinary medicine for immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia (ITP), Evans syndrome, myasthenia gravis, sudden acquired retinal degeneration syndrome (SARDS),[1] and dermatologic autoimmune diseases. However, available studies have demonstrated mixed results. Definitive studies evaluating the safety and efficacy in veterinary patients are not available and are unlikely to be done in the foreseeable future due to the high cost of IVIG. There is some question whether the drug should be used at all in veterinary patients since supply is limited and some countries ration its use for humans. Current literature suggests it might be most beneficial when used as an adjust therapy for ITP and dermatologic autoimmune diseases in dogs.[1]

Although IVIG has been used for IMHA, there is no substantial evidence to support its use. A prospective, randomized, double-blinded, controlled trial of IVIG (with glucocorticoids) in 28 dogs with recently diagnosed IMHA found no statistically significant differences between the treated and placebo groups in survival, length of hospitalization, time to hematocrit stabilization, and transfusion requirements.[2] Although the study population was relatively small, the authors concluded that the cost of the treatment does not lend support to its use as an early intervention treatment in dogs.[2] The ACVIM consensus statement on the treatment of IMHA recommends the use of IVIG only as salvage therapy in dogs that are not responding to treatment with 2 immunosuppressive agents.[3]

Studies suggest that IVIG may be most useful in treating primary immune-mediated thrombocytopenia in dogs. In 1 prospective study, dogs receiving a single dose of IVIG 6% at 0.5 g/kg IV over 6 to 12 hours were compared with dogs receiving corticosteroids alone.[4] The authors concluded that adjunctive emergency therapy of a single IVIG infusion was safe and associated with a significant reduction in platelet count recovery time and duration of hospitalization without increasing the expense of medical care.[4] However, a prospective, randomized study in 20 dogs with ITP comparing vincristine versus IVIG found that there were no significant differences between both groups in median platelet recovery time (2.5 days) or median hospitalization time for dogs that survived (4 days).[5] Seven of 10 dogs in the IVIG group and 10 of 10 in the vincristine group survived to discharge. There were no significant differences in survival at discharge, 6 months, and 1 year. No adverse effects were reported in either group. The authors concluded that vincristine should be the first-line adjunctive treatment for the acute management of canine ITP because of its lower cost and ease of administration.

There have also been case reports of IVIG used for Evans syndrome[6]; SARDS; cancer-associated retinopathy[7]; "stiff dog syndrome"[8]; and dermatologic autoimmune diseases, including Stevens-Johnson syndrome,[9] pemphigus foliaceus,[10] and erythema multiforme,[11,12] but there are no controlled studies for these uses. Although case reports exist, IVIG is not considered first-line therapy for dermatologic autoimmune diseases in dogs.

In humans, IVIG has been used for a variety of immune system–related conditions, including primary and secondary immunodeficiencies, graft vs host disease, Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy, autoimmune hemolytic anemia, juvenile idiopathic arthritis, myasthenia gravis, toxic epidermal necrolysis, systemic vasculitis, and sepsis.

Pharmacology/Actions

Immunoglobulins are produced by B lymphocytes as part of the humoral response to foreign antigens. The actions of intravenous immune globulin (IVIG) antibodies in autoimmune disease are poorly understood and likely multifactorial and modulate the immune system by Fc receptor disruption, pathologic autoantibody neutralization, complement inhibition, Fas-Fas ligand (FasL) binding interference, and cytokine synthesis downregulation.[1] Other actions may include negative feedback and downregulation of antibody production; binding to CD5, interleukin (IL)-1a, IL-6, tumor necrosis factor-alpha, and T-cell receptors; and suppressing pathogenic cytokines and phagocytes.

Pharmacokinetics

Elimination half-life in dogs is reported to be 7 to 9 days. In humans, the onset of action is rapid. Immunoglobulins are primarily eliminated by catabolism, and the mean half-life is about 3 weeks. Fever or infection may decrease antibody half-life because of increased catabolism or consumption.

Contraindications/Precautions/Warnings

Dogs that have had prior hypersensitivity reactions after receiving human albumin should not receive intravenous immune globulin (IVIG). Trace amounts of human albumin may be found in IVIG.

In humans, many adverse reactions are associated with administering IVIG at rates higher than recommended. Follow infusion rate guidelines carefully. At doses used in dogs (0.5 – 1.5 g/kg), IVIG is generally infused over a 6- to 12-hour period. A study in healthy dogs showed that IVIG promoted hypercoagulability and an inflammatory state, which raises concerns about using it in dogs with immune-mediated hemolytic anemia (IMHA).[13]

The FDA has placed a boxed warning on the labeling of IVIG for use in humans, as it has been associated with thrombosis, renal dysfunction, acute renal failure, osmotic nephrosis, and death. For patients at risk for thrombosis or renal failure, IVIG should be administered at the lowest possible dose and infusion rate. Ensure adequate hydration before administration. Higher rates of renal failure are associated with IVIG products containing sucrose.[14]

Adverse Effects

In dogs, intravenous immune globulin (IVIG) can cause increased blood pressure. Local reactions at or near the injection site are possible. Anecdotal reports of anaphylaxis have been reported in dogs receiving IVIG. IVIG can contain trace amounts of human albumin that has been associated with hypersensitivity reactions in dogs. As IVIG can have colloid-like properties, volume overload is possible. In patients with underlying heart disease, careful consideration for dosing and rate of delivery must take place. Thrombotic events have been reported in humans and are possible in dogs. One study done in healthy dogs demonstrated that IVIG promoted hypercoagulability and an inflammatory state.[13]

In humans, adverse effects of IVIG are relatively uncommon, and most are transient and self-limiting, including fever, chills, fa-

cial flushing, fatigue, headache, and nausea. Thrombotic events have been reported. Rarely, acute renal failure, acute tubular necrosis, osmotic nephrosis, and proximal tubular nephropathy have been reported in humans. Increases in creatinine and BUN have been seen as soon as 1 to 2 days following infusion. Hypersensitivity reactions, including anaphylaxis, have been reported but are rare in human patients. Rarely, aseptic meningitis syndrome has been reported in humans, especially with a rapid infusion or high doses. Other rare adverse effects seen in human medicine can include hemolytic anemia as well as transfusion-related acute lung injury (TRALI).

Reproductive/Nursing Safety

Although maternal antibodies cross the placenta, it is unknown whether human intravenous immune globulin (IVIG) crosses the placenta in veterinary species. The drug appears to be safe for use during lactation and nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Fluid volume overload is possible. Other reactions could include pain and tenderness at the injection site.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving intravenous immune globulin (IVIG) and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Vaccines, Live**: IVIG may interfere with immune response and efficacy.

Laboratory Considerations

- **Blood Glucose**: Falsely elevated blood glucose measurements can occur when using the glucose dehydrogenase pyrroloquinoline quinone (GDH-PQQ)–based test. Consider using tests that are not affected, including the glucose oxidase, glucose dehydrogenase nicotine adenine dinucleotide (GDH-NAD), or glucose dehydrogenase flavin adenine dinucleotide (GDH-FAD) methods.
- **Coombs Test**: In humans, the transitory rise of the various passively transferred antibodies may cause positive serological testing results, potentially altering the test's results and interpretation.

Dosages

DOGS:

NOTES:

1. Intravenous immune globulin (IVIG) should be administered through a separate line. The line may be flushed with saline or dextrose prior to administration. An inline filter is recommended during administration. Before administration, IVIG should be allowed to warm to room temperature. Recommendations are to begin infusions slowly (eg, 0.01 mL/kg/minute) and gradually increase the rate, not to exceed ≈0.08 mL/kg per minute, with comprehensive monitoring during the infusion.[1]
2. Various dosages have been used in dogs ranging from 0.5 – 2.2 g/kg, with 1 g/kg being the most commonly used dosage.[1]

Immune-mediated hemolytic anemia (IMHA) in dogs refractory to other immunosuppressive therapies (extra-label): 0.5 – 1.5 g/kg IV over 4 to 12 hours.[15] ACVIM recommends 0.5 – 1 g/kg as salvage therapy in dogs not responding to 2 immunosuppressive drugs.[3] **NOTE**: See ***Contraindications/Precautions/Warnings*** regarding hypercoagulability.

Primary immune-mediated thrombocytopenia (ITP) (extra-label): The optimal dose of IVIG for ITP remains to be identified, and a wide variety of doses have been reported, ranging from 0.28 – 1.3 g/kg.[16] Vincristine is likely a better first-line adjunctive treatment for the acute management of canine ITP due to similar efficacy, but lower cost and ease of administration compared to IVIG.[5]

Evans syndrome, sudden acquired retinal degeneration syndrome (SARDS) (extra-label): 0.5 – 1.3 g/kg doses have been used in case reports.[6,17]

Refractory cases of erythema multiforme, pemphigus foliaceus, Stevens-Johnson syndrome, toxic epidermal necrolysis, and other cutaneous adverse drug reactions (extra-label): No controlled studies were located, and dosage recommendations are based on case reports. One suggested dosage is a 5% to 6% solution given at 0.5 – 1 g/kg IV over a 4- to 6-hour period, 1 to 2 times, 24 hours apart. This treatment may need to be repeated for 3 to 4 days in a row. Further study is needed.[18]

Monitoring

- Blood pressure and TPR prior to infusion and frequently during administration
- Lung auscultation to assess for volume overload
- Renal function tests and urine output
- Clinical efficacy and subsequent monitoring depend on the purpose for use.

Client Information

- Clients should understand that the use of this drug in veterinary medicine is not common, plus the costs and risks associated with its use.
- Monitor for side effects after your animal gets intravenous immune globulin (IVIG), such as difficulty breathing, not eating, vomiting, and lethargy.
- While your animal is taking this medication, it is important to return to your veterinarian for examinations and laboratory work. Do not miss these important follow-up visits.

Chemistry/Synonyms

Intravenous immune globulin (IVIG) consists of fractionated immunoglobulins and is primarily intact IgG. It is obtained from human plasma pooled from thousands of donors. It may also contain trace amounts of IgM, IgA, soluble CD4, CD8, and HLA molecules, and some cytokines. Further processing is performed to inactivate viruses and remove IgG aggregates and other contaminants. Stabilizing agents can include polyethylene glycol, glycine, sorbitol, polysorbate 80, and sugars (ie, maltose, glucose, sucrose).

Immune globulin (human) may also be known as hIVIG, IVIG, IGIV, immunoglobulin, immunglobuline, or immunoglobulinas.

Storage/Stability

Intravenous immune globulin (IVIG) storage requirements vary with each product; refer to the label. Do not freeze these products. Discard unused portions.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Each product may have differing instructions for mixing and dilution. Refer to the product label for specific directions. Generally, intravenous immune globulin (IVIG) should not be mixed with other medications. Some product labels (eg, *Gammaked®*, *Privigen®*) state they can be diluted with 5% dextrose if necessary. Lyophilized products can usually be reconstituted with sterile water, 5% dextrose, or sterile saline. Do not shake; excessive shaking will cause foaming. Any undissolved particles should respond to careful rotation of the bottle; avoid foaming.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Immune Globulin (Human) Injection: 5% (50 mg/mL) preservative-free in 10 mL, 20 mL, 50 mL, 100 mL, and 200 mL (0.5 g, 1 g, 2.5 g, 5 g, and 10 g—depending on the product) single-use bottles; *Flebogamma®*, *Gammaplex®* 5%, *Octagam®*; (Rx)

Immune Globulin (Human) Injection: 10% (100 mg/mL) preservative-free in 10 mL, 20 mL, 50 mL, 100 mL, and 200 mL (1 g, 2 g, 10 g, and 20 g—depending on the product) single-use bottles; *Flebogamma®*, *Gamunex-C®*, *Gammagard® Liquid*, *Gammaked®*, *Gammaplex®* 10%, *Bivigam®*, *Privigen®*, *Panzyga®*, *Octagam®* 10%; (Rx)

Immune Globulin (Human) SC Injection: 10% (100 mg/mL) preservative-free in 10 mL, 25 mL, 50 mL, 100 mL, 200 mL and 300 mL (1 g, 2.5 g, 5 g, 10 g, 20 g, and 30 g) single-use vials; *Gammagard® Liquid*, *Hyqvia®* (also contains recombinant human hyaluronidase); (Rx)

Immune Globulin (Human) SC Injection: 20% (200 mg/mL) preservative-free in 5 mL, 10 mL, 20 mL, and 50 mL (1 g, 2 g, 4 g, and 10 g) single-use vials or prefilled syringes; *Cuvitru®*, *Hizentra®*, *Xembify®*; (Rx)

Immune Globulin (Human) IM Injection: 15% to 18% (150 to 180 mg/mL); preservative-free in 2 mL and 10 mL single-use vials; *Gamastan®*; (Rx)

Immune Globulin (Human) Lyophilized Powder for Solution: 5 g and 10 g kits; *Gammagard S/D®*; (Rx). A 5% or 10% solution can be prepared.

Insulin, Aspart

(***inn***-suh-lin, ***ass***-part) *NovoLog®*

Insulin, Rapid/Short-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Rapid/short-acting insulin used to treat diabetic ketoacidosis (DKA); can be used in place of regular insulin
- ► There are no absolute contraindications, except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, hypophosphatemia (DKA only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to the "foreign" proteins.
- ► Do not confuse insulin types, strengths, and syringes. Insulin aspart is a U100 human product; use only U100 insulin syringes to measure a dose.
- ► Many potential drug interactions

Uses/Indications

Insulin aspart is a rapid, or short-acting, insulin used in diabetic emergencies (eg, diabetic ketoacidosis [DKA]). As an insulin analogue similar in action to regular insulin (ie, rapid/short acting), insulin aspart could be considered for the same indications as regular insulin (eg, hyperkalemia) if regular insulin is not an option, although evidence in veterinary species is lacking. IV insulin administration is recommended in patients with poor tissue perfusion, shock, or cardiovascular collapse, as well as in those that require adjunct therapy for hyperkalemia.

Retrospective studies have shown that early administration (ie, within 6 hours of presentation) of insulin aspart as an IV CRI to canine DKA patients led to resolution of hyperglycemia, acidemia, and ketonemia while being safe and well tolerated.[1] When compared with an intensive SC glargine administration protocol, insulin aspart administered as an IV CRI to cats in the early stages of treatment for diabetes mellitus was shown to decrease long-term insulin requirements and increase remission rates.[2]

In patients with DKA, initial aggressive fluid replacement therapy is of paramount importance to restore tissue perfusion and begin correcting electrolyte or acid-base derangements. Once the patient is stabilized, longer-acting insulin products can be started for maintenance insulin therapy. It is strongly encouraged to consult a veterinary emergency and critical care and/or endocrinology specialist or reference when treating this complex condition.

Insulin aspart has also been used in combination with 50% dextrose to treat hyperkalemia in diarrheic calves.[3]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially by skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information***.

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules). Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers. Insulin aspart is less likely to form hexamers, and its rapid absorption results in a fast onset and short duration of effect.

After SC and IM administration in healthy cats, onset was within 0.25 hours and duration of action was 2.5 to 3 hours.[4] Higher plasma concentrations were achieved following SC administration. Onset, duration of action, and time to peak insulin effect did not differ based on route of administration. Elimination half-life was ≈1.25 hours after SC administration.

In humans, hypoglycemic effect begins within ≈0.25 hours of SC administration, peak effect is between 1 to 3 hours, and duration of effect is 3 to 5 hours. Protein binding is less than 10%. Clearance is 1.2 L/kg/hour.

Contraindications/Precautions/Warnings

Because there are no alternatives for insulin when it is used for diabetic indications, there are no absolute contraindications to its use except during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease, or medication interference) have been ruled out. See ***Insulin, General Information***.

For obese patients, dose calculations should be based on the patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[5]; however, there have been no specific reports of this reaction occurring in dogs or cats.

Similar to regular insulin and other insulin analogue solutions (eg, lispro, glulisine), insulin aspart may be given IV or IM; however, insulin aspart administered IM is limited to anecdotal experience. In patients with moderate to severe dehydration, poor tissue perfusion necessitates insulin aspart be given IM or IV as absorption of SC injections is likely to be impaired or delayed. Short-acting insulin analogues administered IV offer little therapeutic or pharmacokinetic advantage over regular insulin.

Insulin aspart is U100 strength. It is crucial for patient safety to only use U100 syringes when measuring and administering U100 insulin. Calculations can be done to convert to U40 syringes or TB syringes, but these conversions are not recommended due to the potential for introducing dosing errors. See ***Insulin, General Information***.

When writing prescriptions, do not abbreviate units as "U", as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Do not confuse insulin aspart (clear solution that may be administered by a variety of routes) with insulin aspart protamine/insulin aspart mixture (cloudy solution that may be administered only by the SC route). *Fiasp*® is an insulin aspart formulation that also contains niacinamide, which, in humans, promotes a faster onset of action than *NovoLog*®.[6] It is suggested to avoid interchanging these insulins until more is known about the use of *Fiasp*® or insulin aspart protamine/insulin aspart mixtures in animals.

Adverse Effects

Adverse effects of insulin aspart therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, hypophosphatemia (diabetic ketoacidosis [DKA] only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local or allergic reactions to the "foreign" proteins.

Reproductive/Nursing Safety

Insulin aspart given during organogenesis to pregnant laboratory animals did not result in developmental effects; however, maternal hypoglycemia may result in pre- and postimplantation losses and visceral or skeletal abnormalities.[5]

In humans, insulin is considered compatible while nursing.[7]

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilt, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo*® syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 – 15 mL [0.5 – 1 mL/kg], diluted, and slowly administered[8]; see ***Dextrose 50% Injection***). For in-clinic management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon***. Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), it should be closely monitored (both by physical observation and serial blood glucose concentrations) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding regimens should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Antagonists** (eg, **atenolol**, **propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium concentrations, patients receiving concomitant digoxin therapy—especially in patients receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also decrease the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)

- Disopyramide
- Ethanol
- Fenofibrate
- Fluoroquinolones (eg, **ciprofloxacin, enrofloxacin**)
- Fluoxetine
- Hypoglycemics, Oral (eg, **acarbose, glipizide, metformin**)
- Monoamine Oxidase Inhibitors (MAOIs; eg, **amitraz, linezolid, selegiline**)
- Pentoxifylline
- Salicylates (eg, **aspirin, bismuth subsalicylate**)
- Somatostatin Derivatives (eg, **octreotide**)
- Sulfonamides (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- Alpha-2-Adrenergic Agonists (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- Beta-2-Adrenergic Agonists (eg, **albuterol, terbutaline**)
- Corticosteroids (eg, **dexamethasone, prednis(ol)one**)
- Danazol
- Diazoxide
- Estrogens (eg, **diethylstilbestrol [DES], estriol**)
- Isoniazid
- Niacin
- Phenothiazines (eg, **acepromazine, chlorpromazine**)
- Progestins (eg, **megestrol**)
- Thyroid Hormones: Can elevate glucose concentrations in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus and, in particular, diabetic ketoacidosis (DKA) is complex. Insulin is only one component of therapy; treatment may require fluid and electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references.
2. For obese patients, dose calculations should be based on the individual patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Insulin aspart given by IV CRI appears to be a safe and effective alternative when regular insulin is not an option or is unavailable.
4. All dosages are extra-label.

DOGS:

Adjunctive treatment of DKA using an IV CRI: To prepare a CRI that delivers 0.1 units/kg/hour: 2.2 units/kg insulin aspart is added to 240 mL (**NOTE**: Many clinicians add insulin directly to a 250 mL bag without removing the 10 mL of fluid) of 0.9% sodium chloride.[1] Run ≈50 mL of the insulin-containing fluid through the drip set prior to administration (see ***Adsorption*** in ***Compatibility/Compounding Considerations***). The initial administration rate is 10 mL/hour in a separate line to that used for fluid therapy. When starting initial therapy for DKA, serum potassium concentrations must be taken into account and therapy adjusted accordingly to avoid hypokalemia. Adjust infusion rate based on blood glucose concentrations taken every 2 hours. An hourly reduction in blood glucose by 50 – 100 mg/dL is ideal.[9] Once blood glucose approaches 250 mg/dL, adjust fluid type and rate based on periodic measurement of blood glucose concentration (see table) with a goal of keeping blood glucose in the 150 – 300 mg/dL range and continuing the insulin IV infusion at a decreased rate until it can be exchanged for a longer-acting product.

Blood glucose concentration (mg/dL [mmol/L])	Maintenance IV fluid	Rate of insulin IV CRI administration (mL/hour)	Dose of insulin administered (units/kg/hour)*
Greater than 250 (13.8)	0.9% sodium chloride	10	0.09
200-250 (11.1-13.8)	0.45% sodium chloride + 2.5% dextrose	7	0.064
150-199 (8.3-11)	0.45% sodium chloride + 2.5% dextrose	5	0.045
100-149 (5.5-8.2)	0.45% sodium chloride + 5% dextrose	5	0.045
Less than 100 (5.5)	0.45% sodium chloride + 5% dextrose	0 (Stop insulin administration)	0 (Stop insulin administration)

Table adapted from Walsh ES, Drobatz KJ, Hess RS. Use of intravenous insulin aspart for treatment of naturally occurring diabetic ketoacidosis in dogs. *J Vet Emerg Crit Care.* 2016;26(1):101-107.

*CRI prepared by adding insulin aspart 2.2 units/kg to 240 mL of 0.9% sodium chloride

CATS:

Adjunctive treatment of DKA using an IV CRI: Insulin aspart 12.5 units was added to 250 mL of 0.9% sterile sodium chloride for injection. The initial infusion rate was 0.05 units/kg/hour (1 mL/kg/hour) IV CRI and adjusted up to every 15 to 30 minutes in increments of 0.025 – 0.05 units/kg/hour to achieve a target glucose concentration range of 90 – 180 mg/dL.[2] Cats were transitioned to SC glargine on the seventh day at ¼ the total Day 6 insulin aspart dose.

CATTLE:

Adjunctive treatment of hyperkalemia using an IV CRI: In calves with diarrhea, insulin aspart 0.25 units/kg SC along with dextrose 50% 1 mL/kg IV over 5 minutes; sodium bicarbonate 1.3% (40 mL/kg/hour) and IV fluids were administered prior to insulin.[3]

Monitoring

- Diabetic patients should be closely monitored. Each patient requires an individualized treatment plan, frequent reassessment, and adjustments of the plan based on the response of the patient. It is encouraged to review a veterinary endocrinology reference text or consult with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal for monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia.[10] Interpret all monitoring strategies in light of clinical signs. Results from the below monitoring options

may conflict in regard to achieving good glycemic control and good clinical control.

- Patient status and control of clinical signs: body weight, appetite, fluid intake, urine output
- Glucose (blood or interstitial). Because of how often glucose needs to be checked in sick diabetic patients, consider a central line or continuous interstitial glucose monitoring system in dogs and cats. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[9,11–15]
  - For patients that have experienced or are suspected to have experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult a veterinary emergency and critical care and/or endocrinology specialist or review a reference text that specializes in providing information specific for treatment of hypoglycemia.
- Additional monitoring for patients with diabetic ketoacidosis (DKA)[9]:
  - Glucose measurement every 1 to 2 hours initially; adjust insulin therapy and begin dextrose infusion when glucose decreases below 250 mg/dL (14 mmol/L). See ***Dosages***.
  - Hydration status, respiration, pulse every 2 to 4 hours
  - Serum electrolyte (eg, magnesium, phosphorous, potassium), plasma ketones, and total venous CO_2 concentrations every 4 to 8 hours
  - Urine output, glycosuria, and urine ketones every 4 to 8 hours
  - Body weight, packed cell volume, temperature, and blood pressure every 6 to 8 hours
  - Additional monitoring as applicable to address concurrent disease

Chemistry/Synonyms

All commercial preparations of human-labeled insulin currently manufactured in the United States are supplied in solution or suspension at a concentration of 100 units/mL, which is ≈3.5 mg of insulin/mL. Likewise, 1 unit of insulin is ≈35 µg of insulin, and 1 mg insulin is ≈28.8 units.

Insulin aspart injection, USP (rDNA origin) is a rapid-acting human insulin analogue that is produced by recombinant human DNA technology using a genetically modified strain of *Saccharomyces cerevisiae*. It is identical to human insulin, except aspartic acid is substituted for proline at the B chain amino acid position 28. The sterile solution consists of insulin aspart in a clear, colorless aqueous fluid.

Insulin aspart protamine/insulin aspart contains 70% insulin aspart protamine crystals and 30% soluble insulin aspart. It provides biphasic hypoglycemic effects, with an early onset and a second effect of intermediate duration.

Insulin aspart may also be known as aspart, B-28 aspart insulin, insulin aspart protamine, insulin X14, or *NovoLog®*.

For additional information, see ***Insulin, General Information***.

Storage/Stability

Unopened insulin aspart products should be stored in the refrigerator at 2°C to 8°C (36°F-46°F) and protected from temperature extremes and direct sunlight. Do not freeze.[5]

In-use *vials* may be used for 28 days after first use and can be stored at room temperature or in the refrigerator.[5] Store ***in-use*** *pens/devices* at room temperature; do not refrigerate.

Freezing (less than 2°C [36°F]) insulin aspart products may alter the protein structure and decrease potency. Particle aggregation and crystal damage may be visible to the naked eye. Higher temperatures (greater than 30°C [86°F]) and direct exposure to sunlight (as might occur when insulin is stored in a car or on a windowsill) may produce insulin transformation products and fibril formation.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies support that insulin potency and stability are maintained for longer durations.[16,17] Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace with new insulin prior to adjusting insulin therapy.[10]

Compatibility/Compounding Considerations

Diluting insulin: Other than for immediate use, insulin aspart should only be diluted using product-specific sterile diluent, which is supplied by the manufacturer on request. Diluted insulin (10 units/mL) prepared in this manner is stable for 4 weeks and should be stored in the refrigerator, although refrigeration is not required.[5] For immediate use, insulin can be diluted with normal saline for injection, but the potency cannot be predicted after 24 hours.

Adsorption: Insulin aspart adsorbs to infusion materials,[5] although details are lacking. The adsorption of regular insulin to the surfaces of IV infusion solution containers, glass and plastic (including PVC, ethylene vinyl acetate, polyethylene, and other polyolefins), tubing, and filters has been demonstrated.[18] Estimates of loss of regular insulin potency due to adsorption range from 20% to 80%, although reports of 20% to 30% are more common.[19–22] The percent adsorbed is inversely proportional to the concentration of the insulin and may include other factors (eg, amount of container surface area, fill volume of the solution, type of solution, type and length of administration set, temperature, previous exposure of tubing to insulin, presence of other drugs or blood).[20–22] The adsorption process is instantaneous, with the bulk of insulin adsorption occurring within the first 30 to 60 minutes. To saturate binding sites and deliver a more predictable dose to the patient through an IV infusion, it is recommended that the first 50 mL be run through the IV tubing and discarded.

Insulin syringes: Syringes are designed for use with a specific strength of insulin, with the needle covers color-coded according to strength. U100 syringes are available in 0.3 mL, 0.5 mL, and 1 mL size. Measuring U100 insulin to the 1 unit mark in a U100 syringe will contain 1 unit of insulin. Some brands of 0.3 mL syringes include ½ unit markings. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Insulin Aspart Injection Solution Human (rDNA): 100 units/mL in 10 mL vials and 3 mL *Penfill®* cartridges, *FlexPen®*, and *FlexTouch®*; *NovoLog®*; (Rx). **CAUTION**: *Fiasp®* is not interchangeable with *NovoLog®*.

Insulin, Detemir

(***inn***-suh-lin, ***deh***-tih-meer) *Levemir®*

Insulin, Long-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Modified long-acting insulin used for treatment in dogs and cats newly diagnosed with diabetes mellitus and for long-term maintenance therapy
- ► Starting dose for dogs is a much lower dose than with other insulins.
- ► Animals presented with ketoacidosis, anorexia, lethargy, and/or vomiting should first be stabilized with appropriate therapy, including short-acting insulin.
- ► There are no absolute contraindications, except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to the "foreign" proteins.
- ► Do not confuse insulin types, strengths, and syringes: insulin detemir is a U100 human product; only use U100 syringes to measure the dose.
- ► Many potential drug interactions

Uses/Indications

Insulin detemir is a long-acting insulin preparation that can be used in dogs and cats for initial treatment and long-term management of uncomplicated diabetes mellitus. In cats, insulin detemir appears to have a similar profile to glargine insulin in terms of blood glucose control and remission rates; however, cats often require a lower dose of insulin detemir for glycemic control as compared with glargine insulin. Insulin detemir could be considered for use in dogs in which the duration of activity of porcine insulin zinc (lente) or NPH insulin is too short. Compared with humans and cats, dogs show a stronger hypoglycemic response with insulin detemir and should start treatment at a much lower dose than other insulins.[1,2]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially by skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information.***

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules). Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers.

After SC injection, insulin detemir both strongly self-associates and binds protein at the injection site, slowing absorption and prolonging the hypoglycemic effect with no pronounced peak in humans.[3] In circulation, it is 98% protein-bound to albumin and has an elimination half-life of ≈6 hours.[3] A comparison study[4] of 10 healthy young cats given insulin glargine and insulin detemir showed that following administration of 0.5 units/kg SC, the onset of action was 1.8 ± 0.8 and 1.3 ± 0.5 hours for insulin detemir and insulin glargine, respectively. The end of action was 13.5 ± 3.5 hours and 11.3 ± 4.5 hours for insulin detemir and insulin glargine, respectively. Time-to-peak action was 6.9 ± 3.1 hours and 5.3 ± 3.8 hours for insulin detemir and insulin glargine, respectively. The time–action curves for both insulin analogues varied between relatively flat curves in some cats and peaked curves in others. In dogs, blood glucose nadir occurred ≈8 hours after SC administration (range, 4-10 hours).[2,5,6] The duration of action was ≈9 to 15 hours.[6]

Contraindications/Precautions/Warnings

Because there are no alternatives for insulin when it is used for diabetic indications, there are no absolute contraindications to its use except during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease, or medication interference) have been ruled out. See ***Insulin, General Information***.

Insulin detemir is not an appropriate insulin choice for patients presenting with severe ketoacidosis, anorexia, lethargy, and/or vomiting or other conditions when treatment with short-acting insulin (eg, regular insulin) is indicated.

For obese patients, dose calculations should be based on the individual patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[3]; however, there have been no specific reports of this reaction occurring in dogs or cats.

The high molar insulin concentration of the insulin detemir formulation elicits a greater hypoglycemic response in dogs when compared to humans, necessitating a lower starting dose of insulin detemir for dogs.[5] Without the availability of an insulin detemir-specific diluent, the use of this type of insulin in dogs weighing less than 10 to 15 kg (22 to 33 lb) is not recommended.[2]

Insulin detemir is U100 strength insulin. It is crucial for patient safety to only use U100 syringes when measuring and administering U100 insulin. Calculations can be done to convert to U40 syringes or tuberculin (TB) syringes, but these conversions are not recommended because of the potential for introducing dosing errors. See ***Insulin, General Information***.

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local or allergic reactions to the "foreign" proteins. In dogs administered insulin detemir, hypoglycemia was present on 22% of blood glucose curves,[2] and 4 out of 10 dogs experienced clinically relevant hypoglycemia, including 3 episodes that were considered severe.

Injection site reactions have not been reported in published studies in dogs or cats receiving insulin detemir, although the number of animals enrolled in studies has been relatively small.

Reproductive/Nursing Safety

Insulin detemir is considered safe for use during human pregnancy and while nursing[7]; the same is assumed to be true for veterinary patients. In humans, insulin is considered a treatment of choice for gestational diabetes.[8]

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilt, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo*® syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 –15 mL [0.5 – 1 mL/kg], diluted, and slowly administered).[9] See ***Dextrose 50% injection***. For in-hospital management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), the animal should be closely monitored (both by physical observation and serial blood glucose levels) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding regimens should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Antagonists** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium levels, patients receiving concomitant digoxin therapy—especially those receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also *decrease* the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin-Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Ethanol**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**)
- **Fluoxetine**
- **Hypoglycemic Agents, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-Adrenergic Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**)
- **Danazol**
- **Diazoxide**
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Thyroid Hormones**: Can elevate glucose levels in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus is complex. Insulin is only one component of therapy; treatment may require fluid electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references for additional information.
2. For obese patients, dose calculations should be based on the individual patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Key goals of therapy are control of clinical signs associated with diabetes mellitus and avoidance of hypoglycemia.[1,10]
4. All dosages are extra-label.

DOGS:

Initial insulin treatment of uncomplicated diabetes mellitus:

NOTE: Insulin detemir doses in dogs are much lower than for other species and other insulins. See ***Monitoring***.

a) 0.1 unit/kg SC every 12 hours[1]
b) Initial dose, 1 unit/dog (NOT unit/kg) SC every 12 hours, regardless of the size of the dog. In a study, dose adjustments were made in 0.5 – 1 unit/dog (NOT unit/kg) increments. The average insulin detemir dose at study completion was 0.12 unit/kg (range, 0.05 – 0.34 unit/kg).[2]

CATS:

Initial insulin treatment of uncomplicated diabetes mellitus: 0.5 unit/kg SC every 12 hours if blood glucose is more than 360 mg/dL (on initial presentation) or 0.25 unit/kg SC every 12 hours if blood glucose is less than 360 mg/dL (on initial presentation). For a starting dose, round down to the nearest unit, which is generally less than or equal to 2 units/cat every 12 hours regardless of weight.[1,11,12] See ***Monitoring***.

Monitoring

Each patient requires an individualized treatment plan, frequent re-

assessment, and adjustments of the plan based on the response of the patient. It is encouraged to consult a veterinary endocrinology reference text or with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal when monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia. A so-called "loose-control" (ie, managing clinical signs while avoiding hypoglycemia and reducing frequency of hospitalizations for glucose curves) approach to diabetes management in cats using insulin detemir has also been described.[11] Interpret all monitoring strategies based on clinical signs. Results from the monitoring options below may conflict in regard to achieving good glycemic control and good clinical control.

- Patient status and control of clinical signs: body weight, appetite, fluid intake, and urine output
- Glucose (blood or interstitial) curve. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[13–16] A glucose curve can be considered at the following times[1]:
  - After the first dose of a new insulin type—blood glucose can be checked every 2 hours after administration. The goal for monitoring following the first dose of insulin would be solely to identify hypoglycemia. The insulin dose should NOT be increased based on the first-day blood glucose evaluation. If blood glucose falls below 150 mg/dL during the glucose curve, the frequency of monitoring should increase to hourly until blood glucose is greater than 150 mg/dL.[1] Although the insulin detemir dose should never be increased on the first day of therapy, the dose should be decreased by 10% to 50% in dogs, and 50% in cats if blood glucose is less than 150 mg/dL at any time during the day.[1] Repeat glucose curves on subsequent days (and decrease insulin dose if necessary) until nadir is greater than 150 mg/dL.
  - 7 to 14 days after starting insulin or an insulin dose change
  - At least every 3 months, even in animals with well-controlled diabetes. In well-controlled patients, it may be possible to use clinical signs, body weight, +/- serum fructosamine measurements to determine frequency of glucose curve evaluations.[11]
  - Any time clinical signs related to hyperglycemia (eg, polyuria, polydipsia) recur in an animal with previously well-controlled diabetes
  - When hypoglycemia is a concern. **NOTE**: For patients that have experienced or are suspected of having experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult with a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for the treatment of hypoglycemia.
- Urine glucose monitoring is typically only helpful for documenting prolonged hypoglycemia (eg, persistently negative urine glucose testing when monitoring for diabetic remission in cats). As most diabetic patients spend time above the renal threshold for urinary glucose spillage, even patients with well-controlled diabetes may be intermittently glucosuric throughout the day.
- Fructosamine or glycosylated hemoglobin can be evaluated if available and warranted.

Client Information

NOTES for veterinarian:

1. Correct injection techniques should be taught and practiced with the client before the animal's discharge.
2. Emphasis should be placed on matching the appropriate syringe and insulin concentration (eg, do not interchange U40 insulin and syringes with U100 insulin and syringes) and correct needles with pens/devices.

- For this medication to work safely, give the insulin ***exactly*** as your veterinarian has prescribed. Do not give this medicine and contact your veterinarian for guidance if your animal is not eating.
- Your veterinarian will teach you proper injection technique. ***Only*** use U100 insulin syringes with insulin detemir.
- Always double-check the dose in the syringe or pens/devices before you inject your animal. Overdoses may be fatal.
- Prior to using, visually inspect the insulin container. Insulin detemir solutions should be clear and colorless, without visible particles. Do not use insulin if you see crystals on the inside of the vial. There should never be clumps or unexpected particles in the vial.
- After measuring the dose into a syringe, allow the contents to come to room temperature (if the vial is stored in the refrigerator) before giving the injection.
- The injection site should be frequently changed, with the main sites being the back of the neck, side of the animal, or shoulder area.
- Place the used needles and syringes in a sharps disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist will help you obtain these containers.
- Do not reuse needles or syringes.
- Keep insulin products out of temperature extremes.
- Signs of low blood sugar include weakness, depression, lack of energy, sluggishness, staggering gait (ie, stumbling) when walking, behavior changes, muscle twitching, seizures (convulsions), or coma. **If your animal is unconscious or having a seizure, this is a medical emergency.** Take your animal to your veterinarian immediately. **If your animal is conscious and able to swallow**, rub ≈1 tablespoon of corn syrup (*Karo*®) or honey on your animal's gums until it is alert enough to eat. Feed the usual meal and contact your veterinarian for recommendations. Some animals may not show any obvious physical signs of low blood sugar. If your animal is not acting normally, contact your veterinarian to make sure your animal's blood sugar levels are in a safe range.
- Contact your veterinarian at your earliest convenience if you notice excessive thirst, increased frequency of urination, or increased appetite in your animal, as these signs may indicate the insulin dose needs to be adjusted.
- When traveling, do not leave insulin in carry-on luggage that will pass through airport surveillance equipment. Generally, insulin stability is not affected by a single pass through surveillance equipment; however, longer than normal exposure or repeated passes through surveillance equipment may alter insulin potency.
- Do not stop giving this medication to your animal unless instructed to do so by your veterinarian.
- Your veterinarian will need to closely monitor your animal during treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

Insulin detemir is a U100 (ie, 100 units/mL) insulin that contains 14.2 mg insulin detemir insulin/mL. In contrast, all other commercial preparations of U100 human-labeled insulin currently manufactured in the United States contain ≈3.5 mg of insulin/mL.[3]

Insulin detemir is a long-acting human insulin analogue pro-

duced by recombinant DNA technology using a genetically modified strain *of Saccharomyces cerevisiae*. Insulin detemir differs from human insulin in that the amino acid threonine in position B30 has been omitted and that a C14 fatty acid chain has been attached to the amino acid B29. The fatty acid slows absorption from the injection site. It is a clear, colorless, aqueous solution.

Insulin detemir may also be known as NN-304 or *Levemir®*.

Storage/Stability

Unopened insulin detemir *vials* and *pens/devices* should be stored in the manufacturer's carton in the refrigerator at 2°C to 8°C (36°F-46°F).[3] Do not freeze; discard if the product is frozen. Unused product may be stored unrefrigerated if kept below 30°C (86°F) and out of direct heat and sunlight but must be discarded after 42 days.

In-use insulin detemir *vials* may be refrigerated or stored at room temperature; discard 42 days after first use. ***In-use*** *pens/devices* should be stored at room temperature only (do not refrigerate) and discard 42 days after first use.

Discard insulin detemir vials or pens/devices if the solution is discolored, cloudy, or contains visible particles.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies[17,18] support that insulin potency and stability is maintained for longer durations. Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the listed expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace it with new insulin prior to adjusting insulin therapy.[1]

Compatibility/Compounding Considerations

Diluting insulin: Insulin detemir requires a specific diluent that is not readily available. Because dogs require a lower dose of this insulin, it is not recommended to use insulin detemir in dogs weighing less than 10 to 15 kg (22 to 33 lb).[2]

Insulin syringes: Syringes are designed for use with a specific strength of insulin, and needle covers are color-coded for each insulin strength. U100 syringes are available in 0.3 mL, 0.5 mL, and 1 mL size. Drawing U100 insulin to the 1 unit mark in a U100 syringe will result in 1 unit of insulin. Some brands of 0.3 mL syringes include ½ unit markings. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Insulin Detemir Injection Human (rDNA) 100 units/mL in 10 mL vials and 3 mL prefilled pen system; *Levemir®*; (Rx)

Insulin, Glargine

(***inn***-suh-lin, ***glar***-jeen) *Lantus®*

Insulin, Long-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Long-acting insulin used for treatment in patients newly diagnosed with diabetes mellitus and for long-term maintenance therapy. Although short-acting insulins (ie, regular insulin) are typically used to stabilize cats with diabetic ketoacidosis (DKA), insulin glargine can also be considered for management of cats with DKA.
- ► There are no absolute contraindications, except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, hypophosphatemia (DKA only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to "foreign" proteins.
- ► Do not confuse insulin types, strengths, and/or syringes. Insulin glargine is available in 2 strengths, U100 and *U300*. Only use U100 syringes with U100 glargine and the appropriate needle for the *U300* insulin pen to measure dose.
- ► Many potential drug interactions

Uses/Indications

Insulin glargine is a long-acting insulin preparation that can be used for initial treatment and long-term management of diabetes mellitus, especially in cats. U100 insulin glargine is recommended as a first-choice insulin in newly diagnosed diabetic cats.[1] Intermediate-acting insulins (eg, porcine insulin zinc [ie, lente], neutral protamine Hagedorn [NPH]) are considered first-choice insulin therapies in dogs with uncomplicated diabetes mellitus[1]; however, glargine can also be considered if these insulins do not have a long enough duration of activity. Data are emerging regarding the role of *U300* glargine in dogs and cats,[2–5] and it has demonstrated safety and efficacy in client-owned diabetic cats.[6]

In a study evaluating U100 glargine versus regular insulin for feline DKA, glargine administration was found to be an effective and safe alternative to the current standard regular insulin CRI protocol for the management of DKA in cats.[7]

U100 insulin glargine can also be considered for treatment of diabetes mellitus in ferrets,[8] horses,[9] and guinea pigs.[10]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogs lower blood glucose by increasing glucose uptake in peripheral tissues, especially skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information***.

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules). Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers.

After SC injection of insulin glargine, the acidic solution is neutralized, and microprecipitates that slowly release small amounts of insulin glargine are formed, resulting in a relatively constant concentration/time profile over 24 hours, with no pronounced peak in humans. Microprecipitates are not formed when glargine is diluted or administered either IM or IV; thus, a rapid reduction of blood glucose—similar to regular insulin—is produced.[4,11]

In diabetic dogs receiving SC U100 insulin glargine, a hypoglycemic effect was noted 2 hours after administration and persisted for 12 hours. There was no significant difference between mean minimum and maximum blood glucose concentrations.[12] In healthy, nondiabetic dogs given *U300* insulin glargine, the peak effect occurred at 6.3 hours, and the duration was 16.3 hours.[2] In beagles with induced diabetes mellitus receiving *U300* insulin glargine, day-to-day variability of interstitial glucose was ≈20% to 30%.[5] In humans, cleavage of the insulin glargine B-chain N terminus occurs at the injection site and this results in 2 active metabolites (M1 and M2),[13] whereas dogs only form the M1 metabolite.[4]

A small study of 9 healthy cats compared equal doses of U100 insulin glargine, protamine zinc insulin (PZI; mixed beef/pork), and purified pork lente insulin.[14] Results showed no significant difference in onset of action (0.8 to 1.8 hours) or nadir glucose concentrations among different insulin types; time to reach nadir glucose concentration was longer for insulin glargine (≈14 hours) versus PZI insulin (≈4 hours) and lente insulin (≈5 hours). Duration was significantly shorter for lente insulin (10 hours) than for insulin glargine (22 hours) or PZI (21 hours), with glargine and PZI not appearing to be significantly different. This study also showed definite peaks in glargine concentration and in its glucose-lowering effects. In healthy, nondiabetic cats, the onset and duration of effect for *U300* insulin glargine is nearly identical to that of U100 glargine (≈2 hours, and 12 to 17 hours, respectively)[3,15]; however, *U300* glargine resulted in a more evenly distributed metabolic effect over a 24-hour period.[15]

Contraindications/Precautions/Warnings

Because there are no alternatives for insulin when it is used for diabetic indications, there are no absolute contraindications to its use except during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease or medication interference) have been ruled out. See ***Insulin, General Information***.

For obese patients, dose calculations should be based on the patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[16]; however, there have been no specific reports of this reaction occurring in dogs or cats.

It is crucial for patient safety to only use U100 syringes when measuring and administering U100 insulin. Calculations can be done to convert to U40 syringes or TB syringes, but these conversions are not recommended due to the potential for introducing dosing errors. See ***Insulin, General Information***. Do not confuse U100 insulin glargine (*Lantus®, Basaglar®, Semglee®*) with *U300* insulin glargine (*Toujeo®*).

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, hypophosphatemia (DKA only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), weight gain, and local or allergic reactions to the "foreign" proteins.

Clinical signs associated with hypoglycemia were not observed in diabetic cats receiving *U300* insulin glargine, although biochemical hypoglycemia was detected in 12.5% of blood glucose curves.[6]

In a case report, a cat was initially treated with insulin glargine for diabetes mellitus and went into remission, at which time insulin glargine was discontinued.[17] Approximately 36 months later, the diabetes recurred, and insulin glargine therapy was restarted. Within 2 to 3 minutes of the first injection, the cat experienced a hypersensitivity reaction, including collapse, vomiting, diarrhea, facial swelling, and diffuse erythema. This cat recovered with aggressive supportive care. An intradermal skin challenge 6 months later confirmed a hypersensitivity reaction to insulin glargine. This cat was switched to PZI insulin and became well regulated for its diabetes.

Reproductive/Nursing Safety

Insulin glargine is considered safe for use during human pregnancy and while nursing[18]; the same is assumed to be true for veterinary patients. In humans, insulin is considered a treatment of choice for gestational diabetes.[19]

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilt, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo®* syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 – 15 mL [0.5 – 1 mL/kg]), diluted and slowly administered[20]; see ***Dextrose 50% injection***. For inhospital management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), the animal should be closely monitored (both by physical observation and serial blood glucose concentrations) to prevent a recurrence of hypoglycemia (especially with the slower absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding habits should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Antagonists** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia

- **Digoxin**: Because insulin can reduce serum potassium concentrations, patients receiving concomitant digoxin therapy—especially those receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also decrease the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Ethanol**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**)
- **Fluoxetine**
- **Hypoglycemic Agents, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-Adrenergic Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**)
- **Danazol**
- **Diazoxide**
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Thyroid Hormones**: Can elevate glucose concentrations in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus and, in particular DKA, is complex. Insulin is only one component of therapy; treatment may require fluid electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references.
2. For obese patients, dose calculations should be based on the patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Key goals of therapy are control of clinical signs associated with diabetes mellitus and avoidance of hypoglycemia or other complications (eg, DKA).[1,21]
4. All dosages refer to U100 glargine unless otherwise specified and are extra-label.

DOGS:

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label):

a) 0.3 unit/kg SC every 12 hours[1]

b) 0.25 – 0.5 unit/kg SC every 12 hours[12,22]

CATS:

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label): Using either U100 or *U300* glargine insulin: 0.5 unit/kg SC every 12 hours if blood glucose is more than 360 mg/dL or 0.25 unit/kg SC every 12 hours if blood glucose is less than 360 mg/dL.[1,6,21,23] This dosing regimen often equates to 1 – 2 units/cat (NOT units/kg) SC every 12 hours. The initial dose should not exceed 2 unit/cat (NOT unit/kg) SC every 12 hours regardless of the size of the cat. Most cats are well regulated at an average dosage of 0.5 units/kg SC every 12 hours. See ***Monitoring***.

Transitioning poorly controlled cats to *U300* insulin (extra-label): The *U300* insulin glargine starting dose was the same as the last dose of the patient's previously used insulin.[6]

Adjunctive therapy for diabetic ketoacidosis:

a) **Combined IM/SC protocol** (extra-label):

i. 1 – 2 units/cat (NOT unit/kg) IM in combination with 1 – 3 units/cat (NOT unit/kg) SC initially.[24] Blood glucose was monitored every 2 to 4 hours, and insulin glargine 0.5 – 1 units/cat (NOT unit/kg) IM was administered to maintain blood glucose between 180 – 252 mg/dL. Insulin glargine 1 – 2 units/cat (NOT unit/kg) SC was continued every 12 hours. The median time to second IM insulin glargine dose was 14 hours when the insulin glargine IM/SC combination was used and 4 hours with IM insulin glargine alone.[24] No cats developed hypoglycemia during the stabilization period. The median time for all cats to be managed with insulin glargine SC as their sole insulin therapy was 24 hours (range, 18 to 72 hours).

ii. 2 units/cat (NOT units/kg) SC initially while starting rehydration.[7] Then 1 unit/cat (NOT unit/kg) IM 2 hours later. IM injections at 1 unit/cat (NOT unit/kg) were subsequently repeated every 4 hours if the glucose was greater than 250 mg/dL, and SC insulin glargine was continued every 12 hours with 0.25 units/kg (based on ideal body weight) rounded to the next half or whole unit. Once the blood glucose was less than 250 mg/dL, glucose containing solutions were used in addition to insulin therapy to maintain the blood glucose between 180 and 250 mg/dL. Insulin was decreased or stopped (at the discretion of the clinician) when the blood glucose was less than 80 mg/dL.

b) **Glargine in combination with regular insulin** (extra label): insulin glargine 0.25 units/kg SC every 12 hours and regular insulin 1 unit/cat (NOT unit/kg) IM up to every 6 hours for a blood glucose concentration greater than 250 mg/dL[25]

HORSES:

Diabetes mellitus (extra label): From a case report, glargine 0.2 – 0.4 units/kg SC every 24 hours after stabilization with rapid-/short-acting insulin.[9]

FERRETS:

Diabetes mellitus (extra label): 0.5 units/ferret (NOT units/kg) SC between the scapulae every 12 hours if urine dipstick test is positive for glucose[8]

GUINEA PIGS:

Diabetes mellitus, type 1 (extra label): 0.5 units/guinea pig (NOT units/kg) SC once daily administered on the right or left side of the abdomen or thorax[10]

Monitoring

Each patient requires an individualized treatment plan, frequent reassessment, and adjustments of the plan based on the response of the patient. It is encouraged to consult a veterinary endocrinology reference text or with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal when monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia.[1] Interpret all monitoring strategies based on clinical signs. Results from the monitoring options below may conflict in regards to achieving good glycemic and clinical control. Diabetic patients should be closely monitored—especially during the first month of insulin therapy.

- Patient status and control of clinical signs: body weight, appetite, fluid intake, urine output
- Glucose (blood or interstitial) curve. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[26–29] A glucose curve can be considered at the following times[1]:
  - After the first dose of a new insulin type. If performing a glucose curve, glucose can be checked every 3 to 4 hours for 10 to 12 hours after administration. The goal for monitoring following the first dose of insulin would be solely to identify hypoglycemia. The insulin dose should NOT be increased based on first-day glucose evaluation. If glucose falls below 150 mg/dL during the glucose curve, frequency of monitoring should increase to hourly until glucose is greater than 150 mg/dL.[1] Although the glargine dose should never be increased on the first day of therapy, the dose should be decreased by 10% to 50% in dogs and by 0.5 units (total) in cats if glucose is less than 150 mg/dL at any time during the day.[1] Repeat glucose curves on subsequent days (and decrease insulin dose if necessary) until nadir is greater than 150 mg/dL.
  - 7 to 14 days after starting insulin or an insulin dose change
  - At least every 3 months, even in animals with well-controlled diabetes
  - Any time clinical signs recur in an animal with previously well-controlled diabetes
  - When hypoglycemia is suspected. For patients that have experienced or are suspected to have experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult with a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for treatment of hypoglycemia.
- Urine glucose monitoring is typically only helpful for documenting prolonged hypoglycemia (eg, persistently negative urine glucose testing when monitoring for diabetic remission in cats). As most diabetic patients spend time above the renal threshold for urinary glucose spillage, even patients with well-controlled diabetes may be intermittently glucosuric throughout the day.
- Fructosamine or glycosylated hemoglobin can be measured if available and warranted.
- Additional monitoring for patients with DKA[30]:
  - Gucose measurement every 1 to 2 hours initially; adjust insulin therapy and begin dextrose infusion when blood glucose decreases below 250 mg/dL (14 mmol/L)
  - Hydration status, respiration, pulse every 2 to 4 hours
  - Serum electrolyte (eg, magnesium, phosphorous, potassium), plasma ketones, and total venous CO_2 concentrations every 4 to 8 hours
  - Urine output, glycosuria, and urine ketones every 4 to 8 hours
  - Body weight, packed cell volume, temperature, and blood pressure every 6 to 8 hours
  - Additional monitoring as applicable to address concurrent disease

Client Information

NOTES for veterinarian:

1. Correct injection techniques should be taught and practiced with the client before the animal's discharge.
2. Emphasis should be placed on matching the appropriate syringe and insulin concentration (eg, do not interchange U40 insulin and syringes with U100 insulin and syringes) and correct needles with pens/devices.
3. Both veterinary-approved insulins have owner information sheets, client-friendly handouts, and websites to provide client support on administration and use of insulin.

- For this medication to work safely, give the insulin ***exactly*** as your veterinarian has prescribed. Do not give this medicine and contact your veterinarian for guidance if your animal is not eating.
- Your veterinarian will teach you the correct injection technique. ***Only*** use U100 insulin syringes with U100 insulin glargine.
- Always double-check the dose in the syringe or pens/devices before you inject your animal. Overdoses may be fatal.
- Prior to using, visually inspect the insulin container prior to use. Glargine solutions should be clear and colorless, without visible particles. Do not use insulin if crystals are seen. Mixing or shaking the insulin is not needed prior to use.
- After measuring the U100 insulin glargine dose into a syringe, allow the contents to come to room temperature (if the product is stored in the refrigerator) before injection.
- The injection site should be frequently changed, with the main sites being the back of the neck, side of the animal, or shoulder area.
- Place the used needles and syringes in a sharps disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist will help you obtain these containers.
- Do not reuse needles or syringes.
- Keep insulin products out of temperature extremes. Follow the label instructions for storage of the insulin vial and pens/devices.
- Signs of low blood sugar include weakness, depression, lack of energy, sluggishness, staggering gait (ie, stumbling) when walking, behavior changes, muscle twitching, seizures (convulsions), or coma. **If your animal is unconscious or having a seizure, this is a medical emergency.** Take your animal to the veterinarian immediately. **If your animal is conscious and able to swallow**, rub ≈1 tablespoon of corn syrup (*Karo®*) or honey on your animal's gums until it is alert enough to eat. Feed the usual meal and contact your veterinarian for recommendations. Some animals may not show any obvious physical signs of low blood sugar. If your animal is not acting normally, contact your veterinarian to make sure your animal's blood sugar levels are in a safe range.
- Contact your veterinarian at your earliest convenience if you

notice excessive thirst, increased frequency of urination, or increased appetite in your animal, as these signs may indicate the insulin dose needs to be adjusted.
- When traveling, insulin should not be left in carry-on luggage that will pass through airport surveillance equipment. Generally, insulin stability is not affected by a single pass through surveillance equipment; however, longer than normal exposure or repeated passes through surveillance equipment may alter insulin potency.
- Do not stop giving this medication to your animal unless instructed to do so by your veterinarian.
- Your veterinarian will need to closely monitor your animal during treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

All commercial preparations of human-labeled insulin currently manufactured in the United States are supplied in solution or suspension at a concentration of 100 units/mL, which is ≈3.5 mg of insulin/mL. Likewise, 1 unit of insulin equals ≈35 µg of insulin, and 1 mg of insulin is ≈28.8 units.

Glargine is a long-acting human insulin analogue produced by recombinant DNA technology using a nonpathogenic laboratory strain of *Escherichia coli*. Glargine differs from human insulin in that the amino acid asparagine in position A21 has been replaced by glycine, and 2 arginines added to the C-terminus of the B chain. The solutions for injection consist of glargine dissolved in a clear aqueous fluid with a pH ≈4.

Insulin glargine may also be known as HOE901, glargine, *Lantus*®, *Abasaglar*®, *Basaglar*®, *Lusduna*®, *Rezvoglar*® (insulin glargine-aglr), *Semglee*® (insulin glargine-yfgn), *Soliqua*®, *Suliqua*®, or *Toujeo*®.

Storage/Stability

Unopened *vials* and *pens/devices* should be stored in the manufacturer's carton in the refrigerator at 2°C to 8°C (36°F-46°F). Do not freeze; discard if product has been frozen. Unused product may be stored unrefrigerated if kept below 30°C (86°F) and out of direct heat and sunlight but must be discarded after 28 days.[16,31]

In-use insulin glargine *vials* may be refrigerated or stored at room temperature; discard 28 days after first use.[16]

In use U100 insulin glargine *pens/devices* should be stored at room temperature **only** (do not refrigerate); discard 28 days after first use.[16]

In-use *U300* insulin glargine *pens/devices* should be stored at room temperature **only** (do not refrigerate); discard 56 days after first use.[31]

Discard glargine vials or pens/devices if the solution is discolored, cloudy, or contains visible particles.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies support that insulin potency and stability is maintained for longer durations.[32,33] Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace it with new insulin prior to adjusting insulin therapy.[1]

Compatibility/Compounding Considerations

Diluting insulin: The prolonged action of glargine depends on its pH. Insulin glargine must not be diluted or mixed with any other insulin or solution, as the resulting pH change transforms glargine into a rapid-acting insulin.

Insulin syringes: Syringes are designed for use with a specific strength of insulin, with the needle covers color-coded according to strength. U100 syringes are available in 0.3 mL, 0.5 mL, and 1 mL size. Measuring U100 insulin to the 1 unit mark in a U100 syringe will result in 1 unit of insulin. Some brands of 0.3 mL syringes include ½ unit markings. Insulin syringes should not be reused. *U300* glargine was successfully administered to diabetic cats using the manufacturer's pen system, which can accurately deliver a 1 unit dose.[6]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Insulin Glargine Injection Human (rDNA) 100 units/mL in 10 mL vials and/or 3 mL prefilled pen system; *Basaglar*®, *Lantus*®, *Rezvoglar*®, *Semglee*®; (Rx). **NOTE**: Insulins are FDA-licensed (approved) biological products, and *Semglee*® (insulin glargine-yfgn) has been licensed as an interchangeable biosimilar (ie, it can be expected to produce the same clinical result) with *Lantus*®. Please refer to the FDA's Purple Book for more information about FDA-approved biologics, including biosimilar and interchangeable products.

Insulin Glargine Injection Human (rDNA) 300 units/mL in a 1.5 mL and 3 mL prefilled pen system; *Toujeo*®; (Rx). The 1.5 mL pen can dispense a minimum dose increment of 1 unit.

Insulin, Lente

Porcine Zinc Insulin

(***inn***-suh-lin, ***lenn***-tay) *vetsulin*®

Insulin, Intermediate-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► FDA-approved intermediate-acting insulin for the treatment of hyperglycemia and associated clinical signs caused by diabetes mellitus in dogs and cats.
- ► Animals presented with ketoacidosis, anorexia, lethargy, and/or vomiting should first be stabilized with appropriate therapy, including short-acting insulin.
- ► Contraindicated during episodes of hypoglycemia, and in dogs and cats with a systemic allergy to pork, or pork products
- ► Adverse effects include hypoglycemia, hypokalemia, insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to the "foreign" proteins.
- ► Do not confuse insulin types, strengths, and syringes: lente insulin is a U40-approved veterinary product; only use U40 insulin syringes when measuring doses from a vial.
- ► Must shake insulin vials and cartridges vigorously to resuspend prior to administration
- ► Many potential drug interactions

Uses/Indications

Lente insulin is an FDA-approved intermediate-acting preparation used for initial treatment and long-term management of uncomplicated diabetes mellitus in dogs and cats. In a study comparing lente and NPH insulins, glycemic control in newly diagnosed, uncomplicated diabetic dogs was similar[1]; lente and NPH insulins are the first-choice recommended insulins in dogs with uncomplicated diabetes

mellitus.[2] Although the FDA label recommends initiating lente insulin once daily in diabetic dogs, many experts recommend initiating use with this insulin twice daily.

Although lente insulin is FDA-approved for the treatment of diabetes mellitus in cats; either protamine zinc insulin (ie, PZI; FDA-approved for cats) or insulin glargine is recommended as first-choice insulin therapy.[2–6]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially by skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information***.

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules). Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers.

Lente insulin has 2 peaks of activity following SC administration in diabetic dogs: the first is at 2 to 6 hours, and the second is at 8 to 14 hours.[7] The duration of activity varies between 14 and 24 hours. The peak(s), duration of activity, and the dose required to adequately control diabetic signs vary among dogs.

In cats, lente insulin has peak activity between 1.5 and 8 hours after administration.[7] Duration of activity varies between 8 and 12 hours, which may be too short for most cats.

Contraindications/Precautions/Warnings

Lente insulin should not be used during episodes of hypoglycemia and in animals known to have a systemic allergy to pork or pork products. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease, or medication interference) have been ruled out. See ***Insulin, General Information***.

Lente insulin is not an appropriate insulin choice for patients presenting with severe ketoacidosis, anorexia, lethargy, and/or vomiting or other conditions when treatment with short-acting insulin (eg, regular insulin) is indicated.

For obese patients, dose calculations should be based on the patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[8]; however, there have been no specific reports of this reaction occurring in dogs or cats.

Lente insulin is U40 strength. It is crucial for patient safety to only use U40 syringes when measuring and administering U40 insulin. Calculations can be done to convert to U100 syringes or TB syringes, but these conversions are not recommended because of the potential for introducing dosing errors. See ***Insulin, General Information***. The pen delivery system requires the use of needles designed specifically for that product.

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Do not confuse PORCINE zinc insulin (ie, lente insulin) with PROTAMINE zinc insulin (PZI).

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, insulininduced rebound hyperglycemia (ie, Somogyi effect), weight gain, and local reactions to the "foreign" proteins.

Reproductive/Nursing Safety

There is limited information regarding the safe use of veterinary-labeled lente insulin (ie, *vetsulin*®) in breeding, pregnant, and lactating animals.[7] A case series reports that lente has been used to manage gestational diabetes in dogs.[9] In humans, insulin is considered a treatment of choice for gestational diabetes.[10]

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilt, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo*® syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 to 15 mL [0.5 to 1 mL/kg], diluted and slowly administered[11]; see ***Dextrose 50% injection***). For inhospital management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), the animal should be closely monitored (both by physical observation and serial blood glucose levels) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding habits should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Antagonists** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium levels, patients receiving concomitant digoxin therapy—especially those receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also <u>decrease</u> the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may <u>potentiate</u> the hypoglyce-

mic activity of insulin (ie, decrease insulin requirements):
- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin-Converting Enzyme Inhibitors** (**ARBs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Ethanol**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**)
- **Fluoxetine**
- **Hypoglycemic Agents, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):
- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-Adrenergic Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**)
- **Danazol**
- **Diazoxide**
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Thyroid Hormones**: Can elevate glucose levels in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations
- None

Dosages
NOTES:
1. Treatment of diabetes mellitus is complex; insulin is only one component of therapy; treatment may require fluid electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references for additional information.
2. For obese patients, dose calculations should be based on the patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Key goals of therapy are control of clinical signs associated with diabetes mellitus and avoidance of hypoglycemia.[2,12]

DOGS:

Reduction of hyperglycemia and hyperglycemia-associated clinical signs (label dosage; FDA-approved): 0.5 units/kg SC once daily concurrent with or right after a meal.[7] Twice-daily administration should be initiated if the duration of insulin action is determined to be inadequate with once-daily administration. If twice-daily administration is initiated, the 2 doses should each be ≈25% less than the once-daily dose required to attain an acceptable glucose nadir. For example, if a dog receiving 20 units SC once daily has an acceptable nadir but inadequate duration of activity, the dose should be changed to 15 units SC twice daily.

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label): 0.25 – 0.5 units/kg SC every 12 hours; give equal-sized meals at the time of insulin injection.[2]

CATS:

Reduction of hyperglycemia and hyperglycemia-associated clinical signs (label dosage; FDA-approved): Starting dose, 1 – 2 units/cat (NOT units/kg) SC twice daily at ≈12-hour intervals.[7] For cats fed twice daily, injections should be given concurrently with or right after each meal. For cats fed ad libitum, no change in the feeding schedule is needed.

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label): 0.25 – 0.5 units/kg SC every 12 hours; starting dose should not exceed 3 units/cat (NOT units/kg).[2]

Monitoring
Each patient requires an individualized treatment plan, frequent reassessment, and adjustments to the plan based on the response of the patient. It is encouraged to consult a veterinary endocrinology reference text or with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal when monitoring diabetic patients is the control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia. Interpret all monitoring strategies based on clinical signs. Results from the monitoring options below may conflict in regards to achieving good glycemic control and good clinical control.
- Patient status and control of clinical signs: body weight, appetite, fluid intake, urine output
- Glucose (blood or interstitial) curve. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[13–16] A glucose curve can be considered at the following times[2]:
  - After the first dose of a new insulin type—glucose can be checked every 2 hours after administration. The goal for monitoring following the first dose of insulin would be solely to identify hypoglycemia. The insulin dose should NOT be increased based on the first-day glucose evaluation. If glucose falls below 150 mg/dL during the glucose curve, the frequency of monitoring should increase to hourly until glucose is greater than 150 mg/dL.[2] Although the lente insulin dose should never be increased on the first day of therapy, the dose should be decreased by 10% to 50% in dogs and 50% in cats if glucose is less than 150 mg/dL at any time during the day.[2] Repeat glucose curves on subsequent days (and decrease insulin dose if necessary) until nadir is greater than 150 mg/dL.
  - 7 to 14 days after starting insulin or an insulin dose change
  - At least every 3 months, even in animals with well-controlled diabetes
  - Any time clinical signs related to hyperglycemia (eg, polyuria, polydipsia) recur in an animal with previously well-controlled diabetes
  - When hypoglycemia is a concern. **NOTE**: For patients that have experienced or are suspected of having experienced repeated or unexplained hypoglycemia, it is strongly encouraged that pet owners consult with a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for the treatment of hypoglycemia.
- Urine glucose monitoring is typically only helpful for documenting prolonged hypoglycemia (eg, persistently negative urine glu-

cose testing when monitoring for diabetic remission in cats). As most diabetic patients spend time above the renal threshold for urinary glucose spillage, even patients with well-controlled diabetes may be intermittently glucosuric throughout the day.

- Fructosamine or glycosylated hemoglobin can be monitored if available and warranted.

Client Information

NOTES for veterinarian:

1. Correct injection techniques should be taught and practiced with the client before the animal's discharge.
2. Emphasis should be placed on matching the appropriate syringe and insulin concentration (eg, do not interchange U40 insulin and syringes with U100 insulin and syringes) and correct needles with pens/devices.
3. Both veterinary-approved insulins have owner information sheets, client-friendly handouts, and websites to provide client support on administration and use of insulin.

- For this medication to work safely, give the insulin ***exactly*** as your veterinarian has prescribed. Do not give this medicine and contact your veterinarian for guidance if your animal is not eating.
- Your veterinarian will teach you proper injection technique. ***Only*** use U40 syringes with lente insulin. When using the *VetPen*® device, only use matching pen needles.
- Always double-check the dose in the syringe before you inject your animal. Overdoses may be fatal.
- Shake lente insulin vials thoroughly until a uniform, milky suspension is formed. Prior to using, visually inspect the insulin bottle prior to use. Do not use if clumps or white particles persist after mixing.
- After measuring the dose into a syringe, allow the contents to come to room temperature before giving the injection.
- The injection site should be frequently changed, with the main sites being the back of the neck, side of the animal, or shoulder area.
- Place the used needles and syringes in a sharps disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist will help you obtain these containers.
- Do not reuse needles or syringes.
- Signs of low blood sugar include weakness, depression, lack of energy, sluggishness, staggering gait (ie, stumbling) when walking, behavior changes, muscle twitching, seizures (convulsions), or coma. **If your animal is unconscious or having a seizure, this is a medical emergency.** Take your animal to your veterinarian immediately. **If your animal is conscious and able to swallow**, rub ≈1 tablespoon of corn syrup (*Karo*®) or honey on your animal's gums until it is alert enough to eat. Feed the usual meal and contact your veterinarian for recommendations. Some animals may not show any obvious physical signs of low blood sugar. If your animal is not acting normally, contact your veterinarian to make sure your animal's blood sugar level is in a safe range.
- Contact your veterinarian at your earliest convenience if you notice excessive thirst, increased frequency of urination, or increased appetite in your animal, as these signs may indicate the insulin dose needs to be adjusted.
- When traveling, do not leave insulin in carry-on luggage that will pass through airport surveillance equipment. Generally, insulin stability is not affected by a single pass through surveillance equipment; however, longer than normal exposure or repeated passes through surveillance equipment may alter insulin potency.
- Do not stop giving this medication to your animal unless instructed to do so by your veterinarian.
- Your veterinarian will need to closely monitor your animal during treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

Porcine zinc (lente) insulin is a sterile aqueous suspension of purified pork insulin that consists of 35% amorphous zinc insulin and 65% crystalline zinc insulin. Lente insulin is supplied at a concentration of 40 units/mL; it is a cloudy or milky suspension of a mixture of characteristic crystals and particles with no uniform shape. One unit of insulin is equivalent to ≈35 µg of insulin, and 1 mL of U40 insulin contains 1.38 mg insulin, and 1 mg of porcine insulin is ≈28.8 units.

Lente insulin may also be known as *Caninsulin*®, porcine zinc insulin, or *vetsulin*®.

Storage/Stability

Store ***unopened*** and ***in-use*** lente insulin *vials* and *pens/devices* in the manufacturer's carton in the refrigerator at 2°C to 8°C (36°F-46°F). Do not freeze; discard if product has been frozen. Store vials upright; may store pens/devices on their sides. Discard *vials* and *pens/devices* 42 days after first use.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies support that insulin potency and stability is maintained for longer durations.[17,18] Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace it with new insulin prior to adjusting insulin therapy.[2]

Compatibility/Compounding Considerations

Diluting *vetsulin*® is not recommended, as dilution alters the balance of amorphous and crystalline insulin, thereby changing the hypoglycemic effects.[19]

Insulin syringes: Syringes are designed for use with a specific strength of insulin, with the needle covers color-coded according to strength. U40 syringes are available in 0.3 mL, 0.5 mL, and 1 mL size. Drawing U40 insulin to the 1 unit mark in a U40 syringe will contain 1 unit of insulin. Some brands of 0.3 mL and 0.5 mL syringes include ½ unit markings. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Porcine Zinc [Lente] Insulin Suspension: 40 units/mL in 10 mL vials; also available in 2.7 mL cartridges for use in an insulin pen system: *Vetpen*®*8* delivers a dose between 0.5 to 8 units in 0.5 unit increments; *Vetpen*®*16* delivers a dose between 1 and 16 units, in 1 unit increments; *vetsulin*®; (Rx). FDA-approved for use in dogs and cats; NADA# 141-236

HUMAN-LABELED PRODUCTS: NONE

Insulin, Lispro

(***inn***-suh-lin, ***liss***-pro) *Humalog®*

Insulin, Rapid/Short-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Rapid/short-acting insulin used to treat diabetic ketoacidosis (DKA); can be used in place of regular insulin. There is limited clinical experience in dogs and cats with this insulin.
- ► There are no absolute contraindications, except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, hypophosphatemia (DKA only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to the "foreign" proteins.
- ► Do not confuse insulin types, strengths, and syringes. Insulin lispro is a U100 human product; use only U100 insulin syringes to measure a dose. Other insulin lispro formulations (ie, U200, insulin lispro combinations) have not been evaluated in veterinary patients.
- ► Many potential drug interactions

Uses/Indications

Insulin lispro is a rapid, or short-acting, insulin used for diabetic emergencies (eg, diabetic ketoacidosis [DKA]) and for control of the complicated diabetic patient. As an insulin analogue similar in action to regular insulin (ie, rapid/short-acting), insulin lispro could be considered for the same indications as regular insulin (eg, hyperkalemia) if regular insulin is not an option, although evidence in veterinary species is lacking. IV insulin administration is recommended in patients with poor tissue perfusion, shock, cardiovascular collapse, or in those that require adjunct therapy for hyperkalemia.

Insulin lispro is not commonly used for maintenance insulin therapy in diabetic dogs and cats; however, it could be considered in complicated diabetic patients that cannot be regulated using more standard insulin preparations, particularly those in which a profound postprandial hyperglycemic response exists.[1] It is strongly encouraged to consult an endocrinology specialist or reference when using insulin lispro as part of a protocol for long-term maintenance insulin therapy.

Insulin lispro administered as an IV CRI appears to be safe and as effective as regular insulin in dogs[2] and cats with DKA.[3,4] One study describes the safe and effective use of insulin lispro IM for the management of DKA in dogs.[5] In patients with DKA, initial aggressive fluid replacement therapy is of paramount importance to restore tissue perfusion and begin correcting electrolyte or acid-base derangements. Early administration (ie, within 6 hours of presentation) of insulin to patients with DKA leads to earlier resolution of hyperglycemia, acidemia, and ketonemia while being safe and well tolerated.[6] Once the patient is stabilized, longer-acting insulin products can be started for maintenance of insulin therapy. It is strongly encouraged to consult a veterinary emergency and critical care and/or endocrinology specialist or reference when treating this complex condition.

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially by skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information***.

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules). Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers. Insulin lispro is less likely to form hexamers, and its rapid absorption results in a fast onset and short duration of effect.

The hypoglycemic response of insulin lispro administered by continuous IV infusion appears similar to that of regular insulin in cats and dogs.[1,2] Although published studies are lacking, the pharmacokinetics of insulin lispro given IV to dogs and cats appear to be comparable with that of humans. After SC administration in diabetic dogs, the onset of hypoglycemic effect is within 0.5 hours, and the peak effect occurs over 1 to 3 hours.[7]

Contraindications/Precautions/Warnings

Because there are no alternatives for insulin when it is used for diabetic indications, there are no absolute contraindications to its use except during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease, or medication interference) have been ruled out. See ***Insulin, General Information***.

For obese patients, dose calculations should be based on the patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[8]; however, there have been no specific reports of this reaction occurring in dogs or cats.

Similar to regular insulin and other insulin analogue solutions (eg, aspart, glulisine), insulin lispro may be given IV or IM; however, insulin lispro administered IM is limited to anecdotal experience. In patients with moderate to severe dehydration, poor tissue perfusion necessitates regular insulin to be given IM or IV as absorption of SC injections is likely to be impaired or delayed. Short-acting insulin analogues administered IV offer little therapeutic or pharmacokinetic advantage over regular insulin.

Insulin lispro is U100 strength. It is crucial for patient safety to only use U100 syringes when measuring and administering U100 insulin. Calculations can be done to convert to U40 syringes or TB syringes, but these conversions are not recommended because of the potential for introducing dosing errors. See ***Insulin, General Information***.

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Do not confuse insulin lispro (a clear solution that may be administered by a variety of routes) with insulin lispro protamine/insulin lispro mixture (a cloudy solution that may be administered only by the SC route). *Lyumjev®* is an insulin lispro formulation that produces a different hypoglycemic response in humans (slower onset and longer duration) than *Humalog®*.[9] It is suggested to avoid interchanging these insulins until more is known about the use of *Lyumjev®* in animals.

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia

(see ***Overdose/Acute Toxicity***), hypokalemia, hypophosphatemia (diabetic ketoacidosis [DKA] only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local or allergic reactions to the "foreign" proteins.

Reproductive/Nursing Safety

Insulin lispro given at clinically effective doses to pregnant laboratory animals did not result in developmental effects; however, fetal growth retardation was noted at a dosage of 20 units/kg/day.[8]

In humans, insulin is considered compatible with nursing.[10]

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilt, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo*® syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 – 15 mL [0.5 –1 mL/kg], diluted, and slowly administered[11]). See ***Dextrose 50% Injection***. For inhospital management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), it should be closely monitored (both by physical observation and serial blood glucose levels) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding regimens should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Blockers** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium levels, patients receiving concomitant digoxin therapy—especially patients receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also decrease the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin-Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Ethanol**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**)
- **Fluoxetine**
- **Hypoglycemics, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (**MAOIs;** eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-2-Adrenergic Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**)
- **Danazol**
- **Diazoxide**
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Thyroid Hormones**: Can elevate glucose levels in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus and, in particular, diabetic ketoacidosis (DKA) is complex. Insulin is only one component of therapy; treatment may require fluid and electrolyte replacement, management of acid/base disturbances, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references.
2. For obese patients, dose calculations should be based on the individual patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Insulin lispro given by IV CRI appears to be a safe and effective alternative when regular insulin is not an option or is unavailable.
4. All dosages are extra-label.

DOGS:

Adjunctive therapy of DKA using an IV CRI: To prepare an infusion that delivers 0.09 units/kg/hour: 2.2 units/kg insulin lispro is added to 240 mL (**NOTE**: Many clinicians add insulin directly to a 250 mL bag without removing the 10 mL of fluid) of 0.9% sodium chloride. Run ≈50 mL of the insulin-containing fluid through the drip set prior to administration (see ***Adsorption*** in ***Compatibility/Compounding Considerations***). The initial administration rate is 10 mL/hour in a separate line to that used for fluid therapy.[2,12] When starting initial therapy for DKA, potassium levels must be

taken into account and therapy adjusted accordingly to avoid hypokalemia. Adjust infusion rate based on blood glucose determinations taken every 2 hours. An hourly reduction in blood glucose by 50 – 100 mg/dL is recommended.[12] Once blood glucose approaches 250 mg/dL, adjust the fluid type and rate based on the periodic measurement of blood glucose concentration (see table) with a goal of keeping the blood glucose in the 150 – 300 mg/dL range and continuing the insulin IV infusion at a decreased rate until it can be exchanged for a longer-acting product.

Blood glucose concentration (mg/dL [mmol/L])	Maintenance IV fluid	Rate of insulin IV CRI administration (mL/hour)	Dose of insulin administered (units/kg/hour)*
Greater than 250 (13.8)	0.9% sodium chloride	10	0.09
200-250 (11.1-13.8)	0.45% sodium chloride + 2.5% dextrose	7	0.064
150-200 (8.3-11)	0.45% sodium chloride + 2.5% dextrose	5	0.045
100-150 (5.5-8.2)	0.45% sodium chloride + 5% dextrose	5	0.045
Less than 100 (5.5)	0.45% sodium chloride + 5% dextrose	0 (Stop insulin administration)	0 (Stop insulin administration)

Table adapted from Sears KW, Drobatz KJ, Hess RS. Use of lispro insulin for treatment of diabetic ketoacidosis in dogs. *J Vet Emerg Crit Care.* 2012;22(2):211-218.

*CRI prepared by adding insulin lispro 2.2 units/kg to 240 mL 0.9% sodium chloride.

Adjunctive therapy of DKA using an IM protocol:

a) **Glucose greater than 250 mg/dL at the time of diagnosis**: Insulin lispro initial dose of 0.25 units/kg IM with glycemia monitored hourly with a goal of dropping at least 10% in blood glucose between 1 hour and the next.[5] If the goal was *not* achieved, the insulin dose was repeated hourly. If the goal was achieved, the insulin dose was not repeated up to a maximum of 3 hours, after which the insulin dose was repeated anyway. When blood glucose reached 250 mg/dL, the insulin dose was decreased to 0.125 units/kg IM every 3 hours, and the IV fluids were changed to dextrose, starting with a 2.5% solution, and adjusted up to 5% or 7.5% solution as needed in order to keep the blood glucose between 150 and 300 mg/dL until resolution of DKA. If the blood glucose was less than 80 mg/dL or the dog became clinical for hypoglycemia, 0.25 to 0.5 g/kg of 50% dextrose was administered IV, and the insulin therapy was discontinued.

b) **Glucose less than or equal to 250 mg/dL at the time of diagnosis**: Insulin lispro 0.125 units/kg IM every 3 hours, with supplementation of dextrose as described above

Combination with NPH for patients experiencing significant postprandial hyperglycemia on standard insulin protocols: Insulin lispro 0.1 units/kg SC every 12 hours therapy was added to patients ($n = 6$) already receiving NPH treatment but experiencing postprandial hyperglycemia.[1] The median glucose concentrations at 1 hour and 1.5 hours postprandial and serum fructosamine were significantly lower with this combination therapy.[1]

CATS:

Adjunctive therapy of DKA using an IV CRI:

a) Insulin lispro 1.1 units/kg added to 48 mL of 0.9% sodium chloride for CRI. The initial infusion rate of 1 – 2 mL/hour was determined by the cat's blood glucose concentration and adjusted every 1 to 2 hours (see table).[4] When starting initial therapy for DKA, serum potassium levels must be taken into account and therapy adjusted accordingly to avoid hypokalemia. Efficacy and safety were similar to treatment with regular insulin CRI. **NOTE**: Because of the small volume prepared, the insulin solution was allowed to saturate the IV tubing for 30 minutes, then was run through the IV line and discarded. A fresh solution was then prepared and administered.[4]

Blood glucose concentration (mg/dL [mmol/L])	Maintenance IV fluid*	Rate of insulin IV CRI administration (mL/hour)	Dose of insulin administered (units/kg/hour)*
Greater than 250 (13.9)	0.9% sodium chloride	2	0.045
200-250 (11.1-13.9)	0.9% sodium chloride + 2.5% dextrose	1.5	0.032
150-199 (8.4-11)	0.9% sodium chloride + 2.5% dextrose	1.5	0.032
100-149 (5.6-8.3)	0.9% sodium chloride + 5% dextrose	1	0.023
Less than 100 (5.5)	0.9% sodium chloride + 5% dextrose	0 (Stop insulin administration)	0 (Stop insulin administration)

Table adapted from Malerba E, Mazzarino M, Del Baldo F, et al. Use of lispro insulin for treatment of diabetic ketoacidosis in cats. *J Feline Med Surg.* 2019;21(2):115-123.

*CRI prepared by adding insulin lispro 1.1 units/kg to 48 mL 0.9% sodium chloride or lactated Ringer's solution.

b) To prepare a CRI with an initial administration rate of 0.09 units/kg/hour: prepare solution by adding insulin lispro 2.2 units/kg per 240 mL of 0.9% sodium chloride/sterile saline. Run ≈50 mL of the insulin-containing fluid through the drip set prior to administration (see **Adsorption** in ***Compatibility/Compounding Considerations***).[3] Insulin infusions should be run through a fluid line that is separate from that used for fluid therapy.[12] The initial administration rate is 10 mL/hour to deliver insulin at 0.09 units/kg/hour. When starting initial therapy for DKA, serum potassium levels must be taken into account and therapy adjusted accordingly to avoid hypokalemia. Adjust infusion rate based on blood glucose determinations taken every 2 hours. Once blood glucose approaches 300 mg/dL, adjust the fluid type and rate based on periodic measurement of blood glucose concentration (see table) with a goal of keeping the blood glucose in the 150 – 300 mg/dL range and continuing the insulin IV infusion at a decreased rate until it can be exchanged for a longer-acting product.

Blood glucose concentration (mg/dL [mmol/L])	Maintenance IV fluid	Rate of insulin IV CRI administration (mL/hour)	Dose of insulin administered (units/kg/hour)*
Greater than 300 (16.7)	0.9% sodium chloride	10	0.09
200-300 (11.1-16.7)	0.9% sodium chloride + 2.5% dextrose	7	0.064
150-199 (8.3-11)	0.9% sodium chloride + 2.5% dextrose	5	0.045
100-149 (5.5-8.2)	0.9% sodium chloride + 5% dextrose	5	0.045
Less than 100 (5.5)	0.9% sodium chloride + 5% dextrose	0 (Stop insulin administration)	0 (Stop insulin administration)

Table adapted from Anderson JD, Rondeau DA, Hess RS. Lispro insulin and electrolyte supplementation for treatment of diabetic ketoacidosis in cats. *J Vet Intern Med.* 2019;33(4):1593-1601.

*CRI prepared by adding insulin lispro 2.2 units/kg to 240 mL 0.9% sodium chloride.

Monitoring

- Diabetic patients should be closely monitored. Each patient requires an individualized treatment plan, frequent reassessment, and adjustments of the plan based on the response of the patient. It is encouraged to review a veterinary endocrinology reference text or consult with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal for monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia.[13] Interpret all monitoring strategies in light of clinical signs. Results from the below monitoring options may conflict in regards to achieving good glycemic control and good clinical control.
- Patient status and control of clinical signs: body weight, appetite, fluid intake, urine output
- Glucose (blood or interstitial). Because of how often glucose needs to be checked in sick diabetic patients, consider a central line or continuous interstitial glucose monitoring system in dogs and cats. Experience with continuous interstitial glucose monitoring in dogs and cats is that these systems are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[14–17]
  - For patients that have experienced or are suspected to have experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for treatment of hypoglycemia.
- Additional monitoring for patients with diabetic ketoacidosis (DKA)[18]:
  - Glucose measurement every 1 to 2 hours initially; adjust insulin therapy and begin dextrose infusion when glucose decreases below 250 mg/dL (14 mmol/L). See ***Dosages***.
  - Hydration status, respiration, pulse every 2 to 4 hours
  - Serum electrolyte (eg, magnesium, phosphorous, potassium), plasma ketones, and total venous CO_2 concentrations every 4 to 8 hours
  - Urine output, glycosuria, and urine ketones every 4 to 8 hours
  - Body weight, packed cell volume, temperature, and blood pressure every 6 to 8 hours
  - Additional monitoring as applicable to address concurrent disease

Client Information

NOTES for veterinarian:

1. Correct injection techniques should be taught and practiced with the client before the animal's discharge.
2. Emphasis should be placed on matching the appropriate syringe and insulin concentration (eg, do not interchange U40 insulin and syringes with U100 insulin and syringes) and correct needles with pens/devices.
3. Both veterinary-approved insulins have owner information sheets, client-friendly handouts, and websites to provide client support on administration and use of insulin.

- For this medication to work safely, give the insulin ***exactly*** as your veterinarian has prescribed. Do not give this medicine and consult your veterinarian for guidance if your animal is not eating.
- Your veterinarian will teach you proper injection technique. ***Only*** use U100 syringes with insulin lispro.
- Always double-check the dose in the syringe before you inject your animal. Overdoses may be fatal.
- Prior to using, visually inspect the insulin bottle. Insulin lispro should appear as a clear, colorless solution. Do not use insulin solutions if you see crystals on the inside of the vial. There should never be clumps or unexpected particles in the vial.
- After measuring the dose into a syringe, allow the contents to come to room temperature (if the vial is stored in the refrigerator) before injection.
- The injection site should be frequently changed, with the main sites being the back of the neck or shoulder area.
- Place the used needles and syringes in a sharps disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist will help you obtain these containers.
- Do not re-use needles or syringes.
- Keep insulin products out of temperature extremes. Follow the label instructions for storage of the insulin vial and pens/devices.
- Signs of low blood sugar include weakness, depression, lack of energy, sluggishness, staggering gait (ie, stumbling) when walking, behavior changes, muscle twitching, seizures (convulsions), or coma. **If your animal is unconscious or having a seizure, this is a medical emergency.** Take your animal to your veterinarian immediately. **If your animal is conscious and able to swallow**, rub ≈1 tablespoon of corn syrup (*Karo®*) or honey on your animal's gums until it is alert enough to eat. Feed the usual meal and contact your veterinarian for recommendations. Some animals may not show any obvious physical signs of low blood sugar. If your animal is not acting normally, contact your veterinarian to make sure your animal's blood sugar levels are in a safe range.
- Contact your veterinarian at your earliest convenience if you notice excessive thirst, increased frequency of urination, or increased appetite in your animal, as these signs may indicate the insulin dose needs to be adjusted.
- When traveling, do not leave insulin in carry-on luggage that will pass through airport surveillance equipment. Generally, insulin stability is not affected by a single pass through surveillance equipment; however, longer than normal exposure or repeated passes through surveillance equipment may alter insulin potency.

- Do not stop giving this medication to your animal unless instructed to do so by your veterinarian.
- Your veterinarian will need to closely monitor your animal during treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

All commercial preparations of human-labeled insulin currently manufactured in the United States are supplied in solution or suspension at a concentration of 100 units/mL or greater. U100 insulins contain ≈3.5 mg of insulin/mL. Likewise, 1 unit of insulin is ≈35 µg of insulin, and 1 mg of insulin is ≈28.8 units.

Insulin lispro injection, USP (rDNA origin) is a rapid-acting human insulin analogue that is synthesized in a special nonpathogenic laboratory strain of *Escherichia coli*. It is created by the reversal of the lysine and proline amino acids at positions 28 and 29 on the B chain. The sterile solution consists of zinc-insulin lispro crystals dissolved in buffered water for injection.

Insulin lispro may also be known as LY-275585, insulin lispro protamine, insulin lispro-aabc, *Admelog®*, *HumaLOG®*, and *Lyumjev®*. See ***Contraindications/Precautions/Warnings*** as these products are not all considered equivalent.

Storage/Stability

Unopened insulin lispro vials and pens/devices should be stored in the refrigerator at 2°C to 8°C (36°F-46°F) and protected from temperature extremes and direct sunlight. Do not freeze. Discard after 28 days if unopened containers are stored at room temperature below 30°C (86°F).

In-use *vials* may be used for 28 days after first use and should be stored at room temperature or in the refrigerator. Store ***in-use*** *pens/devices* at room temperature (do not refrigerate) and discard 28 days after first use.

Freezing (less than 2°C [36°F]) insulin lispro products may alter the protein structure and decrease potency. Particle aggregation and crystal damage may be visible to the naked eye. Higher temperature (greater than 30°C [86°F]) extremes and direct exposure to sunlight (as might occur when insulin is stored in a car or on a windowsill) may produce insulin transformation products and fibril formation.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies support that insulin potency and stability is maintained for longer durations.[19,20] Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace it with new insulin prior to adjusting insulin therapy.[13]

Compatibility/Compounding Considerations

Diluting insulin: Other than for immediate use, insulin lispro should only be diluted using a product-specific sterile diluent, which is supplied by the manufacturer upon request. Diluted insulin (10 units/mL) prepared in this manner is stable for 4 weeks and should be stored in the refrigerator, although refrigeration is not required.

Adsorption: The adsorption of insulin lispro to the surfaces of IV syringes and infusion sets has been demonstrated and appears similar to that of regular insulin.[21] Less than 10% adsorption occurs in syringes, and adsorption occurs within 5 to 10 minutes. Up to 50% loss occurred in IV bags. The percent adsorbed is inversely proportional to the concentration of the insulin. To saturate binding sites and deliver a more predictable dose to the patient through an IV infusion, it is recommended that the first 20 mL be run through the IV tubing over 1 minute and discarded, although allowing the solution to sit in the tubing for 15 minutes resulted in reaching steady-state more quickly than the 1-minute flush.[21]

Insulin syringes: Syringes are designed for use with a specific strength of insulin, with the needle covers color-coded according to strength. U100 syringes are available in 0.3 mL, 0.5 mL, and 1 mL size. Measuring U100 insulin to the 1 unit mark in a U100 syringe will contain 1 unit of insulin. Some brands of 0.3 mL syringes include ½ unit markings. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Insulin Lispro Injection Human (rDNA): 100 units/mL in 3 mL prefilled pen system and 10 mL vials, and 200 units/mL in 3 mL prefilled pen system. *HumaLOG®*, *Admelog®*, generic; (Rx)

Insulin, Intermediate-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Modified intermediate-acting insulin used for treatment in patients newly diagnosed with diabetes mellitus and for long-term maintenance therapy
- ► Not recommended for use in cats because of its short duration of action in that species
- ► Animals presented with ketoacidosis, anorexia, lethargy, and/or vomiting should first be stabilized with appropriate therapy, including short-acting insulin.
- ► There are no absolute contraindications except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to "foreign" proteins.
- ► Do not confuse insulin types, strengths, and/or syringes: NPH insulin is a U100 human product; use only U100 syringes to measure a dose.
- ► Insulin vials and pens need to be gently rolled prior to administration.
- ► Many potential drug interactions

Uses/Indications

Neutral protamine Hagedorn (NPH) insulin is an intermediate-acting insulin preparation that can be used for initial treatment and long-term management of diabetes mellitus, especially in dogs. In a study comparing lente and NPH insulins, glycemic control in newly diagnosed, uncomplicated diabetic dogs was similar[1]; lente and NPH insulins are the first-choice recommended insulins in dogs with uncomplicated diabetes mellitus.[2] NPH insulin can also be considered

for the treatment of diabetes mellitus in horses, camelids, ferrets, and guinea pigs; it is not recommended for use in cats because of its short duration of action.[2]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially by skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information.***

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules). Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers.

Neutral protamine Hagedorn (NPH) insulin is only administered by the SC route. Following SC administration of NPH (porcine source) in normal dogs, the onset of hypoglycemic effect is 0.5 hours, peak effect occurs after 1 to 2 hours, and duration is 6 to 10 hours.[3] Following SC administration of NPH to 10 diabetic dogs, the median onset of effect was 1.5 hours, median peak effect was 4 hours, and median duration was 8.5 hours.[4] In normal cats given NPH insulin (bovine/porcine source), peak insulin concentration is reached ≈1.5 hours after SC injection, and insulin concentration returned to baseline ≈6 to 8 hours postinjection.[5]

Contraindications/Precautions/Warnings

Neutral protamine Hagedorn (NPH) should not be used during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease, or medication interference) have been ruled out. See ***Insulin, General Information***.

NPH insulin is not an appropriate insulin choice for patients presenting with severe ketoacidosis, anorexia, lethargy, and/or vomiting or other conditions when treatment with short-acting insulin (eg, regular insulin) is indicated.

For obese patients, dose calculations should be based on the individual patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[6]; however, there have been no specific reports of this reaction occurring in dogs or cats.

NPH insulin is U100 strength. It is crucial for patient safety to only use U100 syringes when measuring and administering U100 insulin. Calculations can be done to convert to U40 syringes or TB syringes, but these conversions are not recommended because of the potential for introducing dosing errors. See ***Insulin, General Information***.

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Do not confuse trade names that use letters to identify insulin types (eg, do not confuse *Humulin® N* with *Humulin® R*). Anecdotally, loss of glycemic control has been attributed to changing the NPH insulin product used (eg, switching from *Novolin® N* to *Humulin® N*), although published evidence of this is lacking.

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, insulin-induced rebound hyperglycemia (ie, Somogyi effect), weight gain, and local reactions to the "foreign" proteins.

Reproductive/Nursing Safety

A case series reports that neutral protamine Hagedorn (NPH) insulin has been used to manage gestational diabetes in dogs.[7] NPH is considered safe for use during human pregnancy and while nursing[8]; this is also assumed to be true for veterinary patients.

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilting, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo®* syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 to 15 mL [0.5 to 1 mL/kg], diluted, and slowly administered[9]; see ***Dextrose 50% injection***). For inhospital management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), the animal should be closely monitored (both by physical observation and serial blood glucose levels) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding regimens should be evaluated and adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Blockers** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium levels, patients receiving concomitant digoxin therapy—especially those receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also *decrease* the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- Anabolic Steroids (eg, **boldenone, stanozolol, testosterone**)
- Angiotensin II Receptor Blockers (**ARBs**; eg, **telmisartan**)
- Angiotensin-Converting Enzyme Inhibitors (**ACEIs**; eg, **benazepril, enalapril**)
- Disopyramide
- Ethanol
- Fenofibrate
- Fluoroquinolones (eg, **ciprofloxacin, enrofloxacin**)
- Fluoxetine
- Hypoglycemics, Oral (eg, **acarbose, glipizide, metformin**)
- Monoamine Oxidase Inhibitors (**MAOIs**; eg, **amitraz, linezolid, selegiline**)
- Pentoxifylline
- Salicylates (eg, **aspirin, bismuth subsalicylate**)
- Somatostatin Derivatives (eg, **octreotide**)
- Sulfonamides (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- Alpha-2-Adrenergic Agonists (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- Beta-Adrenergic Agonists (eg, **albuterol, terbutaline**)
- Corticosteroids (eg, **dexamethasone, prednis(ol)one**)
- Danazol
- Diazoxide
- Estrogens (eg, **diethylstilbestrol [DES], estriol**)
- Isoniazid
- Niacin
- Phenothiazines (eg, **acepromazine, chlorpromazine**)
- Progestins (eg, **megestrol**)
- Thyroid Hormones: Can elevate glucose levels in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus is complex. Insulin is only one component of therapy; treatment may require fluid electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references for additional information.
2. For obese patients, dose calculations should be based on the individual patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Key goals of therapy are control of clinical signs associated with diabetes mellitus and avoidance of hypoglycemia.[2,10]
4. All dosages are extra-label.

DOGS:

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label): 0.25 – 0.5 units/kg SC every 12 hours.[2] Consider starting with the lower end of the dosing range for larger dogs and the higher end for smaller dogs.

Combination with insulin lispro for patients experiencing significant postprandial hyperglycemia on standard insulin protocols: Lispro 0.1 units/kg SC every 12 hours was administered to patients ($n = 6$) already receiving neutral protamine Hagedorn (NPH) treatment (median dosage, 0.5 – ≈1 unit/kg SC every 12 hours) but experiencing postprandial hyperglycemia.[11] Fructosamine and the median glucose concentrations at 1 hour and 1.5 hours postprandial were significantly lower with this combination therapy.[11]

HORSES:

Diabetes mellitus: 0.2 – 0.4 units/kg SC every 24 hours[12]

NEW WORLD CAMELIDS:

Severe hyperlipemia: Based on a single-dose study, 0.4 units/kg SC produced a peak effect 4.7 hours after administration; the mean duration of effect was 15.4 hours.[13]

BIRDS:

Diabetes mellitus: 0.067 – 3.3 units/kg IM every 12 to 24 hours. In most cases, twice-daily injections are necessary.[14]

FERRETS:

Diabetes mellitus:

a) 0.5 – 1 units/ferret (NOT unit/kg) SC twice daily[15]
b) 0.1 – 0.5 units/kg IM or SC twice daily to start; adjust to optimal dose. May require insulin to be diluted[16]

SMALL MAMMALS:

Diabetes mellitus in Guinea pigs: 1 unit/Guinea pig (NOT unit/kg) SC every 12 hours. Monitor urine for glucose and ketones, and adjust the dose if needed.[17]

Monitoring

Each patient requires an individualized treatment plan, frequent reassessment, and adjustments to the plan based on the response of the patient. It is encouraged to consult a veterinary endocrinology reference text or with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal when monitoring diabetic patients is the control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia.[2] Interpret all monitoring strategies based on clinical signs. Results from the monitoring options below may conflict in regards to achieving good glycemic and clinical control.

- Patient status and control of clinical signs: body weight, appetite, fluid intake, urine output
- Glucose (blood or interstitial) curve. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[18–21] A glucose curve can be considered at the following times[2]:
  - After the first dose of a new insulin type, glucose can be checked every 2 hours after administration. The goal for monitoring following the first dose of insulin would be solely to identify hypoglycemia. The insulin dose should NOT be increased from the first-day glucose evaluation. If glucose falls below 150 mg/dL during the glucose curve, the frequency of monitoring should increase to hourly until glucose is greater than 150 mg/dL. Although the neutral protamine Hagedorn (NPH) insulin dose should never be increased on the first day of therapy, the dose should be decreased by 10% to 50% in dogs if the glucose is less than 150 mg/dL at any time during the day. Repeat glucose curves on subsequent days (and decrease insulin dose if necessary) until nadir is greater than 150 mg/dL.
  - 7 to 14 days after starting insulin or an insulin dose change
  - At least every 3 months, even in animals with well-controlled diabetes
  - Any time clinical signs recur in an animal with previously well-controlled diabetes
  - When hypoglycemia is suspected. For patients that have ex-

perienced or are suspected of having experienced repeated or unexplained hypoglycemia, it is strongly encouraged that pet owners consult with a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for the treatment of hypoglycemia.

- Urine glucose monitoring is typically only helpful for documenting prolonged hypoglycemia (eg, persistently negative urine glucose testing when monitoring for diabetic remission in cats). As most diabetic patients spend time above the renal threshold for urinary glucose spillage, even patients with well-controlled diabetes may be intermittently glucosuric throughout the day.
- Fructosamine or glycosylated hemoglobin can be monitored if available and warranted.

Client Information

NOTES for veterinarian:

1. Correct injection techniques should be taught and practiced with the client before the animal's discharge.
2. Emphasis should be placed on matching the appropriate syringe and insulin concentration (eg, do not interchange U40 insulin and syringes with U100 insulin and syringes) and correct needles with pens/devices.
3. Both veterinary-approved insulins have owner information sheets, client-friendly handouts, and websites to provide client support on administration and use of insulin.

- For this medication to work safely, give the insulin ***exactly*** as your veterinarian has prescribed. Do not give this medicine and contact your veterinarian for guidance if your animal is not eating.
- Your veterinarian will teach you proper injection technique. ***Only*** use U100 syringes with neutral protamine Hagedorn (NPH) insulin.
- Always double-check the dose in the syringe before you inject your animal. Overdoses may be fatal.
- To avoid bubbles and the potential for inaccurate dosing, NPH suspensions should be rolled gently until thoroughly mixed, not shaken. Prior to using, visually inspect the insulin bottle prior to use. NPH solutions should appear as uniform milky suspensions. Do not use insulin suspensions if clumps or white particles persist after mixing.
- After measuring the dose into a syringe, allow the contents to come to room temperature (if the vial is stored in the refrigerator) before giving the injection.
- The injection site should be frequently changed, with the main sites being the back of the neck, side of the animal, or shoulder area.
- Place the used needles and syringes in a sharps disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist will help you obtain these containers.
- Do not reuse needles or syringes.
- Keep insulin products out of temperature extremes. Follow the label instructions for storage of the insulin vial and pens/devices.
- Signs of low blood sugar include weakness, depression, lack of energy, sluggishness, staggering gait (ie, stumbling) when walking, behavior changes, muscle twitching, seizures (convulsions), or coma. **If your animal is unconscious or having a seizure, this is a medical emergency.** Take your animal to your veterinarian immediately. **If your animal is conscious and able to swallow**, rub ≈1 tablespoon of corn syrup (*Karo®*) or honey on your animal's gums until it is alert enough to eat. Feed the usual meal and contact your veterinarian for recommendations. Some animals may not show any obvious physical signs of low blood sugar. If your animal is not acting normally, contact your veterinarian to make sure your animal's blood sugar level is in a safe range.
- Contact your veterinarian at your earliest convenience if you notice excessive thirst, increased frequency of urination, or increased appetite in your animal, as these signs may indicate the insulin dose needs to be adjusted.
- When traveling, do not leave insulin in carry-on luggage that will pass through airport surveillance equipment. Generally, insulin stability is not affected by a single pass through surveillance equipment; however, longer than normal exposure or repeated passes through surveillance equipment may alter insulin potency.
- Do not stop giving insulin to your animal unless instructed to do so by your veterinarian.
- Your veterinarian will need to closely monitor your animal during treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

Neutral protamine Hagedorn (NPH) insulin is an intermediate-acting, sterile suspension of human insulin, zinc, and protamine sulfate in buffered water for injection. NPH insulin is produced using recombinant DNA technology via a nonpathogenic *Escherichia coli* strain (*Humulin® N*) or using *Saccharomyces cerevisiae* (*Novolin® N*) and is available only as a U100 insulin concentration containing ≈3.6 mg of insulin/mL.

NPH insulin may also be known as isophane, neutral protamine Hagedorn, *Humulin® N*, or *Novolin® N*.

Storage/Stability

Store ***unopened*** neutral protamine Hagedorn (NPH) *vials* and *pens/devices* in the manufacturer's carton in the refrigerator at 2°C to 8°C (36°F-46°F). Do not freeze; discard if product has been frozen.[6] Freezing (less than 2°C [36°F]) may alter the protein structure and decrease potency. Particle aggregation and crystal damage may be visible to the naked eye or may require microscopic examination.

Unopened NPH *vials* may be stored unrefrigerated if kept below 25°C to 30°C (77°F-86°F) and out of direct heat and sunlight but must be discarded after 31 days (*Humulin® N*) or 42 days (*Novolin® N*). Higher temperature extremes (more than 30°C [86°F]) and direct exposure to sunlight (eg, stored in a car or on a windowsill) may produce insulin transformation products and fibril formation, thereby further shortening the insulin shelf-life.

Unopened NPH *pens/devices* may be stored unrefrigerated if kept below 25°C to 30°C (77°F-86°F) and out of direct heat and sunlight but must be discarded after 14 days (*Humulin® N*) or 28 days (*Novolin® N*).

In-use storage requirements vary by manufacturer:

- *Humulin® N vials* can be kept for 31 days refrigerated (2°C to 8°C [36°F-46°F]) or at room temperature (below 30°C [86°F]); *pens/devices* can be kept 14 days at room temperature (below 30°C [86°F]).
- *Novolin® N vials* can be kept 42 days at room temperature (below 25°C [77°F]); *pens/devices* can be kept 28 days at room temperature (below 30°C [86°F]). Do not refrigerate in-use *Novolin® N* products.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies support that insulin potency and stability is maintained for longer durations.[22,23] Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the listed expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may

be prudent to replace it with new insulin prior to adjusting insulin therapy.[2]

Compatibility/Compounding Considerations

Insulin syringes: Syringes are designed for use with a specific strength of insulin, with the needle covers color-coded according to strength. U100 syringes are available in 0.3 mL, 0.5 mL, and 1 mL size. Measuring U100 insulin to the 1 unit mark in a U100 syringe will contain 1 unit of insulin. Some brands of 0.3 mL syringes include ½ unit markings. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

NPH Insulin (Isophane or Neutral Protamine Hagedorn) Human (rDNA): 100 units/mL in 3 mL vials and prefilled pen system and in 10 mL vials; *Humulin® N*, *Novolin® N* (OTC in humans; requires prescription under extra-label provisions of AMDUCA when used in animals). *Humulin®*- or *Novolin®*-brand insulins may be rebranded and sold by large retailers under different trade names.

Mixtures of short-acting insulins combined with intermediate-acting insulins are available.

Insulin, Protamine Zinc

Protamine Zinc Recombinant Human Insulin (rPZI)

(***inn***-suh-lin, ***pro***-ta-meen zeenk) *ProZinc®*

Insulin, Long-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Long-acting insulin for treatment in dogs and cats newly diagnosed with diabetes mellitus and for long-term maintenance therapy
- ► Animals that are presented with ketoacidosis, anorexia, lethargy, and/or vomiting should first be stabilized with appropriate therapy, including short-acting insulin.
- ► There are no absolute contraindications, except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to the "foreign" proteins.
- ► Do not confuse insulin types, strengths, and syringes: protamine zinc insulin is a U40 approved veterinary product; only use U40 insulin syringes to measure dose.
- ► Many potential drug interactions

Uses/Indications

Protamine zinc recombinant human insulin (rPZI) is a long-acting insulin preparation FDA-approved for use in dogs and cats for initial treatment and long-term management of diabetes mellitus. rPZI is a first-choice recommended insulin in newly diagnosed diabetic cats.[1] rPZI and intermediate-acting insulins (eg, porcine insulin zinc [ie, lente]) are considered first-choice insulin therapies in newly diagnosed diabetic dogs.[1,2]

rPZI can also be considered for treatment of hyperlipemia in camelids and ponies, as well as for treatment of ketosis in cattle.[3]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information***.

Pharmacokinetics

Insulin formulations contain insulin polymers (aggregates of multiple insulin molecules); protamine zinc recombinant human insulin (rPZI) is composed of hexamers. Insulin is absorbed from the administration site only after insulin polymers break down into insulin monomers or dimers.

After SC administration of rPZI 0.8 units/kg to healthy (ie, nondiabetic) dogs, median onset of action was 3.5 hours (0.5 to 10 hours), time to glucose nadir was 14 hours (5 to 24 hours), and duration was less than 24 hours (16 to 24 hours).[4] After SC administration to cats (nondiabetic and diabetic), onset of activity was 0.5 to 1.5 hours; peak effect was 4 to 9 hours, and duration of effect was 7 to 18 hours.[5,6]

Contraindications/Precautions/Warnings

Protamine zinc recombinant human insulin (rPZI) is contraindicated in animals that are hypersensitive to human insulin and during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control have been ruled out (eg, expired insulin, concurrent disease, or medication interference). See ***Insulin, General Information***.

PZI insulin is not an appropriate insulin choice for patients presenting with severe ketoacidosis, anorexia, lethargy, and/or vomiting or other conditions when treatment with short-acting insulin (eg, regular insulin) is indicated.

For obese patients, dose calculations should be based on the patient's ideal body weight to avoid inadvertent insulin overdose.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[7,8]; however, there have been no specific reports of this reaction occurring in dogs or cats.

rPZI is a U40-strength insulin. It is crucial for patient safety to only use U40 syringes when measuring and administering U40 insulin. Calculations can be done to convert to U100 syringes or TB syringes, but these conversions are not recommended due to the potential for introducing dosing errors. See ***Insulin, General Information***.

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage, volume checking, and special alert labels.

Do not confuse PROTAMINE zinc insulin (PZI) with PORCINE zinc insulin (ie, lente insulin).

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, insulin-induced rebound

hyperglycemia (ie, Somogyi effect), insulin antagonism and resistance, rapid insulin metabolism, and local or allergic reactions to the "foreign" proteins.

Lethargy, anorexia, hypoglycemia, vomiting, seizures, shaking, diarrhea, and ataxia were reported in an FDA field study in dogs treated with PZI.[9] Half of the hypoglycemic episodes did not have clinical signs. Injection site reactions occurred in 2.5% of dogs and 1.7% of cats.[10]

Reproductive/Nursing Safety

The safe use of PZI in breeding, pregnant, or lactating animals has not been studied[10]; however, in humans, insulin is considered a treatment of choice for gestational diabetes,[11] and insulin is known to be compatible with nursing.[12]

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilt, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo*® syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 – 15 mL [0.5 – 1 mL/kg], diluted, and slowly administered)[13]; see ***Dextrose 50% injection***. For inhospital management, glucagon may also be considered on an as-needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), the animal should be closely monitored (both by physical observation and serial blood glucose concentrations) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting insulin products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding regimens should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Antagonists** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium concentrations, patients receiving concomitant digoxin therapy—especially those receiving concurrent diuretic therapy—should be closely monitored.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may also *decrease* the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Ethanol**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**)
- **Fluoxetine**
- **Hypoglycemics, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-Adrenergic Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**)
- **Danazol**
- **Diazoxide**
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**)
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Thyroid Hormones**: Can elevate glucose concentrations in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus is complex; treatment may require fluid electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references for additional information.
2. For obese patients, dose calculations should be based on the individual's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Key goals of therapy are control of clinical signs associated with diabetes mellitus and avoidance of hypoglycemia or other complications (diabetic ketoacidosis).[1,14]

DOGS:

Reduction of hyperglycemia and hyperglycemia-associated clinical signs (label dosage; FDA-approved): 0.5 – 1 unit/kg SC once daily, concurrent with or right after a meal.[10] The recommended starting dose for insulin-naive dogs is at the lower end of the dosage range, but poorly controlled diabetic dogs or those

transitioning from another insulin product could begin at the mid to higher end of the range. When transitioning from another insulin, protamine zinc recombinant human insulin (rPZI) should be started once daily regardless of the frequency of the previous insulin. Twice-daily administration should be considered if the duration of insulin action is determined to be inadequate with once-daily administration. If twice-daily administration is initiated, the 2 doses should each be ≈25% less than the once-daily dose required to attain an acceptable glucose nadir (eg, 10 units SC once daily becomes 7 units SC twice daily). In field efficacy studies, the mean successful insulin dose was 1.4 units/kg/day.[2]

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label): 0.25 – 0.5 units/kg SC every 12 hours.[1] A starting dose of 0.25 units/kg SC every 12 hours is often used; more potentially challenging cases may require the higher starting dose. Some clinicians have found 0.5 units/kg to be a more effective starting dose. Once-daily administration may be possible in some dogs.[1,15]

CATS:

Reduction of hyperglycemia and hyperglycemia-associated clinical signs (label dosage; FDA-approved): 0.2 – 0.7 units/kg SC every 12 hours, given concurrently with or right after a meal

Initial insulin treatment of uncomplicated diabetes mellitus (extra-label): 1 – 2 units/cat (NOT units/kg) SC every 12 hours.[1] The initial starting dose in cats should not exceed 2 units/cat (NOT units/kg) SC every 12 hours regardless of the size of the cat.

HORSES:

Hyperlipemia in ponies (extra-label):

a) 200 kg (440 lb) pony: 30 units/animal (NOT units/kg) IM every 12 hours on odd days (given with 100 g glucose PO once daily); 15 units/animal (NOT units/kg) IM every 12 hours on even days (given with 100 g glucose PO once daily) until hyperlipemia resolves[16]
b) 0.4 units/kg SC or IM every 24 hours[17]
c) 0.1 – 0.3 units/kg SC or IM every 12 to 24 hours[3,18]

CATTLE:

Adjunctive treatment of ketosis (extra-label): 200 – 300 units per animal (NOT units/kg) SC every 24 to 48 hours[3]

NEW WORLD CAMELIDS:

Severe hyperlipemia (extra-label): 0.2 – 0.4 units/kg SC with glucose every 12 to 24 hours. Duration of effect is generally 8 to 16 hours.[19]

Monitoring

Each patient requires an individualized treatment plan, frequent reassessment, and adjustments of the plan based on the response of the patient. It is encouraged to consult a veterinary endocrinology reference text or with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal when monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia. A so-called "loose-control" (ie, managing clinical signs while avoiding hypoglycemia and reducing frequency of hospitalizations for glucose curves) approach to diabetes management in cats using PZI has also been described.[20] Interpret all monitoring strategies based on clinical signs. Results from the monitoring options below may conflict in regard to achieving good glycemic control and good clinical control.

- Patient status and control of clinical signs: body weight, appetite, fluid intake, and urine output
- Glucose (blood or interstitial) curve. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[21–24] A glucose curve can be considered at the following times[1]:
  - After the first dose of a new insulin type. If performing a glucose curve, glucose can be checked every 2 to 4 hours for 10 to 12 hours after administration. The goal for monitoring following the first dose of insulin would be solely to identify hypoglycemia. The insulin dose should NOT be increased based on first-day glucose evaluation. If glucose falls below 150 mg/dL during the glucose curve, frequency of monitoring should increase to hourly until glucose is greater than 150 mg/dL.[1] Although the PZI dose should never be increased on the first day of therapy, the dose should be decreased by 10% to 50% in dogs and 0.5 units (total) in cats if glucose is less than 150 mg/dL at any time during the day.[1] Repeat glucose curves on subsequent days (and decrease insulin dose if necessary) until nadir is greater than 150 mg/dL.
  - 7 to 14 days after starting insulin or after an insulin dose change
  - At least every 3 months, even in well-controlled diabetics. In well-controlled patients, it may be possible to use clinical signs, body weight, +/- serum fructosamine measurements to determine frequency of glucose curve evaluations.[20]
  - Any time clinical signs recur in an animal with previously well-controlled diabetes
  - When hypoglycemia is suspected. For patients that have experienced or are suspected to have experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult with a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for treatment of hypoglycemia.
- Urine glucose monitoring is typically only helpful for documenting prolonged hypoglycemia (eg, persistently negative urine glucose testing when monitoring for diabetic remission in cats). As most diabetic patients spend time above the renal threshold for urinary glucose spillage, even patients with well-controlled diabetes may be intermittently glucosuric throughout the day.
- Fructosamine or glycosylated hemoglobin if available and warranted

Client Information

NOTES for veterinarian:

1. Correct injection techniques should be taught and practiced with the client before the animal's discharge.
2. Emphasis should be placed on matching the appropriate syringe and insulin concentration (eg, do not interchange U40 insulin and syringes with U100 insulin and syringes) and correct needles with pens/devices.
3. Both veterinary-approved insulins have owner information sheets, client-friendly handouts, and websites to provide client support on administration and use of insulin.

- For this medication to work safely, give the insulin ***exactly*** as your veterinarian has prescribed. Do not give this medicine and contact your veterinarian for guidance if your animal is not eating.
- Your veterinarian will teach you the correct injection technique. ***Only*** use U40 insulin syringes with PZI insulin.
- Always double-check the dose in the syringe before you inject your animal. Overdoses may be fatal.
- Gently roll the vial to mix the contents; do not shake. Once mixed, the suspension has a white, cloudy appearance. Do not use this product if clumps or visible white particles persist after gently rolling the vial.
- After measuring the dose into a syringe, allow the contents to

come to room temperature before giving the injection.
- The injection site should be frequently changed, with the main sites being the back of the neck, side of the animal, or shoulder area.
- Place the used needles and syringes in a sharps disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist will help you obtain these containers.
- Do not reuse needles or syringes.
- Keep insulin products out of temperature extremes. Unused and opened vials of PZI insulin should be stored in the refrigerator.
- Signs of low blood sugar include weakness, depression, lack of energy, sluggishness, staggering gait (ie, stumbling) when walking, behavior changes, muscle twitching, seizures (convulsions), or coma. **If your animal is unconscious or having a seizure, this is a medical emergency.** Take your animal to the veterinarian immediately. **If your animal is conscious and able to swallow**, rub ≈1 tablespoon of corn syrup (*Karo*®) or honey on your animal's gums until it is alert enough to eat. Feed the usual meal and contact your veterinarian for recommendations. Some animals may not show any obvious physical signs of low blood sugar. If your animal is not acting normally, contact your veterinarian to make sure your animal's blood sugar concentrations are in a safe range.
- Contact your veterinarian at your earliest convenience if you notice excessive thirst, increased frequency of urination, or increased appetite in your animal, as these signs may indicate the insulin dose needs to be adjusted.
- When traveling, do not leave insulin in carry-on luggage that will pass through airport surveillance equipment. Generally, insulin stability is not affected by a single pass through surveillance equipment; however, longer than normal exposure or repeated passes through surveillance equipment may alter insulin potency.
- Do not stop giving insulin to your animal unless instructed to do so by your veterinarian.
- Your veterinarian will need to closely monitor your animal during treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

Protamine zinc recombinant human insulin (rPZI) is a sterile aqueous protamine zinc suspension of recombinant human insulin produced with recombinant DNA technology in the yeast *Pichia pastoris*. PZI is available only as a U40 insulin concentration and is a cloudy or milky suspension.

Protamine zinc insulin may also be known as PZI, rhPZI, protamine zinc recombinant human insulin, PZIR, or *ProZinc*®.

Storage/Stability

Unopened and ***in-use*** protamine zinc recombinant human insulin (rPZI) vials should be refrigerated at 2°C to 8°C (36°F-46°F). Do not freeze; discard if product has been frozen. Vials should be stored upright and protected from light. Discard within 60 days (10 mL vial) or 80 days (20 mL vial) of first use.

Although the manufacturer recommends discarding opened bottles of rPZI after 60 days (10 mL vial) or 80 days (20 mL vial), studies support that insulin potency and stability are maintained for longer durations.[25,26] Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the listed expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace with new insulin prior to adjusting insulin therapy.[1]

Compatibility/Compounding Considerations

Insulin syringes: Syringes are designed for use with a specific strength of insulin, and needle covers are color-coded for each insulin strength. Use only U40 syringes with protamine zinc recombinant human insulin (rPZI). U40 syringes are available in 0.3 mL, 0.5 mL, 1 mL, and 2 mL sizes. Drawing U40 insulin to the 1 unit mark in a U40 syringe will result in 1 unit of insulin. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:
Protamine Zinc (rDNA) Insulin (PZI) Aqueous Suspension 40 units/mL in 10 mL and 20 mL vials; *ProZinc*®; (Rx). FDA-approved for use in dogs and cats. NADA# 141-297

HUMAN-LABELED PRODUCTS: NONE

Insulin, Regular (Crystalline Zinc)

(***inn***-suh-lin, ***reh***-gyoo-ler) *Humulin® R, Novolin® R*
Insulin, Rapid/Short-Acting

NOTE: Insulin preparations available to clinicians are in a constant state of change. To maximize the efficacy of therapy and reduce the chance for errors, it is highly recommended to review current references or sources of information pertaining to insulin therapy for dogs and cats.

For additional information, see ***Insulin, General Information.***

Prescriber Highlights

- ► Rapid/short-acting insulin used to treat diabetic ketoacidosis (DKA) and as adjunctive therapy to treat hyperkalemia
- ► There are no absolute contraindications, except during episodes of hypoglycemia.
- ► Adverse effects include hypoglycemia, hypokalemia, hypophosphatemia (DKA only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local reactions to the "foreign" proteins.
- ► Do not confuse insulin types, strengths, and syringes. Regular insulin is a U100 human product; use only U100 insulin syringes to measure a dose.
- ► Many potential drug interactions

Uses/Indications

Regular insulin is a rapid, or short-acting, insulin that is commonly used for diabetic emergencies (eg, diabetic ketoacidosis [DKA]). It is administered by IM or SC injection or IV infusion. IV insulin administration is recommended in patients with poor tissue perfusion, with shock, with cardiovascular collapse, or in those that require adjunct therapy for hyperkalemia.

Regular insulin is the rapid/short-acting insulin most often used in diabetic emergencies (ie, DKA). When regular insulin is not an option, safe and effective alternatives for cats include insulin glargine (SC or IM),[1–3] and for dogs include insulin lispro[4,5] or insulin aspart[6] administered as an IV CRI. Once the patient is stabilized, longer-acting insulin products can be given SC for maintenance insulin therapy.

In patients with DKA, initial aggressive fluid replacement therapy is of paramount importance to restore tissue perfusion and begin correcting electrolyte or acid-base derangements. In one study, early administration (ie, within 6 hours of presentation) of insulin to patients with DKA leads to earlier resolution of hyperglycemia, acidemia, and ketonemia while being safe and well tolerated.[7] It is strongly encouraged to consult a veterinary emergency and critical

care and/or endocrinology specialist or reference when treating this condition.

Regular insulin may also be given IV concomitantly with dextrose IV to treat hyperkalemia.[8] In dogs and cats, ECG changes seen in critical patients with hyperkalemia may be affected by concurrent metabolic derangements (eg, metabolic acidosis, hypermagnesemia, hypocalcemia) and thus may not typify the expected ECG changes (eg, bradyarrhythmias, loss of P wave, wide QRS complexes, peaked T waves) previously described for hyperkalemia.[9] In humans, treatment for hyperkalemia is recommended when serum potassium is greater than 5.5 mEq/L if there are ECG changes or when serum potassium is greater than 6 mEq/L, regardless of ECG findings.[10]

Pharmacology/Actions

The primary action of insulin is to regulate glucose metabolism. Insulin and its analogues lower blood glucose by increasing glucose uptake in peripheral tissues, especially by skeletal muscle and fat. In the liver, insulin increases glucose storage (ie, glycogen) while also inhibiting gluconeogenesis. Insulin's anabolic actions also enhance fatty acid and protein synthesis while inhibiting lipolysis and proteolysis.

For additional information, see ***Insulin, General Information***.

Pharmacokinetics

Insulin formulations contain insulin hexamers (aggregates of 6 insulin molecules). Insulin is absorbed from the administration site only after insulin hexamers break down into insulin monomers or dimers. The rate of hexamer breakdown is largely responsible for differences of time to peak effect and duration of activity of the various insulin types.

When the recombinant human insulin product is given IV to dogs and cats, it has an immediate onset of action, with maximum effects occurring at 15 minutes; duration of action is 1 to 4 hours. After SC administration, onset is generally 10 to 30 minutes, peak is 1 to 2 hours, and duration is 5 to 6 hours. Half-life is 16 to 18 minutes.[11,12] Following IM administration, onset is 10 to 30 minutes, peak is 1 to 4 hours, and duration is 3 to 8 hours.

In alpacas, regular insulin has an immediate onset of action, but the duration of action is less than 1 hour.[13]

Although the kinetics of each insulin product vary markedly among species, regular insulin appears to have the most consistent pharmacokinetics.

Contraindications/Precautions/Warnings

Because there are no alternatives for insulin when it is used for diabetic indications, there are no absolute contraindications to its use except during episodes of hypoglycemia. If animals develop hypersensitivity (local or otherwise) or if insulin resistance develops, a change in type or species source (eg, human, bovine, porcine) of insulin should be considered after other etiologies for poor control (eg, expired insulin, concurrent disease, or medication interference) have been ruled out. See ***Insulin, General Information***.

For obese patients, dose calculations should be based on the patient's ideal body weight to avoid inadvertent insulin overdosing.

In humans, long-term repeated SC/IM injections of insulin at the same site may cause lipodystrophic reactions, which could interfere with insulin absorption[14]; however, there have been no specific reports of this reaction occurring in dogs or cats.

In patients with moderate to severe dehydration, poor tissue perfusion necessitates regular insulin be given IM or IV as absorption of SC injections is likely to be impaired or delayed.

Regular insulin is U100 strength. It is crucial for patient safety to only use U100 syringes when measuring and administering U100 insulin. Calculations can be done to convert to U40 syringes or TB syringes, but these conversions are not recommended due to the potential for introducing dosing errors. See ***Insulin, General Information***.

When writing prescriptions, do not abbreviate units as "U," as this has been shown to increase the rate of transcription and dosage errors. In human medicine, insulin is considered a "high alert" medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Do not confuse trade names that use letters to identify insulin types (eg, do not confuse *Humulin® R* with *Humulin® N*).

Adverse Effects

Adverse effects of insulin therapy may include hypoglycemia (see ***Overdose/Acute Toxicity***), hypokalemia, hypophosphatemia (diabetic ketoacidosis [DKA] only), insulin-induced rebound hyperglycemia (ie, Somogyi effect), and local or allergic reactions to the "foreign" proteins.

Reproductive/Nursing Safety

In humans, regular insulin is considered compatible with pregnancy and nursing[15]; the same is assumed to be true for veterinary patients.

Overdose/Acute Toxicity

Insulin overdose can lead to various degrees of hypoglycemia. Signs may include weakness, shaking, head tilting, lethargy, ataxia, seizures, blindness, bizarre behavior, and coma. Other signs may include restlessness, hunger, and muscle fasciculations. Electrolyte disturbances, including hypokalemia, may occur. Prolonged hypoglycemia can result in permanent brain damage or death.

Mild hypoglycemia can be treated by offering the animal its usual food. More serious signs (eg, seizures) should be treated with oral dextrose solutions (eg, *Karo®* syrup) applied to the buccal mucosa (if the animal is seizing, use caution to avoid being bit or injured) or by IV injections of 50% dextrose solutions (small amounts—usually 2 – 15 mL [0.5 – 1 mL/kg], diluted, and slowly administered[16]; see ***Dextrose 50% injection***). For in-clinic management, glucagon may also be considered on an as needed basis for an insulin overdose. See ***Glucagon.*** Once the animal's hypoglycemia is alleviated (response usually occurs within 1 to 2 minutes), it should be closely monitored (both by physical observation and serial blood glucose concentrations) to prevent a recurrence of hypoglycemia (especially with the slower-absorbed/longer-acting products) and to prevent hyperglycemia from developing. Future insulin dosages or feeding regimens should be evaluated or adjusted based on consultation with the clinician to prevent further occurrences of hypoglycemia.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving insulin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Antagonists** (eg, **atenolol**, **propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Because insulin can reduce serum potassium concentrations, patients receiving concomitant digoxin therapy—especially in patients receiving concurrent diuretic therapy—should be closely monitored.

- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Insulin shifts extracellular potassium into the intracellular space; serum potassium concentration should be closely monitored in patients receiving concomitant diuretic therapy. Diuretics may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements).
- **Reserpine**: Can mask the signs associated with hypoglycemia

The following drugs or drug classes may potentiate the hypoglycemic activity of insulin (ie, decrease insulin requirements):

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Ethanol**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**)
- **Fluoxetine**
- **Hypoglycemics, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may decrease the hypoglycemic activity of insulin (ie, increase insulin requirements):

- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-2-Adrenergic Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**)
- **Danazol**
- **Diazoxide**
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Thyroid Hormones**: Can elevate glucose concentrations in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None

Dosages

NOTES:

1. Treatment of diabetes mellitus and, in particular, diabetic ketoacidosis (DKA) is complex. Insulin is only one component of therapy; treatment may require fluid and electrolyte replacement, management of acid/base disturbances, dietary adjustments, and antimicrobial therapy. Adequate patient monitoring is mandatory. It is strongly encouraged to refer to more thorough discussions of treatment in veterinary endocrinology or internal medicine references for additional information.
2. For obese patients, dose calculations should be based on the individual patient's estimated ideal body weight to avoid inadvertent insulin overdose.
3. Insulin aspart or insulin lispro given by IV CRI appear to be safe and effective alternatives when regular insulin is not an option or is unavailable.
4. All dosages are extra-label.

DOGS:

Adjunctive therapy of diabetic ketoacidosis: Using regular insulin, choose *either* the intermittent IM technique or constant low-dose IV infusion technique.

a) Intermittent IM protocol: Initial dose: 0.1 – 0.2 units/kg IM into muscles of the pelvic limbs; repeat dose of 0.1 units/kg IM every 1 to 2 hours. Initial doses (first 2 to 3 injections) may be reduced by 25% to 50% if hypokalemia is a concern[17]; refer to specific endocrinology references for more information. When small doses are required, regular insulin may be diluted 1:10 with insulin diluents (preferred method) or sterile saline and administered via 0.3 mL U100 insulin syringes. Goal is to slowly lower blood glucose to 200 – 250 mg/dL over a 6- to 10-hour period; an hourly reduction in blood glucose by 50 – 100 mg/dL is ideal.[17] As blood glucose approaches 250 mg/dL, switch to IM regular insulin every 4 to 6 hours or SC (if hydration status is good) every 6 to 8 hours, with an initial dosage of 0.1 – 0.3 units/kg IM or SC, and adjust based on response to therapy. The goal is to keep blood glucose in the 150 – 300 mg/dL range.[17]

b) Constant low-dose infusion technique: To prepare an infusion that delivers 0.1 units/kg/hour: 2.2 units/kg regular insulin is added to 240 mL (**NOTE**: Many clinicians add insulin directly to a 250 mL bag without removing the 10 mL of fluid) of 0.9% sodium chloride. Run ≈50 mL of the insulin-containing fluid through the drip set prior to administration (see ***Adsorption*** in ***Compatibility/Compounding Considerations***). The initial administration rate is 10 mL/hour in a separate line to that used for fluid therapy.[17] When starting initial therapy for DKA, the potassium concentration must be taken into account and therapy adjusted accordingly to avoid hypokalemia. Adjust infusion rate based on hourly blood glucose determinations. An hourly reduction in blood glucose by 50 – 100 mg/dL is ideal.[17] Once blood glucose approaches 250 mg/dL, options include switching to IM regular insulin every 4 to 6 hours or SC (if hydration status is good) every 6 to 8 hours, with an initial dosage of 0.1 – 0.3 units/kg for either IM or SC administration, as described for the IM protocol or continuing the IV infusion at a decreased rate (see table) until exchanged for a longer-acting product[17] with a goal of keeping blood glucose in the 150 – 300 mg/dL range.

Blood glucose concentration (mg/dL [mmol/L])	Maintenance IV fluid	Rate of insulin CRI administration (mL/hour)	Dose of insulin administered (units/kg/hour)*
Greater than 250 (13.8)	0.9% sodium chloride	10	0.09
200-250 (11.1-13.8)	0.45% sodium chloride + 2.5% dextrose	7	0.064
150-200 (8.3-11)	0.45% sodium chloride + 2.5% dextrose	5	0.045
100-150 (5.5-8.2)	0.45% sodium chloride + 5% dextrose	5	0.045
Less than 100 (5.5)	0.45% sodium chloride + 5% dextrose	0 (Stop insulin infusion)	0 (Stop fluid administration)

Table adapted from Macintire DK. Treatment of diabetic ketoacidosis in dogs by continuous low-dose intravenous infusion of insulin. *J Am Vet Med Assoc*. 1993 Apr 15;202(8):1266-72.

*CRI prepared by adding regular insulin 2.2 units/kg to 250 mL 0.9% sodium chloride

Adjunctive treatment of hyperkalemia: **NOTE**: When using either of these protocols, it is imperative that 2.5% to 5% dextrose also be added to the concurrently given maintenance IV fluids to prevent secondary hypoglycemia.[18] See ***Dextrose 50% Injection*** for more information on administering dextrose.

a) 0.25 – 0.5 units/kg slow IV bolus followed by dextrose 50% (4 mL/unit of administered insulin)[8,18]

b) 0.5 – 1 units/kg in parenteral fluids plus 2 g dextrose (eg, 4 mL of dextrose 50%) per unit insulin administered.[19,20]

CATS:

Adjunctive therapy of diabetic ketoacidosis:

a) Intermittent IM protocol: Initial dose, 0.1 – 0.2 units/kg IM; repeat dose of 0.1 units/kg IM every 1 to 2 hours. Initial doses (first 2 to 3 injections) may be reduced by 25% to 50% if hypokalemia is a concern[17]; refer to specific endocrinology references for more information.

b) Constant low-dose infusion technique: 0.05 – 0.1 units/kg per hour IV CRI.[3,17,21–23] To prepare the solution, add the appropriate amount of regular insulin (1.1 or 2.2 units/kg) directly to 250 mL 0.9% sodium chloride/sterile saline. Run ≈50 mL of the insulin-containing fluid through the drip set prior to administration. Use the same IV CRI administration protocol as described above for dogs.

c) Regular insulin plus glargine: Regular insulin 1 unit/cat (NOT unit/kg) IM up to every 6 hours while the blood glucose concentration is greater than 250 mg/dL; used in combination with glargine 0.25 units/kg SC every 12 hours.[2]

Adjunctive treatment of hyperkalemia: When using either of these protocols, it is imperative that dextrose be provided to prevent secondary hypoglycemia[18]; this can be accomplished by adding 2.5% or 5% dextrose to the maintenance fluids. See ***Dextrose 50% Injection*** for more information on administering dextrose.

a) 0.5 – 1 units/kg IM with dextrose 2 g (eg, 4 mL of dextrose 50%)/insulin unit administered as a slow IV bolus.[24]

b) 0.25 – 0.5 units/kg with dextrose 0.5 g/kg slow IV bolus[8,18]

HORSES:

Diabetes mellitus:

a) 0.1 units/kg IM every 6 to 12 hours or 0.1 unit/kg/hour IV CRI. Once stabilized, transition therapy to a longer-acting insulin.[25]

b) 0.05 – 0.1 units/kg IV every 8 to 12 hours[26]

Management of hyperglycemia in critically ill foals during parenteral nutrition support:

a) Continuous IV infusion: 0.01 – 0.07 units/kg/hour IV CRI.[27,28] If blood glucose is more than 150 mg/dL after 2 hours, increase CRI by 50% at 2-hour intervals until blood glucose is below 150 mg/dL. Adding regular insulin 20 units to 500 mL 0.9% sodium chloride is one recommended method to prepare the insulin infusion.[28] Run ≈50 mL of the insulin-containing fluid through the drip set prior to administration (see ***Adsorption*** in ***Compatibility/Compounding Considerations***).

b) Intermittent SC or IM technique: Dosages have varied widely, from 0.01 – 0.1 units/kg IV or SC every 6 to 24 hours[29] to 0.1 – 0.5 units/kg SC.[28] Some clinicians have suggested intermittent injections are not recommended due to risk for hypo- or hyperglycemia being greater than with CRI.[30]

NEW WORLD CAMELIDS:

Severe hyperlipemia: 0.2 units/kg IV with dextrose every 6 hours (more frequently if needed, up to a maximum frequency every hour).[31] Administration of 0.2 units/kg SC had peak effect at ≈4.7 hours, and duration was 8.5 hours.[32]

BIRDS:

Diabetes mellitus: 0.1 – 0.2 units/kg SC or IM.[33] Insulin therapy is sometimes hindered by the highly variable dose needed for individual birds, development of insulin resistance, and development of pancreatic atrophy/insufficiency. Adjust insulin dose every 1 to 2 hours until blood glucose concentration is maintained within normal range. Once stabilized, NPH insulin can be started for long-term therapy.

Monitoring

- Diabetic patients should be closely monitored. Each patient requires an individualized treatment plan, frequent reassessment, and adjustments of the plan based on the response of the patient. It is encouraged to consult a veterinary endocrinology reference text or with a veterinary emergency and critical care and/or endocrinology specialist for further information related to regulating diabetic patients and insulin adjustments. The overarching goal for monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia.[34] Interpret all monitoring strategies in light of clinical signs. Results from the below monitoring options may conflict in regard to achieving good glycemic control and good clinical control.
- Patient status and control of clinical signs: body weight, appetite, fluid intake, urine output
- Glucose (blood or interstitial). Because of how often glucose needs to be checked in sick diabetic patients, consider a central line or continuous interstitial glucose monitoring system in dogs and cats. Experience with continuous interstitial glucose monitoring in dogs and cats is that these devices are easy to apply, user friendly, and provide useful information surrounding glycemic control while the patient is in the clinic or home environment.[35–38]
  - For patients that have experienced or are suspected to have experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for treatment of hypoglycemia.
- Additional monitoring for patients with diabetic ketoacidosis (DKA)[39]:
  - Glucose measurement every 1 to 2 hours initially; adjust insulin therapy and begin dextrose infusion when glucose decreases below 250 mg/dL (14 mmol/L). See ***Dosages***.
  - Hydration status, respiration, pulse every 2 to 4 hours
  - Serum electrolyte (eg, magnesium, phosphorous, potassium), plasma ketones, and total venous CO_2 concentrations every 4 to 8 hours
  - Urine output, glycosuria, and urine ketones every 4 to 8 hours
  - Body weight, packed cell volume, temperature, and blood pressure every 6 to 8 hours
  - Additional monitoring as applicable to address concurrent disease

Chemistry/Synonyms

All commercial preparations of human-labeled insulin currently manufactured in the United States are supplied in solution or suspension at a concentration of 100 units/mL, which is ≈3.5 mg of insulin/mL. Likewise, 1 unit of insulin equals ≈35 µg of insulin, and 1 mg insulin equals ≈28.8 units.

Regular insulin human injection, USP (rDNA origin), is structurally identical to human insulin and is synthesized through rDNA technology in a special nonpathogenic laboratory strain of *Escherichia coli* bacteria (*Humulin® R*) or *Saccharomyces cerevisiae* yeast (*Novolin® R*). It is a rapid-acting, sterile, clear, and colorless or almost colorless solution. Discoloration, turbidity, or unusual viscosity indicates deterioration or contamination.

Regular insulin may also be known as crystalline zinc insulin, regular human insulin, insulin human, recombinant human insulin, *Humulin® R,* and *Novolin® R*.

Storage/Stability

Unopened regular insulin *vials* and pens/devices should be stored in the refrigerator at 2°C to 8°C (36°F-46°F) and protected from temperature extremes and direct sunlight. Do not freeze.

In-use *vials* or *pens/devices*:

- Regular insulin: *Humulin® R* should be stored for 31 days refrigerated or at room temperature. *Novolin® R* vials should be stored for 42 days, and *Novolin® R* pens/devices should be stored for 28 days. *Novolin® R* vials and pens/devices should be stored at room temperature only; do not refrigerate.
- Regular insulin may be stored in plastic or glass syringes refrigerated or at room temperature for 28 days without loss of potency; however, the antibacterial preservatives in the insulin formulations may be lost if stored at room temperature.[40] It is generally accepted that syringes of insulin can be stored for 28 days refrigerated without loss of potency.

Freezing (less than 2°C [36°F]) may alter the protein structure and decrease potency. Particle aggregation and crystal damage may be visible to the naked eye. Higher temperature (greater than 30°C [86°F]) extremes and direct exposure to sunlight (as might occur when insulin is stored in a car or on a windowsill) may produce insulin transformation products and fibril formation.

Although manufacturers recommend discarding opened bottles of insulin after 4 to 6 weeks (or expiration date, whichever comes first), studies[41,42] support that insulin potency and stability is maintained for longer durations. Veterinary internal medicine specialists indicate that the vial may be used for 3 to 6 months after opening and possibly beyond the listed expiration date as long as it is handled carefully, stored in the refrigerator, and the solution does not develop discoloration, flocculent precipitates, or changes in consistency. If a lack of diabetes regulation is noted when using the product beyond the expiration date (3 to 6 months after starting therapy), it may be prudent to replace with new insulin prior to adjusting insulin therapy.[34]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references for more specific information.

Regular insulin is reportedly physically **compatible** with the following drugs/solutions: 0.9% sodium chloride, TPN solutions (4% amino acids, 25% dextrose with electrolytes and vitamins; must occasionally shake bag to prevent separation), ascorbic acid, atropine, bumetanide, calcium gluconate, cefazolin, cimetidine, esmolol, fentanyl, hydromorphone, lidocaine, mannitol, metoclopramide, metronidazole, oxytetracycline, penicillin G potassium/sodium, potassium chloride, sodium bicarbonate, and verapamil. Regular insulin may be mixed with other insulin products (except for glargine) used in veterinary medicine (eg, NPH, PZI). If mixing 2 insulin products in the same syringe, regular insulin should be drawn into the syringe first.

Regular insulin is reportedly physically **incompatible** when mixed with the following drugs/solutions: aminophylline, ampicillin, butorphanol, chlorothiazide, cytarabine, diazepam, dobutamine, famotidine, furosemide, gentamicin, glycopyrrolate, ketamine, pantoprazole, pentobarbital, phenobarbital, piperacillin/tazobactam, polymyxin B, propranolol, quinidine, and thiopental.

Diluting insulin: Other than for immediate use, regular insulin should only be diluted using product-specific sterile diluent, which is supplied by the manufacturer upon request. Diluted insulin (10 units/mL) prepared in this manner is stable for 4 weeks and should be stored in the refrigerator, although refrigeration is not required. For immediate use, regular insulin can be diluted with normal saline for injection, but the potency cannot be predicted after 24 hours.

Adsorption: The adsorption of regular insulin to the surfaces of IV infusion solution containers, glass and plastic (including PVC, ethylene vinyl acetate, polyethylene, and other polyolefins), tubing, and filters has been demonstrated. Estimates of loss of potency range from 20% to 80%, although reports of 20% to 30% are more common.[43–46] The percent adsorbed is inversely proportional to the concentration of the insulin,[43] and may include other factors (eg, amount of container surface area, fill volume of the solution, type of solution, type and length of administration set, temperature, previous exposure of tubing to insulin, presence of other drugs or blood).[44–46] The adsorption process is instantaneous, with the bulk of insulin adsorption occurring within the first 30 to 60 minutes. To saturate binding sites and deliver a more predictable dose to the patient through an IV infusion, it is recommended that the first 50 mL be run through the IV tubing and discarded.

Insulin syringes: Syringes are designed for use with a specific strength of insulin, with the needle covers color-coded according to strength. U100 syringes are available in 0.3 mL, 0.5 mL, and 1 mL sizes. Measuring U100 insulin to the 1 unit mark in a U100 syringe will result in 1 unit of insulin. Some brands of 0.3 mL syringes include ½ unit markings. Insulin syringes should not be reused.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Insulin, Regular Injection Human (rDNA): 100 units/mL in 3 mL vials and pens/devices, and 10 mL vials; *Humulin® R*, *Novolin® R*; (OTC in humans; requires prescription under extra-label provisions of AMDUCA when used in animals). A 500 units/mL concentration is available, as is a 1 unit/mL premixed solution. Most clinics have little need for the 500 units/mL concentration, and the 1 unit/mL solution is not conducive for use in established diabetic ketoacidosis (DKA) protocols. If stocked, adequate safeguards should be implemented to prevent the significant harm that could result from inadvertent use of these strengths.

Interferon Alfa, Human Recombinant

(in-ter-***feer***-on ***al***-fah) *Intron-A®*

Immunomodulator

See also ***Interferon Omega, Feline Origin***

Prescriber Highlights

- ► Cytokine used to alleviate clinical effects of certain viral diseases; little solid evidence available to document safety and efficacy in small animals
- ► Adverse effects: In cats, adverse effects are apparently uncommon with PO dosing; higher dosages given parenterally may cause malaise, fever, allergic reactions, myelotoxicity, and myalgia.

Uses/Indications

Interferon alfa has primarily been used in cats to treat a variety of virus-

induced diseases using either SC or oral/buccal administration. Despite rapid antibody development when injected parenterally and little, if any, absorption after oral administration, the drug does appear to have some efficacy for certain diseases, either via direct antiviral action or, more likely, an immunomodulatory effect. Interferon-alfa has been used in dogs and cats for the adjunctive treatment of a wide variety of viral- or immunosuppression-related conditions (eg, papillomas, keratoconjuntivitis sicca), but the strength of the evidence to support most indications is either weak or absent.[1] Cats naturally infected with feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV) demonstrated favorable clinical and biopathological response to long-term oral interferon alfa.[2,3]

Feline interferon-omega is available in several countries, and it may be useful in treating viral diseases in both cats and dogs. See ***Interferon Omega, Feline Origin***.

Pharmacology/Actions

There are at least 25 subtypes of interferon alfa, each possessing similar but not identical biological activity. The pharmacologic effects of the interferons are widespread and complex. Suffice it to say that interferon alfa has antiviral, antiproliferative, and immunomodulating effects. Its antiproliferative and antiviral activities are thought to be due to its effects on the synthesis of RNA, DNA, and cellular proteins (oncogenes included). The mechanisms for its antineoplastic activities are not well understood but are probably related to these effects as well.

Pharmacokinetics

Interferon alfa is poorly absorbed after oral administration due to its degradation by proteolytic enzymes, and studies have not detected measurable levels in the systemic circulation; however, there may be some absorption in the upper GI mucosa. It may have some immunomodulating effect via stimulation of local lymphoid tissues.

Interferon alfa is widely distributed throughout the body, although it does not penetrate into the CNS well. It is unknown if it crosses the placenta. Interferon alfa is freely filtered by the glomeruli and is absorbed by the renal tubules, where it is metabolized by brush border enzymes of lysosomes. Hepatic metabolism is of minor importance. The plasma half-life in cats has been reported as 2.9 hours.[4]

Contraindications/Precautions/Warnings

When interferon alfa is used parenterally, consider the risks versus benefits in patients with pre-existing autoimmune disease, severe cardiac disease, pulmonary disease, hard-to-control (brittle) diabetes, severe hepatic disease, herpes infections, hypersensitivity to the drug, or CNS disorders.

Adverse Effects

When interferon alfa is used orally in cats, adverse effects are apparently uncommon. Higher dosages given parenterally to cats may cause malaise, fever, allergic reactions, myelotoxicity, and myalgia. Injection site reactions (eg, discomfort, redness) are possible. Cats given human interferon-alfa parenterally may develop significant antibodies to it after 3 to 7 weeks of treatment with resultant loss of efficacy.[4]

When interferon alfa is used systemically in humans, adverse effects are common and include anemia, leukopenias, thrombocytopenia, hepatotoxicity, neurotoxicity, vision loss, hypothyroidism, taste sensation changes, anorexia, nausea, vomiting, diarrhea, dizziness, influenza-like symptoms, transient blood pressure changes, hair loss, skin rashes, hypertriglyceridemia, and dry mouth.[5] Except for the flu-like syndrome, most adverse effects are dose-related and may vary depending on the condition treated. Depression of mild to moderate severity has been noted in up to 25% of humans receiving interferon alfa; it is unclear how this relates to veterinary patients.

Reproductive/Nursing Safety

Interferon alfa did not impair fertility in laboratory animals, although decreased estrogen and progesterone levels and changes to the menstrual cycle were noted in rhesus monkeys. Safety during pregnancy has not been established; high parenteral doses in monkeys did not cause teratogenic effects but did increase abortifacient activity.

It is not known whether this drug is excreted in milk. Studies in mice have shown that mouse interferons are excreted into the milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Decreased food consumption, weight loss, vascular leakage, and bone marrow suppression were observed in laboratory animals receiving up to 11 to 100 times the FDA-approved human dose. Determine dosages carefully.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving interferon alfa and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acyclovir, Vidarabine, Zidovudine**: Additive or synergistic antiviral effects may occur when interferon alfa is used in conjunction with zidovudine (AZT) or acyclovir. This effect does not appear to occur with vidarabine, although increased toxicities may occur. The veterinary significance of these potential interactions is unclear.
- **Colchicine**: Reduced interferon effectiveness
- **Theophylline**: Doubling of theophylline concentration has been noted in humans.

Dosages

NOTE: All dosages are extra-label, and evidence for safety and efficacy is relatively weak. All dosages are for human interferon alfa-2b as interferon alfa-2a is no longer marketed.

DOGS:

Cutaneous T-cell lymphoma and severe cases of oral/cutaneous papillomas: 1.5 – 2 million units/m^2 (NOT units/kg) SC every other day or 3 times weekly until clinical resolution[6,7]

Immunostimulant for the adjunctive treatment of certain dermatologic conditions (eg, pododermatitis, papillomas, digital keratomas): 1000 units PO once daily (given as 1000 unit/mL solution)[8]

Canine transmissible venereal tumor: 1.5 million units/dog (NOT units/kg) as an intra-lesional injection once weekly, along with vincristine 0.025 mg/kg IV, was found to shorten the duration of treatment when compared with vincristine alone.[9]

CATS:

Feline immunodeficiency virus (FIV)- +/- feline leukemia virus (FeLV)-infected cats: Low-dose oral: Using an experimentally produced interferon alfa product, 10 units/kg PO once daily resulted in clinical improvement and prolonged survival.[10] Using recombinant human interferon alfa, 60 units/cat (NOT units/kg), PO or buccally once daily, treated 7 days on, 7 days off[3,11]

Feline calicivirus or feline herpesvirus-1: High-dose SC injection: 10,000 units/kg (diluted in saline) SC once daily for up to 14 days has led to clinical resolution of disease in some cats.[12,13] Low-dose oral: 50 units/cat (NOT units/kg) PO once daily[14]

Monitoring

- Baseline and periodic CBC with platelets and chemistry panel should be performed during treatment.
- Consider measurement of serum triglycerides and thyroid panel, as abnormalities have been noted in humans
- Baseline and periodic ophthalmic examinations to monitor for improvement or progression of ocular effects caused by viral infection
- Efficacy and adverse effects

Client Information

- Owners must be aware of the investigational nature of this compound and understand that efficacy and safety are not necessarily known.
- For oral use: Compounded liquid is given orally (by mouth) or inside the cheek (buccally). It is best not to mix it with food. If your animal vomits or acts sick after getting it on an empty stomach, give the drug with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- It is usually well tolerated.

Chemistry/Synonyms

Prepared from genetically engineered cultures of *Escherichia coli* with genes from human leukocytes, interferon alfa-2b is commercially available as a sterile solution or sterile powder. Human interferon alfa is a complex protein that contains 165 or 166 amino acids.

Interferon may also be known as huIFN-alfa, IFN-alpha, interferon-alpha, or Sch-30500 (interferon alfa-2b); there are many internationally registered trade names available.

Storage/Stability

Store commercially available products in the refrigerator; do not freeze. Do not expose solutions to room temperature for longer than 24 hours. Do not vigorously shake solutions. Avoid exposure to direct sunlight.

An article proposing using this product in cats for the treatment of FeLV states that after dilution of 3 million units in 1 L of sterile saline, the resultant solution remains active for years if frozen or for months if refrigerated; however, data corroborating this were not located.

Compatibility/Compounding Considerations

Interferon alfa products supplied as powder should be reconstituted with the accompanying diluent and swirled gently to dissolve the powder; manufacturers recommend discarding unused portions of reconstituted interferon alfa.

Preparation of solution for 30 units/mL oral administration: Using the 6 million unit vial (see below), dilute the entire contents into a 1 L bag of sterile normal saline; mix well. The resulting solution contains ≈6000 units/mL. Divide into aliquots of either 1 mL or 10 mL and freeze. By diluting further 200-fold (1 mL of 6000 units/mL solution with 200 mL of sterile saline, or 5 mL with 1000 mL of sterile saline), a 30 units/mL solution will result. Some clinicians have advised aliquoting the diluted solution into 1 mL volumes for freezing up to a year; defrost as necessary. Once defrosted, the drug can be refrigerated for up to one week. Freezing the most dilute solutions is associated with loss in the activity unless protein such as albumin (see above) is added during dilution.[12]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

Interferon Alfa-2a (*Roferen® A*) that was used in veterinary medicine has been discontinued.

HUMAN-LABELED PRODUCTS:

Interferon Alfa-2b (human recombinant) (IFN-alpha$_2$; rIFN-a2; a-2-interferon) Powder for Injection: 10 million units/vial, 18 million units/vial, and 50 million units/vial in vials with diluent; *Intron A®*; (Rx)

Interferon Alfa-2b (human recombinant) (IFN-alpha$_2$; rIFN-a2; a-2-interferon) Injection: 6 million units/mL in 3.6 mL vials and 10 million units/mL in 3.2 mL vials; *Intron A®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Interferon Omega, Feline Origin

(in-ter-***feer***-on oh-***may***-ga) *Virbagen® Omega*

Immunomodulator

See also ***Interferon Alfa, Human Recombinant***

Prescriber Highlights

- ► Immunomodulating cytokine approved in Europe for treating feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) in cats and enteral parvovirus in dogs
- ► Appears to be well tolerated; adverse effects include hyperthermia, vomiting, diarrhea (cats), and fatigue (cats).
- ► Increases in ALT and decreases in RBC, WBC, and platelet counts have been seen.
- ► Not commercially available in the United States; treatment may be expensive.

Uses/Indications

Interferon omega is labeled in the EU for dogs 1 month of age or older for the reduction in mortality and clinical signs associated with the enteric form of parvovirus. In cats 9 weeks of age or older, it is labeled for treating feline leukemia virus (FeLV) and/or feline immunodeficiency virus (FIV) in nonterminal clinical stages. It may be of benefit in treating canine distemper, acute feline calicivirus infections, and FIP. In an open-label study of 16 naturally infected cats with FIV/FeLV given labeled doses of interferon omega, improved clinical signs and decreased concurrent virus excretion were noted.[1] Similarly, interferon omega improved clinical signs and reduced viral shedding in cats with feline chronic gingivitis-stomatitis (FCGS) and were infected with feline calicivirus (FCV).[2,3]

Interferon omega may also be of benefit topically for feline herpetic keratitis, but data are still being gathered to document efficacy. Interferon omega treatment has been noted to produce some clinical benefit in dogs with atopic dermatitis, including inconsistent and mild improvement in skin lesions and pruritus.[4]

Pharmacology/Actions

Omega interferon is a type 1 interferon related to interferon alpha. Its principal action is not as a direct anti-viral agent but by inhibiting host mRNA and translation proteins in virusinfected cells, thereby inhibiting viral replication. It may also nonspecifically enhance immune defense mechanisms.

Pharmacokinetics

Omega interferon pharmacokinetics in dogs and cats appear to be similar to that of human interferons. After IV injection, omega interferon is rapidly bound to specific receptor sites on a variety of cells. The highest tissue concentrations are found in the liver and kidneys. Interferon is filtered in the renal glomeruli and catabolized in the kidneys. In dogs, the volume of distribution at steady state is about 0.1 L/kg. Biphasic elimination occurs with an alpha half-life of 3.14 hours and a beta half-life of 0.24 hours. Total body clearance is

6.9 mL/minute/kg. Pharmacologic effects of interferon omega persist after its disappearance from plasma.

Contraindications/Precautions/Warnings

The manufacturer cautions against vaccinating dogs currently being treated with omega interferon and not to vaccinate until the patient appears to have recovered from infection. As both feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infections are known to be immunosuppressive, the manufacturer states that cat vaccinations are contraindicated during and after omega interferon treatment.

There are several different interferons available for use in humans (several subtypes of alpha, beta, or gamma interferon); one cannot be substituted for another.

Adverse Effects

In cats and dogs, hyperthermia (3 to 6 hours postdose) and vomiting have been reported. Slight decreases in RBCs, platelets, and WBCs and increased ALT have been observed, but, reportedly, these indices return to normal within a week of the last injection.

Additionally, soft feces and mild diarrhea and transient fatigue may be noted in cats. IV administration to cats may cause increased incidence and severity of adverse effects, but adverse effects occur uncommonly in this species.

Dogs may develop antibodies to interferon omega if treatment is prolonged (beyond labeled dosage period) or repeated.

Reproductive/Nursing Safety

Safety during pregnancy or lactation has not been established.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses of 10 times the labeled dose in dogs and cats caused mild lethargy, somnolence, slight hyperthermia, and slight increases in respiratory and heart rates. In animals tested, signs resolved within 7 days, and no treatment was required.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving interferon omega and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- Hepatotoxic Agents (eg, **lomustine**, **NSAIDs, rifampin**): Increased risk for hepatotoxicity
- Myelosuppressive Agents (eg, **antineoplastics**, **chloramphenicol, zidovudine**): Concurrent use may result in additive myelosuppression.
- Vaccines: Vaccine administration is contraindicated during interferon omega treatment.

Laboratory Considerations

- None are noted.

Dosages

DOGS:

Parvovirus (extra-label): 2.5 million units/kg IV once daily for 3 days.[5] The earlier the dog is treated, the more likelihood of success.

Atopic dermatitis (extra-label): 1 – 5 million units/kg SC 3 times per week for 4 weeks, then once monthly[4,6]

CATS:

Feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) (extra-label): 1 million units/kg SC once daily for 5 days.[5] Three separate 5-day treatments performed at day 0, day 14, and day 60

FIV (extra-label): 100,000 units/cat (NOT units/kg) PO once daily for 90 days[7]

Feline herpesvirus-1 (FHV-1) facial dermatitis (extra-label): From a case report treating a cat with FHV-1 facial dermatitis: Day 0: 1.5 million units/kg injected, half of which was injected peri-lesionally and intradermally and the other half SC on the lateral thorax. Days 2 and 9: 1.5 million units/kg injected SC on the lateral thorax. On days 19, 21, and 23: 0.75 million units/kg injected peri-lesionally and intradermally as well as 0.75 million units/kg SC on the lateral thorax. The cat was sedated when each peri-lesional and intradermal injection was made.[8]

Feline chronic gingivostomatitis syndrome (FCGS; extra-label): 100,000 units/cat (NOT units/kg) PO once daily for 90 days[2,3,9]

Adjunctive treatment of cowpox virus-associated pneumonia and dermatitis (extra-label): From a case series of 5 cats, all received broad-spectrum antibacterial therapy along with other supportive treatments, and 4 cats received interferon omega, with 3 cats administered 1 million units/kg IV or SC every 24 and 1 cat given 2.5 million units/kg SC every 48 hours. The 2 cats that received interferon and lived were felt to have been diagnosed and treated earlier in the disease course.[10]

Monitoring

- Efficacy
- Baseline and periodic CBC, chemistry panel

Client Information

- Your veterinarian must administer this drug on an inpatient basis to provide the observation and support the animal may need.

Chemistry/Synonyms

Interferon omega of feline origin is a type 1 recombinant interferon obtained from silkworms after inoculation with a recombinant baculovirus. It is provided commercially as a lyophilisate powder with a separate solvent (saline).

Interferon omega may also be known as recombinant omega interferon of feline origin, omega interferon, interferon-omega, IFN-omega, IFN-omega (feline recombinant), rFelFN-omega, and *Virbagen® Omega*.

Storage/Stability

Store the commercial veterinary product in its original carton refrigerated (2°C-6°C [36°F-43°F]); protect from freezing.[5] It has a designated shelf life of 2 years when properly stored. Once reconstituted with the supplied isotonic sodium chloride solution, use it immediately as it contains no preservative; however, there are anecdotal reports that the solution is stable for at least 3 weeks when refrigerated. No data were located on the stability of the reconstituted solution when frozen.

Compatibility/Compounding Considerations

Interferon omega should not be mixed with any other vaccine/immunological product, except the solvent supplied for use with the product.[5]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None in the United States

Recombinant Omega Interferon of Feline Origin: 10 million units/vial; *Virbagen® Omega*; (Rx); licensed for dogs and cats in the EU only. A 5 million unit vial may be available in some countries.

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Iodide (Potassium-, Sodium-)

(***eye***-oh-dide) *SSKI®, Iodoject®*

Antifungal, Nutritional Supplement

Prescriber Highlights

- ► Iodides have been used for actinomycosis/actinobacillosis in ruminants and sporotrichosis in dogs, cats, and horses.
- ► Contraindications include iodide hypersensitivity, lactating animals, hyperthyroidism, renal failure, or dehydration. May cause abortion in cattle
- ► Metallic taste, patient acceptance can be problematic
- ► Do not inject IM; in horses, give IV slowly and with caution, as severe generalized reactions have been reported.
- ► Adverse effects include iodism (signs include excessive tearing, vomiting, anorexia, nasal discharge, muscle twitching, cardiomyopathy, scaly haircoats/dandruff, hyperthermia, decreased milk production, weight gain, coughing, inappetence, and diarrhea).
- ► Cats may be more prone to developing toxicity.

Uses/Indications

The primary use for sodium iodide is in the treatment of actinobacillosis and actinomycosis in cattle. Although sodium iodide 20 mg/kg PO achieved presumed therapeutic iodine concentrations in calves,[1,2] it was not effective at preventing bovine respiratory disease.[1] It has been used as an expectorant with little success in a variety of species, and occasionally as a supplement for iodine deficiency disorders. Iodide has been used as adjunctive therapy for pythiosis in horses, but clinical studies are lacking.[3–6] In dogs, cats, and horses, oral sodium or potassium iodide has been used in the treatment of sporotrichosis.

Use in cats is controversial, as they may be prone to developing adverse effects; cats may require other antifungal (eg, itraconazole) therapy. A study using oral potassium iodide (alone) for sporotrichosis reported a cure rate of 48% and a treatment failure rate of 37%.[7]

Pharmacology/Actions

Although the exact mode of action for their efficacy in treating actinobacillosis is unknown, iodides likely have some effect on the granulomatous inflammatory process. Iodides have little, if any, in vitro antibiotic activity.

Pharmacokinetics

Little published information appears to be available. When given orally to humans, iodide salts are converted into iodine and transported to the thyroid gland. The majority of any remaining iodine is eliminated in the urine. Therapeutic efficacy of IV sodium iodide for actinobacillosis is rapid, with beneficial effects usually seen within 48 hours of therapy.

Contraindications/Precautions/Warnings

Sodium iodide injection labels state that it should not be given to pregnant animals, lactating animals, or those with hyperthyroidism. Do not inject iodide IM.

Animals vary in their susceptibility to iodides; give them with caution until tolerance is determined.[8] Iodides given parenterally should be administered slowly IV and with caution to horses; severe generalized reactions have been reported.

Iodide should not be used in animals in renal failure or in those that are severely dehydrated.

Adverse Effects

In ruminants, the adverse effect profile is related to excessive iodine (see ***Overdose/Acute Toxicity*** below). Young animals may be more susceptible to iodism than adults.

Long-term use or overdoses may cause iodism. Cats are apparently more prone to developing this than other species. Signs can include vomiting, inappetence, depression/lethargy, twitching, hypothermia, and cardiovascular failure. One study reported that 27% of treated cats had increased liver enzymes, and about half of those cats exhibited signs of hepatotoxicity.[7]

The taste of the liquid is unpleasant, so animals may avoid dosing. Administering iodide with food or a fatty liquid (eg, whole milk, ice cream) may improve palatability and reduce nausea and vomiting. Cats reportedly tolerate the taste of sodium iodide better than potassium iodide. Potassium iodide oral tablets 130 mg (available OTC for reducing risk for thyroid cancer after radioactive isotope exposure) or compounded capsules may be useful in small dogs or cats that cannot tolerate oral solutions.

Reproductive/Nursing Safety

Iodides readily cross the placenta and may cause goiter or abnormal thyroid function in the neonate.[9] Anecdotal reports that iodides can cause abortion in cattle persist. Clearly, potential risks versus benefits of therapy must be weighed.

Iodides are excreted in milk. If iodides are required in the nursing dam, switch to milk replacer. Foals have developed goiters when mares have been excessively supplemented.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Excessive iodine in animals can cause excessive tearing, vomiting, anorexia, diarrhea, nasal discharge, muscle twitching, cardiomyopathy, scaly haircoats/dandruff, hyperthermia, decreased milk production and weight gain, coughing, inappetence, and diarrhea.

Refer to the ***Potassium (-Acetate, -Chloride, -Gluconate)*** monograph for discussion of potassium overdoses.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving iodide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **enalapril**): Concurrent use with potassium iodide increases the risk for hyperkalemia.
- **Angiotensin Receptor Blockers** (**ARBs**; eg, **telmisartan**): Concurrent use with potassium iodide increases the risk for hyperkalemia.
- **Antithyroid Medications** (eg, **carbimazole, methimazole**): Iodides may decrease the efficacy of antithyroid medications.
- **Potassium Sparing Diuretics** (eg, **triamterene, spironolactone**): Concurrent use with potassium iodide increases the risk for hyperkalemia.
- **Potassium Supplements**: Concurrent use with potassium iodide increases the risk for hyperkalemia.
- **Thyroid Supplements** (eg, **levothyroxine**): Iodides may enhance the efficacy of thyroid medications.

Dosages

DOGS:

Sporotrichosis (extra-label): Using potassium iodide (*SSKI®*),

40 mg/kg PO every 12 hours with food; using itraconazole for treatment of sporotrichosis is less likely to have adverse effects.[10]

CATS:

Sporotrichosis (extra-label): Generally, azole antifungal agents are recommended, but as a low-cost alternative treatment (from an observational cohort study): using potassium iodide compounded into capsules, initially 2.5 mg/kg PO every 24 hours. Doses were progressively increased at each 5-day period until a clinical response was achieved or signs of toxicity appeared: 5 mg/kg, 10 mg/kg, 15 mg/kg, and 20 mg/kg every 24 hours. Cats with mild adverse clinical effects had therapy suspended for 7 days and resumed 2.5 mg/kg dose increments until the highest dose that did not induce toxicity was attained.[7]

Sporotrichosis (extra-label): Using potassium iodide (KI), 2.5 – 20 mg/kg PO once daily *in combination with* itraconazole 100 mg/day. KI dose escalated in 2.5 mg/kg per day increments every 30 days until a maximum dose of 20 mg/kg per day was reached. Treatment continued until 4 weeks after cats were clinically cured.[11]

HORSES:

Sporotrichosis (extra-label):

a) Sodium Iodide: Loading dose of 20 – 40 mg/kg IV slowly once daily for 2 to 5 days, then 20 – 40 mg/kg PO once daily for at least 3 weeks after all clinical lesions disappear. May administer via oral syringe or mixed in sweet feed. Topical hot packs of 20% sodium iodide may be used on open wounds.[12,13]

b) Organic iodides (eg, ethylene diamine dihydroiodide): 1 – 2 mg/kg of the active ingredient mixed with a small amount of grain once or twice daily for the first week, then reduced to 0.5 – 1 mg/kg once daily for the remainder of the treatment. Treatment should be continued for at least 1 month beyond the complete resolution of all cutaneous nodules. Proven to be superior in efficacy to the inorganic iodides (sodium or potassium iodide).[14]

Conidiobolomycosis (extra-label): From a case report: A mare with *Conidiobolus coronatus* granulomatous tracheitis was successfully treated with 20% sodium iodide at 44 mg/kg IV for 7 days, followed by ethylenediamine dihydroiodide (iodide powder, granules) 1.3 mg/kg PO every 12 hours for 4 months, then every 24 hours for 1 year, then once per week. Excessive lacrimation was occasionally noted but resolved if the drug was held for 1 day.[15]

CATTLE:

Actinomycosis | Lump jaw; actinobacillosis | Woody tongue; necrotic stomatitis (label dosage; not FDA-approved): Sodium Iodide 20%, 66 mg/kg IV slowly. May be repeated at weekly intervals if necessary[8]

Actinobacillosis | Woody tongue (extra-label): Potassium iodide 70 mg/kg IV slowly, given as a 10% or 20% solution; repeat at least one more time at a 7-to 10-day interval. Refractory cases may require more frequent (2- to 3-day interval) treatment. Severe, generalized, or refractory cases may require adjunctive treatment with antibiotics (eg, sulfas, aminoglycosides, or tetracyclines).[16]

SHEEP & GOATS:

Actinobacillosis | Woody tongue (extra-label): Potassium iodide 70 mg/kg IV slowly given as a 10% or 20% solution; repeat at least 1 more time at a 7- to 10-day interval. Refractory cases may require more frequent (2- to 3-day interval) treatment. Severe, generalized, or refractory cases may require adjunctive treatment with antibiotics (eg, sulfas, aminoglycosides, or tetracyclines).[16]

Monitoring

- Clinical efficacy
- Signs of iodism (eg, excessive tearing, nasal discharge, scaly haircoats/dandruff, hyperthermia, decreased milk production and weight gain, coughing, inappetence, and diarrhea)
- Thyroid function tests
- Liver enzymes

Client Information

- Nausea and vomiting (dogs, cats), unpleasant taste (which may make your animal difficult to give the medicine to) occurs commonly, especially if given on an empty stomach. Give the medicine with cream or high fat food. Compounded capsules may be easier to administer in some animals. Excessive tearing (lacrimation/tearing); may need to skip a dose if this is a problem.
- Long-term use or high doses can cause iodide toxicity (*iodism*), which may manifest as vomiting, inappetence, depression/lethargy, twitching, hypothermia, and heart failure. Contact your veterinarian if your animal shows any of these signs.
- Do not use if medicine turns brownish yellow.

Chemistry/Synonyms

Sodium iodide occurs as colorless, odorless crystals, or white crystalline powder. It develops a brown tint upon degradation. Approximately 1 g is soluble in 0.6 mL of water and 2 mL of alcohol.

Potassium iodide occurs as a clear to white granular powder. Approximately 1 g is soluble in 0.7 mL of water. One gram (one mL) of *SSKI®* contains 6 mEq of potassium.

Potassium iodide oral solution may also be known as *SSKI®* (super saturated potassium iodide), or *Pima®*.

Storage/Stability

Commercially available veterinary injectable products should generally be stored at room temperature (15°C-30°C [59°F-86°F]).

Super saturated potassium iodide (*SSKI®*) solution should be stored below 40°C (104°F) and preferably between 15°C and 30°C (59°F-86°F) in a tight, light-resistant container; protect from freezing. Crystallization can occur, particularly if stored at low temperatures; re-warming the contents and shaking will usually redissolve the crystals. If oxidation occurs, the solution will turn brownish yellow in color; discard if this occurs.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Sodium iodide injection is reportedly physically **incompatible** with injectable vitamins B and C.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Sodium Iodide Injection: 20 g/100 mL (20%; 200 mg/mL) in 250 mL vials—available as multi- or single-use vials; generic; (Rx). Labeled for use in nonlactating cattle

Oral iodide powders/granules for addition to feeds are available. Active ingredient is ethylenediamine dihydroiodide.

HUMAN-LABELED PRODUCTS:

Potassium Iodide Solution: 1 g potassium iodide/mL (*SSKI®*); generic; (Rx)

Potassium Iodide Oral Syrup: 62.5 mg potassium iodide/mL (325 mg/5 mL) in pints and gallons; *Pima®*; (Rx)

Potassium Iodide Oral Tablets 65 mg and 130 mg; *Thyrosafe®*, *Iosat®*; (OTC)

There are also radioactive iodine compounds available for thyroid diagnostic and treatment.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Iohexol

(eye-oh-***hex***-ol) *Omnipaque®*

Contrast Agent

Prescriber Highlights

- ► Nonionic, iodinated contrast agent used in medical imaging and to estimate GFR
- ► Contraindications include prior hypersensitivity to iohexol or other iodine-based contrast agents.
- ► Some formulations are contraindicated for intrathecal use; select product for intrathecal use carefully.
- ► Use with caution in animals with renal or hepatic impairment, cardiovascular disease, pheochromocytoma, hyperthyroidism, monoclonal gammopathy, or a history of seizures.
- ► Adverse effects associated with intravascular use may include hypersensitivity and nephrotoxicity; oral use may cause nausea, vomiting, and diarrhea.
- ► Ensure animals are well hydrated prior to iohexol administration.

Uses/Indications

Iohexol, when used as a contrast agent, can be administered (depending on product and procedure) via intravascular (ie, arterial, venous), intrathecal, intracavitary, subcutaneous, or oral routes.

Iohexol can be used as a marker agent for calculating glomerular filtration rates (GFR),[1,2] although the technique requires inputting results from limited-sample iohexol testing into mathematical formulae that have been suggested for dogs[3,4] and cats.[5] Using iohexol clearance to estimate GFR may be useful for the diagnosis of chronic kidney disease (CKD) before the onset of azotemia and when other indicators of renal function (eg, creatinine, symmetric dimethylarginine [SDMA]) are borderline or inconclusive.[6] It may also be used to monitor progression of CKD, especially in those with sarcopenia for which serum creatinine measurements may not accurately reflect declines in GFR. Iohexol clearance tests may also help inform dosage adjustments for nephrotoxic drugs (eg, carboplatin, aminoglycosides).

Pharmacology/Actions

Iohexol is a near-ideal marker for measuring glomerular filtration rate and, thereby, renal function. Its protein binding is negligible; it is nearly 100% excreted unchanged in the urine within 24 hours and can be measured in plasma using a variety of assays.

When used as a radio-contrast agent, organic iodine is relatively radiopaque and can help define adjacent structures.

Iohexol has a lower osmolality when compared with conventional (ionic) radio-contrast agents and, in humans, has been associated with a lower incidence of adverse effects, such as pain, heat sensations, adverse hemodynamic changes, electrocardiographic changes, and endothelial and erythrocyte damage.

Pharmacokinetics

After intravascular administration, iohexol is rapidly distributed throughout the circulation. Protein binding is very low (less than 1%). Within 24 hours, nearly 100% of a dose is excreted in the urine in patients with normal renal function. In dogs, mean pharmacokinetic parameters reported include volume of distribution (Vdss), 221 mL/kg; clearance in dog: about 2.5 – 2.9 mL/kg/minute; mean residence time, 82 minutes; and elimination half-life, 75 minutes.[3,7] Mean clearances of iohexol in cats reported include 2.3 mL/kg/minute[8] and 2.75 mL/kg/minute.[7]

Iohexol has an elimination half-life of about 2 hours in humans.

Contraindications/Precautions/Warnings

Iohexol is contraindicated in patients with a prior hypersensitivity reaction to it.[9] Use with caution in patients with severe renal or hepatic impairment, severe cardiovascular disease, hyperthyroidism, monoclonal gammopathy, or pheochromocytoma.[9] In humans, patients with allergy-mediated disease (eg, asthma, food allergies) may be at increased risk for idiosyncratic reactions to iohexol. Caution is advised for administration in humans with a history of seizures. Use of contrast medium volumes greater than 8 mL and injection into the cerbellomedullary cistern should be avoided in large dogs undergoing myelography.[10,11]

Patients should be well hydrated prior to and following iohexol administration.

Adverse Effects

When used intravascularly, iohexol appears to be well tolerated in animals, but data are limited. In humans, iohexol is considered one of the least toxic contrast agents, rarely causing nephrotoxicity or hypersensitivity reactions. The oral products have been associated with diarrhea, nausea, and vomiting in humans; data are lacking in veterinary species. In dogs, it has been shown that seizures are more likely to be precipitated when large volumes (but not concentration[12]) of iohexol are administered, contrast agent is injected into the cerebellomedullary cistern, and in large breed dogs with cervical lesions.[11]

Reproductive/Nursing Safety

Iohexol use in laboratory animals has not impaired fertility or demonstrated evidence of fetal harm.[6]

Iohexol is distributed into milk in very low quantities, but no adverse effects have been seen in breastfeeding infants whose mothers received iohexol; iohexol is usually compatible with breastfeeding.[13]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The adverse effects of IV overdose can be serious and life-threatening and primarily affect the pulmonary and cardiovascular systems. Clinical signs can include cyanosis, bradycardia, acidosis, pulmonary hemorrhage, convulsions, coma, and cardiac arrest[9]; treatment is supportive.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving iohexol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, propranolol**): Concurrent use reduces the threshold for and increases the severity of contrast reactions. Use together cautiously.
- **CNS Stimulants** (eg, **caffeine**, **doxapram**): Concurrent use with iohexol (especially when used intrathecally) may increase the risk for lowering seizure threshold.
- **Iodine Isotopes**: Iohexol may alter binding to thyroid tissue for up to two weeks.
- **Metformin**: Injection of iodinated contrast materials in metformin-treated human patients has been associated with lactic acidosis and can lead to acute renal failure.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): Concurrent use with iohexol (especially when used intrathecally) may increase the risk for lowering seizure threshold.

- **Phenothiazines** (eg, **acepromazine, chlorpromazine**): Concurrent use with iohexol (especially when used intrathecally) may increase the risk for lowering seizure threshold.
- **QT Prolongation Drugs** (eg, **amiodarone, cisapride, procainamide, quinidine, sotalol**): Iohexol may cause additive prolongation of QT interval.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): Concurrent use with iohexol (especially when used intrathecally) may increase the risk for lowering seizure threshold.

Laboratory Considerations

- **Thyroid Function Tests**: If iodine-containing isotopes are to be used for diagnosing thyroid disease, prior use of iohexol can reduce the iodine-binding capacity of thyroid tissue for up to 2 weeks.[9] Thyroid function tests that do not depend on iodine estimation are not affected.

Dosages

NOTES:

1. Do not confuse dosages listed as mg/kg iohexol with mg/kg iodine content.
2. Iohexol concentrations of 180 mg/mL or 240 mg/mL are most commonly recommended. See ***Chemistry/Synonyms***.
3. Ensure animals are well hydrated prior to iohexol administration.

DOGS:

Estimating glomerular filtration rate (extra-label):

a) A study done in healthy dogs uses an iohexol solution containing 300 mg iodine/mL. Administered doses varied from 129 – 658 mg/kg of iohexol IV over ≈1 minute. Using the 2-sample method, samples were obtained at 2 and 3 hours postdose; with the 3-sample method, samples were obtained at 2, 3, and 4 hours postdose.[3]

b) Iohexol 64.7 mg/kg IV administered over 1 minute.[4] Samples were obtained for the 1-, 2-, or 3- sample method at 60, 90, and 180 minutes, respectively; samples were obtained for the 5-sample method at 5, 15, 60, 90, and 180 minutes.

c) In a study, dogs were administered iohexol at a dose of 90 mg iodine content/kg in nonazotemic animals and 45 mg iodine content/kg in azotemic animals IV. Three samples were drawn at 120, 180, and 240 minutes in non-azotemic animals; 120, 240, and 360 minutes in azotemic animals[7]

GI contrast agent (extra-label):

a) Suspected GI perforation: Using iohexol solution containing 240 mg iodine/mL administered at 700 – 875 mg iodine/kg PO; best administered via orogastric tube (dogs). Radiographs should be obtained immediately following administration of contrast material; additional sets of radiographs can be obtained at 15, 30, and 60 minutes.[14]

b) Dual-purpose contrast medium for radiography and ultrasonography: Using iohexol 647 mg/mL, iohexol 1.5 mL/kg combined with carboxymethylcellulose 0.5% 8.5 mL/kg and administered PO, provided radiographic contrast enhancement of the small intestines without interfering with ultrasonographic assessment of the small intestines.[15]

CATS

Estimating GFR (extra-label):

a) Using a 3-sample method to estimate iohexol clearance: In the study, animals were administered iohexol at a dose of 90 mg iodine content/kg in non-azotemic animals and 45 mg iodine content/kg in azotemic animals IV. Three samples were drawn (at 120, 180, and 240 minutes in non-azotemic animals; 120, 240, and 360 minutes in azotemic animals).[16]

b) 647 mg/kg iohexol IV followed by 1 mL of saline (0.9% NaCl) solution administered to 20 healthy adult and geriatric cats, and a formula for correcting slope-intercept plasma iohexol clearance to estimate GFR was derived.[5]

Contrast agent for patients with suspected GI perforation (extra-label): The recommended dose is a 1:3 dilution of iohexol 240 at 10 mL/kg of body weight; best administered via nasogastric/nasoesophogeal tube. Radiographs should be obtained immediately following the administration of contrast material; additional sets of radiographs can be obtained at 15, 30, and 60 minutes.[14]

HORSES

Estimating GFR (extra-label): 75.5 mg/kg iohexol IV rapid bolus over 1 minute, with plasma iohexol samples measured at 5, 30, and 90 minutes after administration[17]

BIRDS:

Contrast agent (extra-label):

a) 2 – 3 mL/kg IV over 3 to 5 seconds[18,19]

b) In mid-size psittacines using iohexol 240, administer 25 – 30 mL/kg into the crop; solution may be diluted 1:1 with water.[20]

Intestinal permeability (extra-label): 1 mL/kg PO using iohexol 755 mg/mL solution; plasma iohexol concentration was measured 45, 90, and 180 minutes after administration.[21]

RABBITS:

Contrast agent (extra-label): 64.7 mg/kg iohexol (0.1 mL/kg using 300 mg/mL organic iodine) IV rapid bolus over 1 minute[22]

REPTILES

Estimating GFR in green iguanas (extra-label): 75 mg/kg iohexol given IV[23]; blood samples to measure plasma iohexol concentrations are collected at 4, 8, and 24 hours postinjection.

Monitoring

- No specific monitoring outside of adverse effects and hypersensitivity reactions

Client Information

- Only veterinarians administer this medication.
- Patients should be well hydrated prior to and following iohexol administration.

Chemistry/Synonyms

Iohexol is a nonionic iodinated contrast agent that occurs as a white to off-white, hygroscopic, odorless powder; it is very soluble in water and methyl alcohol; it is practically insoluble or insoluble in chloroform and ether. Commercial products list the concentration of the product as organic iodine concentration per mL. For example, *Omnipaque® 180* contains iohexol 288 mg/mL, equivalent to 180 mg/mL of organic iodine content. Iohexol's molecular weight is 821 g/mol. Physical properties of iohexol injection include:

Concentration (mg/mL) organic iodine	Osmolality (mOsm/kg H_2O)	Viscosity (cp) @20°C (68°F)	Viscosity (cp) @37°C (98.6°F)	Specific gravity (g/mL) @37°C (98.6°F)
180	408	3.1	2	1.209
210	460	4.2	2.5	1.244
240	520	5.8	3.4	1.280
300	672	11.8	6.3	1.349
350	844	20.4	10.4	1.406

Iohexol may also be known as WIN-39424, iohexolum, ioheksoli, or ioheksolis. A common trade name is *Omnipaque®*.

Storage/Stability
Store iohexol at room temperature (20-25°C [68-77°F]); excursions permitted between 15°C and 30°C (59°F-86°F). Protect from light; do not freeze. Product may be stored in a contrast media warmer for up to one month at 36° to 38°C (96.8° to 100.4°F).

Compatibility/Compounding Considerations
Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Depending on the concentration, the following drugs are reported **compatible** with iohexol: ampicillin, chloramphenicol sodium succinate, cimetidine, diazepam, diphenhydramine, epinephrine, gentamicin, heparin, hydrocortisone sodium succinate, lidocaine, methylprednisolone sodium succinate, nitroglycerin, protamine, and vasopressin.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Iohexol Injection (preservative-free; concentrations are listed as organic iodine content per mL): 140 mg/mL, 180 mg/mL, 240 mg/mL, 300 mg/mL, and 350 mg/mL in 10 mL, 20 mL, 30 mL, 50 mL, 75 mL, 100 mL, 125 mL, 150 mL, 200 mL, and 500 mL vials or bottles (depending on concentration); *Omnipaque*®; (Rx).

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Ipratropium
(eye-prah-***troh***-pee-um) *Atrovent*®
Inhaled Antimuscarinic

Prescriber Highlights
- ► Inhaled antimuscarinic agent for adjunctive treatment of bronchoconstrictive conditions
- ► Contraindications include hypersensitivity to it or other atropine derivatives.
- ► Use caution in animals with narrow-angle glaucoma, bladder neck obstruction, or prostatic hypertrophy.
- ► Little information available for use in veterinary species
- ► Likely safe; because medication is inhaled, systemic absorption is minimal.
- ► May need to be administered quite often; duration of activity is relatively short.

Uses/Indications
Locally administered (inhaled) ipratropium bromide can be used for the adjunctive treatment of bronchospastic conditions (recurrent airway obstruction [RAO]; heaves). Although ipratropium has been shown to have bronchodilatory effects in experimentally induced bronchoconstriction in cats[1–3] and may prove beneficial for the short-term treatment of bronchospasm, additional research is required to determine its role for clinical use. A combination of ipratropium and albuterol (salbutamol) had greater bronchodilatory effects than ipratropium alone.[2,4]

Ipratropium had little or no effect on exercise capacity in healthy horses or horses with equine asthma.[5,6]

Pharmacology/Actions
Ipratropium inhibits vagally mediated reflexes by antagonizing acetylcholine. Increases in intracellular concentrations of cyclic guanosine monophosphate (cyclic GMP) secondary to acetylcholine are prevented, thereby reducing bronchial smooth muscle constriction. Unlike atropine, ipratropium does not reduce mucociliary clearance.

Pharmacokinetics
Because the medication is inhaled, minimal drug is absorbed in the systemic circulation. In humans, elimination half-life is about 2 hours. In healthy cats, with experimentally induced bronchospasm, inhaled (nebulized) ipratropium gave maximal efficacy for about 4 hours. When combined with albuterol (salbutamol), increased efficacy resulted.[3] In horses, onset of action is ≈30 minutes and duration of effect is ≈4 to 6 hours.

Contraindications/Precautions/Warnings
Ipratropium is contraindicated in patients that are hypersensitive to it or other atropine derivatives.

It should be used with caution in other conditions where antimuscarinics may be harmful, including narrow-angle glaucoma, bladder-neck obstruction, or prostatic hypertrophy.

Adverse Effects
Adverse effects are unlikely to be significant. Tracheal or bronchial irritation (coughing) has been reported on occasion. Allergic responses are possible, and some patients develop systemic anticholinergic effects.

Reproductive/Nursing Safety
Large oral dosages in laboratory animals did not cause teratogenic effects.

Ipratropium is likely to be safe to use during nursing.

Overdose/Acute Toxicity
Overdose is unlikely to be a cause for concern. The drug is not well absorbed orally or after inhalation and oral LD_{50} values for laboratory animals were greater than 1 g/kg.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions
The following drug interactions have either been reported or are theoretical in humans or animals receiving ipratropium and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.
- **Anticholinergic Drugs** (eg, **atropine**): May cause additive antimuscarinic effects
- **Beta-Adrenergic Agonists** (eg, **albuterol**): May have additive therapeutic effects[2,4]

Laboratory Considerations
- No specific concerns were noted.

Dosages
HORSES:

Adjunctive treatment of RAO, heaves (mild to moderate disease) (extra-label): For adult horses, most recommend 180 µg aerosol per horse (NOT µg/kg) inhaled via an equine specific mask every 6 hours (range every 4 to 8 hours). A study in 6 adult horses with heaves were given ipratropium 0.3 mg (300 µg) per horse (NOT µg/kg) via inhalation. Results indicated that some indices of airway function were improved for between 6 to 24 hours after ipratropium administration; however, clinical scores for breathing effort were not clinically significant.[7]

Severe bronchospasm in foals with pneumonia (extra-label): 2 – 3 µg/kg via aerosol every 6 to 8 hours in addition to inhaled albuterol[8]

SMALL MAMMALS:

Bronchodilator in rats (extra-label): One puff (17 µg/puff) into nebulization chamber twice daily[9]

Monitoring

- Clinical efficacy

Client Information

- If using the aerosol metered dose inhalers, do not use after dose indication reaches 0, even if there appears to be medication remaining; active ingredient cannot be assured; do not shake the canister before using.
- Normally given as an aerosol into the lungs, often with other drugs, to help your animal breathe better. Special masks for dogs, cats, and horses are usually used.
- Ipratropium is usually safe but irritation of the throat and lungs can occur.
- No need to shake aerosol before each use. Prime (2 sprays) before first using or if not used in past 3 days.
- Do not store aerosol canister in hot places or dispose of it by burning it.

Chemistry/Synonyms

Ipratropium bromide has a quaternary ammonium structure and occurs as a white or almost white crystalline powder. It is soluble in water and slightly soluble in alcohol. The pH of a 1% solution is between 5 to 7.5.

Ipratropium bromide may also be known as Sch-1000; many trade names are available including *Atrovent®*.

Storage/Stability

The solution for inhalation should be stored at room temperature and protected from light. Keep in foil pouch until time of use. The metered dose inhalers should be stored at room temperature.

Compatibility/Compounding Considerations

The solution for nebulization may be mixed with albuterol or metaproterenol if used within 1 hour.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Ipratropium Bromide Solution for Inhalation: 0.02% (500 µg/vial) preservative free in 25, 30, and 60 unit-dose vials (2.5 mL UD "nebs"); generic; (Rx)

Ipratropium Bromide Aerosol for Inhalation: each actuation delivers 17 µg from the mouthpiece in 12.9 g metered dose inhaler w/mouthpiece (approx. 200 inhalations); *Atrovent® HFA*; (Rx)

Available in combination with albuterol for nebulization (*DuoNeb®*; Rx), and as a metered dose inhaler (*Combivent®* HFA; Rx)

Nasal sprays also are available.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Irbesartan

(ihr-beh-***sar***-tan) *Avapro®*

Angiotensin-II Receptor Blocker (ARB)

Prescriber Highlights

- ► May be useful in the treatment of dogs and cats with hypertension secondary to renal disease
- ► Limited experience in veterinary medicine
- ► Contraindicated for use during pregnancy
- ► Adverse effect profile is not established in dogs and cats, but GI effects, somnolence, hypotension, or activity changes are possible based on adverse effects in humans.

Uses/Indications

Irbesartan may be useful in dogs and cats for the treatment of hypertension associated with renal insufficiency or for proteinuria associated with glomerular disease in combination with an ACE inhibitor; however, experience in veterinary medicine is limited. It may be effective in the adjunctive treatment of heart failure when dogs are unable to tolerate ACE inhibitors, but documentation for this use is lacking. One study, using high irbesartan dosages (60 mg/kg PO twice daily) in dogs with subacute mitral regurgitation, demonstrated no improvement in left ventricular function or prevention of left ventricular remodeling.[1] An experimental study in cats showed that irbesartan at 2 mg/kg, 6 mg/kg, or 10 mg/kg significantly reduced blood pressure associated with exogenously administered angiotensin at 90 minutes.[2]

Pharmacology/Actions

Irbesartan is an angiotensin-II receptor blocker (ARB). By selectively blocking the AT_1-receptor, aldosterone synthesis and secretion is reduced causing vasodilation, decreased potassium excretion, and increased sodium excretion. Although plasma concentrations of renin and angiotensin-II are increased, this does not counteract the blood pressure lowering effects of irbesartan. Irbesartan does not interfere with substance P or bradykinin responses.

Unlike losartan, another ARB, irbesartan does not need to be converted to an active metabolite.

Pharmacokinetics

After single 30 mg/kg oral doses of irbesartan in dogs with experimentally induced renal hypertension, peak concentrations occurred between 3 and 4 hours and elimination half-life was ≈9 hours. After 30 mg/kg doses PO once daily for 8 days, the elimination half-life was ≈21 hours.[3]

A pharmacokinetic/pharmacodynamic study in healthy beagles concluded that irbesartan 5 mg/kg is more appropriate than 2 mg/kg to obtain a hypotensive effect in beagles, but further studies are needed.[4]

In humans, absorption is rapid and bioavailability ranges from 60% to 80%.[5] Peak concentrations occur in ≈1.5 to 2 hours. Bioavailability is not altered by the presence of food. The drug is 90% bound to plasma proteins and weakly crosses the blood–brain barrier and placenta in small quantities. Irbesartan is metabolized in the liver via glucuronidation and oxidation; metabolites are not active. Both metabolites and unchanged drug are eliminated primarily in the feces and, to a lesser extent, urine. Terminal elimination half-life ranges from 11 to 15 hours. Dosages do not need to be adjusted in patients with renal dysfunction.

Contraindications/Precautions/Warnings

Patients that are volume- or sodium-depleted should have these corrected before starting therapy.[5] Do not use in hypotensive patients or patients hypersensitive to it. It should not be used during pregnancy (see ***Reproductive/Nursing Safety***).

Adverse Effects

Adverse effect profiles for dogs and cats are not known due to its limited veterinary use. In humans, the most commonly reported adverse effects include diarrhea, dyspepsia, fatigue, orthostatic dizziness, and hypotension.[5]

Reproductive/Nursing Safety

Irbesartan is not safe to use during pregnancy.[5] Studies in pregnant rats given high doses demonstrated a variety of fetal abnormalities (renal pelvic cavitation, hydroureter, absence of renal papilla). Smaller doses in rabbits caused increased maternal death and spontaneous abortion. In humans, the drug is considered teratogenic, particularly during the second and third trimesters.

Because small amounts of irbesartan have been detected in rat milk and there is significant concern about the safety of the drug in neonates, it is not recommended for use in nursing women.

Overdose/Acute Toxicity

Rats and mice survived acute oral overdoses in excess of 2000 mg/kg.[5] Likely effects seen in an overdose situation include hypotension and either bradycardia or tachycardia; treatment is supportive.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving irbesartan and potentially could be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**): Increased risk for adverse effects (eg, hypotension, hyperkalemia, renal function changes); increased monitoring may be warranted. Combination is not recommended in humans.[5,6]
- **Aspirin**: Possible reduced antihypertensive effect of irbesartan and increased risk for renal impairment; increased monitoring may be warranted
- **Baclofen**: Concurrent use may have additive blood pressure lowering effects.
- **Benzodiazepines** (eg, **diazepam, lorazepam**): Concurrent use may increase risk for hypotension.
- **Buspirone**: Concurrent use may increase risk for hypotension.
- **Cabergoline**: Concurrent use may increase risk for hypotension.
- **Corticosteroids** (eg, **betamethasone, dexamethasone**): May decrease the antihypertensive effects of ARBs
- **Dexmedetomidine**: Concurrent use may result in additive effects on blood pressure and heart rate.
- **Diazoxide**: Concurrent use may increase risk for hypotension.
- **Dichlorphenamide**: Concurrent use may increase risk for hypotension.
- **Digoxin**: Concurrent use may increase digoxin concentrations. Closely monitor digoxin concentrations and therapeutic effects.
- **Diphenhydramine**: Concurrent use may increase risk for hypotension.
- **Doxepin**: Concurrent use may increase risk for hypotension.
- **Fluconazole**: Concurrent use may increase the concentration of irbesartan. Other azole antifungals (eg, itraconazole, ketoconazole) do not appear to have this effect.
- **Insulin**: Concurrent use may increase risk for hypoglycemia.
- **Lithium**: Concurrent use may increase risk for lithium toxicity.
- **Low Molecular Weight Heparins** (eg, **dalteparin, enoxaparin**): Concurrent use may increase risk for hyperkalemia.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam**): Possible reduced antihypertensive effects of irbesartan and increased risk for renal impairment; increased monitoring may be warranted
- **Opioids** (eg, **buprenorphine, butorphanol**): Concurrent use may increase risk for hypotension.
- **Potassium Preparations**: Increased risk for hyperkalemia; increased monitoring of serum potassium may be warranted.
- **Potassium–Sparing Diuretics** (eg, **spironolactone**): Increased risk for hyperkalemia; increased monitoring of serum potassium may be warranted.
- **Yohimbine**: Concurrent use may decrease the efficacy of ARBs.

Laboratory Considerations

- No specific concerns noted

Dosages

DOGS/CATS:

Hypertension, proteinuria, and heart failure (extra-label): 5 mg/kg PO every 12 to 24 hours has been recommended anecdotally for dogs. Dosages for cats are still mostly unknown although the drug does seem to have efficacy for angiotensin-induced hypertension.[2]

Monitoring

- Blood pressure, heart rate
- Baseline and periodic serum electrolytes, BUN, and creatinine
- Adverse effects, possibly including GI effects, somnolence, or activity changes

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give it with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Because this medicine has not been used often in dogs or cats, watch carefully for any side effects and report them to your veterinarian. Possible side effects include diarrhea, vomiting, lack of appetite, fatigue (tiredness), and low blood pressure. Signs of low blood pressure may include fainting, muscle weakness, or exercise intolerance.
- This medicine has caused birth defects and should not be used in pregnant animals. Pregnant women should wear disposable gloves when handling and wash hands after administering this medication.

Chemistry/Synonyms

Irbesartan is a nonpeptide angiotensin-II antagonist and occurs as a white to off-white, crystalline powder. It is practically insoluble in water and slightly soluble in alcohol.

Irbesartan may also be known as BMS 186295, SR 47436, Irbesartanum, *Aprovel®*, *Arbit®*, *Avalide®*, *Avapro®*, *Cavapro®*, *Coaproval®*, *Ecard®*, *Ibsan®*, *Irban®*, *Irbes®*, *Iretensa®*, *Irovel®*, *Irvell®*, *Isart®*, and *Karvea®*.

Storage/Stability

Irbesartan tablets should be stored at room temperature (15°C-30°C [59°F-86°F]).

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Irbesartan Tablets: 75 mg, 150 mg, and 300 mg; *Avapro*®, generic; (Rx)

Irbesartan 150 mg with Hydrochlorothiazide 12.5 mg tablets and Irbesartan 300 mg with Hydrochlorothiazide 12.5 mg or 25 mg tablets; *Avalide*®, generic; (Rx)

Irbesartan is also available in fixed dose combinations with hydrochlorothiazide.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Iron Dextran

(***eye***-urn ***dex***-tran)

Iron preparation; Hematinic

Prescriber Highlights

- ► Iron supplement that may be used alone or with hematopoietic agents in small animals
- ► Contraindications include known hypersensitivity to iron dextran, and the presence of any anemia other than iron deficiency anemia.
- ► Use with caution in patients with significant hepatic impairment, during the acute phase of infectious kidney disease, or in conjunction with oral iron supplements.
- ► Adverse effects include pain with IM injection, prostration, muscular weakness, and anaphylactic-type reactions.
- ► Do not give IV or SC.
- ► High doses may cause increased incidences of teratogenicity and embryotoxicity.
- ► Piglets born from vitamin E- or selenium-deficient sows may demonstrate nausea, vomiting, and sudden death within 1 hour of injection.
- ► IM use in pigs beyond 4 weeks of age may cause muscle tissue staining.

Uses/Indications

Iron dextran is used in the treatment and prophylaxis of iron deficiency anemia, primarily in neonatal food-producing animals. It is also administered when dogs or cats receive erythropoiesis-stimulating agents, such as epoetin (EPO) or darbepoetin (DPO).

Pharmacology/Actions

Iron is necessary for myoglobin and hemoglobin in the transport and utilization of oxygen. During iron deficient states, iron supplementation restores total body iron and hemoglobin concentrations to improve clinical signs associated with the deficiency; however, it does not stimulate erythropoiesis or correct hemoglobin abnormalities.

Ionized iron is a component of the cytochrome oxidase, succinic dehydrogenase, and xanthine oxidase enzymes.

Pharmacokinetics

After IM injection, iron dextran is slowly absorbed primarily via the lymphatic system. About 60% of the iron is absorbed within 3 days of injection, and up to 90% of the dose is absorbed after 1 to 3 weeks; the remaining iron may be absorbed slowly over several months.

After absorption, the reticuloendothelial cells of the liver, spleen, and bone marrow gradually clear the iron from plasma. The dextran component is cleaved and then metabolized or excreted, and the iron component is made available to form hemosiderin, ferritin, or transferrin.

Iron is not readily eliminated from the body. Iron liberated by the destruction of hemoglobin is reused by the body, and only small amounts are lost by the body via hair and nail growth, normal skin desquamation, and GI tract sloughing. Accumulation and potential iron overload can occur with repeated dosing as only trace amounts of iron are eliminated in the feces, bile, or urine.

Contraindications/Precautions/Warnings

Iron dextran is contraindicated in patients with known hypersensitivity to it or with any anemia other than iron deficiency anemia. In humans, it is recommended to not use iron dextran in patients in the acute phase of pyelonephritis. Use with caution in patients with significant hepatic impairment or evidence of iron overload. Patients with significant allergies and/or asthma may be at higher risk for hypersensitivity reactions.[1] Parenteral iron supplementation should not be used concurrently with oral iron supplements.

Iron dextran should only be administered IM; do not administer SC (poor absorption). While IV administration is performed in human patients, safe use of iron dextran IV has not been documented in veterinary patients.

Observe the patient after dosing as rarely anaphylactic-type reactions can occur. See ***Monitoring***.

Adverse Effects

Prostration and muscular weakness may occasionally occur in pigs after iron dextran injection. Iron dextran used in pigs born from vitamin E- or selenium-deficient sows may demonstrate nausea, vomiting, and sudden death within 1 hour of injection. Iron dextran injected IM in pigs beyond 4 weeks of age may cause muscle tissue staining.

Pain on IM injection can occur.[1] Anaphylactic-type reactions (that may result in death) are rare but can occur. Chronic overdoses can cause iron overload and hemosiderosis.

Repeated IM doses (large or small) in the same injection site have been associated with the development of sarcomas in laboratory animals (eg, rabbits, mice, rats, hamsters).[1]

Reproductive/Nursing Safety

Iron crosses the placenta but in what form is unknown. High doses (≈3 times the recommended human dose) may cause increased incidences of teratogenicity and embryotoxicity.[1] Traces of unmetabolized iron dextran are excreted in milk.[1]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose of iron dextran is unlikely to cause acute manifestations; however, it may lead to hemosiderosis.[1] Chelation therapy may be required depending on the extent of the overdose. See ***Deferoxamine***. Iron dextran is not dialyzable.[2]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving iron and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and

perform additional monitoring when appropriate.

- **Angiotensin-Converting Enzyme Inhibitors (ACEIs**; eg, **benazepril**, **enalapril**): In humans, concurrent use of ACE Inhibitors may increase the risk for anaphylactic-type reactions[1]; veterinary significance is uncertain.
- **Chloramphenicol**: Because chloramphenicol may delay the response to iron administration, avoid using it in patients with iron deficiency anemia.
- **Dimercaprol (BAL)**: Concurrent use may increase the risk for nephrotoxicity.
- **Mycophenolate**: Concurrent use may result in decreased efficacy of mycophenolate mofetil.

Laboratory Considerations

- Large doses of injectable iron may discolor the serum to brown and result in falsely elevated **serum bilirubin** values and falsely decreased **serum calcium** values.
- After large doses of iron dextran, **serum iron** values may not be meaningful for up to 3 weeks.

Dosages

DOGS:

Iron supplementation in association with erythropoiesis-stimulating agents (EPO, DPO; extra-label): 10-20 mg/kg IM,[3] to a maximum of 300 mg/dog, at the time EPO or DPO therapy is initiated; generally, no more than once monthly administration is needed.

Iron deficiency anemia: 10 – 20 mg/kg once IM.[3–5] Iron dextran may be repeated at weekly intervals or administered once and followed by oral therapy with ferrous sulfate (see ***Ferrous Sulfate***).[4,6]

CATS:

Iron supplementation in association with erythropoiesis-stimulating agents (EPO, DPO; extra-label): At the time EPO or DPO therapy is initiated, most recommend a single injection of 50 mg/cat (NOT mg/kg) IM[5,7,8] (≈10 mg/kg); generally, no more than once monthly administration is needed.

Prevention of transient neonatal iron deficiency anemia (extra-label): 50 mg/kitten (NOT mg/kg) IM at 18 days of age[6]

Iron deficiency anemia: 50 mg/cat (NOT mg/kg) IM every 3 to 4 weeks[3]

SWINE:

Prevention or treatment of iron deficiency anemia in baby pigs; (label dosage; FDA-approved):

- Using 100 mg of elemental iron/mL solution: 100 mg/piglet (NOT mg/kg) IM at 2 to 4 days of age[9]; inject into the back of the ham. For treatment of iron deficiency anemia, dose may be repeated in ≈10 days.[9]
- Using 200 mg of elemental iron/mL solution: 200 mg/piglet (NOT mg/kg) IM at 1 to 3 days of age; inject into the back of the ham to a depth of at least ½ inch. For treatment of iron deficiency anemia, administer 200 mg/piglet (NOT mg/kg) IM at the first signs of anemia.[10]

BIRDS:

Iron deficiency anemia or following hemorrhage (extra-label): 10 mg/kg IM; repeat in 7 to 10 days if indicated[11]

FERRETS:

Iron deficiency anemia (extra-label): 10 mg/kg IM once weekly[12]

Monitoring

- Baseline and periodic CBC including RBC indices (eg, MCV, MCHC). **NOTE**: RBC indices may take months to normalize.[4]
- Serum iron parameters (eg, ferritin) can be measured to monitor and approximate total body iron concentrations.[4]
- Adverse reactions

Client Information

- In small animal species (eg, dogs, cats), veterinarians administer iron dextran.
- In pigs, inject into the muscle to a depth of at least ½ inch in the back of the ham.
  - Use of this product beyond 4 weeks of age may result in staining of the ham muscle.
  - Disinfect vial stopper prior to use.

Chemistry/Synonyms

Iron dextran is a complex of ferric oxyhydroxide and low molecular weight partially hydrolyzed dextran derivative. The commercially available injection occurs as a dark brown, slightly viscous liquid that is completely miscible with water or normal saline and has a pH of 5.2 to 6.5.

Iron dextran may also be known as iron-dextran complex, *Cosmofer®*, *DexFerrum®*, *Dexiron®*, *Driken®*, *Fercayl®*, *Ferrocel®*, *Ferroin®*, *Ferrum Hausmann®*, *Fexiron®*, *Imferdex®*, *Imferon®*, *InFeD®*, *Uniferon®*, and *Infufer®*.

Storage/Stability

Store iron dextran injection at room temperature (15°C to 30°C [59°F-86°F]); avoid freezing. Discard vials 60 days after first use. The maximum allowable number of vial punctures varies by product and manufacturer -- consult product label.

Compatibility/Compounding Considerations

Iron dextran injection is reportedly physically **incompatible** when mixed with oxytetracycline HCl and sulfadiazine sodium.

Dosage Forms/Regulatory Status/Withdrawal Times

VETERINARY-LABELED PRODUCTS:

Iron Dextran Injection: 100 mg of elemental iron/mL in 100 mL vials and 200 mg of elemental iron/mL in 100 mL or 250 mL vials; *Uniferon®*, generic; (OTC). FDA-approved for use in swine; NADA #106-772 (100 mg/mL), 134-708 (200 mg/mL). No slaughter withdrawal time required.

HUMAN-LABELED PRODUCTS:

Iron Dextran Injection: 50 mg of elemental iron/mL (as dextran) in 2 mL single-dose vials; *InFeD®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Isoflupredone

(eye-so-***floo***-preh-dohn) *Predef 2X®*

Injectable Glucocorticoid

For topical or otic use of isoflupredone, see ***Isoflupredone, Topical*** and ***Corticosteroid/Antimicrobial Preparations***

Prescriber Highlights

► Injectable glucocorticoid labeled for use in horses, cattle, and swine for anti-inflammatory and immunosuppressive effects
► Less likely to cause early parturition than dexamethasone or betamethasone, but avoid use in pregnancy
► May have mineralocorticoid effects in horses and cattle; hypokalemia has been noted

Uses/Indications

Isoflupredone acetate is a potent glucocorticoid and, like other glucocorticoids, can be used for its anti-inflammatory or immunosuppressive effects. Labeled indications for isoflupredone include ad-

junctive treatment of bovine ketosis, alleviating pain and lameness associated with musculoskeletal conditions, acute hypersensitivity reactions, adjunctive treatment of overwhelming infections with severe toxicity (eg, critical pneumonia, peritonitis, endometritis, septic mastitis), shock, supportive therapy in the treatment of stress conditions (eg, surgery), dystocia, retained placenta, inflammatory ocular conditions, snakebite, and parturient paresis.

A study evaluating the effects of isoflupredone in dairy cows, with or without insulin (ultralente 100 units), on energy metabolism, milk production, and overall health during the early lactation phase showed that isoflupredone, with or without insulin, *offered no metabolic, production, or reproductive benefits in lactating dairy cattle.*[1] A study evaluating oxytetracycline, with or without isoflupredone acetate, for treating experimentally induced bronchopneumonia in heifers found that only animals receiving the combination prevented a reduction in dry matter intake and average daily gain (ADG).[2] However, the author of that study has subsequently stated that *Based on the existing literature, it is currently still not possible to fully determine* whether corticosteroids have *a clinical application in managing BRD. Differences in treatment outcomes between the limited corticosteroids that have been studied thus far may reflect the method used for BRD diagnosis in the feedlot setting, timing of medical intervention with respect to onset of infection, involvement of multiple respiratory pathogens in naturally occurring respiratory disease, or simply effects specific to the corticosteroids used.*[3]

In horses, isoflupredone has been used parenterally to reduce inflammation associated with recurrent airway obstruction (RAO; eg, heaves, COPD) as well as intra-articularly for treatment of joint inflammation.

Although the drug could be used in small animals, it is recommended to instead use other more common glucocorticoid agents that are FDA-approved for use in dogs and cats.

Pharmacology/Actions

Isoflupredone's anti-inflammatory potency is ≈17 times that of hydrocortisone (cortisol). The label states that the glucocorticoid activity of isoflupredone is 50 times that of hydrocortisone and 10 times that of prednisolone as measured by liver glycogen deposition in rats. Isoflupredone reportedly has some mineralocorticoid effects and can cause hypokalemia.

For more information on the pharmacologic actions associated with glucocorticoids, see ***Glucocorticoid Agents, General Information***.

Pharmacokinetics

No specific pharmacokinetic values were located. The manufacturer states that gluconeogenic activity persists for 48 hours after dosing in cattle.

Contraindications/Precautions/Warnings

Systemic use of glucocorticoids is generally considered contraindicated in systemic fungal infections (unless used for replacement therapy in patients with hyperadrenocorticism), when administered IM in patients with idiopathic thrombocytopenia, and in patients that are hypersensitive to a particular compound. Because of their ulcerogenic potential, glucocorticoids should be used with extreme caution in patients with active GI ulcers or those susceptible to them. Use this medicine cautiously in patients with diabetes mellitus.

Because isoflupredone can cause hypokalemia, it should not be used in downer cows or animals susceptible to the effects of hypokalemia.

Long-term use in young, growing animals must be undertaken cautiously, as decreased growth may occur.

Adverse Effects

Adverse effects are generally associated with long-term administration of glucocorticoids, particularly if given at higher dosages; these effects generally manifest as signs of hyperadrenocorticism. The drug can cause hypokalemia in dairy cattle, even from a single dose.[4,5] Potential adverse effects include reduced milk production, hypokalemia, delayed wound healing, GI ulceration, increased infection rates, diabetes mellitus exacerbation/hyperglycemia, pancreatitis, hepatopathy, renal dysfunction, osteoporosis, laminitis (horses), hypothyroidism, and hyperlipidemia. When administered to young, growing animals, glucocorticoids can delay growth.

Reproductive/Nursing Safety

Avoid using isoflupredone during pregnancy. Glucocorticoids can induce abortion or early parturition in the later stages of pregnancy; most commonly seen in ruminants. Although isoflupredone (like hydrocortisone, prednisolone, and triamcinolone) appears to have a much lower abortifacient potential than glucocorticoids such as dexamethasone, betamethasone, or flumethasone, it may induce premature parturition with retained placenta, and its use should generally be avoided during the later stages of pregnancy.

Glucocorticoids used during the first trimester have been linked to a variety of teratogenic effects in dogs and laboratory animals.[6]

Glucocorticoid administration may reduce milk production. Glucocorticoids unbound to plasma proteins will enter milk. High dosages or prolonged administration to mothers may potentially inhibit the growth of nursing newborns.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

A single overdose of isoflupredone is unlikely to cause harmful effects. If clinical signs require intervention, use supportive treatment.

Long-term use of glucocorticoids can lead to serious adverse effects, which mainly manifest as signs of hyperadrenocorticism. Refer to ***Adverse Effects*** for additional details.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving isoflupredone or other glucocorticoids and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Digitalis glycosides** (eg, **digoxin**): Increased chance of digitalis toxicosis may occur should hypokalemia develop; diligent monitoring of potassium and digitalis glycoside concentrations is recommended.
- **Fluoroquinolone Antibiotics** (eg, **enrofloxacin, marbofloxacin**): Concurrent use with glucocorticoids may result in an increased risk for tendon rupture.
- **Insulin**: Insulin requirements may increase in patients receiving glucocorticoids.
- **Potassium-depleting Diuretics** (eg, **furosemide, thiazides**): Concomitant use may cause hypokalemia.
- **Salicylates**: Glucocorticoids may reduce salicylate blood concentrations.
- **Ulcerogenic Drugs** (eg, **NSAIDs**): Glucocorticoids may increase the risk for GI ulceration when given concomitantly.

- **Vaccines, Toxoids, Bacterins**: A diminished immune response may occur after vaccine, toxoid, or bacterin administration; patients receiving glucocorticoids at immunosuppressive dosages should generally not receive live attenuated-virus vaccines, as virus replication may be augmented.

Laboratory Considerations

- Glucocorticoids may increase **serum cholesterol**, and **serum** and **urine glucose** concentrations.
- Isoflupredone may decrease **serum potassium** concentration**.**
- Glucocorticoids can suppress the release of thyroid-stimulating hormone (TSH) and reduce $\mathbf{T_3}$ and $\mathbf{T_4}$ values; thyroid gland atrophy has been reported after long-term glucocorticoid administration.
- Reactions to **skin tests** may be suppressed by glucocorticoids.
- Glucocorticoids may cause false negative results of the **nitroblue tetrazolium test** for systemic bacterial infections.

Dosages

HORSES:

Labeled indications (label dosage; FDA-approved):

a. Systemic administration: 5 – 20 mg/horse (NOT mg/kg) IM, repeated as necessary[6]

b. Administration into joint cavity, tendon sheath or bursa: 5 – 20 mg or more (total dose, NOT mg/kg) depending on the size of the joint cavity.[6] Do not use in horses that are intended for human consumption.

Intra-articular administration (extra-label): 4 – 20 mg/joint (NOT mg/kg); has a short to medium duration of action[7]

Recurrent airway obstruction (RAO) (extra-label): In the study, 0.03 mg/kg IM once daily was used.[8] Patients were treated for 14 days; significant decreases in serum potassium concentration occurred.

CATTLE:

Labeled systemic indications (label dosage; FDA-approved): 10 – 20 mg/cow (NOT mg/kg) IM, according to the body size of the animal and severity of the condition. The dose may be repeated in 12 to 24 hours if indicated. See ***Compatibility/Compounding Considerations***.

SWINE:

Labeled systemic indications (label dosage; FDA-approved): 5 mg/136 kg (300 lb) pig (NOT mg/kg) IM.[6] Adjust dose proportionally for a smaller or larger animal.

Monitoring

- Single injections may not require monitoring beyond observation of the patient for efficacy and adverse effects but consider evaluating serum potassium concentration.
- Ongoing use requires enhanced monitoring including renal value and liver enzyme testing, CBC, blood glucose, and serum electrolytes.
- ACTH stimulation tests may be indicated to determine extent of HPA axis suppression.
- Consider thyroid hormone monitoring if use is prolonged or patient exhibits signs associated with thyroid hormone deficiency.

Client Information

- If this medication is used in dairy cattle, warn producer that milk production may be affected.
- If owners are to administer the medication, caution them to only administer as their veterinarian directs.
- Side effects become more likely the longer it is used and when given at higher dosages.

Chemistry/Synonyms

Isoflupredone acetate is a fluorinated synthetic corticosteroid with a molecular weight of 420.5. The commercial injection is in an aqueous suspension that also contains sodium citrate, polyethylene glycol 3350, and povidone.

Isoflupredone acetate may also be known as U-6013, 9-alpha-fluoroprednisolone acetate, and *Predef 2x®*.

Storage/Stability

The injection should be stored at controlled room temperature (20°C-25°C [68°F-77°F]).

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Isoflupredone suspensions are **incompatible** with calcium-containing solutions (eg, lactated Ringer's solution).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

Isoflupredone acetate 2 mg/mL aqueous suspension for injection in 100 mL vials; *Predef 2x®*; (Rx). In the United States, *Predef 2x®* is FDA-approved for use in cattle, horses, and swine.

Meat withdrawal time is 7 days; it is not to be used in calves to be processed for veal. A withdrawal period has not been established for this product in preruminating calves. There is no milk withdrawal time for isoflupredone in the United States, but in Canada a 72-hour withdrawal time is specified.

Isoflupredone is also found in some topical and otic products. For more information see ***Isoflupredone, Topical*** and ***Corticosteroid/Antimicrobial Preparations***.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Isoflurane

(eye-soe-***flure***-ane) *Isoflo®, Iso-Thesia®*

General Anesthetic, Inhalant

Prescriber Highlights

- ► Inhalant general anesthetic commonly used in a wide range of veterinary species
- ► Contraindications include a history of or predilection to malignant hyperthermia.
- ► Use with caution in patients with increased intracranial pressure, head injury, or myasthenia gravis.
- ► Adverse effects include dose-related hypotension, respiratory depression, and GI effects (eg, nausea, vomiting, ileus); cardiodepression is generally minimal at doses causing surgical planes of anesthesia. Arrhythmias are rare.

Uses/Indications

Isoflurane is an inhalant anesthetic commonly used in veterinary medicine. When compared with older anesthetics (eg, halothane, methoxyflurane), isoflurane has fewer myocardial depressant and

catecholamine-sensitizing effects, and it can be used in patients with hepatic or renal disease. The newer inhalant anesthetics, sevoflurane (ability to change depth of anesthesia faster, not as irritating to respiratory system) and desflurane (very fast onset, faster recoveries), have some advantages over isoflurane, but are more expensive. Isoflurane with oxygen can be used for refractory status epilepticus in dogs that are refractory to benzodiazepine boluses; however, isoflurane can increase intracranial pressure.

Pharmacology/Actions

The precise mechanism of how inhalant anesthetics produce their general anesthetic effects is not known. They may interfere with the functioning of nerve cells in the brain by acting at $GABA_A$ receptors and voltage-gated channels.[1] Some key pharmacologic effects noted with isoflurane include CNS depression, depression of body temperature–regulating centers, increased cerebral blood flow, respiratory depression, vasodilatation (hypotension), myocardial depression (less so than with halothane), and muscular relaxation.

Minimum alveolar concentrations (MAC; %) in oxygen reported for isoflurane in various species include the following: dog = 1.3 to 1.4; cat = 1.3 to 1.9; horse = 1.3 to 1.6; cow = 1.1; goat = 1.2 to 1.5; sheep = 1.6; pig = 1.5 to 2; rabbit = 2 to 2.1; and human = 1.2.[2] MAC may be altered by several factors (metabolic acidosis, hypo- and hypernatremia, hypo- and hyperthermia, other CNS depressants and stimulants, age, severe hypotension/hypoxemia/hypercarbia, and pregnancy).

Pharmacokinetics

Isoflurane is rapidly absorbed from the alveoli due to its low blood solubility or blood–gas partition coefficient (1.4). It is rapidly distributed into the CNS and crosses the placenta. The vast majority of the drug is eliminated via the lungs; only ≈0.2% is metabolized in the liver, and only a small amount of inorganic fluoride is formed.

Contraindications/Precautions/Warnings

Isoflurane is contraindicated in patients with a history of, or who are predisposed to, malignant hyperthermia. Isoflurane should only be used in situations in which sufficient monitoring and patient-support capabilities (eg, intubation, ventilation) are available. It should be used with caution in patients with increased intracranial pressure or head injury, or myasthenia gravis. If used in patients with increased intracranial pressure, it is recommended to closely monitor and maintain the expiratory end-tidal isoflurane below 1 to 1.5 minimum alveolar concentration (MAC) (1 MAC = 1.4%) and end-tidal carbon dioxide ($ETCO_2$) level between 35 and 40 mm Hg.[3]

Because of its respiratory depressant effects, intermittent positive pressure ventilation may be required to achieve anesthesia and normocapnia, particularly in horses.

The National Institute for Occupational Safety and Health (NIOSH) has recommended that no worker should be exposed at ceiling concentrations greater than 2 ppm of any halogenated anesthetic agent over a sampling period not to exceed 1 hour.

Adverse Effects

At recommended concentrations, dose-related hypotension secondary to vasodilation may occur. As compared with an equipotent propofol total IV anesthesia (TIVA), isoflurane seems to cause more vasodilation.[4] Hypotension usually responds to fluids, but profound hypotension may require the use of positive inotropic and/or vasopressor drugs. Although cardiodepression (ie, decreased heart rate and contractility) is usually not clinically significant in most species and healthy subjects, it can occur at doses used for surgical anesthetic planes. Arrhythmias have rarely been reported and, in horses, the incidence of intraoperative cardiac arrests has decreased since isoflurane and sevoflurane have replaced halothane.[5] Cats appear to be more sensitive to the cardiovascular effects of inhaled anesthetics than dogs.[6]

Dose-dependent respiratory depression has been reported. GI effects (eg, nausea, vomiting, ileus) may occur; administration of pre-anesthetic antiemetic agents can be considered for use in species that vomit. Providing food to horses before elective procedures may maintain GI motility and decrease the risk for postanesthetic colic.[7]

Malignant hyperthermia has been reported in dogs, horses,[8] pigs, and humans.[9]

Reproductive/Nursing Safety

Isoflurane readily crosses the placenta and maternal-to-fetal equilibration is rapid.[10] Increased postimplantation losses and reduced live birth index occurred in mice and rats given isoflurane for 2 hours every day during periods of organogenesis; fetal malformations were not observed.[11] However, with close monitoring, isoflurane can be safely used in pregnant animals when heart rate, minute ventilation, and blood pressure are maintained within a physiologic range.

The minimum alveolar concentration (MAC) of inhalation agents is 25% to 40% lower during pregnancy; the onset of isoflurane anesthesia is more rapid in pregnant animals.[12]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving isoflurane and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antihypertensive Agents** (eg, **amlodipine, enalapril, telmisartan**): Concomitant use may increase risks for hypotension. Enalapril caused significant decreases in systolic blood pressure in dogs and cats undergoing isoflurane anesthesia.[13,14]
- **Acepromazine**: May enhance the hypotensive effects of isoflurane in dogs[15]
- **Aminoglycosides** (eg, **amikacin, gentamicin**): Use with caution with halogenated anesthetic agents, as additive neuromuscular blockade may occur.
- **Benzodiazepines** (eg, **midazolam**): May reduce MAC requirements
- **Beta-Adrenergic Receptor Antagonists** (eg, **propranolol**): May enhance the cardiovascular depressant effects of isoflurane
- **Dexmedetomidine**: May worsen cardiovascular depression in cats.[6] May reduce minimum alveolar concentration (MAC) requirements in dogs
- **Ketamine**: May reduce MAC requirements in dogs
- **Lidocaine**: May reduce MAC requirements in dogs and rabbits
- **Lincosamides** (eg, **clindamycin**): Use with caution with halogenated anesthetic agents, as additive neuromuscular blockade may occur.
- **Nondepolarizing Neuromuscular Blocking Agents** (eg, **atracurium**): Additive neuromuscular blockade may occur.
- **Opioids** (eg, **buprenorphine, fentanyl, hydromorphone**): Intraoperative opioids can reduce MAC requirements in dogs.
- **Succinylcholine**: With inhalation anesthetics, may induce increased incidences of cardiac effects (eg, bradycardia, arrhythmias, sinus arrest, and apnea) and, in susceptible patients, malignant hyperthermia.
- **Sympathomimetic Agents** (eg, **dopamine, epinephrine, norepinephrine, ephedrine, metaraminol**): Although isoflurane sensitizes the myocardium to the effects of sympathomimetics less so than halothane, arrhythmias may still occur. If these drugs are needed, they should be used with significantly reduced initial doses and with intensive monitoring.

Laboratory Considerations

- **ACTH**: May reduce mean plasma ACTH concentrations collected from the cavernous sinus of anesthetized horses for determining the success of partial pituitary ablation[16]

Dosages

Approximate minimum alveolar concentrations (MAC; %) in oxygen reported for isoflurane in various species include the following: dog = 1.5; cat = 1.2; horse = 1.31; sheep = 1.5; rabbit = 1.92; and human = 1.2. MAC may be altered by several factors (metabolic acidosis, hypo- and hypernatremia, hypo- and hyperthermia, other CNS depressants and stimulants, age, severe hypotension/hypoxemia/hypercarbia, and pregnancy).

NOTES:

1. General anesthesia using inhalants must be performed with adequate monitoring and support and cannot be dosed in a purely textbook fashion.
2. MAC is affected by many variables, including:
   a) Type and location of stimulus
   b) Concurrent administration of MAC-reducing drugs
   c) Type of ventilation, type of breathing system
   d) Age of the animal (younger cats had higher MAC values)
3. Isoflurane should be used with well-maintained anesthetic machines with proper scavenging equipment and in areas with adequate ventilation to prevent escape of gases that could result in exposure of veterinary personnel to anesthetic vapors.

DOGS:

General anesthesia (label dosage; FDA-approved): Induction: 2% – 2.5% isoflurane alone with oxygen following an injectable anesthetic induction agent is usually employed.[17] **NOTE**: Mask induction of anesthesia is highly discouraged due to the level of stress and excitement produced and possible personnel exposure to gas anesthetics. Maintenance: Surgical levels of anesthesia may be sustained with a 1.5% –1.8% concentration of isoflurane in oxygen.[17]

General anesthesia (extra-label): Induction: 3% – 5% isoflurane with relatively rapid oxygen flow rates (3 to 4 L/minute) and using a non-rebreathing circuit. Maintenance: 1% – 3% isoflurane (typically, 1% – 1.5%) in oxygen adjusted to desired anesthetic depth; vaporizer settings will vary with the patient's condition, the type of breathing circuit used, and the fresh gas flow rate.[2,18]

CATS:

General anesthesia (extra-label): MAC for isoflurane ranged from 1.20 ± 0.13% to 2.22 ± 0.35%, and the average MAC was 1.71 ± 0.07%.[19]

HORSES:

General anesthesia (label dosage; FDA-approved): Induction: 3% – 5% isoflurane alone with oxygen following an injectable anesthetic induction agent are usually employed. **NOTE**: Mask induction of anesthesia is highly discouraged due to the level of stress and excitement produced and possible personnel exposure to gas anesthetics. Maintenance: Surgical levels of anesthesia may be sustained with a 1.5% – 1.8% concentration of isoflurane in oxygen.[17]

SMALL RUMINANTS:

General anesthesia (extra-label): Inhalational anesthesia is seldom feasible in the field but is a viable option in situations that can provide suitable accommodations (eg, sterile field, patient positioning) for small ruminants. Isoflurane is a preferred agent for debilitated, pregnant, very young or aged animals, or for prolonged (ie, more than 1 hour) and complicated surgical procedures. Vaporizer should be set to 1% – 3% during maintenance. Oxygen flow rate should be 10 to 20 mL/kg/minute during maintenance anesthesia.[20]

BIRDS:

General anesthesia (extra-label): Induction occurs within 1 to 2 minutes at a concentration of 3% – 5% delivered by mask. After intubation, maintenance at 1.5% – 2% is adequate for most birds. Recovery is rapid; most patients are standing and cage-safe within 5 minutes after anesthesia is discontinued, but there seems to be a direct relationship between anesthesia time and recovery time.[21]

FERRETS/SMALL MAMMALS:

General anesthesia of mice, rats, gerbils, hamsters, guinea pigs, chinchillas, ferrets, rabbits, prairie dogs (extra-label)**:** Premedication with injectables drugs is recommended prior to induction of general anesthesia. In most cases, IV or IM injectable induction agents are preferred; however, face mask induction with isoflurane can be used after adequate sedation. In most cases, 2% – 3% isoflurane in oxygen delivered via a tight-fitting face mask is adequate. Maintenance of anesthesia can be achieved by delivering 1% – 2% of isoflurane, depending on concurrent drugs administered and type of procedure.[22–27]

REPTILES:

General anesthesia (extra-label): It is preferable to induce reptiles with injectable agents and then maintain anesthesia with inhalant gases. For maintenance of general anesthesia, most reptiles require 2% – 3% of isoflurane.

Monitoring

- Ventilatory status
- Cardiac rate and rhythm; blood pressure (particularly with higher anesthetic risk patients)
- Anesthetic depth

Client Information

Isoflurane is used for general anesthesia only by veterinarians.

Chemistry/Synonyms

Isoflurane is an inhalant general anesthetic agent that occurs as a colorless, nonflammable, stable liquid. It has a characteristic mildly pungent, musty, ethereal odor. At 20°C (68°F), isoflurane's specific gravity is 1.496 and vapor pressure is 238 mm Hg. Its boiling point is 48.5°C (119.3°F), and solubility coefficients include blood–gas partition coefficient of 1.4 and oil–gas partition coefficient of 91.

Halogenated inhalation anesthetics are greenhouse gases. Vaporization of isoflurane for 1 hour has the same global warming potential as driving an automobile for 12 miles.[28]

Isoflurane may also be known as compound 469, isofluranum, *AErrane®*, *Forene®*, *Forenium®*, *Forthane®*, *Isoflo®*, *Isofor®*, *Isoforine®*, *Isosol®*, *Isothane®*, *Iso-Thesia®*, *Lisorane®*, *Sofloran®*, *Tensocold®*, *Terrell®*, and *Zuflax®*.

Storage/Stability

Isoflurane should be stored at room temperature; it is relatively unaffected by exposure to light, but should be stored in a tight, light-resistant container. Isoflurane does not attack aluminum, brass, tin, iron, or copper.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Isoflurane for Inhalation: 99.9%/mL in 100 mL and 250 mL; *Aerrane®*, *Isoflo®*, *Isosol®*, generic; (Rx). Products may be FDA-approved for use in horses (those not intended for food) and dogs.

HUMAN-LABELED PRODUCTS:

Isoflurane Liquid for Inhalation in 100 mL and 250 mL; *Forane®*, *Terrell®*, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Isoniazid (INH)

(eye-so-***nye***-ah-zid) *Laniazid®, Nydrazid®*

Antimycobacterial

Prescriber Highlights

- ► May be used for chemoprophylaxis of *Mycobacterium bovis* or *Mycobacterium tuberculosis* in small animal species
- ► Has also been used in cattle for paratuberculosis (*Mycobacterium avium* subsp *paratuberculosis* [MAP]; Johne's disease)
- ► Treating active infections is controversial because of potential public health risks associated with the infections
- ► Contraindicated in patients with acute liver disease and in those that are hypersensitive to it
- ► Isoniazid has a narrow therapeutic index; hepatotoxicity and neurotoxicity are possible.

Uses/Indications

Isoniazid (INH) is sometimes used for chemoprophylaxis in small animal species living in households with a human that has tuberculosis. It can potentially be used in combination with other antimycobacterial drugs to treat infections of *Mycobacterium bovis* or *Mycobacterium tuberculosis* in dogs or cats. Because of the public health risks of tuberculosis, particularly in the face of increased populations of immunocompromised humans, treatment of mycobacterial infections in domestic or captive animals is controversial due to the potential for zoonotic infection.[1]

Isoniazid, alone or in combination, has been used to treat *Mycobacterium avium* subsp. *paratuberculosis* (MAP; Johne's disease) in cattle that are of significant economic, genetic, or sentimental value[2]; however, there is no cure for MAP and treatment is aimed at reducing clinical signs. As treatment does not prevent shedding of the organism but may extend survival time, treatment may therefore increase the risk for environmental contamination from that animal.[3]

In humans, INH is routinely used alone to treat latent tuberculosis infections (positive tuberculin skin test) and in combination with other antimycobacterial agents to treat active disease.

Pharmacology/Actions

Isoniazid inhibits the synthesis of mycolic acids, a component of mycobacterial cell walls; its exact mechanism is not well understood. It is most active against mycobacteria that are dividing and affects both extracellular and intracellular mycobacteria. It is bactericidal against dividing mycobacteria and bacteriostatic against dormant or semi-dormant stages.

Isoniazid is only active against *Mycobacterium tuberculosis*, *Mycobacterium bovis,* and some strains of *Mycobacterium kansasii*. In humans, resistance develops rapidly if used alone against active clinical disease, but not when used for treatment of latent infection.

Isoniazid has an inhibitory effect on monoamine oxidase.

Pharmacokinetics

No information was located on the pharmacokinetics of isoniazid (INH) in dogs or cats. It is reported that INH is absorbed after oral administration to ruminants.[3,4]

In humans, INH is rapidly absorbed after oral or IM administration; food can decrease absorption somewhat and INH may undergo significant first pass metabolism. The drug is highly distributed in the body and crosses into the CSF and caseous material. It is distributed into milk and crosses the placenta. It is only slightly (10%) bound to plasma proteins. In humans, the drug is initially primarily acetylated in the liver. The N-acetylated form is then further biotransformed to isonicotinic acid and monoacetylhydrazine. INH's hepatotoxicity is due to monoacetylhydrazine, which must undergo its own acetylation to become nontoxic. As with some humans, dogs lack N-acetyltransferase, so there is an increased potential for INH toxicity in this species. Elimination half-life in humans that are fast acetylators is 0.5 to 1.6 hours, and half-life is 2 to 5 hours in slow acetylators. Patients with acute or chronic liver disease or severe renal impairment may have substantially longer half-lives, up to 2 times normal. The drug is mostly eliminated in the urine as inactive metabolites.

Contraindications/Precautions/Warnings

Isoniazid (INH) is contraindicated in patients with acute liver disease or those that developed hepatopathy while taking the medication in the past. It is contraindicated in patients that are hypersensitive to it. INH has a narrow therapeutic index and toxicity is a concern (see ***Adverse Effects***). It should be used with caution in patients with decreased hepatic function or severe renal disease.

Adverse Effects

The primary adverse effect associated with INH in dogs is hepatotoxicity manifested by increased serum liver enzymes. Additional adverse effects reported in dogs include CNS stimulation, peripheral neuropathy, and thrombocytopenia. Adverse effects reported in cats include hepatotoxicity and peripheral neuritis.

In cattle, toxic signs (eg, refusal to eat, decreased milk production, rear leg stiffness) can be noted at 30 mg/kg PO. At 60 mg/kg PO, severe ataxia can be seen, and death can occur at doses of 100 mg/kg PO.

In humans, urticaria, hepatotoxicity, and peripheral neuropathy are commonly reported; rarely, blood dyscrasias, systemic lupus erythematous-like syndrome, and seizures have been reported.[5] Hepatotoxicity usually occurs within the first 3 months of treatment, and risk increases with increasing age, and in the postpartum period.

Reproductive/Nursing Safety

Isoniazid (INH) crosses the placenta and has been found to be embryocidal in some laboratory species, but teratogenic effects have not been detected in mice, rabbits, or rats.[5] In humans, concomitant administration of pyridoxine to prevent peripheral neuropathy is recommended for pregnant women receiving INH therapy.

INH can potentially induce abortion in cattle.

INH is excreted in milk in low concentrations (≈1% to 2% of maternal serum concentrations in humans) and it is thought to be safe to use during nursing. Ingested concentrations via milk are not high enough to serve as prophylaxis for tuberculosis in nursing infants.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring. In humans, INH treatment is generally recommended during pregnancy, as the risks of untreated active tuberculosis outweigh the risks of INH therapy.[5]

Overdose/Acute Toxicity

Overdoses of isoniazid (INH) can be very serious. In dogs, the reported LD_{50} is 50 mg/kg; serious toxicity can occur with ingestion of as little as one 300 mg tablet. Ataxia, seizures, myocardial necrosis, metabolic acidosis, rhabdomyolysis, salivation, diarrhea, vomiting, and arrhythmias have been reported after overdoses in dogs. Treatment may include enterogastric lavage, activated charcoal, and benzodiazepines or phenobarbital to control seizures; however, seizures may be difficult to treat. Fluids and acidemia may need correction. Hemodialysis may be indicated.

Pyridoxine (vitamin B_6) can help treat seizures and other CNS effects, as well as acidosis. It has been suggested that pyridoxine be administered IV (preferably over 30 to 60 minutes) on a mg per mg of INH-ingested basis. Pyridoxine is commercially available as a 100 mg/mL, 1 mL vial, but it may be difficult to obtain in an emergency situation. A local human hospital may stock it.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is strongly recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans receiving INH and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetaminophen**: May increase risk for hepatotoxicity
- **Alfentanil**: Prolonged alfentanil duration of action
- **Amiodarone**: Increased amiodarone exposure
- **Antacids** (especially those containing **aluminum**): Decreased INH absorption
- **Benzodiazepines**: Isoniazid (INH) may reduce benzodiazepine metabolism.
- **Clopidogrel**: INH may reduce antiplatelet effect.
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): May reduce INH efficacy
- **Ketoconazole, Itraconazole**: INH may reduce ketoconazole/itraconazole serum concentrations; does not appear to affect other azole antifungals
- **Other Hepatotoxic Drugs** (eg, **azole antifungals, methimazole, phenothiazines, sulfonamides, estrogens**): Increased risk for hepatotoxicity
- **Other Neurotoxic Drugs**: Increased risk for neurotoxicity
- **Pyridoxine**: INH may antagonize or increase the excretion of pyridoxine and reduce formation of the active form. Increased pyridoxine may be required; increased peripheral neuritis may occur secondary to pyridoxine/INH interaction.
- **Rifampin**: Increased risk for hepatotoxicity
- **Theophylline**: Increased risk for theophylline toxicity
- **Warfarin**: Increased risk for bleeding
- **Food Interactions**: In humans, INH may interfere with metabolism of tyramine and histamine found in **cheese** (eg, Swiss, Cheshire) or **fish** (eg, tuna, sardines).

Laboratory Considerations

- Isoniazid (INH) may cause false positive **urine glucose determinations** when using cupric sulfate solution (Benedict's solution, *Clinitest®*); tests utilizing glucose oxidase (*Tes-Tape®, Clinistix®*) are not affected.

Dosages

NOTE: It is recommended to contact local veterinary or public health authorities before treating any animal with a confirmed mycobacterial infection.

DOGS:

Mycobacterium tuberculosis **chemoprophylaxis** (extra-label): 10 mg/kg PO once daily; dose is extrapolated from human data. Treatment of active *M tuberculosis* or *Mycobacterium bovis* infections in dogs is controversial due to zoonotic potential.[1]

CATS:

Second-line treatment (reserved for resistant infections) for feline tuberculosis (extra-label): 10 – 20 mg/kg PO once daily.[6] Treatment of active *M tuberculosis* or *M bovis* infections in cats is controversial due to zoonotic potential.[1]

CATTLE/RUMINANTS:

Attempting to induce clinical remission of paratuberculosis (MAP; Johne's disease) in cattle or other ruminants that are of significant economic, genetic, or sentimental value (extra-label): 11 – 25 mg/kg PO once daily. Treatment typically must be maintained for the life of the animal and treated animals usually continue to shed MAP. Owner must be fully informed about the implications of keeping an animal with clinical MAP on the premises. Strongly advise having owner sign a document stating that the milk and meat from the animal will never be used for human consumption.[2]

Monitoring

- Baseline and periodic physical examination to evaluate for clinical efficacy
- Adverse effects
- Baseline and periodic CBC and chemistry profile

Client Information

- This medicine is best given on an empty stomach. If your animal vomits or acts sick after receiving the medicine on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Do not skip any doses. This medicine must be given regularly as directed to be effective.
- If a dose is missed, do not double the next dose.
- Store this medicine well out of reach of other animals and children as overdoses can be very serious.
- Contact your veterinarian if your animal has any of the following signs: vomiting; decreased appetite; weight loss; diarrhea or loose stools; changes in behavior or activity; yellowing of whites of eyes, gums, or skin (jaundice); or difficulty going up or down stairs.

Chemistry/Synonyms

Isoniazid occurs as colorless, or white, odorless crystals. It is freely soluble in water and sparingly soluble in alcohol.

Isoniazid may also be known as INH, INAH, isonicotinic acid hydrazide, isonicotinylhydrazide, isonicotinylhydrazine, or tubazid. INH is available as many trade names throughout the world; some of the more commonly used names include *Isotamine®*, *Laniazid®*, or *Nydrazid®*. **CAUTION**: *Isopyrin®* is one isoniazid trade name that, in some countries, contains ramifenazone (an NSAID) and *not* isoniazid.

Storage/Stability

Isoniazid (INH) tablets, the oral syrup, and the injection should be stored at temperatures below 40°C (104°F), preferably between 15°C and 30°C (59°F-86°F), in tight, light-resistant containers. The oral syrup and the injection should be protected from freezing. At low temperatures, crystals may form in the injectable solution; crystals should redissolve on warming to room temperature.

Compatibility/Compounding Considerations

It is recommended not to use sugars such as glucose, fructose, or sucrose in compounded oral solutions, as a condensation product may form that can impair absorption. Sorbitol and glycerin are acceptable vehicles. Isoniazid (INH) for injection is intended for IM administration; no information on compatibility with other parenteral drugs was found.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Isoniazid Oral Tablets: 100 mg and 300 mg; generic; (Rx)

Isoniazid Oral Syrup: 10 mg/mL (50 mg/5 mL) in pints; generic; (Rx)

Isoniazid Injection Solution: 100 mg/mL in 10 mL multidose vials; generic; (Rx)

Fixed dose combination products with rifampin are also available:

Tablets: Rifampin 120 mg with Isoniazid 50 mg and Pyrazinamide 300 mg; *Rifater®*; (Rx)

Capsules: Rifampin 300 mg with Isoniazid 150 mg; *IsonaRif®*, *Rifamate®*; (Rx)

Isoproterenol

Isoprenoline

(eye-soe-proe-***ter***-e-nole) *Isuprel®*

Beta-Adrenergic Agonist

Prescriber Highlights

- ► Nonselective beta-adrenergic agonist used for acute bronchial constriction, cardiac arrhythmias (complete AV block), and as adjunctive therapy in shock or heart failure; its use in veterinary medicine is uncommon.
- ► Contraindications include tachyarrhythmias, ventricular arrhythmias that do not require increased inotropic activity, and tachycardia or AV block caused by cardiac glycoside intoxication.
- ► Use caution in patients with coronary insufficiency, hyperthyroidism, renal disease, hypertension, or diabetes; not a substitute for adequate fluid replacement in shock
- ► Adverse effects include tachycardia, hypotension, anxiety, tremors, excitability, headache, weakness, and vomiting; more arrhythmogenic than dopamine or dobutamine
- ► Short duration of activity (including adverse effects)

Uses/Indications

Isoproterenol is infrequently used in veterinary medicine. It can be used in the treatment of acute bronchial constriction, cardiac arrhythmias (complete AV block), and, occasionally, as adjunctive therapy in shock or heart failure (limited use because of resulting increases in heart rate and ventricular arrhythmogenicity).

Pharmacology/Actions

Isoproterenol is a synthetic beta-1 and beta-2-adrenergic agonist that has no appreciable alpha-adrenergic activity at therapeutic doses. It is thought that isoproterenol's beta-adrenergic activity is a result of stimulating cyclic-AMP production. Its primary actions are increased inotropism and chronotropism, relaxation of bronchial smooth muscle, and peripheral vasodilation. Isoproterenol may increase perfusion to skeletal muscle (at the expense of vital organs in shock). Isoproterenol inhibits the antigen-mediated releases of histamine and slow releasing substance of anaphylaxis (SRS-A).

Hemodynamic effects include decreased total peripheral resistance, increased cardiac output, increased venous return to the heart, and increased rate of discharge by cardiac pacemakers. Isoproterenol can increase myocardial oxygen requirements while also decreasing coronary perfusion.

Pharmacokinetics

After oral administration, isoproterenol is rapidly inactivated by the GI tract and metabolized by the liver. Sublingual administration is not reliably absorbed and effects may take up to 30 minutes to be seen. IV administration results in immediate effects, but these only persist for a few minutes after discontinuation.

The pharmacologic actions of isoproterenol are ended primarily through tissue uptake. Isoproterenol is metabolized in the liver and other tissues by catechol-O-methyltransferase (COMT) to a weakly active metabolite.

Contraindications/Precautions/Warnings

Isoproterenol is contraindicated in patients with tachyarrhythmias, ventricular arrhythmias that do not require increased inotropic activity, and tachycardia or AV block caused by cardiac glycoside intoxication.

Use isoproterenol with caution in patients with coronary insufficiency, hyperthyroidism, renal disease, hypertension, or diabetes mellitus. Isoproterenol is not a substitute for adequate fluid replacement in shock.

Adverse Effects

Isoproterenol can cause tachycardia, hypotension, anxiety, tremors, excitability, headache, weakness, and vomiting. Because of isoproterenol's short duration of action, adverse effects are usually transient and do not require cessation of therapy, but may require lowering the dose or infusion rate. Isoproterenol is considered more arrhythmogenic than either dopamine or dobutamine, so it is rarely used in the treatment of heart failure.

Reproductive/Nursing Safety

Safe use of isoproterenol during pregnancy has not been established. Beta-adrenergic agonists have a tocolytic effect and may interfere with uterine contractions at parturition.

It is unknown if isoproterenol is distributed into milk; however, as isoproterenol is rapidly deactivated in the gut, it is unlikely to pose much risk to nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In addition to the signs listed in the ***Adverse Effects*** section, high doses may cause an initial hypertension, followed by hypotension as well as tachycardia and other arrhythmias. High doses are associated with cardiac necrosis.[1] Under experimental conditions, lethal doses of isoproterenol were 10 – 50 μ/kg IV in hypoxic dogs.[2]

Besides halting administration or reducing the drug dosage, treatment is considered to be supportive. If tachycardia persists, a beta-blocker (eg, propranolol) could be considered for treatment (if patient does not have a bronchospastic disease).

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving isoproterenol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anesthetics, Inhalant** (eg, **isoflurane, sevoflurane**): An increased risk for arrhythmias if isoproterenol is administered to patients that have received cyclopropane or a halogenated hydrocarbon anesthetic agent. Propranolol may be administered should an arrhythmia occur.
- **Beta-Blockers** (eg, **atenolol**, **propranolol**): May antagonize isoproterenol's cardiac, bronchodilating, and vasodilating effects by blocking the beta effects of isoproterenol. Beta-blockers may be administered to treat the tachycardia associated with isoproterenol use, but use with caution in patients with bronchospastic disease.
- **Digoxin**: An increased risk for arrhythmias may occur if isoproterenol is used concurrently with digitalis glycosides.

- **Linezolid**: Increased hypertensive effects possible
- **Oxytocin**: Increased risk for hypertension
- **Selegiline**: Increased hypertensive effects possible
- **Sympathomimetic agents, Other** (eg, **phenylpropanolamine**): Isoproterenol should not be administered with other sympathomimetic agents as increased toxicity may result.
- **Theophylline, Aminophylline**: Isoproterenol may reduce theophylline levels.

Laboratory Considerations
- None noted

Dosages
NOTE: Because of the cardiostimulatory properties of isoproterenol, its parenteral use in human medicine for the treatment of bronchospasm has been largely supplanted by beta-2-adrenergic selective drugs (eg, terbutaline) and administration methods (nebulization). Use with care.

DOGS/CATS:

Sinoatrial arrest, sinus bradycardia, complete AV block, or as an alternative to atropine for calcium channel blocker overdose (extra-label):

a) Dilute injection as described for IV infusion (see ***Compatibility/Compounding Considerations***). Infuse solution to effect at a rate of 0.04 – 0.08 µg/kg/minute IV CRI.[3]

b) Isoproterenol increases heart rate and cardiac output and decreases blood pressure. If administered carefully with close monitoring of blood pressure, it can provide potent augmentation of forward blood flow and tissue perfusion. Dose is 0.02 – 0.5 µg/kg/minute IV.[4]

Monitoring
- Cardiovascular status: heart rate and rhythm; blood pressure; central venous pressure; cardiac output
- Respiratory rate and thoracic auscultation during anaphylaxis
- Urine output
- Blood gases

Client Information
- Isoproterenol for injection should be used only by trained personnel in a setting where adequate monitoring can be performed.

Chemistry/Synonyms
Isoproterenol HCl is a synthetic beta-adrenergic agent that occurs as a white to practically white, crystalline powder that is freely soluble in water and sparingly soluble in alcohol. The pH of the commercially available injection is 3.5 to 4.5.

Isoproterenol HCl may also be known as isoprenaline hydrochloride, isopropylarterenol hydrochloride, isopropylnoradrenaline hydrochloride, *Imuprel®*, *Isolin®*, *Isoprenaline Macure®*, *Isuprel®*, *Lenoprel®*, *Norisodrine Aerotrol®*, *Proterenal®*, *Saventrine®*, and *Vapo-iso®*.

Storage/Stability
Store isoproterenol protected from light at room temperature 20°C to 25°C (68°F-77°F). Isoproterenol salts will darken with time on exposure to air, light, or heat. Sulfites or sulfur dioxide may be added to preparations as an antioxidant. Solutions may become pink or brownish-pink if exposed to air, alkalis, or metals. Do not use solutions that are discolored pink or darker, or contain a precipitate. If isoproterenol is mixed with other drugs or fluids that result in a solution with a pH greater than 6, it is recommended that it be used immediately.

Compatibility/Compounding Considerations
Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Isoproterenol for injection is reported to be physically **compatible** with all commonly used IV solutions (except sodium bicarbonate 5%), and the following drugs: calcium chloride/gluceptate, cimetidine HCl, dobutamine HCl, heparin sodium, magnesium sulfate, multivitamin infusion, oxytetracycline HCl, potassium chloride, succinylcholine chloride, tetracycline HCl, verapamil HCl, and vitamin B complex with C.

It is reported to be physically **incompatible** when mixed with aminophylline or sodium bicarbonate.

Commercially available as 0.2 mg/mL injection. For direct IV injection, dilute 1 mL of the commercially available injection to a volume of 10 mL with 0.9% sodium chloride injection or 5% dextrose injection. For IV infusion, solutions may be prepared by diluting 1 to 10 mL of the 0.2 mg/mL injection with 500 mL of 5% dextrose, 0.9% sodium chloride, or LRS injection to provide infusion solutions containing 0.4 – 4 µg/mL. For example, 5 mL (1 mg) of the 0.2 mg/mL injection in 500 mL of 5% dextrose would yield a concentration of 2 µg/mL. As the injection concentrate contains no bacteriostatic or antimicrobial agent, each vial/ampule is intended for single use only; any unused solution should be discarded.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Isoproterenol HCl for Injection: 0.2 mg/mL in 1 mL and 5 mL ampules or single-dose vials; *Isuprel®*, generic; (Rx)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Isotretinoin
(eye-so-***tret***-i-noyn) *Accutane®*

Retinoid, Synthetic, Second-generation

Prescriber Highlights
- ► May be useful in treatment of a variety of dermatologic conditions associated with epithelial cell proliferation and differentiation
- ► Isotretinoin is a known teratogen and is absolutely contraindicated during pregnancy.
- ► Caution in patients with hypertriglyceridemia, severe renal or hepatic dysfunction, or hypersensitivity
- ► The most common adverse effect in dogs is keratoconjunctivitis sicca (KCS). Other potential adverse effects in small animal species include GI effects (anorexia, vomiting, abdominal distention), CNS effects (lassitude, hyperactivity, collapse), pruritus, erythema of feet and mucocutaneous junctions, polydipsia, and swollen tongue.
- ► Obtaining the medication for veterinary patients may be difficult and cost may be prohibitive.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies isotretinoin as a hazardous drug. **Pregnant women must avoid contact with this medication**; isotretinoin should NOT be dispensed to households with pregnant women.

Uses/Indications
Isotretinoin may be useful for the treatment of a variety of dermatologic conditions in dogs, including follicular abnormalities such as follicular dysplasias (eg, color dilution alopecia), lamellar ichthyosis, intracutaneous cornifying epitheliomas, multiple epidermal inclusion cysts, idiopathic seborrhea, sebaceous adenitis, keratoacanthoma, benign pilomatrixomas, comedo syndrome in schnauzers, and

as palliative treatment for cutaneous T-cell lymphoma. There is little scientific evidence available to support its use in veterinary patients; however, a recent study showed that isotretinoin 9-cis, in combination with surgery, significantly increased the survival rate and prolonged the time to tumor recurrence of thyroid carcinoma in dogs, as compared with doxorubicin-treated or untreated dogs.[1]

Use of isotretinoin in cats is more limited; with potential use for actinic keratosis, solar-induced squamous cell carcinoma, Bowen's disease (ie, multicentric in situ squamous cell carcinoma), sebaceous adenitis, and acne.

Because of the concerns of teratogenic effects in humans, availability to veterinarians may be difficult as it may be restricted by manufacturers and drug distributors.

Pharmacology/Actions

Isotretinoin is a retinoid that appears to regulate epithelial cell proliferation and differentiation, although its exact mechanism of action is unknown. It affects monocyte and lymphocyte function, which can cause changes in cellular immune responses. The effects on skin include reduction of sebaceous gland size and activity, thereby reducing sebum production. It also has anti-keratinization and anti-inflammatory activity and may indirectly reduce bacterial populations in sebaceous pores.

Pharmacokinetics

Isotretinoin is rapidly absorbed from the GI tract once the capsule disintegrates and the drug is dispersed in the GI contents, which may require up to 2 hours after dosing. Animal studies have shown that only ≈25% of a dose reaches the systemic circulation, and food or milk in the GI tract increases the amount of drug absorbed. Isotretinoin is distributed into many tissues, but it is not stored in the liver (unlike vitamin A). It crosses the placenta and is highly bound to plasma proteins. It is unknown if it enters milk. Isotretinoin is metabolized in the liver and is excreted in the urine and feces. Isotretinoin metabolites possess retinoid activity, but it is unclear if or how they contribute to the drug's efficacy or toxicity. In humans, terminal half-life is ≈10 to 20 hours.

Contraindications/Precautions/Warnings

Isotretinoin is contraindicated in pregnancy. Isotretinoin is a known teratogen. Major anomalies have been reported in children of women taking the medication, and it should not be used to treat animals that live in households with pregnant women.

Isotretinoin should be used with caution in patients with hypertriglyceridemia, severe renal or hepatic disease, or sensitivity to isotretinoin, and should only be used when potential benefits outweigh the risks.

Avoid excessive exposure to sunlight, as the effects of UV lights are enhanced by retinoids.

The National Institute for Occupational Safety and Health (NIOSH) classifies isotretinoin as a hazardous drug. Pregnant women must avoid contact with the medication and it should not be dispensed to households with pregnant women.

Adverse Effects

There is limited experience with isotretinoin in veterinary medicine; however, there appears to be a low incidence of adverse effects, particularly in dogs. The most common adverse effect seen in dogs is KCS, which is not seen in cats. Other potential adverse effects in dogs include GI effects (anorexia, vomiting, diarrhea, abdominal distention), CNS effects (lassitude, hyperactivity, behavioral changes, collapse), stiffness of limbs, pruritus, exfoliative dermatitis, erythema of feet and mucocutaneous junctions, cheilitis, polydipsia, and swollen tongue.

Incidence of adverse effects may be higher in cats. Reported adverse effects include blepharospasm, periocular crusting, erythema, diarrhea and, especially, weight loss secondary to anorexia. If adverse effects occur, the time between doses may be extended (eg, instead of giving daily, alternate between giving daily for 1 week and giving every other day for 1 week) to reduce total amount given.

Adverse effects in humans include pancreatitis, osteoporosis, corneal opacities and cataracts, arthralgia, and inflammatory bowel syndrome.

Reproductive/Nursing Safety

Isotretinoin is a known teratogen. Major anomalies have been reported in children of women taking the medication. It is absolutely contraindicated in pregnant veterinary patients as well. Isotretinoin also appears to inhibit spermatogenesis.

It is not known whether this drug is excreted in breast milk. At this time, it is not recommended for use in nursing mothers.

Overdose/Acute Toxicity

A common finding in dogs after overdose is hypersalivation. Because of the drug's potential adverse effects, GI decontamination protocols should be considered with acute isotretinoin overdoses when warranted.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving isotretinoin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Vitamin A** or **Other Retinoids**: Isotretinoin used with other retinoids (eg, **etretinate**, **tretinoin**, or **vitamin A**) may cause additive toxic effects.
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Concomitant use may further increase risk for osteoporosis.
- **Cyclosporine**: Isotretinoin may increase cyclosporine concentrations.
- **Tetracyclines**: Use with tetracyclines may increase the potential for the occurrence of pseudotumor cerebri (cerebral edema and increased CSF pressure).

Laboratory Considerations

- Increases in serum **triglyceride** and **cholesterol** concentrations may be noted, which can be associated with corneal lipid deposits.
- **Platelets** may be increased.
- **ALT** (SGOT), **AST** (SGPT), and **LDH** concentrations may be increased.

Dosages

DOGS:

Sebaceous adenitis, schnauzer comedo syndrome, keratoacanthoma, pilomatrixoma, idiopathic seborrhea, ichthyosis, and sebaceous gland hyperplasia and adenoma (extra-label): Dosage can vary, and there are no prospective, well-controlled, clinical studies to support any dosage regimen. Most recommend an initial dose of 1 mg/kg PO once or twice daily, given with food. Clinical efficacy may not be seen for 6 to 8 weeks. If efficacy is noted, dose may be decreased to 0.5 mg/kg, or the time between doses may be extended to every other day. Long-term treatment may be required.

Epitheliotropic lymphoma; palliative treatment (extra-label): 3 – 4 mg/kg PO once daily or divided twice daily has been suggested

CATS:

Feline acne (extra-label): 5 – 10 mg/cat (NOT mg/kg) PO once daily has been suggested

Epitheliotropic lymphoma; **palliative treatment** (extra-label): 10 mg/cat (NOT mg/kg) once daily has been suggested

Monitoring

- Efficacy and adverse effects
- Baseline and periodic (eg, 1 to 2 months later if clinical signs appear) liver enzymes
- Dogs: baseline and monthly Schirmer tear tests—especially in older dogs and KCS-susceptible breeds
- Cats: body weight

Client Information

- **Pregnant women must not be exposed to isotretinoin.** It should not be handled by pregnant women and should not be used in households with pregnant women, as severe birth defects can result.
- This medicine is best given with food but should be given the same way (with food or without) each time. If your animal vomits or acts sick after getting it on an empty stomach, give with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Dogs tolerate this medication better than cats. The most common side effect in dogs is dry eye syndrome (KCS). In cats, gastrointestinal effects (eg, loss of appetite, diarrhea, weight loss) may limit use.

Chemistry/Synonyms

A synthetic retinoid, isotretinoin occurs as a yellow-orange to orange, crystalline powder. It is insoluble in both water and alcohol. Commercially, it is available in soft gelatin capsules as a suspension in soybean oil.

Isotretinoin may also be known as isotretinoinum, 13-cis-retinoic acid, Ro-4-3780, and *Accutane*®.

Storage/Stability

Capsules should be stored at room temperature in tight, light-resistant containers. The drug is photosensitive and will degrade with light exposure. Expiration dates of 2 years are assigned after manufacture.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Isotretinoin Oral Capsules: 10 mg, 20 mg, 25 mg, 30 mg, 35 mg, and 40 mg (regular and soft gel); *Absorica*®, *Accutane* ®, *Amnesteem*®, *Claravis*®, *Sotret*®, *Myorisan*®; Rx

NOTE: Because of the known teratogenic effects, availability is restricted by manufacturers and drug distributors; obtaining the medication for veterinary patients may be difficult.

Isoxsuprine

(eye-***sox***-suh-preen) *Vasodilan*®

Vasodilator

Prescriber Highlights

- ► Peripheral vasodilator that may have some efficacy in the treatment of navicular disease in horses; efficacy after oral administration is questionable
- ► No commercially available products in the United States; must be compounded
- ► Contraindicated immediately postpartum or in the presence of arterial bleeding
- ► Adverse effects are unlikely after oral administration.

Uses/Indications

Isoxsuprine is used principally for the treatment of navicular disease, sesamoiditis, and laminitis in horses; however, results of clinical trials using the drug are mixed.[1] Although some equine studies appear to show an improvement in lameness scores, there are minimal changes in laminar blood flow to explain the effect. Dosages that cause vasodilation in horses are likely to only be achieved with IV dosing; however, IV formulations are not commercially available and may induce neurologic adverse effects.

There have been anecdotal reports of isoxsuprine being helpful for treating dogs with a Raynaud's-like syndrome (periodic digital cyanosis, onychogryphosis)[2] and improving microcirculation in birds.[3]

Isoxsuprine has been used in humans for the treatment of cerebral vascular insufficiency, dysmenorrhea, and premature labor, but efficacies are unproven for these indications.

Pharmacology/Actions

Isoxsuprine causes direct vascular smooth muscle relaxation, primarily in skeletal muscle. Although it stimulates beta-adrenergic receptors, it is believed that this action is not required for vasodilation to occur. In horses with navicular disease, isoxsuprine raises distal limb temperatures significantly. Isoxsuprine relaxes uterine smooth muscle and may have positive inotropic and chronotropic effects on the heart. At high doses, isoxsuprine decreases blood viscosity and reduces platelet aggregation. Isoxsuprine does not appear to possess significant analgesic properties in horses.[4]

Pharmacokinetics

In humans, isoxsuprine is almost completely absorbed from the GI tract, but in horses, bioavailability is low after oral administration (2.2%), probably due to a high first-pass effect. Despite plasma concentrations of isoxsuprine being undetectable after a single oral dose and less than 5 ng/mL after repeated oral dosing, glucuronide metabolites are detectable in plasma and urine after a single oral dose.[5–7] After IV administration in horses, the elimination half-life is between 2 and 3 hours, with a large volume of distribution (6.8 to 10.5 L/kg) and high plasma clearance (43 to 53.8 mL/minute/kg).

Contraindications/Precautions/Warnings

Isoxsuprine should not be administered to animals immediately postpartum or in the presence of arterial bleeding.

Adverse Effects

After parenteral administration, horses may show signs of CNS stimulation (uneasiness, hyperexcitability, nose-rubbing), tachycardia, increased cardiac output, or sweating. Signs are typically short-lived. Adverse effects are unlikely after oral administration, but hypotension, tachycardia, and GI effects (eg, hyporexia, diarrhea) are possible.

Reproductive/Nursing Safety

No specific lactation safety information was found.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Serious toxicity is unlikely in horses after an inadvertent oral overdose, but signs listed in the ***Adverse Effects*** section could be seen. Treat clinical signs supportively if necessary. CNS hyperexcitability may be treated with diazepam and hypotension with IV fluids.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

No clinically significant drug interactions have been reported for this agent.

Laboratory Considerations

- None were noted.

Dosages

HORSES:

Orthopedic conditions, such as navicular disease (extra-label): 1.2 mg/kg PO every 8 to 12 hours initially, then decrease frequency to once a day, then to every other day. **NOTE**: Efficacy is controversial.

BIRDS:

Frostbite (extra-label): 10 mg/kg PO once daily[8]

Monitoring

- Clinical efficacy
- Adverse effects (eg, tachycardia, GI disturbances, CNS stimulation)

Client Information

- This medicine may be given with or without food.
- Tablets may be crushed and made into a slurry, suspension, or paste by adding corn or cherry syrup just before administration.
- This medicine may cause gastrointestinal effects (eg, lack of appetite, diarrhea). Fast heart rates, low blood pressure, and stimulatory effects (eg, uneasiness, nose-rubbing, overly excited) are possible but not common.

Chemistry/Synonyms

Isoxsuprine, a peripheral vasodilating agent, occurs as an odorless, bitter-tasting, white, crystalline powder with a melting point of about 200°C (392°F). It is slightly soluble in water and sparingly soluble in alcohol.

Isoxsuprine HCl may also be known as Caa-40, isoxsuprini hydrochloridum, phenoxyisopropylnorsuprifen, *Dilum®*, *Duvadilan®*, *Fadaespasmol®*, *Fenam®*, *Inibina®*, *Isodilan®*, *Isotenk®*, *Uterine®*, *Vadosilan®*, *Vasodilan®*, *Vasolan®*, *Vasosuprina Ilfi®*, *Voxsuprine®*, and *Xuprin®*.

Storage/Stability

Store tablets in tightly closed containers at room temperature (15°C to 30°C [59°F-86°F]).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Isoxsuprine HCl Tablets: 10 mg and 20 mg; no longer commercially available in the United States

Isoxsuprine HCl oral powder is available for compounding.

Itraconazole

(it-ruh-***kon***-uh-zohl) *Itrafungol®, Sporanox®*

Antifungal, Azole

Prescriber Highlights

- ► Oral triazole antifungal approved for treatment of *Microsporum canis* in cats; also used for systemic and cutaneous mycoses in a variety of species
- ► Avoid compounded oral itraconazole dosage forms, as they may not be absorbed.
- ► Contraindications include hypersensitivity to this drug or other azole antifungal agents, hepatic or renal impairment, and pregnancy.
- ► Adverse effects in dogs include anorexia, hepatotoxicity, ulcerative skin lesions, edema, and vasculitis. Rarely, erythema multiforme or toxic epidermal necrolysis may occur.
- ► Adverse effects in cats are dose-related and include GI effects (eg, anorexia, weight loss, vomiting), hepatotoxicity, and depression.
- ► Many potential drug interactions

Uses/Indications

In cats, itraconazole is indicated for the treatment of dermatophytosis caused by *Microsporum canis*. Itraconazole has been used in dogs and cats in the treatment of non-life-threatening systemic mycoses that do not involve the CNS, including aspergillosis, cryptococcal meningitis,[1] blastomycosis,[2–4] coccidioidomycosis,[5] sporotrichosis,[6] and histoplasmosis.[5,7,8] It can also be useful as adjunctive treatment for pythiosis,[9–12] lagenidiosis, zygomycosis, phaeohyphomycosis, and hyalohyphomycosis. Itraconazole may reach therapeutic concentrations in ocular or CNS tissue if there is associated inflammation and compromise of the barriers[13]; fluconazole may work better for some systemic mycoses (eg, cryptococcosis) affecting these systems. Itraconazole may also be useful for the treatment of fungal osteomyelitis,[14] onychomycosis, and *Malassezia* spp dermatitis.

In horses, itraconazole may be useful in the treatment of sporotrichosis and *Coccidioides immitis* osteomyelitis.

Pharmacology/Actions

Itraconazole is a fungistatic triazole compound that inhibits a fungal CYP450-dependent demethylation enzyme that produces ergosterol in the fungal cell membrane. The resultant intracellular accumulation of methylated sterols weakens the cellular membranes of susceptible fungi, thereby increasing membrane permeability and allowing leakage of cellular contents and impairing uptake of purine and pyrimidine precursors. Itraconazole has efficacy against a variety of pathogenic fungi, including yeasts and dermatophytes. In vivo studies using laboratory models have shown that itraconazole has fungistatic activity against many strains of *Candida* spp, *Aspergillus* spp, *Cryptococcus* spp, *Histoplasma* spp, *Blastomyces* spp, and *Trypanosoma cruzi*. Itraconazole and terbinafine combination treatment

may have synergistic antifungal effects against *Candida albicans*.

Itraconazole has anti-inflammatory activities that, although poorly understood, likely occur via suppression of T-lymphocyte proliferation, inhibition of calcium-dependent proinflammatory activities by neutrophils, and inhibition of leukotriene B_4. Itraconazole demonstrated antiviral activity in a cellular model of type I feline coronavirus infection.[15]

Pharmacokinetics

Itraconazole absorption is highly dependent on gastric pH and the presence of food.

Oral liquid dosage forms:

In cats, bioavailability of the commercial oral solution (human and feline labels) was 78%.[16] The veterinary-labeled oral solution can be administered to cats with or without food; giving with food increases itraconazole exposure (area under the curve [AUC]) by 30% but results in a delayed and lower peak concentration. Absorption characteristics differ between itraconazole oral solution (human- and feline-labeled products) and capsules.[17] In cats, brand-name liquid formulations have increased absorption as compared with capsules,[18] but this does not appear to apply to dogs.[17] The human-labeled oral solution has adequate oral bioavailability in dogs, cats, and other species, and it is suggested to be given *without* food for optimal absorption.[17] Suspensions compounded from bulk powders will likely not be absorbed.[18]

Oral solid dosage forms:

The commercially available capsules are specially formulated to increase oral bioavailability. Capsules compounded from bulk powders are not absorbed to a significant extent.[19] Bioavailability may be 50% or less when human-labeled itraconazole capsules are given to humans on an empty stomach; when given with food, bioavailability may approach 100%.[17,20] The human-labeled itraconazole tablet formulation is best absorbed when given with a high-fat meal. In humans, oral absorption of itraconazole capsules is reduced when administered concurrently with agents that decrease gastric acid secretion (eg, famotidine, omeprazole).[21] In dogs[19,22] and cats[22], studies comparing the pharmacokinetics of generic versus brand-name itraconazole capsules concluded that generic itraconazole is bioequivalent to the drug's innovator (ie, *Sporanox*®).

Itraconazole has high protein binding (eg, 99% in cats[23] and humans[21]) and is widely distributed throughout the body. In dogs, volume of distribution is 17 L/kg.[24] Skin, sebum, the female reproductive tract, and pus all have concentrations of itraconazole greater than those found in serum. Only minimal concentrations are found in CSF,[24] urine, aqueous humor, and saliva.

Itraconazole is metabolized by the liver to many different metabolites, including hydroxyitraconazole, which is active. Itraconazole's metabolism is a saturable process. In cats, administration of the veterinary-labeled oral solution resulted in a half-life of 12 hours after 1 dose and 36 hours after daily administration for 7 days.[23] In dogs, half-life is 33 to 58 hours,[17,24] and clearance is 234 mL/kg/hour after IV administration.[24] In humans, itraconazole's serum half-life ranges from 21 to 64 hours. Because of its long half-life, itraconazole does not reach steady-state plasma concentrations for at least 6 days after the start of therapy. If loading doses are given, steady-state concentrations will be approached sooner. Itraconazole may persist in tissue for several weeks to months after its discontinuation. The drug is eliminated primarily in the feces and, to a lesser extent, in the urine.

In horses, the oral itraconazole solution appears to be better absorbed than capsules. Volume of distribution of the oral solution was 6.3 L/kg, and protein binding was 99%. Elimination half-life was 11.3 hours. Oral absorption of capsules was 33% of the oral solution.[25]

Contraindications/Precautions/Warnings

Itraconazole should not be used in patients that are hypersensitive to it or other azole antifungal agents.

Itraconazole may have a negative inotropic effect,[26] particularly at higher dosages, and should be used with caution in animals with reduced cardiac function.

Itraconazole should only be used in patients with hepatic or renal impairment when the potential benefits outweigh the risks.

Neuropathy has occurred in humans receiving long-term itraconazole therapy[21,27]; veterinary significance is uncertain.

African grey parrots appear to be highly sensitive to itraconazole and can develop anorexia and depression. Other antifungals or reduced dosages of itraconazole are recommended in this species.[28]

Compounding capsules from bulk powders may not yield a dosage form that is well absorbed. Itraconazole absorption may be impaired in patients with achlorhydria (or hypochlorhydria) and could result in therapeutic failure.

Adverse Effects

In dogs, anorexia and hepatotoxicity are the most common adverse effects observed, especially at higher doses.[3] Anorexia is often the clinical marker for toxicity; it is commonly dose-dependent and occurs in the second month of treatment. Approximately 10% of dogs receiving 10 mg/kg/day and 5% of dogs receiving 5 mg/kg/day developed hepatic toxicosis (as determined by increased ALT activity) serious enough to discontinue treatment, at least temporarily.[2,3] Some dogs (ie, 7% or more) given itraconazole may develop ulcerative skin lesions, vasculitis, or limb edema requiring drug discontinuation.[3,29] These signs generally resolve after stopping the drug. Re-exposure after dermal lesions have resolved is not recommended because these types of reactions are likely idiosyncratic, not dose-dependent, and may cause more severe clinical signs. Rarely, serious erythema multiforme or toxic epidermal necrolysis reactions have been noted.

In cats, adverse effects appear to be dose dependent.[29] GI effects (eg, anorexia, diarrhea, hypersalivation, vomiting), hepatotoxicity (eg, increased ALT activity, jaundice), weight loss, and depression have been noted. Increased ALT activity occurred in 13% of cats, although in one report of 21 shelter cats, no cats experienced an increase of ALT activity outside the upper limit of normal.[30] As in dogs, doses above 10 mg/kg may be associated with a greater frequency of adverse effects, including hepatotoxicity. In one retrospective review of cats receiving dosages as high as 27 mg/kg/day, 31% cats experienced GI adverse effects.[31]

If adverse effects occur and ALT activity is markedly increased, the drug should be discontinued. Increased liver enzymes in the absence of other signs does not necessarily mandate dose reduction or drug discontinuation. Once ALT activity returns to normal and other adverse effects have resolved, the drug may be restarted at a lower dose or by using longer dosing intervals with intense monitoring.

Itraconazole (unlike ketoconazole) does not have appreciable effects on hormone synthesis and likely has fewer adverse effects than ketoconazole in small animal species.

Other adverse effects reported in humans include nausea, vomiting, diarrhea, fatigue, skin rash, edema, hypokalemia, and hypertension.[21]

Reproductive/Nursing Safety

Itraconazole did not impair fertility in rats. In laboratory animals, itraconazole has caused dose-related maternotoxicity, fetotoxicity, and teratogenicity at high doses (ie, 5 to 20 times the labeled dose). In a repeated dose study, 16 pregnant queens receiving itraconazole 5 mg/kg PO for a total of 21 days (7 days on alternate weeks) during gestation or lactation showed a high frequency of fetal resorption, abnormal fetuses, and abnormal maternal behaviors.

Itraconazole enters maternal milk. Use with caution in lactating animals; consider milk replacer.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information on the acute toxicity of itraconazole is available. Itraconazole dosages up to 25 mg/kg/day given on alternate weeks to healthy cats resulted in hypersalivation and increased liver enzyme activity. Inflammatory lesions were also seen in the lungs and kidneys of some cats and were believed to be caused by a component of the liquid vehicle (hydroxypropyl-beta-cyclodextrin [HP-beta-CD]). Administration of oral antacids may help reduce absorption. If a large overdose occurs, gastric decontamination should be considered, and supportive therapy provided as required. Itraconazole is not removed by dialysis, but dialysis would remove HPbetaCD in cases in which the oral solution was ingested.[32] Itraconazole effects may be reversed by IV lipid emulsion therapy.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

In humans, itraconazole is a potent inhibitor of CYP3A4 and P-glycoprotein and is metabolized by CYP3A4; veterinary significance is uncertain. The following drug interactions have either been reported or are theoretical in humans or animals receiving itraconazole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring should be performed when appropriate.

- **Amphotericin B**: Laboratory animal studies have shown that itraconazole used concomitantly with amphotericin B may be antagonistic against *Aspergillus* spp or *Candida* spp; the clinical importance of these findings is not clear.
- **Antacids, Oral** (eg, **aluminum, calcium and magnesium containing**): May reduce oral absorption of itraconazole, which should be administered at least 1 hour before or 2 hours after antacids
- **Histamine H_2-Blockers** (eg, **famotidine**, **ranitidine**): Increased gastric pH may reduce itraconazole absorption.
- **Highly Protein Bound Drugs** (eg, **NSAIDs, phenytoin, salicylates, sulfonamides, sulfonylurea antidiabetic agents** [eg, **glipizide, glyburide**], **warfarin**): Because itraconazole is highly bound to plasma proteins (ie, 99%), it could theoretically displace other highly bound drugs; a temporary increase in serum concentrations may occur. These interactions have not been shown to be of clinical concern.
- **Isoniazid**: May decrease itraconazole concentrations
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May increase itraconazole concentrations; itraconazole may increase macrolide antibiotic concentrations
- **Meloxicam**: Itraconazole may decrease peak meloxicam concentrations and reduce meloxicam exposure.
- **Phenobarbital, Primidone**: May decrease itraconazole concentrations
- **Proton Pump Inhibitors** (**PPIs**; eg, **omeprazole, pantoprazole**): Increased gastric pH may reduce itraconazole absorption.
- **Rifampin**: May decrease itraconazole concentrations; itraconazole may increase rifampin concentrations; concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.[33]
- **Sucralfate**: May reduce itraconazole absorption
- **Toceranib**: Increased toceranib or itraconazole concentrations may occur

Itraconazole may increase the absorption and/or reduce the metabolism of the following drugs (increasing plasma concentrations or exposure with resulting increased risk for toxicity):

- **Benzodiazepines** (eg, **alprazolam, diazepam, oral midazolam**): Itraconazole may increase benzodiazepine concentrations. In humans, concurrent use with oral midazolam is contraindicated.[21,27]
- **Buspirone**: Itraconazole may increase plasma concentrations of buspirone.
- **Busulfan**: Itraconazole may increase busulfan concentrations.
- **Calcium-Channel Blocking Agents** (eg, **amlodipine, diltiazem**): Itraconazole may increase concentrations and the risk for toxicity. Increased itraconazole concentrations may occur. Negative inotropic effects may be potentiated. Use this combination cautiously in patients with heart failure.
- **Cannabidiol**
- **Ciprofloxacin**: May result in increased itraconazole exposure
- **Cisapride**: Itraconazole may increase cisapride concentrations and the risk for toxicity; in humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.[21,27]
- **Colchicine**: In humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated in patients with hepatic or renal impairment.[21,27]
- **Corticosteroids** (eg, **dexamethasone, predniso(lo)ne**): Itraconazole may inhibit the metabolism of corticosteroids; increased hepatotoxic and GI adverse effects are possible.
- **Cyclophosphamide**: Itraconazole may inhibit the metabolism of cyclophosphamide and its metabolites; increased toxicity can occur.
- **Cyclosporine**: Itraconazole increases cyclosporine concentrations and decreases cyclosporine dose requirements.[34]
- **Digoxin**: Itraconazole may increase digoxin concentrations.
- **Disopyramide**: Use together (in humans) is contraindicated.
- **Doxorubicin**: Itraconazole increases doxorubicin exposure.
- **Ergot Alkaloids** (eg, **bromocriptine, cabergoline, pergolide**): Itraconazole increases ergot alkaloid concentrations; use together (in humans) is contraindicated.
- **Fentanyl/Alfentanil**: Itraconazole may increase fentanyl or alfentanil concentrations; in humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.
- **Ivermectin**: Itraconazole may increase the risk for neurotoxicity.
- **Loperamide**
- **Methadone**: In humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.
- **Praziquantel**: Increased plasma concentrations of praziquantel
- **Quinidine**: Increased risk for quinidine toxicity; use together (in humans) is contraindicated.
- **Rivaroxaban**: Increased risk for rivaroxaban toxicity; in humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.
- **Sildenafil**: Itraconazole increases sildenafil exposure.
- **Sulfonylurea Antidiabetic Agents** (eg, **glipizide, glyburide**): Itraconazole may increase concentrations of these agents; hypoglycemia is possible.
- **Tamsulosin**: Increased risk for tamsulosin toxicity; in humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clo-**

mipramine): Itraconazole may decrease metabolism and increase TCA concentrations.

- **Vincristine/Vinblastine**: Itraconazole may inhibit vinca alkaloid metabolism and increase concentrations; in humans, concurrent use or use within 2 weeks of discontinuing itraconazole is contraindicated.
- **Warfarin**: Itraconazole may cause increased prothrombin times in patients receiving warfarin or other coumarin anticoagulants.

Laboratory Considerations

None

Dosages

NOTE: Because commercial itraconazole solutions yield higher peak serum concentrations and overall drug exposure than commercial itraconazole capsules in cats, lower doses can be used with solutions.[18] This does not appear to be the case with dogs.[17] Capsules should be administered with food to maximize absorption. Compounded formulations should be avoided.

DOGS:

Susceptible systemic mycoses (extra-label): Typically, 5 – 10 mg/kg PO once daily (or divided and given every 12 hours) with food; recommendations for treatment duration vary and are determined by the infective agent and site of infection. In general, treatment for systemic mycoses should be maintained for at least 30 to 60 days after clinical resolution. Infections such as pythiosis, lagenidiosis, zygomycosis, phaeohyphomycosis, or hyalohyphomycosis may require 10 – 15 mg/kg PO once daily for many months, as well as surgical resection and additional antifungal agents (eg, terbinafine). **NOTE**: Itraconazole dosages greater than or equal to 10 mg/kg/day are associated with an increased risk for adverse effects.

Blastomycosis (extra-label): 5 mg/kg PO once daily for 1 month beyond resolution of clinical signs.[2–4] Dosages up to 10 mg/kg per day may be used, but the risk for adverse effects increases with higher doses. One study found equivalent results in dogs treated with fluconazole.[2]

Histoplasmosis (extra-label): Median dosage was 10 mg/kg/day PO, but dosages ranged from 4.3 – 33.8 mg/kg/day.[8]

Dermatophytosis, onychomycosis (extra-label): 5 – 10 mg/kg PO once daily[35]; treatment should continue until mycologic cure (2 negative skin cultures taken 2 weeks apart)

***Malassezia* spp dermatitis** (extra-label):

a) **Daily**: 5 mg/kg PO every 24 hours and continued for 1 week after complete resolution of clinical signs[36,37]

b) **Pulse therapy**: 5 mg/kg PO every 24 hours for 2 consecutive days per week[36,37]

***Trypanosoma cruzi* infection (American trypanosomiasis [ie, Chagas disease])** (extra-label): 10 mg/kg PO once daily with amiodarone 7.5 mg/kg PO once daily (with or without amiodarone loading dosage protocol). **NOTE**: Itraconazole 100 mg (total dose; NOT mg/kg) PO every 48 hours was administered to dogs with low body weight; itraconazole dose was rounded down to the nearest 100 mg increment dose.[38]

Pythiosis (extra-label): 5 – 10 mg/kg PO once daily in combination with terbinafine 6 – 12 mg/kg PO once daily.[9–12] This combination may be used in conjunction with mefenoxam 4 mg/kg PO every 12 hours[9–11] or prednisone.[12]

CATS:

Dermatophytosis caused by *Microsporum canis* (label dosage; FDA-approved): 5 mg/kg PO (with or without food) once daily for 7 days given on alternating weeks for 3 treatment cycles. Cats must be treated during weeks 1, 3, and 5 and left untreated during weeks 2 and 4.

Generalized dermatophytosis in shelter cats (extra-label): 5 mg/kg PO once daily for 21 days with concurrent twice-weekly lime sulfur rinses. Treating otherwise healthy cats without biochemical monitoring is reasonable and cost effective; however, if cats become depressed or anorexic, biochemical monitoring is indicated.[30,39]

***Malassezia* spp dermatitis** (extra-label):

a) **Daily**: 5 – 10 mg/kg PO once daily and continued for 1 week after complete resolution of clinical signs[35,37,40]

b) **Pulse therapy**: 5 mg/kg PO once daily for 2 consecutive days per week[36,37]

Susceptible systemic mycoses (extra-label):

a) 5 – 10 mg/kg PO once daily (or divided and given every 12 hours) with food. Treatment duration may be months (ie, 2 or more), and treatment is generally recommended to continue for at least 30 to 60 days after clinical resolution of signs. Certain infections may require additional surgical treatment or additional antifungals (eg, amphotericin B, terbinafine).

b) In a pharmacokinetics study, 100 mg/cat (NOT mg/kg) PO every 48 hours resulted in serum concentrations that should be safe and effective.[41]

c) **Fungal osteomyelitis**: From 2 case reports, 1 cat received itraconazole 10 mg/kg PO every 12 hours for at least 5 weeks and showed marked improvement prior to being lost to follow-up.[14] A second cat received itraconazole 12.8 mg/kg PO every 12 hours with amphotericin B 0.55 mg/kg as a twice-weekly SC infusion. Itraconazole caused inappetence and vomiting, and the itraconazole dose was reduced to 9 mg/kg PO every 12 hours and continued until the patient was seronegative twice, 1 month apart (≈2 years).[42]

d) **Cryptococcosis**: From a retrospective study, 50 – 100 mg/cat (NOT mg/kg) PO once daily. Fluconazole appeared to have greater efficacy with a shorter treatment duration.[1]

Sporotrichosis (extra-label):

a) **Monotherapy**: 10 mg/kg PO every 24 hours for 2 to 3 months, or 1 month after clinical cure, has been recommended.[43–46] Other dosages have included 8.3 – 27.7 mg/kg PO daily[31] or 50 – 100 mg/cat (NOT mg/kg) PO with food every 24 hours.[6] Treatment resulted in 38% to 71% of cats being clinically cured; nasal mucosal involvement, respiratory signs, and high fungal loads in skin lesions were predictors of treatment failure.[6,31] In one study, itraconazole was more effective and better tolerated than ketoconazole.[31]

b) **Combination therapy**:

i. Itraconazole 100 mg/cat/day PO (NOT mg/kg) in combination with potassium iodide initially, 2.5 mg/kg/day PO, increased by 2.5 mg/kg/day every 30 days until clinical cure was attained or the dosage reached 20 mg/kg/day. This combination cured 96% of treatment-naive cats; the median potassium iodide dosage was 3.1 mg/kg/day, and median time of treatment was 14 weeks (range, 8 to 30 weeks).[47] Itraconazole 100 mg/cat (NOT mg/kg) PO once daily in combination with potassium iodide 5 mg/kg/day PO was effective in cats that failed to respond to itraconazole monotherapy.[48]

ii. Itraconazole 100 mg/cat/day PO (NOT mg/kg) in combination with intralesional amphotericin B (conventional) resulted in clinical remission in 85% of patients. Amphotericin B was reconstituted with 10 mL 1% lidocaine and multidirectionally directly infiltrated into each lesion until swelling occurred.[49]

HORSES:

Guttural pouch mycosis, mycotic rhinitis, or osteomyelitis (extra-label): Using the oral solution, 5 mg/kg PO every 24 hours should be sufficient for treatment.[50] **NOTE**: Itraconazole oral solution is better absorbed than capsules,[25] and compounded formulations may not be absorbed (see ***Compatibility/Compounding Considerations***).

BIRDS:

NOTE: All dosages are extra-label.

a) 5 – 10 mg/kg PO every 12 to 24 hours. Use with caution in African grey parrots.[51]
b) Aspergillosis: 5 – 10 mg/kg PO once daily in Amazon parrots; 2.5 – 5 mg/kg PO once daily in African grey parrots[52]

RABBITS, RODENTS, SMALL MAMMALS:

Mice (extra-label): Blastomycosis: 50 – 150 mg/kg every 24 hours

Hedgehogs (extra-label): Dermatophytosis: 10 mg/kg PO twice daily using a commercial oral solution[53]

Rats (extra-label): Vaginal candidiasis: 2.5 – 10 mg/kg every 24 hours

Guinea pigs (extra-label): Systemic candidiasis: 5 mg/kg every 24 hours[54]

Rabbits (extra-label): Dermatophytosis: 5 – 10 mg/kg PO once daily

REPTILES:

Susceptible fungal diseases (extra-label):

a) 10 – 20 mg/kg PO every 24 hours[55]
b) 10 mg/kg PO every 48 hours for 14 days or 10 mg/kg every 24 hours for 7 days followed by every 48 hours for 7 days[56]

Monitoring

- Clinical efficacy
- With long-term therapy, periodic laboratory monitoring of renal and hepatic markers is recommended.
- Fungal cultures (eg, Dermatophyte Test Media [DTM]) for dermatophytosis
- Urine antigen testing for systemic mycoses
- Consider monitoring itraconazole serum trough concentrations (when available) with prolonged treatment of systemic infections.
- GI signs (eg, inappetence, vomiting, diarrhea)
- Itraconazole is contraindicated in humans with evidence of ventricular dysfunction. It is unknown if this applies to animals; consider monitoring cardiac function in animals with pre-existing heart disease.
- Physical assessment for ulcerative skin lesions in dogs

Client Information

- Give this medicine as directed by your veterinarian.
- Use the syringe provided with the FDA-approved oral solution for cats. Do not invert the bottle when withdrawing the solution. Rinse and dry the syringe after administration and screw the cap tightly onto the bottle.
- The veterinary-labeled oral solution may be given to cats with or without food. Preferably, give the oral solution to other mammals on an empty stomach. Give capsules or capsule contents with a fatty food (eg, butter, cream, ice cream, cheese).
- This medicine interacts with many others. Do not give your animal other medications without first talking to your veterinarian or veterinary pharmacist.
- Vomiting and loss of appetite are the most common side effects seen in dogs and cats. Liver toxicity and serious skin effects are also possible.

Chemistry/Synonyms

Itraconazole, a synthetic triazole antifungal, is structurally related to fluconazole. It occurs as a white or almost-white powder. It is practically insoluble in water, very slightly soluble in alcohol, and highly lipophilic. The log-P octanol/water partition coefficient is 5.66.[24] The human-labeled commercial oral solution has a pH of 2.

Itraconazole may also be known as itraconazolum, oriconazole, R-51211, or *Sporanox*®; many other trade names are available.

Storage/Stability

Itraconazole capsules should be stored between 15°C and 25°C (59°F-77°F) and protected from light and moisture.

Veterinary-labeled itraconazole solution should be stored upright at 20°C to 25°C (68°F-77°F), with excursions permitted between 15°C to 30°C (59°F-86°F). Human-labeled itraconazole oral solution should be stored at temperatures less than 25°C (77°F) and protected from freezing.

Compatibility/Compounding Considerations

Compounding capsules or solutions from bulk chemicals or powders likely will not yield dosage forms that are absorbed. The oral bioavailability and solubility of itraconazole are dependent on complexation with acidified high-molecular weight polyethylene glycol (PEG) or cyclodextrin molecules,[24] a technology used in the brand name (ie, *Itrafungol*®, *Sporanox*®) and generic commercially produced human drug products for itraconazole, but typically not in compounded dosage forms. Studies have demonstrated that itraconazole compounded from the bulk chemical produces inferior blood concentrations as compared with FDA-approved itraconazole products.[18,22,57,58] Inferior blood concentrations of itraconazole may contribute to treatment failure and fatality if compounded itraconazole is used in life-threatening infections (eg, blastomycosis, pythiosis). Compounded itraconazole products should NOT be used unless they have been prepared from FDA-approved commercial capsules or documented bioavailability and stability data are provided.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Itraconazole Oral Solution: 10 mg/mL in 52 mL; *Itrafungol*®; (Rx). Labeled for use in cats. NADA# 141-474. Cherry–caramel flavor

HUMAN-LABELED PRODUCTS:

Itraconazole Capsules: 100 mg; *Sporanox*®; generic; (Rx)

Itraconazole Oral Solution: 10 mg/mL in 150 mL; *Sporanox*®; (Rx). Cherry–caramel flavor

Ivermectin

(eye-ver-***mek***-tin) *Heartgard®, Ivomec®*
Antiparasitic

Prescriber Highlights

- ► Used in dogs and cats to prevent heartworm disease by eliminating tissue stages of heartworm larvae, as well as in cats to remove and control hookworms
- ► Used in horses, cattle, and sheep as a broad-spectrum ecto- and endoparasiticide. Best used as part of a comprehensive parasite management program that includes fecal egg count reduction testing to treat only those animals with high endoparasite burden
- ► Also used as an antiparasiticide in a wide variety of other species
- ► Contraindications include animals that are hypersensitive to it and in chelonians, indigo snakes, crocodilians, and skinks.
- ► Use of doses higher than those used for heartworm prevention should be undertaken with caution in breeds susceptible to *MDR1* mutation (also known as *ABCB1*-1delta) because they are at higher risk for CNS toxicity.
- ► Use very cautiously (or avoid use) with other drugs that affect P-glycoprotein (P-gp).
- ► Use as a microfilaricide in dogs should be avoided, as dogs may exhibit a shock-like reaction that is presumably a result of dying microfilaria.
- ► Adverse effects in horses include swelling and pruritus at the ventral midline, which can be seen »24 hours after ivermectin administration due to a hypersensitivity reaction to dead *Onchocerca* spp microfilaria.
- ► In cattle, ivermectin should only be administered via SC route and not by IM or IV routes; ivermectin can induce serious adverse effects by killing parasitic larvae in vital areas of the body; it may also cause discomfort or transient swelling at the injection site.

Uses/Indications

In dogs, ivermectin is FDA-approved only for use as a heartworm preventive. In cats, ivermectin is FDA-approved for heartworm prevention and removal and control of hookworms. This drug has also been used in dogs and cats in an extra-label manner as a broad-spectrum endo- and ectoparasiticide, although isoxazolines are active effective against a wider spectrum of ectoparasites. Ivermectin and doxycycline individually suppress embryogenesis in parasites and weaken adult heartworms; when these drugs are used together as adulticide pretreatment, they provide more rapid adulticidal activity and reduce pulmonary pathology caused by heartworm death. The combination is also more effective at reducing *Wolbachia* spp numbers than doxycycline alone. The American Heartworm Society does **NOT** recommend using macrocyclic lactones in dogs at prophylactic doses as a slow-kill adulticide method for *Dirofilaria immitis*[1]; however, in cats, monthly ivermectin for 2 years may be used to reduce worm burdens.[2]

In horses, ivermectin is FDA-approved for the control of large strongyles (adults), small strongyles (adults, fourth-stage larvae), pinworms (adults, fourth-stage larvae), ascarids (adults, third- and fourth-stage larvae), hairworms (adults), large-mouth stomach worms (adults), neck threadworms (microfilariae), bots (oral and gastric stages), lungworms (adults, fourth-stage larvae), intestinal threadworms (adults), and summer sores (cutaneous third-stage larvae) secondary to *Habronema* spp or *Draschia* spp. For a list of individual species covered, refer to specific product information.[3]

In cattle, ivermectin is FDA-approved for the treatment and control of GI roundworms (adults, fourth-stage larvae), lungworms (adults, fourth-stage larvae), cattle grubs (parasitic stages), sucking lice, mites, and horn flies. For a list of individual species covered, refer to specific product information.[4,5]

In swine, ivermectin is FDA-approved for the treatment and control of GI roundworms (adults, fourth-stage larvae), somatic roundworm larvae, lungworms (adults), lice, and mange mites. For a list of individual species covered, refer to specific product information.[4]

In sheep, ivermectin is FDA-approved for the treatment and control of GI roundworms (adults, fourth-stage larvae), lungworms (adults, fourth-stage larvae), and nasal bots (larval stages). For a list of individual species and life cycles covered, refer to specific product information.[6]

In reindeer, ivermectin is FDA-approved for the treatment and control of warbles.

In American bison, ivermectin is FDA-approved for the treatment and control of grubs.

Pharmacology/Actions

Ivermectin binds glutamate-gated chloride ion channels within invertebrate nerve and muscle cells, increasing cell permeability to chloride ions. The resulting cell hyperpolarization causes paralysis and death of the parasite. Mammals lack glutamate-gated chloride ion channels, and ivermectin has low affinity for other chloride ion channels. Ivermectin may also have activity at gamma-aminobutyric acid (GABA)-gated chloride channels.

Ivermectin kills third- and fourth-larval stage *Dirofilaria immitis* and microfilariae and reduces the life span of adult heartworms. Resistance by *D immitis* to macrocyclic lactones is a concern. The American Heartworm Society has stated: *It is now generally accepted that isolated instances of resistant heartworms have been identified. The extent, the degree of spread, and the reasons for resistance are not well understood and are controversial. . . . The data suggest that owner compliance is the biggest factor in the 'failure' of preventives.*[1]

Studies have shown that ivermectin has some antitumor properties[7–9] and the potential to reverse drug resistance in cancer cells[10], but clinical significance[11] is not yet established.

Although structurally similar to macrolide antibiotics, avermectins have no antibacterial properties.

Pharmacokinetics

In monogastric animals, ivermectin is up to 95% absorbed after oral administration. Oral absorption is reduced in ruminants as the drug may bind to solid material in the rumen. In a variety of species, SC administration results in greater bioavailability and overall drug exposure (AUC), but absorption after oral administration is more rapid.[12] Ivermectin is absorbed after transdermal administration, but results in lower overall exposure than parenteral and oral routes.

Ivermectin is highly bound to plasma proteins (≈90%). Ivermectin is well distributed to most tissues but does not readily penetrate into the CSF. Animals with the *MDR1* mutation (also known as *ABCB1*-1delta; eg, dogs, cats, mice) produce a defective P-glycoprotein (P-gp) transporter,[13] allowing ivermectin to enter into the CNS and increasing the risk for neurotoxicity.

Ivermectin has a long terminal half-life in most species (see below). It is metabolized in the liver via oxidative pathways and is primarily excreted in the feces. In humans, ivermectin is metabolized principally by cytochrome CYP3A4 and, to a lesser extent, by CYP2D6 and CYP2E1. Less than 5% of the drug (as parent compound or metabolites) is excreted in the urine.

Pharmacokinetic parameters of ivermectin have been reported for various species.[12]

- Dogs: Bioavailability was 95%, volume of distribution was 2.5 to 5.3 L/kg, and elimination half-life was 2 to 4 days.[14] Plasma ivermectin concentrations in collies with ivermectin toxicosis were

similar to those of nonsensitive dogs.[15]

- Cats: After SC administration, volume of distribution was 9.8 L/kg, and elimination half-life was 2.5 days.[16]
- Horses: After oral administration, the half-life was ≈3 to 4 days.[17] Ivermectin pharmacokinetics may differ between horse breeds.[18]
- Cattle: SC bioavailability was 33 to 55%, volume of distribution was 1.2 – 3.4 L/kg, elimination half-life was 4 to 6 days, and total body clearance was 0.3 to 0.5 L/kg/day. Compared with other routes, topical (pour-on) administration resulted in a lower overall AUC; half-life was ≈5 days in one study.[19]
- Sheep: Bioavailability was 100% with intra-abomasal administration and 25% with intraruminal administration; volume of distribution was ≈5 to 13 L/kg, and elimination half-life was 2 to 7 days.[20]
- Goats: AUC following topical (pour-on) administration was 40% lower than with oral administration;[21] elimination half-life was ≈4 to 6 days and varied by breed.[22]
- Swine: Volume of distribution was 2 to 4 L/kg and elimination half-life was ≈1.5 to 3.5 days.

Contraindications/Precautions/Warnings

Ivermectin is contraindicated in animals with hypersensitivity to it and in chelonians, indigo snakes, crocodilians, and skinks.[23]

Ivermectin is not recommended for use in puppies younger than 6 weeks of age or in dogs without a current negative heartworm test. Secondary to a defect in the P-glycoprotein transport mechanism, dogs with the *MDR1* mutation (also known as *ABCB1*-1delta) can show adverse neurologic effects after receiving a single dose greater than 120 µg/kg and can develop life-threatening neurologic toxicity at doses of 300 µg/kg.[24] Ivermectin should not be used extra-label in breeds susceptible to the *MDR1* mutation (eg, collies, shelties, Australian shepherds) unless the dog has been tested and found to not have the genetic defect; see ***Appendix*** for more information. At higher doses, neurotoxicity can occur (rare) in dogs tested normal/normal, so it is advised to continually monitor for adverse effects. When ivermectin is used at labeled heartworm preventive dosages, toxicity is not observed regardless of the *MDR1* status. It is recommended that if any adverse effects occur at any dose amount, ivermectin should be discontinued.

The injectable products for use in cattle and swine should be given SC only; do **NOT** give IM or IV.

Products should not be used off-label when a labeled product is available for the target species. If using a product in a species for which it is not labeled (ie, extra-label), be certain of the dosage and/or dilutions. There are many reports of overdoses in small animals that received incorrectly diluted large animal injectable products.

Adverse Effects

Neurotoxicity is possible in dogs, particularly in those with the *MDR1* mutation (also known as *ABCB1*-1delta), which is seen most commonly in certain collie-type breeds. There are also case reports of dogs without the *MDR1* mutation developing neurotoxicity after receiving ivermectin at high doses (eg, to treat demodicosis).[25] Heartworm-positive dogs may exhibit a shock-like reaction if ivermectin is used at microfilaricide doses, presumably due to a reaction associated with the dying microfilariae. Vomiting and diarrhea are possible but rare.

In horses, swelling and pruritus at the ventral midline can be seen ≈24 hours after ivermectin administration due to a hypersensitivity reaction to dead *Onchocerca* spp microfilariae. This reaction is preventable by administering a glucocorticoid just prior to and 1 to 2 days after ivermectin administration. If untreated, swelling usually subsides within 7 to 10 days and pruritus resolves within 3 weeks. There are case reports of horses developing neurotoxicity after receiving recommended oral dosages.[26]

When used to treat *Hypoderma* spp larvae (ie, cattle grubs) in cattle, ivermectin can induce serious adverse effects when larvae die in vital areas of the body. Larvae killed in the vertebral canal (*Hypoderma bovis*) can cause paralysis and staggering, and those killed around the esophagus (*Hypoderma lineatum*) can induce salivation and bloat. These adverse effects can be avoided by treating for grubs immediately after the heel fly (ie, warble fly) season, before the larvae migrate into these vital areas. Cattle may experience discomfort or transient swelling at the injection site. Using a maximum of 10 mL at any one injection site can help minimize these effects.

In mice and rats, ivermectin may cause neurologic toxicity at doses slightly more than usually prescribed (less than 0.5 mg/kg).[27]

In birds, death, lethargy, or anorexia may be seen. Orange-cheeked waxbill finches and budgerigars may be more sensitive to ivermectin than other species.

For additional information, refer to ***Overdose/Acute Toxicity***.

Reproductive/Nursing Safety

Ivermectin is considered safe to use during pregnancy. Teratogenicity has been noted in rats and rabbits at doses of 4.5 and 8 times the maximum recommended dose, respectively.[28] However, adverse fetal effects have not been demonstrated in dogs, horses, cattle, or swine. Testicular hypoplasia was noted on pathology in dogs receiving doses 3 times and 5 times the labeled doses of an ivermectin/pyrantel pamoate/praziquantel combination product monthly for 6 months.[29] A separate study of the same product demonstrated a dose-related decrease in testicular maturation in beagle puppies as compared with control. Reproductive performance in adult male animals is apparently unaltered.

Ivermectin is excreted in milk in low concentrations; it is unlikely to pose significant risk for nursing offspring.

Overdose/Acute Toxicity

Common clinical signs associated with an overdose may include ataxia, mydriasis, blindness, tremors, vomiting, seizures, and cardiovascular and respiratory depression.

In dog breeds without the *MDR1* mutation (also known as *ABCB1*-1delta), signs of acute toxicity rarely occur at single doses of 1 mg/kg (1000 µg/kg) or less. Mydriasis occurs at 2.5 mg/kg, and tremors occur at 5 mg/kg. At doses of 10 mg/kg, severe tremors and ataxia are seen. Deaths occurred when doses exceeded 40 mg/kg, but LD_{50} is 80 mg/kg.[30] Beagles receiving 0.5 mg/kg/day PO for 14 weeks developed no signs of toxicity but developed mydriasis and had some weight loss when given 1 – 2 mg/kg/day for the same time period. Half of the dogs receiving 2 mg/kg/day for 14 weeks developed signs of depression, tremors, ataxia, anorexia, and dehydration.

In dog breeds with the *MDR1* mutation, ivermectin enters the CNS at much higher concentrations than unaffected dogs. Doses of 60 µg/kg (10 times the recommended heartworm prophylaxis dose) demonstrated no signs of toxicity in sensitive collies.[31] Dogs with the *MDR1* mutation can show adverse neurologic effects after receiving a single dose greater than 120 µg/kg and develop life-threatening neurologic toxicity at doses of 300 µg/kg.[24] In cases of overdoses, signs of neurotoxicity can develop within 4 hours in breeds homozygous for the *MDR1* mutation.

Dogs that receive an overdose of ivermectin or develop signs of acute toxicity should receive supportive therapy for treatment of clinical signs. Gastric decontamination should be considered for acute massive oral ingestions in dogs or cats. For both oral and injected ivermectin overdoses, the use of repeated activated charcoal doses can interrupt enterohepatic recirculation.

Ivermectin has a large safety margin in cats. Kittens receiving doses of at least 110 µg/kg and adult cats receiving at least 750 µg/kg showed no adverse effects. The margin of safety is narrower in kit-

tens, as significant clinical signs have been seen at 300 µg/kg. Acute toxic signs associated with massive overdoses in cats will appear within 10 hours of ingestion. Signs may include agitation, vocalization, anorexia, mydriasis, rear limb paresis, tremors, and disorientation. Blindness, head pressing, wall climbing, absence of oculomotor menace reflex, and a slow and incomplete response to pupillary light may also be seen. Neurologic signs usually diminish over several days and most animals completely recover within 2 to 4 weeks. Supportive care is recommended.

In horses, doses of 1.8 mg/kg PO (9 times the recommended dose) did not produce signs of toxicity, but doses of 2 mg/kg caused signs of visual impairment, depression, and ataxia.[30,32]

In cattle, toxic effects generally do not appear until doses of 30 times the recommended dose are injected.[33] At 8 mg/kg SC, cattle showed signs of ataxia, listlessness, and, occasionally, death. An oral drench of 4 mg/kg elicited an acute toxic syndrome.[30]

Sheep have shown signs of ataxia and depression at ivermectin doses of 4 mg/kg; the propylene glycol vehicle may have contributed to the toxic signs.[30]

Swine have shown signs of toxicosis (eg, lethargy, ataxia, tremors, lateral recumbency, mydriasis) at doses of 30 mg/kg.[30] Neonatal pigs may be more susceptible to ivermectin overdoses, presumably due to a more permeable blood–brain barrier. Accurate dosing practices are recommended.

IV lipid emulsion has been successfully used to treat dogs, cats, ponies, and an African lion with neurotoxicity and retinopathy/blindness caused by large ivermectin overdoses.[34–46]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

In humans, ivermectin is a substrate of CYP3A4. The following drug interactions have either been reported or are theoretical in humans or animals receiving ivermectin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

NOTE: Combined treatment with any of the drugs listed below when ivermectin is used as a single treatment or as heartworm prophylaxis is unlikely to be of clinical significance.

- **Benzodiazepines**: Effects may be potentiated by ivermectin; use together is not advised in humans.
- **Gabapentin**: Effect may be potentiated by ivermectin; use together is not advised in humans.
- **Ketamine**: It has been recommended not to use ivermectin in reptiles within 10 days of administering ketamine.[47]
- **Mitotane**: May decrease ivermectin exposure and efficacy
- **Phenobarbital**: Effect may be potentiated by ivermectin; use together is not advised in humans. Phenobarbital reduced the ivermectin plasma concentration and overall drug exposure.[48]
- **Pregabalin**: Effect may be potentiated by ivermectin; use together is not advised in humans.
- **Warfarin**: Concurrent ivermectin use may increase prothrombin time/INRs.

Caution is advised if using other drugs that can inhibit **P-glycoprotein (P-gp)**. Dogs at risk for the *MDR1* mutation (also known as *ABCB1*-1delta; eg, collies, Australian shepherds, shelties, long-haired whippets, breeds with "white feet") should not receive ivermectin above heartworm preventive doses with the following drugs unless they are tested as normal. Many P-gp inhibitors also inhibit CYP3A4 in humans and may alter ivermectin metabolism. Drugs and drug classes involved include the following:

- **Amiodarone**
- **Azithromycin**
- **Bromocriptine**
- **Carvedilol**
- **Cetirizine**: In horses, pretreatment (12 hours before cetirizine, but not 1.5 hours) with ivermectin significantly increased cetirizine plasma AUC, mean residence time, and terminal half-life.[49] However, because of cetirizine's large therapeutic index, clinical significance is not likely.
- **Clarithromycin, Erythromycin**
- **Cyclosporine**
- **Diltiazem**
- **Fluoxetine**
- **Grapefruit Juice**
- **Itraconazole, Ketoconazole**: At least one reference states that ivermectin should never be used with ketoconazole in dogs.[50]
- **Methadone, Pentazocine**
- **Quinidine**
- **Paroxetine**
- ***Solanum* spp** (nightshades): Horses ingesting nightshades and receiving oral ivermectin developed neurotoxicity.[51] The authors suggest that *Solanum* spp may alter P-gp in horses or other mammals.
- **Spinosad**: Spinosad is a potent inhibitor of canine P-gp. It has been recommended that spinosad should not be used with high extra-label doses of ivermectin.[52] In healthy beagles, spinosad has been shown to alter ivermectin pharmacokinetics and may alter blood–brain barrier permeability and increase the risk for neurotoxicity.[53]
- **Spironolactone**
- **St. John's Wort**
- **Tacrolimus**
- **Verapamil**

Laboratory Considerations

- At doses of 50 µg/kg or higher, ivermectin may yield false negative Knott's test results in animals with occult heartworm infection.

Dosages

For combination products, refer to the product label for specific approved dosage suggestions.

DOGS:

NOTE: When using ivermectin for prophylaxis or treatment of dirofilariasis, it is recommended to review the most recently published guidelines provided by the American Heartworm Society.[1]

Heartworm prevention (label dosage; FDA-approved): Minimum dosage of 6 µg/kg (0.006 mg/kg) PO per month.[31] For maximum effectiveness, heartworm prophylaxis should be given year-round; however, if seasonal treatment is chosen, administration should begin at least 1 month prior to the anticipated start of heartworm transmission and should continue for up to 6 months after transmission typically ceases.[1]

Adjunctive treatment for adult heartworm infection (extra-label): Approved heartworm preventives are given at labeled doses on day 1 of the treatment protocol and repeated every 30 days.[1]

Microfilarial keratitis (extra-label): 100 – 300 µg/kg (0.1 – 0.3 mg/kg) PO once per month. Additional treatment included prednisone 1 mg/kg/day PO for 5 to 6 days in conjunction with ivermectin and cyclosporine ophthalmic ointment applied twice daily chronically.[54]

Ectoparasiticide (miticide): **WARNING**: Do not use the dosing regimens listed below in dogs with the *MDR1* **mutation** (also known as *ABCB1*-1delta), or susceptible breeds unless they test as normal/normal. If normal/normal, a drug reaction is unlikely but still possible; continue to monitor for adverse effects. **NOTE**: Isoxazolines (eg, fluralaner, sarolaner) have largely supplanted avermectins for the treatment of demodicosis[55–57] and other ectoparasite indications.

a) **Generalized demodicosis** (extra-label): The usual recommended target dose is 600 µg/kg (0.6 mg/kg) PO once daily until 4 weeks after 2 negative skin scrapings taken 4 to 6 weeks apart. Start at a low dose and increase as follows: **Day 1**: 50 µg/kg (0.05 mg/kg) PO; **Day 2**: 100 µg/kg (0.1 mg/kg) PO; **Day 3**: 150 µg/kg (0.15 mg/kg) PO; **Day 4**: 200 µg/kg (0.2 mg/kg) PO; **Day 5**: 300 µg/kg (0.3 mg/kg) PO. Then increase by 100 µg/kg (0.1 mg/kg) every 3 to 7 days until the final target dose is reached. Treatment may be required for several months. If the animal does not have a reaction at a lower but therapeutic dose (above 300 µg/kg [0.3 mg/kg]), it may be attempted to treat at that lower dose but on an alternate-day treatment schedule to avoid adverse effects at higher doses.[50,58,59]

b) **Sarcoptic mange, cheyletiellosis** (extra-label):
SC: If skin scrapings are positive, 200 – 400 µg/kg (0.2 – 0.4 mg/kg) SC every 2 weeks for 3 treatments. If skin scrapings are not taken or are negative and a therapeutic trial is performed, or if there are positive results after the second injection, give a third injection. If there is no response after the second injection, reconsider diagnosis.
Alternatively, a PO dose for sarcoptic mange can be considered: 200 – 400 µg/kg (0.2 – 0.4 mg/kg) PO once weekly for 4 treatments[58]

c) **Otodectic acariosis** (extra-label): 300 µg/kg (0.3 mg/kg) SC every 2 weeks or topical application of 0.5 mL (using 100 µg/mL [0.1 mg/mL] concentration) per ear for 1 to 2 treatments.[58] Refer to ***Antiparasitic Preparations, Otic*** for alternative dosage forms.

d) **Nasal mites** (extra-label): 300 µg/kg (0.3 mg/kg) SC every 1 to 2 weeks for 2 to 3 treatments[58]

CATS:

NOTE: When using ivermectin for prophylaxis or treatment of dirofilariasis, it is recommended to review the most recently published guidelines provided by the American Heartworm Society.[60]

Heartworm prevention and control of hookworms (label dosage; FDA-approved): The individual minimum monthly prophylactic dose of ivermectin is 24 µg/kg (0.024 mg/kg).[61] Preventives should be started in kittens at 8 weeks of age and administered to all cats in heartworm endemic areas during the heartworm season. Use is not precluded by antibody or antigen seropositivity.[60]

HORSES:

Large and small strongyles, pinworms, ascarids, hairworms, large-mouth stomach worms, neck threadworms, bots, lungworms, intestinal threadworms, and summer sores (label dosage; FDA-approved): 200 µg/kg (0.2 mg/kg) PO. Treat foals initially at 6 to 8 weeks of age. Continue treatment, as appropriate, as part of an overall internal parasite control program.[62]

BOVINE:

GI roundworms (including inhibited stage of *Ostertagia ostertagi* in cattle), lungworms, grubs, sucking lice, and mange mites: (label dosage; FDA-approved):

a) **Injection**: 200 µg/kg (0.2 mg/kg) SC under the loose skin in front of or behind the shoulder. For most effective results against grubs, treat cattle as soon as possible after the end of the heel fly (ie, warble fly) season.[4]

b) **Topical pour-on**: 500 µg/kg (0.5 mg/kg) topically as a narrow strip from withers to tailhead[5]

Treatment and control of grubs (*Hypoderma bovis*) in American bison (label dose; FDA-approved): 200 µg/kg (0.2 mg/kg) SC under the loose skin in front of or behind the shoulder[4]

SHEEP/GOATS:

GI roundworms; lungworms; and nasal bots in sheep (label dosage; FDA-approved): Using the approved oral drench for sheep, 200 µg/kg (0.2 mg/kg) PO.[63]

Adjunctive treatment of meningeal worm (***Parelaphostrongylus tenuis***) (extra-label): To prevent further migration: ivermectin 300 µg/kg (0.3 mg/kg) SC once daily for 5 days with fenbendazole 50 mg/kg PO once daily for 5 days[64]

REINDEER:

Treatment and control of warbles (*Oedemagena tarandi*) (label dose; FDA-approved): 200 µg/kg (0.2 mg/kg) SC under the loose skin in front of or behind the shoulder[4]

CAMELIDS:

GI helminths (extra-label): In new world camelids: 200 µg/kg (0.2 mg/kg) PO once[65]

Adjunctive treatment of meningeal worm (*Parelaphostrongylus tenuis*) (extra-label): To prevent further migration: ivermectin 300 µg/kg (0.3 mg/kg) SC once daily for 5 days with fenbendazole 50 mg/kg PO once daily for 5 days. Camelids are very susceptible to GI ulcers; give prophylaxis or treat with omeprazole or ranitidine.[66]

Sarcoptic mange (extra-label): 200 – 400 µg/kg (0.2 – 0.4 mg/kg) SC every 15 days for 3 treatments[67]

SWINE:

Susceptible parasites (eg, **GI roundworms, lungworms, lice, mange mites)** (label dosage, FDA-approved): 300 µg/kg (0.3 mg/kg) SC in the neck immediately behind the ear[4]

GI nematodes (*Strongyloides ransomi, Ascaris suum, Metastrongylus salmi, Hyostrongylus rubidus, Trichuris suis*) (extra-label): 100 µg/kg (0.1 mg/kg) PO daily for 7 days[68]

BIRDS:

Susceptible parasites (all are extra-label):

a) **Ascarids, *Capillaria* spp, and other intestinal worms; *Knemidokoptes pilae* (eg, scaly face and leg mites)**: Dilute ivermectin to a 2000 µg/mL (2 mg/mL) concentration. After diluting product, use immediately.
- **Most birds**: 220 µg/kg (0.22 mg/kg) IM[69]
- **Amazons**: 100 µg /bird (0.1 mg/bird; NOT mg/kg) IM
- **Macaws**: 200 µg /bird (0.2 mg/bird; NOT mg/kg) IM
- **Finches**: 20 µg /bird (0.02 mg/bird; NOT mg/kg) IM

b) **Ascarids, *Coccidia* spp, and other intestinal nematodes; *Oxyspirura* spp, gapeworms, *Knemidokoptes pilae* (eg, scaly face and leg mites)**: Dilute bovine preparation (10 mg/mL) 1:4 with propylene glycol
- **Most species**: 200 µg/kg (0.2 mg/kg) IM or orally, repeat in 10 to 14 days
- **Budgerigars**: 12.5 µg/bird (0.0125 mg/bird [0.01 mL of diluted product]; NOT mg/kg), IM or PO[70]

c) **Ectoparasites**: ≈200 µg/kg (0.2 mg/kg) topically.[71,72] For routine prevention of common ectoparasites, this dose should be repeated monthly. For the treatment of an existing infestation, repeat doses are required 2 and 4 weeks after the initial application.

FERRETS:

Heartworm prevention (extra-label): 20 µg/kg (0.02 mg/kg) PO once monthly[73]

Heartworm infection (extra-label): 50 µg/kg (0.05 mg/kg) PO once monthly[74]

RABBITS/RODENTS/SMALL MAMMALS:

NOTE: All are extra-label.

Rabbits:

a) ***Sarcoptes scabiei, Notoedres cati***: 300 – 400 µg/kg (0.3 – 0.4 mg/kg) SC, repeat in 14 days[75]

b) **Ear mites**: 200 µg/kg (0.2 mg/kg) SC, repeat in 2 weeks. All rabbits in the colony should be treated and cages cleaned and disinfected.[76] Similarly, 200 – 440 µg /kg (0.2 – 0.44 mg/kg) PO or SC, repeat in 8 to 18 days[75]

c) **Cheyletiellosis**: From a retrospective study, 200 – 480 µg/kg (0.2 – 0.48 mg/kg) SC; 2 or 3 doses were administered at a mean interval of 11 days[77]

Rodents and lagomorphs for treatment of sarcoptoid and some fur mites: 200 – 250 µg/kg (0.2 – 0.25 mg/kg) SC. Cages should be thoroughly cleaned and disinfected.[76]

Mice, rats, gerbils, guinea pigs, chinchillas: 200 µg/kg (0.2 mg/kg) SC or PO every 7 days for 3 weeks

Hamsters: 200 – 500 µg/kg (0.2 – 0.5 mg/kg) SC or PO every 14 days for 3 weeks[78]

Guinea pigs for treatment of *Trixacarus caviae* mites: 400 µg/kg (0.4 mg/kg) SC, every 10 days for 4 injections[79]

Ectoparasites in rabbits, rodents, guinea pigs, and ferrets: 200 – 400 µg/kg (0.2 – 0.4 mg/kg) topically[72]

Ectoparasites in hamsters, gerbils, mice, rats, and guinea pigs weighing 50 to 300 g (0.11 to 0.66 lb) (extra label): 500 – 1000 µg/kg (0.5 – 1 mg/kg) topically.[80] Treatment can be repeated after 4 weeks if necessary.

REPTILES:

Most nematodes, ectoparasites (extra-label): For lizards, snakes, and alligators: 200 µg/kg (0.2 mg/kg) IM, SC, or PO once; repeat in 2 weeks. A third treatment can be given if still positive after the second treatment. **NOTE**: Ivermectin is toxic to chelonians, indigo snakes, and skinks.[81,82]

Monitoring

- Clinical efficacy
- Adverse effects/toxicity (especially lethargy, ataxia, tremors, mydriasis, blindness, hypersalivation and vomiting)
- Antiparasitic resistance in horses and livestock (ie, fecal egg count reduction [FECR] test)[83]

Client Information

- The manufacturer of large animal ivermectin products recommends washing hands prior to eating. Avoid contact with eyes.
- Liquid products are flammable; use in a well-ventilated area and do not smoke around the product.
- Pour-on products should be applied along the midline of the back in a narrow strip between the withers and tailhead. Do not apply when the hair or hide is wet. Efficacy may be reduced if rain occurs within 2 hours of administration.
- Chewable tablets should be administered in a manner that encourages the animal to chew the tablet. Chewables may be broken into pieces for animals that normally swallow treats whole.
- Heartworm preventives must be administered every 30 days; late or missed doses may cause treatment failure.
- May be given with or without food. If your animal vomits or acts sick after receiving the drug on an empty stomach, give with food or a small treat. If vomiting continues, contact your veterinarian.
- Overdose can be serious. Do not use in species for which the product is not intended (eg, do not administer a horse product to dogs). Measure medicine carefully; for horse pastes, ensure the ring is placed at the prescribed weight and locked in place. Keep flavored chewable tablets out of reach of children and animals.
- This drug is usually tolerated well. If your animal shows signs of lethargy, weakness, stumbling, blindness, seizures, excessive drooling, vomiting, and/or other unusual behavior, contact your veterinarian immediately.
- Dispose of unused product carefully, as it can be toxic to fish and wildlife.
- To minimize antiparasitic resistance, ivermectin treatment in grazing species (eg, horses, cattle, small ruminants) should be part of a comprehensive internal parasite control program.

Chemistry/Synonyms

Ivermectin, an avermectin anthelmintic, occurs as an off-white to yellowish powder. It is very poorly soluble in water (4 µg/mL) but is soluble in ethanol, propylene glycol, polyethylene glycol, and vegetable oils.

Ivermectin may also be known as ivermectina, ivermectine, ivermectinum, or MK 933; many trade names are available.

Storage/Stability

Ivermectin is photolabile in solution; protect from light. Unless otherwise specified by the manufacturer, store ivermectin products at room temperature (20°C-25°C [68°F-77°F]); excursions between 15°C to 30°C (59°F-86°F) are permitted for most products. Solutions are flammable and must be stored away from heat, sparks, open flame, or other sources of ignition.

Environmental exposure to ivermectin may adversely affect fish and other waterborne organisms. Dispose of unused ivermectin by incineration or in an approved landfill. Use caution during treatment to prevent feedlot water runoff from entering lakes, streams, and ground water.

Ivermectin 1% oral solution (equine tube wormer product) is stable at 1:20 and 1:40 dilutions with water for 72 hours when stored in a tight container, at room temperature, and protected from light.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

If compounding from the concentrated injectable forms, institute multiple check systems to reduce the chance for overdose.

Dosage Forms/Regulatory Status

VETERINARY PRODUCTS:

NOTE: Because milk withdrawal times have not been established, the drug is not FDA-approved for use in lactating dairy animals or females of breeding age.

Ivermectin Oral Tablets (Plain or Chewable): 68 µg, 136 µg, and 272 µg with 6 doses per carton; *Heartgard®*, generic; (Rx). FDA-approved for use in dogs 6 weeks of age and older. NADA# 140-886

Ivermectin Oral Chewable Tablets: 55 µg and 165 µg with 6 doses per carton; *Heartgard® for Cats*; (Rx). FDA-approved for use in cats 6 weeks of age and older. NADA# 141-078

Ivermectin for Injection: 10 mg/mL (1%) in 50 mL, 100 mL, 200 mL, 250 mL, 500 mL, and 1000 mL bottles; *Ivomec® 1% Injection for Cattle* and *Swine*; generic; (OTC). FDA-approved for use in cattle (not female dairy cattle of breeding age) and swine. Slaughter withdrawal time (when used as labeled): cattle = 35 days, swine = 18 days, reindeer = 56 days, and bison = 56 days. No milk withdrawal time has been established. Do not use in calves to be processed for veal. NADA# 128-409

Ivermectin 1.87% Oral Paste in 6.08 g syringes (sufficient to treat one 566 kg (1250 lb) horse); *Eqvalan*®; (OTC). FDA-approved for use in horses not intended for food purposes. NADA# 134-314

Ivermectin Oral Solution: 0.08% in 240 mL, 960 mL, 1000 mL, and 5000 mL containers; *Ivomec*® *Drench for Sheep*; (OTC). FDA-approved for use in sheep. Slaughter withdrawal time is 11 days. NADA# 131-392

Ivermectin Topical Parasiticide Pour-on for Cattle: 5 mg/mL in 250 mL and 1000 mL squeeze-pour system, 2500 mL and 5000 mL collapsible containers, and 20 L pack; *Ivomec*® *Pour-on for Cattle*; generic; (OTC). FDA-approved for use in cattle (not female dairy cattle of breeding age). Slaughter withdrawal time is 48 days; milk withdrawal has not been established. NADA# 140-841

Ivermectin Spot-on Solution: 50 µg and 450 µg/pipette; *Xeno*® *50-Mini, Xeno*® *450*; (SAES product). Not for use in animals intended for human consumption, including eggs from treated birds.

Combination Products:
Ivermectin for Injection: 10 mg/mL (1%) and Clorsulon 100 mg/mL; *Ivomec*® *Plus Injection for Cattle*; generic; (OTC). FDA-approved for use in cattle (not female dairy cattle of breeding age). Slaughter withdrawal at labeled doses is 40 days. No milk withdrawal has been established. For further information, see ***Ivermectin/Clorsulon***. NADA# 140-833

Ivermectin/Pyrantel Oral Tablets: 68 µg/57 mg, 136 µg/114 mg, and 272 µg/227 mg; *Heartgard*® *Plus Chewables*; generic; (Rx). FDA-approved for use in dogs 6 weeks of age and older. In dogs over 45 kg (100 lb), use the appropriate combination of these chewable tablets. NADA# 140-971

Ivermectin/Pyrantel/Praziquantel Oral Tablets:
34 µg/28.5 mg/28.5 mg, 68 µg/57 mg/57 mg, 136 µg/114 mg/114 mg, and 272 µg/228 mg/228 mg; *Iverhart Max*®; generic; (Rx). FDA-approved for use in dogs 8 weeks of age and older. In dogs over 45 kg (100 lb), use the appropriate combination of these chewable tablets. NADA# 141-441

Ivermectin 1.87% and Praziquantel 14.03% Oral Paste in 6.42 g oral syringes (sufficient to treat one 598.7 kg (1320 lb) horse); *Equimax*®; (OTC). FDA-approved for use in horses or ponies 4 weeks of age and older and not intended for food purposes. NADA# 141-215

Ivermectin 1.55% and Praziquantel 7.75% in 7.35 g oral syringes; *Zimecterin*® *Gold*; (OTC). FDA-approved for use in horses or ponies 8 weeks of age and older and not intended for food purposes. NADA# 141-214

HUMAN-LABELED PRODUCTS:
Ivermectin Tablets: 3 mg; *Stromectol*®; (Rx)

Ivermectin 0.5% Topical Lotion (*Sklice*®) is available as a pediculocide; Ivermectin 1% Topical Cream (*Soolantra*®) is indicated for treatment of acne rosacea.

For the complete list of references, see **wiley.com/go/budde/plumb**

Ivermectin/Clorsulon

(***klor***-su-lon) *Ivomec*® *Plus*
Internal/External Antiparasitic and Flukicide

Prescriber Highlights

- ► Combination injectable internal/external antiparasitic with an adult flukicide (*Fasciola hepatica*) for cattle only
- ► For SC use only; not for IV or IM use
- ► Usually well tolerated; injection site discomfort or swelling is possible
- ► Not for use in female dairy cattle of breeding age or in calves to be used for veal
- ► Use in species other than cattle may result in severe adverse reactions and/or death.
- ► Slaughter withdrawal is 21 days.

Uses/Indications

Ivermectin, in combination with clorsulon, is FDA-approved for the effective treatment and control of internal parasites, including GI roundworms (adults and fourth-stage larvae), lungworms (adults and fourth-stage larvae), adult liver flukes (*Fasciola hepatica*), and external parasites, including cattle grubs (parasitic stages), sucking lice, and mange mites (cattle scab).[1]

Pharmacology/Actions

In infected hosts, adult *Fasciola hepatica* ingests clorsulon-bound erythrocytes. Clorsulon causes a concentration-dependent inhibition of glucose uptake. It inhibits the glycolytic enzymes 3-phosphoglycerate kinase and phosphoglyceromutase, thereby blocking the Embden-Meyerhof glycolytic pathway; the fluke is deprived of its main metabolic energy source and dies. Clorsulon 7 mg/kg PO is effective against immature and adult *F hepatica* 14 weeks postinfection[2–4]; however, clorsulon 2 mg/kg SC is effective only against adult flukes (14 weeks postinfection).

For information on ***Ivermectin***, refer to that specific monograph.

Pharmacokinetics

After oral administration in cattle, the drug is absorbed rapidly, with peak concentrations occurring in about 4 hours. ≈75% of the circulating drug is found in plasma and 25% in erythrocytes. At 8 to 12 hours after administration, clorsulon levels peak in the fluke. SC injections in cattle result in maximum plasma levels 6 hours after administration, with a plasma half-life of ≈26 hours.

Contraindications/Precautions/Warnings

Must be administered SC only; do not give IV or IM. Adequate animal restraint is required to ensure proper route of administration. This product is only for use in cattle, as severe reactions, including fatalities in dogs, may occur.

Divide doses greater than 10 mL between 2 injection sites to reduce occasional discomfort or site reaction. Different injection sites should be used for other parenteral products.[1]

Adverse Effects

Discomfort and local swelling may occur at injection sites.[1]

Reproductive/Nursing Safety

Clorsulon is considered safe for use in pregnant or breeding animals. Use of ivermectin/clorsulon commercial products at recommended dosages in breeding bulls and cows showed no effect on breeding performance.[1]

Overdose/Acute Toxicity

Refer to the ***Ivermectin*** monograph for further information.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consulta-

tion center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions/Laboratory Considerations

None identified when used as directed.

Dosages

CATTLE:

Susceptible roundworms, lungworms, adult liver flukes, cattle grubs, sucking lice, and mange mites (label dosage; FDA-approved): ivermectin 200 µg/kg and clorsulon 2 mg/kg SC behind the shoulder.[1] Divide doses greater than 10 mL between 2 injection sites. For most effective results against grubs, treat cattle as soon as possible after the end of the heel fly (ie, warble fly) season.

Monitoring

- Clinical efficacy
- Fecal egg count reduction testing (FECRT) and fecal sedimentation for fluke recovery

Client Information

- Follow withdrawal times for slaughter (21 days for *Ivermax® Plus*).
- Do not use in female dairy cattle of breeding age.
- Do not use in pre-ruminating calves or those to be processed for veal.
- Do not allow water runoff from feedlots to enter lakes, streams, or ponds, as free ivermectin may adversely affect fish.
- The viscosity of the product increases when ambient temperature is at or below 5°C (41°F), making administration of the product difficult. In such conditions it is suggested warm the product and injection equipment to a temperature of about 15°C (59°F).

Chemistry/Synonyms

Ivermectin, an avermectin anthelmintic, occurs as an off-white to yellowish powder. It is very poorly soluble in water (4 µg/mL) but is soluble in ethanol, propylene glycol, polyethylene glycol, and vegetable oils. Although structurally similar to macrolide antibiotics, avermectins have no antibacterial properties.

Ivermectin may also be known as ivermectina, ivermectine, ivermectinum, or MK 933; many trade names are available.

Clorsulon, a benzenesulfonamide, has a chemical name of 4-amino-6-(trichloroethenyl)-1,3-benzenedisulfonamide. It is a white to off-white powder that is slightly soluble in water and freely soluble in methyl alcohol. Clorsulon may also be known as clorsulone, clorsulonum, MK-401, or *Curatrem®*.

Storage/Stability

Unless otherwise instructed by the manufacturer, store clorsulon at room temperature (15°C to 30°C [59°F-86°F]) and protected from light. Consult the product label for storage duration of in-use vials and the maximum number of vial punctures allowed.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The viscosity of the product increases in cool temperatures.[1] Administration in temperatures at or below 5°C (41°F) may be difficult and warming the product and injection equipment to a temperature of about 15°C (59°F) is recommended.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Clorsulon 10% (100 mg/mL) and Ivermectin 1% (10 mg/mL) Injection in 50 mL, 200 mL, 500 mL, and 1000 mL; *Ivomec® Plus*, generic; (OTC). FDA-approved for SC injection use in cattle. Do not use within 21 days of slaughter; do not use in female dairy cattle of breeding age or in pre-ruminating calves or those intended for veal. NADA #140-833

NOTE: Clorsulon 8.5% (85 mg/mL) Oral Drench; *Curatrem®*; (OTC) is no longer in production. It was FDA-approved for use in cattle with a slaughter withdrawal of 8 days when used as labeled. Clorsulon drench was not FDA-approved for use in female dairy cattle of breeding age, and a milk withdrawal was not established.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Kaolin/Pectin

(***kay***-oh-lin/***pek***-tin) *Kaopectolin®*

GI Adsorbent/Protectant

Prescriber Highlights

- ► Adsorbent for treatment of diarrhea and GI toxins; no studies to support efficacy
- ► Most products marketed in the United States contain bismuth subsalicylate, which may be contraindicated in some species.
- ► Should not be relied on to control severe diarrheas or replace adequate fluids and electrolytes in severe or chronic diarrheas
- ► Adverse effects include transient constipation.

Uses/Indications

Although its efficacy is in question, kaolin/pectin is used primarily in veterinary medicine as an oral antidiarrheal agent. It has also been used as an adsorbent agent following the ingestion of certain toxins. Administration may be difficult due to the large oral volumes that may be necessary. No studies documenting the clinical efficacy of this combination in either human or veterinary species were located.

Pharmacology/Actions

Kaolin/pectin is thought to possess adsorbent and protective qualities. Presumably, bacteria and toxins are adsorbed in the gut, and the coating action of the suspension may protect inflamed GI mucosa. The pectin component decreases pH in the intestinal lumen by forming galacturonic acid. Kaolin/pectin can improve stool consistency within 24 to 48 hours, but it does not reduce the ions or amount of fluid lost from the GI tract.[1]

Pharmacokinetics

Neither kaolin nor pectin is absorbed after oral administration. Up to 90% of the pectin administered may be decomposed in the gut.

Contraindications/Precautions/Warnings

There are no absolute contraindications to kaolin/pectin therapy, but it should not be relied on to control severe diarrheas.

Kaolin/pectin should not replace adequate fluid and electrolyte monitoring or replacement therapy in severe or chronic diarrheas.

Branded products that previously contained kaolin/pectin (eg, *Kaopectate®*) may now contain other active ingredients (eg, bismuth subsalicylate). Read product label carefully. Because of the potential for adverse effects caused by the salicylate component, this drug should be used cautiously, if at all, in cats.

Adverse Effects

Kaolin/pectin generally has no adverse effects. Constipation may occur but is usually transient and associated with high dosages. High dosages in debilitated or very old or young patients may rarely cause fecal impaction. In rats, kaolin/pectin has been demonstrated to increase fecal sodium and potassium loss in diarrhea.[1]

In humans, kaolin/pectin is recommended for use only under the direct supervision of a physician in patients less than 3 years of age or if it must be used longer than 48 hours.

Reproductive/Nursing Safety

Adsorbent antidiarrheal products should be safe to use during pregnancy and lactation. The addition of other active ingredients (eg, opioids) may alter this recommendation.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Kaolin/pectin is highly insoluble and is not absorbed systemically. Overdose is unlikely to cause any serious effects, but constipation requiring treatment may occur.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving kaolin/pectin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Digoxin**: Some evidence exists that kaolin/pectin may impair the oral absorption of digoxin. Separate doses by at least 2 hours.
- **Clindamycin, Lincomycin**: Kaolin/pectin may inhibit oral absorption. If kaolin is to be used with either of these antibiotics, administer kaolin/pectin at least 2 hours before or 3 to 4 hours after the antibiotic dose.
- **Penicillamine**: Kaolin/pectin may inhibit oral absorption. Separate doses by at least 2 hours.
- **Sulfa-/Trimethoprim**: Kaolin/pectin may inhibit oral absorption. Separate doses by at least 2 hours.

Laboratory Considerations

None noted

Dosages

NOTE: Evidence to support the efficacy of kaolin/pectin is weak. All dosages are anecdotal and extra-label as no products have undergone the FDA approval process for use in animals.

DOGS/CATS:

Noninfectious diarrhea (label dosage; not FDA-approved): 1 to 3 tablespoonsful (15 – 45 mL)/animal (NOT tablespoonsful [mL]/kg) PO as needed at the first sign of diarrhea and after each loose bowel movement[2]

Diarrhea (label dosage; not FDA-approved): 2.3 – 6.8 kg (5 – 15 lb): 1 teaspoonful (5 mL) PO; 7.3 – 22.7 kg (16 – 50 lb): 2 teaspoonsful (10 mL) PO; over 23.2 kg (51 lb): 1 tablespoonful (15 mL) PO. Administer dose once daily[3] or every 12 hours,[4]

Diarrhea and loose stools (extra-label): 1 – 2 mL/kg PO 4 to 6 times daily as needed

HORSES:

Noninfectious diarrhea (extra-label): After the first sign of diarrhea and after each loose bowel movement, administer: Adults: 6 – 10 fl oz (180 – 300 mL)/horse (NOT fl oz [mL]/kg) PO; Foals: 3 – 4 fl oz (90 – 120 mL)/foal (NOT fl oz[mL]/kg)[2]

Diarrhea and loose stools (extra-label):

1. 2 – 4 quarts/450 kg (992 lb) body weight PO twice daily[5]
2. 1 fl oz/8 kg (17.6 lb) body weight PO 3 to 4 times daily[6]
3. 2 – 4 mL/kg PO every 8 to 12 hours[7]
4. Foals: 3 – 4 oz/foal PO every 6 to 8 hours (authors believe that bismuth subsalicylate is superior)[8]

CATTLE:

Noninfectious diarrhea (extra-label): After the first sign of diarrhea and after each loose bowel movement, administer: Adults: 6 – 10 fl oz (180 – 300 mL)/animal (NOT fl oz [mL]/kg]) PO; calves: 3 – 4 fl oz (90 – 120 mL)/calf (NOT fl oz[mL]/kg)[2]

Diarrhea and loose stools (extra-label): 0.25 – 1 mL/kg PO every 4 hours[7]

SHEEP/GOATS:

Diarrhea and loose stools (extra-label): 0.25 – 1 ml/kg PO every 4 hours[7]

SWINE:

Diarrhea and loose stools (extra-label): 0.2 mL/kg PO every 4 hours[9]

BIRDS: ALL DOSAGES LISTED ARE EXTRA-LABEL.

1. **Canary or parakeet**: 1 drop/bird (NOT drop/kg) PO twice daily; or 1-½ droppersful/bird (NOT droppersful/kg) placed in ⅔ oz drinking water
2. **Medium-sized birds**: 0.5 mL/bird (NOT mL/kg) PO
3. **Large birds**: 1 mL/bird (NOT mL/kg) PO 1 to 4 times daily[10]
4. 2 mL/kg PO 2 to 4 times daily[11]

FERRETS:

Diarrhea and loose stools (extra-label): 1 – 2 mL/kg PO 3 to 4 times daily[12]

RABBITS/RODENTS/SMALL MAMMALS:

Diarrhea and loose stools in guinea pigs (extra-label): 0.2 mL/animal (NOT mL/kg) PO 3 to 4 times daily[13]

Monitoring

- Clinical efficacy
- Fluid and electrolyte status in severe diarrhea

Client Information

- This medicine is used as an aid in the treatment of noninfectious diarrhea, upset stomach, or nausea.
- Kaolin is very safe when used as directed.
- Constipation is the most common side effect.
- Shake suspensions well before measuring the dose.
- If diarrhea persists or if the animal appears listless or develops a high fever, contact your veterinarian.
- When using this medicine in cats, be sure to check the product label to make sure it does not contain bismuth subsalicylate, as this substance is toxic to cats.

Chemistry/Synonyms

Kaolin is a naturally occurring hydrated aluminum silicate that is powdered and refined for pharmaceutical use. Kaolin is a white/light, odorless, almost tasteless powder that is practically insoluble in water. Light kaolin is preferred for use in pharmaceutical preparations.

Pectin is a carbohydrate polymer consisting primarily of partially methoxylated polygalacturonic acids. Pectin is a course or fine, yellowish-white, almost odorless with a mucilaginous flavor. It is obtained from the inner rind of citrus fruits or apple pomace. One gram of pectin is soluble in 20 mL of water and forms a viscous, colloidal solution.

In the United States, kaolin and pectin are generally used together in an oral suspension formulation in most proprietary products.

Kaolin may also be known as bolus alba, E559, hydrated aluminum silicate, China clay, porcelain clay, white bole, argilla, weisser ton, *Kaopectolin®*, *Kao-Pec®*, *Kao-Pect®*, *Kao-Pront®*, *Kaogel®*; many multi-ingredient trade names are available.

Storage/Stability

Store kaolin/pectin in airtight containers at room temperature between 15°C and 30°C (59°F-86°F); protect from freezing. Shake well before using.

Compatibility/Compounding Considerations

It is physically **incompatible** when mixed with alkalis, heavy metals, salicylic acid, tannic acid, or strong alcohol. If using raw kaolin powder, wear an appropriate particulate mask as pneumonitis can occur if inhaled.

Dosage Forms/Regulatory Status

There are a variety of kaolin/pectin products available over the counter (OTC) without a prescription. Several products are labeled for veterinary use but are not FDA-approved. Many products that formerly contained kaolin (eg, *Kaopectate®*) no longer contain kaolin. In the United States, *Kaopectate®* now contains bismuth subsalicylate as its active ingredient.

VETERINARY-LABELED PRODUCTS:

Kaolin/Pectin: kaolin 5.8 g/pectin 0.268 g/fl oz (30 mL, 2 tablespoonsful) in 1 quart and 1 gallon containers; generic, (OTC). Products may be labeled for use in horses, cattle, dogs, and cats.

Kaolin/Pectin: kaolin 5.8 g/pectin 0.13 g/fl oz (30 mL, 2 tablespoonfuls) in 960 mL and 1 gallon containers; generic; (OTC)

Kaolin/Pectin: kaolin 800 mg/pectin 80 mg/teaspoonful (5 mL) in 118 mL and 237 mL bottles; generic; (OTC)

Kaolin/Pectin: kaolin 900 mg/pectin 50 mg/teaspoonful (5 mL) in 118 mL bottles; generic; (OTC)

HUMAN-LABELED PRODUCTS:

Kaolin/Pectin Antidiarrheal Suspension: kaolin 90 g/pectin 2 gm per 30 mL in 180 mL, 360 mL, 473 mL, and UD 30 mL; *Kaopectolin®* (various), generic; (OTC)

Ketamine

(***kee***-ta-meen) *Ketaset®, Ketaflo®, Vetalar®*

Dissociative General Anesthetic; NMDA-Receptor Antagonist

Prescriber Highlights

- ► Dissociative general anesthetic that also inhibits N-methyl-D-aspartate (NMDA) receptors and may be for adjunctive therapy to control pain
- ► Contraindications include animals with prior hypersensitivity reactions, animals to be used for human consumption, or using this product as the sole agent for general anesthesia. Relative contraindications include significant blood loss; malignant hyperthermia; increased intraocular pressure or open globe injuries; and procedures involving the pharynx, larynx, or trachea. Caution is advised in animals with significant hypertension, heart failure, arterial aneurysm, hypertrophic cardiomyopathy, hyperthyroidism, hepatic or renal insufficiency, or seizure disorder.
- ► Adverse effects include hypertension, hypersalivation, respiratory depression, hyperthermia, emesis, vocalization, erratic and prolonged recovery, dyspnea, myoclonus, seizures, muscular tremors, hypertonicity, opisthotonos, and cardiac arrest, as well as pain with IM injection.
- ► Animals' eyes remain open after ketamine administration, so ocular protection (eg, lubricants, towel) should be used.
- ► Exposure to handling or loud noises should be minimized during the recovery period.
- ► Dosages should be determined carefully. Care should be taken to not confuse CRI dosages (ie, mg/kg/hour vs µg/kg/minute).

Uses/Indications

Ketamine is FDA-approved for use in humans, subhuman primates, and cats; however, it has also been used in many other species. The FDA-approved indications for cats include *for restraint, or as the sole anesthetic agent for diagnostic, or minor, brief, surgical procedures that do not require skeletal muscle relaxation. . . and in subhuman primates for restraint*.[1]

Ketamine is used to induce general anesthesia in many species and as a CRI to provide analgesia and decrease the amount of inhalant used to maintain a surgical plane of anesthesia. It has been used intranasally in combination with midazolam in cats to induce sedation.[2]

Ketamine can decrease the "wind-up" pain effect. There is increasing interest in using ketamine to prevent exaggerated pain associated with surgery and chronic states of pain in animals.

Pharmacology/Actions

Ketamine is a rapid-acting, general anesthetic that has significant analgesic activity and a relative lack of cardiovascular depressant effects in healthy animals. Ketamine depresses the thalamoneocortical system, dissociating it from the limbic system, which is activated. Ketamine binds the phencyclidine-binding site of the N-methyl-D-aspartate (NMDA) receptors, reducing receptor activity and release of glutamate, an excitatory neurotransmitter. It is unclear whether muscarinic antagonism or inhibition of catecholamine reuptake is responsible for some of ketamine's clinical effects (eg, tachycardia, bronchodilation).[3]

In healthy animals, the effects of ketamine on the cardiovascular system include increased cardiac output, heart rate, mean aortic pressure, pulmonary artery pressure, and central venous pressure. The effects on total peripheral resistance are described as being variable. Cardiovascular effects are secondary to increased sympathetic tone; ketamine has negative inotropic effects if the sympathetic system is blocked or in sick animals experiencing depletion of catecholamines.

Ketamine can cause apneustic breathing (ie, rapid breaths followed by breath holding). This drug does not cause significant respiratory depression at usual doses, but it can cause respiratory rates to decrease at higher doses. Ketamine can cause bronchodilation and decreased airway resistance in humans with asthma.

Ketamine possesses analgesic effects at subanesthetic doses. Analgesia is secondary to effects on NMDA excitatory glutamate receptors through decreases in the activity of areas in the CNS that respond to pain-invoking stimuli. The analgesic effects of ketamine can be synergistic with other analgesics. Ketamine's actions on the NMDA receptors also impact opioid and monoaminergic receptors, which contributes to the antinociceptive effects of this drug.

At standard doses, ketamine generally either causes no change in muscle tone or increased muscle tone. Ketamine does not impede pinnal and pedal, photic, corneal, laryngeal, or pharyngeal reflexes. Muscle tone may decrease with high doses. Changes in body temperature correspond with muscle tone, with hypothermia accompanying hypotonia at higher doses. In cats, ketamine causes a slight hypothermic effect, as body temperature decreases (on average) by 1.6°C (33.9°F) after high anesthetic doses (ie, ≈20 mg/kg).

In some species, ketamine has demonstrated anti-inflammatory effects.[4] In response to endotoxin stimulation in dogs, ketamine caused reductions in tumor necrosis factor-alpha activity; however, it had minimal effects on stabilizing blood pressure.[5]

Pharmacokinetics

Ketamine undergoes significant first-pass metabolism, limiting absorption after oral administration. Peak concentrations occur ≈10 minutes after IM injection in cats. A ketamine spray sublingually to cats appears to be absorbed enough to have pharmacologic action.[6] Ketamine is distributed into all body tissues rapidly, with the highest concentrations found in the brain, liver, lungs, and fat. Plasma protein binding is ≈50% in dogs[7] and horses,[8] and 40% to 50% in cats.[9]

In most species, ketamine is metabolized in the liver principally by demethylation and hydroxylation. These metabolites, along with unchanged ketamine, are eliminated in the urine. In dogs, CYP2B11 plays an active role in metabolizing ketamine. One active metabolite (norketamine) has 10% to 30% of the activity of the parent compound. In cats, ketamine is almost exclusively excreted unchanged in the urine. The elimination half-life in cats, horses, and calves is ≈1 hour and is 2 to 3 hours in humans. Similar to thiobarbiturates, redistribution of ketamine out of the CNS is more likely to determine the duration of anesthesia than is elimination half-life. In horses, S-ketamine is eliminated faster than the racemic mixture.

The duration, but not intensity, of anesthesia can be prolonged by increasing the ketamine dose.

Contraindications/Precautions/Warnings

Ketamine is contraindicated in animals that have exhibited prior hypersensitivity reactions to it and in animals to be used for human consumption. Use of ketamine in animals with significant hypertension, heart failure, or arterial aneurysms could be dangerous. The manufacturer warns against its use in animals with hepatic or renal insufficiency; in humans with renal insufficiency, the duration of action is not prolonged. Because ketamine does not provide good muscle relaxation, it is contraindicated when used alone for major surgery.[1]

Ketamine should only be used in situations in which sufficient monitoring and patient-support capabilities (eg, intubation, ventilation) are available.

It was believed that ketamine can cause increases in intracranial pressure (ICP) and should not be used in animals with elevated ICP or if head trauma has occurred. More recent studies in human medicine have shown that ketamine, when administered with gamma-aminobutyric acid (GABA) agonists to mechanically ventilated animals, does not increase ICP. In humans[10] and animals[3,11,12] with head injuries that have increased ICP, ketamine decreased ICP pressure and improved cerebral perfusion pressure.

Because of its epileptogenic potential, ketamine should generally not be used (unless used with caution) in animals with pre-existing seizure disorders. Some contrast agents used during myelography can induce seizures, so ketamine should be used with caution in animals undergoing this procedure. Ketamine may be beneficial in treating self-sustaining status epilepticus (SSSE) in humans[13] and dogs.[14]

Ketamine is considered to be relatively contraindicated in animals with increased intraocular pressure or open globe injuries and for procedures involving the pharynx, larynx, or trachea. Animals that have lost significant amounts of blood may require significantly reduced ketamine doses.

Ketamine can increase heart rate, blood pressure, and myocardial oxygen consumption; its use should be avoided in cats with hypertrophic cardiomyopathy (HCM) and in animals in which increased heart rate, blood pressure, or myocardial oxygen consumption can be detrimental (ie, result in shock or congestive heart failure). Ketamine's effects on respiratory function may be enhanced in animals with unstable cardiopulmonary function. Use ketamine with caution in animals with pulmonary disease. Because of ketamine's tendencies to increase sympathetic tone (increased norepinephrine release), it should be used with caution in animals in which increased sympathetic tone concurrently exists (eg, pheochromocytoma, hyperthyroidism). Humans with hyperthyroidism and those receiving exogenous thyroid replacement may be susceptible to developing severe hypertension and tachycardia when given ketamine. The veterinary significance of this potential problem is unknown.

Animals' eyes can remain open after receiving ketamine, so an ophthalmic lubricating ointment should be applied to prevent injury or excessive drying of the cornea. Additionally, during field anesthesia, the animal's eyes should also be protected (eg, covered with a towel) from damage from the sun.

It is recommended to minimize handling and loud noises during the recovery period to reduce the incidences of emergence reactions during anesthetic recovery; however, vital signs should also be monitored during the recovery phase.

In horses, it has been recommended to avoid excessive ketamine doses close to time of recovery to reduce the potential for muscle rigidity or CNS excitement.[15]

Because ketamine can increase blood pressure, careful control of postsurgical (eg, declawing) hemorrhage should be managed.

In human medicine, ketamine is considered a high-alert medication (ie, medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking with special alert labels.

Adverse Effects

At lower doses, adverse effects are generally minimal in most species. Emesis, salivation, and vocalization may occur. Other reported effects include hyperthermia, nystagmus, erratic and prolonged recovery, dyspnea, and cardiac arrest. Musculoskeletal effects may include tremors, myoclonus, hypertonicity, and convulsions. Respiratory depression has been noted at high doses. The manufacturer suggests myoclonic jerking and/or tonic/clonic convulsions can be controlled by ultrashort-acting barbiturates or acepromazine.[1]

When used alone, ketamine may induce seizures. Seizures have been reported in up to 20% of cats that receive ketamine (alone) at therapeutic dosages. Diazepam is suggested if treatment for seizures is necessary. Ketamine has been reported to rarely cause blindness[16] or death. In cats, ketamine administered at 5 – 10 mg/kg has been documented to cause mild, self-limiting hyperthermia[17,18]; low doses

of acepromazine 0.01 – 0.02 mg/kg IV may alleviate this effect. Anecdotal reports of ketamine causing acute congestive heart failure in cats with mild to moderate heart disease have been reported.

Pain after IM injection may occur.

Ketamine has been shown to have a confounding effect on the psychomotor subscale of the feline pain scale.[19]

Atropine or glycopyrrolate can sometimes be administered to reduce the incidence of hypersalivation and other autonomic signs.

Increased liver enzymes and hepatotoxicity have occurred in humans receiving repeated doses or prolonged ketamine infusions.[20–22]

Reproductive/Nursing Safety

Ketamine crosses the placenta. Developmental delays and increased fetal resorption have been noted in laboratory animals.[23] This drug may stimulate uterine contractions.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Ketamine is considered to have a wide therapeutic index (ie, ≈5 times greater as compared with pentobarbital). When ketamine is given too rapidly or in excessive doses, significant respiratory depression may occur. It is recommended that ketamine overdoses be treated using mechanically assisted respiratory support versus analeptic agents (eg, doxapram). Although there is no specific reversal agent for ketamine, in cats, yohimbine with 4-aminopyridine has been suggested for use as a partial antagonist.[24]

For patients that have experienced or are suspected of having experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ketamine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-2 Agonists** (eg, **dexmedetomidine, medetomidine**, **xylazine**): In dogs, medetomidine can potentially reduce the metabolism of ketamine via inhibition of CYB2B11 (in vitro).[25] Dexmedetomidine (used in dogs) may reduce this drug interaction risk considerably. Xylazine reduced norketamine formation in canine and equine liver microsomal preparations.[26]
- **Barbiturates** (eg, **pentobarbital, phenobarbital**): May prolong the recovery time after ketamine anesthesia; lower doses of each agent may be needed
- **Benzodiazepines** (eg, **diazepam, midazolam**): May prolong the recovery time after ketamine anesthesia; lower doses of each agent may be needed
- **Halothane**: When ketamine is used with halothane, recovery rates may be prolonged, and the cardiac stimulatory effects of ketamine may be inhibited.
- **Ivermectin**: It has been recommended that ivermectin not be used in reptiles that have received ketamine within 10 days.[27]
- **Neuromuscular Blockers** (eg, **succinylcholine**, **tubocurarine**): May cause enhanced or prolonged respiratory depression
- **Opioids** (eg, **buprenorphine, fentanyl, hydromorphone, morphine**): May prolong the recovery time after ketamine anesthesia; lower doses of each agent may be needed
- **Theophylline, Aminophylline**: In humans, ketamine may lower the seizure threshold; veterinary significance is unknown.
- **Thyroid Hormones**: When given concomitantly with ketamine, thyroid hormones have induced hypertension and tachycardia in humans; beta-blockers (eg, propranolol) may be beneficial in the treatment of these effects.

Laboratory Considerations

- Ketamine increases plasma cortisol, which limits the use of cortisol as a biomarker for pain.[28–30]

Dosages

NOTES:

1. Ketamine is used in many different combinations with other agents. The following are representative, but not necessarily inclusive; it is suggested to refer to a recent veterinary anesthesia reference for more information.[31,32]
2. Do not confuse IV CRI dosages listed as mg/kg/*HOUR* with those listed as µg/kg/*MINUTE*.

DOGS:

Adjunct to anesthesia (extra-label):

a) **High-volume surgical sterilization program under field conditions**: Ketamine 4.5 mg/kg, medetomidine 0.04 mg/kg, and hydromorphone 0.09 mg/kg combined and given IM. Meloxicam 0.2 mg/kg IM given after surgery[33]

b) **In combination with an opioid and dexmedetomidine (ie, doggie magic) to provide anesthesia and pain management**[34]: Reference contains tables for conversion of animal weight to various µg/m^2 doses of dexmedetomidine using the 0.5 mg/mL concentration; opioid concentrations used are butorphanol 10 mg/mL, hydromorphone 2 mg/mL, and buprenorphine 0.3 mg/mL. Ketamine concentration is 100 mg/mL. These drugs may be available in other concentrations, but only the products with these concentrations should be used for this protocol. To reverse the dexmedetomidine portion of these drug combinations, give atipamezole IM at the same volume as the amount of dexmedetomidine given.

i. **Geriatric dogs or dogs with renal or liver dysfunction as a premedication prior to propofol, followed by maintenance on isoflurane or sevoflurane**: Dexmedetomidine 62.5 µg/m^2 IM or IV; combine with equal volumes of one of the opioids noted above and ketamine.

ii. **Slightly heavier sedation in American Society of Anesthesiologists (ASA) class II or III dogs for radiography**: Dexmedetomidine 125 µg/m^2 IM or IV; combine with equal volumes of one of the opioids noted above and ketamine.

iii. **Dogs undergoing minor surgery with PennHip or Orthopedic Foundation for Animals (OFA)-types of radiography that require significant muscle relaxation**: Dexmedetomidine 250 µg/m^2 IM or IV; combine with equal volumes of one of the opioids noted above and ketamine.

iv. **Inducing a surgical plane of anesthesia for ovariohysterectomy (OHE), castration, or other abdominal surgery**: Dexmedetomidine 375 µg/m^2 IM or IV; combine with equal volumes of one of the opioids noted above and ketamine. Provides rapid immobilization; lateral recumbency occurs in 5 to 8 minutes. Dogs can be intubated and maintained on oxygen. Supplemental low doses of isoflurane (0.5%) or sevoflurane (1%) can be used.

v. **Immobilizing extremely fractious and wolf-hybrid dogs**: Dexmedetomidine 500 µg/m^2 IM; combine with equal volumes of one of the opioids noted above and ketamine—this dose is rarely required.

Premedication before surgery or for anesthesia induction (extra-label):

a) **Ketamine/benzodiazepine combinations**:
   i. Ketamine 5.5 mg/kg combined with diazepam 0.28 mg/kg IV[35]
   ii. Ketamine 10 mg/kg combined with midazolam 0.5 mg/kg IV[35]

b) Ketamine 3 mg/kg in combination with dexmedetomidine 15 µg/kg, and *either* buprenorphine 40 µg/kg, butorphanol 0.2 mg/kg, *OR* hydromorphone 0.05 mg/kg as a single IM injection was given to dogs undergoing castration.[36] Some dogs required intubation and supplemental isoflurane when anesthesia was considered inadequate during surgery. The combination using buprenorphine was deemed most suitable by the authors. Administration of atipamezole postoperatively shortened recovery times.

c) Ketamine 15 mg/kg IM immediately following xylazine 1 mg/kg IM. Onset is within 3 to 7 minutes; duration is ≈24 minutes.[37]

d) Ketamine 5 – 7.5 mg/kg IM in combination with medetomidine 40 µg/kg IM. Onset is within 7 to 11 minutes; duration is 30 to 50 minutes. A higher ketamine dose provides faster onset and longer duration. Do not reverse with atipamezole.[37]

e) Premedicate with medetomidine 25 µg/kg IM in combination with butorphanol 0.1 mg/kg IM. Fifteen minutes after premedication, ketamine 5 mg/kg IM can be given. Onset of sedation is ≈6 minutes after ketamine administration; pedal reflex is lost after ≈14 minutes and returns after ≈53 minutes. Dogs became sternally recumbent and standing 35 minutes and ≈1 hour, respectively, after pedal reflex returns. Do not reverse with atipamezole.[37]

Adjunctive pain control (extra-label): **NOTE**: Do NOT confuse IV CRI dosages listed as mg/kg/*HOUR* with those listed as µg/kg per *MINUTE*.

a) Ketamine 0.5 mg/kg IV loading dose, followed by ketamine 0.1 – 0.6 mg/kg/*HOUR* IV CRI[38]

b) **Intraoperative use**: If anesthesia was induced with a drug other than ketamine, give a loading dose of ketamine 0.5 mg/kg IV, ketamine 10 – 20 µg/kg/*MINUTE* IV CRI.

c) **Postoperative analgesia**: Ketamine 2 – 10 µg/kg/*MINUTE* IV CRI[39]

d) **Ketamine/lidocaine**: Ketamine 0.5 – 3 mg/kg in combination with lidocaine 1.5 – 2 mg/kg IV followed by ketamine 0.03 – 0.1 mg/kg/*MINUTE* with lidocaine 25 – 100 µg/kg per *MINUTE* with IV CRI[40–42]

e) **Ketamine/lidocaine/dexmedetomidine**: Ketamine 1 mg/kg in combination with lidocaine 2 mg/kg and dexmedetomidine 1 µg/kg IV followed by ketamine 40 µg/kg/*MINUTE*, lidocaine 100 µg/kg/*MINUTE*, and dexmedetomidine 3 µg/kg/*HOUR* IV CRI during surgery. At the conclusion of surgery, IV CRI rates were reduced to ketamine 10 µg/kg/*MINUTE*, lidocaine 25 µg/kg/*MINUTE*, and dexmedetomidine 1 µg/kg/*HOUR* and continued for an additional 4 hours.[43,44]

f) **Ketamine/lidocaine/fentanyl**: Ketamine 0.6 mg/kg/*HOUR* in combination with lidocaine 3 mg/kg/*HOUR* and fentanyl 3.6 µg/kg/*HOUR* IV CRI (no loading dose was used in this study).[45]

g) **Morphine/lidocaine/ketamine|MLK**: Morphine 3.3 – 4 µg/kg/*MINUTE*, lidocaine 50 µg/kg/*MINUTE*, and ketamine 10 µg/kg/*MINUTE* admixed in IV fluids and administered as an IV CRI.[46–49] Refer to ***Compatibility/Compounding Considerations*** for more information.

h) **Dexmedetomidine/morphine/lidocaine/ketamine | DMLK**: Dexmedetomidine 0.5 µg/kg/*HOUR*, morphine 0.2 mg/kg per *HOUR*, lidocaine 3 mg/kg/*HOUR*, and ketamine 0.6 mg/kg per *HOUR* admixed in IV fluids and administered as an IV CRI.[50] Refer to ***Compatibility/Compounding Considerations*** for more information.

Refractory status epilepticus (extra-label): 5 mg/kg IV bolus. Although ketamine was usually administered as a single agent, it may be used in conjunction with other anticonvulsants (eg, diazepam, levetiracetam) to manage status epilepticus.[51]

CATS:

Combination as a premedication or immobilizing agent:

a) **Label dosage** (FDA-approved): 11 mg/kg IM for restraint; 22 – 33 mg/kg IM for diagnostic or minor surgical procedures not requiring skeletal muscle relaxation.[1] Anesthetic duration is ≈30 to 45 minutes; recovery usually occurs in 4 to 5 hours but may be as long as 24 hours with higher doses.

b) **Ketamine/benzodiazepine combinations** (extra-label): Ketamine 5 mg/kg combined with diazepam 0.25 mg/kg IV[52]

c) **In combination with an opioid and dexmedetomidine (ie, kitty magic, DKT, or triple combination) to provide sedation and analgesia** (extra-label): Ketamine concentration is 100 mg/mL. Opioid concentrations used in the reference are butorphanol (10 mg/mL), hydromorphone (2 mg/mL), and buprenorphine (0.3 mg/mL). Dexmedetomidine concentration is 0.5 mg/mL. These drugs may be available in other concentrations, but only the products with these concentrations should be used for this protocol.[34] See the table below for volumes used to attain the desired degree of patient sedation.

Total Volume (NOT mL/kg) of *Each* Drug (Ketamine/Dexmedetomidine*/Opioid) to Be Given IM

Cat body weight	Mild†	Moderate‡	Profound§
2-3 kg (4-7 lb)	0.025 mL	0.05 mL	0.1 – 0.15 mL
3-4 kg (7-9 lb)	0.05 mL	0.1 mL	0.2 – 0.25 mL
4-6 kg (9-13 lb)	0.1 mL	0.2 mL	0.3 – 0.35 mL
6-7 kg (14-15 lb)	0.2 mL	0.3 mL	0.4 – 0.45 mL
7-8 kg (15-18 lb)	0.3 mL	0.4 mL	0.5 – 0.55 mL

*Dexmedetomidine can be reversed immediately with an equal volume (of dexmedetomidine used) of atipamezole.[34]

†For sedation or as a premedication prior to anesthetic induction

‡For castration or minor surgical procedures

§Invasive surgical procedures, including OHE and declawing

d) **Combining ketamine with an opioid and dexmedetomidine** (extra-label):
   i. Ketamine 3 mg/kg in combination with dexmedetomidine 25 µg/kg and either butorphanol 0.2 mg/kg OR hydromorphone 0.05 mg/kg given as a single IM injection (with or without reversal by atipamezole) in cats undergoing castration.[53] Cats were also given meloxicam 0.2 mg/kg SC immediately prior to the conclusion of surgery. Supplemental isoflurane was given when the level of anesthesia was considered inadequate during surgery.
   ii. Ketamine 5 mg/kg in combination with dexmedetomidine 10 µg/kg and butorphanol 0.2 mg/kg as a single IM injection showed that this combination was suitable for castration, but recovery was better in the group that received dexmedetomidine, alfaxalone 3 mg/kg, and butorphanol.[54]
   iii. Ketamine 3 mg/kg in combination with dexmedetomidine 15 µg/kg and methadone 0.3 mg/kg IM provided anesthesia and analgesia and was suitable for cats undergoing ovariec-

tomy with comfortable and reliable recoveries.[55]

e) **Combining ketamine, butorphanol, midazolam, and medetomidine for OHE** (extra-label): Ketamine 60 mg/m^2 (≈3 mg/kg), midazolam 3 mg/m^2 (≈0.2 mg/kg), medetomidine 600 µg/m^2 (≈30 µg/kg), and *either* butorphanol 6 mg/m^2 (≈0.4 µg/kg) *OR* buprenorphine 180 µg/m^2 (≈9 µg/kg), and give as a single IM injection in the quadricep muscles 10 minutes prior to surgery.[56] In addition, *either* carprofen 4 mg/kg *OR* meloxicam 0.3 mg/kg can be given SC for additional analgesia.

f) **Combining ketamine with butorphanol and midazolam** (extra-label): Ketamine 3 mg/kg, butorphanol 0.4 mg/kg, and midazolam 0.4 mg/kg IM.[57] Substituting dexmedetomidine 5 µg/kg for ketamine produced excellent sedation and recovery but caused more cardiovascular depression and hematologic changes.

Combining ketamine with an opioid, medetomidine, and midazolam to immobilize cats requiring more sedation (extra-label): ketamine 1 – 5 mg/kg in combination with butorphanol 0.2 mg/kg, medetomidine 0.015 – 0.02 mg/kg, and midazolam 0.05 – 0.2 mg/kg and given IM. For painful procedures, consider also adding buprenorphine 0.02 – 0.04 mg/kg *OR* substituting butorphanol and buprenorphine with *either* morphine 0.5 mg/kg IM *OR* hydromorphone 0.1 mg/kg IM.

Highly aggressive cats (extra-label): Spray ketamine 1 mL into the open mouth or directed into the cat's mouth using a feline urethral catheter from a distance. The drug should be sprayed quickly so the cat does not chew and/or swallow the catheter.[58]

Adjunctive analgesia (extra-label):

a) Ketamine 0.5 mg/kg IV loading dose, followed by ketamine 0.1 – 0.6 mg/kg/*HOUR* IV CRI[38]

b) **Intraoperative use**: If anesthesia was induced with a drug other than ketamine, give a loading dose of ketamine 0.5 mg/kg IV followed by ketamine 10 – 20 µg/kg/*MINUTE* IV CRI; CRI rate can be decreased to 2 – 10 µg/kg/*MINUTE* for postoperative analgesia.[39]

c) **Morphine/lidocaine/ketamine (MLK) combination**: To a 500 mL bag of lactated Ringer's solution, add morphine sulfate 10 mg, lidocaine 120 mg, and ketamine 100 mg. Infuse IV at 10 mL/kg/*HOUR* CRI, which will provide morphine 0.2 mg/kg/*HOUR*, lidocaine 40 µg/kg/*MINUTE*, and ketamine 2 mg/kg/*HOUR*. Dexmedetomidine can be added to this mixture if needed.[59]

HORSES:

NOTE: Preferred agents for a short-term anesthesia induction protocol (ie, 20 minutes or less) include xylazine, first administered as a sedative, followed by a combination of ketamine and diazepam.[60] However, other alpha-2 agonists (eg, detomidine, romifidine) or benzodiazepines (eg, midazolam) have been substituted. For longer procedures requiring anesthesia (ie, more than 30-minute duration), protocols most commonly used a combination of guaifenesin, ketamine, and xylazine (GKX) or isoflurane. Thorough discussions of balanced, partial, and total IV anesthesia for horses can be found in the literature.[15,61]

The following dosages are some examples of published protocols:

Field anesthesia: (extra-label):

a) Sedate with xylazine 1 mg/kg IV or 2 mg/kg IM given 5 to 10 minutes (longer for IM route) before induction of anesthesia with ketamine 2 mg/kg IV. Horses must be adequately sedated (ie, head to knees) before receiving ketamine, which can cause muscle rigidity and seizures. If adequate sedation does not occur, do ***ONLY ONE*** of the following:

i. Re-administer xylazine at up to half the original dose.

ii. Add butorphanol 0.02 – 0.04 mg/kg IV. Butorphanol can be given with the original xylazine dose if there is suspicion the horse will be difficult to tranquilize (eg, high-strung thoroughbreds), or it can be added before induction with ketamine. This combination will improve induction, increase analgesia, and increase recumbency time by ≈5 to 10 minutes.

iii. Add diazepam 0.03 mg/kg to the ketamine dose and give IV. This combination will improve induction when sedation is marginal, improve muscle relaxation during anesthesia, and prolong anesthesia by ≈5 to 10 minutes.

iv. Administer IV guaifenesin 5% solution to effect to increase sedation and muscle relaxation.[62]

b) Premedicate with xylazine 0.7 mg/kg, butorphanol 0.025 mg/kg, and acepromazine at 0.05 mg/kg IV. Induce anesthesia with ketamine 5 mg/kg and diazepam 0.03 mg/kg IV. This combination produced rapid induction, more favorable surgical conditions, and improved recovery quality as compared with the same regimen using a lower ketamine dose of 2.2 mg/kg.[63]

c) **Field castration of ponies**:

i. Premedicate with detomidine 0.02 mg/kg IV; induce with ketamine 2.2 mg/kg IV and midazolam 0.06 mg/kg IV[64]

ii. Premedicate with butorphanol 0.05 mg/kg IV and romifidine 0.1 mg/kg IV, then ketamine 2.2 mg/kg or 3 mg/kg IV with diazepam 0.02 mg/kg IV.[65] Additional ketamine doses of 0.5 mg/kg IV were administered when anesthesia was deemed inadequate during surgery.

Part of induction protocols (extra-label): **NOTE**: Use with caution; this is not recommended for field anesthesia.

a) For healthy animals: Premedicate with xylazine 0.44 – 0.66 mg/kg IV (OR 200 – 300 mg/450 kg [992 lb] horse [NOT mg/kg]). Wait for sedation and muscle relaxation to occur (≈5 minutes), then rapidly infuse guaifenesin 5% solution (50 mg/mL) IV using pressurization until marked sedation and muscle relaxation is achieved, generally a total dose of 30 – 50 mg/kg. Administer ketamine 2.2 mg/kg IV (or 1000 mg/450 kg [992 lb] horse [NOT mg/kg]) at a point that allows for slow onset to occur without the animal becoming excessively weak and collapsing from the effects of guaifenesin. Recumbency generally occurs ≈60 seconds following ketamine administration. The slow administration of guaifenesin can also be used in healthy animals in place of a supplemental dose of xylazine when the level of initial sedation is inadequate.

For compromised animals: Premedicate with xylazine 0.22 – 0.44 mg/kg IV (or 100 – 200 mg/450 kg [992 lb] horse [NOT mg/kg]) depending on the status and demeanor of the animal to minimize cardiovascular effects in compromised animals. Slow IV administration of guaifenesin 5% solution (50 mg/mL) can be used initially to gradually achieve the desired level of sedation (see ***Guaifenesin, Intravenous*** monograph for additional details on administration), then rapidly infuse guaifenesin using pressurization until marked sedation and muscle relaxation is achieved, generally a total dose of 30 – 50 mg/kg IV. To induce anesthesia, decrease the ketamine dose as the degree of compromise increases: ketamine 1.34 – 1.55 mg/kg (or 600 – 700 mg/450 kg [992 lb] horse [NOT mg/kg]) IV for extremely compromised animals at a point that allows slow onset to occur without the animal becoming excessively weak and collapsing from the growing effects of guaifenesin. Experience may be required to get the timing right.

Recumbency takes longer (up to a couple minutes) when the ketamine dose is reduced in compromised animals.[66]

b) Using ketamine and propofol after xylazine sedation:

i. In a retrospective study (n = 100), horses were sedated with xylazine 0.99 ± 0.2 mg/kg IV.[67] Some horses also received butorphanol IV. After visually apparent sedation, a combination of propofol 0.40 ± 0.1 mg/kg and ketamine 2.8 ± 0.3 mg/kg were given (separately or in combination) via IV bolus. Following induction, 6 horses required a single administration of additional ketamine 0.7 ± 0.4 mg/kg. Anesthesia was maintained with guaifenesin in 34 horses and with isoflurane and oxygen in 66 horses.

ii. In a smaller study under experimental conditions, premedication occurred with xylazine 1 mg/kg IV, and anesthesia was induced with propofol 0.5 mg/kg IV followed by ketamine 3 mg/kg IV.[68] Anesthesia was maintained with isoflurane.

Partial IV anesthesia | PIVA (extra-label): Ketamine 0.4 – 3 mg/kg/hour IV CRI IV CRI (**NOTE**: ketamine 0.5 – 2 mg/kg/hour IV CRI is more commonly used). IV CRI should be discontinued 20 to 30 minutes before the inhalant anesthetic is turned off and the horse is moved to the recovery stall. This drug combination can also be combined with lidocaine and alpha-2 agonist (eg, dexmedetomidine, xylazine) CRIs.[69,70]

Total IV anesthesia:

a) Guaifenesin/ketamine/xylazine | GKX | "Triple-drip" (extra-label): Guaifenesin 50 mg/mL, ketamine 1 – 2 mg/mL (2 mg/mL concentration used for more painful or noxious procedures), and xylazine 0.5 mg/mL. To prepare this mixture, add ketamine (100 mg/mL) 10 mL for 1 mg/mL *OR* 20 mL ketamine for 2 mg/mL and xylazine (100 mg/mL) 5 mL to a 1000 mL bag of guaifenesin 5%. Most clinicians prefer to induce with ketamine/xylazine or ketamine/xylazine/diazepam and then use GKX for maintenance. Use GKX 1.5 – 2.2 mL/kg/*HOUR* IV CRI depending on the procedure, animal response, and ketamine concentration.

b) Guaifenesin/ketamine/detomidine | GKD (extra-label): In ponies sedated with detomidine 0.02 mg/kg IM and induced with ketamine 2 mg/kg IV: Guaifenesin 100 mg/mL, ketamine 4 mg/mL, and detomidine 0.04 mg/mL at 0.8 mL/kg/*HOUR* IV CRI for the first hour and 0.6 mL/kg/*HOUR* IV CRI for the final 30 minutes.[71,72] To prepare this mixture, add ketamine (100 mg/mL) 40 mL and detomidine (10 mg/mL) 4 mL to a 1000 mL bag of guaifenesin 10%.

c) Ketamine/medetomidine/midazolam (extra-label):

i. Premedicate with medetomidine 7 µg/kg IV then induce general anesthesia with ketamine 2.2 mg/kg IV followed by ketamine 3 mg/kg/*HOUR*, medetomidine 5 µg/kg/*HOUR*, and midazolam 0.1 mg/kg/*HOUR* IV CRI.[73]

ii. Alternatively, premedicate with acepromazine 0.01 – 0.02 mg/kg IV, medetomidine 7 µg/kg IV, and methadone 0.1 mg/kg IV; induce general anesthesia with ketamine 2.2 mg/kg IV and midazolam 0.06 mg/kg IV; maintain anesthesia with ketamine 3 mg/kg/*HOUR*, medetomidine 5 µg/kg/*HOUR*, and midazolam 0.1 mg/kg/*HOUR* IV CRI.[74]

d) Ketamine/midazolam/xylazine (extra-label): Premedicate with xylazine 1 mg/kg IV; induce with ketamine 2.2 mg/kg IV. The total intravenous anesthesia (TIVA) regimen consisted of ketamine 0.03 mg/kg/*MINUTE*, midazolam 0.002 mg/kg/*MINUTE*, xylazine 0.016 mg/kg/*MINUTE* IV CRI.[75] Additional ketamine was required in 50% of horses, and the regimen was deemed inferior to those in which midazolam was replaced with propofol 0.05 – 0.1 mg/kg per *MINUTE* IV CRI. In a retrospective review, the average doses were ketamine 0.045 mg/kg/*MINUTE*, xylazine 0.024 mg/kg/*MINUTE*, and midazolam 0.002 mg/kg/*MINUTE* IV CRI. Premedication included an alpha-2 agonist, but the specific agent and dose, other premedication, and anesthesia induction protocol were not standardized. During anesthesia, 33% of horses received a ketamine bolus.[76]

CATTLE/RUMINANTS:

Chemical restraint (mild sedation of standing animals to semi-anesthetized recumbency | Ketamine stun (extra-label): **NOTE**: The following are abbreviated suggested initial dosages. A thorough discussion including dosages for other combinations using ketamine and redosing recommendations is available.[77] Use in combination with local anesthetic blockade improves level of sedation.

a) Ketamine stun; IV recumbent (for short procedures requiring a high level of systemic analgesia and/or animal cooperation [eg, castration, biopsy, flushing joints, casting]): Ketamine 0.3 – 0.5 mg/kg with xylazine 0.025 – 0.05 mg/kg and butorphanol 0.05 – 0.1 mg/kg combined in one syringe and given IV. The upper end of the dosage range is used anecdotally unless contraindicated.[77] Duration of sedation is ≈15 to 25 minutes.

b) Ketamine stun; IM, SC recumbent: Ketamine 0.1 mg/kg with butorphanol 0.025 mg/kg and xylazine 0.05 mg/kg combined in one syringe and given IM or SC. Duration of sedation is ≈45 minutes with SC administration.

c) Ketamine stun; IV standing: Sedate with xylazine 0.02 – 0.0275 mg/kg IV, then ketamine 0.05 – 0.1 mg/kg IV slowly. An opioid (eg, butorphanol 0.05 – 0.1 mg/kg IV or IM [small ruminants], butorphanol 0.02 – 0.05 mg/kg IV or IM [larger ruminants], or morphine 0.05 – 0.1 mg/kg IV or IM) can be added to improve analgesia and level of sedation.

d) Ketamine stun; IM, SC standing: Ketamine 0.04 mg/kg with butorphanol 0.01 mg/kg and xylazine 0.02 mg/kg combined in one syringe and given IM or SC. In a 500 kg (≈1100 lb) cow, this combination equates to butorphanol 5 mg, xylazine 10 mg, and ketamine 20 mg (ie, 5–10–20 technique).

Injectable anesthesia (extra-label): Several protocols have been discussed using ketamine in combination with other anesthetic and analgesic compounds (including IM, IV, and IV CRI protocols).[77] The reader is referred to the full article for details on ketamine use for this purpose.

Adjunctive analgesia (extra-label):

a) Ketamine 0.4 – 1.2 mg/kg/*HOUR* IV CRI[78]

b) Ketamine/lidocaine/fentanyl in goats: IV premedication: fentanyl 10 µg/kg, lidocaine 2 mg/kg, and ketamine 1.5 mg/kg. Induce with propofol 3 mg/kg IV, then begin ketamine 3 mg/kg/*HOUR* with lidocaine 3 mg/kg/*HOUR* and fentanyl 10 µg/kg/*HOUR* all via IV CRI in addition to either propofol or isoflurane to maintain anesthesia.[79]

CAMELIDS (IE, LLAMAS/ALPACAS):

Anesthetic agent (extra-label):

a) **Alpacas**: Ketamine 0.2 – 0.5 mg/kg with butorphanol 0.05 – 0.1 mg/kg and xylazine 0.2 – 0.5 mg/kg combined in one syringe and given IM[80]

b) **Llamas**: Ketamine 0.2 – 0.3 mg/kg with butorphanol 0.07 – 0.1 mg/kg and xylazine 0.2 – 0.3 mg/kg combined in one syringe and given IV[80]

Procedural pain (eg, castrations) when recumbency (up to 30

minutes) is desired (extra-label):

a) **Alpacas**: Ketamine 4.6 mg/kg with butorphanol 0.046 mg/kg and xylazine 0.46 mg/kg combined in one syringe and given IM[78]

b) **Llamas**: Ketamine 3.7 mg/kg with butorphanol 0.037 mg/kg and xylazine 0.37 mg/kg combined in one syringe and given IM.[78] During anesthesia, 50% of the original ketamine and xylazine dose may be administered in order to prolong the effect up to 15 minutes.

NOTE: If performing mass castrations on 3 or more animals, a bottle using the following drug combination can be made: ketamine 1 g, butorphanol 10 mg, and xylazine 100 mg. Give this mixture at 1 mL/18 kg (40 lb) for alpacas, and 1 mL/22 kg (50 lb) for llamas. Handle the animal quietly and allow plenty of time before starting the procedure. Expect 20 minutes of surgical time. The animal should stand 45 minutes to 1 hour after injection of this drug combination.[78]

SWINE:

Injectable anesthesia (extra-label):

a) Administer atropine, then ketamine 11 mg/kg IM. To prolong anesthesia and increase analgesia, administer additional ketamine 2 – 4 mg/kg IV. Injection of local anesthetic agents at the surgical site (eg, lidocaine 2%) may enhance analgesia.[81]

b) Ketamine 22 mg/kg with acepromazine 1.1 mg/kg combined in one syringe and given IM[82]

c) Ketamine 4.4 mg/kg IM or IV after sedation[83]

d) Ketamine 8 mg/kg with detomidine 0.18 mg/kg and butorphanol 0.3 mg/kg combined in one syringe and given IM.[84] Tolazoline reversal shortened the duration of recovery without compromising recovery quality.

BIRDS:

Injectable anesthesia:

a) **Ketamine as a single agent** (extra-label): Birds weighing as follows (**NOTE**: Be aware of units when calculating doses. Birds weighing less than 250 g [0.6 lb] require a higher dose per kg than birds weighing more than 250 g [0.6 lb]):

i. Less than 100 g (0.2 lb) (eg, canaries, finches, budgies): 0.1 – 0.2 mg/g IM

ii. 250 g to 500 g (0.6 to 1.1 lb) (eg, parrots, pigeons): 0.05 – 0.1 mg/g IM

iii. 500 g to 3 kg (1.1 to 6.6 lb) (eg, chickens, owls, hawks): 0.02 – 0.1 mg/g IM

iv. More than 3 kg (6.6 lb) (eg, ducks, geese, swans): 0.02 – 0.05 mg/g IM[85]

b) **In combination with acepromazine** (extra label): Ketamine 25 – 50 mg/kg combined with acepromazine 0.5 – 1 mg/kg and administered IM[86]

c) **In combination with diazepam** (extra label): Ketamine 10 – 50 mg/kg with diazepam 0.5 – 2 mg/kg combined in a syringe and given IM or IV; doses can be split in half for IV use.

d) **In combination with xylazine** (extra label): Ketamine 10 – 30 mg/kg with xylazine 2 – 6 mg/kg combined in a syringe and administered IM. Xylazine is not recommended to be used in debilitated birds because of its cardiodepressant effects.

FERRETS:

Injectable anesthesia (extra-label): Ketamine 5 mg/kg with butorphanol 0.1 mg/kg and medetomidine 80 µg/kg combined in one syringe and given IM.[87] Maintenance of anesthesia may require supplementation with isoflurane (0.5% to 1.5%) during abdominal surgery.

Adjunctive postoperative analgesia (extra-label): Ketamine 0.3 – 0.4 mg/kg/*HOUR* IV CRI in combination with fentanyl 2.5 – 5 µg/kg/*HOUR* IV CRI[88]

RABBITS/RODENTS/SMALL MAMMALS:

Chemical restraint (extra-label):

Mice:

a) Ketamine 50 – 100 mg/kg IM or intraperitoneal (IP); 50 mg/kg IV

b) **In combination with diazepam**: Ketamine 200 mg/kg with diazepam 5 mg/kg IM or IP

c) **In combination with xylazine**: Ketamine 100 mg/kg with xylazine 5 – 15 mg/kg IM or IP[89]

Rats:

a) Ketamine 50 – 100 mg/kg IM or IP; 40 – 50 mg/kg IV

b) **In combination with diazepam**: Ketamine 40 – 60 mg/kg with diazepam 5 – 10 mg/kg IP

c) **In combination with xylazine**: Ketamine 40 – 75 mg/kg with xylazine 5 – 12 mg/kg IM or IP[89]

Hamsters/gerbils:

a) Ketamine 100 mg/kg IM

b) **In combination with diazepam**: Ketamine 50 mg/kg with diazepam 5 mg/kg IM

c) **In combination with xylazine**: Not recommended[89]

Guinea pigs:

a) Ketamine 10 – 30 mg/kg IM

b) **In combination with diazepam**: Ketamine 60 – 100 mg/kg with diazepam 5 – 8 mg/kg IM

c) **In combination with xylazine**: Ketamine 85 mg/kg with xylazine 12 – 13 mg/kg IM[89]

Rabbits:

a) Ketamine 20 – 60 mg/kg IM or IV
In combination with diazepam: Ketamine 60 – 80 mg/kg with diazepam 5 – 10 mg/kg IM
In combination with xylazine: Ketamine 10 mg/kg with xylazine 3 mg/kg IV[89] or ketamine 6 mg/kg with xylazine 0.6 mg/kg IV[90]; another reference does not recommend xylazine for pet rabbits.[91]

b) Ketamine 20 – 50 mg/kg IM or 15 – 20 mg/kg IV
In combination with diazepam for induction: Diazepam 5 – 10 mg/kg IM, after 30 minutes give ketamine 20 – 40 mg/kg IM or diazepam 0.2 – 0.5 mg/kg and ketamine 10 – 15 mg/kg IV to effect
In combination with diazepam for anesthesia without inhalants: Diazepam 5 – 10 mg/kg IM, after 30 minutes give ketamine 60 – 80 mg/kg IM

Injectable anesthesia (extra label):

Rodents: Ketamine 100 mg/kg with midazolam 5 mg/kg and buprenorphine 0.05 mg/kg combined in one syringe and given IP

Rabbits:

a) Ketamine 10 mg/kg with midazolam 0.05 mg/kg and buprenorphine 0.03 mg/kg combined in one syringe and given IM[92]

b) Following premedication with acepromazine 0.1 mg/kg and buprenorphine 0.02 mg/kg IM, anesthesia was induced with propofol 2 mg/kg IV and ketamine 1 mg/kg IV; anesthesia was maintained with propofol 0.8 mg/kg/*MINUTE* IV CRI and ketamine 0.1 – 0.2 mg/kg/*MINUTE* IV CRI.[93]

c) Ketamine 1 – 5 mg/kg IV combined with propofol 1 – 5 mg/kg IV can be administered together in a 1:1 mg/kg ratio; higher doses had faster anesthesia onset and longer duration.[94]

d) Medetomidine 0.1 mg/kg with ketamine 10 mg/kg administered intranasally into 2 nares over 30 seconds using a syringe and catheter prior to isoflurane anesthesia.[95] When the rabbits swallowed during intubation, half of the initial induction dose

was repeated. Onset of anesthesia was within 5 minutes. Intranasal administration during dorsal recumbency caused dyspnea in all rabbits, and 2 rabbits died; administration during sternal recumbency was better tolerated, with no fatalities.

REPTILES:

NOTE: Reversal of all reptile dosages with atipamezole is 4 to 5 times the medetomidine dose.[96]

Anesthesia (extra-label): Ketamine 22 – 88 mg/kg IM[97]

Medium to small land tortoises (extra-label): Ketamine 5 – 10 mg/kg with medetomidine 100 – 150 µg/kg combined and given IV or IM

Freshwater turtles (extra-label): Ketamine 10 – 20 mg/kg with medetomidine 150 – 300 µg/kg combined and given IV or IM

Chelonians (extra-label): Ketamine 4 – 10 mg/kg with butorphanol 0.5 – 1 mg/kg and medetomidine 40 – 50 µg/kg IM[98]

Iguanas (extra-label): Ketamine 5 – 10 mg/kg with medetomidine 100 – 150 µg/kg combined and given IV or IM

Monitoring

- Depth of anesthesia and analgesia
- Ventilation (eg, $ETCO_2$)
- Cardiovascular status (eg, heart rate and rhythm, blood pressure, pulse oximetry)
- Monitor eyes to prevent drying out or injury
- Body temperature

Chemistry/Synonyms

Ketamine HCl, a phencyclidine derivative, occurs as white, crystalline powder. It has a melting point of 258°C to 261°C (496°F-501°F), emits a characteristic odor, and will precipitate as the free base at high pH. One gram is soluble in 5 mL of water and in 14 mL of alcohol. The commercially available injections are racemic mixtures of R- and S- ketamine, with a pH between 3.5 to 5.5. Ketamine 1 mg is equivalent to ketamine hydrochloride 1.15 mg.

Ketamine HCl may also be known as CI-581, CL-369, CN-52372-2, ketamini hydrochloridum, *Amtech®*, *Brevinaze®*, *Calypsol®*, *Cost®*, *Inducmina®*, *Keta®*, *Keta-Hameln®*, *Ketaject®*, *Ketalin®*, *Ketanest®*, *Ketaset®*, *Ketasthesia®*, *Keta-sthetic®*, *Ketava®*, *Ketina®*, *Ketmin®*, *Ketolar®*, *Narketan®*, *Velonarcon®*, *VetaKet®*, or *Vetalar®*.

Storage/Stability

Ketamine injection should be stored between 15°C to 30°C (59°F-86°F) and protected from light. The discard dates after first vial puncture vary by manufacturer; refer to the specific product label for further information.

The solution may darken with prolonged exposure to light; this does not affect the drug's potency. Do not use this product if precipitates appear.

Ketamine may be mixed with sterile water for injection, 5% dextrose, and 0.9% sodium chloride for diluent purposes.

A human-labeled ketamine product (50 mg/mL) maintained over 90% potency when stored in polypropylene syringes for 180 days.[99]

Compatibility/Compounding Considerations

Ketamine may be mixed with sterile water for injection, 5% dextrose, and 0.9% sodium chloride for diluent purposes. Ketamine is physically **compatible in the same syringe** with xylazine, cefazolin, diphenhydramine, fentanyl, hydromorphone, lidocaine, midazolam, and morphine.

Mixing ketamine with barbiturates or diazepam in the same syringe or IV bag is *not* recommended, as precipitation may occur. Although there are many anecdotal reports of mixing ketamine with diazepam or midazolam in the same syringe just prior to injection, there does not appear to be any published information documenting the drugs' stability after combining. Do not use if a visible precipitate forms.

A study in laboratory rodents, evaluating the stability, sterility, pH, particulate formation, and efficacy of compounded ketamine, acepromazine, and xylazine (KAX) supported the finding that the drugs are stable and efficacious for at least 180 days after mixing if stored in the dark at room temperature.[100]

The manufacturer states that dexmedetomidine 0.5 mg/mL solution for injection can be mixed with butorphanol 2 mg/mL or ketamine 50 mg/mL solution in the same syringe and possesses no pharmacologic risk.[101]

Ketamine is **Y-site compatible** with cefazolin, diphenhydramine, dobutamine, epinephrine, magnesium sulfate, morphine, penicillin G potassium/sodium, potassium chloride, propofol, and ranitidine.

Ketamine appears to be **Y-site incompatible** with ampicillin sodium, dexamethasone sodium phosphate, furosemide, heparin, insulin (regular), and sodium bicarbonate.

- **Morphine/Lidocaine/Ketamine ("MLK") Recipe**:

NOTE: When preparing solutions, be certain that you are **NOT** using the lidocaine product that contains epinephrine.

To prepare IV infusion solution using the veterinary lidocaine 2% solution, add 1 gram (50 mL) to 1 liter of compatible solution (eg, 0.9% sodium chloride, 5% dextrose). This solution will give an approximate lidocaine concentration of 1 mg/mL (1000 µg/mL). When using a mini-drip (60 drops/mL) IV set, each drop will contain ≈17 µg of lidocaine. In small dogs and cats, a less concentrated solution may be used for greater dosage accuracy.

A combination IV infusion for analgesia and sedation in postoperative patients (dogs, **NOT** cats) that require sedation to sleep the night after surgery is described[102]: For this technique, plan on adding the drugs to a bag of fluids for which the administration rate will not change, which usually means picking a fluid and administration rate calculated to provide maintenance needs for water. For example, to calculate a drug plan for a 20 kg dog that is to receive morphine, lidocaine, ketamine, and medetomidine for the first 8 to 24 hours postoperatively, drug doses to consider might include:

Morphine: 0.1 mg/kg/hour x 20 kg = 2 mg/hour
Lidocaine: 2.5 mg/kg/hour x 20 kg = 50 mg/hour
Ketamine: 0.1 mg/kg/hour x 20 kg = 2 mg/hour
Medetomidine: 2 µg/kg/hour x 20 kg = 40 µg/hour (**NOTE**: This is **NOT** the dose for dexmedetomidine; see the ***Dexmedetomidine*** monograph for use as a CRI).

The maintenance fluid administration rate for a 20 kg dog lying quietly in a cage is roughly 800 mL/day or 33 mL/hour. Therefore, a 1 L bag contains ≈30 hours of treatment, and to a 1 L bag one must add:

Morphine: 2 mg/hour x 30 hours = 60 mg = 6 mL (when using 10 mg/mL morphine)
Lidocaine: 50 mg/hour x 30 hours = 1500 mg = 75 mL (when using 2% [20 mg/mL] lidocaine)
Ketamine: 2 mg/hour x 30 hours = 60 mg = 0.6 mL (when using 100 mg/mL ketamine)
Medetomidine: 40 µg/hour x 30 hours = 1200 µg= 1.2 mL (when using 1000 µg/mL medetomidine)

If the drugs are added to a 1 L bag of fluid, the final volume is greater than 1 liter—in this case 1083 mL. Therefore, 83 mL should be removed from the bag *before* addition of the medications.[102]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Ketamine HCl for Injection: 100 mg/mL in 10 mL vials; *Ketaject®*, *Ketaset®*, *Keta-sthetic®*, *VetaKet®*, *Vetalar®*; generic; (Rx, C-III). FDA-approved for use in cats and subhuman primates

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

Food Animal Residue Avoidance Databank (FARAD) recommends a 3-day meat and 2-day milk withdrawal for ketamine in cattle, goats, and sheep.[103] The recommended meat withdrawal time for ketamine in swine is 2 days. **NOTE**: FARAD withdrawal intervals are dosage-dependent; consult FARAD website for further information.

HUMAN-LABELED PRODUCTS:
Ketamine HCl Injection: 10 mg/mL in 20 mL vials, 50 mg/mL in 10 mL vials, and 100 mg/mL in 10 mL vials; *Ketalar*®; generic; (Rx, C-III)

Ketoconazole, Systemic

(kee-toe-***kah***-na-zole) *Nizoral*®

Antifungal, Azole

Prescriber Highlights

- ► Oral imidazole antifungal historically used for systemic mycoses, but newer agents are generally preferred
- ► Contraindications include known hypersensitivity and liver disease; additionally, some clinicians believe ketoconazole is contraindicated in cats.
- ► Use caution in thrombocytopenia.
- ► Potentially teratogenic and embryotoxic
- ► Adverse effects: GI effects (eg, anorexia, vomiting, and/or diarrhea) are most common; hepatic toxicity, thrombocytopenia, reversible lightening of haircoat, transient dose-related suppressant effect on gonadal and adrenal steroid synthesis
- ► Many drug interactions are possible.

Uses/Indications

Because of ketoconazole's comparative lack of toxicity as compared with amphotericin B, easy oral administration, and relatively good efficacy, it has been used to treat several types of fungal infections in dogs, cats, and other small species. However, other antifungal agents (eg, fluconazole, itraconazole) are usually preferred, as they have less toxicity, less expense (ie, fluconazole), and/or have enhanced efficacy. In humans, ketoconazole is indicated only for systemic fungal infections in patients who have failed or are intolerant to other options.

In dogs, ketoconazole or itraconazole are recommended when systemic therapy is required for the treatment of *Malassezia* dermatitis. Itraconazole may be preferred due to improved tolerability, but availability and cost may dictate treatment.[1]

Use of ketoconazole in cats is controversial due to its potential for causing hepatotoxicity; some clinicians consider it contraindicated in cats.

Ketoconazole has also been used historically for the medical treatment of hyperadrenocorticism in dogs, but other treatments (mitotane or trilostane) are now recommended.

Ketoconazole interferes with the metabolism of drugs by CYP450 3A isoenzymes, including cyclosporine. This drug interaction has been used in dogs to reduce cyclosporine dosage/cost.[2,3]

Pharmacology/Actions

At usual doses and serum concentrations, ketoconazole is fungistatic against susceptible fungi. At higher concentrations for prolonged periods of time or against very susceptible organisms, ketoconazole may be fungicidal. It is believed that ketoconazole inhibits a fungal cytochrome P450-dependent demethylation enzyme that produces ergosterol in the cell membrane. The resultant intracellular accumulation of methylated sterols weakens the cellular membranes of susceptible fungi, increasing membrane permeability and allowing leakage of cellular contents and impairing uptake of purine and pyrimidine precursors.

Ketoconazole has activity against most pathogenic fungi, including *Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus neoformans, Histoplasma capsulatum, Microsporum* spp, and *Trichophyton* spp. Higher concentrations are necessary to treat most *Aspergillus* spp and *Sporothrix* spp. Resistance to ketoconazole has been documented for some strains of *Candida albicans*.

Ketoconazole has in vitro activity against *Staphylococcus aureus* and *Staphylococcus epidermidis*, *Nocardia* spp, enterococci, herpes simplex virus types 1 and 2, and some protozoa. The clinical implications of this activity are unknown, but synergism between imidazole antifungal and antimicrobials against susceptible bacteria has been demonstrated.[4]

Via inhibition of 5-lipooxygenase, ketoconazole possesses some anti-inflammatory activity. The drug can suppress the immune system, likely by suppressing T-lymphocyte proliferation.

Ketoconazole also has endocrine effects; steroid synthesis is directly inhibited by blocking several P450 enzyme systems. Measurable reductions in testosterone or cortisol synthesis can occur at dosages used for antifungal therapy, but higher dosages are generally required to reduce concentrations of testosterone or cortisol to be clinically useful in the treatment of prostatic carcinoma or hyperadrenocorticism. Effects on mineralocorticoids are negligible. Other P450 effects include inhibition of vitamin D activation.

Pharmacokinetics

Although it is reported that ketoconazole is well absorbed after oral administration, oral bioavailability of ketoconazole tablets in dogs is highly variable. One study in 6 healthy dogs found the bioavailability ranged from 4% to 89% after ketoconazole 400 mg (19.5 – 25.2 mg/kg) was administered to fasted dogs.[5] Peak serum concentrations ranged from 1.1 to 45.6 µg/mL and occurred 1 to 4.25 hours after dosing. This wide interpatient variation may have significant clinical implications from both a toxicity and efficacy standpoint, particularly because ketoconazole is often used in life-threatening infections and assays for measuring serum concentrations are not readily available. Administration of ketoconazole with food may increase absorption.

Oral absorption of tablets in horses is poor. Single doses of ketoconazole compounded in corn syrup (30 mg/kg) yielded nondetectable drug concentrations in blood, but when given via NG tube in a 0.2 normal hydrochloric acid solution, bioavailability increased to 23% and a peak serum concentration of 3.8 µg/mL was reached 1.5 to 2 hours after administration.[6] Ketoconazole distributed into synovial and peritoneal fluids, endometrial tissue, and into the urine.

Ketoconazole absorption is enhanced in an acidic environment, and drugs that raise gastric pH may lessen absorption (see ***Drug Interactions***). The decision whether to administer ketoconazole with meals or during a fasted state to maximize absorption is controversial. The manufacturer recommends giving ketoconazole with food in human patients. Dogs or cats that develop anorexia and/or vomiting during therapy may benefit from administration with meals.

After absorption, ketoconazole is distributed into the bile, cerumen, saliva, urine, and synovial fluid. Ketoconazole unreliably reaches CSF in humans; CSF concentrations are generally less than 10% of those found in the serum but may be increased if the meninges are inflamed. High concentrations of the drug are found in the liver, adrenals, and pituitary gland, whereas more moderate con-

centrations are found in the kidneys, lungs, bladder, bone marrow, and myocardium. At usual doses (10 mg/kg), drug concentrations attained are likely inadequate in the brain, testes, and eyes to treat most infections; higher dosages are required. Ketoconazole is 84% to 99% bound to plasma proteins.

Ketoconazole is metabolized into several inactive metabolites by the liver; its metabolism may be saturable as mean residence time increases with repeated doses.[7] These metabolites are excreted primarily into the feces via the bile. Approximately 13% of a given dose is excreted in the urine, and only 2% to 4% of the drug is excreted unchanged in the urine. Half-life in dogs is ≈1 to 6 hours (average of 2.7 hours).

Contraindications/Precautions/Warnings

Ketoconazole is contraindicated in patients with known hypersensitivity to it and in animals with acute or chronic liver disease. It should be used with caution in patients with thrombocytopenia. Because of its effects on cortisol synthesis, it should be used with caution in dogs undergoing stressful events (eg, surgery, trauma, critical illness).

Use in cats is controversial, as anorexia, weight loss, and hepatotoxic effects are possible.

Many potential drug interactions are possible with ketoconazole. It is a potent inhibitor of CYP3A12 (and possibly other isoenzymes) and can inhibit P-glycoprotein. Certain drug combinations are contraindicated (see ***Drug Interactions***).

Long-term use of ketoconazole in small animal species has been associated with development of cataracts.[8]

Adverse Effects

GI signs (eg, anorexia, vomiting, diarrhea, weight loss) are the most common adverse effects seen with ketoconazole therapy and are more prevalent in cats. Dividing the dose and/or giving it with meals may minimize these adverse effects. Appetite stimulants such as mirtazapine (cats) or capromorelin (dogs) may also be of benefit.

Hepatotoxicity manifesting as cholangiohepatitis and increased liver enzymes has been reported with ketoconazole and may be either idiosyncratic in nature or a dose-related phenomenon. Anorexia and lethargy are often the clinical marker for toxicity[9]; hepatotoxicity is commonly dose-dependent and may occur at any time during treatment.[9] Cats may be more prone than dogs to developing hepatotoxicity. If adverse effects occur and ALT activity is markedly increased or hyperbilirubinemia occurs, the drug should be discontinued. Increased liver enzymes (ie, ALT, ALP) in the absence of other signs does not necessarily mandate dose reduction or drug discontinuation. Once ALT activity returns to normal and other adverse effects have resolved, the drug may be restarted at a lower dose or using longer dosing intervals with intense monitoring.

A retrospective study reviewed liver histopathology reports from 15 dogs with probable hepatotoxicity associated with therapeutic ketoconazole dosages.[9] Clinical signs included lethargy, anorexia, and vomiting, and liver enzymes were elevated in all dogs. Because many dogs that received ketoconazole were also receiving other drugs (eg, corticosteroids, phenobarbital), there was an array of liver pathology ranging from hepatocellular cholestasis to chronic hepatitis; the most consistent finding in each of the liver biopsy samples was an accumulation of ceroid-lipofuscin-laden macrophages, which are nonspecific changes associated with historic hepatocyte injury (a finding similar to that in humans with ketoconazole hepatotoxicity). Within the group of 15 dogs evaluated in this study, 7 died from liver injury: fulminant hepatic failure (n = 3), progressive chronic hepatitis (n = 3; pyogranulomatous [n = 2] and lymphoplasmacytic [n = 1]), and 1 was euthanized due to postoperative complications from a surgical liver biopsy with a presumed poor prognosis.

Uncommon adverse effects that have also been reported include thrombocytopenia, ataxia, and behavior changes (eg, anxiety).[10] A reversible lightening of the haircoat may also occur in patients treated with ketoconazole. Cataracts in dogs, anecdotally attributed to ketoconazole therapy, has been reported.[11]

Ketoconazole has a transient dose-related suppressant effect on adrenal steroid synthesis. Doses of 30 mg/kg/day have been demonstrated to suppress serum cortisol concentrations in dogs with hyperadrenocorticism (see ***Dosages***).[12] Dogs undergoing high dose antifungal therapy may need additional glucocorticoid support during periods of acute stress.[13] There are case reports of ketoconazole-induced hypoadrenocorticism in dogs receiving antifungal treatment with ketoconazole, which resolved after discontinuation of ketoconazole.[13,14]

Reproductive/Nursing Safety

Ketoconazole is a known teratogen and embryotoxin in rats, and dystocia has occurred with ketoconazole administration in the third trimester.[15] There have been reports of mummified fetuses and stillbirths in dogs that have been treated. Ketoconazole may cause infertility in male dogs by decreasing testosterone synthesis. Doses as low as 10 mg/kg depressed serum testosterone concentrations in dogs within 3 to 4 hours after administration but concentrations returned to normal within 10 hours.[12] Testosterone production rebounds once the drug is discontinued. In one dog treated with ketoconazole for 3 months, infertility occurred with decreased testosterone and azoospermia. Testosterone concentration and sperm quality were restored 100 days after discontinuing ketoconazole.[13]

Ketoconazole is excreted in milk. In humans, mothers who are under treatment with ketoconazole are advised not to breast feed.[15] Consider use of milk replacer if ketoconazole must be used in a lactating animal.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No reports of acute toxicity associated with overdose were located. The oral LD_{50} in dogs after oral administration is greater than 500 mg/kg. If an acute overdose occurs in humans, the manufacturer recommends employing supportive measures, including gastric lavage with activated charcoal within the first hour after ingestion.[15] Administration of oral antacids may help reduce absorption.

Chronic toxicity occurred in dogs given 20 – 40 mg/kg/day for up to 1 year. Signs included decreased food consumption, emesis, and, most notably, liver toxicity. Increased liver enzymes and histopathological changes in the liver were seen. These changes were reversible on discontinuation of ketoconazole. Jaundice and death occurred after 2 to 4 weeks of 80 mg/kg/day doses.[16]

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

Ketoconazole is a potent inhibitor of CYP2B11, 2C21/41, 2D15, and 3A12 in dogs[17]; in humans it inhibits CYP3A4 and P-glycoprotein. The following drug interactions have either been reported or are theoretical in humans or animals receiving ketoconazole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alcohol**: Ethanol may interact with ketoconazole and produce a disulfiram-like reaction (vomiting).
- **Antacids** (eg, **aluminum, calcium,** and **magnesium contain-**

ing): May reduce oral absorption of ketoconazole; administer ketoconazole at least 1 hour before or 2 hours after

- **Antiarrhythmics** (eg, **amiodarone, disopyramide, quinidine**[18]): Ketoconazole may reduce metabolism and increase risk for ventricular arrhythmia and other adverse effects. Concurrent use is contraindicated in humans.
- **Benzodiazepines** (eg, **diazepam**, **midazolam**): Ketoconazole may increase benzodiazepine concentrations. A study in greyhounds showed that ketoconazole significantly decreased the elimination of midazolam.[7] Concurrent oral use is contraindicated in humans.
- **Bromocriptine**: Plasma concentrations of bromocriptine may be elevated.
- **Buprenorphine**: Ketoconazole may increase opioid concentrations and risk for toxicity.
- **Buspirone**: Plasma concentrations of buspirone may be elevated.
- **Busulfan**: Ketoconazole may increase busulfan concentrations.
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**): Ketoconazole may increase concentrations of this class of drug.
- **Cannabidiol**: Ketoconazole may increase cannabidiol concentrations.
- **Cisapride**: Ketoconazole may increase cisapride concentrations and possibility for ventricular arrhythmia; use together is contraindicated in humans.
- **Colchicine**: Increased risk for colchicine toxicity.[19] Concurrent use is contraindicated in humans with renal or hepatic impairment and not recommended in other patients.
- **Corticosteroids** (eg, **dexamethasone, predniso(lo)ne**): Ketoconazole may inhibit the metabolism of corticosteroids; potential for increased adverse effects.[20]
- **Cyclophosphamide**: Ketoconazole may inhibit the metabolism of cyclophosphamide and its metabolites; potential for increased toxicity.[21]
- **Cyclosporine**: Increased cyclosporine concentrations; this interaction has been used in dogs to reduce cyclosporine dosage and cost.[3]
- **Digoxin**: Ketoconazole may increase digoxin concentrations.
- **Doxorubicin**: Increased doxorubicin exposure
- **Fentanyl/Alfentanil**: Ketoconazole may increase fentanyl or alfentanil concentrations.
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**): Increased risk for QT prolongation
- **Fluoxetine**: Increased risk for QT prolongation; increased fluoxetine peak concentrations and exposure; clinical significance is unclear[22]
- **Haloperidol**: Increased haloperidol concentrations and increased risk for QT prolongation
- **H_2-Receptor Antagonist** (eg, **famotidine**, **ranitidine**): Increased gastric pH may reduce ketoconazole absorption.
- **Hepatotoxic Drugs, Other** (eg, **androgens, estrogens,** NSAIDs): Because ketoconazole can cause hepatotoxicity, it should be used cautiously with other hepatotoxic agents.
- **Hydroxyzine**: May increase risk for QT prolongation
- **Isoniazid**: May reduce ketoconazole concentrations and efficacy; concomitant use is not recommended in humans.
- **Ivermectin**: Ketoconazole increases ivermectin concentration and residence time, and may increase risk for neurotoxicity.[23,24] One reference states that ivermectin should never be used with ketoconazole in dogs.[25]
- **Macrolide Antibacterials** (eg, **azithromycin, clarithromycin, erythromycin**): May increase ketoconazole concentrations
- **Maropitant**: In humans, ketoconazole can increase plasma concentrations of NK_1-receptor antagonists, the class of antiemetics maropitant belongs to.
- **Methadone**: Increased plasma methadone concentrations and risk for ventricular arrhythmia; concurrent use is contraindicated in humans
- **Metronidazole**: May increase risk for QT prolongation
- **Mirtazapine**: Ketoconazole may increase mirtazapine concentrations, increasing risk for QT prolongation and ventricular arrhythmias.
- **Mitotane**: Mitotane and ketoconazole are not recommended for use together to treat hyperadrenocorticism, as the adrenolytic effects of mitotane may be inhibited by ketoconazole's inhibition of cytochrome P450 enzymes.
- **Ondansetron**: Increased risk for cardiotoxicity
- **Phenobarbital**: May decrease ketoconazole concentrations
- **Praziquantel**: Increased plasma concentrations of praziquantel; concurrent use is not recommended in humans.
- **Proton Pump Inhibitors** (PPIs; eg, **omeprazole**, **pantoprazole**): Increased gastric pH may reduce ketoconazole absorption.
- **Rifampin**: May decrease ketoconazole concentrations; ketoconazole may increase rifampin concentrations; increased potential for hepatotoxicity.
- **Rivaroxaban**: Increased rivaroxaban concentrations or exposure may occur; concurrent use is not recommended in humans.
- **Sildenafil**: May increase sildenafil exposure
- **Sotalol**: Increased risk for QT prolongation
- **Sucralfate**: May reduce absorption of ketoconazole
- **Sulfonylureas** (eg, **glipizide**, **glyburide**): Ketoconazole may increase concentrations; hypoglycemia is possible.
- **Tamsulosin**: Increased tamsulosin concentration is possible; concurrent use is not recommended in humans.
- **Theophylline**: Ketoconazole may decrease serum theophylline concentrations in some patients; theophylline concentrations should be monitored.
- **Toceranib**: May increase toceranib or ketoconazole concentrations via CYP3A4 inhibition
- **Tramadol**: May increase tramadol exposure[26]
- **Trazodone**: May substantially increase trazodone concentrations
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Ketoconazole may reduce metabolism and increase adverse effects.
- **Vinca Alkaloids** (eg, **vinblastine, vincristine, vinorelbine**): Ketoconazole may inhibit vinca alkaloid metabolism and increase concentrations.
- **Warfarin**: Ketoconazole may cause increased prothrombin times in patients receiving warfarin or other coumarin anticoagulants.

Laboratory Considerations

- Ketoconazole can reduce serum cortisol concentrations and affect adrenal function tests. After stopping ketoconazole, cortisol concentrations usually return to baseline within 24 hours.

Dosages

NOTE: All dosages are extra-label.

DOGS:

NOTE: Oral ketoconazole has been used historically to treat various systemic mycoses, including blastomycosis and histoplas-

mosis. However, to obtain efficacy comparable to itraconazole alone, ketoconazole must be combined with amphotericin B.[27] Triazole antifungals (eg, itraconazole, fluconazole) are now generally recommended. Ketoconazole may be considered for these infections when drug cost determines whether treatment occurs. Ketoconazole continues to be a low-cost and effective treatment for *Malassezia* dermatitis.[28]

***Malassezia* dermatitis**: 5 – 10 mg/kg PO once daily.[1,29] Most clinicians recommend treatment for 3 to 4 weeks, until complete resolution of clinical signs. Use in combination with topical treatments (eg, miconazole/chlorhexidine shampoo) is recommended.[1,24]

Onychomycosis: 5 – 10 mg/kg PO every 12 hours, continued for 1 to 3 months beyond regrowth of healthy claws[30]

Reducing the dosage requirements of cyclosporine (CSA; consider monitoring cyclosporine concentrations): 2.5 – 10 mg/kg PO once daily.[2,31–33] Cyclosporine dosage reduction by ketoconazole occurs in a dose-dependent fashion (ie, higher ketoconazole doses result in a greater cyclosporine dosage reduction).[2,32,33]

Systemic mycoses: 5 – 10 mg/kg PO every 12 to 24 hours.[34–36] Treatment duration can vary but generally should continue for at least 1 month after complete resolution of clinical signs. Other azole antifungals (eg, fluconazole, itraconazole) have a more favorable efficacy and safety profile.

CATS:

NOTE: Use is controversial, and some clinicians recommend against using ketoconazole in cats because of its toxic potential. Consider using other antifungals (eg, fluconazole, itraconazole) instead, especially for dermatophytosis.

Systemic mycoses: Ketoconazole 10 mg/kg (or 50 mg/cat [NOT mg/kg]) PO with food every 12 to 24 hours.[37–39] Treatment may be required for many months. Other azole antifungals (eg, fluconazole, itraconazole) have a more favorable efficacy and safety profile.

HORSES:

Susceptible yeasts and *Aspergillus* spp: Using the commercial oral solution (**NOTE**: Not marketed in the United States): 5 mg/kg PO once daily

***Scopulariopsis* spp pneumonia**: Oral ketoconazole tablets may be administered via NG tube by mixing them with 0.2 normal hydrochloric acid and dosed at 30 mg/kg every 12 hours.[40,41]

BIRDS:

Susceptible fungal infections: 20 – 30 mg/kg PO twice daily (based on the kinetics determined in a single trial of Moluccan cockatoos)[42]

Severe refractory candidiasis in psittacines:

a) 5 – 10 mg/kg as a gavage twice daily for 14 days. For local effect in crop, dissolve ¼ of a 200 mg tablet (50 mg) in 0.2 mL of 1 normal hydrochloric acid and add 0.8 mL of water. Solution turns pale pink when dissolved. Add mixture to food for gavage.
b) To add to water for most species: 200 mg/L for 7 to 14 days. As drug is not water soluble at neutral pH, dissolve in acid prior to adding to water (see above).
c) To add to feed for most species: 10 – 20 mg/kg for 7 to 14 days. Add to favorite food or add to mash.[43]

RABBITS/RODENTS/SMALL MAMMALS:

Rabbits: 10 – 40 mg/kg per day PO for 14 days[44]

Hamsters, gerbils, mice, rats, guinea pigs, chinchillas: **For systemic mycoses/candidiasis**: 10 – 40 mg/kg per day PO for 14 days[30]

REPTILES:

Susceptible fungal infections in most species: 15 – 30 mg/kg PO once daily for 2 to 4 weeks[45]

Monitoring

- Liver biochemistry panel: Evaluate prior to therapy, then after 1 week and 1 month of the initial treatment period[9]; continue to monitor monthly for 3 to 6 months, then every 2 to 3 months thereafter.
- CBC with platelets
- Efficacy
- Signs of adrenal insufficiency (eg, lethargy, decreased appetite, vomiting, diarrhea)
- Adverse effects including vomiting, diarrhea, inappetence, lethargy, and jaundice

Client Information

- Give with food, especially foods high in fat (eg, cream, cheese, butter)
- Gastrointestinal effects (eg, lack of appetite, vomiting) are the most likely side effect seen (especially in cats).
- Liver toxicity is possible; watch for severe vomiting; no appetite; or yellowing of gums, skin, or whites of the eyes (jaundice). If seen, stop giving the medicine and contact your veterinarian immediately.
- May cause birth defects in animals and reduce fertility in males; use only when absolutely necessary in pregnant or breeding animals. Pregnant women should use caution when handling this medicine.

Chemistry/Synonyms

An imidazole antifungal agent, ketoconazole occurs as a white to slightly beige powder with pK_as of 2.9 and 6.5. It is practically insoluble in water.

Ketoconazole may also be known as ketoconazolum and R-41400; many trade names are available.

Storage/Stability

Ketoconazole tablets should be stored at room temperature 20°C to 25°C (68°F-77°F) in well-closed containers, protected from moisture.

Compatibility/Compounding Considerations

Compounded preparation stability: Ketoconazole oral suspension compounded from the commercially available tablets has been published.[46] Triturating twelve (12) ketoconazole 200 mg tablets with 60 mL of *Ora Plus*® and *qs ad* to 120 mL with *Ora Sweet*® or *Ora-Sweet-SF*® yields a 20 mg/mL ketoconazole oral suspension that retains greater than 95% potency for 60 days when stored at both 5°C (41°F) and 25°C (77°F) and protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE FOR SYSTEMIC USE

Ketoconazole is available in topical formulations (eg, spray, shampoo, medicated wipe, otic flush); all formulations also contain an antibacterial agent and may have additional therapeutic ingredients; generic; (OTC).

HUMAN-LABELED PRODUCTS:

Ketoconazole Tablets: 200 mg (scored); generic; (Rx)

Topical forms are also available.

Ketoprofen

(kee-toe-***proe***-fen) *Ketofen®*

Nonsteroidal Anti-Inflammatory Drug (NSAID)

Prescriber Highlights

- ► Nonsteroidal anti-inflammatory agent approved for use in horses and cattle; used extra-label in other species for anti-inflammatory, analgesic, and antipyretic purposes
- ► Use with caution in patients that have GI ulceration or bleeding, hypoproteinemia, breeding animals (especially late in pregnancy), renal or hepatic impairment; may mask signs of infection (inflammation, hyperpyrexia)
- ► Adverse effects include gastric mucosal damage and GI ulceration, renal crest necrosis, hepatitis; may cause vomiting and anorexia. Do not administer intra-arterially and avoid SC injections in horses.

Uses/Indications

Ketoprofen is FDA-approved for use in horses for the alleviation of inflammation and pain associated with musculoskeletal disorders.[1] It is also approved for control of pyrexia associated with bovine respiratory disease in beef heifers, beef steers, beef calves 2 months of age and older, beef bulls, replacement dairy heifers, and dairy bulls. Like other NSAIDs, ketoprofen is used extra-label in a variety of species and conditions. Historically, ketoprofen was used for short-term analgesia in dogs and cats, but the availability of NSAIDs labeled in the United States for administration to those species has decreased its use.

Pharmacology/Actions

Similar to other NSAIDs, ketoprofen possesses antipyretic, analgesic, and anti-inflammatory activity. Its mechanism of action is the nonselective, reversible inhibition of cyclooxygenase (COX-1 and COX-2) catalysis of arachadonic acid to prostaglandin precursors (endoperoxides), thereby inhibiting the synthesis of prostaglandins in tissues. Ketoprofen purportedly has inhibitory activity on lipoxygenase, but the evidence for this action is weak as in vitro studies have not confirmed lipoxygenase activity in studied species.

Ketoprofen is a racemic mixture of S(+) and R(-) enantiomers. The S(+) enantiomer is associated with antiprostaglandin activity and toxicity and the R(-) form is associated with analgesia.

In cats, ketoprofen significantly reduced serum prostaglandin E2 (inflammatory marker) concentrations for up to 36 hours and serum thromboxane B2 (platelet inhibition marker) concentrations after SC administration in one study.[2] The S(+) enantiomer was responsible for COX inhibition.

Pharmacokinetics

In rats, dogs, and humans, ketoprofen is rapidly and nearly completely absorbed after oral administration. The presence of food or milk decreases oral absorption.

Oral absorption is poor in horses. It has been reported that when comparing IV vs IM injections in horses, the areas under the curve are relatively equivalent. Volume of distribution is low in adult horses. Volume of distribution is reportedly higher in foals and doses may need to be higher (1.5 times) with longer durations between doses in neonates.[3] The drug enters synovial fluid and is highly bound to plasma proteins (99% in humans, and ≈93% in horses). In horses, the manufacturer reports that the onset of activity is within 2 hours and peak effects 12 hours postdose.[1]

One study in eight thoroughbred horses also showed different pharmacokinetic parameters for the R(-) and S(+) enantiomers. After IV administration, mean systemic clearance was 0.345 L/kg/hour for R(-) and 0.167 L/kg/hour for S(+), mean steady-state volume of distribution was 0.344 L/kg for R(-) and 0.298 L/kg for S(+), and mean elimination half-life was 2.49 hours for R(-) and 2.86 hours for S(+). Oral bioavailability was calculated at 69.5% for R(-) and 88.2% for S(+) when the injectable formulation was used and 53% for both R(-) and S(+) when a paste was used.[4]

Ketoprofen is eliminated via the kidneys, both as a conjugated metabolite (primarily glucuronidation in horses) and as unchanged drug.

After SC administration to calves, peak concentration was reached 1.5 hours after administration, while after IV/IM administration to cattle peak concentration was reached at 0.75 hours. Half-life is 2 to 3 hours.[1,5]

After IM administration of racemic ketoprofen to 6-day-old piglets, S(+) ketoprofen was rapidly absorbed and had a relatively short half-life (3.5 hours).[6]

One study in loggerhead turtles compared IV and IM administration and found slightly different parameters for the R(-) and S(+) enantiomers.[7] After IM administration, mean bioavailability was 75% for R(-) and 64% for S(+), mean volume of distribution (adjusted for bioavailability) was 0.13 L/kg for R(-) and 0.09 L/kg for S(+), mean time to peak concentration was 0.19 hours for R(-) and 0.35 hours for S(+), and mean peak concentration was 6.94 µg/mL for R(-) and 10.07 µg/mL for S(+). Area under the curve for the S(+) enantiomer was more than twice that for the R(-) enantiomer. After IV administration, mean volume of distribution was 0.11 L/kg for R(-) and 0.07 L/kg for S(+), mean systemic clearance was 0.04 L/kg/hour for R(-) and 0.01 L/kg/hour for S(+), and mean elimination half-life was 2.12 hours for R(-) and 3.6 hours for S(+). Area under the curve for the S(+) enantiomer was more than twice that for the R(-) enantiomer.

Contraindications/Precautions/Warnings

Ketoprofen is contraindicated in patients with a known hypersensitivity to it and in those with impaired renal function or are dehydrated.[1,5] Use ketoprofen with caution in patients that are dehydrated, on concomitant diuretic therapy, or have pre-existing gastric ulcers, renal, cardiovascular, and/or hepatic dysfunction as they are at greatest risk for toxicity.[1] In these cases, ketoprofen should be used only when the potential benefits outweigh the risks. Ketoprofen may mask the clinical signs of infection (eg, signs of inflammation, pyrexia).

Avoid intra-arterial injection,[1] and avoid SC injections in horses.

Because there are approved NSAIDs for use in dogs and cats in the US, extra-label use of ketoprofen is not recommended.

Adverse Effects

In horses, ketoprofen appears to have low toxicity, and reports indicate that it appears relatively safe to use and may have a lower incidence of adverse effects as compared with phenylbutazone or flunixin.[8,9] Gastric mucosal damage and GI ulceration, renal crest necrosis, and mild hepatitis may occur.

Although not labeled for IM use in horses, it is reportedly effective when administered IM[5] and may only cause occasional inflammation at the injection site.

In dogs or cats, ketoprofen may cause vomiting, anorexia, and GI ulcers. When used perioperatively in dogs, ketoprofen can decrease platelet aggregation but this may not have clinical significance.[10] In healthy dogs receiving 2 mg/kg PO daily for 10 days, reduced creatinine clearance was noted in the dogs receiving ketoprofen.[11] Reducing the dose to 1 mg/kg SC then 0.25 mg/kg PO daily effectively eliminated all renal adverse effects and reduced incidence of GI bleeding in another study of long-term administration to dogs, suggesting that these effects were dose-dependent. In cats treated with 2 mg/kg SC daily for 3 days, fewer GI effects were observed in younger cats (less than 3 months old) as compared with older cats (more than 6 months old), suggesting that effects may also be age dependent.[12]

Reproductive/Nursing Safety

The manufacturer cautions against ketoprofen use in breeding horses because effects on fertility, pregnancy, or fetal health have not been established; it also states that, in cattle, the effects of ketoprofen on bovine reproductive performance, pregnancy, lactation, or on animals of reproductive age intended for breeding has not been investigated.[13] However, rat and mice studies have not demonstrated increased teratogenicity or embryotoxicity.[14] Rabbits receiving maternally toxic doses exhibited increased embryotoxicity, but not teratogenicity. Because nonsteroidal anti-inflammatory agents inhibit prostaglandin synthesis, thus adversely affecting neonatal cardiovascular systems (premature closure of patent ductus), ketoprofen should not be used late in pregnancy. Studies in male rats demonstrated no changes in fertility.[14]

It is presently unknown whether ketoprofen enters equine milk. Ketoprofen does enter canine[14] and bovine[15] milk; use with caution.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The LD_{50} in dogs after oral ingestion has been reported to be 2000 mg/kg, but exposures as low as 0.44 mg/kg in dogs have caused GI ulcers. Cats have developed renal toxicity at doses as low as 0.7 mg/kg. Horses given ketoprofen at doses up to 11 mg/kg administered IV once daily for 15 days exhibited no signs of toxicity.[1] Severe laminitis was observed in a horse given 33 mg/kg/day (15 times over label dosage) for 5 days. Anorexia, depression, icterus, and abdominal swelling were noted in horses given 55 mg/kg/day (25 times over label dosage) for 5 days, and necropsy findings included gastritis, nephritis, and hepatitis.[1]

As with any NSAID, overdose can lead to GI and renal effects. Decontamination with emetics and/or activated charcoal is appropriate.[14] The use of GI protectants (eg, omeprazole, famotidine, sucralfate) can be considered. If renal effects are suspected, fluid diuresis is warranted.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ketoprofen and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**): May result in renal dysfunction and/or increased blood pressure
- **Aminoglycosides** (eg, **gentamicin, amikacin**): May increase risk for nephrotoxicity
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**): May result in renal dysfunction and/or increased blood pressure
- **Anticoagulants** (eg, **heparin, enoxaparin, warfarin**): May increase risk for bleeding
- **Aspirin**: May increase risk for GI adverse effects or risk for bleeding
- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, propranolol**): May increase blood pressure
- **Bisphosphonates** (eg, **alendronate**): May increase risk for GI ulceration
- **Clopidogrel**: May increase risk for bleeding
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): May significantly increase the risk for GI, platelet, or renal adverse effects, especially in dogs
- **Cyclosporine**: May increase risk for nephrotoxicity
- **Desmopressin**: May increase risk for hyponatremia
- **Digoxin**: May result in increased serum concentration of digoxin and a prolonged half-life of digoxin
- **Diuretics** (eg, **furosemide, spironolactone**): May increase risk for renal toxicity and reduce diuretic efficacy
- **Highly Protein Bound Drugs** (eg, **aspirin, phenytoin, valproic acid, oral anticoagulants, sulfonamides, sulfonylurea antidiabetic agents** [eg, **glipizide**]): Because ketoprofen is highly bound to plasma proteins (99%), it could theoretically displace other highly bound drugs and cause a transient increase in serum concentrations of each drug. These interactions are unlikely to be of clinical concern because increased free drug concentrations will equilibrate through increased clearance.
- **Methotrexate**: Severe toxicity has occurred in humans when NSAIDs have been used concurrently with methotrexate; use together with extreme caution.
- **Nonsteroidal Anti-Inflammatory Agents** (**NSAIDs**; eg, **carprofen, flunixin, robenacoxib, phenylbutazone**): Use of other NSAIDs significantly increases risk for NSAID-related adverse effects.
- **Probenecid**: Probenecid reduces plasma clearance of ketoprofen and decreases its protein binding, causing a significant increase in serum concentrations and half-life of ketoprofen; concurrent use is not recommended.
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, paroxetine, sertraline**): May increase risk for bleeding
- **Trazodone**: May increase risk for bleeding
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): May increase risk for bleeding

Laboratory Considerations

Ketoprofen may cause:

- Falsely elevated **blood glucose** values when using the glucose oxidase and peroxidase method using ABTS as a chromogen
- Falsely elevated **serum bilirubin** values when using DMSO as a reagent
- Falsely elevated **serum iron** concentrations when the Ramsey method is used or falsely decreased serum iron concentrations when bathophenanthroline disulfonate is used as a reagent

Dosages

DOGS:

Anti-inflammatory/analgesic (extra-label): **NOTE**: Use of an NSAID labeled for dogs is recommended.

Acute pain:

a) 2 mg/kg SC, IM, or IV once; may repeat once daily for up 3 days[16]

b) 1 mg/kg PO once daily for 3 to 5 days[17]

Chronic pain:

a) For extended parenteral use, 0.5 mg/kg SC, IM, or IV once daily[16]

b) 0.25 mg/kg PO once daily[17]

CATS:

Anti-inflammatory/analgesic (extra-label): **NOTE**: Use of an NSAID labeled for cats is recommended.

Acute pain:

a) 2 mg/kg SC once daily for up 3 consecutive days[16]

b) 1 mg/kg PO once daily for 3 to 5 days[17]

Chronic pain: 0.25 mg/kg PO once daily[17]

HORSES:

Alleviation of inflammation and pain associated with musculoskeletal disorders (label dosage; FDA-approved): 2.2 mg/kg IV once daily for up to 5 days[1]

Alleviation of inflammation and pain associated with musculoskeletal disorders (extra-label): 2 mg/kg IV, IM once a day for up to 5 days[5]

CATTLE:

Control of pyrexia associated with bovine respiratory disease (BRD) in beef heifers, beef steers, beef calves 2 months of age and older, beef bulls, replacement dairy heifers, and dairy bulls (label dosage; FDA-approved): 3 mg/kg SC once daily for up to 3 days if pyrexia persists

Treatment of clinical signs related to fever, pain, and inflammation associated with a variety of conditions (eg, mastitis, musculoskeletal injury, respiratory tract infections (extra-label): 3 mg/kg IV or IM once daily for up to 3 days[5]

SHEEP:

Postoperative analgesic (extra-label): 3 mg/kg IV or IM as a single dose[18,19]

GOATS:

Anti-inflammatory/analgesic/antipyretic (extra-label):

a) 3 mg/kg IV or IM once daily

b) 2.5 mg/kg IV, may be repeated after 12 hours.[20] Dosage determined based on a pharmacokinetic study, and the safety and efficacy of this dosage have not been evaluated.

SWINE:

Reducing pyrexia in respiratory tract disorders and supportive treatment of postpartum dysgalactiae syndrome (MMA syndrome—mastitis, metritis, agalactia) in conjunction with antibiotic therapy (extra-label): 3 mg/kg deep IM once daily for up to 3 days[21]

BIRDS:

Anti-inflammatory/analgesic (extra-label): 2 mg/kg IM or SC every 8 to 24 hours[22]

FERRETS:

Postoperative analgesic (extra-label): 1 – 3 mg/kg SC, IM every 12 to 24 hours[23]

RABBITS:

Anti-inflammatory/analgesic (extra-label): 1 – 3 mg/kg IM every 12 to 24 hours[23–25]

RATS/MICE:

Analgesic (extra-label): 5 mg/kg SC, IM every 12 to 24 hours[23,26]

Monitoring

- Efficacy: level of analgesia, evidence of decreased inflammation, resolution of pyrexia
- Adverse effects (eg, vomiting, diarrhea, decreased appetite, hematemesis, hematochezia, melena)
- Baseline physical exam, CBC, serum chemistry panel (including renal and liver parameters), urinalysis; consider fecal occult blood testing when clinically appropriate. Repeat after the first few weeks of treatment, and periodically with long-term use.

Client information

- Do not inject this drug into an artery or under the skin (subcutaneously, SC) in horses.
- This medicine must only be used for a few days in cats to reduce risk of developing severe side effects.
- Most common side effects are gastrointestinal-related (eg, reduced appetite, vomiting, diarrhea in small animals). Ulcers, bleeding, and/or liver and kidney problems can also occur. If bloody vomit or stools are observed, discontinue the medication immediately and contact your veterinarian.
- While your animal is taking this medication, it is important to return to your veterinarian for regular examinations and monitoring. Do not miss these important follow-up visits.

Chemistry/Synonyms

Ketoprofen is a propionic-acid derivative NSAID that occurs as an off-white to white, fine to granular powder. It is practically insoluble in water but freely soluble in alcohol at 20°C (68°F). Ketoprofen has a pK_a of 5.9 in a 3:1 methanol:water solution. Ketoprofen has both an S(+) enantiomer and R(-) enantiomer. The commercial product contains a racemic mixture of both. The S(+) enantiomer has greater anti-inflammatory potency than the R(-) form.

Ketoprofen may also be known as *Anafen®*, *Ketofen®*, ketoprofenum and RP-19583; many trade names are available.

Storage/Stability

Ketoprofen injection should be stored below 25°C (77°F), with brief excursions permitted between 0°C and 40°C (32°F-104°F) and used within 4 months of first vial puncture.[13]

Ketoprofen oral capsules should be stored at room temperature (20°C-25°C [68°F-77°F]) in tight, light-resistant containers.[14]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

Ketoprofen Injection: 100 mg/mL in 50 mL and 100 mL multidose vials; *Ketofen®*, generic; (Rx). FDA-approved for use in horses not intended for food. Slaughter withdrawal, 48 hours; not for use in female dairy cattle 1 year of age or older, including dry dairy cows; in beef calves less than 2 months of age, or in dairy or veal calves. A withdrawal period has not been established for this product in pre-ruminating calves. NADA #141-269.

A combination solution for injection containing ketoprofen 120 mg/mL with tulathromycin 100 mg/mL (*Draxxin® KP*) is also available for the treatment of bovine respiratory disease. See also ***Tulathromycin***.

HUMAN-LABELED PRODUCTS:

Ketoprofen Capsules: 50 mg and 75 mg; generic; (Rx)

Ketoprofen Extended-Release Capsules: 200 mg; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Ketorolac

(***kee***-toe-role-ak) *Toradol®*

Nonsteroidal Anti-inflammatory Drug (NSAID)

Prescriber Highlights

- ► NSAID used primarily for short-term analgesia. It is also used topically as an ophthalmic (see ***Ketorolac, Ophthalmic***).
- ► Contraindications include active or historical GI bleeding or ulcers, prior hypersensitivity reactions, concurrent NSAIDS or aspirin, bleeding disorders, suspected or confirmed cerebrovascular bleeding, and advanced renal or hepatic dysfunction.
- ► Use with caution in animals with pre-existing hematologic, renal, or hepatic disease; animals with CHF; and geriatric animals.
- ► Adverse effects may include GI ulcers and perforation; hepatic and renal toxicity; and inhibition of platelet aggregation. Consider co-dosing with misoprostol and/or sucralfate in dogs to reduce risk for GI ulcers.
- ► Long-term use is not recommended.

Uses/Indications

Ketorolac is used primarily for its analgesic effects for short-term treatment of mild to moderate pain in dogs[1,2] and rodents. Because of the availability of approved, safer, and longer-acting NSAIDs, ketorolac's use in dogs is questionable.

Safe and effective ketorolac use has been demonstrated in healthy horses,[3,4] but it was not superior to phenylbutazone or flunixin.

Pharmacology/Actions

Like other NSAIDs, ketorolac exhibits analgesic, anti-inflammatory, and antipyretic activity, probably through its inhibition of cyclooxygenase with the resultant impediment of prostaglandin synthesis. Ketorolac may exhibit a more potent analgesic effect than some other NSAIDs. It inhibits both COX-1 and COX-2 receptors.

Pharmacokinetics

After 0.5 mg/kg IV injection in dogs, ketorolac's volume of distribution is ≈1 L/kg, and the elimination half-life averages about 11 hours.[2] After oral administration, ketorolac is rapidly absorbed; in dogs, peak concentrations occur in ≈50 minutes, and oral bioavailability is ≈50% to 75%. The duration of analgesic effect in dogs is ≈6 hours.[1,2]

Ketorolac is distributed marginally through the body. It does not appear to cross the blood–brain barrier and is highly bound to plasma proteins (99%). The volume of distribution in dogs is reported to be ≈0.33 to 0.42 L/kg (similar in humans). The drug does cross the placenta.

In one study, horses received 0.5 mg/kg IV, IM, and PO. The drug was rapidly absorbed after IM and PO administration with 71% IM bioavailability and 57% oral bioavailability.[5]

Ketorolac is primarily metabolized via glucuronidation and hydroxylation. Both the unchanged drug and metabolites are excreted mainly in the urine. Patients with the diminished renal function will have longer elimination times than normal. In normal dogs, the elimination halflife is between 4 and 8 hours.

In a small, single-dose study of juvenile loggerhead sea turtles, 0.25 mg/kg ketorolac injected intramuscularly achieved what is presumed to be effective concentrations for ≈ 7 hours.[6] In another small study in Eastern box turtles, 0.25 mg/kg injected intramuscularly maintained presumed effective concentrations for 24 hours.[7]

Contraindications/Precautions/Warnings

Ketorolac is contraindicated in animals with active or recent GI ulcers or bleeding, advanced renal disease or at risk for renal failure due to volume depletion, a history of hypersensitivity to the drug, or suspected or confirmed cerebrovascular bleeding or bleeding disorder. It is relatively contraindicated in animals with a history of hematologic, renal, or hepatic disease, heart failure (may cause fluid retention), and in geriatric patients. In humans, ketorolac can cause serious skin adverse effects, such as Stevens-Johnson syndrome.

Because ketorolac has a tendency to cause gastric erosion and ulcers in dogs, long-term use (greater than 3 days) is not recommended in this species. In humans, combined parenteral and oral dosing should not exceed 5 days.[8] The minimum effective dose should be used.

Do not confuse ketoROLAC with ketAMine or ketoPROFEN.

Adverse Effects

Ketorolac use is limited in domestic animals because of its adverse effect profile and a lack of veterinary-labeled products. The primary issue in dogs is ketorolac's GI toxicity. GI ulceration can be common if the drug is used chronically. Most clinicians who have used this medication in dogs limit treatment to less than 3 days and give misoprostol with or without sucralfate concurrently. Like with other NSAIDs, platelet inhibition and renal and hepatic toxicity are possible with this drug as well. Transient azotemia was observed in 20% of clinically normal dogs that received ketorolac prior to ovariohysterectomy.[9]

In humans, common adverse effects include abdominal pain, dyspepsia, nausea, vomiting, and constipation or diarrhea.[8]

Reproductive/Nursing Safety

Ketorolac does cross the placenta. The use of NSAIDs during late pregnancy is typically avoided in humans due to the possibility of premature closure of the ductus arteriosus. In rats, administration of ketorolac caused dystocia and higher pup mortality.[8]

Most NSAIDs are excreted in milk. Ketorolac was detected in human breast milk at maximum milk:plasma ratio of 0.037. It is unlikely to pose a great risk to nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available. Cats have developed renal toxicity at doses as low as 0.7 mg/kg. The oral LD_{50} is 200 mg/kg in mice. GI effects, including GI ulceration, are likely in overdoses in small animals. Metabolic acidosis was reported in 1 human patient. Consider GI emptying in large overdoses; patients should be monitored for GI bleeding. Treat ulcers with sucralfate; consider giving misoprostol early.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ketorolac and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **enalapril**): Increased risk for nephrotoxicity
- **Alprazolam**: Hallucinations reported in some human patients taking with ketorolac
- **Aminoglycosides** (eg, **gentamicin, amikacin**): Increased risk for nephrotoxicity
- **Angiotensin Receptor Blockers** (ARBs; eg, **telmisartan**): Increased risk for nephrotoxicity
- **Anticoagulants** (eg, **heparin, LMWH, warfarin**): Increased risk for bleeding possible

- **Aspirin**: Increased likelihood of GI adverse effects (blood loss); this combination is contraindicated in humans
- **Bisphosphonates, Oral** (eg, **alendronate**): May increase the risk for GI ulceration
- **Corticosteroids** (eg, **dexamethasone, predniso(lo)ne**): Concomitant administration with NSAIDs may significantly increase the risks for GI adverse effects.
- **Cyclosporine**: May increase the risk for nephrotoxicity
- **Digoxin**: May increase the digoxin serum concentration and half-life
- **Diuretics** (eg, **furosemide**): May decrease diuretic efficacy and increase the risk for nephrotoxicity
- **Fluconazole**: May increase NSAID levels
- **Methotrexate**: Serious toxicity has occurred when NSAIDs have been used concomitantly with methotrexate; use together with extreme caution.
- **Muscle relaxants, Nondepolarizing** (eg, **atracurium**): Ketorolac may potentiate effects.
- **NSAIDs** (eg, **carprofen**): Therapeutic duplication; increased risk for adverse effects. This combination is contraindicated in humans.
- **Pentoxifylline**: May increase the risk for bleeding; this combination is contraindicated in humans.
- **Probenecid**: May cause a significant increase in serum levels and half-life of ketorolac. This combination is contraindicated in humans.
- **SSRIs** (eg, **fluoxetine**): Increased risk for bleeding

Dosages

DOGS:

NOTE: An NSAID that is FDA-approved for use in dogs is recommended.

Postoperative analgesic (extra-label): 0.5 mg/kg IV or IM preoperatively, may repeat every 6 hours.[1,2] Because ketorolac had limited efficacy during the intraoperative period, consider using only postoperatively.[2]

RABBITS/RODENTS/SMALL MAMMALS:

Analgesic (extra-label): **Mice**: 0.7 – 10 mg/kg PO once daily. **Rats**: 3 – 5 mg/kg PO 1 to 2 times a day; 1 mg/kg IM 1 to 2 times a day[10]

Monitoring

- Analgesic and anti-inflammatory efficacy
- GI: appetite, feces (occult blood, diarrhea)
- CBC and serum chemistry prior to use; repeat if adverse effects associated with GI, renal, or hepatic toxicity are noted after use.

Client Information

- Human NSAID that can be useful for the short-term treatment of pain in dogs or small mammals. Not for use in cats
- Give this medicine with food to decrease risk for upset stomach, vomiting and diarrhea.
- Gastrointestinal side effects (eg, vomiting, ulcers, bleeding) are highly possible if this medicine is used for more than a few days. Liver, kidney, and blood problems can also occur.
- Notify your veterinarian if signs of gastrointestinal distress (lack of appetite, vomiting, diarrhea, black feces, or blood in stool) occur or if your animal becomes depressed.

Chemistry/Synonyms

Ketorolac tromethamine, a carboxylic acid derivative and an NSAID agent, occurs as an off-white crystalline powder with a pK_a of 3.54 (in water). More than 500 mg are soluble in 1 mL of water at room temperature. The commercially available injection is a clear, slightly yellow solution with a pH of 6.9 to 7.9. Sodium chloride is added to make the solution isotonic.

Ketorolac tromethamine may also be known as RS-37619-00-31-3; many trade names are available.

Storage/Stability

Store both the tablets and injection protected from light at room temperature 20°C to 25°C (68°F-77°F). Protect the tablets from excessive humidity. The injection is stable for at least 48 hours in commonly used IV solutions.

Compatibility/Compounding Considerations

Do not mix with other drugs in the same syringe.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Ketorolac Tromethamine Tablets: 10 mg; generic; (Rx)

Ketorolac Tromethamine Injection: 15 mg/mL and 30 mg/mL in 1 mL and 2 mL single-dose vials and 10 mL multiple-dose vials; generic; (Rx)

A topical ophthalmic preparation is also available; see ***Ketorolac, Ophthalmic*** for further information.

L-Theanine

(el thee-ah-neen) *Anxitane®, Composure®*

Nutritional Anxiolytic Agent

Prescriber Highlights

- ► Used as a calming (anxiolytic) agent in dogs and cats. Limited evidence documenting efficacy
- ► Nutraceutical; not an FDA-approved drug
- ► Appears to be tolerated well

Uses/Indications

L-theanine is a nutritional supplement that is used as an anxiolytic for dogs and cats. There are limited published data that document efficacy in animals. In a study in beagles with anxiety towards humans, the 5 beagles treated with L-theanine showed greater human interaction and approach than the 5 beagles in the placebo control group.[1] L-theanine also reduced storm-related anxiety in dogs.[2] Open-label studies in cats conclude that L-theanine improves anxiety-related emotional disorders.[3] After chronic twice-daily administration in cats, improvement in stress parameters was seen as soon as 15 days, with continued improvement by 30 days.[4]

For human use, *Natural Standard*[5] has assigned the following grades (A to F scale) of scientific evidence for common/studied uses for L-theanine: Anxiety = C, Blood pressure control = C, Mood = C, Cognition = D.

Pharmacology/Actions

L-theanine is thought to increase nutritional serotonin, dopamine, and gamma-aminobutyric acid (GABA) levels in the CNS. Rat studies have found that L-theanine significantly lowered levels of 5-hydroxyindole in the brain and that it may inhibit glutamic acid excitotoxicity.[5] In humans, L-theanine has been shown to increase alpha waves in the brain that indicate a relaxed state.[6]

Pharmacokinetics

Only pharmacokinetic data for laboratory animals were located. The L-form of theanine is preferentially absorbed from the intestine with peak concentrations occurring ≈1 to 2 hours postdose. In rats, it is hydrolyzed by phosphate-independent glutaminase in kidneys to glutamic acid and ethylamine. No drug is detectable after 24 hours.

Contraindications/Precautions/Warnings

L-theanine is contraindicated in patients hypersensitive to it. A veterinary-labeled product (*Anxitane*®) warns: *Not intended for use in animals with severe phobias, separation anxiety or in animals with a known history of aggression.*

Do not confuse L-THEAnine with L-THREOnine.

Adverse Effects

L-theanine is relatively safe and adverse effects are not frequently reported in animals or humans. Some human patients taking L-theanine have reported headaches, reduced blood pressure, or alterations in cognition.

Reproductive/Nursing Safety

Product label states *safe use in pregnant animals or animals intended for breeding has not been proven*.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available, but it is likely relatively non-toxic. A 13-week study in rats determined no-observed-adverse-effect-level (NOAEL) of 4000 mg/kg/day, the highest dose tested.[7] Products containing L-theanine may contain other ingredients that may have toxic potential.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving L-theanine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antihypertensive Agents**: L-theanine potentially can reduce blood pressure and cause additive effects.
- **D-Theanine; D,L-Theanine**: Can reduce the absorption of L-theanine

Dosages

DOGS/CATS:

Reduction of mild to moderate anxiety (extra-label):

a) Dogs: Based on the size of the dog, 10 – 100 mg/dog (not mg/kg) PO twice daily. Consult label of product being used for specific dosage. Use in conjunction with behavior therapy.

b) Cats: 10 – 25 mg/cat (not mg/kg) PO once or twice daily. Consult label of product being used for specific dosage. Use in conjunction with behavior therapy.

Monitoring

- Efficacy; reduction in stress indicators

Client Information

- Follow label directions or give as your veterinarian has recommended.
- Shake liquid well before use.

Chemistry/Synonyms

Theanine is a nonprotein amino acid found primarily in tea leaves. Younger and fresher tea leaves tend to be richer in caffeine, while older, drier leaves may have higher theanine levels. The L-form is used in nutritional supplements, as it appears to be better absorbed from the gut. Standardized methods for quantifying L-theanine have not been established.

L-theanine may also be known as glutamylethylamide, or L-N-ethylglutamine. *Suntheanine*® is common trade name.

Storage/Stability

Store bulk powder, tablets, or capsules at room temperature away from moisture. Keep chewable tablets away from children or animals. The *Anxitane*® label states to keep tablets in original blister pack until used.

Compatibility/Compounding Considerations

No information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The following are considered nutritionals by the FDA and are not approved drugs. Other products containing L-theanine may be marketed for use in dogs and cats.

L-theanine Tablets (chewable): 50 mg and 100 mg; *Anxitane*® *S* (50 mg) and *M&L* (100 mg); (OTC). Chicken flavor

L-theanine Tablets (chewable): 205 mg (with extracts of *Magnolia officinalis* and *Phellodendron amurense* 450 mg and dried whey protein concentrate 100 mg); *Solliquin*® (OTC)

L-theanine Tablets (soft chews): 35 mg (with extracts of *Magnolia officinalis* and *Phellodendron amurense* 75 mg and dried whey protein concentrate 25 mg); *Solliquin*® (OTC)

L-theanine Tablets (chewable): 10.5 mg (with thiamine 67 mg and colostrum calming complex 11 mg) and 21 mg (with thiamine 134 mg and colostrum calming complex 22 mg); *Composure*® (*Mini*; 10.5 mg) and (regular; 21 mg) *Bite-sized Chews*; (OTC)

Liquid: L-theanine 21 mg/2.5 mL (with thiamine 134 mg/2.5 mL and colostrum calming complex 22 mg/2.5 mL); *Composure*® *Max Liquid*; (OTC)

HUMAN-LABELED PRODUCTS:

No FDA-approved products noted. Nutritional supplements as bulk powder or capsules containing 100 mg, 150 mg, or 200 mg of L-theanine are available. *Suntheanine*® is a common trade name.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Lactulose

(***lak***-tyoo-lose) *Cephulac®, Kristalose®*

Ammonia Detoxicant/Osmotic Laxative

Prescriber Highlights

- ► Nonabsorbable disaccharide laxative used to reduce blood ammonia concentrations and to manage constipation
- ► Avoid use in patients with GI obstruction. Patients with gut dysbiosis may have reduced response.
- ► Use with caution in diabetic patients and those with pre-existing fluid or electrolyte imbalances
- ► Adverse effects include flatulence, gastric distention, and cramping; diarrhea and dehydration are signs of overdose.
- ► Cats dislike the taste of lactulose liquid, so administration may be difficult; lactulose crystals mixed into cat food may be more accepted.

Uses/Indications

Lactulose is used primarily as an adjunctive treatment to reduce ammonia blood concentrations in the prevention and treatment of hepatic encephalopathy (HE; also known as portosystemic encephalopathy [PSE]) in small animal species, pet birds, and, potentially, horses. It results in improvement in clinical signs but does not alter the underlying disease. In small animal species, it is also used as a laxative.

Pharmacology/Actions

Lactulose is a disaccharide (galactose/fructose) that is not hydrolyzable by the gut enzymes of mammals and, potentially, birds. On reaching the colon, lactulose is metabolized by resident bacteria, resulting in the formation of lactic, formic, and acetic acids, as well as carbon dioxide (CO_2). The production of these free fatty acids increases osmotic pressure in the bowel, drawing in water for a laxative effect and acidifying colonic contents. This acidification causes ammonia (NH_3) to migrate from the blood into the colon, where it is trapped as the ammonium ion (NH_4^+) and expelled with the feces. By forming free fatty acids, lactulose can also be considered a prebiotic. Reversible changes in fecal microflora (increased number of Firmicutes and Actinobacteria, and decreased numbers of Bacteroidetes and Fusobacteria) have been demonstrated in healthy dogs following lactulose administration.[1]

Pharmacokinetics

In humans, less than 3% of an oral dose of lactulose is absorbed in the small intestine. The absorbed drug is not metabolized and is excreted unchanged in the urine within 24 hours.

Contraindications/Precautions/Warnings

Lactulose syrup contains some free lactose and galactose and may alter the insulin requirements in diabetic patients. In patients with pre-existing fluid and electrolyte imbalances, lactulose may exacerbate these conditions if it causes diarrhea and should therefore be used cautiously. Lactulose should not be given to patients with intestinal obstruction. Patients with gut dysbiosis (potentially including antibiotic-induced dysbiosis) may experience reduced effectiveness because the effects of lactulose depend on GI bacterial degradation.

Adverse Effects

Signs of flatulence, gastric distention, and cramping may occur early in therapy but generally abate with time. Excessive doses can also lead to diarrhea with potential dehydration, hypokalemia, and hypernatremia; in these cases, the dose should be reduced. Cats dislike the taste of lactulose syrup, and administration may be difficult. Lactulose granules (crystals) have been more successfully administered after being mixed in food.

Reproductive/Nursing Safety

Lactulose does not impair fertility in laboratory animals and has no known teratogenic or mutagenic effects.

It is unknown if lactulose is excreted in milk, but it would be unexpected.

Overdose/Acute Toxicity

Excessive doses may cause flatulence, diarrhea, cramping, and dehydration. Fluids and electrolytes should be replaced, if necessary.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with a 24-hour poison consultation center that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving lactulose and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Antacids, Oral** (eg, **aluminum, calcium, magnesium**): Nonabsorbable antacids may reduce the colonic acidification effects (and thus, efficacy) of lactulose.
- **Antidiarrheal Agents** (eg, **kaolin/pectin, loperamide**): May counteract laxative effect and reduce ammonia-lowering effect
- **Anti-Infective Agents, Oral** (eg, **amoxicillin, cephalexin, clindamycin, tylosin**): Theoretically, orally administered antibiotics could eliminate the bacteria responsible for metabolizing lactulose, thereby reducing its efficacy.
- **Diuretics** (eg, **furosemide**): May have additive effects on serum electrolytes
- **Glutamine**: May antagonize the ammonia lowering effects of lactulose
- **Laxatives, Other** (eg, **polyethylene glycol 3350, psyllium**): Lactulose should not be used with other laxatives, as the loose stools that are formed can be falsely attributed to the lactulose with resultant inadequate therapy for hepatic encephalopathy.
- **Neomycin**: Theoretically, neomycin could eliminate the bacteria responsible for metabolizing lactulose, thereby reducing its efficacy. However, some data suggest that synergy may occur when lactulose is used with neomycin for the treatment of hepatic encephalopathy.

Laboratory Considerations

- None noted

Dosages

DOGS:

NOTE: If using the crystals for oral solution: One gram of the crystals is equivalent to 1.5 mL of the liquid.

Hepatic encephalopathy (extra-label):

a) Orally: 1 – 3 mL/10 kg (NOT mL/kg) PO every 6 to 8 hours; adjust dose to achieve 3 to 4 soft stools per day.[2]

b) Retention enema for acute hepatic encephalopathy: 1 – 10 mL/10 kg (NOT mL/kg). After administering a cleansing enema, administer diluted lactulose solution (1 part lactulose to 2 to 3 parts warm water) as a retention enema for 30 minutes.[2–4]

Constipation (extra-label): 0.25 – 0.5 mL/kg PO every 6 to 8 hours. Alternatively, 2.5 – 15 mL/dog (NOT mL/kg) PO every 8 to 12 hours. Adjust dosage to obtain the stool quality desired.

CATS:

NOTE: If using the crystals for oral solution: One gram of the crystals is equivalent to 1.5 mL of the liquid.

Hepatic encephalopathy (extra-label):

a) Orally: 1 – 3 mL/10 kg (NOT mL/kg) PO every 6 to 8 hours; adjust dose to achieve 3 to 4 soft stools per day.[2]

b) Retention enema for acute hepatic encephalopathy: 1 – 10 mL/10 kg (NOT mL/kg). After administering a cleansing enema, administer diluted lactulose solution (1 part lactulose to 2 to 3 parts warm water) as a retention enema for 30 minutes.[2–4]

Constipation (extra-label):

a) Liquid: 0.5 mL/kg (usually 2 – 3 mL/cat) PO every 8 to 12 hours; adjust dosage to obtain the stool quality desired. For acute, severe constipation, can also be administered as an enema as listed above for hepatic encephalopathy.[5]

b) Crystals: ¼ – ½ teaspoonful/cat (≈1.25 – 2.5 mL/cat) twice daily mixed with food is commonly recommended; adjust dosage to obtain the stool quality desired.

HORSES:

Reduction of ammonia (extra-label): From a study in healthy horses, 333 mg/kg PO 3 times daily for 11 days significantly reduced blood ammonia.[6] One horse developed laminitis.

BIRDS:

Hepatic encephalopathy; to stimulate appetite, improve intestinal flora (extra-label):

Cockatiel: 0.03 mL/bird (NOT mL/kg) PO 2 to 3 times a day[7]

Amazon: 0.1 mL/bird (NOT mL/kg) PO 2 to 3 times a day. Reduce dosage if diarrhea develops. May be used for weeks

REPTILES:

Laxative (extra-label): **Green Iguana**: 0.3 mL/kg PO every 12 hours[8]

Hepatic lipidosis (extra-label): **Bearded dragons, leopard geckos, tortoises**: 0.5 mL/kg PO every 24 hours[9–11]

Monitoring

- Clinical efficacy (2 to 3 soft stools per day) and serum ammonia concentrations when used for HE
- Postenema: Measure pH of enema effluent and repeat if pH is greater than 6[2]
- In long-term use (ie, months) or in patients with pre-existing fluid/electrolyte problems, serum electrolytes should be periodically monitored.
- According to the product label, glucose control should be evaluated in diabetic patients. Although disruption of glycemic control is primarily theoretical, it seems prudent to monitor for glycemic control in the initial stages of treatment.

Client Information

- This medicine is used to treat constipation or to reduce ammonia concentrations in small animal species and birds with liver disease.
- Lactulose is generally well tolerated, although diarrhea, abdominal pain, or cramping may occur, particularly early in treatment. Contact your veterinarian if your animal develops diarrhea.
- Lactulose may be mixed in food or other liquids to improve palatability, but make sure the entire dose is consumed.
- When lactulose is used for problems related to liver disease (*hepatic encephalopathy*), contact your veterinarian if signs worsen or fewer than 2 to 3 soft stools are produced each day.

Chemistry/Synonyms

A synthetic derivative of lactose, lactulose is a disaccharide containing one molecule of galactose and one molecule of fructose. It occurs as a white powder that is very slightly soluble in alcohol and very soluble in water. The commercially available solutions are viscous, sweet liquids with an adjusted pH of 3 to 7.

One gram of the lactulose crystals for oral solution (*Kristalose®*) is equivalent to 1.5 mL of the liquid.

Lactulose may also be known as lactulosum; many trade names are available, including *Constulose®, Enulose®, and Kristalose®*.

Storage/Stability

Lactulose syrup should be stored protected from light in tight containers, preferably at room temperature (20°C-25°C [68°F-77°F]); avoid freezing. Darkening of the solution may occur, but this does not affect drug potency. Exposure to heat or light may cause extreme darkening or cloudiness; these solutions should be discarded. Lactulose solutions may precipitate; crystals dissolve with gentle reheating.

Compatibility/Compounding Considerations

For use as a retention enema, some human references recommend mixing 300 mL lactulose solution with 700 mL water or physiologic saline.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Lactulose Solution: 1 g/1.5 mL (labeled as 10 g/15 mL or 20 g/30 mL); (per 10 g contains less than 1.6 g galactose, less than 1.2 g lactose, and less than or equal to 1.2 g of other sugars); *Generlac®*, *Constulose®*, and *Enulose®*, generic; (Rx)

Lactulose Crystals for Oral Solution: Lactulose (less than 0.3 g galactose and lactose/10 g) in 10 g and 20 g packets; *Kristalose®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Lanthanum

(***lan***-tha-num) *Fosrenol®, Lantharenol®*

Oral Phosphate Binding Agent

Prescriber Highlights

► Orally administered phosphate binder
► May be useful when aluminum or calcium containing phosphate binders cannot be used
► Limited experience and relatively little published in veterinary literature; products labeled for use in cats in some countries
► Contraindications include ileus, GI obstruction, and fecal impaction.
► Use caution in animals that have GI ulcers.
► Appears safe; adverse effects may include vomiting, nausea, and inappetence.
► Chewable tablets should be crushed prior to administration.
► Expense is a limiting factor.

Uses/Indications

Lanthanum carbonate is potentially useful as an orally administered phosphate binding agent for patients with chronic kidney disease. While phosphorous dietary restrictions are the mainstay of controlling hyperphosphatemia in small animals, binding agents such as aluminum, sevelamer, or lanthanum can be considered for use in patients whose phosphate levels are not controlled with diet alone or that will not consume very-low phosphorous diets. Lanthanum has a potential advantage over calcium or aluminum containing phosphate binders in that it does not appear to be absorbed, even at high doses or with continued use, though palatability can be an issue.

Pharmacology/Actions

Lanthanum carbonate's mechanism of action to reduce hyperphosphatemia is by dissociating in the acid environment of the upper GI tract to release lanthanum ions. These ions bind to dietary phosphate and form highly insoluble lanthanum phosphate complexes that are then eliminated in the feces.

Pharmacokinetics

Following oral doses, lanthanum bioavailability is very low (less than 0.002%). In humans, the small amount of systemically available lanthanum is very highly bound to plasma proteins (greater than 99%). Studies in dogs, mice, and rats have shown that lanthanum concentrations in tissues increase over time and can be several orders of magnitude higher than that found in the plasma. Highest tissue concentrations are found in the GI tract, bone, and liver; it does not cross the blood–brain barrier. Terminal half-life is ≈36 hours but is increased in patients with kidney disease. In rats, absorbed lanthanum is cleared primarily via biliary excretion into the feces. In dogs, mean recovery of an oral dose of lanthanum averages 94%.

Contraindications/Precautions/Warnings

Lanthanum carbonate is contraindicated in patients with bowel obstruction, ileus, or fecal impaction. It should be used with caution in patients where the GI tract is not intact (eg, GI ulcers, colitis) as there is an increased chance for oral absorption. While on this drug, the risk for GI obstruction is greater in patients with reduced GI motility or alterations in GI anatomy (eg, history of GI surgery, diverticula). Tablets should be crushed completely prior to administration to reduce the risk for serious adverse GI events.[1]

Adverse Effects

Limited information is available for dogs and cats, but it appears that lanthanum is well tolerated. Vomiting has been reported in some cats and food avoidance can occur when lanthanum carbonate is mixed into food.

Healthy cats given 1 g/kg PO over 3 months did not show any bone histological changes.[2]

In humans, adverse effects most commonly reported include nausea, vomiting, and diarrhea. These are generally self-limiting and usually abate with continued use.

Reproductive/Nursing Safety

Lanthanum carbonate did not impact fertility or reproductive performance in rats. Administration to pregnant rabbits at 5 times the maximum human labeled daily dose resulted in reduced fetal weight, delayed ossification, and increased postimplantation loss. In pregnant rats, it led to underweight and sexually under-developed offspring.

It is unknown if lanthanum is excreted into milk; use with caution in nursing dams.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No specific information was located. It is likely that an acute overdose would be tolerated, with the chance that it might cause GI effects. Only supportive treatment should be required. In a poster presentation of a dose escalation study in cats, cats tolerated oral dosages up to 1 g/kg but vomited repeatedly after receiving 2 g/kg.[3]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions with lanthanum have either been reported or are theoretical in humans or animals receiving lanthanum and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

Lanthanum carbonate may **decrease** the amount absorbed or the pharmacologic effect of the drugs listed below; separate oral doses of lanthanum and these drugs by 2 hours to help reduce the potential for this interaction.

- **ACE Inhibitors** (eg, **enalapril**)
- **Allopurinol**
- **Antacids** (eg, **aluminum, magnesium, calcium** preparations): May form insoluble complexes, reducing efficacy
- **Chloroquine**
- **Corticosteroids** (eg, **dexamethasone, predniso(lo)ne**)
- **Digoxin**
- **Ethambutol**
- **Fluoroquinolones** (eg, **enrofloxacin**)
- **H_2-Receptor Antagonists** (eg, **famotidine**)
- **Iron Salts**
- **Isoniazid**
- **Levothyroxine**
- **Penicillamine**
- **Phenothiazines** (eg, **acepromazine**)
- **Tetracyclines** (eg, **doxycycline**)

Laboratory Considerations

- Lanthanum has radiopaque properties that may interfere with abdominal radiographic imaging.

Dosages

DOGS:

NOTE: If tablets are used, they should be crushed completely prior to administration.

Phosphate binder (extra-label): 5 – 20 mg/kg PO every 12 hours; titrate to effect[4]

IRIS treatment recommendations for reduction of phosphate intake in dogs with chronic kidney disease (CKD) [if plasma phosphate concentration is above 1.6 mmol/L (5 mg/dL) after dietary restriction]; (extra-label): starting dose of 30 – 60 mg/kg/day in divided doses given with each meal. Dose required will vary based on dietary phosphate intake and stage of kidney disease. Titrate to effect.[5]

CATS:

Phosphate binder (extra-label): Initially, 30 mg/kg/day PO divided 2 to 3 times a day and administered on or in food. A common dose is 200 mg PO twice daily. **NOTE**: Dosage is to effect.[6,7] Dosages as high as 95 mg/kg/day PO have been noted.[8,9]

IRIS treatment recommendations for reduction of phosphate intake in CKD [if plasma phosphate concentration is above 1.5 mmol/L (4.6 mg/dL) after dietary restriction]; (extra-label): starting dose of 30 – 60 mg/kg/day in divided doses given with each meal. Dose required will vary based on dietary phosphate and stage of kidney disease. Titrate to effect.[10]

Monitoring

- Serum phosphorous. For chronic kidney disease (CKD), most clinicians recommend a target phosphorous range of 0.9 to 1.5 mmol/L (2.7 to 4.6 mg/dL). For stage 3 CKD a more realistic upper limit might be 1.6 mmol/L (5.0 mg/dL). For stage 4 CKD, a more realistic upper limit might be 1.9 mmol/L (6.0 mg/dL).
- Other electrolytes such as potassium, calcium, bicarbonate, chloride, and calcium–phosphate product
- GI motility

Client Information

- Used to bind up phosphorous found in food and prevent it from being absorbed. Only helpful if your animal is eating.
- Administer this medicine at mealtimes. Mix this medicine into or sprinkle on top of food. If using tablets, crush them completely

before mixing into food. Do not give as intact tablet. Entire dose should be immediately consumed.
- Sometimes can cause vomiting.
- While your animal is taking this medication, it is important to return to your veterinarian for lab work. Do not miss these important follow-up visits.

Chemistry/Synonyms
Lanthanum is a chemical element with the symbol La and atomic number 57. When used pharmacologically, it is administered as lanthanum carbonate. Lanthanum carbonate occurs as a white to off-white powder that is insoluble in water.

Lanthanum carbonate may also be known as Bay-78-1887, and by the trade names *Lantharenol®*, *Renalzin®*, and *Fosrenol®*.

Storage/Stability
Store tablets at room temperature (25°C [77°F]); excursions are permitted to 15°C-30°C (59°F-86°F). Protect from moisture.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES

A lanthanum carbonate (octa-hydrate), kaolin, and vitamin E labeled product (*Renalzin®*) for use in cats had been available in several countries (not United States) but appears to be no longer marketed. It had been reported that 1 mL contained 200 mg of lanthanum carbonate.

HUMAN-LABELED PRODUCTS:

Lanthanum Carbonate Oral Chewable Tablet: 500 mg, 750 mg, and 1000 mg; *Fosrenol®*; (Rx)

Lanthanum Carbonate Oral Powder: 750 mg and 1000 mg; *Fosrenol®*; (Rx). Contains ≈ 357 mg lanthanum carbonate per g of powder.

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Leflunomide
(le-***floo***-noh-myde) *Arava®*

Immunomodulator

Prescriber Highlights
- ► Immunomodulating drug used in small animal medicine as an immunosuppressant, particularly in patients refractory to treatment with conventional medications or when glucocorticoids are contraindicated
- ► Appears to be well tolerated by dogs and cats, but numbers treated are low
- ► Teratogenic and carcinogenic
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies leflunomide as a hazardous drug; use appropriate precautions when handling.

Uses/Indications
Leflunomide is an immunomodulating drug used as an immunosuppressant in small animal medicine, particularly in patients that are refractory to treatment with conventional medications or when glucocorticoids are contraindicated. Leflunomide has been used in dogs to treat immune-mediated blood disorders (eg, IMHA,[1] IMT,[2] Evans syndrome[3]), systemic and cutaneous reactive histiocytosis, immune-mediated polyarthritis,[2,4,5] inflammatory bowel disease,[2] pancytopenia,[2] vasculitis,[2] and granulomatous meningoencephalitis. Clinical response to leflunomide is noted within 1 to 3 weeks of initiating therapy.[2]

Leflunomide has been used with methotrexate to treat rheumatoid arthritis in cats.[6,7]

A leflunomide analogue (FK778) has been used in transplant rejection protocols in dogs.[8]

Pharmacology/Actions
Leflunomide is a pyrimidine synthesis inhibitor that inhibits autoimmune T-cell proliferation and autoantibody production by B cells. Leflunomide acts almost exclusively via its primary active metabolite, teriflunomide (A77 1726), which reversibly inhibits the mitochondrial enzyme dihydroorotate dehydrogenase. The disruption of this enzyme prevents formation of ribonucleotide uridine monophosphate (rUMP), resulting in decreased DNA and RNA synthesis, inhibition of cell proliferation, and G1 cell cycle arrest. These cytostatic effects occur primarily in lymphocytes, sparing GI, hematopoietic,[9] and other rapidly dividing cells. Leflunomide also has antiviral and tyrosine kinase inhibiting properties, the importance of which is unclear. An antiplatelet effect also has been demonstrated.[10]

Pharmacokinetics
In healthy dogs (n = 4), after a single dose of leflunomide 4 mg/kg PO, the following mean values for teriflunomide were reported: time to peak concentration (T_{max}), 5 hours; peak concentration (C_{max}), 5 µg/mL; elimination half-life, 21.3 hours; and mean residence time (MRT), 27 hours. It is not understood why the apparent half-life for dogs is so much shorter (≈1 day) than it is for humans (15 days).[11] In another study, healthy dogs received leflunomide 4 mg/kg PO as a single dose, and teriflunomide values were reported as T_{max}, 1.4 hours; C_{max}, 18.9 µg/mL; t1/2, 25 hours; and MRT, 175 hours.[12]

In healthy cats (n = 6), after a single dose of teriflunomide (A77 1726) 4 mg/kg IV, the following mean values were reported: volume of distribution (Vd_{ss}), 97 mL/kg; clearance, 1.1 mL/kg/hour; and elimination half-life, 71.8 hours. After a single dose of leflunomide 4 mg/kg PO, bioavailability was 100%; peak teriflunomide concentration occurred ≈8 hours after dosing, and elimination half-life was 59 hours.[13]

In humans, leflunomide is rapidly converted to the active metabolite teriflunomide (A77 1726; M1) in the GI mucosa and liver. Peak concentrations of A77 1726 occur between 6 and 12 hours after an oral dose. The presence of food in the gut does not appear to affect oral bioavailability. Teriflunomide is highly bound to albumin (greater than 99%). It is further degraded in the liver as glucuronides and an oxalinic acid compound that are excreted in the urine and bile. Half-life is ≈15 days, but teriflunomide (A77 1726) can be detected in patients up to 2 years after it is discontinued.

Contraindications/Precautions/Warnings
Leflunomide is contraindicated in patients hypersensitive to it and in patients with severe hepatic impairment. It should be used with extreme caution in patients with severe immunodeficiency and in patients with significant renal impairment, bone marrow dysplasia, or active infection. Use leflunomide with additional (close) monitoring when needed in patients receiving other immunosuppressive drugs, or drugs known to be hepatotoxic.

The National Institute for Occupational Safety and Health (NIOSH) classifies leflunomide as a hazardous drug; *personal protective equipment (PPE) should be used accordingly* to minimize the risk of exposure.[14]

Adverse Effects
Adverse effects of leflunomide appear to be dose-related.[1,2] In a retrospective analysis, leflunomide was discontinued in 8 of 92 dogs because of adverse effects.[2] Across studies, reported adverse effects in dogs include diarrhea, decreased appetite, lethargy, vomiting, respiratory signs (ie, dyspnea, cough), increased liver enzymes, unexplained hemorrhage, leukocytopenia, lymphopenia, thrombocy-

topenia, hypercholesterolemia, and anemia.[1,2,15,16] Vomiting and lethargy have been reported in cats.[13]

In humans, GI effects (eg, diarrhea, nausea), alopecia, and rash are reported most commonly. Serious adverse effects have included hematologic toxicity, dermatologic effects (eg, TEN, Stevens-Johnson), peripheral neuropathy, interstitial lung disease, hypertension, and severe hepatotoxicity.

Reproductive/Nursing Safety

Leflunomide is contraindicated during pregnancy. Embryo lethality and a variety of teratogenic effects in laboratory animals have been detailed at or below doses used clinically. For sexually intact females, verify pregnancy status prior to administration.

Leflunomide is excreted in milk in rats; milk replacer should be used if the dam is receiving the drug.

Overdose/Acute Toxicity

Acute toxicologic studies in mice and rats have demonstrated that the minimally toxic dose is 200 mg/kg and 100 mg/kg, respectively. The LD_{50} in rabbits is 132 mg/kg. Cholestyramine or activated charcoal is recommended to accelerate elimination.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Leflunomide acts almost exclusively via its primary active metabolite, **teriflunomide**. The following drug interactions have either been reported or are theoretical in humans or animals receiving leflunomide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Charcoal, Activated**: Can increase elimination and decrease teriflunomide drug concentrations; may be used when more rapid elimination is desirable
- **Cholestyramine**: Can increase elimination and decrease teriflunomide drug concentrations; may be used when more rapid teriflunomide elimination is desirable (eg, toxic ingestion, severe toxicity)
- **Furosemide**: May increase furosemide exposure
- **Hepatotoxic Agents, Other**: Increased risk for toxicity
- **Immunosuppressants, Other** (eg, **antineoplastic agents, azathioprine, cyclosporine, high-dose glucocorticoids**): May have additive immune suppressing effect
- **Loperamide**: May inhibit loperamide metabolism
- **Methotrexate**: Increased adverse effects and increased ALT activity possible
- **Mitoxantrone**: May increase mitoxantrone exposure
- **Rifampin**: Can increase teriflunomide peak concentrations
- **Terbinafine**: May inhibit terbinafine metabolism
- **Theophylline**: May decrease theophylline concentrations
- **Vaccines, Modified Live Virus**: Live virus vaccines should be used with caution, if at all, during leflunomide therapy.
- **Warfarin**: Leflunomide may increase or decrease prothrombin time.
- **Zidovudine**: May increase zidovudine exposure

Dosages

DOGS:

Immune-mediated hemolytic anemia (IMHA) (extra-label): 2 mg/kg PO once daily.[1] Most recommendations for initial dosages range from 3 – 4 mg/kg PO once daily,[4,5] although 2 mg/kg PO once daily may also be effective.[1,2]

Immune-mediated polyarthritis (extra-label): 3 – 4.5 mg/kg PO once daily for at least 6 weeks. Adjust dose based on cytologic evaluation of synovial fluid and clinical signs.[4,5]

CATS:

Immunosuppressive agent (extra-label): Based on limited PK/PD information, an initial dosage of 2 – 3 mg/kg (practical dosage 10 mg per cat [NOT mg/kg]) PO once daily is reasonable.[13] Depending on the indication for use and response to treatment, dosage reduction (or increased time between dosages) can be considered over time once a positive clinical response occurs.

Adjunctive therapy for rheumatoid arthritis (extra-label): Initially, leflunomide 10 mg/cat (NOT mg/kg) PO once daily with methotrexate 2.5 mg/cat (NOT mg/kg) PO 3 times on 1 day per week (ie, methotrexate 7.5 mg/cat [NOT mg/kg] is divided and given as 3 separate 2.5 mg doses over 1 day). When significant improvement occurs, reduce leflunomide dosage to 10 mg/cat (NOT mg/kg) PO twice weekly and methotrexate to 2.5 mg/cat (NOT mg/kg) PO once weekly.[6,7]

Monitoring

- Clinical efficacy
- Adverse effects: GI effects (eg, vomiting, diarrhea, inappetence), infection (eg, fever, lethargy)
- Check CBC prior to starting therapy, then every 2 weeks for the first 2 months of therapy, then every 1 to 2 months (sooner if patient condition warrants) thereafter until therapy is complete.[1]
- Liver enzymes (ie, ALP, ALT) every 2 weeks for the first 2 months of treatment; consider checking values every 1 to 2 months (sooner if patient condition warrants) for the duration of therapy as long as patient is doing well.[1] In humans, it is recommended to check at baseline, at least monthly for the first 6 months, then every 6 to 8 weeks chronically.
- Trough concentrations of teriflunomide (active metabolite of leflunomide) may be considered[1]; concentrations between 20 to 30 µ/mL has been suggested for dogs with spontaneous immune-mediated disease. Based on pharmacokinetic data, it is reasonable to measure drug concentrations 1 to 2 weeks after initiating therapy or dosage changes, with samples obtained at any time within the dosing interval (ie, trough measurement is not required).

Client Information

- Use caution when handling this medication. Pregnant women must use caution when handling leflunomide, as this drug can cause birth defects.
- It may take 1 to 3 weeks to determine if leflunomide is effective.
- This medicine may be given with food or on an empty stomach. Give with food if animal vomits or acts sick after getting a dose.
- Side effects can include decreased appetite, lethargy (tiredness), vomiting, and diarrhea.
- Contact your veterinarian right away if you see bleeding or signs of infection (eg, fever, extreme tiredness, not wanting to eat).
- Your veterinarian will need to do periodic blood tests while your animal is taking leflunomide. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Leflunomide is an isoxazole immunomodulator with a melting point

of 165°C to 166°C (329°F-331°F). It occurs as a white or almost white powder. It is poorly soluble in water (21 mg/L).

Leflunomide may also be known as HWA 486, RS 34821, or SU 101; a common trade name is *Arava*®.

Storage/Stability
Leflunomide tablets should be stored at room temperature (15°C-30°C [59°F-86°F]) and protected from light.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Leflunomide Tablets: 10 mg and 20 mg; *Arava*®, generic; (Rx)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Leucovorin
Folinic Acid
(loo-koe-***vor***-in)
Folic Acid Derivative

Prescriber Highlights
- ► Primarily used in dogs, cats, and horses to help reverse neurotoxicity or hematologic toxicity associated with dihydrofolate reductase inhibitors (eg, pyrimethamine, trimethoprim, or ormetoprim)
- ► Leucovorin does not require conversion by dihydrofolate reductase for it to be active.

Uses/Indications
Leucovorin calcium is the calcium salt of folinic acid and is used as an antidote for toxicity from folic acid antagonists (eg, methotrexate, pyrimethamine, trimethoprim, ormetoprim). In dogs, cats, and horses, it is more commonly used to help reverse or prevent hematologic toxicity associated with pyrimethamine, trimethoprim, or ormetoprim. In humans, it is used routinely as a rescue agent following high-dose methotrexate chemotherapy

Pharmacology/Actions
Reduced folates act as coenzymes in the synthesis of purine and pyrimidine nucleotides necessary for DNA synthesis. Folates are also required for maintenance of normal erythropoiesis.

Leucovorin is a reduced form of folic acid that, unlike folic acid, does not require dihydrofolate reductase conversion for it to become biologically active. It is further converted to active reduced forms, of which 5-methyltetrahdyrofolate (5-methyl THF) is predominantly responsible for its activity. Although, leucovorin is a mixture of diastereoisomers, only the (-)-L-isomer (citrovorum factor) becomes biologically active.

Leucovorin inhibits thymidylate synthase by stabilizing the binding of fluorodeoxyuredylic acid to the enzyme. This effect can potentiate the activity, but also the toxicity, of fluorouracil (5-FU).

Leucovorin has a protective effect against methotrexate-induced chromosomal damage.

Pharmacokinetics
There is limited information available on the pharmacokinetics of leucovorin in animals. In dogs, the elimination half-life of the active L-isomer of leucovorin is ≈50 minutes. It is extensively metabolized and excreted into the urine. The inactive D-form elimination half-life is ≈2.5 hours. Apparent volume of distribution for both forms is 0.6 L/kg.

In humans, oral bioavailability of leucovorin following a 25 mg dose is 97%, but bioavailability decreases as dose is increased above 25 mg; doses of 50 mg and 100 mg have bioavailabilities of 75% and 37%, respectively. IM bioavailability is similar to IV. Oral doses of 25 mg yield peak leucovorin concentrations in ≈60 minutes, and peaks of the active reduced folates occur between 1.7 and 2.4 hours after dosing. After IV administration, peak total reduced folate concentrations occur in ≈10 minutes. Approximately 50% of oral body stores of reduced folates are found in the liver. Elimination occurs in the urine, primarily as 10-formyl-THF or 5,10-methyl-THF. Elimination half-life is ≈5.7 hours for total reduced folates.

Contraindications/Precautions/Warnings
Leucovorin is contraindicated in patients that are hypersensitive to it.[1] It should be used with caution in patients with megaloblastic anemia due to reduced cobalamin concentrations, as folinic acid therapy may mask the associated clinical signs.

Use with extreme caution in patients receiving systemic fluorouracil. See ***Drug Interactions***.

Large IV doses of leucovorin should be given as a slow infusion rather than a bolus due to the calcium content.

Do not confuse leucovorin with *Leukeran*® (chlorambucil); do not confuse foLINIC acid with foLIC acid, or foLINATE with foLATE.

Adverse Effects
Adverse effects have not been noted when leucovorin has been used in animals. In humans, adverse GI effects can be seen after oral administration; seizures and hypersensitivity reactions have rarely been reported. Pyrexia may occur after parenteral administration.

Reproductive/Nursing Safety
Leucovorin had no effect on the outcome of pregnancy in experimental studies in rabbits.[2] It is not known if leucovorin enters milk.[1] Because leucovorin is a biologically active form of folic acid, and folic acid supplementation is used before and during pregnancy in humans, leucovorin may be safe to administer during pregnancy or nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity
Except in situations where drug interactions are possible, an inadvertent overdose is typically not concerning; however, excessive doses of leucovorin may reduce the effect of folic acid antagonists.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions
The following drug interactions have either been reported or are theoretical in humans or animals receiving leucovorin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Barbiturates, Primidone, Phenytoin**: Large doses of leucovorin may reduce the antiseizure efficacy of these agents by decreasing blood concentrations of the antiepileptic drugs.
- **Dihydrofolate Reductase Inhibitors** (eg, **ormetoprim, pyrimethamine, trimethoprim**): Leucovorin may reduce therapeutic effect.
- **Fluorouracil (5-FU), Capecitabine (5-FU prodrug)**: Leucovorin may increase both the antineoplastic efficacy and toxicity of 5-FU.

Laboratory Considerations

- None noted

Dosages

DOGS/CATS:

Folate deficiency and myelosuppression associated with pyrimethamine, trimethoprim, ormetoprim (extra-label): Extrapolating from human dosages, 0.1 – 0.3 mg/kg PO once daily could be considered. A practical dose would be to round up to the nearest ½ tablet.

Methotrexate overdose (extra-label):

NOTE: Leucovorin is most effective if given within 48 hours of an overdose.

a) The dose of leucovorin is dependent on the serum methotrexate concentration. Administer leucovorin 25 – 200 mg/m^2 (NOT mg/kg) parenterally every 6 hours until methotrexate concentrations are less than 1×10^{-8} M.[3]

b) A case report in 2 dogs described leucovorin administration when MTX assay was unavailable. GI decontamination was performed (apomorphine; charcoal/sorbitol times 3 over 6 hours), followed by leucovorin calcium 200 mg/m^2 (NOT mg/kg) IV every 6 hours for 8 doses. Forced alkaline diuresis and N-acetylcysteine (IV) were also administered.[4]

c) 20 mg IV every 6 hours for 6 doses was given to a 13-kg dog after ingestion of methotrexate 7.7 mg/kg and a blood concentration of 0.09 µmol/L at 12 hours. GI decontamination, gastroprotectants, IV fluids, and antibiotics were also given. The dog developed no signs of toxicosis.[5]

HORSES:

Macrocytic anemia and neutropenia associated with pyrimethamine and/or trimethoprim (especially in pregnant mares; extra-label): 0.1 – 0.3 mg/kg PO once daily, although administration of green hay or pasture, which have high tetrahydrofolate concentrations, may be more practical.[6]

Monitoring

- CBC at baseline and prior to each treatment
- Methotrexate serum concentrations (contact a local human hospital) if used for methotrexate overdoses

Client Information

- If being used for methotrexate (chemotherapy) toxicity, this medication should only be administered in an inpatient setting.
- Oral leucovorin may be given with or without food.
- Give this medicine as directed by your veterinarian. It is very important to not miss any doses.
- Your veterinarian will need to monitor your animal while it is taking this medicine. Do not miss these important follow-up visits.

Chemistry/Synonyms

Leucovorin calcium occurs as a yellowish-white or yellow, odorless powder. It is very soluble in water and practically insoluble in alcohol. It is a mixture of diastereoisomers of 5-formyl tetrahydrofolic acid.

Leucovorin calcium may also be known as folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, citrovorin, folidan, folinic, FTHF, NSC-3590, calcium folinate, calcifolin, calfonat, folinic acid calcium salt, or leucovorin calcium; many international trade names are available.

Storage/Stability

Leucovorin calcium tablets should be stored at 20°C to 25°C (68°F-77°F) in a sealed container protected from light.

Leucovorin powder for reconstitution and injection should be stored at 20°C to 25°C (68°F-77°F) protected from light.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The powder for injection is reconstituted by adding 5 or 10 mL of bacteriostatic water for injection or sterile water for injection. As bacteriostatic water for injection contains benzyl alcohol, it is not recommended in neonates or very small animals. If reconstituting with sterile water for injection, the resulting solution should be administered immediately; solutions made with bacteriostatic water for injection are stable up to 7 days.

Leucovorin calcium is **compatible** for dilution with lactated Ringer's, Ringer's, or 0.9% sodium chloride. Leucovorin calcium is **incompatible** with solutions containing fluorouracil.

A 5 mg/mL oral suspension can be compounded using twenty-four 25 mg tablets, crushed and mixed with 30 mL *Cologel®* and a 2:1 mix of simple and wild cherry syrups *qs ad* to 120 mL. This suspension is stable for 28 days under refrigeration.[7]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

NOTE: Strengths listed are in terms of leucovorin base.

Leucovorin Calcium Oral Tablets: 5 mg, 10 mg, 15 mg, and 25 mg tablets; generic; (Rx)

Leucovorin Calcium Injectable Solution: 10 mg/mL single use vial; generic; (Rx)

Leucovorin Calcium Powder for Injection: 50 mg, 100 mg, 200 mg, 350 mg, and 500 mg in single use vials; generic; (Rx)

Leuprolide

(loo-***proe***-lide) *Lupron®*

GnRH-analogue Agonist

Prescriber Highlights

- ► Used for treatment of adrenal associated endocrinopathy in ferrets and to suppress gonadal activity in birds
- ► Doses listed are for depot formulation; do not confuse with daily injectable formulation.
- ► At studied doses in birds and ferrets the duration of effect is generally 4 to 6 weeks.
- ► Contraindicated in pregnancy (teratogenic) and in animals with uterine bleeding
- ► Use with caution in lactating animals
- ► Extremely costly (especially for ferrets); may be obtained in smaller aliquots from compounding pharmacies
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies leuprolide as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

The primary use for leuprolide is for treatment of adrenal associated endocrinopathy in ferrets. Vulvar swelling, pruritus, dysuria, and aggression can be reduced within days to weeks while hair regrowth can take 1 to 2 months.[1] Leuprolide may be more effective earlier in the disease process than later and when treating ferrets with adrenal hyperplasia or adenomas rather than adenocarcinoma.

In captive birds, 30-day depot leuprolide can suppress gonadal activity for 2 to 3 weeks.[2] Leuprolide has been used to treat malignant ovarian neoplasias in birds.

In dogs and cats, leuprolide has been used experimentally to induce estrus and treat hormone-responsive incontinence.

Commercial product labels may include the dosing interval (eg, "for administration every 6 months") but the duration of effect in veterinary patients is seldom that long.

Pharmacology/Actions

Leuprolide is a gonadotropin-releasing hormone (GnRH) agonist. GnRH is also known as luteinizing hormone-releasing hormone. GnRH agonists such as leuprolide act via negative feedback to inhibit release of the gonadotropins, luteinizing hormone (LH), and follicle stimulating hormone (FSH) from the pituitary gland. Decreased LH and FSH lead to decreased serum estrogen and androgen concentrations.

Pharmacokinetics

No veterinary pharmacokinetic data are available. The depot formulation appears to have sustained effects in birds and ferrets.

Duration of effect in ferrets varies when using the 30-day formulation. Clinical effects can persist from 1.5 to 8 months.[1]

In birds, when using the 30-day formulation, the duration of clinical effects may be up to 3 weeks.[3]

Contraindications/Precautions/Warnings

Leuprolide is contraindicated in any veterinary patient hypersensitive to leuprolide or any other gonadotropin-releasing hormone agonist, with uterine bleeding, and during pregnancy.

Prolonged QT intervals may occur in humans receiving leuprolide, increasing risk for cardiac arrhythmias including torsades de pointes. Use caution when combined with other medications that may prolong QT intervals. Hyperglycemia and increased risk for developing diabetes have been reported in humans. Seizures have also been reported.

The National Institute for Occupational Safety and Health (NIOSH) classifies leuprolide as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Little information is available on the adverse effect profile of leuprolide in birds. Currently, this drug appears safe at recommended doses. There is a case report of a suspected anaphylactic reaction and death in 2 elf owls (*Micrathene whitneyi)*.[3]

In ferrets, adverse effects reported include pain and irritation at injection site, dyspnea, and lethargy. Tolerance (higher dosages required over time to obtain the same effect) has been reported.

In humans, the most common adverse effects include general pain, hot flashes, GI signs (eg, nausea, vomiting), decreased sleep, and edema.

Reproductive/Nursing Safety

Leuprolide is contraindicated in pregnancy. Major fetal abnormalities may result.

It is not known whether leuprolide is excreted in milk; use with caution.

Overdose/Acute Toxicity

Due to expense and dosing method, acute overdose is unlikely. Studies in lab animals at dosages of up to 5 g/kg IM produced no untoward effects.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving leuprolide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antidiabetic Agents** (eg, **glipizide, insulin**): Leuprolide may worsen glycemic control and diminish the effectiveness of antidiabetic agents.
- **QT Prolonging Agents** (eg, **amiodarone**, **cisapride, procainamide, sotalol**): Leuprolide may prolong QT intervals. This effect may be increased with agents that also prolong QT intervals; use with caution with other QT prolonging agents.

Laboratory Considerations

- Diagnostic tests measuring **pituitary gonadotrophic** and **gonadal functions** may be misleading during and for several months after discontinuing therapy.

Dosages

Note: The doses listed are for the **depot** injection; do not confuse with the daily injection formulation.

BIRDS:

GnRH-agonist (extra-label): The 30-day depot formulation is used most frequently in avian medicine; duration of effect in birds is generally less than 4 weeks. A wide range of dosages have been reported for birds, ranging from 100 µg/kg (0.1 mg/kg) to 1.2 mg/kg. For palliative treatment of ovarian neoplasias in cockatiels or macro-orchidism, very high dosages (1.5 – 3.5 mg/kg) have been recommended. However, most recommend dosages between 400 and 1000 µg/kg (0.4 – 1 mg/kg) IM repeated every 2 to 3 weeks.[2,4,5]

FERRETS:

Adrenal associated endocrinopathy (extra-label): Dosages are for the 30-day depot formulation and vary by the source. No published evidence currently supports one dosage over another. Initially, 100 – 200 µg/ferret (0.1 – 0.2 mg/ferret [NOT per kg]) (some references recommend 100 µg/ferret (0.1 mg/ferret) (NOT µg/kg) in females or those under 1 kg (2.2 lb) and 200 µg/ferret (0.2 mg/ferret [NOT µg/kg]) in males or those greater than 1 kg (2.2 lb) IM every 4 to 6 weeks. All patients may require 200 µg/ferret (0.2 mg/ferret [NOT µg/kg]) in time and some become refractory to treatment at any dosage.[1,6]

GUINEA PIGS:

Ovarian cysts (extra-label): Leuprolide acetate depot 100 – 300 µg/kg (0.1 – 0.3 mg/kg) SC or IM every 3 to 4 weeks as needed to control clinical signs has been tried,[7] but another source states that the treatment is unproven and personal experience has been unrewarding.[8]

Monitoring

- Clinical effects in birds: decreased egg-laying
- Clinical effects in ferrets: decreased vulvar swelling, pruritus, undesirable sexual behaviors, aggression, and increased hair regrowth
- Adverse effects

Client Information

- Leuprolide is a treatment and will not cure adrenal diseases in ferrets. Life-long treatment is necessary.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

A synthetic nonapeptide analogue of GnRH (gonadotropin-releasing hormone, gonadorelin, luteinizing hormone-releasing hormone), leuprolide acetate occurs as a white to off-white powder. In water more than 250 mg are soluble in 1 mL.

Leuprolide may also be known as leuproprelin, leuprorelinum, abbott-43818, leuprolide acetate, TAP-144, *Carcinil®, Daronda®, Eligard®, Elityran®, Enanton®, Enantone®, Enantone-Gyn®, Ginecrin®, Lectrum®, Leuplin®, Lucrin®, Lupride®, Lupron®, Procren®, Procrin®, Prostap®, Reliser®, Trenantone®, Uno-Enantone®*, and *Viadur®*.

Storage/Stability

Store the injection formulation at room temperatures less than 30°C (86°F); do not freeze and protect from light (store in carton until use).

Store the depot formulation at room temperatures less than 30°C (86°F). After reconstituting the depot suspension use immediately or discard it within 2 hours (no preservative).

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Whether the solution containing microspheres (depot formulation) can be frozen for later use is controversial. Some have frozen the solution and state it is still effective. The manufacturer states the depot form is not to be frozen as the microspheres are destroyed. No studies are known that support the stability of the depot activity when frozen and thawed. Some compounding pharmacies may divide the lyophilized powder into individual dosages in vials. If freezing is desirable, recommend putting individual aliquots into tuberculin syringes before freezing; do not re-freeze once thawed.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Leuprolide Acetate Injection: 1 mg/0.2 mL (2.8 mL multi-dose vial); generic; (Rx)

Leuprolide Acetate for SC Injection (kits): 7.5 mg (regular—30 day), 22.5 mg, 30 mg, and 45 mg; *Eligard®*, *Fensolvi®*; (Rx)

Leuprolide Acetate Microspheres for IM Injection (kits): 3.75 mg, 7.5 mg, 11.25 mg (regular—30 day and 3 month), 15 mg, 22.5 mg, 30 mg, and 45 mg; *Lupron® Depot* and *Lupron® Depot-Ped* and *Lupron® Depot-3*, *-4*, or *-6 Month*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Levamisole

(leh-***vam***-i-sole) *LevaMed®*

Antiparasitic

Prescriber Highlights

- ► Antinematodal parasiticide labeled for nematode infections in cattle, sheep, and swine
- ► Not approved for use in milk-producing animals
- ► Use with caution in severely debilitated animals; animals with significant hepatic impairment; or in cattle that are stressed due to vaccination, dehorning, long-distance transport, or castration.
- ► Adverse effects in large animal species include muzzle foaming, lip licking, head shaking, and excitement or tremor.
- ► Many adverse effects reported in small animal species, including GI upset and neurotoxicity

Uses/Indications

Levamisole is a broad-spectrum anthelmintic that is FDA-approved for use in nematode infections in various species, although use today in veterinary medicine is limited. Many products for oral use are no longer commercially marketed ostensibly due to increased resistance and the potential for adverse effects. Depending on the product, levamisole is indicated for the treatment of many nematodes in cattle, sheep, goats, swine, and poultry.

Levamisole has historically been used in dogs as a microfilaricide to treat *Dirofilaria immitis* infection but is rarely used today. It has also garnered some interest as an immunostimulant in the adjunctive therapy of various neoplasms or in combination with glucocorticoids for treating systemic lupus erythematosus.

Levamisole is not generally used in horses as an antiparasitic agent because of its narrow margin for safety and limited efficacy against many equine parasites; however, it has been tried as an immune stimulant. In horses with equine protozoal myeloencephalitis, levamisole may be useful for the control of clinical signs secondary to inflammation after treatment with antiprotozoal therapy. Anecdotal reports of beneficial effects in the treatment of nasal viral papillomas and chronic obstructive pulmonary disease have also been suggested.[1]

In cattle and sheep, levamisole has relatively good activity against abomasal nematodes, small intestinal nematodes (not particularly good against *Strongyloides* spp), large intestinal nematodes (not *Trichuris* spp), and lungworms. Adult forms of species that are usually covered by levamisole include *Haemonchus* spp, *Trichostrongylus* spp, *Teladorsagia* spp, *Osteragia* spp, *Cooperia* spp, *Nematodirus* spp, *Bunostomum* spp, *Oesophagostomum* spp, *Chabertia* spp, and *Dictyocaulus vivapurus*. Levamisole is less effective against the immature forms of these parasites and generally ineffective in cattle against arrested larval forms but has shown efficacy against arrested larval forms of *Teladorsagia* (formerly *Ostertagia) circumcincta* and *Haemonchus contortus* in sheep.[2]

In swine, levamisole is indicated for the treatment of *Ascaris suum*, *Oesophagostomum* spp, *Strongyloides* spp, and *Metastrongylus* spp.

Pharmacology/Actions

Levamisole stimulates the parasympathetic and sympathetic ganglia in susceptible worms. At higher concentrations, levamisole interferes with nematode carbohydrate metabolism by blocking fumarate reduction and succinate oxidation. The net effect is a paralyzing effect on the worm that is then expelled alive. Levamisole's effects are considered to be nicotine-like in action.

Levamisole's mechanism of action for its immune-stimulating effects is not well understood. It is believed that levamisole restores cell-mediated immune function in peripheral T lymphocytes and stimulates phagocytosis by monocytes. Its immune-stimulating effects appear to be more pronounced in animals that are immunocompromised.

Pharmacokinetics

Levamisole is absorbed from the gut after oral dosing and through the skin after dermal application, although bioavailabilities are variable. It is reportedly distributed throughout the body. Levamisole is primarily metabolized with less than 6% excreted unchanged in the urine. Plasma elimination half-life is 1.8 to 4 hours in dogs, 4 to 6 hours in cattle, and 3.5 to 6.8 hours in swine. Metabolites are excreted in both the urine (primarily) and feces.

Contraindications/Precautions/Warnings

Do not use levamisole in dairy animals of breeding age.[3] It should be used cautiously in animals that are severely debilitated and in animals with significant hepatic impairment. If possible, delay use in cattle that are stressed due to vaccination, dehorning, long-distance transport, or castration.[4] Use levamisole with caution if delaying treatment is not possible.

It is important to accurately assess body weight prior to dosing, as underdosing can lead to ineffective treatment and may encourage the development of parasite resistance.[3]

Levamisole use in goats is somewhat controversial, as there is ev-

idence that it is toxic in fiber-producing goats. Oral routes are preferred but some clinicians have administered it SC; IM administration is contraindicated.

Avoid administering levamisole IM to birds.

One reference states that levamisole is contraindicated in cats with FIV or FIP and likely ineffective in cats with FeLV.[5]

Do not confuse levamisole with leucovorin, levETIRAacetam, or levOCARNitine.

Adverse Effects

Adverse effects that may be seen in dogs include GI disturbances (eg, vomiting, diarrhea), neurotoxicity (eg, panting, shaking, agitation, or other behavioral changes), immune-mediated anemia, agranulocytosis, dyspnea, pulmonary edema, immune-mediated skin eruptions (eg, erythroedema, erythema multiforme, toxic epidermal necrolysis), and lethargy.

Adverse effects seen in cats include hypersalivation, excitement, mydriasis, and vomiting.

Adverse effects that may be seen in cattle can include muzzle foaming or hypersalivation, excitement or trembling, lip licking, and head shaking.[3] These effects are generally noted with higher than recommended doses or if levamisole is used concomitantly with organophosphates. Signs generally subside within 2 hours.

In sheep, levamisole may cause transient excitability in some animals after dosing. In goats, levamisole may cause depression, hyperesthesia, and salivation.

In swine, levamisole may cause salivation or muzzle foaming. Swine infected with lungworms may develop coughing or vomiting.[6]

Reproductive/Nursing Safety

There is little information available regarding the safety of this drug in pregnant animals. Levamisole has been implicated in causing an abortion in goats. Although levamisole is considered relatively safe to use in large animals that are pregnant, use it only if the potential benefits outweigh the risks.

Levamisole is excreted in cows' milk; do not administer to dairy animals of breeding age.[3]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Toxicity

Signs of levamisole toxicity often mimic those of organophosphate toxicity. Signs may include hypersalivation, hyperesthesias, irritability, clonic seizures, CNS depression, dyspnea, defecation, urination, and collapse. These effects are best treated by supportive means as animals generally recover within hours of dosing. An acute levamisole overdose can result in death due to respiratory failure. If respiratory failure occurs, artificial ventilation with oxygen should be instituted until recovery occurs. Cardiac arrhythmias may also be seen. If the ingestion was oral, GI decontamination protocols and/or administration of charcoal with cathartics may be indicated.

In pet birds (eg, cockatoos, budgerigars, Mynah birds, parrots), 40 mg/kg has been reported as a toxic dose when administered SC. IM injections may cause more severe toxicity. Depression, ataxia, leg and wing paralysis, mydriasis, regurgitation, and death may be seen after a toxic dose in birds.

In humans, the active metabolite of levamisole, aminorex, has amphetamine-like effects. Dosages of 50 – 200 mg daily can cause agranulocytosis.[7]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving levamisole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Albendazole and Ivermectin**: After intraruminal combined administration of albenazole, ivermectin, and levamisole to parasitized lambs, reduced albendazole-sulfoxide and enhanced ivermectin systemic exposure were noted.[8]
- **Anticholinesterases** (eg, **neostigmine, organophosphates**): Could theoretically enhance the toxic effects of levamisole; use together with caution
- **Aspirin**: Levamisole may increase salicylate concentrations.
- **Chloramphenicol**: Fatalities have been reported after concomitant levamisole and chloramphenicol administration; avoid using these agents together.
- **Nicotinic Drugs** (eg, **diethylcarbamazine, morantel, pyrantel**): Could theoretically enhance the toxic effects of levamisole; use together with caution
- **Warfarin**: Increased risk for bleeding

Dosages

DOGS:

Adjunctive therapy for systemic lupus erythematosus (extra-label): 2 – 5 mg/kg (maximum of 150 mg/dog; NOT mg/kg) PO every 48 hours in combination with prednisone 0.5 – 1 mg/kg PO every 12 hours. Taper prednisone dose over 1 to 2 months. Continue levamisole for 4 months or longer if a relapse occurs.[9]

HORSES:

Adjunctive treatment for equine protozoal myeloencephalitis (extra-label):

a) Anecdotally, 1 mg/kg PO every 12 hours for the first 2 weeks in conjunction with antiprotozoal treatment and for the first week of each month thereafter[10]
b) 2.2 mg/kg PO every 24 hours for 3 days, then off for 4 days, repeated for a period of 4 to 6 weeks[1]
c) 1 – 2 mg/kg PO daily[11]

CATTLE:

Susceptible nematodes (label dosage; FDA-approved):

a) **Using the 46.8 g powder packet**:
   i. Standard oral drench: Place the contents of one packet in a 1 quart (960 mL; 32 fl oz) container, fill with water, and swirl until dissolved. Administer as a single oral drench dose of 15 mL/90.7 kg (200 lb) body weight, which provides an 8 mg/kg dose.[3]
   ii. Concentrated drench solution (for use with a 20 mL automatic syringe): Place the contents of one packet in a standard household measuring container and add water to the 8 ¾ fl oz (260 mL) level. Swirl until dissolved. Administer as a single oral drench dose of 2 mL/45.4 kg (100 lb) body weight, which provides an 8 mg/kg dose.[3]
b) **Using the 362.7 g bottle**: When ready to use, add water to the powder in the bottle up to the fill line located on the bottle. Swirl to mix thoroughly before using. Administer as a single oral drench dose of 2 mL/45.4 kg (100 lb) body weight, which provides an 8 mg/kg dose.[3]
c) **Using the 544.5 g bottle**: When ready to use, add water to the powder in the bottle up to the 3 L mark. Swirl to mix thoroughly before using. Administer as a single oral drench dose of 2 mL/45.4 kg (100 lb) body weight, which provides an 8 mg/kg dose.[3]

SWINE:

Susceptible nematodes (label dosage; FDA-approved): Reconstitute bottle to 500 mL and agitate thoroughly before using. Add 10 mL of stock solution to 1 gallon water and mix thoroughly. Offer as the sole source of drinking water, resuming use of regular water once all medicated water has been consumed. Allow 1 gallon of medicated water for each 45.4 kg (100 lb) body weight of pigs to be treated.[6]

SHEEP:

Susceptible nematodes (label dosage; FDA-approved):

a) **Using the 46.8 g powder packet**
   i. Standard oral drench: Place the contents of one packet in a 1 gallon (128 fl oz) container, fill with water, and swirl until dissolved. Administer as a single oral drench dose of 15 mL/22.7 kg (50 lb) body weight, which provides an 8 mg/kg dose.
   ii. Concentrated drench solution (for use with a 20 mL automatic syringe): Place the contents of one packet in a standard household measuring container and add water to the 17 ½ fl oz (520 mL) level. Swirl until dissolved. Administer as a single oral drench dose of 2 mL/22.7 kg (50 lb) body weight, which provides an 8 mg/kg dose.

b) **Using the 362.7 g bottle**: When ready to use, add water to the powder in the bottle up to the fill line located on the bottle. Swirl to mix thoroughly before using. Administer as a single oral drench dose of 1 mL/22.7 kg (50 lb) body weight, which provides an 8 mg/kg dose.[3]

c) **Using the 544.5 g bottle**: When ready to use, add water to the powder in the bottle up to the 3 L mark. Swirl to mix thoroughly before using. Administer as a single oral drench dose of 1 mL/22.7 kg (50 lb) body weight, which delivers an 8 mg/kg dose.[3]

GOATS:

Anthelmintic (extra-label): Use 1.5 times the sheep dosage (ie, 12 mg/kg PO once)[12–14]

REPTILES:

Anthelmintic (extra-label):

a) **Nematodes**: 5 – 10 mg/kg PO; repeat in 2 weeks followed by a fecal examination 14 days after the second dose. If the fecal examination is positive, a third dose is given.

b) **Acanthocephalans or pentastomes**: As stated above, but may also be given SC or intracoelomic[15]

Monitoring

- Clinical efficacy (eg, fecal flotation, fecal egg count reduction test)
- Adverse effects and toxicity observation

Client Information

- This medicine can be very toxic if too much is given. Follow directions on the product label unless otherwise directed by your veterinarian. Careful estimation of the body weight of the animal is essential to minimize the chance of overdose or underdose.
- The most common side effects seen in large animal species include foaming at the mouth, salivation, lip licking, and excitement or trembling.
- The most common side effects seen in small animal species include vomiting, enlarged pupils, diarrhea, drooling, and lack of energy. When this medicine is given by mouth to dogs, giving with food may help prevent vomiting.
- Serious side effects can occur. Report any concerns to your veterinarian.
- Avoid skin contact with liquid forms of this medicine, as it can be absorbed through the skin.
- Levamisole is not approved for use in dairy animals of breeding age.

Chemistry/Synonyms

Levamisole is the levo-isomer of dl-tetramisole, and it has a greater safety margin than does the racemic mixture. Levamisole hydrochloride occurs as a white to pale, cream-colored, odorless or nearly odorless crystalline powder. One gram is soluble in 2 mL of water.

Levamisole HCl may also be known as cloridrato de levamizol, ICI-59623, levamisoli hydrochloridum, NSC-177023, R-12564, RP-20605, l-tetramisole hydrochloride, *Amtech®*, *Ascaridil®*, *Decaris®*, *Ergamisol®*, *Immunol®*, *Ketrax®*, *LevaMed®*, *Levasole®*, *Meglum®*, *Prohibit®*, *Solaskil®*, *Vermisol®*, and *Vizole®*.

Storage/Stability

Store levamisole hydrochloride products at room temperature (15°C to 30°C [59°F-86°F]) unless otherwise instructed by the manufacturer; avoid temperatures greater than 40°C (104°F). Store levamisole phosphate injection at temperatures at or below 21°C (70°F); refrigeration is recommended and avoid freezing. Once mixed with water, levamisole drench solution may be stored in closed containers for up to 90 days.[3]

Compatibility/Compounding Considerations

Compounded preparation stability: Levamisole oral solution compounded from the commercially available tablets and active pharmaceutical ingredient powder has been published.[16] Triturating 2500 mg (2.5 g) of levamisole hydrochloride powder with 100 mL sterile water yields a 25 mg/mL levamisole hydrochloride oral solution that retains greater than 97% potency for 90 days when stored at both 4°C (39°F) and 25°C (77°F) and protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ACRI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

NOTE: FDA's Green Book still lists many approved levamisole products, but most are no longer marketed. The following products may be available:

Levamisole Hydrochloride Soluble Drench Powder: 46.8 g packet; 362.7 and 544.5 g bottle. *LevaMed®* (OTC). FDA-approved for use in cattle and sheep. Slaughter withdrawal at label dosages is 48 hours in cattle and 72 in hours sheep. Not indicated for dairy animals of breeding age.

Levamisole Hydrochloride Soluble Powder: 18.15 g bottle; *LevaMed®* Soluble Pig Dewormer (OTC); FDA-approved for use in swine. Slaughter withdrawal at labeled dosages is 72 hours.

HUMAN-LABELED PRODUCTS: NONE

Levetiracetam

(lee-ve-tye-***ra***-see-tam) *Keppra®*
Anticonvulsant

Prescriber Highlights

- ► Levetiracetam is a broad-spectrum anticonvulsant that can be used as adjunct therapy for canine epilepsy or when phenobarbital or bromides are not tolerated. Dogs may become refractory to therapy over time.
- ► In cats, levetiracetam may be used as a second-line drug when phenobarbital alone does not control seizures but can also be tried as sole therapy when phenobarbital is not tolerated.
- ► Appears to be well tolerated; adverse effects may be transient and can include sedation in dogs, and lethargy, decreased appetite, and ataxia in cats
- ► In dogs, phenobarbital may cause significant drug interactions with levetiracetam.
- ► Owner compliance with dosing frequency (every 8 hours) of immediate-release tablets and oral solution may be problematic.
- ► Do not confuse immediate-release and extended-release tablets; use caution when prescribing and dispensing.

Uses/Indications

Levetiracetam can be useful as adjunct therapy to phenobarbital and bromides in patients with canine epilepsy. Convincing evidence for efficacy of levetiracetam monotherapy is lacking.[1–3] Levetiracetam has been shown to be useful in the treatment of status epilepticus and acute repetitive seizures (ie, cluster seizures) in dogs.[4] It has been used at home for oral pulse therapy to abort seizure activity,[5] and SC administration at home may be useful in dogs that develop status epilepticus or acute repetitive seizures that do not always respond sufficiently to benzodiazepine (via rectal and/or intranasal administration).[4] A small open-label study found that the addition of rectal levetiracetam to standard treatment (rectal/IV diazepam and IV phenobarbital) significantly increased response rate for dogs with cluster seizures compared to the standard treatment alone.[6] In addition, in a study, IV levetiracetam was used successfully to treat refractory seizures in a dog that ingested a lethal dose of fluorouracil (5-FU).[7] In one case report, levetiracetam was successfully used to manage a dog with paroxysmal exertion-induced dyskinesia.[8] Another study found levetiracetam to be effective for reactive seizures that were thought to be due to exogenous toxicity.[9] Levetiracetam may have reduced efficacy in dogs over time (ie, "honeymoon effect"), and there have been reports that phenobarbital can significantly affect levetiracetam pharmacokinetics in dogs.[3,10] Lack of efficacy has also been noted when levetiracetam was used as adjunct therapy in dogs with refractory epilepsy.[11]

Levetiracetam appears to be useful as add-on therapy in cats when phenobarbital does not control seizures or as sole therapy in cats that are unable to tolerate phenobarbital.[12] Studies have shown levetiracetam to be more effective than phenobarbital and well tolerated as a monotherapy agent in cats with myoclonic seizures.[13]

Pharmacokinetic data in horses suggest that levetiracetam may be efficacious when given orally.[14–16]

Pharmacology/Actions

The exact mechanism of levetiracetam's antiseizure activity is not well understood. Levetiracetam appears to affect the release of neurotransmitters in the CNS by selective binding to the presynaptic protein SV2A on synaptic vesicles, and it may selectively prevent hypersynchronization of epileptiform burst-firing and propagation of seizure activity.[17] It does not affect normal neuronal excitability.

Pharmacokinetics

In dogs, levetiracetam (immediate-release tablet or oral solution) is rapidly and almost completely absorbed after oral administration. Volume of distribution is 0.5 to 0.7 L/kg.[18–20] Protein binding is minimal, and ≈90% of a dose is renally eliminated.[21] Peak concentration (C_{max}, ≈34 µg/mL; range, 9.2 to 60 µg/mL) occurs 0.6 to 2.2 hours after a single dose of immediate-release tablets, and elimination half-life (T½) is 2.2 to 4.4 hours.[18,22,23] Concurrent phenobarbital reduces C_{max} and T½.[24–26] Repeat oral doses do not appreciably alter pharmacokinetic values.[24,26] In a study, peak concentrations occurred 40 minutes after IM administration; the drug was completely absorbed, and peak concentration was similar to IV administration.[27] SC levetiracetam (60 mg/kg, undiluted) yielded drug concentrations between 65 µg/mL and 114 µg/mL, 15 to 420 minutes after administration.[28] In fasted dogs given an extended-release tablet formulation at 30 mg/kg PO, maximum plasma drug concentration, time to reach maximum plasma concentration, disappearance half-life, and bioavailability were 27 µg/mL, 3.4 hours, 4.4 hours, and 100%, respectively. Pharmacokinetics were similar when dogs were fed, with the exception of the time to reach maximum plasma concentration, which was longer (6.6 hours), and bioavailability, which was greater (126%).[29] Data from different studies suggest that administering extended-release tablets every 12 hours should maintain therapeutic levels in dogs.[22,23,29,30] In a study in dogs, when levetiracetam solution for injection was administered rectally at 40 mg/kg, the maximum serum concentration was 36 µg/mL and time to reach maximum serum concentration was 1.5 to 1.7 hours. Presence of feces may limit absorption.[31,32] Bioequivalence of generic extended-release tablets to *Keppra XR®* has been demonstrated in dogs.[22]

In cats, oral bioavailability of immediate-release levetiracetam is ≈100%, and elimination half-life is ≈3 hours. The authors concluded that 20 mg/kg administered IV or PO every 8 hours should be adequate in most cats.[33] Similar pharmacokinetic values were reported in cats concurrently receiving phenobarbital.[12] In healthy cats receiving a single 500 mg tablet dose of extended-release levetiracetam, serum concentrations remained above 5 µg/mL for 21 hours, with an average peak concentration of ≈90 µg/mL.[34] CSF concentrations appear to parallel serum concentrations, suggesting adequate CSF concentrations are attained after oral administration in cats.[35] With daily administration of extended-release levetiracetam tablets for 7 days, median peak and trough serum concentrations were 92.3 µg/mL and 7 µg/mL, respectively. In a small pilot study, a compounded liposomal levetiracetam cream was administered to the inner pinna at 60 mg/kg every 8 hours for 6 days, which resulted in serum concentrations above 5 µg/mL.[36]

In 1- to 10-day-old foals receiving levetiracetam (32 mg/kg PO and IV as single doses), oral absorption was ≈100%. Peak concentration (38.3 µg/mL) occurred after 0.9 hours, and elimination half-life was 7.8 hours.[15] In adult horses, terminal half-life and volume of distribution at steady-state after IV administration of levetiracetam at 20 mg/kg were 6.22 hours and 630 mL/kg, respectively. When immediate-release and extended-release tablets were crushed and administered orally at 30 mg/kg, maximum plasma concentration, terminal half-life, bioavailability, clearance/bioavailability, and time to peak concentration were 50.72 µg/mL and 53.58 µg/mL, 6.38 hours and 7.07 hours, 96% and 98%, 76.8 mL/kg/hour and 76.8 mL/kg/hour, and 0.66 hours and 0.64 hours, respectively.[14,37] No difference was found between these formulations; however, the extended-release tablets were crushed, which may have affected its pharmacokinetic profile. The authors concluded that oral administration of 30 mg/kg of either the regular or extended-release tablets in healthy adult horses is likely to achieve therapeutic concentrations for at least 12 hours.[14] In another study, generic immediate-release levetiracetam tablets administered to healthy adult horses resulted in equivalent

pharmacokinetic parameters as branded levetiracetam.[38] Healthy adult horses receiving levetiracetam 30 mg/kg PO every 12 hours achieved trough levetiracetam CSF and serum concentrations of 33.7 µg/mL and 28.8 µg/mL, respectively, after 4 days.[16]

In humans, levetiracetam is rapidly and nearly completely absorbed after oral administration. Peak levels occur ≈60 minutes after administration. The presence of food in the gut delays the rate but not the extent of drug absorbed, and the drug can be administered regardless of feeding status. Less than 10% of the drug is bound to plasma proteins. Although not extensively metabolized, the drug's acetamide group is enzymatically hydrolyzed to the carboxylic acid metabolite that is apparently not active. Hepatic CYP450 isoenzymes are not involved. In humans, half-life is ≈7 hours and ≈66% of a given dose is excreted unchanged via renal mechanisms, primarily glomerular filtration and active tubular secretion. Clearance can be significantly reduced in patients with impaired renal function.

Contraindications/Precautions/Warnings

Levetiracetam is contraindicated in patients that have previously exhibited hypersensitivity to it or any of its components. Respiratory failure and cardiac arrest were reported in a dog with cluster seizures that received an undiluted levetiracetam injection of 60 mg/kg IV.[39]

Levetiracetam should be used with caution in patients with renal impairment; changes in dose or frequency should be considered. One small retrospective study found that dogs with chronic kidney disease (CKD) had a higher incidence of adverse effects from levetiracetam than dogs without CKD.[40] In humans, renal elimination of levetiracetam correlates with creatinine clearance; total clearance is reduced by 40% in patients with mild renal impairment and up to 60% in patients with severe renal impairment.[17,41]

Anecdotally, it has been reported that extended-release tablets may not fully disintegrate in the canine GI tract. Some neurologists have had experience with this situation and found that these patients still had levetiracetam concentrations within the therapeutic range. The presumption amongst many neurologists is that what is found in the stool is the matrix of the pill and that the medication is still being absorbed.[42]

Discontinuation should be done gradually to decrease risk for withdrawal seizures.

LevETIRAcetam should not be confused with levOCARNitine or levOFLOXacin. Do not confuse immediate-release tablets with extended-release tablets; use caution when prescribing or dispensing. Immediate-release prescriptions can be written as "levetiracetam" or "levetiracetam IR" (immediate-release). "Levetiracetam ER" or "Levetiracetam XR" refers to extended-release tablets.

Adverse Effects

Levetiracetam appears to be well tolerated in dogs and cats. The most common adverse effects reported include sedation and ataxia in dogs and reduced appetite, ataxia, hypersalivation, and lethargy in cats. These effects may be transient. Changes in behavior and GI effects (eg, vomiting) can occur.[43] Transient head-lowering has been observed in horses.[14]

In a study, IM administration produced less muscle inflammation in dogs than the saline control solution.[27] In another study, SC administration of undiluted levetiracetam solution for injection was well-tolerated, but the sample size was small (n = 4 healthy dogs).[28]

A systematic review and meta-analysis of adverse effects of antiepileptic drugs in dogs showed a strong level of evidence for levetiracetam's safety profile as monotherapy and adjunct therapy. Only type I adverse effects (ie, dose-dependent, predictable) were reported and these included vomiting and sedation, followed by ataxia and hyperactivity. Less common adverse effects included anorexia, polyphagia, and polydipsia, followed by polyuria, diarrhea, aggression, disobedience, and attention-seeking.[44]

In humans, adverse effects include sedation, asthenia, anxiety, and headache. Neuropsychiatric adverse effects (eg, aggression, agitation, irritability, depression) have also been reported. It is recommended to withdraw the drug slowly to prevent withdrawal seizures.

Reproductive/Nursing Safety

In pregnant dogs or cats, levetiracetam should be used with caution. At high dosages, levetiracetam has caused increased embryofetal mortality in rabbits and rats. At doses equivalent to the maximum human therapeutic dose, levetiracetam has caused minor skeletal abnormalities and retarded offspring growth in rats.[45]

Levetiracetam is excreted into maternal milk, and its safety in nursing offspring is unknown. Levetiracetam should be used with caution in nursing patients.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Levetiracetam is a relatively safe agent. Dogs receiving 1200 mg/kg/day (≈20 times the therapeutic dose) developed only salivation and vomiting.[46] Other clinical signs seen with overdose in dogs include lethargy, hyperthermia, and recumbency. Human patients receiving 6000 mg/kg during drug testing developed only drowsiness.[45] Other effects noted in human overdoses (doses not specified) after the drug was released included depressed levels of consciousness, agitation, aggression, and respiratory depression.

Treatment is supportive based on clinical signs; levetiracetam can be removed with hemodialysis.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving levetiracetam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Carbamazepine**: Concurrent use may result in signs of carbamazepine toxicity (eg, nystagmus, ataxia, dizziness).
- **CNS Depressants** (eg, **antihistamines**, **benzodiazepines, gabapentin, opioids**): May increase risk for CNS depression
- **Methotrexate**: May increase methotrexate concentrations and risk for toxicity
- **Phenobarbital**: In dogs, ongoing (21 days in the study) phenobarbital use significantly increased levetiracetam clearance and reduced half-life; levetiracetam dose adjustments (increases) may be required.[24,25] Pharmacokinetic values of levetiracetam appear unchanged in cats concurrently receiving phenobarbital.[12]

Laboratory Considerations

- No specific laboratory interactions or considerations were noted.

Dosages

DOGS:

Refractory epilepsy (extra-label):

a) Using immediate-release tablets: 20 mg/kg PO every 8 hours,[10] although recommendations up to 30 mg/kg PO every 8 hours have been noted. Because of the drug's safety, doses may be increased (every 1 to 2 weeks; up to 60 mg/kg PO every 8 hours) further until efficacy is achieved, adverse effects become ap-

parent, or drug cost becomes prohibitive. If using as an add-on to phenobarbital therapy, levetiracetam exposure is reduced and half-life may be shortened; levetiracetam dose adjustment (increase) may be necessary.[24,25,47]

b) Using extended-release tablets: Begin with 30 mg/kg PO with or without food every 12 hours. Because of the drug's safety, doses may be increased (up to 60 mg/kg PO every 12 hours) further until efficacy is achieved, adverse effects become apparent, or drug cost becomes prohibitive. Administering every 24 hours may be acceptable in some dogs. Tablets should not be split or crushed. The smallest extended-release tablet is 500 mg, so it cannot be practically administered in small dogs.[22,23,29] Higher doses may be needed if using concurrently with phenobarbital.[24]

Prevention of seizures following surgical correction of portosystemic shunt (extra-label): 20 mg/kg PO every 8 hours for a minimum of 24 hours prior to surgery may decrease the likelihood of seizures after portosystemic shunt ligation,[48] although another study found that perioperative use did not reduce postattenuation neurologic signs or seizures.[49]

Status epilepticus or acute repetitive (cluster) seizures (extra-label):

a) **IV use**: 30 mg/kg or 60 mg/kg IV were considered safe and effective in 56% of treated dogs.[4] In healthy dogs from a single-dose pharmacokinetic study, a 60 mg/kg IV bolus dose of levetiracetam was well tolerated and achieved plasma drug concentrations within or above the therapeutic range reported for humans for at least 8 hours after administration.[19] IV doses should be administered over 5 to 15 minutes.

b) **Rectal use**: 40 mg/kg rectally using a 200 mg/mL suspension compounded with levetiracetam powder and sterile water in combination with benzodiazepine and IV phenobarbital.[32] A study in healthy dogs reported that levetiracetam at 40 mg/kg (using commercial levetiracetam 100 mg/mL solution for injection) administered rectally achieved target concentrations in the target range within 10 minutes of administration.[31]

c) **Home administration as pulse therapy for cluster seizures**: 30 mg/kg PO every 8 hours until seizure-free for 24 hours[50]

d) **Home administration in dogs that do not always respond sufficiently to benzodiazepine (rectal and/or intranasal administration)**: 60 mg/kg SC; based on a pilot study in healthy dogs[28]

Reactive seizures (extra-label): From one open-label study, 60 mg/kg IV loading dose followed by maintenance dosage of 20 mg/kg PO every 8 hours until reaching a 6-month seizure-free period. Levetiracetam may then be tapered slowly and discontinued.[9]

CATS:

Epilepsy (extra-label):

a) Based on the drug's pharmacokinetics in cats and the presumed therapeutic levels for the drug, 20 mg/kg IV or PO every 8 hours. Doses up to 40 mg/kg PO every 8 hours may be necessary.[33]

b) As an add-on to phenobarbital treatment: Initially, 20 mg/kg PO every 8 hours. If ineffective, levetiracetam dose should be increased in 20 mg/kg increments.[12,51]

c) Using extended-release tablets: 500 mg/cat (NOT mg/kg) PO once daily[52]

Myoclonic seizures (extra-label): 60 – 75 mg/kg PO divided every 8 hours achieved a reduction greater than or equal to 50% in the number of myoclonic seizure days in 100% of patients.[13]

HORSES:

Anticonvulsant (extra-label): Based on pharmacokinetic studies and presumed therapeutic levels: 30 mg/kg PO every 12 hours using immediate-release tablets.[14,16] Crushing extended-release tablets has yielded similar serum concentrations (see ***Pharmacokinetics***) but may be cost-prohibitive.

Monitoring

- The levetiracetam therapeutic range for animals has not been specifically determined, but it is thought to be similar to humans at 5 – 45 µg/mL. Because the drug appears to be very safe, therapeutic drug monitoring is usually unnecessary but can be considered to establish individual patient variation in drug absorption or half-life.[53]
- Owners should be encouraged to keep a record of seizure activity (eg, seizure frequency, severity, and duration; severity and duration of any postictal signs) to document efficacy and report any potential levetiracetam-associated adverse effects.

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give the medicine with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Give this medicine as directed by your veterinarian.
- Lethargy (ie, tiredness, lack of energy) and reduced appetite are the most common side effects.
- Do not crush or allow your pet to chew the extended-release tablets. The matrix of the extended-release tablets may not fully disintegrate in the GI tract and is sometimes seen in the dog's feces. However, the medication is still being absorbed.
- Do not discontinue therapy without talking with your veterinarian first as withdrawal seizures or severe neurologic side effects may result.

Chemistry/Synonyms

Levetiracetam, a pyrrolidone-derivative antiepileptic agent, occurs as an odorless, bitter-tasting, white to off-white crystalline powder. It is very soluble in water and soluble in ethanol. It is a chiral molecule with one asymmetric carbon atom. Levetiracetam is not related chemically to other antiseizure medications.

Levetiracetam may also be known as S-Etiracetam, UCB-22059, UCB-L059, and *Keppra®*.

Storage/Stability

Levetiracetam tablets and oral solution should be stored at 25°C (77°F); excursions between 15°C and 30°C (59°F-86°F) are permitted.

Compatibility/Compounding Considerations

A levetiracetam 50-mg/mL oral suspension prepared with immediate-release levetiracetam tablets crushed and suspended in *Ora-Blend®* was determined to be stable when stored at either 4°C (39.2°F) or 25°C (77°F) in plastic prescription bottles for 91 days.[54]

Extended-release tablets should be taken whole; do not split or crush tablets or allow animal to chew it. In a study, a 200 mg/mL rectal suspension was prepared by mixing levetiracetam powder with sterile water; a new suspension was prepared every month, and it was stored at room temperature and away from direct sunlight; analysis of potency and stability was not reported.[32]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Levetiracetam Oral Tablets (film-coated, scored): 250 mg, 500 mg, 750 mg, and 1000 mg; *Keppra®*, generic; (Rx)

Levetiracetam Extended-Release Oral Tablets (film-coated): 500 mg and 750 mg; *Keppra XR®*, generic; (Rx). Do not crush or split.

Levetiracetam Oral Solution: 100 mg/mL in 473 mL, 480 mL, and

500 mL; *Keppra*®, generic; (Rx). May also contain acesulfame K, ammonium glycyrrhizinate, or maltitol

Levetiracetam Concentrate for Injection: 100 mg/mL in 5 mL single-use vials, 5 mg/mL in 100 mL, 15 mg/mL in 100 mL, and 10 mg/mL in 100 mL; *Keppra*®, generic; (Rx)

Levothyroxine

(lee-voe-thye-***rox***-een)

Thyro-Tabs® Canine, Leventa®, Synthroid®

Thyroid Hormone

Prescriber Highlights

- ► Used for the treatment of hypothyroidism in all species
- ► Contraindications include thyrotoxicosis and untreated adrenal insufficiency.
- ► Use with caution in geriatric animals and those with concurrent hypoadrenocorticism (treated), cardiac disease, and diabetes mellitus.
- ► Adverse effects are associated with iatrogenic hyperthyroidism (eg, tachycardia, polyphagia, polyuria/polydipsia, excitability, nervousness, and excessive panting); some cats may appear apathetic.
- ► Review drug–drug and drug–laboratory interactions prior to prescribing.
- ► Should not be confused with liothyronine or desiccated thyroid

Uses/Indications

Levothyroxine is indicated for the treatment of hypothyroidism in all species. In horses, it has been used as an adjunct therapy to treat equine metabolic syndrome (EMS).[1]

Pharmacology/Actions

Levothyroxine is a synthetic form of thyroxine (T_4), which is the principal hormone released by the thyroid. Levothyroxine is mainly converted (deiodinated) to triiodothyronine (T_3) peripherally in the human body. In humans, T_3 is the primary hormone responsible for activity. Approximately 80% of T_3 found in the peripheral tissues is derived from T_4.

Thyroid hormones affect the rate of many physiologic processes, including increasing fat, protein, and carbohydrate metabolism, protein synthesis, gluconeogenesis, cellular metabolism, oxygen consumption, body temperature, heart rate and cardiac output, blood volume, enzyme system activity, and growth and maturity. Thyroid hormones also promote mobilization and utilization of glycogen stores. The thyroid hormone is particularly important for adequate development of the CNS. Although the exact mechanisms of how thyroid hormones exert their effects are not fully understood, it is known that thyroid hormones (primarily triiodothyronine) act at the cellular level by controlling DNA transcription and protein synthesis.

Pharmacokinetics

In dogs, orally administered levothyroxine has relatively low bioavailability (ie, 10% to 20%) and short elimination half-life as compared with humans. Peak serum concentrations reportedly occur 4 to 6 hours after oral administration and the serum half-life is ≈10 to 14 hours. However, there can be wide interpatient variability in pharmacokinetic parameters. Elimination in the feces may account for 50% of a dose.

An oral liquid formulated for dogs (*Leventa*®, not approved in the United States) appears to be better absorbed than tablet formulations. When comparing oral tablets given at 200 µg twice daily with oral liquid given at 200 µg once daily, the relative bioavailability of the liquid was 206% (median) that of the tablets.[2]

Studies in dogs have shown that levothyroxine absorption is affected by delivery with food; administration with food causes less medication to be absorbed and delays time to full absorption.[2] Because absorption of levothyroxine is affected by food at different rates and the levothyroxine dose is titrated individually to each animal, it is important that owners give this medication to their animal at the same time each day, in a consistent manner relative to food, and that the same method of delivery is used each time.

Contraindications/Precautions/Warnings

Levothyroxine (and other replacement thyroid hormones) are contraindicated in animals with thyrotoxicosis or untreated adrenal insufficiency. It should be used with caution, and at a lower initial dosage, in animals with concurrent hypoadrenocorticism (treated), cardiac disease, diabetes mellitus, or in senior animals. For these animals, the recommendation for reduction in the initial levothyroxine dose varies and ranges from 25% to 75% of the usual dose. Because levothyroxine can cause an increased basal metabolic rate that may exacerbate electrolyte disturbances, dogs with hypoadrenocorticism should receive replacement mineralocorticoid and glucocorticoid therapy before receiving levothyroxine.

Do not confuse levothyroxine with liothyronine or desiccated thyroid.

Adverse Effects

The most commonly reported adverse effects include anorexia, dermatitis, vomiting, otitis externa, lethargy, polydipsia, diarrhea, leukocytosis, pruritus, tachypnea, polyuria, hyperactivity, and seborrhea.[3] Case reports of rare incidences of fixed drug eruptions and erythema multiforme have been reported in dogs treated with levothyroxine.

Hypersensitivity to 2 inactive ingredients, magnesium stearate and polyvinylpyrrolidone, found in certain levothyroxine products has been observed in dogs. Reactions include cutaneous reactions that resolve after medication has been discontinued. Dogs that experienced this reaction were then treated with levothyroxine products that did not contain magnesium stearate or polyvinylpyrrolidone and tolerated the medication well.[4]

Reproductive/Nursing Safety

Levothyroxine is considered safe for use during pregnancy, as thyroid hormone is essential for fetal development.[5] In humans, levothyroxine is considered the drug of choice for hypothyroidism during pregnancy.

Levothyroxine requirements may increase during pregnancy. In humans, increasing levothyroxine dose on confirmation of pregnancy is recommended.[6] In hypothyroid bitches, one small study found that standard levothyroxine supplementation was adequate to maintain a euthyroid state during pregnancy[7]; however, thyroid status should be monitored regularly throughout pregnancy and in the postparturient period.

Minimal amounts of thyroid hormones are excreted in milk and should not affect nursing offspring. The World Health Organization (WHO) considers levothyroxine to be compatible with breastfeeding.[8]

Overdose/Acute Toxicity

Long-term overdoses produce signs of hyperthyroidism, including tachycardia, polyphagia, chronic vomiting and diarrhea, weight loss, polyuria/polydipsia, excitability, nervousness, and excessive panting. The dose should be reduced and/or temporarily withheld until signs subside. Some cats (≈10%) may exhibit signs of apathy (eg, listlessness, anorexia).[9] Toxicosis occurred in a dog that routinely consumed the feces of a housemate receiving levothyroxine.

A single, acute overdose in small animals is less likely to cause severe thyrotoxicosis as compared with long-term overdoses. Vomiting,

diarrhea, hyperactivity to lethargy, hypertension, tachycardia, tachypnea, dyspnea, and abnormal pupillary light reflexes may be noted in dogs and cats 1 to 9 hours after ingestion. If ingestion occurred within 2 hours, treatment to reduce absorption of the drug should be accomplished using standard protocols (eg, emetics, cathartics, charcoal) unless contraindicated by the animal's condition. Treatment is supportive based on clinical signs. Oxygen, artificial ventilation, cardiac glycosides, beta-blockers (eg, propranolol), fluids, dextrose, and antipyretic agents have all been suggested if necessary. One case of a healthy dog that ingested up to 10 g/kg was managed with gut decontamination, and the dog had normal T_3 concentrations 6 days postingestion and normal T_4 concentrations after 36 days.[10]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving levothyroxine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Amiodarone**: May decrease the metabolism of T_4 to T_3
- **Antacids, Oral** (eg, **aluminum, calcium,** or **magnesium salts**): May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Antidiabetic Agents** (eg, **insulin, oral agents**): Levothyroxine may increase requirements for insulin or oral agents.
- **Antithyroid Agents** (eg, **carbimazole, methimazole**): Decreased conversion of T_4 to T_3
- **Cholestyramine**: May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Corticosteroids, High-Dose** (eg, **dexamethasone, fludrocortisone, prednis(ol)one**): Decreased conversion of T_4 to T_3
- **Digoxin**: Potential for reduced digoxin concentrations and/or therapeutic response
- **Estriol**: May decrease serum free thyroxine concentration
- **Ferrous Sulfate**: May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Fiber Supplements** (eg, **psyllium), High Fiber Diet**: May reduce levothyroxine absorption
- **Ketamine**: May cause tachycardia and hypertension
- **Lanthanum**: May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Phenobarbital**: Possible increased metabolism of thyroxine; dosage adjustments may be needed
- **Proton Pump Inhibitors** (**PPIs;** eg, **omeprazole, pantoprazole**): Reduced gastric acid may reduce levothyroxine absorption.
- **Rifampin**: Possible increased clearance of thyroxine; dosage adjustments may be needed.
- **Sertraline**: May increase levothyroxine requirements; likely applies to other SSRIs
- **Sevelamer**: May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Sodium Polystyrene Sulfonate**: May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Sucralfate**: May reduce levothyroxine absorption; doses should be separated by 4 hours
- **Sympathomimetics** (eg, **epinephrine**, **norepinephrine**): Levothyroxine can potentiate effects.
- **Theophylline, Aminophylline**: Levothyroxine may decrease theophylline concentration.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Increased risk for CNS stimulation and cardiac arrhythmias
- **Warfarin**: Thyroid hormones increase the catabolism of vitamin K-dependent clotting factors that may increase the anticoagulation effects in animals on warfarin.

Laboratory Considerations

- **Renal function tests**: Hypothyroid dogs can have a decreased glomerular filtration rate (GFR); restoration to a euthyroid state can increase GFR and reduce serum creatinine concentrations.

The following drugs may have effects on thyroid function tests; results should be evaluated accordingly.

- **Effects on serum total T_4 (TT_4)**: *Decreases* may be caused by aminoglutethimide, anabolic steroids/androgens, antithyroid drugs (eg, propylthiouracil [PTU], carbimazole, methimazole), asparaginase, barbiturates, corticosteroids, danazol, diazepam, heparin, methadone, mitotane, nitroprusside, phenylbutazone, phenytoin, salicylates (large doses), sulfonamides, and sulfonylureas; *increases* may be caused by estrogens (**NOTE**: Estrogens may have no effect on canine T_3 or T_4 concentrations), fluorouracil, insulin, and propranolol.
- **Effects on serum total T_3**: *Decreases* may be caused by antithyroid drugs (eg, PTU, carbimazole, methimazole), barbiturates, corticosteroids, heparin, propranolol, salicylates (large doses), and sulfonamides; *increases* may be caused by estrogens, fluorouracil, and thiazides.
- **Effects on T_3 uptake resin**: *Decreases* may be caused by antithyroid drugs (eg, PTU, carbimazole, methimazole), estrogens, and fluorouracil; *increases* may be caused by anabolic steroids/androgens, asparaginase, corticosteroids, danazol, heparin, phenylbutazone, and salicylates (large doses).
- **Effects on serum TSH**: *Decreases* may be caused by corticosteroids, danazol; *increases* may be caused by aminoglutethimide, antithyroid drugs (eg, PTU, carbimazole, methimazole), sulfonamides, and toceranib.[11]
- **Effects on serum free T_4**: *Decreases* may be caused by antithyroid drugs (eg, PTU, methimazole), barbiturates, corticosteroids, and NSAIDs; *increases* may be caused by furosemide and heparin.

Dosages

DOGS:

Hypothyroidism:

Oral therapy:

a) **Replacement therapy for diminished thyroid function** (label dosage; FDA-approved): The initial recommended daily dose is 0.022 mg/kg (22 µg/kg) PO in single or divided doses. The dosage is then adjusted by monitoring serum TT_4 concentrations 4 to 6 hours after a dose is given, every 4 to 8 weeks until an adequate maintenance dose is established. In field studies, the majority of dogs required at least one dosage adjustment, and most dogs were maintained on an oral dosage of 0.018 – 0.026 mg/kg/day (18 – 26 µg/kg/day). Administer consistently, with or without food.[3]

b) Oral tablets (extra-label): **NOTE**: Initial dosages vary. There is inadequate published evidence or general consensus supporting one recommendation over another. Initial dosages of 0.01 – 0.02 mg/kg (10 – 20 µg/kg) PO every 12 to 24 hours are typical. A maximum initial dosage of 0.8 mg/dog (NOT mg/kg) every 12 hours is often recommended. Lower doses (eg, 25% reduction) are recommended in dogs with certain concurrent conditions (see ***Contraindications/Precautions/***

Warnings). Average maintenance dosage was ≈0.017 mg/kg (≈17 µg/kg) PO every 12 or 24 hours.[12] If it is not possible to give on an empty stomach, give with consistent timing with regard to food intake.

c) Oral solution (extra-label): 0.02 mg/kg (20 µg/kg) PO every 24 hours resulted in euthyroid status in ≈80% to 90% of dogs[13,14]

Myxedema crisis (extra-label): 0.001 – 0.009 mg/kg (1 – 9 µg/kg) IV[15]; median dosage was 0.005 mg/kg (5 µg/kg) IV every 12 hours. **NOTE**: In humans, it is recommended to administer doses no faster than 0.1 mg/minute (100 µg/minute) during crises. Consider giving a lower dose in dogs with underlying heart disease or heart failure. If administration of parenteral levothyroxine is not possible, can attempt to give oral solution or crushed/slurried tablets via nasoesophageal or orogastric tube. Begin PO therapy after the animal is stabilized and can swallow.[16,17]

CATS:

Hypothyroidism (extra-label): 0.05 – 0.15 mg/cat (50 – 150 µg/cat; NOT mg/kg or µg/kg) PO once daily.[18,19] The dosage is then adjusted in 50% increments based on serum TT_4 and TSH concentrations every 4 to 8 weeks until an adequate maintenance dose is established.

Post-antithyroid medication, thyroidectomy, or radioiodine treatment (extra-label): Cats with hyperthyroidism and chronic kidney disease (IRIS stages 2 and 3) treated with radioiodine that received levothyroxine 0.1 mg/cat (100 µg/cat; NOT mg/kg or µg/kg) PO once daily had significantly lower increases in serum creatinine and BUN over the next 12 months than nontreated cats.[20]

HORSES:

Correction of conditions associated with low circulating thyroid hormone | Hypothyroidism (label dosage; NOT FDA-approved):

a) 0.01– 0.06 mg/kg (10 – 60 µg/kg) PO once daily or divided[21]; adjust dosage to maintain thyroid hormone concentrations in the normal range

b) 0.02 mg/kg (20 µg/kg) PO once daily has been recommended as a starting dose, but 0.05 – 0.1 mg/kg (50 – 100 µg/kg) PO once daily may be well tolerated.[22] Horses were administered levothyroxine in a small meal of grain, which may have affected absorption. Dose may vary based on whether the drug is given to fasted horses or whether it is fed with a meal. Adjust dosage to maintain thyroid hormone concentrations in the normal range.

Adjunctive treatment for equine metabolic syndrome (EMS) (extra-label): High doses of levothyroxine can be administered to induce weight loss in horses with EMS. Recommended dosage is 0.1 mg/kg (100 µg/kg) PO once daily for 3 to 6 months.[23] In horses that weigh 450 to 525 kg (992 to 1157 lb), it is recommended that the dose be rounded to 48 mg/horse/day (NOT mg/kg). A further increase in dose by 50% (to 0.15 mg/kg [150 µg/kg]) may be contemplated if there has been negligible impact on body condition after 3 months. When target body condition has been achieved, the dose is decreased to 0.05 mg/kg (50 µg/kg) for 2 weeks and then 0.025 mg/kg (25 µg/kg) for an additional 2 weeks before withdrawal to allow restoration of the suppressed thyroid axis. This therapy is used in combination with daily calorie restrictions and exercise. Levothyroxine has been shown to cause hyperphagia in horses, so open pasture grazing should be avoided.[23,24]

BIRDS:

Hypothyroidism (extra-label): One 0.1 mg (100 µg) tablet in 30 – 120 mL of water daily; stir water and offer for 15 minutes and remove. Use high dose for budgerigars and low dose for water drinkers.[25]

REPTILES:

Hypothyroidism in tortoises (extra-label): 0.02 mg/kg (20 µg/kg) PO every other day[26]

Monitoring

Levothyroxine monitoring in dogs varies but is generally done 1 to 2 months after initiation of therapy or dose changes, or as needed based on clinical signs. Dose adjustments should be based on both clinical response and thyroid concentrations. Once a therapeutic dose is established, consider monitoring 1 to 2 times per year. The following are general recommendations:

- **Clinical response**: The goal of therapy is to have resolution of clinical signs caused by hypothyroidism. Improvement in activity should be evident within the first 1 to 2 weeks of treatment; weight loss should be evident within 8 weeks. Achievement of a normal hair coat may take several months, and the coat may initially appear worse as telogen hairs are shed. Neurologic deficits improve rapidly after treatment, but complete resolution may take 8 to 12 weeks.[18]
- **Serum TT_4**: A minimum of 6 to 8 weeks should pass after starting therapy or changing the dosage before measuring TT_4. Peak serum TT_4 should be measured 4 to 6 hours after dose administration and should be within the upper half of the reference range.[18] Concentrations slightly above reference range are acceptable in the absence of adverse effects; concentrations slightly below reference range are acceptable if clinical response is adequate and serum TSH is within reference range.
- **Serum TSH**: May be useful if TSH was abnormal prior to therapy, or if TT_4 concentrations are out of range. Concentrations are not dependent on the timing of sampling relative to the timing of dose administration.[18]
- **Medication regimen**: If concentrations are unexpectedly out of range, consider asking owner about administration patterns (eg, missed doses), if the brand of levothyroxine was changed, whether new medications were started or previous medications were stopped, and/or levothyroxine expiration date.

Client Information

- Dogs require a higher dose of thyroid hormone than humans. Cats may require a similar dose as an adult human.
- Side effects most often occur when too much of the medicine is given. Dogs may have a fast or racing heart rate; vomiting; diarrhea; increased appetite, thirst, and urination; excitability/nervousness; and panting. Cats may appear withdrawn or apathetic (uncaring).
- This medicine should ideally be given without food and must always be given the same way. It is important to follow your veterinarian's directions.
- The animal should have improved activity within the first 1 to 2 weeks of treatment. Weight loss should start to occur within 8 weeks of starting therapy. The hair coat may initially appear worse but should be normal in several months. Neurologic signs improve rapidly after treatment, but complete resolution may take 8 to 12 weeks.
- Your veterinarian will need to monitor your animal closely while it is taking this medicine. Do not miss these important follow-up visits.

Chemistry/Synonyms

Levothyroxine sodium is prepared synthetically for commercial use and is the levo isomer of thyroxine that is the primary secretion of the thyroid gland. It occurs as an odorless, light yellow to buff-colored, tasteless, hygroscopic powder that is very slightly soluble in water and slightly soluble in alcohol. The commercially available powders for injection also contain mannitol.

100 µg of levothyroxine is approximately equivalent to 65 mg (1 grain) of desiccated thyroid.

Levothyroxine sodium may also be known as T_4, T_4 thyroxine so-

dium, levothyroxin natrium, levothyroxinum natricum, 3,5,3',5'-tetra-iodo-L-thyronine sodium, thyroxine sodium, L-thyroxine sodium, thyroxinum natricum, tirossina, and tiroxina sodica. Many trade names are available in other countries, and had been available in the United States until 2016, when some products were removed from the market after the FDA issued warning letters to manufacturers of unapproved products, including *Thyforon®*, *Thyrosyn®*, *Soloxine®*, *Levocrine®*, *Thyromed®*, *Thyroid Chewable Tablets®*, *Thyrokare®*, *Thyroxine L®*, *Leventa®*, *Thyrozine®*, *Nutrived®*, *Levoxine®*, *Thyro-Tabs® Canine*, and *Thyro-L®*.

Storage/Stability

Levothyroxine is unstable when exposed to light, heat, and moisture. Levothyroxine sodium tablets should be stored in tight containers protected from light and moisture at a controlled room temperature of 20°C to 25°C (68°F-77°F), with excursions allowed between 15°C to 30°C (59°F-86°F). The injectable product should be stored protected from light at 20°C to 25°C (68°F-77°F) and reconstituted immediately before use; unused injection should be discarded after reconstituting. Stored levothyroxine oral solutions (not available in the United States) should be refrigerated (2°C-8°C [36°F-46°F]); unused solution should be discarded 6 months after first opening.

Levothyroxine sodium is reportedly unstable in aqueous solutions. If using a commercial liquid preparation, it is suggested to obtain validated stability data for the product.

Compatibility/Compounding Considerations

Levothyroxine sodium injection should **NOT** be mixed with other drugs or IV fluids.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Levothyroxine Sodium Tablets, USP: 0.1 mg, 0.2 mg, 0.3 mg, 0.4 mg, 0.5 mg, 0.6 mg, 0.7 mg, 0.8 mg, and 1 mg; *Thyro-Tabs Canine®*; (Rx). Approved for use in dogs. NADA# 141-448. Unapproved products were removed from the market subsequent to January 2016 FDA warning letter.

Levothyroxine Sodium Powder (Veterinary): 0.22% (1 g of T_4 in 454 g of powder): One level teaspoonful contains 12 mg of T_4. Available in 0.45 kg (1 lb) and 4.5 kg (10 lb) containers; many trade name products may be available and include *Thyrozine Powder®*, *Levoxine® Powder*; *Thyro-L®*, *Thyrosyn Powder®*, *Thyrokare® Powder*; (Rx). Labeled for use in horses. **NOTE**: These products are not FDA-approved.

Levothyroxine Sodium Oral Solution (not available in the United States) 1 mg/mL (1000 µg/mL) in 30 mL bottles; *Leventa®*; (POM-V). Contains ≈50% ethanol.

HUMAN-LABELED PRODUCTS:

Levothyroxine Sodium Tablets: 0.025 mg (25 µg), 0.05 mg (50 µg), 0.075 mg (75 µg), 0.088 mg (88 µg), 0.1 mg (100 µg), 0.112 mg (112 µg), 0.125 mg (125 µg), 0.137 mg (137 µg), 0.15 mg (150 µg), 0.175 mg (175 µg), 0.2 mg (200 µg), and 0.3 mg (300 µg); *Synthroid®*, *Levoxyl®*, *Levothroid®*, *Unithroid®*, generic; (Rx)

Levothyroxine Sodium Liquid-filled Oral Capsules: 0.013 mg (13 µg), 0.025 mg (25 µg), 0.05 mg (50 µg), 0.075 mg (75 µg), 0.088 mg (88 µg), 0.1 mg (100 µg), 0.112 mg (112 µg), 0.125 mg (125 µg), 0.137 mg (137 µg), 0.15 mg (150 µg), and 0.2 mg (200 µg); *Tirosint®*, generic; (Rx)

Levothyroxine Sodium Oral Solution (per mL): 0.013 mg (13 µg), 0.025 mg (25 µg), 0.0375 mg (37.5 µg), 0.044 mg (44 µg), 0.05 mg (50 µg), 0.0625 mg (62.5 µg), 0.075 mg (75 µg), 0.088 mg (88 µg), 0.1 mg (100 µg), 0.112 mg (112 µg), 0.125 mg (125 µg), 0.137 mg (137 µg), and 0.15 mg (150 µg), 0.175 mg (175 µg) and 0.2 mg (200 µg) in 1 mL ampules; *Tirosint®-Sol*; (Rx)

Levothyroxine Sodium Oral Solution: 20 µg/mL in 100 mL bottles; *Thyquidity®*; (Rx)

Levothyroxine Powder for Injection lyophilized: 0.1 mg (100 µg), 0.2 mg (200 µg), and 0.5 mg (500 µg) in 5 mL vials; generic; (Rx)

Levothyroxine Solution for Injection: 20 µg/mL, 40 µg/mL, 100 µg/mL in 5 mL vials; generic; (Rx)

Levothyroxine tablet combinations with liothyronine (T_3) are also available.

Lidocaine, Local Anesthetic

Lignocaine

(***lye***-doe-kane***)*** *Xylocaine®*

Local Anesthetic

This monograph discusses the use of lidocaine for local anesthesia only. For information regarding lidocaine's use as an antiarrhythmic, systemic analgesic, and prokinetic, please refer to ***Lidocaine, Systemic****.*

Prescriber Highlights

- ► Local anesthetic with a quick onset (5 minutes) and short duration of action (1 hour)
- ► Indicated for infiltration, nerve block, and epidural anesthesia in dogs, cats, cattle, and horses
- ► Local anesthetics are absorbed from the site of administration; significant systemic absorption or unintended systemic administration can lead to severe CNS and cardiac adverse effects, including death.
- ► Cats appear to be more sensitive to the adverse effects of lidocaine.
- ► Adverse effects are unlikely when the correct administration technique is used. Clinicians should be knowledgeable in the diagnosis and management of local anesthetic toxicity, and resources for treating acute emergencies must be readily available.

Uses/Indications

Lidocaine is indicated for epidural, nerve block, and infiltration anesthesia in dogs, cats, cattle, and horses. It is also used IV for systemic analgesia and to treat ventricular arrhythmias (see ***Lidocaine, Systemic***). Local analgesia can have a MAC-sparing effect on inhalant anesthesia and leads to better postoperative recovery.[1-6]

Topical application of lidocaine to the mucosa of the laryngeal cartilages of dogs and cats reduces cough response on intubation[7-9]; it is likely that this use is also applicable to other species. Fentanyl IV also reduces coughing in dogs,[10] and lidocaine may not be needed when fentanyl is included in the anesthetic plan in this species.

Topical application of ophthalmic lidocaine formulations to the eye reduces corneal sensitivity in dogs and horses.[11,12]

Some clinicians prefer a combination of lidocaine (faster onset) and bupivacaine (longer duration) but studies in a variety of species suggest the onset of effect is similar to that of either lidocaine or bupivacaine alone[13-16] and the duration of analgesia is shorter than bupivacaine alone (but longer than lidocaine alone).[13,15,17-20] To achieve a faster onset but longer duration nerve block, use only lidocaine prior to the procedure and repeat the block at the end of the procedure using only bupivacaine.

An extensive description of the most common local blocks and epidural/spinal injection in small animals can be found in other reference texts.[21-24]

Pharmacology/Actions

Local anesthetics block sodium ion channels on the nerve cell membrane, thereby altering electrical excitability, depolarization, and action potential propagation. They block the generation and conduction of impulses in motor, sensory, and autonomic nerve fibers around the site of application. Nerve fiber diameter, conduction velocity, and myelination determine loss of nerve function. Clinically, the progressive loss of nerve function occurs in the following order: pain, temperature, touch, proprioception, and skeletal muscle tone. Anesthetic effect is lost in reverse order.

Lidocaine as a sole agent (without adjuvants) produces local anesthesia typically within 3 to 5 minutes after administration and persists for ≈1 hour. Compared to bupivacaine, lidocaine has a faster onset and shorter duration of action.

Pharmacokinetics

Local anesthetics are absorbed from their site of administration into the systemic circulation. The rate and extent of systemic absorption increases with the dose and volume given,[25] repeated administration, administration in the head and neck region, and administration into highly vascularized sites.

In dogs receiving lidocaine 5 – 10 mg/kg administered intra-articularly, peak serum concentrations of 0.5 to 3 µg/mL occurred after 30 minutes. Elimination half-life was ≈73 minutes.[26] In a separate study by the same authors with similar methodology, addition of epinephrine 10 µg/mL solution to lidocaine 2%, a lower peak concentration occurred after 70 minutes, with an elimination half-life of ≈2.6 hours.[27] Although not the same as tissue infiltration, bioavailability after IM administration to dogs was 92% and half-life was ≈1 hour.[28]

Epinephrine may be added to lidocaine formulations at a very low concentration (5 or 10 µg/mL) to cause vasoconstriction at the site of administration, thereby reducing the rate of systemic absorption. Epinephrine increases the speed of analgesia onset, prolongs the duration of action at the site of administration, and minimizes systemic lidocaine toxicity.

Sodium bicarbonate added to lidocaine injection will alkalinize the solution, which increases the non-ionized fraction of the drug. This shortens the onset and increases the duration of action of the solution.

Opioids (eg, buprenorphine) and alpha-2 adrenergic agonists (eg, dexmedetomidine) can also be added to lidocaine to enhance duration and sensory analgesia of the local block.

Refer to the ***Lidocaine, Systemic*** monograph for further pharmacokinetic information on systemic administration.

Contraindications/Precautions/Warnings

Lidocaine is contraindicated in patients with a known hypersensitivity to it or to another amide-type local anesthetic agent. Although risk is low with correct administration technique, use with caution in patients with hepatic or renal disease, atrioventricular (AV) block, or other conduction abnormalities, or impaired cardiovascular function as inadvertent systemic administration may cause adverse effects. Chondrolysis has occurred in humans receiving intra-articular infusions of local anesthetics, and intra-articular lidocaine has demonstrated chondrotoxicity in horses.[29,30]

Injections should be made aseptically, aspirating frequently and relocating the needle if blood is aspirated. Check anesthetic depth before beginning manipulations.

Cats tend to be more sensitive to the adverse effects of lidocaine if inadvertently given systemically; use with caution.

Lidocaine may be included in some IM injections to reduce pain upon administration; verify compatibility prior to mixing.

In humans, epidural use should be undertaken with extreme caution in patients with severe CNS disease.[31] Epidural injections should be administered incrementally, with aspiration prior to injection. Local anesthetics with preservatives should not be used for epidural or caudal anesthesia.

Lidocaine formulations that contain epinephrine should be used with caution, if at all, in patients with cardiovascular disease or hyperthyroidism, or for anesthesia of the digits, ears, nose, or penis. Avoid lidocaine/epinephrine when nerve integrity or collateral circulation is compromised as it causes intense vasoconstriction and diminished blood flow; ischemic injury could result.

Adverse Effects

Local anesthetics are generally well tolerated when administered correctly. The most common adverse effects reported after local administration are dose-related and mild. CNS signs include drowsiness, depression, ataxia, and muscle tremors. Nausea and vomiting may occur but are usually transient. Adverse effects are related to high plasma concentrations (greater than or equal to 6 µg/mL), which may result from the dose or lidocaine concentration used, rapid absorption from the injection site, and/or unintentional intravascular injection.

Epidural administration may cause hypotension, urinary retention, and/or ataxia; other adverse cardiac and neurologic effects are uncommon and generally only occur at high plasma lidocaine concentrations (eg, unintentional subarachnoid injection) and are usually associated with PR and QRS interval prolongation and QT interval shortening. Lidocaine may increase ventricular rates if used in patients with atrial fibrillation. Uncommon but severe reactions include seizures, coma, respiratory arrest, and even death.

Lidocaine formulations that contain epinephrine may cause tachycardia and hypertension. Addition of sodium bicarbonate to lidocaine injection reduces pain ('sting') on administration. (See ***Pharmacokinetics***)

Reproductive/Nursing Safety

Lidocaine crosses the placenta. No fetal toxicity was observed in rats receiving up to 6.6 times the labeled human dose. Maternal and fetal toxicity have occurred with lidocaine use during labor and delivery in women.[32]

Although local anesthetics are excreted in breastmilk, lidocaine is excreted in concentrations of ≈40% of that found in the serum and it is considered unlikely to pose significant risk to nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Toxic blood levels are most likely to occur after unintended intravascular administration. To avoid this, ALWAYS aspirate before injecting the local anesthetic. Toxic effects may occur rapidly and simultaneously. Cardiac conduction and excitability are depressed and may lead to AV block, ventricular arrhythmias, and cardiac arrest; arrhythmias may be refractory to treatment. In addition, myocardial contractility is depressed and peripheral vasodilation occurs, leading to decreased cardiac output and arterial blood pressure. CNS stimulation (eg, nystagmus, restlessness, tremors, and shivering progressing to convulsions) may precede CNS depression, coma, and respiratory arrest. Tremors occurred in dogs with a serum lidocaine concentration of 2.7 µg/mL,[33] and seizures occurred in dogs with a mean serum concentration of ≈8 to 10 µg/mL,[34] but another study provoked seizures at 47 µg/mL.[35] The mean cumulative dose that induced seizures in dogs was 21 – 22 mg/kg IV,[35,36] and the cumulative lethal dose was 80 mg/kg IV.[37] The mean convulsive dose in cats was 11.7 mg/kg IV and the mean cardiotoxic dose was 47.3 mg/kg IV.[38]

If signs of overdose are present, management must begin with delivery of oxygen via a patent airway as successful oxygen delivery may prevent convulsions caused by toxicity. Cardiovascular support should be provided and may include IV fluids and vasopressor drugs (eg, dobutamine, norepinephrine). Prolonged resuscitative efforts may

be required. Lipid emulsion 20% 1.5 mL/kg IV over 30 minutes can be beneficial in lidocaine toxicity.[39,40] See ***Fat Emulsion, Intravenous***.

Drug Interactions

Drug interactions in animals receiving lidocaine as a local anesthetic are unlikely when administered correctly. The following drug interactions have either been reported or are theoretical in humans or animals receiving lidocaine (systemically) and may be of significance in veterinary patients after unintended intravascular administration. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-2-Adrenergic Agonists** (eg, **dexmedetomidine, xylazine**): Systemic absorption of lidocaine may increase the ataxic effects of alpha 2 agonists in horses.
- **Anesthetics, Inhalant** (eg, **isoflurane, sevoflurane**): Lidocaine infusions perioperatively have been shown to reduce MAC requirements in dogs,[41] horses,[42,43] and cats.[44] In dogs and horses, this effect may be of benefit, but in cats, additive cardiodepression has been shown.[44] However, in horses, lidocaine with inhalant anesthetics can cause tremors and ataxia and affect the quality of anesthetic recovery; it has been recommended to discontinue lidocaine CRIs at least 30 minutes before the start of the recovery period.[45]
- **Antiarrhythmics, Other** (eg, **procainamide, propranolol, quinidine**): If systemically absorbed, lidocaine may cause additive or antagonistic cardiac effects and toxicity may be enhanced.
- **Beta-Adrenergic Antagonists** (eg, **atenolol, esmolol, propranolol, sotalol**): Lidocaine levels or effects may be increased.
- **Ketamine**: If systemically absorbed, lidocaine may increase ataxic effects in horses.

Severe, prolonged hypertension may result when using lidocaine/epinephrine combination products with the following:

- **Ergot Alkaloids**
- **Monoamine Oxidase Inhibitors** (MAOIs; eg, **amitraz, linezolid, selegiline**)
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**)
- **Vasopressors** (eg, **dobutamine**, **norepinephrine**)

Laboratory Considerations

- Lidocaine administered intramuscularly may increase **creatine phosphokinase** levels.
- Lidocaine may falsely increase serum **creatinine**.

Dosages

NOTES:

1. Lidocaine formulation concentration, administration volume, site of administration, administration technique (eg, aspiration prior to injection), and underlying patient condition(s) are important interrelated factors that determine lidocaine's safe and effective use.
2. All dosages below use 2% lidocaine (20 mg/mL) unless otherwise specified.

DOGS:

Epidural and infiltration anesthesia (label dosage; not FDA-approved): *Epidural*: 1 mL/4.5 kg (10 lb) of body weight (4.4 mg/kg); *Infiltration*: dilute to 0.5% concentration (for each 1 mL of lidocaine 2% solution, dilute with 3 mL sterile water)

Local anesthesia | Tissue infiltration (line block): (extra-label):

a) 1 – 5 mg/kg is a generally recommended dose for local block[46]
b) 4 – 6 mg/kg. For larger areas, an equal or lower volume of 0.9% sodium chloride may be used to expand the volume.[47]

Regional anesthesia (extra-label):

a) **Regional IV anesthesia (Bier block) of the forelimb**: 3 mg/kg, using 0.5% lidocaine solution, IV in the cephalic vein provided local anesthesia for ≈20 to 30 minutes after tourniquet removal.[48] Prior to using this technique, it is encouraged to review the details of this procedure found in the citation to understand the safe use of the tourniquet and minimize potential for unintentional systemic administration with resulting adverse effects.
b) **CRI via peritoneal wound catheter**: 2 mg/kg/*hour* delivered via infusion or elastomeric pump[49]
c) **Retrobulbar and sub-Tenon injections**: Under general anesthesia, 2 mL of lidocaine 2% is administered in the retrobulbar space or under Tenon's capsule; an additional 1 mL is given if ocular akinesia is not achieved within 10 minutes. Compared to retrobulbar injection, results from sub-Tenon's administration were faster, longer, and more reliable.[50,51]

Epidural anesthesia (extra-label): **NOTE**: only use preservative-free formulations

a) Morphine 0.1 mg/kg combined with lidocaine 2% solution to bring total volume to 0.2 mL/kg[52]
b) Lidocaine 6 mg/kg. Morphine 0.1 mg/kg OR tramadol 1 mg/kg (not available in US) can be added to further reduce pain scores and prolong the duration of analgesia.[53]

Cough suppression prior to endotracheal intubation (extra-label): 0.4 mg/kg topically applied to laryngeal cartilages after induction of general anesthesia[7]

CATS:

Epidural and infiltration anesthesia (label dosage; not FDA-approved): *Epidural*: using lidocaine solution 2%, 1 mL per 4.5 kg (10 lb) of body weight (4.4 mg/kg); *Infiltration*: dilute to 0.5% concentration (each 1 mL of lidocaine 2% solution diluted with 3 mL sterile water)[54]

Local anesthesia | Tissue infiltration (line block): (extra-label): 2 – 4 mg/kg. For larger areas, an equal or lower volume of 0.9% sodium chloride may be used to expand the volume.[47]

Caudal (sacrococcygeal or coccygeal, or low) epidural anesthesia (extra-label):

a) Lidocaine 4 mg/kg administered lumbosacrally with EITHER morphine 0.1 mg/kg OR methadone 0.3 mg/kg delayed the need for rescue analgesia for up to 18 hours compared to lidocaine alone.[55]
b) Coccygeal epidural: 0.1 – 0.2 mL/kg of lidocaine 2% (without epinephrine). The needle is inserted between the first 2 coccygeal vertebrae and directed at a 30° to 45° angle.[56]

Cough suppression prior to endotracheal intubation (extra-label): 4 mg (0.2 mL of Lidocaine 2%)/cat (NOT mg/kg)[9]

HORSES:

Epidural, nerve block, and infiltration anesthesia (label dosage; not FDA-approved): *Epidural*: Lidocaine 2%, 5 – 15 mL; *Nerve block*: Lidocaine 2%, 5 – 20 mL; *Infiltration:* Dilute to 0.5% concentration (each 1 mL of lidocaine 2% solution diluted with 3 mL sterile water).

Local anesthesia, palmar nerve block (extra-label): 1.5 mL injected SC immediately palmar to the medial and lateral neurovascular bundles and immediately proximal to the collateral cartilages of the foot.[57]

Caudal (sacrococcygeal or coccygeal, or low) epidural anesthesia and analgesia (extra-label):

a) Lidocaine 0.2 mg/kg provided analgesia for ≈60 to 80 minutes.[58] Addition of neostigmine (1 µg/kg) extended analgesia to 150 minutes in a separate study.[59]
b) Caudal epidural in donkeys: Lidocaine 0.4 mg/kg administered into Co2-Co3 produced analgesia within 4 minutes and lasted 75 minutes. A dose of lidocaine 0.2 mg/kg combined

with tramadol 0.5 mg/kg (not available in US) produced analgesia within 6 minutes and lasted 180 minutes.[60]

Regional IV anesthesia (or Bier block): 1.3 mg/kg, using lidocaine 2% diluted with saline solution 0.9% to a total volume of 60 mL and administered into the cephalic vein. It provides local anesthesia until the tourniquet is removed (30 minutes).[61]

CATTLE:

Epidural, nerve block, and infiltration anesthesia (label dosage; not FDA-approved): *Epidural*: Lidocaine 2%, 5 – 15 mL; *Nerve block*: Lidocaine 2%, 5 – 20 mL; *Infiltration*: Dilute to 0.5% concentration (each 1 mL of lidocaine 2% solution diluted with 3 mL sterile water).[54]

Local anesthesia (extra-label): 3 mg/kg infiltrated subcutaneously[62]

Caudal epidural anesthesia and analgesia (extra-label): 0.22 – 0.5 mg/kg[63]

SHEEP/GOATS:

Local anesthesia (extra-label):

a) 5 mg/kg; analgesia duration ≈80 to 100 minutes[64,65]
b) Paravertebral anesthesia: Using lidocaine 2% solution, 3 mL infiltrated around each paravertebral nerve. Addition of epinephrine (5 µg/mL) extended duration of analgesia from 65 minutes to 95 minutes.[66] Refer to ***Compatibility/Compounding Considerations*** below.

Epidural anesthesia in **goats** (extra-label): 2.86 mg/kg, analgesia onset was 3 minutes, duration was 85 minutes. Ataxia occurred in all patients.[67]

CAMELIDS:

Local anesthesia (extra-label): Incisional and intratesticular block: 2 mL injected into each testicle and 2 mL SC along the prescrotal incision site (6 mL total, not exceeding 4 mg/kg)[68]

Epidural anesthesia (extra-label): 0.22 mg/kg (0.01 mL/kg of 2% solution) provides analgesia for ≈70 minutes. When the same dose is combined with xylazine 0.17 mg/kg, the duration of analgesia increases to 5.5 hours.[69]

SMALL MAMMALS:

Sciatic-femoral nerve block in rabbits (extra-label): 1 mg/kg per nerve guided by nerve stimulator[70]

REPTILES:

Intrathecal anesthesia in red-eared slider turtles (extra-label): 4 mg/kg provides regional anesthesia of the tail, cloaca, and hind limbs for ≈1 hour.[71]

Monitoring

- Adequacy of analgesia and anesthesia
- Cardiovascular and respiratory function as well as state of consciousness, after each injection
- Plasma lidocaine concentrations greater than or equal to 6 µg/mL are associated with increased risk for adverse effects.

Client Information

- This medication causes temporary loss of feeling. The area where it was injected may not have usual function for several hours.
- This drug should only be used by or on the order of a licensed veterinarian familiar with its use and in a setting where adequate patient monitoring can be performed.

Chemistry/Synonyms

Lidocaine hydrochloride is an amide-class local anesthetic. It occurs as a white or almost white, odorless, slightly bitter tasting crystalline powder with a melting point between 74°C (165.2°F) and 79°C (174.2°F) and a pK_a of 7.86. It is very soluble in water and alcohol.

Lidocaine hydrochloride is also known as lignocaine hydrochloride and lidocaini hydrochloridum. Many trade names are available including *Xylocaine*® and *Lignol*®.

Storage/Stability

Lidocaine should be stored at room temperature, at 15°C to 30°C (59°F-86°F).

Lidocaine stored under field conditions for equine use was found to maintain pH and potency without microbial contamination in a variety of storage conditions and with repeated vial use over 12 months.[72]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Lidocaine HCl is **compatible** with D_5W, lactated Ringer's, and 0.9% sodium chloride solutions, and combinations of these solutions. It is also **compatible** with the following drugs (partial list): bupivacaine, buprenorphine, butorphanol tartrate, dexamethasone sodium phosphate, epinephrine, fentanyl citrate, hydromorphone, methadone, midazolam, and morphine sulfate.

Lidocaine HCl is reported to be **variably compatible** with propofol and sodium bicarbonate. Lidocaine solutions to which sodium bicarbonate have been added (to reduce pain on infiltration) should be used immediately and promptly discarded.

The recommended final concentration of epinephrine is 5 µg/mL. To reach this concentration, add 0.1 mL of epinephrine 1 mg/mL to 20 mL of local anesthetic. Lidocaine solution to which epinephrine has been added should be used immediately and promptly discarded.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Lidocaine HCl for Injection: 2% (20 mg/mL) in 100 mL and 250 mL multiuse vials; (contains preservatives); generic; (Rx). Information regarding its use in food-producing species is conflicting; when using in a food animal, it is suggested to contact FARAD (see ***Appendix***). The ARCI (Association of Racing Commissioners International) has designated this drug as a class 2 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Lidocaine HCl injection: 0.5%, 1%, 1.5%, 2%, and 4% in 5 mL, 10 mL, 20 mL, 30 mL, and 50 mL single- and multidose vials, 2 mL and 5 mL amps, 5 mL syringes and cartridges; *Xylocaine*® and *Xylocaine mpf*®, generic; (Rx)

Lidocaine HCl with Epinephrine Injection: All are (Rx).

Lidocaine 0.5% with Epinephrine 5 µg/mL in 50 mL multidose vials

Lidocaine 1% with Epinephrine 5 µg/mL in 10 mL and 30 mL single-dose vials

Lidocaine 1% with Epinephrine 10 µg/mL in 20 mL, 30 mL, and 50 mL multidose vials

Lidocaine 1.5% with Epinephrine 5 µg/mL in 5 mL, 10 mL, and 30 mL single-dose vials

Lidocaine 2% with Epinephrine 5 µg/mL in 10 mL and 20 mL single-dose vials

Lidocaine 2% with Epinephrine 10 µg/mL in 20 mL, 30 mL, and 50 mL multidose vials

Topical liquids, patches, ointment, cream, lotion, gel, spray, and jelly are also available.

Lidocaine (Intravenous; Systemic)

Lignocaine

(***lye***-doe-kane) *Xylocaine®*

Antiarrhythmic, Analgesic, Prokinetic

For other uses of lidocaine, see ***Lidocaine, Local Anesthetic***; ***Lidocaine, Ophthalmic***; ***Lidocaine, Topical***

Prescriber Highlights

- ► Local anesthetic and antiarrhythmic (ventricular tachyarrhythmias) agent; may be useful as an IV anesthetic/analgesic adjunct
- ► Contraindications include known hypersensitivity to the amide-class local anesthetics; severe degree of SA, AV, or intraventricular heart block (if not being artificially paced); or Adams-Stokes syndrome.
- ► Use with caution in cats as they appear to be more sensitive to the cardiodepressant and CNS effects of lidocaine; many clinicians avoid anesthetic use of lidocaine IV in cats. Use with caution in patients with liver disease, congestive heart failure, shock, hypovolemia, severe respiratory depression, marked hypoxia, bradycardia, or incomplete heart block with PVCs, unless the heart rate is first accelerated.
- ► Most common adverse effects reported are dose-related (serum concentration) and mild. CNS signs include drowsiness, depression, ataxia, muscle tremors; GI signs include nausea, and vomiting (usually transient); adverse cardiac effects usually occur only at high plasma concentrations in most species, but cats are more susceptible.
- ► When an IV bolus is given too rapidly, dose-dependent hypotension may occur; consider starting with a lower dose. Seizures are possible.
- ► Do **NOT** use the product containing epinephrine IV.

Uses/Indications

Besides its use as a local, regional, and topical anesthetic agent, lidocaine is frequently used to treat ventricular arrhythmias (eg, ventricular tachycardia, premature ventricular complexes [PVCs]) in all species. Lidocaine is indicated as an antiarrhythmic agent when PVCs are frequent and/or polymorphic (ie, 2 or more different abnormal QRS-T configurations can be identified), when PVCs appear in runs of more than 2 or 3, when there is marked tachycardia such that there are signs of diminished diastolic filling time and cardiac output (eg, pale mucous membranes, prolonged CRT, hypotension, weak pulses, pulse deficits), or when R on T phenomenon is seen on the ECG.[1,2]

Lidocaine may also have benefit in dogs to terminate supraventricular tachycardia in the presence or absence of an accessory pathway and paroxysmal atrial fibrillation initiated by elevated vagal tone in dogs with normal cardiac function.[3–5] In critically ill dogs, lidocaine may be beneficial secondary to its free radical scavenging abilities, analgesic effects, and antiarrhythmic properties. A retrospective study in dogs undergoing laparotomy for septic peritonitis found that dogs that received lidocaine (50 µg/kg/MINUTE) in addition to an opioid during surgery had significantly increased short-term (48 hour) survival rates versus dogs that received an opioid alone.[6] IV lidocaine could potentially be useful in dogs with gastric dilation volvulus (GDV) to reduce cardiac arrhythmias, acute kidney injury, and hospitalization times.[7]

Cats may be more sensitive to the cardiovascular and CNS effects of the drug[8,9] and most clinicians do not use it IV in this species as an analgesic.[10]

In horses, lidocaine has been used as part of partial intravenous anesthesia (PIVA) protocols for its analgesic, anti-inflammatory, and prokinetic effects. It may be useful to prevent postoperative ileus and reperfusion injury and for the adjunctive treatment of endotoxemia. It appears to increase survival rate in horses undergoing exploratory celiotomy for small intestinal disease.[11]

Low-dose IV lidocaine infusions for hyperalgesia and neuropathic pain states induced by trauma or surgical procedures have been documented to be useful. It has MAC-sparing effects in dogs,[12–14] horses,[15,16] and small ruminants[17,18] but does not reduce propofol requirements in dogs.[19–21]

Intrathecal administration of high-dose lidocaine is an acceptable secondary method for euthanasia in animals under anesthesia when other euthanasia agents or methods are unavailable, cost-prohibitive, or unwarranted due to environmental concerns.[22]

Pharmacology/Actions

Lidocaine is considered to be a class IB antiarrhythmic agent (membrane-stabilizing that shortens the myocardial cell action potential). Lidocaine acts by combining with inactive fast sodium channels, which inhibits recovery after repolarization. Class IB agents demonstrate rapid rates of attachment and dissociation to sodium channels in ventricular conducting tissue more so than atrial tissue. At therapeutic concentrations, lidocaine causes phase 4 diastolic depolarization attenuation, decreased automaticity, and either a decrease or no change in membrane responsiveness and excitability. These effects will occur at serum concentrations that will not inhibit the automaticity of the SA node, and will have little effect on AV node conduction or His-Purkinje conduction.

The systemic analgesic effects are not well understood but are likely via several mechanisms, including reducing ectopic activity of damaged afferent neurons, action at different molecular sites, such as Na^+, Ca^{2+}, and K^+ channels and N-methyl-D-aspartate (NMDA) receptors.

Lidocaine does not demonstrate GI prokinetic effects in dogs[23,24]; however, it apparently has some enhancing effects on intestinal motility in rabbits[25] and in horses with postoperative ileus.[26–28] The mechanism for this effect is not well understood, but probably involves more than just blocking increased sympathetic tone. The results of the prokinetic action of lidocaine in horses undergoing colic surgery are controversial, but they suggest that lidocaine could be used as an analgesic that does not impair GI motility.[29] In a cohort study, the administration of lidocaine to horses undergoing colic surgery due to small intestine lesions did not affect the prevalence, volume, and duration of reflux and did not improve the survival rate.[30]

Systemic and topical lidocaine reduces cough response on intubation.[31,32]

Lidocaine has been shown to inhibit reactive oxygen species (ROS) formation and lipid peroxidation, which may improve clinical outcomes in dogs with gastric dilatation and volvulus.[33]

Pharmacokinetics

Lidocaine is not effective orally, as it has a high first-pass effect. If high oral doses are given, toxic signs occur (possibly due to active metabolites) before therapeutic concentrations can be reached. Following a therapeutic IV bolus dose, the onset of action is generally within 2 minutes and has a duration of action of 10 to 20 minutes. If a constant rate infusion (CRI) is started without an initial IV bolus, it may take up to an hour for therapeutic concentrations to be reached. IM injections may be given every 1.5 hours in dogs, but because monitoring and adjusting doses are difficult with this route of administration, it should be avoided; administration by the IO route can be considered if IV is not possible.

After injection, the drug is rapidly redistributed from the plasma into highly perfused organs (kidney, liver, lungs, heart) and distributed widely throughout body tissues. It has a high affinity for adipose

tissue and is bound to plasma proteins, primarily alpha$_1$-acid glycoprotein. It has been reported that lidocaine binding to this protein is highly variable and concentration-dependent in dogs and may be higher in dogs with inflammatory disease. The apparent volume of distribution (V_d) has been reported to be 4.5 L/kg in dogs, 1.9 L/kg in cats,[34] and ≈2.5 L/kg in horses.[35]

Lidocaine is rapidly metabolized in the liver to active metabolites (monoethylglycinexylidide [MEGX] and glycinexylidide [GX]). The terminal half-life of lidocaine has been reported to be 0.9 hours in dogs, 1.7 hours in cats,[34] and ≈1 hour in horses.[35] Lidocaine clearance in horses exceeds hepatic blood flow, suggesting metabolism also occurs at extra-hepatic sites.[36] Lidocaine, MEGX, and GX concentrations may progressively increase with prolonged infusions, and dosage modification may be required.[37–39] The half-lives of lidocaine and MEGX may be prolonged in patients with cardiac failure or hepatic disease. Less than 10% of a parenteral dose is excreted unchanged in the urine.

In healthy beef cattle, elimination half-life after IV administration of 1.5 mg/kg was ≈1 hour.[40] Following a 2 mg/kg IV bolus and 100 µg/kg/*MINUTE* IV CRI in calves, plasma lidocaine concentrations ranged from 1.85 to 2.06 µg/mL.[41] Following an inverted L epidural nerve block in healthy Holstein cows, lidocaine elimination half-life in serum was 4.2 hours and mean residence time was 5.1 hours[42]; in milk, the time to maximum concentration occurred 1.75 hours after administration, and the time of the last detectable milk concentration was 32.5 hours.

In humans, lidocaine is readily absorbed after oral administration, but bioavailability is only 35% due to extensive first-pass metabolism. Absorption from injection sites, including muscle, is rapid. Protein binding is ≈66% to alpha $_1$-acid glycoprotein, with considerable variability. It is widely distributed, including into the CNS and breast milk. Lidocaine is extensively and rapidly metabolized, with an elimination half-life of 1 to 2 hours.

Contraindications/Precautions/Warnings

Lidocaine is contraindicated in patients with known hypersensitivity to the amide-class local anesthetics, a severe degree of SA, AV, or intraventricular heart block (if not being artificially paced), Adams-Stokes syndrome, and Wolff-Parkinson-White (WPW) syndrome.

Cats tend to be more sensitive to the CNS and cardiodepressant effects of lidocaine; use with caution especially in cats with concurrent illnesses or under general anesthesia. Most clinicians avoid the use of IV lidocaine in cats for anesthetic/analgesic purposes. Lidocaine IV CRI does not appear to affect thermal antinociception in cats.[43] When administered to cats anesthetized with isoflurane, lidocaine causes greater cardiovascular depression than an equipotent dose of isoflurane alone and thus, lidocaine is not recommended as part of a balanced anesthesia protocol.[43,44]

Lidocaine should be used with caution in patients with liver disease, congestive heart failure, shock, hypovolemia, severe respiratory depression, or marked hypoxia. Consider reducing doses by 30% to 50% in animals with liver dysfunction. It should also be used with caution in patients with bradycardia or incomplete heart block having PVCs unless the heart rate is first accelerated.[45]

If an IV bolus is given too rapidly, dose-dependent hypotension may occur; consider starting with a lower dose as this effect is dose-dependent.[46] In humans, it is recommended to administer IV bolus injections over 2 to 4 minutes. Sedation and vomiting also may occur during IV bolus administration, which may increase the risk for aspiration, particularly in patients with brachycephalic obstructive airway syndrome. When preparing lidocaine for IV injection, be certain of the concentration and do NOT use products containing epinephrine. The veterinary label lidocaine injection (local anesthetic) contains propylene glycol, which is known to cause hypotension with IV administration.[47]

In human medicine, lidocaine is considered a high-alert medication (ie, medication that requires special safeguards to reduce the risk for errors).[48] Consider instituting practices such as redundant drug dosage and volume checking, and special alert labels.

Adverse Effects

At usual doses, and if the serum concentration remains within the proposed therapeutic range (1 – 5 µg/mL), serious adverse effects are rare. The most common adverse effects reported are dose-related and mild. CNS signs include drowsiness, depression, ataxia, and muscle tremors. Nausea and vomiting may occur but are usually transient; the combination of sedation and vomiting may increase the risk for aspiration.

Adverse cardiac effects generally only occur at high plasma concentrations and are usually associated with PR and QRS interval prolongation and QT interval shortening. Lidocaine may increase ventricular rates if used in patients with atrial fibrillation. Horses are less sensitive than other species to lidocaine's adverse cardiovascular effects but appear more sensitive to the drug's CNS effects. Ataxia and a tendency for poor recovery were noted in horses given lidocaine infusion until the end of surgery, compared to horses in which the infusion was stopped 30 minutes before the end of surgery.[49]

Reproductive/Nursing Safety

Lidocaine crosses the placenta. No fetal harm was demonstrated in rats given 5 to 6.6 times the maximum recommended human dose. In humans, lidocaine is considered compatible with pregnancy.[50]

Lidocaine is excreted into milk at concentrations of ≈40% of that found in the serum and would be unlikely to pose significant risk to nursing offspring. In humans, it is considered compatible with breastfeeding.[51]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In dogs, toxicity may result if serum concentrations of greater than 8 µg/mL are attained, although one study noted muscle tremors at concentrations of ≈1.8 – 3.4 µg/mL with corresponding doses of 10 – 13 µg/kg.[52] The lethal dose in dogs is thought to be 16 to 28 mg/kg.[52] Clinical signs related to lidocaine toxicity may include ataxia, nystagmus, depression, seizures, bradycardia, hypotension, and, at very high concentrations, circulatory collapse.

Because lidocaine is rapidly metabolized, cessation of therapy or reduction in infusion rates with monitoring may be all that is required for minor signs. Seizures or excitement may be treated with benzodiazepines. If circulatory depression occurs, treat with fluids, vasopressor agents (eg, dobutamine, norepinephrine), and, if necessary, begin CPR. IV lipid emulsion 20% can be beneficial for the treatment of lidocaine toxicity.[53–55] See ***Fat Emulsion, Intravenous***.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Lidocaine is a substrate of CYP 1A and 3A in humans. The following drug interactions have either been reported or are theoretical in humans or animals receiving lidocaine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-2 Receptor Agonists** (eg, **dexmedetomidine, xylazine**): Lidocaine may increase the ataxic effects of alpha$_2$ agonists in horses.
- **Anesthetics, Inhalant** (eg, **isoflurane, sevoflurane**): Lidocaine infusions perioperatively have been shown to reduce MAC requirements in dogs,[12] horses,[15,16] and cats.[8] In dogs and horses, this effect may be of benefit, but in cats, additive cardiodepression has been shown.[8] In horses, lidocaine with inhalant anesthetics can cause tremors and ataxia and affect the quality of anesthetic recovery; it has been recommended to discontinue lidocaine CRIs at least 30 minutes before the start of the recovery period.[49]
- **Antiarrhythmics, Other** (eg, **procainamide, propranolol, quinidine**): When administered with lidocaine, may cause additive or antagonistic cardiac effects and toxicity may be enhanced
- **Beta-Blockers** (eg, **atenolol, esmolol, propranolol, sotalol**): Lidocaine concentration or effects may be increased.
- **Ceftiofur**: May reduce lidocaine protein binding, increasing free lidocaine concentration, which may increase risk for lidocaine toxicity[37]
- **Cimetidine**: Lidocaine concentration or effects may be increased.
- **Diuretics** (eg, **furosemide**): Hypokalemia may reduce the antiarrhythmic effects of lidocaine.
- **Ketamine**: Lidocaine may increase ataxic effects in horses.
- **Mitotane**: May decrease lidocaine concentration
- **Neuromuscular Blockers** (eg, **atracurium, succinylcholine**): Large doses of lidocaine may prolong succinylcholine-induced apnea.
- **Phenobarbital**: May decrease lidocaine concentration.

Laboratory Considerations

- Lidocaine may cause increased **creatine kinase (CK)** and **serum creatinine** concentrations.

Dosages

NOTES:

1. **Monitoring for adverse effects is critical**.
2. Do not confuse CRI dosages listed as µg/kg/*MINUTE* with those listed as mg/kg/*HOUR*.

DOGS:

Antiarrhythmic agent (extra-label):

Ventricular tachycardia: initial boluses of 2 mg/kg slowly IV, up to 8 mg/kg; or rapid IV infusion at 0.8 mg/kg/*MINUTE* IV CRI; if effective, then 25–80 µg/kg/*MINUTE* IV CRI; can also be used intratracheally for CPR.[2]

Refractory ventricular fibrillation (VF)/pulseless ventricular tachycardia (VT): The treatment of choice is electrical defibrillation, but patients with VF refractory to defibrillation may benefit from treatment with amiodarone. If amiodarone is not available, lidocaine 2 mg/kg slow IV/intraosseous push may be of benefit[56]; however, this should be done with caution, as lidocaine has been shown to increase proarrhythmia activity when used with monophasic defibrillating shocks.[57,58]

Cardioversion of orthodromic atrioventricular reciprocating tachycardia (OAVRT): With continuous ECG recording, 2 mg/kg IV over 20 to 30 seconds, repeated every 2 minutes to a cumulative dose of 8 mg/kg. Median lidocaine dose to cardiovert was 2 mg/kg. Maintenance of cardioversion with a lidocaine CRI 25 – 60 µg/kg/*MINUTE* IV CRI was required in some dogs.[59]

Adjunctive treatment of GDV or other critical illnesses (eg, septic peritonitis) to decrease arrhythmias and minimize risk for acute kidney injury: Loading dose of 1 – 2 mg/kg IV, then 17 – 50 µg/kg/*MINUTE* (1 – 3 mg/kg/*HOUR*) IV CRI.[6,7,60] In one study, lidocaine infusion continued for at least 3 hours following GDV surgery.[60]

Adjunctive systemic analgesia under general anesthesia (extra-label):

NOTE: For additional information on morphine/lidocaine/ketamine (MLK)-type CRIs, refer to other anesthesia-specific references.

a) **Lidocaine as a single agent**: 1 – 2 mg/kg IV followed by 25 – 50 µg/kg/*MINUTE* IV CRI.[61–63]
b) **Lidocaine/dexmedetomidine**: Lidocaine 2 mg/kg IV with dexmedetomidine 2 µg/kg IV followed by lidocaine 3 mg/kg/*HOUR* IV CRI with dexmedetomidine 3 µg/kg/*HOUR* IV CRI during surgery.[64]
c) **Lidocaine/dexmedetomidine/ketamine**: Lidocaine 2 mg/kg with dexmedetomidine 1 µg/kg and ketamine 1 mg/kg IV followed by lidocaine 100 µg/kg/*MINUTE* IV CRI with dexmedetomidine 3 µg/kg/*HOUR* IV CRI and ketamine 40 µg/kg/*MINUTE* IV CRI during surgery. At the conclusion of surgery, rates were reduced to lidocaine 25 µg/kg/*MINUTE* IV CRI, dexmedetomidine 1 µg/kg/*HOUR* IV CRI, and ketamine 10 µg/kg/*MINUTE* IV CRI and continued for an additional 4 hours.[65,66]
d) **Lidocaine/fentanyl/ketamine**: Lidocaine 3 mg/kg/*HOUR* IV CRI combined with fentanyl 3.6 µg/kg/*HOUR* IV CRI and ketamine 0.6 mg/kg/*HOUR* IV CRI (no loading dose was used in this study).[67]
e) **Lidocaine/ketamine**: Lidocaine 1.5 – 2 mg/kg with ketamine 0.5 – 3 mg/kg IV followed by lidocaine 25 – 100 µg/kg/*MINUTE* IV CRI with ketamine 0.03 – 0.1 mg/kg/*MINUTE* IV CRI[68–70]
f) **Morphine/lidocaine/ketamine (MLK)**: Lidocaine 50 µg/kg per *MINUTE*, morphine 3.3 – 4 µg/kg/*MINUTE*, and ketamine 10 µg/kg/*MINUTE* admixed in IV fluids and administered as an IV CRI.[71–74] Refer to ***Compatibility/Compounding Considerations*** for more information.
g) **Dexmedetomidine/morphine/lidocaine/ketamine (DMLK)**: Lidocaine 3 mg/kg/*HOUR*, dexmedetomidine 0.5 µg/kg per *HOUR*, morphine 0.2 mg/kg/*HOUR*, and ketamine 0.6 mg/kg per *HOUR* admixed in IV fluids and administered IV as CRI.[75] Refer to ***Compatibility/Compounding Considerations*** for more information.

CATS:

CAUTION: Cats are reportedly very sensitive to the CNS effects of lidocaine and can develop cardiovascular depression. There are several sources that state that lidocaine should not be used in cats as an injectable analgesic. If using in cats, monitor carefully.

Antiarrhythmic: Initially, 0.2 – 0.7 mg/kg IV slowly, may repeat once or twice.[76] Alternatively, 0.25 – 0.5 mg/kg IV slowly, can repeat at 0.15 – 0.25 mg/kg IV over 5 to 20 minutes; if effective, 10 – 20 µg/kg/*MINUTE* (0.6 – 1.2 mg/kg/*HOUR*) IV CRI.[77]

HORSES:

Ventricular tachyarrhythmias: 0.25 – 0.5 mg/kg IV slowly; can repeat in 5 to 10 minutes. The sum total of IV boluses should not exceed 2 mg/kg. If multiple boluses are required, begin lidocaine 50 µg/kg/*MINUTE* (3 mg/kg/*HOUR*) IV CRI.[1]

Postoperative ileus/colic: Initially, IV bolus of lidocaine 1.3 – 1.4 mg/kg followed by lidocaine 30 – 50 µg/kg/*MINUTE* (1.8 – 3 mg/kg/*HOUR*) IV CRI for 24 hours (for postoperative ileus).[26,27,78,79]

Adjunctive systemic analgesia under general anesthesia:

a) **Lidocaine alone**: 1.5 – 5 mg/kg IV loading dose administered

over 15 minutes followed by 25 – 100 µg/kg/*MINUTE* IV CRI.[80,81] One study determined the loading dose did not confer additional advantage.[82]

b) **Lidocaine/ketamine**: Loading doses: ketamine 3 mg/kg IV, followed by lidocaine 2 mg/kg administered IV over 10 minutes; maintenance dosage: lidocaine 3 mg/kg/*HOUR* with ketamine 3 mg/kg/*HOUR* IV CRI. Xylazine 1.1 mg/kg IV was given prior to loading doses. Addition of morphine did not provide additional benefit.[83] Another study demonstrated efficacy with a lidocaine (only) loading dose of 1.5 mg/kg IV over 10 minutes followed by lidocaine 2.4 mg/kg/*HOUR* with ketamine 3.6 mg/kg/*HOUR* IV CRI.[84]

c) **Lidocaine/ketamine/medetomidine**: A loading dose of lidocaine 1.5 mg/kg administered IV over 10 minutes was followed by a combination of lidocaine 2 mg/kg/*HOUR* with ketamine 2 mg/kg/*HOUR* and medetomidine 3.6 µg/kg/*HOUR* IV CRI. After 50 minutes, lidocaine and ketamine CRI rates were reduced to 1.5 mg/kg/*HOUR*, and medetomidine was reduced to 2.75 µg/kg/*HOUR*.[85] Refer to ***Compatibility/Compounding Considerations*** for more information.

d) **Lidocaine/xylazine**: A loading dose of lidocaine 1.3 mg/kg IV over 5 minutes with xylazine 0.55 mg/kg IV over 1 minute were followed by lidocaine 1.5 mg/kg/*HOUR* with xylazine 1.1 mg/kg/*HOUR* IV CRI. A higher lidocaine CRI rate caused significant ataxia.[86]

Partial IV Anesthesia (PIVA): Based on the drug's pharmacokinetics, lidocaine 1.5 – 5 mg/kg IV followed by lidocaine 75 µg/kg per *MINUTE* (4.5 mg/kg/*HOUR*) IV CRI should yield a plasma concentration of 3000 ng/mL (3 µg/mL) and provide an ≈30% reduction in MAC. The rate of administration of the loading dose has varied in studies ranging from 1 to 20 minutes, with 10 to 15 minutes being most common. Administration rate is more relevant in conscious horses but is less so in anesthetized horses because the neurologic effects (ataxia, vision disturbances) are blunted and not observed. Discontinue the CRI at least 30 minutes prior to the start of recovery to minimize risk for rough recovery. Has been used in PIVA protocols with ketamine, medetomidine, or morphine.[80]

Total IV anesthesia (TIVA): After induction with propofol, lidocaine 1 mg/kg IV bolus over 1 minute followed by lidocaine 50 µg/kg/*MINUTE* IV CRI in combination with propofol 0.1 mg/kg/*MINUTE*, medetomidine 3.5 µg/kg/*HOUR*, and butorphanol 24 µg/kg/*HOUR* IV CRI.[87]

CATTLE:

Analgesia: In an experimental study, beginning 40 minutes after induction of general anesthesia, lidocaine 2 mg/kg IV bolus was followed by 100 µg/kg/*MINUTE* IV CRI.[41]

GOATS:

Analgesia:

a) **Lidocaine alone**: 2.5 mg/kg IV over 3 minutes followed by lidocaine 100 µg/kg/*MINUTE* IV CRI[88]

b) **Lidocaine/ketamine**: Lidocaine 2.5 mg/kg with ketamine 1.5 mg/kg IV over 3 minutes followed by lidocaine 100 µg/kg per *MINUTE* with ketamine 50 µg/kg/*MINUTE* IV CRI[88]

Total IV anesthesia (TIVA): Lidocaine 1 mg/kg combined with alfaxalone 2 mg/kg and administered IV over 10 minutes to induce general anesthesia[18]; anesthesia maintained with lidocaine 3 mg/kg/*HOUR* and alfaxalone 9.6 mg/kg/*HOUR* IV CRI.

SHEEP:

Analgesia: Anesthesia was induced with ketamine 3.3 mg/kg and midazolam 0.1 mg/kg IV followed by morphine 1 mg/kg IM.[17] Lidocaine 20 µg/kg/*MINUTE* with ketamine 10 µg/kg/*MINUTE* IV CRI was then started.

SMALL MAMMALS:

Analgesia in rabbits: Lidocaine 2 mg/kg IV over 5 minutes followed by 50 – 100 µg/kg/*MINUTE* IV CRI.[89] Following ovariohysterectomy, rabbits receiving lidocaine 100 µg/kg/*MINUTE* IV CRI for 2 days had better GI motility, food intake, fecal output, and number of normal behaviors than rabbits receiving only buprenorphine.[25]

Ventricular arrhythmias in rabbits and guinea pigs: Under emergency situations, lidocaine 1 – 4 mg/kg IV bolus is relatively safe.[90]

Monitoring

- ECG, blood pressure, heart rate, pulse quality, pulse oximetry
- Signs of toxicity (eg, depression, vomiting, nausea, ataxia, muscle tremors, PR and QRS interval prolongation, QT interval shortening, bradycardia, hypotension)
- If available and indicated, serum lidocaine concentrations may be monitored. Therapeutic concentrations are considered to range from 1 to 6 µg/mL.

Client Information

- Lidocaine should only be used by professionals familiar with its use and in a setting where adequate patient monitoring can be performed.

Chemistry/Synonyms

A potent local anesthetic and antiarrhythmic agent, lidocaine HCl occurs as a white, odorless, slightly bitter, crystalline powder with a melting point between 74°C and 79°C (165.2°F-174.2°F) and a pK_a of 7.86. It is very soluble in water and alcohol. The pH of the commercial injection is adjusted to 5 to 7, and the pH of the commercially available infusion in dextrose 5% is adjusted to 3.5 to 6.

Lidocaine may also be known as lidocaini hydrochloridum, and lignocaine hydrochloride; many trade names are available; a common trade name is *Xylocaine*® (Astra).

Storage/Stability

Lidocaine for injection should be stored at 20°C to 25°C (68°F-77°F); avoid freezing. Temperatures up to 40°C (104°F) may be tolerated.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Lidocaine is physically **compatible** with most commonly used IV infusion solutions, including 5% dextrose, lactated Ringer's, 0.9% sodium chloride, and combinations of these. It is also reportedly physically **compatible** with: aminophylline, atropine, buprenorphine, butorphanol, calcium salts, chloramphenicol sodium succinate, clindamycin, dexamethasone sodium phosphate, dexmedetomidine, digoxin, diphenhydramine, dobutamine, doxycycline, epinephrine, erythromycin, famotidine, fentanyl, furosemide, glycopyrrolate, heparin, hydrocortisone sodium succinate, hydromorphone, hydroxyzine, ketamine, insulin (regular), mannitol, metoclopramide, midazolam, morphine, ondansetron, oxytetracycline, penicillin G potassium, phenylephrine, potassium chloride, procainamide, propranolol, sodium bicarbonate, sodium lactate, verapamil, and Vitamin B-Complex with C.

Lidocaine **may not be compatible** with dopamine, epinephrine, isoproterenol, or norepinephrine as these require low pH for stability. Lidocaine is reportedly physically **incompatible** when mixed with ampicillin, cefazolin, diazepam, pantoprazole, pentobarbital, or sulfa-/trimethoprim.

- **"MLK" Recipe**:

  NOTE: When preparing solutions, be certain that you are not using the lidocaine product that contains epinephrine.

To prepare IV infusion solution using the veterinary lidocaine 2% solution, add 1 g (50 mL) to 1 L of compatible solution (eg, 0.9% sodium chloride, Dextrose 5%). This solution will give an approximate lidocaine concentration of 1 mg/mL (1000 µg/mL). When using a mini-drip (60 drops/mL) IV set, each drop will contain ≈17 µg of lidocaine. In small dogs and cats, a less concentrated solution may be used for greater dosage accuracy.

A combination IV infusion for analgesia and sedation in postoperative patients (dogs, NOT cats) that require sedation to sleep the night after surgery is described[91]: For this technique, plan on adding the drugs to a bag of fluids for which the administration rate will not change, which usually means picking a fluid and administration rate calculated to provide maintenance needs for water. For example, to calculate a drug plan for a 20 kg dog that is to receive morphine, lidocaine, ketamine, and medetomidine for the first 8 to 24 hours postoperatively, drug doses to consider might include:

Morphine: 0.1 mg/kg/HOUR x 20 kg = 2 mg/HOUR
Lidocaine: 2.5 mg/kg/HOUR x 20 kg = 50 mg/HOUR
Ketamine: 0.1 mg/kg/HOUR x 20 kg = 2 mg/HOUR
Medetomidine: 2 µg/kg/HOUR x 20 kg = 40 µg/HOUR (**NOTE**: This is not the dose for dexmedetomidine).

The maintenance fluid administration rate for a 20 kg dog lying quietly in a cage is roughly 800 mL/day or 33 mL/hour. Therefore, a 1 L bag contains ≈30 hours of treatment, and to a 1 L bag one must add:

Morphine: 2 mg/HOUR x 30 hours = 60 mg = 6 mL (when using 10 mg/mL morphine)
Lidocaine: 50 mg/HOUR x 30 hours = 1500 mg = 75 mL (when using 2% [20 mg/mL] lidocaine)
Ketamine: 2 mg/HOUR x 30 hours = 60 mg = 0.6 mL (when using 100 mg/mL ketamine)
Medetomidine: 40 µg/HOUR x 30 hours = 1200 µg = 1.2 mL (when using 1000 µg/mL medetomidine)

If the drugs are added to a 1 L bag of fluid, the final volume is greater than 1 L—in this case 1083 mL. Therefore, 83 mL should be removed from the bag *before* addition of the medications.[91]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:
There are injectable lidocaine products labeled for use in veterinary medicine (dogs, cats, horses, and cattle) as an injectable anesthetic, but it is not FDA-approved for use as an antiarrhythmic agent. Information regarding its use in food-producing species is conflicting; when using lidocaine in a food animal, it is suggested to contact the Food Animal Residue Avoidance Databank (FARAD). See ***Appendix*** for more information.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

Lidocaine HCl for Injection: 2% (20 mg/mL) in 100 mL and 250 mL multi-use vials; (contains preservatives and propylene glycol); generic; (Rx)

HUMAN-LABELED PRODUCTS:
Lidocaine Hydrochloride Injection: 0.5%, 1%, 1.5%, 2%, and 4% in 5 mL, 10 mL, 20 mL, 30 mL, and 50 mL single- and multi-dose vials; 2 mL and 5 mL ampules; 5 mL syringes and cartridges; *Xylocaine*® and *Xylocaine MPF*®, generic; (Rx)

Lidocaine Hydrochloride with Dextrose Injection: 1.5% with 7.5% dextrose and 5% with 7.5 % dextrose in 2 mL ampules and single-dose amps; *Xylocaine MPF*®, generic; (Rx)

Premixed with 5% dextrose for IV infusion in concentrations of 4 mg/mL and 8 mg/mL; injections with epinephrine, topical liquids, patches, ointment, cream, lotion, gel, spray, and jelly available.

Lincomycin

(lin-koe-***mye***-sin) *Lincocin*®, *Lincomix*®
Lincosamide Antibiotic

Prescriber Highlights

- Antibiotic similar to clindamycin, with a broad spectrum against many anaerobes, gram-positive aerobic cocci, and *Toxoplasma* spp
- Contraindications include in horses, rodents, ruminants, and lagomorphs; hypersensitivity to lincosamides.
- Use caution in liver or renal dysfunction; consider reducing dosage if severe.
- Adverse effects include gastroenteritis, pain at the injection site if given IM; rapid IV administration can cause hypotension and cardiopulmonary arrest.

Uses/Indications

Lincomycin is FDA-approved in dogs and cats for infections caused by susceptible gram-positive organisms, particularly streptococci and staphylococci.[1] It is also approved in swine for the treatment of infectious arthritis and mycoplasma pneumonia. Lincomycin is also FDA-approved to control American foulbrood in honey bees.

Lincomycin is considered a first-tier antimicrobial for the treatment of bacterial dermal infections in dogs.[2] However, clindamycin is generally better absorbed, more active, likely less toxic, and has largely supplanted the use of lincomycin for oral and injectable therapy in small animals.

The World Health Organization (WHO) has designated lincomycin as a Highly Important antimicrobial for human medicine.[3] The Office International des Epizooties (OIE) Antimicrobial Classification has designated lincomycin as a Veterinary Highly Important Antimicrobial Agent.[4]

Pharmacology/Actions

The lincosamide antibiotics, lincomycin and clindamycin, share mechanisms of action and have similar spectrums of activity, although lincomycin is usually less active. Complete cross-resistance occurs between the 2 drugs, and at least partial cross-resistance occurs between the lincosamides and erythromycin. They may act as bacteriostatic or bactericidal agents, depending on the concentration of the drug at the infection site and the susceptibility of the organism. Lincosamides can accumulate in cells (eg, leukocytes, macrophages). They are believed to act by binding to the 50S ribosomal subunit of susceptible bacteria, thereby inhibiting peptide formation and protein synthesis for the bacteria's cell wall.

Most aerobic gram-positive cocci, including staphylococci and streptococci, are susceptible to the lincosamides. Enterococci are inherently resistant. Many strains of *Staphylococcus pseudintermedius* are resistant. Other organisms that are generally susceptible include *Corynebacterium diphtheriae, Nocardia asteroides, Erysepelothrix* spp, and *Mycoplasma* spp. Anaerobic bacteria are generally susceptible to the lincosamides, although there is a low prevalence of resistance in the *Bacteroides fragilis* group.

Pharmacokinetics

In cats, after IV or oral doses of 15 mg/kg, the following pharmacokinetic parameters (means) were reported: Bioavailability (oral): 82%; volume of distribution (steady-state): 0.98 L/kg; clearance: 0.17 L/kg/hour; elimination half-life: 4.2 hours. The skin to plasma

ratio 2 hours postdose was about 2:1.[5] Protein binding in cats is low (less than 20%). IM dosage of 10 mg/kg had a mean bioavailability of 83%. Bone to serum ratio measured 30 to 45 minutes after IM dosing was ≈0.7:1.[6]

In dogs, lincomycin is well absorbed after PO and IM administration. Serum levels peak within 0.5 to 2 hours of administration. Biliary and fecal excretion accounts for 40% to 75% of the dose in dogs. The elimination half-life of lincomycin is reportedly 3 to 4 hours in small animals.

In humans, lincomycin is rapidly absorbed from the gut, but only ≈30% to 40% of the total dose is absorbed. Food both decreases the extent and the rate of absorption. Peak serum levels are attained ≈2 to 4 hours after oral dosing. IM administration gives peak levels about double those reached after oral dosing and peak at ≈30 minutes postinjection.

Lincomycin is distributed into most tissues. Therapeutic levels are achieved in bone, synovial fluid, bile, pleural fluid, peritoneal fluid, skin, and heart muscle. CNS levels may reach 40% of those in the serum if meninges are inflamed but may be inadequate to treat meningitis. Lincomycin is 57% to 72% bound to plasma proteins, depending on the drug's concentration. The drug crosses the placenta and can be distributed into milk at concentrations equal to those found in plasma.

Lincomycin is partially metabolized in the liver. The unchanged drug and metabolites are excreted in the urine, feces, and bile. Half-life (about 5.5 hours) can be 2 to 3 times longer in patients with renal or hepatic dysfunction.

Contraindications/Precautions/Warnings

Although there have been case reports of parenteral administration of lincosamides to horses, cattle, and sheep, the lincosamides are considered **contraindicated** for use in **horses**, **ruminants, rabbits**, **hamsters**, and **guinea pigs** because of serious GI effects that may occur, including death.

Lincomycin is contraindicated in patients with known hypersensitivity to it or to clindamycin or patients having a pre-existing monilial (ie, candidiasis) infection.

Lincomycin is generally not recommended for use in neonatal animals because of its effects on gut flora. It should be used with caution in patients with a history of GI disease (eg, colitis), and in patients with a history of asthma or significant allergies.

In patients with hepatic or renal insufficiency, consider dose reduction or using alternative drugs.

Cross-resistance has been demonstrated between clindamycin and lincomycin.

Adverse Effects

Adverse effects reported in dogs and cats include gastroenteritis, emesis, and loose stools, and, infrequently, bloody diarrhea in dogs. IM injections reportedly cause pain at the injection site. Rapid IV administration can cause hypotension and cardiopulmonary arrest.

Swine may develop GI disturbances while receiving the medication. Fatal colitis can occur in horses.

In humans, adverse effects include stomatitis, nausea, vomiting, neutropenia, leukopenia, and skin rashes.

Reproductive/Nursing Safety

In rats exposed to lincomycin, there were no observed effects on fertility, breeding performance, or survival of offspring from birth to weaning. Lincomycin crosses the placenta, and cord blood concentrations are ≈25% of those found in maternal serum. Safe use during pregnancy has not been established, but the drug has not been implicated in causing teratogenic effects.

Because lincomycin is distributed into milk, nursing animals of mothers given lincomycin may develop diarrhea.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

There is little information available regarding lincomycin overdose. In dogs, oral doses of up to 300 mg/kg/day for up to 1 year or parenterally at 60 mg/kg/day SC for 30 days did not result in toxicity or pathologic findings at necropsy.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving lincomycin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Cyclosporine**: Lincomycin may reduce levels.
- **Erythromycin**: In vitro antagonism when used with lincomycin; concomitant use should likely be avoided
- **Kaolin**: Kaolin (found in several over-the-counter antidiarrheal preparations) has been shown to reduce the oral absorption of lincomycin by up to 90% if both are given concurrently; if both drugs are necessary, separate doses by at least 2 hours.
- **Neuromuscular Blocking Agents** (eg, **pancuronium**): Lincomycin possesses intrinsic neuromuscular blocking activity and should be used cautiously with other neuromuscular blocking agents.

Laboratory Considerations

- Slight increases in **liver biochemical analytes** (ie, AST, ALT, ALP) may occur; no apparent clinical significance associated with these increases.

Dosages

DOGS:

Susceptible infections (label dosage; FDA-approved): Skin infections (eg, pustular dermatitis, abscesses, infected wounds [including bite and fight wounds]), upper respiratory tract infections (eg, tonsillitis, laryngitis), metritis, and secondary bacterial infections associated with the canine distemper-hepatitis complex: 15.4 mg/kg PO every 8 hours or 22 mg/kg PO every 12 hours; 11 mg/kg every 12 hours or 22 mg/kg every 24 hours IV (diluted in 0.9% sodium chloride or 5% dextrose and administered as a slow infusion) or IM. Treatment may continue for periods as long as 12 days.[1,7,8] **NOTE**: Some clinicians have given the drug SC in an extra-label manner.

Pyoderma (susceptible staphylococci) (extra-label): Although uncommonly recommended and used, 20 – 30 mg/kg PO every 12 hours has been used.

CATS:

Susceptible infections (label dosage; FDA-approved): Localized infections, such as abscesses, pneumonitis, and feline rhinotracheitis: 15.4 mg/kg PO every 8 hours or 22 mg/kg PO every 12 hours; 11 mg/kg every 12 hours or 22 mg/kg every 24 hours IV (diluted in 0.9% sodium chloride or 5% dextrose and administered as a slow infusion) or IM. Treatment may continue for periods as long as 12 days. **NOTE**: Some clinicians have given the drug SC in an extra-label manner.

Skin infections (extra label): Based on pharmacokinetic values and reported MICs, a dosage of 15 mg/kg PO every 12 hours is

supported for treating skin infections.[5]

SWINE:

Mycoplasmal pneumonia or infectious arthritis caused by susceptible bacteria (label dosage; FDA-approved): 11 mg/kg IM once daily for 3 to 7 days, or added to drinking water at a rate of 250 mg/gallon (average of 8.36 mg/kg/day)[8]

BIRDS:

Pododermatitis (bumblefoot) (extra-label): 50 mg/kg PO twice daily[9]

FERRETS:

Susceptible infections (extra-label): 10 – 15 mg/kg PO 3 times daily; 10 mg/kg IM twice daily[10]

HONEY BEES:

Control of American foulbrood (label dosage; FDA-approved): For each hive, mix 100 mg lincomycin with 20 g confectioners' sugar and dust over the top bars of the brood chamber once weekly for 3 weeks.[11] Feed the drug in the spring or late fall, and complete treatment at least 4 weeks before main honey flow.

Monitoring

- Clinical efficacy
- Adverse effects, particularly severe diarrheas
- Hepatic and renal function

Client Information

- Use this medicine for infections of skin, wounds, and bone.
- Report severe, continued, or bloody diarrhea to your veterinarian immediately.
- Do **NOT** give this medicine to horses, cattle, sheep, goats, deer, rabbits, mice, rats, hamsters, or guinea pigs, as it may cause fatal diarrhea.
- This medicine is best given on an empty stomach, but do not "dry pill," or it may cause throat burns. Give a small amount of food or a small amount of water (a little over a teaspoonful) after pilling.
- Bitter taste: may require disguising in food to get the animal to take it

Chemistry/Synonyms

Lincomycin is an antibiotic obtained from cultures of *Streptomyces lincolnensis* that is available commercially as the monohydrate hydrochloride. It occurs as a white to off-white, crystalline powder that is freely soluble in water. The powder may have a faint odor and has a pK_a of 7.6. The commercially available injection has a pH of 3 to 5.5 and occurs as a clear to slightly yellow solution.

Lincomycin may also be known as U-10149, NSC-70731, *Lincomix®, or Lincocin®*.

Storage/Stability

Store lincomycin capsules, tablets, and soluble powder at room temperature (20°C-25°C [68°F-77°F]) in tight containers. Store lincomycin injectable products at room temperature; avoid freezing.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Lincomycin HCl for injection is reportedly physically **compatible** for at least 24 hours in the following IV infusion solutions and drugs: 5% dextrose, 5% dextrose in 0.9% sodium chloride, 10% dextrose, 0.9% sodium chloride, lactated Ringer's injection, amikacin sulfate, chloramphenicol sodium succinate, cimetidine HCl, cytarabine, heparin sodium, penicillin G potassium (4 hours only), polymyxin B sulfate, tetracycline HCl, and vitamin B complex with C.

Drugs that are reportedly physically **incompatible** when mixed with lincomycin, data conflicts, or compatibility is concentration and/or time-dependent include ampicillin sodium, carbenicillin disodium, and phenytoin sodium.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Lincomycin Oral Solution: 50 mg/mL in 20 mL dropper bottles; *Lincocin® Aquadrops*; (Rx). FDA-approved for use in dogs and cats

Lincomycin Sterile Injection: 100 mg/mL in 20 mL vials; *Lincocin®*; (Rx). FDA-approved for use in dogs and cats

Lincomycin Sterile Injection: 25 mg/mL, 50 mg/mL, 100 mg/mL, and 300 mg/mL in 100 mL vials; FDA-approved for use in swine. Slaughter withdrawal (when used as labeled) = 48 hours. *Lincocin® Sterile Solution*, *Lincomix® Injectable*, generic; (OTC). Not all strengths appear to be marketed.

Lincomycin Soluble Powder (*Lincomix®*, generic; [Rx]) is FDA-approved for use in honey bees. The withholding period for the honey super is 49 days.[12]

There are also several lincomycin feed/water additive products for use in swine and/or poultry.

HUMAN-LABELED PRODUCTS:

Lincomycin Injection: 300 mg (as hydrochloride)/mL in 2 mL and 10 mL vials; *Lincocin®*, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Linezolid

(lih-***neh***-zoh-lid) *Zyvox®*

Oxazolidinone Antibiotic

Prescriber Highlights

- ► Use of linezolid in veterinary medicine should be very limited because of this antibiotic's importance in human medicine. Veterinary infectious disease specialists should be consulted prior to treatment initiation.
- ► Antibiotic reserved for multidrug-resistant gram-positive infections with documented resistance to other antibiotics
- ► Excellent oral bioavailability with PK parameters similar to IV administration
- ► Most common adverse effects are GI-related, but myelosuppression has been documented in veterinary patients; other serious adverse effects, including hypertension, lactic acidosis, seizures, and serotonin syndrome, have been reported in humans.
- ► Displays weak monoamine oxidase inhibitory effects; many drug interactions are possible

Uses/Indications

Linezolid is an antibacterial that should only be used for the treatment of gram-positive infections (with documented resistance to other antibiotics and susceptibility to linezolid) including methicillin-resistant *Staphylococcus aureus* (MRSA), methicillin-resistant *S pseudintermedius* (MRSP), and multidrug-resistant *Enterococcus* spp (including vancomycin-resistant *Enterococcus* [VRE]).

It is important to note there is little published information regarding safe and effective use of linezolid in veterinary patients. Because this drug is used for multidrug-resistant infections in humans, its use in veterinary medicine should be reserved for documented infections where cultures and susceptibilities suggest that the infection is resistant to all other options and is considered treatable, and where consultation with an infectious disease expert has concluded

linezolid is a viable and reasonable treatment.[1]

The World Health Organization (WHO) classifies linezolid as a Critically Important, High Priority antibiotic for human use.[2]

Pharmacology/Actions

Linezolid binds to the bacterial 23S ribosomal RNA of the 50S subunit resulting in inhibition of bacterial protein synthesis. Linezolid prevents the formation of the 70S initiation complex needed for the bacterial translation process. It is bacteriostatic against enterococci and staphylococci and bactericidal against most streptococci strains. It is less active against gram-negative bacteria and anaerobes. Linezolid's effects are time dependent.

Resistance patterns have been shown to be linked to a mutation of the 23S rRNA.[3]

Linezolid also has weak, nonselective monoamine oxidase inhibitory effects.

Pharmacokinetics

In dogs, the bioavailability of linezolid after oral administration is more than 95% and it exhibits a pharmacokinetic profile similar to IV use. Linezolid is widely distributed throughout the body with low protein binding (less than 35%) and a volume of distribution nearly equal to total body water. Peak concentrations are reached quickly (T_{max} = 0.78 to 0.95 hours; C_{max} = 26.8 to 28.2 µg/mL).[4] In humans, time to peak concentration was slightly delayed by administration with a high-fat food (T_{max} increased from 1.5 hours to 2.2 hours); C_{max} was decreased by 17%, but overall AUC remained stable.[5] In humans, renal impairment does not alter the serum concentration of linezolid [5]; however, the concentration of linezolid metabolites, which are renally eliminated, are 2 to 3 times higher in patients with renal impairment.[6]

Linezolid is metabolized by oxidation into 2 metabolites with no significant antibacterial efficacy.

Linezolid undergoes renal tubular reabsorption but is primarily excreted via the kidneys unchanged (30%) or as metabolites (50%).[4] Approximately 15% is excreted in bile almost entirely as metabolites. The elimination half-life in dogs following IV and PO administration was 3.91 hours and 3.6 hours, respectively, with no measurable concentrations after 24 to 48 hours.[4] In dogs after IV administration, clearance was measured as 1.99 mL/minute/kg.

Pharmacokinetic studies in rats and mice resulted in pharmacokinetic profiles similar to that of dogs.[4]

Contraindications/Precautions/Warnings

Linezolid is contraindicated in patients with a history of hypersensitivity to oxazolidinone antibiotics or in patients that have received monoamine oxidase inhibitors (MAOIs) within the past 14 days.[5]

In humans, lactic acidosis, myelosuppression, peripheral and optic neuropathy, serotonin syndrome, and superinfection have been reported, with most cases associated with a treatment duration greater than 2 weeks.[5] The risk for thrombocytopenia appears to be increased in patients with impaired renal function.[7–10] Additionally, linezolid should be used with caution in patients with diabetes, uncontrolled hypertension, uncontrolled hyperthyroidism, pheochromocytoma, and seizure disorders.

In humans, it has been recommended to avoid consuming foods high in tyramine (eg, aged cheeses, and cured or processed meats) while taking linezolid, as this combination has caused unexpected and significant increases in blood pressure[5]; significance in veterinary medicine is unknown.

Do not confuse the trade names *Zyvox*® (linezolid) with *Zosyn*® (piperacillin/tazobactam).

Adverse Effects

In a case report of a dog that received 23 weeks of linezolid 20 mg/kg PO every 12 hours to treat methicillin-resistant *S pseudintermedius* (MRSP) bacteremia and discospondylitis, mild anemia and thrombocytopenia were observed at treatment weeks 4 and 7; a compensated lactic acidosis was observed at week 7.[11] All adverse effects resolved by treatment week 14. Vomiting, lethargy, and anorexia were noted in 2 dogs receiving 13 – 14 mg/kg every 12 hours; the adverse effects resolved with ≈50% dosage reduction.[12] A macrocytic, hypochromic, regenerative anemia occurring in a dog after 105 days of linezolid treatment resolved after the drug was discontinued. Reversible myelosuppression (eg, neutropenia, thrombocytopenia, anemia) also has been documented in a cat.[13]

In humans, commonly reported adverse effects (more than 10%) include diarrhea, nausea, and vomiting.[5] Other adverse effects include headache, rash, and dizziness. Myelosuppression, including leukopenia, thrombocytopenia, and anemia, has also been reported in humans, and was reversible after treatment discontinuation. Serotonin syndrome was reported in humans using linezolid alone or in combination with other medication, although the overall incidence was low.[14] Rare but serious adverse effects include lactic acidosis and peripheral and optic neuropathy.[5] Treatment duration exceeding 14 days increases the incidence of myelosuppression and neurologic adverse effects[5]; additionally, impaired renal function appears to increase the risk for thrombocytopenia.[7–10]

Reproductive/Nursing Safety

Linezolid was not teratogenic in animal models, but embryo and fetal toxicities were documented concurrently with maternal toxicities including decreased neonatal survival and decreased birth weights.[5] As linezolid should be reserved for use in serious infections only, the potential benefits of treatment likely outweigh the risks.

Linezolid is excreted into milk, reaching concentrations similar to maternal plasma, and caution should be used when administered to nursing patients.[5]

Overdose/Acute Toxicity

In dogs receiving a single oral dose of 2000 mg/kg/day, reported signs of toxicity were vomiting and tremors, but there were no deaths.[15] In dogs receiving repeated IV and oral doses of 40 mg/kg/day over 30 days, adverse effects noted were anemia, leukopenia, thrombocytopenia, and bone marrow hypoplasia.[4] In rats receiving oral doses up to 3000 mg/kg/day, decreased activity and ataxia were seen.[5] The minimum lethal dose was more than 5000 mg/kg in rats and more than 2000 mg/kg in dogs.[16] The reported LD_{50} in rabbits was 100 mg/kg following oral administration.

In the event of an overdose, supportive care is recommended. Approximately 30% of linezolid is removed via dialysis.[5] For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving linezolid and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Blood Glucose Lowering Agents** (eg, **insulin, sulfonylureas** [eg, **glipizide**]): Linezolid may exacerbate hypoglycemic effects of blood glucose lowering agents.
- **Carbamazepine**: May worsen the adverse effects of monoamine oxidase inhibitors (MAOIs). Avoid combination within 14 days of treatment.
- **Chloramphenicol**: Potential for additive myelosuppression

- **Dipyrone**: Potential for additive myelosuppression
- **Food, Tyramine Containing** (eg, **aged cheese, cured meats, sauerkraut**): Food high in tyramine has caused unexpected and serious increases in blood pressure in humans taking MAOIs.
- **monoamine oxidase Inhibitors** (MAOIs; eg, **amitraz, selegiline**): Additive MAO inhibition may worsen serotonergic effect, resulting in serotonin syndrome. Avoid combination within 14 days of MAOI treatment.
- **Opioids** (eg, **buprenorphine, fentanyl, hydrocodone, tramadol**): Concurrent use may worsen serotonergic effects and may worsen adverse effects of MAOIs. Consider therapy modification.
- **Reserpine**: Use of MAOIs may worsen the adverse effects of reserpine. Addition of reserpine to linezolid therapy may cause paradoxical effects (eg, excitation, hypertension). Consider therapy modification.
- **Rifampin**: Reduced peak linezolid concentration and AUC may occur.
- **Selective Serotonin Reuptake Inhibitors** (SSRIs; eg, **fluoxetine, sertraline**): Concurrent use may increase risk for serotonin syndrome. Avoid combination.
- **Serotonergic Agents** (eg, **buspirone, dextromethorphan, metoclopramide, mirtazapine, ondansetron, trazodone**): Additive serotonergic effects increase the risk for serotonin syndrome. Avoid combination.
- **Sympathomimetics** (eg, **albuterol**, **dopamine, epinephrine, phenylephrine, phenylpropanolamine**): May worsen hypertensive effect. Reduce initial doses of sympathomimetics and monitor blood pressure closely.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Concurrent use may increase risk for serotonin syndrome. Avoid combination.

Laboratory Considerations

- None

Dosages

DOGS/CATS

NOTE: Based on pharmacokinetic information in dogs,[4] linezolid could be given by the IV route at these same dosages.

Multidrug-resistant bacterial infections (extra-label): 10 mg/kg PO every 8 to 12 hours[11–13,17]

Nocardiosis unresponsive to standard therapies (extra-label): 8 – 20 mg/kg PO every 12 hours[18]

Monitoring

- Culture and susceptibility documenting resistance to other antimicrobials and susceptibility to linezolid
- Baseline and periodic CBC if treatment duration will exceed 14 days
- Clinical efficacy
- Neurologic examination as needed
- Venous blood gas, serum lactate

Client Information

- It is important to give this medication exactly as prescribed and to complete the full course of therapy, even if your animal seems better. Missing doses or stopping treatment early may result in treatment failure.
- The most common side effects are gastrointestinal upset (eg, excessive drooling, vomiting, diarrhea, poor appetite).
- Linezolid can be given with or without food, but if your animal experiences nausea or vomiting after administration, try giving the medication with food. If side effects persist, contact your veterinarian.
- While your animal is being treated with linezolid, talk with your veterinarian before making changes to diet (including treats), additional medications, and flea/tick treatments (eg, collars, spot-on treatments).

Chemistry/Synonyms

Linezolid is an oxazolidinone antibacterial that occurs as a white to off-white crystalline powder. It has a pK_a of 1.8 and is slightly soluble in ethanol and water.

Linezolid may also be known as linezolide, U-100766, *Zyvox®*, and many other trade names internationally.

Storage/Stability

Linezolid tablets and powder for reconstitution should be stored at 25°C (77°F) and protected from light and moisture.[5] Following reconstitution, linezolid oral suspension should be stored at room temperature and discarded after 21 days.

Store unopened IV bags at 25°C (77°F) in the protective overwrap to protect from light and freezing. The solution may develop a yellow color over time but there is no effect on potency. The IV bags are intended for single use only.

Compatibility/Compounding Considerations

Linezolid IV solution is **compatible** with 0.9% sodium chloride injection, 5% dextrose injection, and lactated Ringer's injection.[5] The manufacturer recommends linezolid be administered separately from other medication and the IV line should be flushed before and after linezolid administration.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Linezolid Tablets: 600 mg; *Zyvox®*, generic; (Rx)

Linezolid Powder for Oral Suspension: 20 mg/mL after reconstitution in 150 mL bottles; *Zyvox®*, generic; (Rx)

Linezolid IV Solution: 2 mg/mL in 300 mL IV bag; generic; (Rx)

Linezolid IV Solution (preservative free): 2 mg/mL in 100 mL and 300 mL IV bag; *Zyvox®*, generic; (Rx)

Liothyronine
Triiodothyronine

(lye-oh-***thye***-roe-neen) *Cytomel®, Triostat®*

Thyroid Hormone

Prescriber Highlights

- ► Form of T_3 (active thyroid hormone) primarily used in cats as part of the T_3 suppression test for diagnosing hyperthyroidism
- ► Occasionally used for treatment of hypothyroidism, but only recommended when patients are unresponsive to levothyroxine; generally, it is not recommended in dogs
- ► Shorter duration of effect than levothyroxine
- ► Contraindications include in patients with severe cardiac disease, heart failure, thyrotoxicosis, or untreated adrenal insufficiency.
- ► Use with caution in patients with cardiac disease, in those being treated for adrenal insufficiency or diabetes mellitus, and in elderly patients.
- ► Do not confuse with levothyroxine or desiccated thyroid.

Uses/Indications

In cats, liothyronine is used to perform a T_3 suppression test as part of the diagnosis of hyperthyroidism.

Liothyronine is not recommended for initial therapy of hypothyroidism because only serum T_3 concentrations are normalized, whereas T_4 concentrations remain low. Because serum T_4 concentrations are important in the feedback regulation of the hypothalamic-pituitary-thyroid axis, dogs receiving T_3 supplementation may be more susceptible to iatrogenic thyrotoxicosis. Occasionally, animals not responding to levothyroxine due to inadequate GI absorption will respond to liothyronine; however, it is generally not recommended in dogs due to its shorter duration of effect that requires 3 times daily administration and its likelihood to cause iatrogenic hyperthyroidism. Combination products that contain both T_3 and T_4 should also be avoided for similar reasons.[1]

Pharmacology/Actions

Liothyronine is a synthetic form of triiodothyronine (T_3). In humans, T_3 is the primary hormone responsible for activity. Approximately 80% of T_3 found in the peripheral tissues is derived from thyroxine (T_4), which is the principal hormone released by the thyroid gland. Thyroid hormones affect the rate of many physiologic processes including fat, protein, and carbohydrate metabolism. Thyroid hormones increase protein synthesis, increase gluconeogenesis, and promote mobilization and utilization of glycogen stores. Thyroid hormones also increase oxygen consumption, body temperature, heart rate and cardiac output, blood volume, enzyme system activity, and growth and maturity. Thyroid hormones are particularly important for adequate development of the central nervous system.

Pharmacokinetics

In dogs, peak plasma concentrations of liothyronine occur 2 to 5 hours after oral dosing. The plasma half-life is ≈5 to 6 hours. In contrast to levothyroxine, it is believed that liothyronine is nearly completely absorbed by dogs and absorption is not as affected by stomach contents or intestinal flora changes.

Contraindications/Precautions/Warnings

Liothyronine and other thyroid replacement hormones are contraindicated in patients with severe cardiac disease, heart failure, thyrotoxicosis, or untreated adrenal insufficiency. Liothyronine should be used with caution and at a lower initial dose in patients with adrenal insufficiency, cardiac disease, or diabetes mellitus, and in elderly patients.

Adverse Effects

When liothyronine is administered at an appropriate dose to patients requiring thyroid hormone replacement, adverse effects are uncommon.

In humans, the most common adverse effects are clinical signs of hyperthyroidism including arrhythmias, irritability, insomnia, tremors, muscle weakness, increased appetite, weight loss, diarrhea, and skin rashes.[2]

Reproductive/Nursing Safety

Minimal amounts of thyroid hormones are excreted in milk and should not adversely affect nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Chronic overdoses will produce signs of hyperthyroidism, including tachycardia, polyphagia, polyuria, polydipsia, excitability, nervousness, and excessive panting. The dose should be reduced and/or temporarily withheld until signs subside. Some cats may exhibit signs of apathetic hyperthyroidism (eg, listlessness, anorexia).

Acute, massive overdoses can produce signs resembling a thyroid storm, such as fever, CNS effects (eg, agitation, seizures), GI and hepatic dysfunction (eg, vomiting, jaundice), and cardiovascular effects (eg, sinus tachycardia, atrial fibrillation, ventricular tachycardia, heart failure). After oral ingestion, treatment to reduce absorption of the drug should be accomplished using standard protocols (eg, emetics or gastric lavage, cathartics, charcoal) unless contraindicated by the patient's condition. Treatment is supportive and based on clinical signs. Oxygen, artificial ventilation, cardiac glycosides, beta-blockers (eg, propranolol), fluids, dextrose, and antipyretic agents have all been suggested for use if necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving liothyronine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antidepressants, Tricyclic/Tetracyclic** (eg, **amitriptyline**, **clomipramine**): Increased risk for CNS stimulation and cardiac arrhythmias
- **Antidiabetic Agents** (eg, **glipizide, insulin**): May increase requirements for insulin or oral agents.
- **Cholestyramine**: May reduce liothyronine absorption; separate doses by 4 hours
- **Digoxin**: Potential for reduced digoxin concentrations
- **Ketamine**: May cause tachycardia and hypertension
- **Sympathomimetics** (eg, **epinephrine**, **norepinephrine**): May potentiate the sympathomimetic effects
- **Warfarin**: Thyroid hormones increase the catabolism of vitamin K-dependent clotting factors that may increase the anticoagulation effects in patients on warfarin.

Laboratory Considerations

- **Renal function tests**: Hypothyroid dogs can have decreased GFR (creatinine clearance); restoration to a euthyroid state can increase GFR and reduce serum creatinine concentrations.

The following drugs may have effects on thyroid function tests; evaluate results accordingly:

- **Effects on serum T_4**: aminoglutethimide, anabolic steroids/androgens, antithyroid drugs (eg, propylthiouracil [PTU], methimazole), asparaginase, barbiturates, corticosteroids, danazol, diazepam, estrogens, fluorouracil, heparin, insulin, lithium carbonate, mitotane (o,p-DDD), nitroprusside, phenylbutazone, phenytoin, propranolol, salicylates (large doses), sulfonamides, and sulfonylureas
- **Effects on serum T_3**: antithyroid drugs (eg, PTU, methimazole), barbiturates, corticosteroids, estrogens, fluorouracil, heparin, lithium carbonate, phenytoin, propranolol, salicylates (large doses), sulfonamides, and thiazides
- **Effects on T_3 uptake resin**: anabolic steroids/androgens, antithyroid drugs (eg, PTU, methimazole), asparaginase, corticosteroids, danazol, estrogens, fluorouracil, heparin, lithium carbonate, phenylbutazone, and salicylates (large doses)
- **Effects on serum TSH**: aminoglutethimide, antithyroid drugs (eg, PTU, methimazole), corticosteroids, danazol, lithium carbonate, and sulfonamides
- **Effects on free thyroxine index (FTI)**: antithyroid drugs (eg, PTU, methimazole), barbiturates, corticosteroids, heparin, lithium carbonate, and phenylbutazone

Dosages

DOGS:

Hypothyroidism (extra-label): Initially, 4 – 6 µg/kg PO every 8 hours.[1] Dose should be adjusted based on postdose serum T_3 concentrations. Once clinical control is achieved, the dosing frequency may be decreased to twice daily; if clinical signs recur, then frequency should be increased back to every 8 hours.

CATS:

T_3 suppression test to diagnose hyperthyroidism (extra-label): Measure baseline T_3 and T_4 concentrations, then administer liothyronine 25 µg/cat (NOT µg/kg) PO every 8 hours for 7 doses. Measure T_3 and T_4 concentrations again 2 to 4 hours after the last dose.[3] In euthyroid cats, the second T_4 concentration should be either less than 1.5 µg/dL (20 nmol/L) or at least 50% lower than the baseline T_4 concentration. Cats with hyperthyroidism fail to suppress. The measurement of T_3 concentrations before and after liothyronine administration helps to confirm that all doses were given and that the drug was adequately absorbed.[4]

Hypothyroidism (extra-label): Initially, 4.4 µg /kg PO 2 to 3 times daily.[5] Dose should be adjusted based on postdose serum T_3 concentrations. Once clinical control is achieved, the dosing frequency may be decreased to twice daily; if clinical signs recur, then frequency should be increased back to every 8 hours.

Monitoring

- Clinical response: The goal of therapy is resolution of clinical signs of hypothyroidism.
- Serum total T_3: Draw serum just prior to dosing (trough) and again 2 to 4 hours after administering the drug.
- Serum total T_4: Unlike levothyroxine, T_4 concentrations will remain low with liothyronine treatment.
- Serum TSH: May be useful if TSH was abnormal prior to therapy

Client Information

- It is important to give this medication exactly as your veterinarian has prescribed. Missing doses or stopping treatment early may result in treatment failure.
- The most common side effects of this medicine are signs of too much thyroid hormone, such as increased hunger or thirst, excitability, or excessive panting. Contact your veterinarian if any of these signs occur.

Chemistry/Synonyms

Liothyronine is a synthetically prepared sodium salt of the naturally occurring hormone T_3 and occurs as an odorless, light tan crystalline powder. It is very slightly soluble in water and slightly soluble in alcohol. Each 25 µg of liothyronine is equivalent to ≈60 to 65 mg (1 grain) of thyroglobulin or desiccated thyroid and 100 µg or less of levothyroxine.

Liothyronine sodium may also be known as T_3, T_3 thyronine sodium, L-triiodothyronine, sodium L-triiodothyronine, liothyroninum natricum, sodium liothyronine, l-tri-iodothyronine sodium, 3,5,3'-Tri-iodo-L-thyronine sodium, or *Cytomel*®.

Storage/Stability

Liothyronine tablets should be stored at room temperature (15°C-30°C [59°F-86°F]) in tight containers.

The injection should be stored refrigerated (2°C-8°C [36°F-46°F]).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Liothyronine Sodium Tablets: 5 µg, 25 µg, and 50 µg; *Cytomel*®, generic; (Rx)

Liothyronine Sodium Injection Solution: 10 µg/mL in 1 mL vials; *Triostat*®, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Lipid Emulsion, Intravenous (ILE)

Fat Emulsion, Intravenous

Parenteral Nutritional Agent; Antidote *Intralipid*®

Prescriber Highlights

- ► Parenteral calorie and fatty acid source
- ► Can be useful in overdoses and poisonings to reduce free-drug blood concentrations of lipid-soluble toxins or drugs. Not a substitute for standard supportive measures in intoxicated patients. Only 20% lipid emulsion IV infusions should be used when treating toxicoses.
- ► The use of IV lipid emulsion (ILE) in toxicoses primarily consists of case reports and case series; the ideal dosages and protocols are still to be determined.
- ► Potentially serious adverse effects can occur (eg, hypersensitivity, lipemia, lipid overload).

Uses/Indications

IV lipid emulsions (ILEs), with or without dextrose and amino acids, can be used as a source of calories or essential fatty acids when parenteral feeding is required.

ILE may also be used as a rescue treatment for intoxications caused by lipid-soluble drugs and toxins when traditional treatments are not effective.[1,2] As certain treatments available for humans (eg, hemoperfusion, hemodialysis, long-term ventilator, or intensive care) are either widely unavailable or cost-prohibitive in veterinary medicine, early intervention with ILE for lipid-soluble (ie, lipophilic) toxin or drug toxicosis in patients with severe clinical signs may be a relatively low cost and safe intervention. A drug or toxin is considered lipophilic, and hence potentially amenable to ILE rescue treatment, when its oil:water partition coefficient ("log *P*") exceeds 2 (the greater the log *P* value, the more lipophilic the substance is).[1] Log *P* values can usually be found at the PubChem website. Note that lipophilicity/log *P* is not the only determinant to whether a toxicosis will respond to ILE treatment and contacting a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended.

Most veterinary cases of lipid infusion in the management of toxicoses involve dogs and cats but it has been used in other species, including goats, a pony,[3] and a lion.[4]

Evidence exists that ILE could be useful for reducing free-drug concentrations for drugs or drug classes such as local anesthetics (eg, bupivacaine, mepivacaine, ropivacaine, lidocaine), macrocyclic lactones (eg, ivermectin, moxidectin), calcium channel blockers (eg, diltiazem, verapamil, amlodipine), beta-blockers (eg, propranolol, carvedilol), antidepressants (eg, bupropion, doxepin, sertraline, clomipramine), antipsychotics (eg, chlorpromazine, quetiapine), antiepileptics (eg, carbamazepine, lamotrigine[5–7]), cannabis and synthetic cannabinoids, and muscle relaxants (eg, baclofen, cyclobenzaprine).[8–10]

It has also been used in the management of poisoning with permethrin, grayanotoxins, loperamide, NSAIDs, cocaine, metaldehyde, bromethalin,[11] minoxidil, carbamate,[12] methamphetamine,[12] dextroamphetamine sulfate,[12] and tremorgenic mycotoxins.[13] A case report describes successful use of ILE to resuscitate a foal after IV lidocaine-induced cardiovascular collapse.[14] Another case report describes the use of low dose ILE in 2 goats with ivermectin overdose.

Pharmacology/Actions

IV lipid emulsion (ILE) administration is an efficient method of providing calories (1 mL of a 20% emulsion provides ≈2 kcal) and serves as a source of essential fatty acids. In addition, ILE can have immunosuppressive effects, increase pro-inflammatory cytokines, and affect pulmonary function.

When used for toxicologic indications, ILE's exact mechanism of action is unknown, but it may serve as a lipid sink or shuttle for lipid-soluble compounds, reducing the amount of free drug in the circulation, thereby reducing the drug's toxic effects. Other hypotheses include improving cardiac performance and function by increasing intracellular calcium and/or providing an energy substrate for myocytes, and increasing the pool of fatty acids, thus overcoming the inhibition of mitochondrial fatty acid metabolism by drugs such as bupivacaine. In experimental studies, cardiac output has been shown to improve with lipid therapy due to decreased tissue toxin concentrations, increased liver metabolism, and accelerated unbinding of toxin from ion channels.[15]

Pharmacokinetics

IV lipid emulsion (ILE) appears to be removed from the blood stream about as rapidly as chylomicrons, but the rate of removal requires prior lipolysis of ILE into free fatty acids and seems to be increased with heparin-activated lipoprotein. In humans, elimination half-life is ≈30 minutes, with clearance from the bloodstream in 5 to 6 hours.

Contraindications/Precautions/Warnings

IV lipid emulsions (ILEs) are contraindicated in patients with severe egg yolk allergies, abnormal lipid metabolism, hyperlipemia, increased bleeding tendency, hypokalemia, or hypophosphatemia. In humans, ILEs are used with caution in premature and low birth weight infants (black box warning; lipemia), patients with blood coagulation disorders, pulmonary disease, renal impairment, severe liver damage, and those at risk for lipid emboli.[16]

The volume of lipid administered over a short period can result in fluid overload. If this is a concern, temporarily stop or reduce the administration rate of other fluids.[16]

Strict aseptic technique and good IV catheter care are imperative when using ILE with or without amino acids and dextrose. When used alone, ILE may be administered via a peripheral line but when combined with amino acids and dextrose as central parenteral nutrition (CPN), a dedicated central line is required due to the solution's hypertonicity.

Use with caution in neonates, as an increased risk for lipid emboli has been reported in premature human infants.[16]

When managing poisoned patients, ILE is not a substitute for standard supportive care. Delayed toxicity is a potential risk, as the toxin diffuses out of the lipid or as the lipid is metabolized; therefore, animals must be monitored.

Although there are no studies specifically addressing the role or safety of lipids in critically ill animals, human data suggest that lipid administration may be associated with significant immunosuppression, exacerbation of pre-existing pulmonary pathology, and increased infection rates. Data also suggest that withholding lipids for moderate periods of time is not associated with an increase in morbidity or mortality.[17]

Adverse Effects

Although IV lipid emulsion's (ILE's) adverse effect profile and incidence rates in veterinary patients have not been thoroughly reported, they are likely similar to those seen in human patients. Adverse effects reported in veterinary cases include pancreatitis, hyperlipemia, unilateral facial pruritus, extravasation with pain and local swelling, prolonged gross lipemia (lasting more than 48 hours), hemolysis, and suspected corneal lipidosis.[10,18–22] Because of the high volume given over a short period, volume overload can be a concern.[2] One case report described suspected acute respiratory distress syndrome (ARDS) in a dog treated with ILE.[23]

In humans, adverse effects associated with ILE are infrequent and usually associated with ILE used for nutritional support. The most commonly reported adverse effects are sepsis or thrombophlebitis secondary to IV administration, but these can occur whether or not IV lipids are used in parenteral nutrition therapy. Lipid overload syndrome (hyperlipemia, hepatomegaly, icterus, splenomegaly, lipid embolism, thrombocytopenia, hemolysis, and prolonged clotting times) can occur, particularly if doses are too high or administration is too fast. More rarely (in less than 1% of cases), ILE can cause pulmonary toxicity, GI effects, somnolence, headache, flushing, lipid emboli, hyperlipemia, pancreatitis, hypercoagulability, and hypersensitivity. ILE effects on pulmonary function and oxygenation are temporary and resolve after discontinuation.

Reproductive/Nursing Safety

IV lipid emulsion (ILE) has been used in the management of poisonings and as parenteral nutrition in pregnant humans. When used in situations where it is clearly needed, the benefits of using ILE during pregnancy would likely outweigh the risks.

No data regarding the safe use of ILE during lactation are available, and although ILE is likely safe, nursing may not be appropriate for mothers that require ILE.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In the case of an inadvertent overdose, stop the infusion until the lipid has cleared. This can be evaluated in a gross manner by visually inspecting the plasma (hematocrit tubes), or by laboratory methods (eg, triglyceride concentrations, plasma light-scattering activity by nephelometry).

When using IV lipid emulsion (ILE) for drug toxicity and in cases where severe hyperlipemia is present, heparin therapy 75 – 250 units/kg SC every 6 hours can be considered. Heparin may increase lipid clearance (not proven) and the use of heparin may potentially affect the mechanism of action of ILE for lipid-soluble toxicosis. Some advocate using heparin when hyperlipemia occurs in dog breeds susceptible to pancreatitis (eg, Shetland sheepdog, miniature schnauzer, Yorkshire terrier, obese animals), although there is no direct proof that hyperlipemia secondary to ILE increases the risk for pancreatitis. Otherwise, heparin therapy is not recommended unless clinical signs or advanced diagnostics indicate otherwise. Monitor partial thromboplastin time (PTT) prior to use of heparin to ensure the patient is not already coagulopathic. If PTT exceeds 2 to 2.5 times the normal dose, the dose of heparin should either be reduced to 75 units/kg SC every 6 to 8 hours or discontinued.[24]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interaction has either been reported or is theoretical in humans or animals receiving IV lipid emulsion (ILE) and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Lipid-Soluble Drugs**: IV lipid emulsion (ILE) may affect the pharmacokinetics of lipid-soluble drugs by serving as a lipid sink or shuttle for free drug in circulation. At present, clinical significance is not clear; however, when ILE is used as a nutritional

agent, concurrently with a lipid-soluble drug, be aware of possible decreased drug efficacy.

Laboratory Considerations

Blood samples for diagnostics should be collected prior to administration of IV lipid emulsion (ILE) to minimize effects from hyperlipemia.[25] This interference can be physical or chemical, particularly for electrophoretic testing methods, nonspecific interference in immunoassays, and most commonly interference in spectrophotometric testing methods, as lipid particles can absorb light.

- Falsely high **potassium**, **hemoglobin, MCH,** and **MCHC** values can occur if samples are drawn during or shortly after ILE infusion.
- Some analyzers (eg, *Hemocue®*) may report falsely high **blood glucose** values.
- **Serum bilirubin, phosphate, creatinine, oxygen saturation, AST,** and **lactate dehydrogenase** values may be affected by ILE.

Dosages

Nutritional agent for parenteral nutrition (extra-label): **NOTE**: If using IV lipid emulsion (ILE) for parenteral nutrition, it is recommended to consult with a veterinary nutritionist and refer to more detailed references.[26,27] The following are examples:

a) Most recommendations are to consider IV lipids as energy substrates, and to administer them at 30% to 40% of total calories. In veterinary medicine, lipid administration ranges from 25% to 60% of calories administered.[17] Traditionally, ILE administration is not recommended at more than 2 g/kg/day for parenteral nutrition therapy.[28]

b) There are 2 strategies employed by nutritionists to supply calories. One approach is to provide daily resting energy requirements (RER) with a mixture of all 3 nutrients (protein, dextrose, lipids) starting with a provision of adequate protein (4 – 6 g/100 kcal). Another approach is to supply the daily RER in dextrose and lipids and add protein "on top." This approach asserts that proteins not catabolized for energy can be used to maintain protein synthesis.

Hyperalimentation may occur more frequently with the second approach. Generally, either approach can be used for central parenteral nutrition, but with peripheral parenteral nutrition, care should be taken with the second approach to keep the solution below 600 mOsm/L. Some nutritionists supplement lipids alone at RER for up to 3 days. For example, in a 10 kg (22 lb) dog with RER of 370 kcal/day, *Intralipid®* 20% solution (2 kcal/mL) could supply RER peripherally at 8 mL/hour. The lipid component of parenteral nutrition is controversial, and some nutritionists do not include lipids in parenteral nutrition for critically ill patients because of concerns of increased complications due to infection, immunosuppression, free radical generation, and inflammation. Use caution when using imbalanced strategies.[29]

Rescue agent for fat-soluble drug toxicoses and other toxicoses (extra-label): **NOTE**: For additional guidance, it is highly recommended to contact an animal poison center. See ***Appendix*** for contact information. The dosages listed below are for the use of ILE 20%, which is recommended for all suggested treatment protocols in small animal medicine. Additional information on using ILE for this purpose has been published.[19,20,30] Many treatment protocols exist; the following are examples:

a) 1.5 – 4 mL/kg over 1 minute, followed by 0.25 mL/kg/minute IV CRI over 30 to 60 minutes in dogs. In animals nonresponsive after this traditional dosing protocol, additional individual bolus doses can be administered slowly at up to 7 mL/kg IV. Authors have recommended intermittent IV boluses of 1.5 mL/kg every 4 to 6 hours for the initial 24 hours with anecdotal success.[1] In addition, it is likely safe to assume that follow-up IV CRI doses of 0.05 mL/kg/hour can be continued until clinical signs improve (not to exceed 24 hours). That said, there have been no safety studies evaluating the use of ILE in the clinically poisoned veterinary patient, and careful monitoring and risk assessment is important.

b) 1.5 mL/kg IV over 5 to 15 minutes, followed by 0.25 mL/kg per minute IV CRI over 1 to 2 hours. This dose can be repeated in several hours if clinical signs of toxicosis return. Prior to repeating the dose, a peripheral blood sample should be evaluated for evidence of lipemia; additional doses should not be given if serum is lipemic.[31]

c) 2.25 mL/kg IV initial loading dose of ILE 20%, followed by 0.025 mL/kg/minute) IV CRI for up to 6.5 hours. This regimen aims to produce a modestly elevated plasma lipid concentration and is derived from pharmacokinetic and pharmacodynamics modeling.[25]

d) **For severe, protracted neurotoxicity caused by lipophilic substances (eg, permethrin, ivermectin, and other macro-lactones)**[2]: Initially, administer 1.5 mL/kg IV slowly over 1 to 2 minutes then begin 0.25 mL/kg/minute IV CRI for 30 to 60 minutes. If there is a risk for volume overload, consider a reduced rate of 0.07 mL/kg/minute for 4 hours. Evaluate patient 4 to 6 hours after stopping ILE administration. If insufficient or no clinical improvement, repeat dose once or twice as soon as the plasma/serum is no longer lipemic and there are no signs of hemolysis. Maximum total dose of ILE is 16.5 mL/kg in 60 minutes.

e) **For severe, potentially life-threatening cardiotoxicity induced by IV administered lipophilic substances**[2]: Initially, administer 1.5 mL/kg IV slowly over 1 minute then immediately begin 0.25 mL/kg/minute IV CRI. Evaluate patient after 5 minutes. If necessary, a second ILE bolus of 1.5 mL/kg IV over 1 minute can be administered. A final IV bolus may be given 5 minutes later, for a maximum of 3 total boluses. Alternatively, the CRI can be increased to 0.5 mL/kg/minute. As soon as heart function and circulation are restored, the CRI can be continued for a minimum of 10 minutes or until a maximum dose time of 30 minutes has been reached. Maximum total dose of ILE is 10 – 12 mL/kg in 30 minutes.

f) **Ivermectin overdose in 2 goats**: Initially, 2 mL/kg IV slowly over 15 minutes, followed by 0.008 mL/kg/minute IV CRI for 24 to 48 hours[32]

Monitoring

- When used for toxicity indications:
  - Drug concentrations (serum or plasma) to evaluate response to IV lipid emulsion (ILE) therapy. This information will aid in data collection for future retrospective study analysis. Although blood sampling times should be based on the pharmacokinetics of the drug, general recommendations for sampling times are time 0 (at the time of presentation), then 30 minutes, 1 hour, 6 hours, 12 hours, and 24 hours after administration of ILE.[24]
  - Monitor serum every 2 hours and consider additional infusions if the patient is still showing signs and the serum is clear of lipemia. Do not repeat ILE if the serum is very orange or yellow. If no improvement is noted after 3 doses (bolus and IV CRI), discontinue ILE therapy.[19]
  - Ensure tissue perfusion and oxygenation are maximized prior to administration of lipids. Animal studies suggest an adverse outcome of resuscitation and lipid infusion in the presence of hypoxia, possibly due to changes in the binding capacity of the lipid.

- Patients should be monitored for volume overload or allergic reactions during the infusion.[33] If there is concern for volume overload, either stop the infusion or decrease to 0.07 mL/kg/minute.

- When used for nutritional support, monitoring can be complicated and may include blood glucose, serum triglycerides, presence of lipemia, PCV, total protein, IV catheter patency and site status, hydration status, vital signs (eg, temperature, respiration rate, heart rate), serum electrolytes (including phosphorous), renal parameters (eg, BUN, creatinine) and hepatic enzyme monitoring (eg, ALT, AST, ALP), and CBC. It is recommended to consult with a veterinary nutritionist and refer to a veterinary nutrition reference for detailed information.

Client Information

- IV lipid emulsion (ILE) products should only be used by professionals in a setting where adequate patient monitoring is available.

Chemistry/Synonyms

IV lipid emulsion (ILE) products are emulsified soybean (*Intralipid*®; *Nutrilipid*®), or soybean and fish oils (*SMOFlipid*®) that provide the fatty acids linoleic, stearic, linolenic, oleic, and palmitic acids. Egg yolk phospholipids serve as the primary emulsifying agent and glycerol is used to adjust tonicity. Osmolarity varies with product, but ranges from 200 to 293 mOsm/L. The pH of ILE is between 6 and 9. Initially the pH is ≈9, but secondary to hydrolysis of triglycerides into free fatty acids (FFA), the pH decreases to 6 at the end of the product's shelf-life.

ILE may also be known as intravenous fat emulsion (IVFE), IVLE, and IFE.

Storage/Stability

Unopened IV lipid emulsion (ILE) products should be stored at room temperature (not above 25°C [77°F]) and not allowed to freeze.[16] If accidentally frozen, product should be discarded. If a partial amount of a bag or bottle is used, the remaining product should be stored protected in the refrigerator (2°C-8°C [36°F-46°F]) and discarded 24 hours after opening. A new bag or vial must be used within 24 hours.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

IV lipid emulsion (ILE) is **compatible** when mixed with the usual components used in parenteral nutrition (dextrose, amino acids, parenteral multivitamins, and trace elements), but as concentrations and mixing order can affect compatibility, it is advisable to contact a hospital pharmacist or refer to a drug compatibility reference for more information. This is particularly important as the opaque nature of ILE makes detection of precipitates very difficult.

Admixtures must be prepared with strict aseptic technique. Do not add additives directly to ILE, and in no case, add lipid emulsion to the total parenteral nutrition container first. The correct order of mixing is as follows: 1) transfer dextrose to the admixture container; 2) transfer amino acid solution; then 3) transfer lipid emulsion. Alternatively, amino acids, dextrose, and lipid emulsion may be simultaneously transferred to the admixture container; gently agitate the mixture. Use these admixtures promptly; store under refrigeration (2°C-8°C [36°F-46°F]) for 24 hours or less and use within 24 hours after removal from refrigeration.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Fat Emulsion (plant-based; soybean), IV 10%, 20%, and 30%; depending on product, in 100 mL, 250 mL, 500 mL, and 1000 mL bottles or bags; *Intralipid*®, *Nutrilipid*®; (Rx)

Fat Emulsion (fish oil and plant-based), IV 20% depending on product, in 100 mL, 250 mL, and 500 mL bags; *SMOFlipid*®; (Rx)

Lisinopril

(lye-***sin***-oh-pril) *Prinivil*®, *Zestril*®

Angiotensin-Converting Enzyme (ACE) Inhibitor

Prescriber Highlights

- ACE inhibitor that may be useful as a vasodilator in the treatment of heart failure or hypertension; it may also be of benefit in the treatment of chronic renal failure or protein-losing nephropathies.
- May be less expensive than other ACE inhibitors and possibly can be dosed once daily. When compared to enalapril and benazepril, limited information or clinical experience for use in dogs or cats is available.
- Use caution in patients with renal insufficiency (doses may need to be reduced), hyponatremia, coronary or cerebrovascular insufficiency, or hepatic disease.
- Adverse effects may include GI distress (anorexia, vomiting, diarrhea), weakness, hypotension, renal dysfunction, and hyperkalemia.

Uses/Indications

The principal uses of lisinopril in veterinary medicine at present are as a vasodilator in the treatment of heart failure or hypertension. Studies have demonstrated that ACE inhibitors, particularly when used in conjunction with furosemide, improve the quality of life in dogs with heart failure. It is not clear, however, whether it has any significant effect on survival times. Lisinopril may also be of benefit in treating the effects associated with valvular heart disease (mitral regurgitation) and left to right shunts.[1] Lisinopril is being explored as adjunctive treatment in chronic renal failure and protein-losing nephropathies.[2]

Lisinopril may have advantages over other ACE inhibitors in that it may be dosed once daily but there is little published information on its use (efficacy, safety, dosing) in veterinary species.

Pharmacology/Actions

Unlike enalapril, lisinopril does not need to be converted in the liver to an active metabolite. Lisinopril prevents the formation of angiotensin-II (a potent vasoconstrictor) by competing with angiotensin-I for the enzyme angiotensin-converting enzyme (ACE). ACE has a much higher affinity for lisinopril than for angiotensin-I. Because angiotensin-II concentrations are decreased, aldosterone secretion is reduced, and plasma renin activity is increased. Lisinopril has a higher affinity for ACE than either enalapril or captopril.

The cardiovascular effects of lisinopril in patients with CHF include decreased total peripheral resistance, pulmonary vascular resistance, mean arterial and right atrial pressures, and pulmonary capillary wedge pressure, no change or decrease in heart rate, and increased cardiac index and output, stroke volume, and exercise tolerance. Renal blood flow can be increased with little change in hepatic blood flow. In animals with glomerular disease, ACE inhibitors probably decrease proteinuria and help to preserve renal function.

Pharmacokinetics

In dogs, lisinopril's bioavailability ranges from 25% to 50%, with peak concentrations occurring ≈4 hours after dosing. Lisinopril is distributed poorly into the CNS. It is unknown if it is distributed into maternal milk, but it does cross the placenta. Half-lives are increased

in patients with renal failure or severe CHF. Duration of action in dogs has been described as being 24 hours, but effects tend to drop off with time.

No information was located for cats.

Contraindications/Precautions/Warnings

Lisinopril is contraindicated in patients that have demonstrated hypersensitivity to the ACE inhibitors. It should be used with caution and close supervision in patients with renal insufficiency, and doses may need to be reduced.

Lisinopril should be used with caution in patients with hyponatremia or sodium depletion, coronary or cerebrovascular insufficiency, or hepatic failure. Patients with severe CHF should be monitored closely upon initiation of therapy.

Adverse Effects

Lisinopril's adverse effect profile in dogs is reportedly similar to other ACE inhibitors, principally GI distress (anorexia, vomiting, diarrhea). Potentially, weakness, hypotension, renal dysfunction, and hyperkalemia could occur.

Reproductive/Nursing Safety

Lisinopril crosses the placenta. High doses in rodents have caused decreased fetal weights and increases in fetal and maternal death rates; teratogenic effects have not been reported. Current recommendations for humans are to discontinue ACE inhibitors as soon as pregnancy is detected.

It is not known whether lisinopril is excreted in the milk; use with caution.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The ASPCA Animal Poison Control Center (APCC) has over 3500 lisinopril exposure cases in its files, mostly involving dogs, but some birds and cats. The lowest dosage documented to cause hypotension in dogs is 27 mg/kg. Generally, dosages below 20 mg/kg cause mild signs only, most commonly vomiting and lethargy. Higher dosages warrant decontamination. Only a single cat out of 218 cats developed hypotension at a dosage of 4.9 mg/kg. In birds, only mild somnolence occurred at 41 mg/kg.

There were 1882 single-agent exposures to lisinopril reported to the ASPCA Animal Poison Control Center (APCC) from 2009 to 2013. There were 1781 dogs exposed and 156 that became symptomatic. The most common clinical signs included lethargy (24%), tachycardia (18%), vomiting (14%), and hypotension (13%). Of the 98 cats, 7 were symptomatic, with 29% hypertensive, 29% tachycardic, and 29% vomiting.

In overdose situations, the primary concern is hypotension; supportive treatment with volume expansion with normal saline is recommended to correct blood pressure. Because of the drug's long duration of action, prolonged monitoring and treatment may be required. Recent overdoses should be managed using gut-emptying protocols when warranted.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving lisinopril and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anesthetics**: Concurrent use may increase the risk for hypotension.
- **Angiotensin Receptor Blockers** (eg, **telmisartan**): Concurrent use of an ACE inhibitor with an angiotensin II receptor antagonist may cause additive effects on the renin-angiotensin system causing hyperkalemia, hypotension, syncope, and acute kidney injury
- **Antacids, Aluminum-, Calcium-, or Magnesium-Containing**: Reduced oral absorption of lisinopril may occur if given concomitantly with antacids; it is suggested to separate dosing by at least 2 hours.
- **Antihypertensive Agents and Vasodilators** (eg, **amlodipine, hydralazine, nitrates, prazosin, sildenafil**): Concurrent use may increase the risk for hypotension and other adverse effects; doses should be titrated carefully.
- **Buspirone**: Concurrent use may increase the risk for hypotension.
- **Cabergoline**: Concurrent use may lead to additive hypotension.
- **Corticosteroids** (eg, **dexamethasone, fludrocortisone, predniso(lo)ne**): May decrease the antihypertensive effects of ACE inhibitors
- **Darbepoetin; Epoetin**: ACE inhibitors may interfere with erythropoietin.
- **Digoxin**: Levels may increase 15% to 30% when an ACE inhibitor is added, automatic reduction in dosage is not recommended, but monitoring of serum digoxin levels should be performed.
- **Diphenhydramine**: Concurrent use may increase the risk for hypotension.
- **Disopyramide**: Hypoglycemic effects may be enhanced.
- **Diuretics** (eg, **furosemide**): Concomitant diuretics may cause hypotension if used with lisinopril; titrate dosages carefully.
- **Doxepin**: Concurrent use may increase the risk for hypotension.
- **Glycerin, Oral**: Concurrent use may increase the risk for hypotension.
- **Heparin, Low Molecular Weight Heparins** (eg, **dalteparin, enoxaparin**): Concurrent use may increase the risk for hyperkalemia.
- **Lanthanum**: Reduced oral absorption of lisinopril may occur if given concomitantly; it is suggested to separate dosing by at least 2 hours.
- **Nonsteroidal Anti-inflammatory Agents** (**NSAIDs**; eg, **carprofen, meloxicam, robenacoxib**): May reduce the clinical efficacy of lisinopril when it is being used as an antihypertensive agent; combination may result in decreased renal function
- **Opioids** (eg, **butorphanol, hydrocodone, morphine**): Concurrent use may increase the risk for hypotension.
- **Potassium** or **Potassium Sparing Diuretics** (eg, **spironolactone**): Hyperkalemia may develop.

Laboratory Considerations

- ACE inhibitors may cause a reversible decrease in localization and excretion of **iodohippurate sodium** I^{123}/I^{134}, or **Technetium** Tc^{99} pentetate renal imaging in the affected kidney in patients with renal artery stenosis, that may lead to confusion in test interpretation.

Dosages

DOGS:

Adjunctive treatment of heart failure or for other uses when an ACE inhibitor is indicated: Anecdotally, 0.5 mg/kg PO once or twice daily. In a single-dose pharmacokinetic study, lisinopril

0.5 mg/kg PO reduced ACE activity to a similar degree as enalapril 0.5 mg/kg PO.

CATS:

Adjunctive treatment of heart failure or for other uses when an ACE inhibitor is indicated (extra-label): 2.5 mg total PO once daily in combination with a low sodium diet decreased arterial blood pressure.[3] Anecdotally: 0.25 – 0.5 mg/kg PO once daily.

Monitoring

- Clinical signs of CHF
- Serum electrolytes, creatinine, BUN, urine protein:creatinine ratio
- CBC with differential, periodic
- Blood pressure (if treating hypertension or signs associated with hypotension arise)

Client Information

- Lisinopril is used to treat heart failure, high blood pressure, and some forms of kidney disease in dogs and cats.
- This medicine is usually well tolerated but vomiting and diarrhea can occur. Give this medicine with food if vomiting or lack of appetite becomes a problem. If a rash or signs of infection occur (eg, fever), contact your veterinarian immediately.
- Very important to give lisinopril as prescribed. Do not stop or reduce the dosage without your veterinarian's guidance.
- Your animal will likely need to have blood pressure and lab tests performed while receiving lisinopril.

Chemistry/Synonyms

An oral angiotensin-converting enzyme inhibitor (ACE inhibitor), lisinopril is directly active and not a prodrug like enalapril. It occurs as a white crystalline powder. One milligram is soluble in 10 mL of water, 70 mL of methanol. It is practically insoluble in alcohol, chloroform, or ether.

Lisinopril may also be known as L-154826, lisinoprilum, and MK-521; many trade names are available.

Storage/Stability

Store lisinopril tablets at room temperature in tight containers unless otherwise directed by the manufacturer.

Compatibility/Compounding Considerations

Compounded preparation stability: Lisinopril oral suspension, compounded from the commercially available tablets, has been published.[4] Triturating ten (10) lisinopril 10 mg tablets with 50 mL of *Ora Plus*® and qs ad to 100 mL with *Ora Sweet*® yields a 1 mg/mL lisinopril oral suspension that retains greater than 95% potency for 91 days when stored at 4°C (39.2°F) and protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The ARCI (Racing Commissioners International) has designated this drug as a class 3 substance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Lisinopril Oral Tablets: 2.5 mg, 5 mg, 10 mg, 20 mg, 30 mg, and 40 mg; *Prinivil*®, *Zestril*®; (Rx).

Lisinopril Oral Solution: 1 mg/mL; *Qbrelis*®; (Rx).

Also available are fixed-dose combinations of lisinopril with hydrochlorothiazide.

Lokivetmab

Canine Atopic Dermatitis Immunotherapeutic (CADI)

(loe-ki-***vet***-mab) *Cytopoint*®

Antipruritic, Monoclonal Antibody

Prescriber Highlights

- ► Used to treat clinical signs associated with allergic and atopic dermatitis in dogs only
- ► Reduced pruritus seen within 1 to 3 days in most dogs and lasts for 4 to 8 weeks; maximum effect achieved after the second dose
- ► Appears safe, well tolerated, and effective in reducing pruritus

Uses/Indications

Lokivetmab is indicated for the treatment of pruritus associated with allergic and atopic dermatitis in dogs of any age.[1,2] Lokivetmab provides dose-related relief of pruritus within 24 to 72 hours[3,4] that lasts for 4 to 8 weeks.[4,5] In studies, the majority of dogs with atopic dermatitis achieve significant reduction of pruritus after the first dose; however, maximum effect is achieved after the second dose.[5,6] Treatment with monthly lokivetmab injections was deemed noninferior to cyclosporine in controlling signs of atopic dermatitis over a 12-week study period.[7] The mean clinical scores of the cyclosporine and lokivetmab groups did not differ significantly at any time point. Lokivetmab efficacy may be improved with concurrent administration of topical treatments intended to repair the skin barrier.[8]

In a retrospective study in dogs with allergic dermatitis that received lokivetmab, 88% of dogs were determined to achieve treatment success defined as a 20 mm decrease in pruritus visual analogue scale (PVAS) scores and 77% of dogs attained a more than 50% improvement in pruritus scores.[3] A history of positive response to other anti-allergy treatment (eg, glucocorticoids, cyclosporine, allergen-specific immunotherapy) was predictive of a better response to lokivetmab. In addition, 71% of dogs with an inadequate response to oclacitinib responded to lokivetmab. In another study, significant reduction in clinical pruritus scores and skin lesions were also observed in lokivetmab treated dogs.[7]

Lokivetmab effectively treated pruritus in a dog with widespread cutaneous mastocytosis[9]; the skin lesions improved but did not resolve.

Pharmacology/Actions

Lokivetmab is a caninized monoclonal antibody that neutralizes interleukin-31 (IL-31). IL-31 is produced by cutaneous activated T helper cells in dogs with atopic dermatitis; it binds to receptors in the spinal cord that then send signals to the brain to stimulate peripheral nerves to cause pruritus. By neutralizing the action of IL-31, lokivetmab disrupts this itch signal that is activated in dogs with allergic and atopic dermatitis; this action may delay disease flares when used in advance of predictable allergen exposure.[10] Lokivetmab has also been shown to reduce transepidermal water loss (an indicator of skin barrier function) in dogs with atopic dermatitis.[11]

The degree and duration of response to lokivetmab vary in individual dogs.[5] In a retrospective study, a response occurred within 24 hours in ≈56% of dogs, between 1 to 3 days in another ≈40%, and after more than 3 days in 4%.[3] Duration of response was variable; the administration interval was less than 4 weeks in ≈20% of dogs, 4 weeks in ≈46%, and greater than 4 weeks in ≈34% of dogs. In a study conducted in a canine model of IL-31 induced pruritus, a single SC dose of lokivetmab (2 mg/kg) produced a significant reduction in pruritus starting at 3 hours postinjection and it was maintained for 42 days.[4]

Pharmacokinetics

Lokivetmab remains in the circulation for several weeks and has an onset of efficacy within 1 to 3 days of administration and a duration of activity for at least 1 month after a single dose.[2] Efficacy may persist for up to 2 months in some patients. Elimination is via protein-degradation pathways.

Contraindications/Precautions/Warnings

Lokivetmab is approved for use in dogs only and should not be used in any other species.

The US label lists no contraindications, precautions, or warnings; however, in other countries, lokivetmab is labeled as contraindicated in dogs hypersensitive to it.[12,13]

When giving lokivetmab concurrently with vaccinations, administer at separate injection sites.[13]

Adverse Effects

In the primary field safety study, pruritus as an adverse effect was reported less frequently in the lokivetmab-treated group versus placebo[14]; otitis and dermatitis occurred at a similar frequency between treatment groups and may be attributed to lokivetmab's mechanism of action (ie, reduces pruritus but does not affect inflammation related to allergic and atopic dermatitis). Adverse effects are more likely to occur during the first few days postinjection and include vomiting (7% to 15.5%), diarrhea (3.7% to 13.4%), lethargy (6% to 9.9%), pain at injection site (5.1%), anorexia (4.9%), and lameness (2.1%).[3,7,14]

Hypersensitivity-related effects (eg, anaphylaxis, facial edema, urticaria) may occur rarely; when they occur, they may cause temporary or persistent formation of antibodies to lokivetmab.[15] In studies, treatment-induced immunogenicity was found in up to 2.5% of treated dogs; antibodies to lokivetmab may reduce its efficacy in some dogs.[7,14,16]

Reproductive/Nursing Safety

Lokivetmab has not been tested in pregnant, lactating, or breeding animals.[2] Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In a long-term safety study, lokivetmab was administered at up to 10 mg/kg SC once monthly for 7 consecutive doses without adverse effects.[16]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

- No specific drug interactions have been reported and would not be expected to occur based on lokivetmab's mechanism of action as a monoclonal antibody biologic immunotherapy drug. A wide variety of concomitant medications were safely used in field safety studies, including parasiticides, antibiotics, antifungals, antidepressants, antiemetics, corticosteroids, NSAIDs, vaccines, immunotherapy, antihistamines, and other antipruritics (eg, oclacitinib, cyclosporine).[2]

Laboratory Interactions

- **Intradermal allergy testing (IDT):** One injection of lokivetmab did not interfere with circulating immunoglobulin E (IgE) concentrations in a model of *Dermatophagoides farinae*-sensitized beagles 2 weeks postinjection.[17]

Dosages

DOGS:

Allergic and atopic dermatitis (label dosage; USDA-approved): Administer SC at a minimum dose of 2 mg/kg (0.9 mg/lb) of body weight according to the table below.[2] Repeat administration every 4 to 8 weeks as needed for individual patients. Before administration, collect the number of vials indicated under each presentation according to the dog's body weight.

a) **Dogs weighing less than 2.3 kg (less than 5 lb)**: Aseptically withdraw 0.2 mL/kg (0.09 mL/lb) from a single 10 mg (Sky) vial and administer SC. Discard any remaining product.

b) **Dogs weighing 2.3 kg to 18.1 kg (5 to 40 lb)**: Aseptically withdraw the full volume of the appropriate vial according to the table below and administer SC.

c) **Dogs weighing greater than 18.1 kg (greater than 40 lb)**: A single dose requires a combination of vials, as outlined in the table below. Aseptically draw the full volume from each vial into 1 syringe and administer SC as a single injection.

Body weight in kg (lb)	10 mg/vial (Sky)	20 mg/vial (Plum)	30 mg/vial (Blush)	40 mg/vial (Navy)
less than 2.3 (5)	less than 1 vial (0.2 mL/kg)			
2.3 to 4.5 (5-10)	1 vial			
4.6 to 9.1 (10.1-20)		1 vial		
9.2 to 13.6 (20.1-30)			1 vial	
13.7 to 18.1 (30.1-40)				1 vial
18.2 to 22.7 (40.1-50)	1 vial +			1 vial
22.8 to 27.2 (50.1-60)		1 vial +		1 vial
27.3 to 31.7 (60.1-70)			1 vial +	1 vial
31.8 to 36.3 (70.1-80)				2 vials
36.4 to 40.8 (80.1-90)	1 vial +			2 vials
40.9 to 45.4 (90.1-100)		1 vial +		2 vials
45.5 to 49.9 (100.1-110)			1 vial +	2 vials
50 to 54.4 (110.1-120)				3 vials
54.5 to 59 (120.1-130)	1 vial +			3 vials
59.1 to 63.5 (130.1-140)		1 vial +		3 vials
63.6 to 68 (140.1-150)			1 vial +	3 vials

Body weight in kg (lb)	10 mg/vial (Sky)	20 mg/vial (Plum)	30 mg/vial (Blush)	40 mg/vial (Navy)
68.1 to 72.6 (150.1-160)				4 vials
72.7 to 77.1 (160.1-170)	1 vial +			4 vials
77.2 to 81.6 (170.1-180)		1 vial +		4 vials
81.7 to 86.2 (180.1-190)			1 vial +	4 vials
86.3 to 90.7 (190.1-200)				5 vials

Atopic dermatitis (extra-label): 1 mg/kg SC once a month, as the recommended minimum dosage[4,13]

Monitoring

- Efficacy manifests as lessening of pruritus
- Regular monitoring of treated dogs is recommended.
- Any adverse effects suspected to be associated with lokivetmab should be reported to the manufacturer and the USDA. Refer to the important contact information in the ***Appendix*** for further information related to reporting adverse effects.

Client Information

- This product does not cure the underlying allergic condition but should help to relieve itching caused by it.
- This drug is safe for most dogs but very rarely may cause an allergic reaction. Contact your veterinarian immediately if you see signs of excessive lethargy, weakness, collapse, difficulty breathing, sudden onset of noisy breathing, vomiting, or facial swelling.
- Your veterinarian will need to monitor your dog's condition while receiving this medicine to help identify the needed frequency of injections. Do not miss these important follow-up visits.

Chemistry/Synonyms

Lokivetmab (ATCvet code QD11AH) may also be known as Canine Atopic Dermatitis Immunotherapeutic, CADI, ZTS-00103289, Immunoglobulin G2, anti-(*Canis familiaris* interleukin 31) (*Canis familiaris*-Mus musculus monoclonal PF-06443537 gamma2-chain), disulfide with *Canis familiaris*-Mus musculus monoclonal PF-06443537 kappa-chain, dimer, and *Cytopoint*®.

Storage/Stability

Store vials upright in original packaging between 2°C and 8°C (36°F-46°F). Do not freeze. Prolonged exposure to higher temperatures and/or direct sunlight may adversely affect potency. Product contains no preservatives. Vials are single-use only; discard vials after puncture.[2]

Compatibility/Compounding Considerations

No information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Lokivetmab Solution: 10 mg, 20 mg, 30 mg, and 40 mg in 1 mL vials; *Cytopoint*®; USDA Veterinary License No. 190; (Rx)

HUMAN-LABELED PRODUCTS: NONE

Lomustine

CCNU

(loe-mus-teen) *Gleostine*®, *CeeNu*®

Oral Antineoplastic

Prescriber Highlights

- ► Oral antineoplastic usually used for treatment of CNS neoplasms, mast cell tumors, and histiocytic sarcomas or as a rescue agent for lymphoma protocols
- ► Caution is advised in patients with anemia, myelosuppression, pulmonary function impairment, current infection, impaired renal or hepatic function, or a sensitivity to lomustine.Significant adverse effects include myelosuppression (eg, anemia, refractory thrombocytopenia, leukopenia) with nadirs in dogs occuring ≈1 to 3 weeks after treatment, idiosyncratic hepatocellular injury (dogs), corneal de-epithelization, renal toxicity, and pulmonary infiltrates or fibrosis. Additional adverse effects include anorexia, vomiting, diarrhea, stomatitis, and alopecia.
- ► Teratogenic
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies lomustine as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Lomustine may be useful in the adjunctive treatment of CNS neoplasms, lymphomas, mast cell tumors, and sarcomas (histiocytic sarcoma [dogs], fibrosarcoma [cats]) in dogs and cats.[1-5] Lomustine is usually dosed in a pulse fashion (ie, higher dose every 2 to 6 weeks depending on the protocol), but metronomic dosing (ie, low dose, daily) could potentially be useful in dogs that do not have other standard-care treatment options.[6,7]

Pharmacology/Actions

Lomustine's mechanism of action is not totally understood, but it is cell cycle-phase nonspecific. Lomustine is believed to inhibit DNA, RNA, and protein synthesis through alkylation and carbamoylation.

Cross-resistance has occurred between lomustine and carmustine.

Pharmacokinetics

In humans, lomustine is absorbed rapidly and extensively from the GI tract, and some absorption occurs after topical administration. Lomustine and its active metabolites are widely distributed in the body, including across the blood–brain barrier. Lomustine is metabolized extensively in the liver to both active and inactive metabolites that are eliminated primarily in the urine. Lomustine half-life in humans is very short (≈15 minutes), but its biologic activity is significantly longer because of the longer elimination times of active metabolites (16 to 48 hours).

Contraindications/Precautions/Warnings

Lomustine is contraindicated in patients hypersensitive to it. Lomustine should be used only when its potential benefits outweigh its risks with the following conditions: anemia, myelosuppression, pulmonary function impairment, current infection, and impaired renal or hepatic function.

Fatalities have resulted from inadvertent daily administration of high-dose pulse therapy[8]; consider only administering high-dose pulse therapy in the clinic.

The National Institute for Occupational Safety and Health (NIOSH) classifies lomustine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[9]

Adverse Effects

Lomustine can cause fatal adverse effects, particularly when used at higher dosages and for prolonged treatment periods. The most seri-

ous adverse effects are myelosuppression (eg, anemia, thrombocytopenia, leukopenia) and idiosyncratic hepatotoxicity. CBC nadirs in dogs generally occur ≈1 to 3 weeks after treatment is given but can range from 1 to 6 weeks. Neutropenia in cats (nadir is variable; usually 1 to 4 weeks but can range from 1 to 6 weeks) is usually the dose-limiting factor, but there is significant interpatient variation for dosage tolerance in cats. Neutropenia is common dogs and cats, although secondary infections or sepsis are relatively uncommon.

Lomustine may cause hepatotoxicity in dogs[10,11]; hepatotoxicity is reportedly less common in cats.[12] Because some studies in rats have shown that alpha-lipoic acid may reduce the incidence/severity of hepatotoxicity associated with some chemotherapeutic agents, alpha-lipoic acid (5 mg/kg PO every 12 hours) has been used in some canine treatment protocols using lomustine[13]; alpha-lipoic acid is generally not recommended for use in cats because of toxicity concerns.[14-16] S-adenosyl-methionine (SAMe) plus silymarin (*Denamarin®*) has also been used in dogs for the same purpose.[17,18]

Other potential adverse effects include GI effects (eg, anorexia, vomiting, diarrhea [more commonly seen in dogs]), stomatitis, alopecia, corneal de-epithelization and, rarely, renal toxicity, and pulmonary infiltrates or fibrosis.

A retrospective study of 185 dogs receiving lomustine reported the following adverse effects: neutropenia (57%), increased ALT (49%), GI toxicosis (38%; ≈the majority of which were because of vomiting), anemia (34%), thrombocytopenia (14%), azotemia (12%), and hepatic failure (1.2%).[11] The authors concluded that lomustine-induced toxicity is common in dogs but usually is not life-threatening.

Reproductive/Nursing Safety

Lomustine is a teratogen in laboratory animals. Use only during pregnancy when the benefits to the mother outweigh the risks to the offspring. Lomustine can suppress gonadal function.

Lomustine and its metabolites have been detected in maternal milk. Nursing neonates should be given a milk replacer when the dam is receiving lomustine.

Overdose/Acute Toxicity

The lowest reported fatal dose in a dog following IV and oral administration of lomustine was 5 mg/kg and 10 mg/kg, respectively.[19] Because lomustine can be toxic, overdoses should be treated aggressively, with gastric decontamination protocols employed when possible.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving lomustine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medications may result in additive myelosuppression; avoid combination when possible.
- **Vaccines** (live and inactivated): Lomustine may diminish vaccine efficacy and enhance adverse effects of vaccines.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary staff, and pet owners and because chemotherapy indications, treatment protocols, monitoring, and safety guidelines often change, the following are usual dosage ranges for this drug and should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[20-24] are strongly recommended.

DOGS:

Chemotherapy indications (extra-label): 50 – 90 mg/m^2 (NOT mg/kg) PO every 2 to 6 weeks, depending on the indication and protocol

Metronomic chemotherapy for primary or metastatic tumors (extra-label): 1.8 – 3.8 mg/m^2 (median=2.84 mg/m^2; NOT mg/kg) PO once daily[6]

CATS:

Chemotherapy indications (extra-label):

1) 40 – 60 mg/m^2 (NOT mg/kg) PO every 3 to 6 weeks depending on the indication and protocol[25]
2) 10 mg/cat (NOT mg/kg) PO every 3 weeks depending on the indication and protocol[26]

Monitoring

- Baseline CBC with platelet count, serum chemistry profile, and urinalysis
- CBC with platelet count 1 week after dosing and prior to next dose; as a general rule, if platelets are less than 50,000/µL, stop therapy until thrombocytopenia is resolved.[27]
- Serum chemistry profiles before each treatment (especially in dogs)

Client Information

- Lomustine is a chemotherapy (anticancer) drug. The drug and its byproducts can be hazardous to other animals and humans. On the day your animal receives the drug and for a few days after, all bodily waste (eg, urine, feces, litter), blood, or vomit should be handled only while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in the regular trash.
- Bone marrow suppression can occur. The greatest effects on bone marrow are usually within a few weeks after treatment. Your veterinarian will do blood tests to watch for this. Do not miss these important follow-up visits.
- If you see bleeding, bruising, or fever (indicating an infection) or if your animal becomes very tired easily, contact your veterinarian right away.
- Lomustine can cause damage to the liver, kidney, and lungs. It is important to understand the need to immediately report any signs associated with toxicity (eg, abnormal bleeding, bruising, urination, depression, infection, shortness of breath, yellowing of whites of the eyes, skin, or gums).
- Ensure dosing regimen is completely understood if dispensing for owners to administer at home.

Chemistry/Synonyms

Lomustine, a nitrosourea derivative alkylating agent, occurs as a yellow powder that is practically insoluble in water and soluble in alcohol.

Lomustine may also be known as CCNU, lomustinum, NSC-79037, RB-1509, WR-139017, *CeeNu®*, and *Gleostine®*.

Storage/Stability

Store capsules in a well-closed container at room temperature between 20°C and 25°C (68°F-77°F). Avoid exposure to temperatures above 40°C (104°F).[28]

Compatibility/Compounding Considerations

Precautions (eg, use of a biological safety cabinet) must be taken to avoid exposure from capsule contents when compounding dosage forms from commercially available capsules. Recent studies suggest many of the compounded formulations do not contain the expected

active drug content, and use of the FDA-approved product is recommended whenever possible.[29,30]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Lomustine Capsules: 5 mg, 10 mg, 40 mg, and 100 mg with mannitol; *Gleostine*®; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Loperamide

(loe-***pair***-a-mide) *Imodium*®
Opioid Antidiarrheal

Prescriber Highlights

- ► Opioid GI motility modifier used primarily in dogs for treatment of noninfectious, intractable diarrhea
- ► Contraindications include dogs with *MDR1* genetic mutation (also known as *ABCB1-1*delta) or unknown *MDR1* status, known hypersensitivity to narcotic analgesics, or diarrhea caused by infectious etiologies or toxin ingestion.
- ► Use with caution in patients with respiratory disease, hepatic encephalopathy, hypothyroidism, hypoadrenocorticism (Addison's disease), head injury, increased intracranial pressure, acute abdominal conditions (eg, bowel obstruction), and in severely debilitated patients.
- ► Adverse effects in dogs include constipation, bloat, and sedation; potential for paralytic ileus, toxic megacolon, pancreatitis, and CNS effects.
- ► Use in cats may result in excitatory behavior.
- ► Calculate doses carefully in small dogs and cats to avoid overdose.

Uses/Indications

Loperamide is used as a GI motility modifier in small animal species (primarily dogs) with noninfectious, intractable diarrhea. Some have found that loperamide is useful for treating or helping to reduce chemotherapy-induced (eg, toceranib) diarrhea in dogs.[1,2] In combination with maropitant, loperamide may be useful in preventing paclitaxel-induced GI adverse effects in dogs.[3]

Anecdotally, loperamide has been used for short-term management of diarrhea in cats, although adverse effects (eg, excitatory behavior, constipation) may limit therapy.

Pharmacology/Actions

Loperamide acts on the circular and longitudinal muscles by binding to mu-opioid receptors in the GI tract to decrease GI motility and excessive GI propulsion. Loperamide also decreases intestinal secretion induced by the cholera toxin, prostaglandin E_2, and diarrhea caused by factors in which calcium is the second messenger (noncyclic AMP/GMP mediated). Opioids may also enhance mucosal absorption and increase anal sphincter tone. It has no analgesic activity.

Pharmacokinetics

By altering GI motility, loperamide may alter its own absorption. In a small study of 2 wild-type *MDR1* homozygotes (*MDR1* normal/normal) and 3 *MDR1* mutant (also known as *ABCB1-1*delta) homozygotes (*MDR1* mutant/mutant) dogs, oral bioavailability was 46 and 67%, respectively, peak concentration occurred at 1 and 3.6 hours after administration, and half-life was ≈10 and ≈12 hours.[4]

In humans, peak concentrations are reached 2.5 to 5 hours after administration. Loperamide is metabolized in the liver by CYP450 and exhibits an extensive first-pass metabolism; it has a half-life of ≈11 hours and is eliminated in the feces via biliary excretion.

Contraindications/Precautions/Warnings

Loperamide is contraindicated in patients with known hypersensitivity to it. Loperamide is a P-glycoprotein substrate that is contraindicated in dogs that are homozygous (*MDR1* mutant/mutant) for the *MDR1* genetic mutation (also known as *ABCB-1*delta) due to loss of P-glycoprotein function needed to excrete loperamide from the CNS. Alternative antidiarrheals should be considered in untested dogs of high-risk breeds (eg, herding breeds: collies, Shetland sheepdogs, Australian shepherds) that may have the gene mutation. Dogs that are heterozygous for the mutation (*MDR1* mutant/normal) should receive loperamide at reduced dosages if no alternative therapies are available.

Opioid GI motility modifiers should be avoided if diarrhea is due to an infectious etiology or an ingested toxin. All opioids should be used with caution in patients with hypothyroidism, hypoadrenocorticism (Addison's disease), or in severely debilitated patients.

Opioid antidiarrheals should be used with caution in patients with head injuries or increased intracranial pressure and acute abdominal conditions (eg, bowel obstruction), as it may obscure the diagnosis or negatively impact clinical resolution. Loperamide should be used with extreme caution in patients suffering from respiratory disease or from acute respiratory dysfunction (eg, pulmonary edema). Opioid antidiarrheals should be used with extreme caution in patients with hepatic encephalopathy; hepatic coma may result. Loperamide should be used cautiously in patients with hepatic impairment as first-pass metabolism may be reduced.

Adverse Effects

In dogs, salivation, constipation, bloat, and sedation are the most likely adverse effects encountered when recommended dosages are used. Potentially, paralytic ileus, toxic megacolon, pancreatitis, and CNS effects (eg, sedation, ataxia) could be seen. Dogs with the *MDR1* genetic mutation (also known as *ABCB-1*delta*; MDR1* mutant/mutant) can develop severe CNS depression, ataxia, mydriasis and salivation after receiving a single 0.1 mg/kg PO dose of loperamide.[5] Naloxone may reverse CNS effects.[6] See ***Overdose/Acute Toxicity***.

Loperamide use in cats may cause excitatory behavior and constipation.

In humans, cardiotoxicity has been seen in patients receiving higher dosages.[7]

Reproductive/Nursing Safety

Rats experienced significant impairment of fertility at dosages of 20 – 40 mg/kg/day; this effect was not observed at 10 mg/kg/day. Loperamide is excreted in human maternal milk in small amounts; use with caution during lactation.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In dog toxicity studies, dosages of 1.25 – 5 mg/kg/day produced vomiting, depression, severe salivation, and weight loss. Breeds with either homozygous (*MDR1* mutant/mutant) or heterozygous (*MDR 1* mutant/normal) *MDR1* gene mutations (also known as *ABCB-*1delta) are more sensitive to CNS depression with loperamide than other breeds.[8]

Adverse effects seen in dogs with loperamide overdose include vomiting, lethargy, diarrhea, hypersalivation, hypothermia, bradycardia, vocalization, depression, sedation, circling, ataxia, limb weakness, non-reactive pupils and disorientation.[8-10]; in cats, vomiting, lethargy, and mydriasis are the most common.

Treatment should follow standard decontamination protocols,[11] although the use of emetics (eg, apomorphine, ropinirole) should be

avoided because they may have additive CNS and/or respiratory depressant effects. Naloxone may be used to treat severe CNS or respiratory depression[8,9,11,12]; repeated doses of naloxone may be required. Intravenous lipid emulsion (ILE) rescue may be useful.[13]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Loperamide is a substrate of P-glycoprotein and human CYP2C8 and 3A4 isoenzymes. The following drug interactions have either been reported or are theoretical in humans or animals receiving loperamide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: By inhibiting P-glycoprotein, amiodarone may increase loperamide plasma concentrations.
- **Carvedilol**: By inhibiting P-glycoprotein, carvedilol may increase loperamide plasma concentrations.
- **CYP2B11 Substrates** (eg, **ketamine, midazolam, progesterone, propofol**): Loperamide can inhibit metabolism of this isoenzyme in dogs and potentially increase blood concentrations of substrates.
- **CYP2D15 Substrates** (eg, **imipramine, metoprolol, propranolol**): Loperamide can inhibit metabolism of this isoenzyme in dogs and potentially increase blood concentrations of substrates.
- **CYP3A12 Substrates** (eg, **cyclosporine, erythromycin, medetomidine, tacrolimus**): Loperamide can inhibit metabolism of this isoenzyme in dogs and potentially increase blood concentrations of substrates.
- **Desmopressin**: Loperamide may increase serum desmopressin concentrations.
- **Erythromycin**: By inhibiting P-glycoprotein, erythromycin may increase loperamide plasma concentrations.
- **Gemfibrozil**: Increased loperamide plasma concentrations
- **Ketoconazole, Itraconazole**: By inhibiting P-glycoprotein, these drugs may increase loperamide plasma concentrations.
- **Moxidectin**: Loperamide reduced moxidectin clearance and increased moxidectin plasma concentration and AUC.[14]
- **Quinidine**: By inhibiting P-glycoprotein, quinidine may increase loperamide plasma concentrations.
- **QT-Prolongation Agents**: Loperamide may enhance the QT-prolonging effect.
- **Sulfamethoxazole/Trimethoprim**: Increased loperamide plasma concentrations due to inhibition of first-pass metabolism
- **Verapamil**: By inhibiting P-glycoprotein, verapamil may increase loperamide plasma concentrations.

Laboratory Considerations

- Plasma **amylase** and **lipase** values may be increased for up to 24 hours following administration of opioids.

Dosages

DOGS:

NOTE: Avoid use in dogs with the *MDR1* genetic mutation as they are more sensitive to loperamide; there is no published evidence of a safe dosage for these patients. See ***Contraindications/Precautions/Warnings***.

Antidiarrheal agent (label dosage, not FDA-approved): Dosed based on body weight: 4.5 kg – 11.4 kg, 1 mg/dog (NOT mg/kg); 11.8 kg – 18.2 kg, 2 mg/dog (NOT mg/kg); 18.6 kg – 27.3 kg, 4 mg/dog (NOT mg/kg). Administer 1 dose every 8 hours as needed for the temporary relief of diarrhea; do not exceed 3 doses per 24 hours, or 3 days of treatment.[15]

Antidiarrheal (extra-label): Anecdotal dosage range from 0.08 – 0.1 mg/kg PO 3 times daily as needed, but dosages as high as 0.2 mg/kg PO 3 to 4 times daily have been noted.

CATS:

NOTE: Use is controversial; cats may react with excitatory behavior.

Antidiarrheal (extra-label): Anecdotal dosages ranging from 0.04 – 0.16 mg/kg PO every 12 hours have been noted. Practically, ¼ or ½ of a 2 mg tablet may be used, although the oral liquid dosage form is necessary to dose accurately.

RABBITS, RODENTS, SMALL MAMMALS:

Antidiarrheal agent (extra-label):

1. **Rabbits**: 0.1 mg/kg in 1 mL of water PO every 8 hours for 3 days, then once daily for 2 days[16]
2. **Mice, Rats, Gerbils, Hamsters, Guinea pigs, Chinchillas**: 0.1 mg/kg PO every 8 hours for 3 days, then once daily for 2 days; give in 1 mL of water.[17]

Monitoring

- Clinical efficacy
- Hydration and serum electrolytes especially in cases of severe diarrhea
- Adverse CNS effects (eg, sedation, depression, disorientation, ataxia, mydriasis, non-reactive pupils)

Client Information

- This medicine is used to treat diarrhea.
- Loperamide is generally well tolerated with few side effects. Loperamide can be toxic in dogs with a certain genetic mutation (MDR1; also known as *ABCB*-1delta) most commonly found in "white feet" breeds (eg, collies, Shetland sheepdogs, Australian shepherds).
- If diarrhea continues or if your animal appears listless or develops a high fever, contact your veterinarian immediately.
- Loperamide is available OTC (over the counter; without a prescription). Do not give loperamide (or any other OTC medication) to your animal without first consulting your veterinarian.

Chemistry/Synonyms

A synthetic piperidine-derivative antidiarrheal, loperamide occurs as a white to faintly yellow powder with a pK_a of 8.6. It is soluble in alcohol and slightly soluble in water.

Loperamide may also be known as PJ 185, or R 18553; a common trade name is *Imodium*®.

Storage/Stability

Loperamide capsules or oral solution should be stored at room temperature (20°C-25°C; 68°F-77°F), in well-closed containers protected from light. It is recommended that the oral solution not be diluted with other solvents.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

Loperamide HCl Oral Liquid: 2 mg/mL in 10 mL; generic; (OTC). Not approved by the FDA.

Loperamide HCl Tablets: 2 mg; *Difixin®*; (OTC)

HUMAN-LABELED PRODUCTS:

Loperamide HCl Oral Liquid: 1 mg/5 mL (0.2 mg/mL) and 1 mg/7.5 mL (0.13 mg/mL) in 60 mL, 90 mL, 118 mL, and 120 mL solution or suspension; *Imodium® A-D*, generic; (OTC)

Loperamide HCl Capsules and Tablets: 2 mg; *Imodium® A-D*; other proprietary named products are available as well as generics; (OTC and Rx)

Loratadine

(lor-***at***-eh-deen) *Claritin®, Alavert®*

Antihistamine, Second-Generation

Prescriber Highlights

- ► Oral nonsedating antihistamine
- ► Limited experience in dogs or cats; efficacy (if any) has not been determined.

Uses/Indications

Loratadine is a nonsedating second-generation antihistamine. Although loratadine could be useful in treating histamine-mediated conditions in dogs and cats, there is no evidence documenting its efficacy. A double-blind, placebo-controlled, randomized clinical trial evaluating the efficacy of loratadine for the treatment of canine atopic dermatitis did not show sustained relief of pruritus in any of the dogs.[1] Guidelines for atopic dermatitis treatment in dogs state that antihistamines have modest efficacy in some dogs; loratadine should be given continuously (ie, daily) as preventive therapy before an acute flare.[2] Antihistamines may also be used as steroid-sparing agents and with essential fatty acids to improve potential efficacy.[3]

Pharmacology/Actions

Loratadine is a long-acting oral second-generation antihistamine from the piperidine class. It blocks peripheral histamine (H_1) receptors. Unlike some antihistamines, loratadine is not an alpha-1 antagonist, and at therapeutic dosages it does not have significant antimuscarinic activity.

Pharmacokinetics

No information was located for dogs or cats.

In humans, loratadine is rapidly absorbed from the GI tract; peak plasma concentrations occur in ≈1 hour. Food has variable effects on time to peak, but overall bioavailability is increased. It is extensively metabolized in the liver and its primary metabolite (desloratadine) is active. Loratadine is highly bound to plasma proteins (98%); plasma protein binding for desloratadine is lower. Minimal amounts of the drug enter the CNS at therapeutic dosages. Severe renal impairment does not appreciably alter blood concentrations of the drug or its active metabolite. Elimination half-life is ≈ 9 hours (loratadine) and 28 hours (desloratadine). Elimination occurs mostly as metabolites via urine and feces.

Contraindications/Precautions/Warnings

Loratadine is contraindicated in patients that are hypersensitive to it or desloratadine. Use with caution in dogs with keratoconjunctivitis (KCS), as loratadine has been shown to decrease tear production in humans. Lower dosages are recommended in humans with significant renal or hepatic impairment.

Adverse Effects

Adverse effects are not well-documented for loratadine in small animal species. At higher dosages in humans, it could have adverse CNS effects (eg, sedation, lethargy, paradoxical excitement), have GI effects (eg, vomiting), and/or cause tachycardia. Dry mouth and decreased tear production are possible.

Reproductive/Nursing Safety

Loratadine did not alter fertility of mice at 40 mg/kg and rats at 25 mg/kg; there is no evidence of teratogenicity in rats or rabbits given oral doses up to 96 mg/kg.[4] Loratadine and its metabolite are found in breast milk at concentrations roughly equivalent to maternal plasma, but the American Academy of Pediatrics has listed loratadine as compatible with breastfeeding in humans.[5]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Mild overdoses of loratadine are generally not serious, but moderate to severe overdoses can cause cardiac (eg, tachycardia) and CNS (eg, sedation) effects. Clinical signs usually occur within 30 minutes to 7 hours postingestion and can persist for 12 to 24 hours or more. Clinical signs in dogs have been noted at doses as low as 0.25 mg/kg, but doses as high as 72 mg/kg have been tolerated without serious effects or death.[6]

Common clinical signs associated with loratadine overdose in dogs include tachycardia, lethargy, and vomiting. Consider GI decontamination for patients that have ingested larger quantities of loratadine. Treatment is supportive; hemodialysis does not appear to be effective in removing loratadine or desloratadine from the body.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving loratadine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: In humans, QT-interval prolongation and torsades de pointes have been reported[7]; clinical monitoring has been recommended.
- **Cimetidine**: May increase loratadine (and desloratadine) concentrations; no clinical effects noted in humans
- **Macrolide Antibiotics (eg, clarithromycin, erythromycin)**: May increase loratadine (and desloratadine) concentrations
- **Ketoconazole**: May increase loratadine (and desloratadine) concentrations; no clinical effects noted in humans

Laboratory Considerations

- **Intradermal allergy testing (IDT)**: Antihistamines may suppress IDT results. It is recommended to discontinue loratadine at least 7 days prior to testing in dogs.[2]

Dosages

NOTE: No published evidence was located that supports efficacy and safety for pruritus or atopic dermatitis.

DOGS:

Antihistamine (extra-label): Anecdotal dosages range from 0.25 – 1.1 mg/kg PO once daily or divided twice daily.[8-10]

Practically it could be dosed as follows:
- Small dogs: 5 mg/dog (NOT mg/kg) PO once daily
- Medium dogs: 10 mg/dog (NOT mg/kg) PO once daily
- Large dogs: 10 mg/dog (NOT mg/kg) PO twice daily

CATS:

Antihistamine (extra-label): Anecdotal dosages of 0.5 mg/kg PO once daily[11,12] or 2.5 – 5 mg/cat (NOT mg/kg) PO once daily[13,14] have been noted.

Monitoring

- No specific monitoring is required beyond clinical efficacy and adverse effects.

Client Information

- Use only products that contain loratadine as a single active ingredient. Decongestants found in human-label combination products can be toxic to animals.
- Antihistamines should be used on a regular, ongoing basis in animals that respond to them. They work better if used before exposure to an allergen (eg, pollens).
- This medicine may be given with or without food. If your animal vomits or acts sick after receiving the medication on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Causes less sleepiness than some other antihistamines, but sleepiness can still occur. Not used commonly in veterinary medicine so possible side effects are not well known.

Chemistry/Synonyms

Loratadine is a piperidine derivative related structurally to azatadine. It is a white to off-white powder that is insoluble in water but very soluble in acetone, chloroform, methyl alcohol, and toluene.

Loratadine may also be known as SCh-29851, loratadiini, loratadin, loratadinum, or loratadyna.

Storage/Stability

Loratadine products should be stored between 20°C to 25°C (68°F-77°F). Loratadine syrup or tablets should be stored in tight, light-resistant containers. The orally dispersing tablets should be protected from humidity.

Compatibility/Compounding Considerations

- No specific information is noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Loratadine Tablets, Oral Disintegrating Tablets, Chewable Tablets, and Gelcaps: 5 mg and 10 mg; generic; (OTC). Many proprietary brands are available; 2 common ones are *Claritin*® and *Alavert*®. **NOTE**: Oral dispersible tablets may contain xylitol (unknown quantity); avoid use in dogs. Chewable tablets may contain flavorings such as grape, citrus, or mint.

Loratadine Oral Solution/Syrup: 1 mg/mL (labeled as 5 mg/5 mL); generic; (OTC). Many proprietary brands are available; 2 common ones are *Claritin*® and *Alavert*®. May be flavored with grape or bubble gum. Do not use products containing propylene glycol in cats.

NOTE: *Do not use formulations containing pseudoephedrine, such as Claritin-D, to treat dogs and cats due to potential unpredictable adverse effects.*

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Lorazepam

(lor-***ayz***-eh-pam) *Ativan*®

Benzodiazepine

Prescriber Highlights

► Benzodiazepine used as an anxiolytic in dogs and cats and as an alternative to diazepam for treating status epilepticus
► Can be administered IV for status epilepticus, or intranasally if IV access is difficult or delayed
► Most common adverse effects include activity or behavior changes (sedation, lethargy, hyperactivity, aggression) and increased appetite
► DEA Schedule IV (C-IV) controlled substance

Uses/Indications

Lorazepam is used to treat seizures and status epilepticus in dogs and for adjunctive treatment of behavior disorders (eg, fears, phobias, anxiety) in dogs and cats. As compared with diazepam, there are limited data using lorazepam in small animal medicine, but lorazepam has some advantages such as safer use in patients with liver dysfunction and in obese or geriatric patients. It appears to be as effective as diazepam, and may have a longer anticonvulsant duration of action.[1] Rectal administration of lorazepam is not recommended for status epilepticus.[2]

In human medicine, lorazepam is often used in place of diazepam for treating status epilepticus and anxiolytic indications. It is also used to treat chemotherapy-induced nausea and emesis, alcohol withdrawal, and akathisia secondary to antipsychotic drugs.

Pharmacology/Actions

Lorazepam is considered a long-acting benzodiazepine in humans, but it has a much shorter half-life in dogs. Lorazepam and other benzodiazepines depress CNS subcortical levels (primarily limbic, thalamic, and hypothalamic), thereby producing anxiolytic, sedative, skeletal muscle relaxation, and anticonvulsant effects. Lorazepam binds to gamma-aminobutyric acid type A (GABAA) receptors and increases the affinity of the receptor for GABA, which results in increased chloride conductance and hyperpolarization of the postsynaptic cell membrane. Other postulated mechanisms include antagonism of serotonin, increased release of GABA, and diminished release or turnover of acetylcholine in the CNS. Benzodiazepine-specific receptors have been located in the mammalian brain, kidney, liver, lung, and heart; receptors are lacking in the white matter of all species studied.

Pharmacokinetics

In dogs, lorazepam 0.2 mg/kg IV reached peak concentrations of ≈165 ng/mL, which remained above 30 ng/mL (considered necessary for anticonvulsant activity in humans) for 60 minutes.[3] Intranasal administration of lorazepam at 0.2 mg/kg in dogs reached peak concentrations of ≈106 ng/mL; in 3 out of 6 dogs studied, concentrations remained above 30 ng/mL for 60 minutes. Concentrations reached 30 ng/mL between 3 to 9 minutes after intranasal administration.[3] Although elimination half-life has been reported as ≈1 hour in dogs, concentrations in the brain may persist longer than in the serum, as lorazepam has a high affinity for benzodiazepine receptors in the CNS. Rectal administration of lorazepam in dogs does not

appear to yield serum concentrations high enough for efficacious treatment of status epilepticus due to a high first-pass effect.[2] Lorazepam is converted into inactive glucuronide metabolites in the liver in most species.[4] The primary elimination route is via urine in dogs.

In cats, lorazepam is efficiently glucuronidated[4, 5]; elimination is ≈50% in the urine (primarily as the glucuronide) and 50% in the feces.[5]

In humans, absolute bioavailability is ≈90% after oral administration and, unlike diazepam, lorazepam is relatively rapidly and completely absorbed after IM dosing. Sublingual administration has similar bioavailability as oral dosing, but serum concentrations peak sooner. Elimination half-life appears to be much longer in humans (12 hours) than in dogs (≈1 hour).

Contraindications/Precautions/Warnings

Lorazepam is contraindicated in patients with known hypersensitivity to benzodiazepines, patients with acute narrow-angle glaucoma, and patients with severe respiratory insufficiency (unless they are being mechanically ventilated).

Lorazepam should be used with caution, if at all, in patients that have a history of aggression, as behavioral disinhibition may occur.

When using lorazepam to treat unwanted behaviors, behavior disorders, or with long-term administration, withdraw it gradually at the end of the treatment to prevent a possible rebound effect. Physical dependency has been induced in dogs, although it appears to be less intense than with diazepam.[6]

Injectable lorazepam must not be given intra-arterially; arteriospasm may occur, resulting in necrosis.[7] Use repeated high doses or CRIs with caution as the injection contains propylene glycol and benzyl alcohol.

Do not confuse LORazepam with other sound-alike/look-alike drugs (eg, CLONazepam, ALPRAZolam). Consider writing part of the drug's name in uppercase letters (tall-man designations) on prescriptions/orders to reduce the risk for errors.

Adverse Effects

In small animals, benzodiazepines can cause increased appetite, aggression, paradoxical increased activity/excitement/anxiety/agitation, and vocalization. Sedation, muscle relaxation, ataxia, somnolence, and lethargy can occur with initiation of therapy, with dosage increases, or at higher doses.

Lorazepam injection contains both propylene glycol 400 (0.18 mL/mL of injection) and 2% benzyl alcohol. Repeated high doses or CRIs may have toxic effects in dogs and cats.

Reproductive/Nursing Safety

Lorazepam crosses the placenta. Congenital anomalies, fetal resorption, and increased fetal loss have been observed in laboratory animals. In humans, the use of benzodiazepines during pregnancy resulted in premature births and low birth weights. "Floppy infant" syndrome has been seen in human neonates whose mothers receive high doses immediately prior to delivery.[8, 9]

Lorazepam is distributed into milk. Sedation and inability to suckle have occurred in human neonates of lactating mothers taking benzodiazepines.[9]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose effects of lorazepam are generally limited to CNS depression. The most common clinical signs observed in dogs are sedation, lethargy, hyperactivity, ataxia, and vomiting. In cats, the most common clinical signs are ataxia, lethargy, vocalization, and agitation. Large overdoses can cause hypotension, coma, and death (rare). Repeated high doses or CRIs of the injectable formulation may cause propylene glycol or benzyl alcohol toxicity.

Treatment of acute orally ingested lorazepam toxicity consists of standard protocols for GI decontamination and supportive systemic measures. In patients with normal renal function, diuresis with IV fluids/electrolytes and mannitol may enhance excretion of lorazepam. The use of analeptic agents (CNS stimulants such as caffeine) is generally not recommended. Flumazenil may be considered for adjunctive treatment of severe overdoses of benzodiazepines, but its use does not replace proper supportive therapy. Flumazenil is not recommended in patients with seizure disorders as it may induce seizures.[7, 9]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving lorazepam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: Concurrent use may increase bioavailability and pharmacologic effects of benzodiazepines.
- **Anesthetic Agents** (eg, **alfaxalone, ketamine, propofol**): Combination may increase the risk for CNS and/or respiratory depression.
- **Antacids, Calcium- or Magnesium-Containing**: May slow the rate, but not the extent of oral absorption; administer 2 hours apart to avoid this potential interaction.
- **Antihypertensive Agents** (eg, **atenolol, lisinopril**): Concurrent use may increase risk for hypotension and orthostasis. Monitor blood pressure.
- **Carbonic Anhydrase Inhibitors** (**CAIs**; eg, **dichlorphenamide, methazolamide**): Benzodiazepines may interfere with the beneficial effects of CAIs by inhibiting respiratory responses to hypoxia. Avoid combination.
- **Cannabidiol**: Increased risk for CNS depression
- **Digoxin**: Serum levels may be increased; monitor serum digoxin concentrations and clinical signs of toxicity.
- **Fluoxetine, Fluvoxamine**: Concurrent use may increase lorazepam concentrations and lead to an increased risk for CNS and respiratory depression.
- **Hepatic Enzyme Inducers** (eg, **betamethasone, carbamazepine, rifampin**): Concurrent use may decrease benzodiazepine levels.
- **Hepatic Enzyme Inhibitors** (eg, **cimetidine, erythromycin, isoniazid, ketoconazole, itraconazole**): Metabolism of lorazepam may be decreased, and excessive sedation may occur.
- **Ifosfamide**: Concurrent use may increase the risk for ifosfamide-induced neurotoxic effects. Carefully monitor for adverse effects; discontinue both drugs if signs of encephalopathy occur.
- **Nondepolarizing Neuromuscular Blockers** (eg, **atracurium, pancuronium**): Concurrent use may potentiate, attenuate, or have no neuromuscular blocking effect.
- **Opioids** (eg, **buprenorphine, morphine**): Combination may increase the risk for CNS and/or respiratory depression.
- **Phenobarbital**: Combination may increase the risk for CNS and/or respiratory depression.
- **Phenothiazines** (eg, **acepromazine**): Combination may increase the risk for CNS and/or respiratory depression.
- **Theophylline/Aminophylline**: Concurrent use may de-

crease the levels and effectiveness of benzodiazepines. Withdrawing theophylline from a stable patient may increase the risk for benzodiazepine toxicity. Monitor and adjust doses accordingly.

- **Tricyclic Antidepressants (TCAs**; eg, **amitriptyline, clomipramine**): Lorazepam may increase concentrations of these drugs; clinical significance is not known. However, concurrent use may increase the risk for CNS and/or respiratory depression. Anticholinergic effects may be additive.
- **Yohimbine**: Limited data indicate that yohimbine may decrease therapeutic effects of anxiolytic drugs.

Laboratory Considerations

- Benzodiazepines may decrease the thyroidal uptake of I^{123} or I^{131}.

Dosages

DOGS:

Status epilepticus (extra-label): 0.2 mg/kg IV.[1] In humans, IV doses should be administered no faster than 2 mg/minute.[7] If IV access cannot be readily achieved (or for at-home use by pet owners), the IV dose can be administered intranasally; however, the delay in onset (3 to 9 minutes; see ***Pharmacokinetics***) may negate its practical use and midazolam IN may be more advantageous. Do not administer rectally.[2]

Behavior indications (eg, fears, anxieties, phobias, night waking; extra-label): No published evidence supporting any one dosage over the other was located. It is suggested to start therapy at the lower end of the dose range, choosing a practical dose for the patient based on available tablet sizes; adjust dose to desired effect. If used on an as-needed basis to treat episodic or situational anxiety, oral lorazepam may be most efficacious when administered prior to the triggering event, as the time to onset may be highly variable.

a) 0.02 – 0.2 mg/kg PO 1 to 3 times daily or on an as-needed basis

b) 0.02 – 0.5 mg/kg PO every 8 to 24 hours[10]

CATS:

Behavior indications (eg, fears, anxieties, phobias, night waking; extra-label): No published evidence supports any one dosage over the other. It is suggested to start therapy at the lower end of the dose range, choosing a practical dose for the patient based on available tablet sizes; adjust dose to desired effect. If used on an as-needed basis to treat episodic or situational anxiety, oral lorazepam may be most efficacious when administered prior to the triggering event, as the time to onset may be highly variable.

a) 0.025 – 0.08 mg/kg PO 1 to 2 times daily[10] or on an as-needed basis

b) 0.125 – 0.25 mg/cat (NOT mg/kg) PO every 12 to 24 hours[11]

Monitoring

- No specific monitoring is required beyond clinical efficacy and adverse effects.

Client Information

- When using lorazepam for thunderstorm phobias or other triggers that upset your animal (eg, owner separation anxiety), try to give this medicine about an hour before the event or trigger.
- Common side effects include drowsiness, sedation, and increased appetite. However, the drug can change your animal's behavior or work in the opposite way from what is expected.
- Tablets are relatively tasteless and readily dissolve in saliva. If administering the pill is difficult, place it inside your animal's cheek and follow up after about a minute with a small treat to facilitate swallowing of the medicine.
- If the whites of your animal's eyes, skin, or gums have a yellowish tint, or if your animal stops eating or seems depressed, contact your veterinarian immediately.
- Lorazepam is a controlled drug by the federal Drug Enforcement Agency (DEA). Use of this medication in animals or humans other than those for whom they are prescribed is illegal.

Chemistry/Synonyms

Lorazepam occurs as a white or practically white, practically odorless powder. It is insoluble in water and sparingly soluble in alcohol. Each mL of lorazepam for injection contains 0.18 mL of polyethylene glycol 400 and 2% benzyl alcohol in propylene glycol.

Lorazepam may also be known as BRN-07599084, CB-8133, Ro-7-8408, Wy-4036, lorazapamum, anxiedin, azurogen, bonatranquan, delormetazepam, lorazin, lorazon, lorenin, norlormetazepam, novhepar, novolorazem, o-Chloroxazepam, sinestron, *Ativan*®, and *Lorazepam Intensol*®; many international trade names are available.

Storage/Stability

Lorazepam tablets should be stored in airtight containers at room temperature (20°C-25°C [68°F-77°F]). The oral solution and injection should be stored refrigerated (2°C-8°C [36°F-46°F]) and protected from light.

The injection must be further diluted immediately prior to IV injection with an equal volume of D_5W, normal saline, or sterile water for injection. Do not shake the syringe vigorously; instead, gently invert it repeatedly until the injection is diluted and completely mixed in solution. Do not use if the solution is discolored or a precipitate forms. IV injections should be administered slowly (2 mg/minute).[7]

Lorazepam is a DEA Schedule IV (C-IV) controlled substance that should be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Lorazepam can be further diluted in D_5W or normal saline for IV infusion. (**NOTE**: This is not stated in the label information.) When used in this manner, lorazepam injection is most soluble in final concentrations of 0.1 to 0.2 mg/mL. For example, if the 2 mg/mL injection is used, further dilution with 9 mL or 19 mL of D_5W or normal saline would yield a final concentration of 0.2 or 0.1 mg/mL. The injection is very viscous; mix well before use. Because precipitation/crystallization can occur, observe the solution before and during the infusion. D_5W may be less prone to crystallization formation than is normal saline. Solutions for infusion mixed in this manner should be used within 12 hours of preparation.

Drugs reported to be **compatible** with lorazepam injection include (partial listing):

- **Syringe**: Hydromorphone, dimenhydrinate
- **Y-Site**: Albumin, amikacin, amphotericin B cholesteryl, atracurium, cefotaxime, ciprofloxacin, cisplatin, dexamethasone, diltiazem, diphenhydramine, dobutamine, doxorubicin, famotidine, fentanyl, fosphenytoin, furosemide, gentamicin, heparin, hydroxyethyl starches, hydromorphone, levetiracetam, methadone, metronidazole, morphine, piperacillin-tazobactam, propofol, ranitidine, vancomycin, and vecuronium

Drugs reported to be **incompatible** with lorazepam include (partial listing):

- **Syringe**: Buprenorphine and pantoprazole
- **Y-Site**: Aztreonam, gallium nitrate, imipenem-cilastatin, omeprazole, and ondansetron

Dosage Forms/Regulatory Status

Lorazepam is a DEA Schedule II controlled substance; report prescribing and/or dispensing to state monitoring programs where required

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Lorazepam Tablets: 0.5 mg, 1 mg, and 2 mg; *Ativan*®, generic; (Rx; C-IV)

Lorazepam Concentrated Oral Solution: 2 mg/mL in 10 mL and 30 mL with dropper; *Lorazepam Intensol*®; (Rx; C-IV)

Lorazepam Injection: 2 mg/mL and 4 mg/mL in 1 mL prefilled syringes, 1 mL single use vials and 10 mL multidose vials; *Ativan*®, generic; (Rx; C-IV)

Losartan

(loe-***sar***-tan) *Cozaar*®

Angiotensin II Receptor Blocker (ARB)

Prescriber Highlights

- ► May be useful in dogs for the adjunctive treatment of proteinuria
- ► Limited data and experience in veterinary medicine to support clinical use in dogs or cats. Telmisartan is preferred in dogs and cats, as there is more research and clinical experience.
- ► Contraindications include volume and/or electrolyte depletion, hypotension, and hypersensitivity to losartan and possibly other angiotensin II receptor blockers (ARBs).
- ► Use caution in patients with hepatic impairment
- ► Not safe during pregnancy

Uses/Indications

Losartan may be useful for the adjunctive treatment of proteinuria in dogs,[1] but there is limited information on its safety and efficacy for veterinary species.

Any potential clinical usefulness of losartan in cats is in question, as one study in 6 cats with experimentally induced (angiotensin I given IV) hypertension did not show that losartan had any significant or consistent effect on blood pressure or pressor response.[2] Telmisartan is FDA-approved for use in cats, and its use would be preferred over losartan.

In dogs, potential clinical usefulness is tempered with the concern that dogs do not metabolize much losartan into an active metabolite (E-3174; EXP-3174)[3] that in humans is thought to produce much of the drug's therapeutic effect and allow once-daily dosing. A study measuring hemodynamic functions in dogs with experimental tachycardia-induced heart failure demonstrated that losartan was ≈3 times less potent than E-3174 in improving some measured functions (eg, reduced pulmonary artery pressure, mean arterial pressure, pulmonary capillary wedge pressure and peripheral resistance, and increased stroke volume).[4]

Additional studies are necessary to determine where losartan fits into the veterinary drug armamentarium.

Pharmacology/Actions

Losartan is an angiotensin II receptor blocker (ARB). By selectively blocking the AT1 receptor, aldosterone synthesis and secretion is reduced, resulting in vasodilation, decreased potassium excretion, and increased sodium excretion. Although plasma concentrations of renin and angiotensin II are increased, this does not counteract the blood pressure lowering effects of losartan. Losartan does not interfere with substance P or bradykinin responses.

In humans, losartan is converted in the liver, likely via P-450 2C9, into the active metabolite (E-3174). E-3174 is a reversible, noncompetitive inhibitor of the AT1 receptor and is more potent than losartan. Dogs do not appear to produce much of the active metabolite,[3] which, as compared with human patients, may considerably alter the dosing strategy, adverse effects, and efficacy of the drug.

Pharmacokinetics

In dogs, losartan, given as single oral doses, was rapidly absorbed with peak concentrations occurring within one hour and a bioavailability of 23% to 33%. Volume of distribution was 0.3 L/kg. Plasma protein binding was ≈97% with free drug between 2% and 3%. Elimination half-life was between 2 and 3 hours. It is thought that the majority of drug is eliminated in the bile/feces, but significant enterohepatic recirculation occurs.[3]

No losartan pharmacokinetic data were located for cats.

In humans, the pharmacokinetics of losartan differ markedly from what is seen in dogs. After oral dosing, absorption is rapid with a bioavailability of the parent compound of ≈33%. Presence of food can slow absorption but does not affect the extent. Significant first-pass metabolism converts much of the absorbed drug into a carboxylic metabolite (E-3174), which is responsible for much of the drug's therapeutic efficacy. Bioavailability of E-3174 is ≈14% of the administered dose. Peak concentrations of losartan and E-3174 occur at ≈1 and 4 hours, respectively. Free fractions of losartan/E-3174 are 1.3%/0.2%. Terminal half-lives are ≈2 hours for losartan and 8 hours for E-3174. Area under the curve for E-3174 is ≈4 times that of the parent compound. Approximately 10% of the drug and active metabolite are excreted unchanged in the urine with the remainder excreted primarily via bile and feces and as other metabolites in the urine.

Contraindications/Precautions/Warnings

Losartan is contraindicated in patients that are hypersensitive to it. It is not known if cross-reactivity occurs between other angiotensin II receptor blockers (ARBs) and losartan. Hypotensive patients should not receive this drug. Patients that are volume- or electrolyte-depleted should not receive this drug until they are rehydrated, and their electrolytes have been replenished and corrected.

Losartan should be used with caution in patients with hepatic impairment; dosage reduction may be warranted.

Adverse Effects

The adverse effect profile for losartan is not known when it is used clinically in veterinary species. In humans, adverse effects are not common. Adverse effects reported include dry cough, orthostatic dizziness, hypotension, nasal congestion, and back pain.[5] Changes in renal function and hyperkalemia are possible. Very rarely in humans, hypersensitivity and hepatopathy with increased liver enzymes have been reported.

Reproductive/Nursing Safety

Losartan is not considered safe to use during pregnancy. Studies in pregnant rats given high doses of angiotensin II receptor blockers (ARBs) demonstrated a variety of fetal abnormalities (eg, renal pelvic cavitation, hydroureter, absence of renal papilla). Smaller doses in rabbits caused increased maternal death and spontaneous abortion. In humans, the drug is considered teratogenic, particularly during the second and third trimesters. If pregnancy is detected in patients receiving losartan, the drug should be discontinued as soon as possible.

Because losartan and its active metabolite have been detected in substantial quantities in rat milk, there is significant concern about the safety of the drug during nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Significant lethality was observed in mice and rats after oral administration of 1 g/kg. Hemodialysis is not effective in removing losartan or its active metabolites.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving losartan and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **benazepril, enalapril**): Increased risk for adverse effects (eg, hypotension, hyperkalemia, renal function changes); increased monitoring may be warranted
- **Aspirin**: Possible reduced antihypertensive effects of losartan and increased risk for renal impairment; increased monitoring may be warranted
- **Baclofen**: Concurrent use may have additive blood pressure lowering effects.
- **Benzodiazepines** (eg, **diazepam, lorazepam**): Concurrent use may increase risk for hypotension.
- **Buspirone**: Concurrent use may increase risk for hypotension.
- **Cabergoline**: Concurrent use may increase risk for hypotension.
- **Clarithromycin**: Concurrent use may increase the risk for increased losartan concentrations.
- **Corticosteroids** (eg, **betamethasone, dexamethasone**): May decrease the antihypertensive effects of angiotensin II receptor blockers (ARBs)
- **Dexmedetomidine**: Concurrent use may result in additive effects on blood pressure and heart rate.
- **Diazoxide**: Concurrent use may increase risk for hypotension.
- **Dichlorphenamide**: Concurrent use may increase risk for hypotension.
- **Digoxin**: Concurrent use may increase digoxin concentration. Closely monitor digoxin concentration and therapeutic effects.
- **Diphenhydramine**: Concurrent use may increase risk for hypotension.
- **Doxepin**: Concurrent use may increase risk for hypotension.
- **Insulin**: Concurrent use may increase risk for hypoglycemia.
- **Low Molecular Weight Heparins** (eg, **dalteparin, enoxaparin**): Concurrent use may increase risk for hyperkalemia.
- **Nonsteroidal anti-inflammatory Drugs (NSAIDs**; eg, **carprofen, meloxicam**): Possible reduced antihypertensive effects of losartan and increased risk for renal impairment; increased monitoring may be warranted.
- **Opioids** (eg, **buprenorphine, butorphanol**): Concurrent use may increase risk for hypotension.
- **Potassium Preparations, Potassium-Sparing Diuretics** (eg, **spironolactone**): Increased risk for hyperkalemia; increased monitoring of serum potassium may be warranted.
- **Yohimbine**: Concurrent use may decrease the efficacy of ARBs.

Laboratory Considerations

None were noted.

Dosages

DOGS:

NOTE: There is little clinical experience using this drug in veterinary patients and very limited data published on its clinical usage. Losartan use at this time is experimental and use in clinically ill dogs and cats should be approached with caution. Given the differences in metabolization and lower concentrations of active metabolites noted in dogs, dosages and/or medication frequency may need to be adjusted to provide clinical effectiveness.

Adjunctive treatment of proteinuria in dogs with glomerular disease (extra-label): The International Renal Interest Society (IRIS) has published their consensus-recommended dosages: Azotemic dogs: Initial dose of 0.125 mg/kg PO per day and an escalating dose of 0.25 mg/kg per day. Nonazotemic dogs: 0.5 mg/kg per day and an escalating dose of 1 mg/kg per day. Concurrent administration of an ACE inhibitor is generally recommended.[1]

Monitoring

- Patients treated with losartan should be monitored for response to therapy as well as side effects.[1]
- Monitoring is recommended 1 to 2 weeks after starting losartan therapy and 1 to 2 weeks after increasing losartan dose or dose frequency.[1]
- Monitoring after starting or changing dosages should include UPC, serum creatinine, serum potassium, and blood pressure to verify the desired therapeutic effect was achieved.[1]
- In all dogs receiving losartan, UPC, urinalysis, systemic arterial blood pressure, serum albumin, creatinine, and potassium concentrations should be monitored at least quarterly.[1]

Client Information

- This medication may be given with or without food.
- Because this medication has not been used often in dogs or cats, side effects are not well known; watch carefully for any side effects and report them to your veterinarian. Possible side effects could include diarrhea, vomiting, lack of appetite, fatigue (tiredness), and low blood pressure (eg, fainting, weakness, intolerance to exercise).
- This drug has caused birth defects and should not be used in pregnant animals. If humans in the household are pregnant, they should be very careful not to ingest these tablets, wear disposable gloves when administering doses, and wash their hands after touching these tablets.

Chemistry/Synonyms

Losartan potassium [CAS Registry: 114798-26-4 (losartan); 124750-99-8 (losartan potassium); ATC: C09CA01] occurs as a white to off-white, hygroscopic crystalline powder. It is freely soluble in water and methyl alcohol; soluble in isopropyl alcohol and slightly soluble in acetonitrile.

Losartan potassium may also be known as DuP-753, E-3340, or MK-0954. A common trade name is *Cozaar*®.

Storage/Stability

Store losartan tablets at room temperature (up to 30°C [86°F]) and protect from light.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The manufacturer of the human-labeled tablets (Merck & Co)

describes a method to prepare an extemporaneous suspension containing losartan potassium 2.5 mg/mL: Add 10 mL of purified water to a 240 mL polyethylene terephthalate (PET) bottle containing ten 50 mg tablets of losartan potassium; shake contents for more than 2 minutes.[5] Allow concentrated suspension to stand for 60 minutes following reconstitution, then shake for an additional minute. Prepare a mixture containing equal parts (by volume) of syrup (*Ora-Sweet*®) and suspending vehicle (*Ora-Plus*®) separately. Dilute the concentrated suspension of losartan potassium with 190 mL of the *Ora-Sweet*® and *Ora-Plus*® mixture; shake the container an additional minute to disperse ingredients. Shake suspension before dispensing each dose. Store in the refrigerator (2°C-8°C [36°F-46°F]) for up to 30 days.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Oral Tablets: 25 mg, 50 mg, and 100 mg; *Cozaar*®, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Lotilaner

(loh-teh-***lan***-er) *Credelio*®

Isoxazoline Ectoparasiticide

Prescriber Highlights

- ► Chewable oral tablet for treatment and prevention of flea infestation in dogs and cats; treatment and control of American dog tick, black-legged tick, lone star tick, and brown dog tick infestation in dogs; and treatment and control of black-legged tick infestation in cats
- ► Must be administered with food
- ► Treatment can begin at any time of the year.
- ► Appears to be well tolerated when administered at the label dosage
- ► The FDA has warned that drugs in the isoxazoline class have the potential for causing neurologic adverse effects (eg, including muscle tremors, ataxia, and seizures) in dogs and cats.

Uses/Indications

Lotilaner is FDA-approved for the treatment and prevention of flea infestations (*Ctenocephalides felis*) and the treatment and control of infestations of American dog tick (*Dermacentor variabilis*, wood tick), black-legged tick (*Ixodes scapularis*, deer tick), lone star tick (*Amblyomma americanum*), and brown dog tick (*Rhipicephalus sanguineus*) for 1 month in dogs and puppies 8 weeks of age and older with a body weight of 2 kg (4.4 lb) or more.[1] Lotilaner may be used as part of a treatment strategy to control flea allergy dermatitis.[2]

In cats, lotilaner is FDA-approved for treatment and prevention of flea infestations (*Ctenocephalides felis*) for 1 month in cats and kittens 8 weeks of age and older weighing 2 pounds or more, as well as for the treatment and control of *Ixodes scapularis* (black-legged tick) infestations for 1 month in cats and kittens 6 months of age or older and weighing 2 pounds or more.[3]

Lotilaner is used extra-label to treat generalized demodicosis and sarcoptic mange in dogs.[4,5] When dogs with sarcoptic mange were treated with monthly label-recommended doses, pruritus ceased within 2 weeks, skin scrapings were negative in 1 month and active lesions in all dogs were absent at 2 months.[5] In dogs, lotilaner has demonstrated efficacy against *Ambylomma cajennense* (sensu lato),[6] *Ixodes holocyclus*,[7] and *Haemaphysalis longicornis*.[8]

In the European Union (EU), lotilaner is indicated for immediate and persistent killing activity for 1 month for fleas (*C felis* and *C canis*) and ticks (*R sanguineus, Ixodes ricinus* [castor bean tick], *I hexagonus* [hedgehog tick], and *Dermacentor reticulatus* [ornate cow/dog tick]) in dogs.[9] In cats, lotilaner has EU approval for the treatment of flea and tick infestations in cats 8 weeks of age and older and weighing 0.5 kg (1.1 lb) or more,[5] and can improve signs of flea allergy dermatitis.[9,10]

Pharmacology/Actions

Lotilaner is an isoxazoline insecticide and acaracide. Lotilaner inhibits gamma-aminobutyric acid (GABA)-gated chloride channels in insect and acarine peripheral and central nervous systems,[11] blocking transfer of chloride ions across cell membranes. The resulting neuronal hyperexcitation results in rapid death of susceptible insects and acarines. A difference between insect and acarine GABA receptor sensitivity to lotilaner in comparison to mammals is believed the reason for differential toxicity.[12] Lotilaner kills adult fleas and ticks only after they have bitten and fed.

In dogs, lotilaner begins killing fleas within 2 to 4 hours of infestation or administration,[1,13] with ≈99.8% of fleas killed within 8 hours[13,14] and 100% of fleas killed within 12 hours.[1,14] This speed of kill (ie, ≈99.8% of fleas killed within 8 hours, 100% of fleas killed within 12 hours) is maintained for 35 days after administration.[14] Fleas are killed before laying eggs.

In cats, lotilaner begins killing fleas within 8 hours of administration.[15] Efficacy was >99% against *I ricinus* in lotilaner-treated cats for up to 35 days, with >90% killing noted within 12 hours for the first 7 days following administration and within 18 hours for days 8 to 35.[16]

Lotilaner is 97% to 100% effective against the 4 major ticks when administered 48 hours after infestation, with ≈70% reduction in the number of live ticks observed on treated dogs at 4 hours after lotilaner administration. Effectiveness is maintained for 30 to 35 days after administration.[1,16–18]

Pharmacokinetics

In dogs, lotilaner peak levels occur 2 hours after oral administration.[13] Food increases absorption. Lotilaner is highly protein bound.[11] Biliary excretion is the major route of elimination.[9] Average elimination half-life is 9.6 days in beagles 2 months of age versus 28 days in beagles 10 months of age[19] and 30.7 days in adult beagles.[11]

In cats, peak lotilaner levels occur 4 hours after oral administration. Bioavailability approaches 100% when given with food but is only 8.4% when fasting. Maximum lotilaner concentration was ≈9 times higher when given with food versus fasting. Volume of distribution at steady state was 5.37 L/kg. Clearance was 0.13 L/kg/day, and the terminal half-life was 28.7 days after IV administration, and 33.6 days following oral administration.[20]

Contraindications/Precautions/Warnings

Lotilaner is contraindicated in patients with a known hypersensitivity to it.[1,3] In the United States, lotilaner is not approved for use in puppies or kittens less than 8 weeks of age, in kittens that weigh less than 0.9 kg (2 lb) or in dogs that weigh less than 2 kg (4.4 lb). Use lotilaner with caution in dogs or cats with a history of seizures or epilepsy.

Adverse Effects

In preapproval field studies (284 dogs over 90 days), no serious adverse effects were noted. The most common adverse effects in dogs included weight loss (1.5%), elevated BUN, polyuria, and diarrhea (1% each). Additionally, 1 dog experienced head tremors, and 1 dog with a history of seizures experienced seizure activity 6 days after lotilaner administration. Vomiting also has been reported.[1]

Field studies in cats did not result in significant adverse events. Adverse effects may include weight loss (2.2%), tachypnea (1.3%), vomiting (1.3%), diarrhea (0.9%), anorexia (0.9%), and elevated BUN (0.9%).[3]

The FDA has warned that in dogs and cats treated with drugs in the isoxazoline class have the potential for causing neurologic adverse effects, including muscle tremors, ataxia, and seizures.[21]

Reproductive/Nursing Safety

The label states that safe use in breeding, pregnant, or lactating dogs[1] and cats[3] has not been evaluated. No evidence[10] of reproductive or teratogenic effects was noted in laboratory studies of rats.[9]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No clinically relevant, treatment-related effects were observed when lotilaner was administered to beagles[1] or kittens[22] 8 weeks of age at 3 and 5 times the label dose every 28 days for 8 doses.[1]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

In a field study, lotilaner was administered with other medications (eg, vaccines, antibiotics, NSAIDs, anthelmintics, anesthetics) with no observed adverse effects.[1]

Laboratory Considerations

- None noted

Dosages

DOGS:

For labeled indications; treatment and prevention of flea infestations *(Ctenocephalides felis)*, and the treatment and control of black-legged tick *(Ixodes scapularis)*, American dog tick *(Dermacentor variabilis)*, lone star tick *(Amblyomma americanum),* and **brown dog tick *(Rhipicephalus sanguineus)* infestations for 1 month in dogs and puppies 8 weeks of age and older weighing 2 kg (4.4 lb) of body weight or more** (label dosage; FDA-approved): Minimum dosage is 20 mg/kg PO once per month with food[1]

Patient weight	Tablet size (mg)	Number of tablets
2 kg to 2.7 kg (4.4 lb to 6 lb)	56.25	1
>2.8 kg to 5.5 kg (6.1 lb to 12 lb)	112.5	1
>5.5 kg to 11.4 kg (12.1 lb to 25 lb)	225	1
>11.5 kg to 22.7 kg (25.1 lb to 50 lb)	450	1
>22.8 kg to 45.5 kg (50.1 lb to 100 lb)	900	1

For dogs weighing more than 100 lb (45.5 kg), administer the appropriate combination of chewable tablets.

Generalized demodicosis (extra-label): Minimum dosage 20 mg/kg PO once every 4 weeks for 3 treatments was effective in reducing and eliminating live mite counts in dogs with naturally occurring *Demodex* spp infestation.[4]

Sarcoptic mange (extra-label): Treat according to manufacturer's label recommendations PO once every 4 weeks for 3 treatments (see table above for label dosages).[5]

CATS:

Treatment and prevention of flea infestations (*Ctenocephalides felis*) for 1 month in cats and kittens 8 weeks of age and older weighing 0.9 kg (2 lb) or greater (6 mg/kg), as well as the treatment and control of black-legged tick (*Ixodes scapularis*) infestations for 1 month in cats and kittens 6 months of age or older and weighing 0.9 kg (2 lb) or more (label dosage; FDA-approved): Minimum dose of 6 mg/kg orally once a month[3]

Patient weight	Tablet size (mg)	Number of tablets
0.9 kg to 1.8 kg (2 lb to 4 lb)	12	1
1.9 kg to 7.7 kg (4.1 lb to 17 lb)	48	1
Over 7.7 kg (17 lb)	Appropriate combination of tablets	

Treatment of flea and tick infestations in cats 8 weeks of age and older and weighing 0.5 kg (1.1 lb) or more (extra-label): 6 – 24 mg/kg PO once per month with food[22]

Patient weight	Tablet size (mg)	Number of tablets
0.5 kg to 2 kg (1.1 lb to 4.4 lb)	12	1
>2 kg to 8 kg (4.4 lb to 17.6 lb)	48	1
>8 kg (17.6 lb)	Appropriate combination of tablets	

Monitoring

- Efficacy of parasiticide activity
- Adverse effects (eg, muscle tremors, ataxia, seizures)

Client Information

- This medicine must be given with food or within 30 minutes before or after feeding.
- Be sure your animal consumes the full dose each time. Watch your animal for a few minutes after giving the medicine to be sure they do not spit out any part of the dose.
- If your dog or cat vomits within 2 hours of dosing, give another full dose. If a dose is missed, give it when you remember and start a new monthly dosing schedule.
- Treatment may start at any time of the year. In areas where fleas are common year-round, monthly treatment should continue the entire year without stopping.
- To minimize the likelihood of flea reinfestation, treat all animals in a household with an approved flea control product.
- Lotilaner kills adult fleas and ticks only after they have bitten your animal but before the fleas or ticks can lay eggs or transmit disease. Existing flea eggs will hatch and must feed in order to be killed.
- Wash hands after handling tablets.
- Contact your veterinarian if you see any side effects including neurologic problems such as tremors, difficulty walking, or seizures.

Chemistry/Synonyms

Lotilaner is a member of the isoxazoline family. It has a molecular weight of 596.8. Chewable tablets contain only the active S-enantiomer. Its ATCvet code is QP53BE04.

Lotilaner may also be known as *Credelio*®.

Storage/Stability

Chewable tablets should be stored at 15°C to 25°C (59°F-77°F); excursions are permitted between 5°C and 40°C (41°F-104°F). Keep out of reach of children.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:
Lotilaner Chewable (beef-flavored) Tablets: 56.25 mg, 112.5 mg, 225 mg, 450 mg, and 900 mg; *Credelio*®; (Rx). FDA-approved for use in dogs. NADA# 141-494

Lotilaner Chewable (vanilla and yeast-flavored) Tablets: 12mg and 48 mg; *Credelio*® CAT; (Rx). FDA-approved for use in cats. NADA# 141-528

HUMAN-LABELED PRODUCTS: NONE

Lufenuron/Lufenuron Combination Products

(loo-***fen***-yur-on) *Program*®*, Sentinel*®*, Sentinel*® *Spectrum*®
Chitin Synthesis Inhibitor; Insect Growth Regulator
For information on the combination products, see ***Milbemycin Oxime*** *and* ***Praziquantel/Praziquantel Combinations Products****.*

Prescriber Highlights
- ► Used as a single agent for flea control in dogs and cats
- ► Also found in some antiparasitic products in combination with milbemycin oxime ± praziquantel
- ► Adverse effects are rarely seen at recommended oral doses; injectable lufenuron product can cause a local tissue reaction in cats.

Uses/Indications
Lufenuron is FDA-approved for oral use in dogs and cats for the control of flea populations[1,2]; however, the oral products with lufenuron as a single agent are no longer marketed. The 6-month injectable (*Program*®) is indicated for flea control in cats.[3] The lufenuron/milbemycin oxime combination product (*Sentinel*®) is labeled for prevention and control of flea populations, prevention of heartworm disease, control of adult hookworms, and the removal and control of adult roundworms and whipworms.[4] The oral chewable lufenuron/milbemycin oxime/praziquantel combination tablet (*Sentinel*® *Spectrum*®) extends the antiparasitic spectrum to also include treatment and control of tapeworms.[5]

Lufenuron has also been used in aquatic species (eg, salmonids,[6] stingrays,[7] loggerhead sea turtles[8]) for treatment of fish lice and copepods; however, no products are approved in the US for use in aquatics or for food species.

Lufenuron showed initial promise as a treatment for cutaneous fungal infections[9] (eg, dermatophytosis) but the early enthusiasm has dampened considerably as efficacy appears limited.[10,11]

Pharmacology/Actions
Lufenuron inhibits chitin synthesis, polymerization, and deposition in fleas, thereby preventing eggs from developing into adults. After biting a lufenuron-treated dog or cat, lufenuron is deposited in a female flea's eggs. These eggs are prevented from hatching, thereby breaking the flea life cycle. Lufenuron does not kill adult fleas. Therefore, pre-existing flea populations may continue to develop after treatment and noticeable control may not be observed for several weeks without additional flea control products.

It is believed that lufenuron's nonspecific effect on chitin synthesis is related to serine protease inhibition. Lufenuron's effect on chitin synthesis is specific to insects; lufenuron does not inhibit chitin synthesis in fungi.[12] However, a study in *Microsporum canis* infected cats found that pre-treatment with oral lufenuron prior to enilconazole or griseofulvin potentially had an immunomodulatory effect and could be of benefit in long-lasting infections that have been unsuccessfully treated with conventional drugs.[13]

Pharmacokinetics
Approximately 40% of an oral dose is absorbed with the remainder eliminated in the feces. To maximize oral absorption, the manufacturer recommends administering in conjunction with or immediately after (within 30 minutes) a full meal. The drug is absorbed in the small intestine and stored in adipose tissue that acts as a depot reservoir to slowly redistribute the drug back into the circulation. In dogs administered oral lufenuron, the drug was detected in the SC layer of the skin, not on the skin surface.[14]

After cats receive the lufenuron injectable product, 2 to 3 weeks are required before blood lufenuron concentrations are high enough to be effective. Cats require a substantially higher oral dose per kg than do dogs for equivalent efficacy. The drug is apparently not metabolized; it is excreted unchanged into the bile and eliminated in the feces.

Contraindications/Precautions/Warnings
Lufenuron injection should only be given SC; do NOT inject IM.[3] The feline-labeled injectable product should not be used in dogs as severe local reactions are possible.

Oral lufenuron (*Program*® *Flavor Tabs*) is indicated for use in dogs and cats 4 weeks of age and older[2] (oral suspension and *Program*® *Cat Flavor Tabs* are 6 weeks of age and older[2,15]); the feline injectable lufenuron (ie, *Program*® *6 Month for Cats*) is indicated for use in cats 6 weeks of age and older.[3] The lufenuron/milbemycin oxime combination product (ie, *Sentinel*®) is indicated for use in dogs and puppies 4 weeks and older and weighing at least 2 pounds.[4] The lufenuron/milbemycin oxime/praziquantel combination product (ie, *Sentinel*® *Spectrum*®) is indicated for use in dogs and puppies 6 weeks and older and weighing at least 2 pounds.[5]

For lufenuron combination products containing milbemycin oxime, dogs should be tested for pre-existing heartworm infections because some dogs with a high number of circulating heartworm microfilariae will develop a transient, shock-like syndrome after receiving milbemycin oxime. Infected dogs should be treated for heartworm infection to remove adult heartworms and microfilariae prior to initiating milbemycin oxime treatment.

Adverse Effects
Adverse effects reported in dogs and cats after oral lufenuron include vomiting, diarrhea, anorexia, lethargy/depression, pruritus/urticaria, erythema, and dyspnea.[1,2,15]

Adverse effects following lufenuron injection in cats include pain on injection, injection site lumps/granulomas, vomiting, listlessness/lethargy, and anorexia.[3] After receiving the injectable product, a small lump or tissue reaction at the injection site has been noted in some cats. A few weeks may be required for this to dissipate. There is one published case report of a cat that developed an injection-site sarcoma post lufenuron injection[16]; the FDA's adverse drug experience (ADE) database noted that "injection site neoplasm" had been reported 13 times between 1987 and April 30, 2013.

Reproductive/Nursing Safety
The oral lufenuron products appear to be safe to use in pregnant, breeding, or lactating animals[4]; safety of the injectable product in reproducing cats has not been formally established.[3] In dogs, lufenuron concentrates in the milk at concentrations greater than 60 times the concentrations found in blood; nursing puppies from treated dams may have blood lufenuron concentrations 8 to 9 times greater than the dam.[4,17]

Overdose/Acute Toxicity

Growing puppies were dosed at levels up to 30 times for 10 months without overt effect on growth or viability noted. Cats receiving oral dosages of up to 17 times apparently were unaffected. Kittens receiving a single dose of 266 mg/kg PO had no apparent adverse effects.[9]

Acute toxicity of lufenuron injection was evaluated in cats receiving 10 times the labeled dose, and cumulative toxicity was evaluated over a 2-month period in cats receiving 3 times the recommended dose. No clinical signs of toxicity were observed other than injection site reactions.[3]

Drug Interactions

Limited data are available; the manufacturer states that when used with a variety of adulticides, vaccines, antibiotics, anthelmintics, and steroids, no adverse effects or interactions were noted in either dogs or cats.

Laboratory Considerations

None

Dosages

DOGS:

Lufenuron as a single agent (*Program*®) for prevention and control of flea populations (label dosage; FDA-approved): lufenuron 10 mg/kg (minimum) PO once monthly given with or immediately after a meal. Dosed by body weight range: up to 4.5 kg (10 lb), 45 mg; 5 to 9.1 kg (11 to 20 lb), 90 mg; 9.5 to 20.5 kg (21 to 45 lb), 204.9 mg; 20.9 to 40.9 kg (46 to 90 lb), 409.8 mg; over 40.9 kg (90 lb), provide the appropriate combination of tablets based on body weight.[2] **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron/milbemycin oxime combination product (*Sentinel*®) for heartworm prevention, control of fleas and hookworms, and control and removal of ascarids and whipworms (label dosage; FDA-approved): lufenuron 10 mg/kg (minimum) in combination with milbemycin oxime 0.5 mg/kg (minimum) PO once monthly given with or immediately after a meal.[4] Dosed by body weight range (see table below):

Body weight in kg (lb)	Lufenuron mg/tablet	Milbemycin oxime mg/tablet	Number of tablets to administer
0.9 to 4.5 (2-10)	46	2.3	1
5 to 11.4 (11-25)	115	5.75	1
11.8 to 22.7 (26-50)	230	11.5	1
23.2 to 45.5 (51-100)	460	23	1
Greater than 45.5 (100)	--	--	Appropriate combination of tablets

Lufenuron/milbemycin oxime/praziquantel combination product (*Sentinel*® *Spectrum*®) for heartworm prevention, prevention and control of fleas, treatment and control of roundworms, hookworms, whipworms, and tapeworms (label dosage; FDA-approved): lufenuron 10 mg/kg (minimum) in combination with milbemycin oxime 0.5 mg/kg (minimum), and praziquantel 5 mg/kg (minimum) PO once monthly with or immediately after a meal.[5] Dosed by body weight range (see table below):

Body weight in kg (lb)	Lufenuron mg/tablet	Milbemycin oxime mg/tablet	Praziquantel mg/tablet	Number of tablets to administer
0.9 to 3.6 (2-8)	46	2.3	22.8	1
3.7 to 11.4 (8.1-25)	115	5.75	57	1
11.4 to 22.7 (25.1-50)	230	11.5	114	1
22.8 to 45.5 (50.1-100)	460	23	228	1
Greater than 45.5 (100)	--	--	--	Appropriate combination of tablets

Lufenuron/nitenpyram (*Program*® *and Capstar*® *Flea Management System*®) to kill adult fleas and prevent flea eggs from hatching (label dosage; FDA-approved): lufenuron 10 mg/kg (minimum) PO once monthly used concurrently with nitenpyram 11.4 mg (dogs weighing less than 11.3 kg [25 lb]) OR nitenpyram 57 mg (dogs weighing more than 11.3 kg [25 lb]) PO once or twice weekly.[18] **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron/milbemycin oxime/nitenpyram (*Sentinel*® *and Capstar*® *Flea Management System*®) to prevent heartworm disease, prevent and control of flea populations, control of hookworms, and the removal and control of roundworm and whipworm infections (label dosage; FDA-approved): lufenuron 10 mg/kg (minimum) in combination with milbemycin oxime 0.5 mg/kg PO once monthly used concurrently with nitenpyram 11.4 mg (dogs weighing less than 11.3 kg [25 lb]) OR nitenpyram 57 mg (dogs weighing more than 11.3 kg [25 lb]) PO once or twice weekly.[19] **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Adjunctive therapy for dermatophytosis using lufenuron as a single agent (extra-label): While efficacy is questionable, the following dosages have been suggested:

a) 65 – 100 mg/kg PO once every 2 weeks for 2 treatments.[11] If significant improvement is not seen, a different antifungal agent should be selected. If improvement is seen, re-treat monthly thereafter until at least 2 negative fungal cultures are obtained.

b) 54.2 – 68.3 mg/kg PO once[9]

CATS:

Lufenuron as a single agent (*Program*®) for control of flea populations (label dosage; FDA-approved):

- **Injectable**: 10 mg/kg (recommended minimum dose) SC once every 6 months. Shake well before administration.[3] Dosed by body weight range (see table below):

Body weight in kg (lb)	Syringe size (mL)	Lufenuron dose (mg)
Up to 4 kg (8.8)	0.4 (small)	40
4.1 to 8 kg (8.9-17.6)	0.8 (large)	80

- **Oral** (label dosage; FDA-approved): lufenuron 30 mg/kg (minimum) PO once monthly given with or immediately after a meal. **NOTE**: These products remain listed in the FDA's Green Book but may no longer be marketed.

a) *Suspension* dosed by body weight: up to 4.5 kg (10 lb), 135 mg; 4.6 to 9 kg (11 to 20 lb), 270 mg; over 10 kg (20 lb), provide the appropriate combination of packs based on body weight.[1]

b) *Tablets* dosed by body weight: up to 4.5 kg (10 lb), 135 mg; 5 to 9.1 kg (11 to 20 lb), 270 mg; over 9.1 kg (20 lb), provide the appropriate combination of tablets.[2,15]

Lufenuron with nitenpyram (*Program® and Capstar® Flea Management System®*) to kill adult fleas and prevent flea eggs from hatching (label dosage; FDA-approved): lufenuron 30 mg/kg (minimum) PO once monthly used concurrently with nitenpyram 11.4 mg/cat (NOT mg/kg) PO once or twice weekly. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.[18]

Adjunctive treatment of dermatophytosis (extra-label):
While efficacy is questionable, the following dosages have been suggested; re-treat after 14 days and monthly thereafter until at least 2 negative fungal cultures are obtained.

a) 80 mg/kg PO for house cats[11,20]

b) 100 mg/kg PO for cats housed in catteries

RABBITS/RODENTS/SMALL MAMMALS:

For control of flea populations in rabbits: 30 mg/kg PO once monthly[21]

For control of flea populations in ferrets: 30 mg/kg PO once monthly[22]

Monitoring

- Efficacy. It may take longer to see effect in colder geographic areas due to prolonged flea cycle in colder temperatures.
- Adverse effects (eg, vomiting, diarrhea, anorexia, lethargy/depression, pruritus/urticaria, erythema, dyspnea; pain on injection and injection site lumps/granulomas [injectable only]).

Client Information

- This medicine helps to control fleas by preventing development of flea eggs. It does not kill adult fleas.
- Give this medication with food.
- Oral products must be used every 30 days to work well.
- All animals in a household need to be treated for this treatment to work.
- Side effects are rare when given by mouth but vomiting after a dose is the most common side effect. If your animal vomits within 2 hours after dosing, the drug should be given again.
- If a dose is missed, give the medicine and then resume monthly treatments.
- Do not split tablets unless instructed to do so.

Chemistry/Synonyms

A benzoylphenylurea derivative, lufenuron is classified as an insect development inhibitor. The drug is lipophilic.

Lufenuron may also be known as CGA-184699, *Program®*, and *Sentinel®*.

Storage/Stability

The commercially available tablets and suspension and lufenuron injection suspension should be stored at room temperature between 15°C and 30°C (59°F-86°F). Lufenuron combinations with milbemycin oxime (+/- praziquantel) should be stored at controlled room temperature between 15°C and 25°C (59°F-77°F).

Compatibility/Compounding Considerations

- No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Lufenuron Oral Suspension: 135 mg and 270 mg in 6-tube packs; *Program® Suspension*; (OTC). FDA-approved for use in cats and kittens 6 weeks of age or older. NADA #141-026. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron 6-Month Injectable for Cats: 100 mg/mL in 10 prefilled syringe packages; *Program® 6 Month for Cats*; (Rx). FDA-approved for use in cats and kittens 6 weeks of age or older. NADA #141-105

Lufenuron Flavor Tabs for Dogs and Cats: 45 mg, 90 mg, 204.9 mg, and 409.8 mg; *Program Flavor Tabs* (OTC). FDA-approved for use dogs, puppies, cats, and kittens 4 weeks of age or older. NADA #141-035. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron Flavor Tabs for Cats: 135 mg and 270 mg; *Program® Cat Flavor Tabs*; (OTC). FDA-approved for use cats and kittens 6 weeks of age or older. NADA #141-062. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron Flavor Tabs used concurrently with Nitenpyram Oral Tablets: lufenuron 45 mg, 90 mg, 204.9 mg, and 409.8 mg; used concurrently with nitenpyram 11.4 mg or 57 mg; *Program® Flavor Tabs* and *Capstar® Flea Management System;* (OTC). FDA-approved for use in dogs, puppies, cats, and kittens 4 weeks of age or older. NADA #141-205. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron/Milbemycin oxime Oral Tablets for Dogs: lufenuron 46 mg/milbemycin oxime 2.3 mg; lufenuron 115 mg/milbemycin oxime 5.75 mg; lufenuron 230 mg/milbemycin oxime 11.5 mg; lufenuron 460 mg/milbemycin oxime 23 mg; *Sentinel® Flavor Tabs*; (Rx). FDA-approved for use in dogs and puppies 4 weeks of age or older and weighing at least 0.9 kg (2 lb). NADA #141-084. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron/Milbemycin oxime Oral Tablets used concurrently with Nitenpyram Flavored Tablets: lufenuron 46 mg/milbemycin oxime 2.3 mg, lufenuron 115 mg/milbemycin oxime 5.75 mg, lufenuron 230 mg/milbemycin oxime 11.5 mg; lufenuron 460 mg/milbemycin oxime 23 mg; used concurrently with nitenpyram 11.4 mg or 57 mg; *Sentinel® Flavor Tabs* and *Capstar® Flea Management System;* (Rx). FDA-approved for use in dogs and puppies 4 weeks of age or older. NADA #141-204. **NOTE**: This product remains listed in the FDA's Green Book but may no longer be marketed.

Lufenuron/Milbemycin oxime/Praziquantel Chewable Oral Tablets: lufenuron 46 mg/milbemycin oxime 2.3 mg/praziquantel 22.8 mg; lufenuron 115 mg/milbemycin oxime 5.75 mg/praziquantel 57 mg; lufenuron 230 mg/milbemycin oxime 11.5 mg/praziquantel 114 mg; lufenuron 460 mg/milbemycin oxime 23 mg/praziquantel 228 mg; *Sentinel® Spectrum®*; (Rx). FDA-approved for use in dogs and puppies 6 weeks of age or older and weighing at least 0.9 kg (2 lb). NADA #141-333

HUMAN-APPROVED PRODUCTS: NONE

Lysine
L-lysine

(***lye***-seen)

Nutritional Amino Acid; Anti-Feline Herpes Virus

Prescriber Highlights

- ► Amino acid that has questionable efficacy to suppress the shedding and reduce the severity of clinical signs associated with FHV-1 infections in cats
- ► Long-term treatment may be required.
- ► Usually well tolerated
- ► Most effective when administered as a bolus

Uses/Indications

Lysine has demonstrated efficacy for cats under experimental conditions to suppress shedding[1] and reduce the severity of conjunctivitis caused by feline herpesvirus-1 (FHV-1) infections.[2] Published studies, however, have not shown lysine to be effective to prevent or reduce the recurrence of FHV-1 upper respiratory tract infections in shelter cats,[3] and may even paradoxically exacerbate clinical disease or viral shedding.[4,5] Because of lysine's overall safety, and lack of studies in client-owned cats, lysine may be considered in that population to lessen viral shedding in latent infections and severity of clinical signs in cats undergoing primary virus exposure.[3,6-8]

Pharmacology/Actions

Lysine is an amino acid that is thought to compete with arginine for incorporation into many herpesviruses. As it is believed that arginine is required for producing infective viral particles, when lysine is incorporated, the virus becomes less infective.[9] Physiologic data from cats question this proposed mechanism.[10]

Pharmacokinetics

No specific information was located.

Contraindications/Precautions/Warnings

There are no specific contraindications.

The stress associated with lysine administration to shelter cats may negate beneficial effects in this population.[6] Lysine-enriched dry diets fed to shelter cats failed to control upper respiratory[7,8] and ocular[7] disease.

Adverse Effects

Adverse effects were not observed in clinical trials in cats.

Human patients taking lysine have occasionally complained of abdominal pain and diarrhea.

Reproductive/Nursing Safety

Lysine showed no teratogenic effects when given to pregnant rats, but reduced fetal weight and increased fetal mortality have been documented.[11] In humans, lysine crosses the placenta and is naturally found in breast milk; significance in veterinary medicine is unknown.[11]

Because safety has not been established in animals, this treatment should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Significant toxicity is unlikely. GI effects (eg, nausea, vomiting, diarrhea) may occur. Reports of nephrotoxicity have been reported in humans as well as in canines receiving 4500 mg/kg/day IV over 3 days.[12]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving lysine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Arginine**: Arginine may negate the anti-herpesvirus effects of lysine. It is unlikely that the concentration of arginine found in feline diets would be significant.
- **Calcium, Oral**: Concomitant use of lysine with calcium supplements may increase calcium absorption from the gut and decrease calcium loss in the urine.

Laboratory Considerations

- None noted

Dosages

CATS:

Preventing or reducing recurrent feline herpesvirus infections (extra-label): Although efficacy is not proven for any dosage, many clinicians recommend its use for household cats. It is recommended to administer lysine mixed in a very small amount of food to be eaten all at once and not simply applied over the food bowl to be eaten throughout the day. Of note, the stress of bolus administration (ie, "pilling" or squirting the medication directly into the cat's mouth) may negate any beneficial effects obtained from lysine.[13]

- **Kittens**: 250 mg/kitten (NOT mg/kg) PO once daily OR 125 – 250 mg/kitten (NOT mg/kg) PO twice daily[3]
- **Adult cats**:

  a) 250 – 500 mg/cat (NOT mg/kg) PO every 12 to 24 hours[3,13]

  b) 400 mg PO every 24 hours[1,14]

Reducing the severity of conjunctivitis caused by FHV-1 infection (extra-label): 500 mg/cat (NOT mg/kg) PO twice daily[2]

Monitoring

- Efficacy based on lack of or diminished clinical signs caused by feline herpesvirus upper respiratory infection

Client Information

- This medicine is a nutritional supplement that may lessen the signs related to herpesvirus infections in cats. This medicine will not cure the infection.
- If unable to administer this medicine all at once, it can be mixed with a small (treat-sized) amount of soft, moist food. Ensure the cat ingests the entire lysine-food mixture and receives the full dose.
- Side effects are not likely.
- Treatment, if helpful, may need to be long-term to control clinical signs related to feline herpesvirus infections.

Chemistry/Synonyms

An aliphatic amino acid, lysine has the chemical name L-2,6-diaminohexanoic acid and has a molecular weight of 146.2. It occurs as an odorless, white or almost white crystalline powder, or as colorless crystals, and is freely soluble in water and very slightly soluble in alcohol. It may be commercially available as the acetate or hydrochloride salts, or as the base.

Lysine may also be known as L-lysine. Many trade names are available.

Storage/Stability

Unless otherwise specified on the label, lysine should be stored at room temperature in tight containers.

Compatibility/Compounding Considerations

- No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: There are many products containing lysine as one of many ingredients. No lysine products were located in FDA's Green Book of approved animal drugs. The following products were located with veterinary labeling where lysine is the sole active ingredient:

L-lysine Gel: 250 mg per 1.25 mL: *Viralys® Gel, Enisyl®* Paste, generic; (OTC). Labeled for use in cats and kittens.

L-lysine Powder: (in a palatable base) ≈250 mg per rounded scoop: *Viralys® Powder, Felisyl®*, generic; (OTC). Labeled for use in cats and kittens.

L-lysine chews: 500 mg per soft chewable treat; *Optixcare®*; (OTC). Other brands may have varying amounts of lysine per chewable treat/tablet.

L-Lysine Powder Feed Additive: in 16 oz jars and 5 lb pails; L-*Lysine Powder-Pure®*; (OTC) Labeled for use in horses.

HUMAN-LABELED PRODUCTS:

L-Lysine Tablets and Capsules: 312 mg, 334 mg, 500 mg, and 1000 mg; *Enisyl®*, generic; (OTC)

Lysine is considered a nutrient in the US; therefore, it is exempt from FDA drug approval requirements. There are many products available including tablets and capsules that usually range in strengths from 250 mg to 1000 mg. Combination products are also available.

Magnesium Hydroxide

Milk of Magnesia

(mag-***nee***-zee-um hye-***droks***-ide)

Antacid, Laxative

Prescriber Highlights

- ► May be used as an antacid or a laxative in small and large animal species
- ► In ruminants, the powder formulation is much more effective than the boluses.
- ► Magnesium hydroxide is contraindicated in patients with renal disease and should be used cautiously in patients with electrolyte restrictions or gastric outlet obstruction.
- ► In cattle, rumen pH should be determined before use, as oral magnesium hydroxide should only be used with documented rumen acidosis.
- ► Most common adverse effect is diarrhea
- ► Long-term use may lead to electrolyte abnormalities.
- ► Many potential drug interactions with orally administered drugs

Uses/Indications

Magnesium hydroxide alone, or in combination with aluminum salts, has been used for the adjunctive treatment of esophagitis, gastric hyperacidity, peptic ulcers, and gastritis. In foals and small animal species, because of difficulty in administration, frequency of dosing required, and availability of histamine-2 blocking agents (eg, ranitidine), proton pump inhibitors (eg, omeprazole), and sucralfate, antacids have largely been relegated to adjunctive roles for these indications.

Magnesium hydroxide alone may be used as an oral laxative in small animal species.

In ruminants, magnesium hydroxide is used to increase rumen pH and as a laxative in the treatment of rumen overload syndrome (ie, acute rumen engorgement, rumen acidosis, grain overload, engorgement toxemia, rumen impaction).

Pharmacology/Actions

Oral antacids used in veterinary medicine are generally relatively non-absorbable salts of aluminum, calcium, or magnesium. Up to 20% of an oral dose of magnesium can be absorbed. Antacids decrease HCl concentrations in the GI tract. One gram of these compounds generally neutralizes 20 to 35 mEq of acid (in vitro). Antacids will rarely bring the gastric fluid pH to near-neutral conditions; however, at a pH of 3.3, 99% of all gastric acid is neutralized, thereby reducing gastric acid back-diffusion through the gastric mucosa and thus, reducing the amount of acid presented to the duodenum. Pepsin proteolytic activity is reduced by raising the pH and can be minimized if the pH of the gastric contents can be increased to greater than 4.

In cattle, orally administered magnesium hydroxide can act as a rumen alkalinizing agent and decrease rumen antimicrobial activity.

Contraindications/Precautions/Warnings

Magnesium-containing antacids are contraindicated in patients with renal disease. Some products have significant quantities of sodium or potassium and should be used cautiously in patients who should have these electrolytes restricted in their diet. Aluminum-containing antacids may inhibit gastric emptying; use cautiously in patients with gastric outlet obstruction.

Oral magnesium hydroxide should only be used clinically in ruminants with documented rumen acidosis and should not be used for treatment of other suspected rumen disorders or hypomagnesemia.[1]

Adverse Effects

In monogastric animals, the most common side effects of magnesium-containing antacid therapy are diarrhea or frequent loose stools. Many products also contain aluminum and calcium salts, which can cause constipation and may balance the laxative actions of magnesium.

Magnesium-containing antacids can cause hypermagnesemia in patients with severe chronic kidney disease (CKD). Hypophosphatemia can develop in patients being fed a low phosphate diet with chronic use of magnesium antacids that also contain aluminum.

In ruminants, alkalinization of the rumen may enhance the absorption of ammonia, histamine, or other basic compounds.

Reproductive/Nursing Safety

In humans, magnesium crosses the placenta and is found in milk. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs associated with an overdose of magnesium salts are an extension of the adverse effects profile. See ***Adverse Effects***. Adverse GI effects and electrolyte imbalances should be treated as necessary based on clinical presentation.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving oral magnesium salts and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides (eg, amikacin, gentamicin)**: May result in

neuromuscular weakness

- **Quinidine**: Increased absorption or pharmacologic effect of quinidine may occur.
- **Sodium Polystyrene Sulfonate** (***Kayexalate®***): Antacids may decrease the potassium lowering effectiveness of the sodium polystyrene sulfonate and may cause metabolic alkalosis in patients with renal failure.
- **Sustained- or Extended-Release Medications**: When magnesium hydroxide is used at laxative dosages, it may alter the absorption of these drugs by altering GI transit times.
- **Sympathomimetic Agents**: Increased absorption or pharmacologic effect of the sympathomimetic agent may occur.
- **Tacrolimus**: Concurrent use may result in increased tacrolimus exposure.

Oral magnesium salts can **decrease** the amount absorbed or the pharmacologic effect of the drugs listed below; separate oral doses of oral magnesium salts and these drugs by 2 hours to help reduce this interaction.

- **Allopurinol**
- **Aspirin**
- **Azole antifungals** (eg, **ketoconazole, itraconazole**)
- **Beta-blockers** (eg, **atenolol**)
- **Cefpodoxime**
- **Corticosteroids** (eg, **dexamethasone, prednisone**)
- **Digoxin**
- **Ethambutol**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin, marbofloxacin**)
- **Gabapentin**
- **H_2 Antagonists** (eg, **famotidine, ranitidine**)
- **Iron Salts**
- **Isoniazid**
- **Levothyroxine**
- **Macrolides** (eg, **azithromycin**)
- **Misoprostol**
- **Mycophenolate mofetil**
- **Penicillamine**
- **Phenothiazines**
- **Phenytoin**
- **Rifampin**
- **Tetracyclines** (eg, **doxycycline, minocycline**)

Dosages

DOGS:

Adjunctive treatment of hypomagnesemia in dogs with GI disease and severe hypocalcemia (extra-label): 5 – 15 mL/dog (NOT mL/kg) PO once daily[2]

CATS:

Antacid (extra-label): 5 – 15 mL/cat (NOT mL/kg) PO 1 to 2 times daily[3]

CATTLE:

NOTE: In ruminants, the powder formulation is more effective than the boluses.

Rumen overload syndrome (extra-label):

a) Adult animals: Up to 1 g/kg of magnesium hydroxide mixed in 2 to 3 gallons of warm water and given PO by tube. May repeat (use smaller doses) at 6- to 12-hour intervals. If the rumen has been evacuated, do not exceed a total dose of 225 g initially. Dehydration and systemic acidosis must be concomitantly corrected.

b) Calves: As above but use 1/8 – 1/4 the amount.[5]

SHEEP/GOATS:

NOTE: In ruminants, the powder formulation is more effective than the boluses.

Rumen overload syndrome (extra-label): As above for cattle but use 1/8 – 1/4 the amount.[5]

Monitoring

- Monitoring parameters are dependent upon the indication for the product. Patients receiving high-dose or long-term therapy should be monitored for electrolyte imbalances (eg, sodium, potassium, phosphorous, magnesium) and acid-base status.

Client Information

- Oral magnesium hydroxide products are available over the counter (OTC), without prescription; do not give on a regular basis without veterinary supervision.
- Generally well tolerated; constipation or diarrhea can occur.

Compatibility/Compounding Considerations

- No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: No magnesium hydroxide or magnesium oxide products are FDA-approved.

Magnesium Hydroxide Oral Bolus: 17.9 – 27 g (**NOTE**: products may also contain ginger, capsicum, and methyl salicylate). The following may be available: *Magnalax®*, *Carmilax®*, *Polymag®*, *Rumen Bolus®*, *Instamag®*, *Polyox®II*, *Laxade®*; (OTC)

Magnesium Hydroxide Oral Powder: 350 – 361 g/lb (**NOTE**: products may also contain ginger, capsicum, and methyl salicylate). The following may be available: *Carmilax Powder®*, *Magnalax®*, *Polyox®*, *Laxade®;* (OTC)

Magnesium Hydroxide 80 mg/mL, 1 gallon jug; generic; (OTC). See also ***Saline Cathartics***.

HUMAN-LABELED PRODUCTS:

The following is a list of some magnesium hydroxide products available; it is not meant to be all-inclusive.

Magnesium Hydroxide

Chewable Tablets: 400 mg; *Pedia-Lax®*; (OTC)

Oral Liquid (Milk of Magnesia): 400 mg/5 mL in 129 mL, 355 mL, 360 mL, and 780 mL, pint, gallon, and UD 15 mL and 30 mL; liquid concentrate: 800 mg/5 mL (160 mg/mL) in 240 mL and 1200 mg/5 mL (240 mg/mL) in 400 mL; generic; (OTC). See also ***Saline Cathartics***.

Aluminum Hydroxide and Magnesium Hydroxide

Suspension (**NOTE**: Many products and concentrations exist; an example of a representative product is *Maalox®* Suspension, which contains aluminum hydroxide 200 mg and magnesium hydroxide 200 mg/5 mL.)

Other dosage forms that are available commercially include: tablets, chewable tablets, and aerosol foam suspension.

Magnesium, IV

Magnesium Chloride, Magnesium Sulfate

(mag-***nee***-zee-um)

Parenteral Electrolyte

*See also **Magnesium Hydroxide** and **Saline Cathartics***

Prescriber Highlights

- ► Used for treatment of hypomagnesemia in many species and for adjunctive therapy of malignant hyperthermia in swine
- ► Contraindications include significant myocardial damage or atrioventricular block; use with caution in patients with impaired renal function.
- ► Adverse effects are usually a result of overdose and can include drowsiness or other CNS depressant effects, muscular weakness, bradycardia, hypotension, respiratory depression, and prolonged QT intervals on ECG. Very high levels may cause neuromuscular blocking activity and, eventually, cardiac arrest.
- ► Monitor serum magnesium levels to avoid hypermagnesemia.
- ► Do not confuse mEq/mL and mg/mL concentrations or mEq/kg and mg/kg dosages.

Uses/Indications

Magnesium is used parenterally in many species for treatment of hypomagnesemia and to resolve clinical signs associated with hypomagnesemia (eg, seizures, refractory arrhythmias). It is also used in swine for adjunctive therapy of malignant hyperthermia. A case report of administering magnesium IV to a dog with generalized tetanus has been published.[1] In dogs and cats, routine use of magnesium during CPR is not recommended for cardiac arrhythmias; however, it may be considered as treatment for torsades de pointes.[2] A quick reference on magnesium in dogs and cats, including its role, deficit, clinical signs, and supplementation, has been published.[3]

In humans, IV magnesium has been used as a treatment of hypertensive crisis in patients with pheochromocytoma.

Pharmacology/Actions

Magnesium is used as a cofactor in a variety of enzyme systems and is involved in muscular excitement and neurochemical transmission.

Pharmacokinetics

In humans, IV magnesium results in immediate effects. Onset after IM administration is ≈1 hour. Magnesium is ≈30% to 35% bound to proteins, and the remainder exists as free ions. Duration of effect is ≈30 minutes after IV administration and 3 to 4 hours after IM administration. It is excreted by the kidneys at a rate proportional to the serum concentration and glomerular filtration rate.[4]

Contraindications/Precautions/Warnings

Parenteral magnesium is contraindicated in patients with myocardial damage or atrioventricular block. Because magnesium is renally cleared, it should be used with caution in patients with impaired renal function, as hypermagnesemia and magnesium intoxication can result.[4] Consider reducing the dose for patients with renal insufficiency.

When administering magnesium IV for treatment of hypomagnesemia, consider reducing potassium supplementation as hyperkalemia may result. Some magnesium products contain aluminum, which may accumulate with prolonged administration in patients with impaired renal function.[4] Patients receiving parenteral magnesium, especially in those with reduced renal function, should be observed and monitored carefully to avoid hypermagnesemia. See ***Monitoring***.

SC administration can cause necrosis of the skin. Only solutions containing a combination of calcium and magnesium should be given SC.

Magnesium sulfate for injection is considered a high-risk medication; additional dose determination and dose preparation safety checks should be employed.

Adverse Effects

Adverse effects of parenteral magnesium are generally the result of magnesium overdose and may include nausea, vomiting, drowsiness or other CNS depressant effects, muscular weakness, bradycardia, hypotension, hypocalcemia, respiratory depression, and prolonged QT intervals on ECG. Very high magnesium levels may cause neuromuscular blocking activity and eventually cardiac arrest.

Reproductive/Nursing Safety

In humans, continuous use of magnesium in pregnant women longer than 5 to 7 days has resulted in bone abnormalities in their offspring, including skeletal demineralization and osteopenia.[5] Magnesium should only be used when maternal benefits outweigh the risks to the fetus.

Magnesium is excreted in milk and should only be used when the benefits outweigh the risks.

Overdose/Acute Toxicity

Clinical signs of an overdose of magnesium are an extension of its adverse effects. See ***Adverse Effects***. Treatment of hypermagnesemia is dependent on the serum magnesium level and any associated clinical effects. Ventilatory support and administration of calcium 10 – 50 mg/kg IV[6] may be required for severe hypermagnesemia. Magnesium is dialyzable.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving parenteral magnesium and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides** (eg, **amikacin, gentamicin**): Concurrent use may result in neuromuscular weakness.
- **Calcium**: Concurrent use of calcium salts may negate the effects of parenteral magnesium.
- **CNS Depressant Drugs** (eg, **barbiturates, general anesthetics**): Additive CNS depression may occur.
- **Digoxin**: Because serious conduction disturbances can occur, parenteral magnesium should be used with extreme caution with digitalis cardiac glycosides.
- **Neuromuscular Blocking Agents** (eg, **atracurium**): Excessive neuromuscular blockade is possible.

Dosages

NOTES:

1. Do not confuse magnesium dosages, which can be represented in mEq, mmol, and mg. Check dosages and concentrations carefully.
2. One gram of magnesium sulfate hexahydrate contains 8.1 mEq of magnesium. One gram of magnesium chloride contains 9.85 mEq of magnesium. Do not confuse dosages.
3. In adult humans, the maximum infusion rate for IV administration of magnesium sulfate is 150 mg/minute (with the exception of seizures during eclampsia). This is ≈2 mg/kg per minute for an average adult human. If this recommendation is extrapolated to animals, the maximum rate would be

≈0.016 mEq/kg/minute (0.027 mg/kg/minute of magnesium sulfate). Magnesium sulfate is diluted in 5% dextrose or 0.9% sodium chloride to a concentration of 200 mg/mL (20%) or less for IV administration.

DOGS/CATS:

Hypomagnesemia (extra-label):

Supplemental magnesium for animals with refractory hypokalemia, endocrine diseases (eg, DKA), or for critically ill animals (extra-label): 0.75 mEq/kg/day IV in combination with potassium supplementation[7]

Suspected or confirmed severe hypomagnesemia (extra-label): Dosage recommendations vary; most clinicians recommend a loading dose of magnesium sulfate of 0.15 – 0.3 mEq/kg (18.5 – 37 mg/kg) IV slowly over 10 to 20 minutes, followed by 0.75 – 1 mEq/kg/day (92 –123 mg/kg/day) given over 12 to 24 hours as an IV CRI. Some clinicians suggest reducing total daily dose after the first day.

Refractory ventricular arrhythmias (extra-label): 0.15 – 0.3 mEq/kg IV administered over 5 to 15 minutes.[8] Not recommended for routine use during CPR[2]

HORSES:

Hypomagnesemia (extra-label): Magnesium sulfate 25 – 150 mg/kg/day IV CRI diluted in 0.9% sodium chloride, 5% dextrose, or polyionic isotonic solutions for adult horses. Magnesium sulfate 100 – 150 mg/kg/day IV CRI should meet the daily requirements of foals and adult horses. **NOTE**: 100 mg/kg of magnesium *sulfate* provides 9.9 mg/kg of magnesium, whereas 100 mg/kg of magnesium *chloride* provides 12 mg/kg of magnesium. This distinction is critical as overdosing can be fatal.

Ventricular arrhythmias from quinidine intoxication (torsades de pointes) or refractory ileus and synchronous diaphragmatic flutter (extra-label): 50 – 100 mg/kg IV diluted in 0.9% sodium chloride over 30 minutes are considered safe.

Foals with ischemic encephalopathy (extra-label): Magnesium sulfate 50 mg/kg/hour IV CRI for the first hour, followed by 25 mg/kg/hour IV CRI has been proposed. This regimen can be continued for several days, adjusting the dose based on serum magnesium concentrations.[8]

Hypomagnesemia under general anesthesia during colic surgery (extra-label): Magnesium sulfate 25 mg/kg IV over 120 minutes[9]

Adjunctive treatment of perinatal asphyxia syndrome in foals (extra-label): Magnesium sulfate 50 mg/kg diluted to 10 mg/mL (1%) in 0.9% sodium chloride or 5% dextrose and given IV over 1 hour, then 25 mg/kg/hour IV CRI for 24 hours[10] or for 1 to 3 days

CATTLE:

Hypomagnesemia (grass and other magnesium-related tetanies) (extra-label):

a) A typical treatment for an adult beef cow has been slow IV administration (over at least 5 minutes) of 100 mL of the 25% Epsom salt solution. This solution provides 2.5 g of magnesium (0.025 g of magnesium/mL of solution). This solution is highly hypertonic (ie, 2028 mOsm/L). Hypomagnesemia is most commonly treated using commercially available combined calcium, magnesium, and phosphorous solutions; 500 mL of these solutions typically contain 1.6 to 2.7 g of magnesium in the form of a borogluconate, chloride, or hypophosphite salt (the phosphorous in hypophosphite salt form is unavailable to ruminants and therefore worthless). Combined calcium and magnesium solutions are preferred for IV administration to 25% Epsom salt solution because ruminants with hypomagnesemia frequently have hypocalcemia, and hypercalcemia provides some protection against the toxic effects of hypermagnesemia. The maximum safe rate of administration of magnesium in cattle is 0.04 mL of 25% Epsom salt solution/kg per minute. For a 500 kg beef cow with hypomagnesemia, this corresponds to a maximum safe rate of administration of 20 mL/minute. **NOTE**: In a seizing, hypomagnesemic beef cow, rectal administration may be the only safe and practical way to administer magnesium. After evacuating the rectal contents, an enema containing 60 g of Epsom salts (magnesium sulfate heptahydrate) or magnesium chloride in 200 mL of water can be placed in the descending colon (NOT the rectum) and the tail held down for 5 minutes. This treatment regimen increases plasma magnesium concentrations within 10 minutes. If enema solutions are prematurely evacuated, the chance for therapeutic success is eliminated; some degree of colonic mucosal injury is expected due to the high osmolarity of 30% solutions (≈2400 mOsm/L).[11]

b) 350 mL (250 mL of 25% calcium borogluconate and 100 mL of 10% magnesium sulfate) slow IV.[12] If not a proprietary mixture, give calcium first. Relapses occur frequently after IV therapy, and 350 mL SC of magnesium sulfate 20% may give more sustained magnesium levels. Alternating calcium and magnesium may prevent adverse effects. Continue control measures for 4 to 7 days to prevent relapse.

SHEEP/GOATS:

Hypomagnesemia (extra-label): 50 – 100 mL IV of calcium/magnesium solution[12]

SWINE:

Adjunctive therapy of malignant hyperthermia syndrome (extra-label): Using magnesium sulfate 50%, incremental doses of 1 g injected IV slowly, until heart rate and muscle tone are reduced. Use calcium if magnesium-related cardiac arrest occurs.[13]

Monitoring

- Serum magnesium: Total serum magnesium (tMg) measures magnesium in the serum in its 3 forms (ie, ionized, bound, and complexed). Unfortunately, it does not correlate well with total body magnesium but may be useful, especially when suspecting hypermagnesemia. Ionized magnesium (iMg) is preferred by some clinicians but alone may not be clinically useful due to methodology concerns and the low percentages of total body magnesium it represents. The iMg/tMg ratio may be more useful. In patients with normal renal function, pre-magnesium levels (iMg/tMg) are compared with levels after an IV loading dose. If the ratio is elevated, it suggests that a larger portion of stored body magnesium is being mobilized in response to a decrease in whole-body magnesium content. Alternatively, after an IV load, a 24-hour urine magnesium collection can be obtained. Retention of greater than 20% of the magnesium loading dose is considered suggestive of cellular magnesium depletion, and greater than 50% retention is considered diagnostic.[14]
- Clinical signs associated with hypomagnesemia (eg, tetany, seizures, ECG changes [eg, prolonged PR interval and/or QRS complexes]) or hypermagnesemia (eg, loss of deep tendon reflexes, hypotension, respiratory paralysis)[4]
- Serum calcium, potassium if indicated

Client Information

Only your veterinarian can give injectable magnesium.

Chemistry/Synonyms

Magnesium sulfate occurs as small, usually needle-like, colorless crystals with a cool, saline, bitter taste. It is freely soluble in water and sparingly soluble in alcohol. Magnesium sulfate injection has a

pH of 5.5 to 7. One gram of magnesium sulfate hexahydrate contains 8.1 mEq of magnesium. Magnesium chloride contains 9.25 mEq of magnesium per gram.

When using commercially available magnesium sulfate injections:

- Magnesium sulfate 4% (40 mg/mL) injection contains 0.325 mEq/mL of elemental magnesium
- Magnesium sulfate 8% (80 mg/mL) injection contains 0.65 mEq/mL of elemental magnesium
- Magnesium sulfate 50% (500 mg/mL) injection contains 4 mEq/mL of elemental magnesium
- Magnesium sulfate 1% in dextrose 5% injection contains 0.081 mEq/mL elemental magnesium
- Magnesium sulfate 2% in dextrose 5% injection contains 0.162 mEq/mL elemental magnesium
- Magnesium chloride 200 mg/mL injection contains 1.97 mEq/mL of elemental magnesium

Magnesium sulfate may also be known as 518, Epsom salts, magnesii sulfas, magnesium sulfuricum heptahydricum, magnesium sulphate, sal amarum, sel anglais, and sel de sedlitz; many trade names are available.

Storage/Stability

Store magnesium sulfate and magnesium chloride for injection at room temperature (15°C to 30°C [59°F-86°F]); avoid freezing. Refrigeration may result in precipitation or crystallization.

Compatibility/Compounding Considerations

Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Magnesium sulfate 50% must be diluted to 20% or less before administration. Dextrose 5% injection and sodium chloride 0.9% injection are commonly used as diluents.

Magnesium sulfate is reportedly physically **compatible** with the following IV solutions: dextrose 5%, lactated Ringer's solution, and sodium chloride 0.9%. It is also **compatible** with chloramphenicol sodium succinate, cisplatin, hydrocortisone sodium succinate, isoproterenol HCl, metoclopramide HCl (in syringes), norepinephrine bitartrate, penicillin G potassium, potassium phosphate, and verapamil HCl. Additionally, magnesium is **compatible at Y-sites** with sodium, amikacin sulfate, ampicillin sodium, cefazolin sodium, cefotaxime sodium, cefoxitin sodium, clindamycin phosphate, doxycycline phosphate, erythromycin lactobionate, esmolol HCl, gentamicin sulfate, heparin sodium, labetalol HCl, metronidazole (RTU), oxacillin sodium, piperacillin sodium, potassium chloride, tetracycline HCl, tobramycin sulfate, trimethoprim/sulfamethoxazole, vancomycin HCl, and vitamin B complex with C.

Magnesium sulfate has some concentration-dependent compatibility with calcium gluconate; low concentrations of both magnesium and calcium may be **compatible**. Contact a hospital pharmacist for specific information.

Magnesium sulfate is reportedly physically **incompatible** with alkali hydroxides, alkali carbonates, salicylates, and many metals. It is **incompatible** with 10% lipids, dobutamine HCl, polymyxin B sulfate, procaine HCl, and sodium bicarbonate solutions.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

There are no parenteral magnesium-only products FDA-approved for veterinary medicine. There are, however, several proprietary magnesium-containing products available that may also include calcium, phosphorus, potassium, and/or dextrose; refer to the individual product's labeling for specific dosage information. Trade names for these products include *Norcalciphos®*, *Cal-Dextro® Special*, and *#2* and *CMPK®*, and *Cal-Phos® #2;* (Rx).

HUMAN-LABELED PRODUCTS:

Magnesium Sulfate in 5% Dextrose, Injection: 1% (10 mg/mL; 0.081 mEq/mL) in single-dose containers; 2% (20 mg/mL; 0.162 mEq/mL) in 500 mL and 1000 mL single-dose containers; generic; (Rx)

Magnesium Sulfate Injection, solution: 4% (40 mg/mL; 0.325 mEq/mL) in 50 mL, 100 mL, 500 mL, and 1000 mL; 8% (80 mg/mL; 0.65 mEq/mL) in 50 mL; 50% (500 mg/mL; 4 mEq/mL) in 2 mL, 10 mL, 20 mL, and 50 mL vials; generic; (Rx)

Magnesium Chloride Injection: 20% (200 mg/mL; 1.97 mEq/mL) in 50 mL multi-dose vials; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Mannitol

(***man***-i-tole) *Osmitrol®*

Osmotic Diuretic

Prescriber Highlights

- ► Used for acute oliguric renal failure, to reduce intraocular, treat cerebral edema, to enhance urinary excretion of some toxins, and, with other diuretics, to rapidly reduce edema
- ► Contraindications include anuria, hypovolemia, severe dehydration, severe pulmonary congestion, and pulmonary edema.
- ► Stop treatment if patient develops signs of heart failure, pulmonary congestion, or acute kidney injury.
- ► Adverse effects include fluid and electrolyte imbalances, GI (eg, nausea, vomiting), cardiovascular (eg, pulmonary edema, congestive heart failure, tachycardia), and CNS effects (eg, lethargy, coma).
- ► Fluid, electrolyte, and acid-base imbalances must be corrected prior to administration. Adequate monitoring of urine output, fluid, electrolyte, and neurologic status is mandatory.
- ► Ensure crystals are dissolved in solution before administering; warming the solution prior to administration and use of an in-line IV filter (5 micron) is recommended.

Uses/Indications

Mannitol is used in many species to promote diuresis in oliguric acute kidney injury, reduce intraocular pressure, treat cerebral edema, enhance urinary excretion of some toxins (eg, aspirin, some barbiturates, bromides, ethylene glycol), and, in conjunction with other diuretics, to rapidly reduce edema when appropriate (see ***Contraindications/Precautions/Warnings***). In stable cats with minimal renal compromise, mannitol has been used for IV fluid diuresis in an attempt to expel calcium oxalate uroliths.[1] In humans, it is also used as an irrigating solution during transurethral prostatic resections.

Mannitol may be used as emergency osmotic therapy for acute glaucoma in animals that are refractory to topical medications (eg, prostaglandin analogues, carbonic anhydrase inhibitors, beta-blockers, miotic agents).

Pharmacology/Actions

After IV administration, mannitol is freely filtered at the glomerulus and poorly reabsorbed in the tubule. The increased osmotic pressure prevents water from being reabsorbed at the tubule. To be effective, there must be sufficient renal blood flow and filtration for mannitol to reach the tubules. Although water is proportionately excreted at a higher rate, the excretion of sodium, chloride, bicarbonate ions, uric acid, and urea is also enhanced. Diuresis typically occurs within 1 to 3 hours.

Mannitol produces immediate reduction of cerebral edema (and

thus, intracranial pressure) through its diuretic effects. The reduction in cerebral edema allows for improved cerebral blood flow and oxygenation of cerebral tissues. Mannitol also has free radical scavenging effects to help diminish tissue injury caused by cerebral hypoxia.

Mannitol may have a nephroprotective effect by preventing the accumulation of nephrotoxins in the tubular fluid. Additionally, it may minimize renal tubular swelling via its osmotic properties, and it may increase renal blood flow and glomerular filtration by causing renal arteriole dilatation, decreased vascular resistance, and decreased blood viscosity.

Pharmacokinetics

Mannitol is poorly absorbed from the GI tract. After IV dosing, mannitol is distributed to the extracellular compartment. It does not cross the blood–aqueous barrier or the blood–brain barrier unless the patient has received very high doses, is acidotic, or there is loss of integrity of the barrier.

Only 7% to 10% of mannitol is metabolized, with the remainder excreted unchanged in the urine. The elimination half-life of mannitol is ≈100 minutes in adult humans but may be prolonged by renal impairment. Half-lives in cattle and sheep are reported to be between 40 and 60 minutes.

Contraindications/Precautions/Warnings

Mannitol is contraindicated in patients that are hypersensitive to it, anuric, severely hypovolemic, or that have severe pulmonary congestion/edema. Only administer mannitol after correcting fluid, electrolyte, and acid-base imbalances. In humans, mannitol is also labeled as contraindicated in patients with intracranial bleeding; however, there is conflicting clinical evidence to support this contraindication as mannitol has been safely used in these patients without untoward effects (ie, worsening intracranial hemorrhage).

Use extreme caution when administering mannitol in hypovolemic patients, as the diuretic effect of mannitol can exacerbate hypovolemia. Patients treated with mannitol should be treated concurrently with isotonic crystalloid fluids and/or colloids to minimize the risk for hypovolemia. Hypertonic saline may be a better choice to treat elevated intracranial pressure and to increase intravascular volume in these patients. Adequate fluid replacement must be administered to dehydrated animals before mannitol therapy is started.

Use mannitol with caution when treating cerebral edema. Intermittent boluses of mannitol are preferred as CRIs will cause the blood-brain barrier to become more permeable and worsen cerebral edema. Similarly, mannitol should be used with caution when treating elevated intraocular pressure caused by secondary glaucoma (eg, uveitis, neoplasia), as the resulting inflammation may increase the permeability of the blood–aqueous barrier and cause an increase in intraocular pressure (IOP).

Mannitol should also be used with caution when treating ethylene glycol toxicity or other hyperosmolar states (eg, hyperosmolar hyperglycemia), as it can exacerbate intravascular hyperosmolarity. See ***Laboratory Considerations***.

Mannitol therapy should be discontinued if heart failure, pulmonary congestion, azotemia, or oliguria/anuria develop during therapy.

Crystals may form in mannitol solutions. To prevent inadvertent administration of crystals, warming of mannitol solutions (see ***Storage/Stability***) and using an in-line IV filter (5 micron) is recommended.

Adverse Effects

Mannitol therapy may cause imbalances of fluids (eg, volume depletion, volume overload in oliguric patients), electrolytes (eg, hypernatremia, hypokalemia, pseudohyponatremia), and acid-base status (eg, metabolic acidosis).

Mannitol affects canine whole blood coagulation and platelet function in vitro. Clinical significance is uncertain.

Other adverse effects include GI (nausea, vomiting), cardiovascular (pulmonary edema, congestive heart failure, tachycardia), acute kidney injury (if osmolality is more than 320 mOsm/L), and CNS effects (lethargy, coma). Mannitol is a vesicant, and the solutions are hyperosmotic; injection site reactions may occur.

Risks of mannitol therapy include the development of acute kidney injury, rebound cerebral edema, and blood–brain and blood–aqueous barrier disruption with repeated or high doses.

Reproductive/Nursing Safety

Mannitol crosses the placenta but has not demonstrated adverse embryo or fetal effects. It is not known whether this drug is excreted in milk, but it is unlikely that it would pose significant risk to nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Inadvertent overdoses can cause excessive excretion of sodium, potassium, and chloride. If urine output is inadequate, water intoxication, acute kidney injury, neurotoxicity,[2] or pulmonary edema may occur. Treat overdoses by discontinuing mannitol administration; monitor and correct electrolyte and fluid imbalances. Hemodialysis is effective in clearing mannitol.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving mannitol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides** (eg, **amikacin, gentamicin**): Mannitol may increase the nephrotoxic effect of aminoglycosides.
- **Blood Products:** Concurrent administration of mannitol with blood products through the same administration set may result in pseudoagglutination or hemolysis. See ***Compatibility/Compounding Considerations***.
- **Bromides:** Mannitol may enhance urinary bromide excretion.
- **Cyclosporine**: Concurrent use of cyclosporine with mannitol may increase the risk for nephrotoxicity.
- **Desmopressin:** Concurrent use may increase the risk for hyponatremia.
- **Diuretics** (eg, **furosemide**): Concurrent use of mannitol with diuretics may increase the risk for nephrotoxicity.
- **Hypotensive Agents** (eg, **amlodipine, enalapril, sildenafil, telmisartan**): Concurrent use may increase risk for hypotension.
- **Sotalol**: Mannitol's effects on potassium and magnesium may increase the risk for QT prolongation if it is administered with sotalol.

Laboratory Considerations

- Mannitol can interfere with **blood inorganic phosphorus** concentrations.
- Mannitol can give a false positive **ethylene glycol test**.

Dosages

NOTES:

1. Crystals may form in mannitol solutions. To prevent inadver-

tent administration of crystals, warming of mannitol solutions (see ***Storage/Stability***) and using an in-line IV filter (5 micron) is recommended.

2. Administer mannitol only after correcting fluid, electrolyte, and acid-base imbalances and determining that the patient is not anuric.

DOGS/CATS:

Osmotic diuresis (label dosage; not FDA-approved): 1.5 – 2 g/kg IV over 30 minutes[3]

Oliguric acute kidney injury (extra-label): Most clinicians recommend mannitol 0.25 – 0.5 g/kg as a slow IV bolus over 10 to 20 minutes. Recommendations range from 0.25 – 1 g/kg IV over 10 to 40 minutes, but no evidence was located that supports one recommendation over the other. If substantial diuresis occurs, can either start mannitol 60 – 120 mg/kg/hour IV CRI or give as intermittent repeated boluses of 0.25 – 0.5 g/kg IV every 4 to 6 hours.[4] Some clinicians recommend that total daily dose should not exceed 2 g/kg per day.

Adjunctive treatment of acute glaucoma refractory to topical agents (extra-label): Most clinicians recommend mannitol 0.5 – 1 g/kg as a slow IV bolus over 10 to 20 minutes. Recommendations range from 0.5 – 2 g/kg IV over 20 to 30 minutes, but no evidence was located that supports one recommendation over the other. Withholding water for 1 to 4 hours postdose is often recommended.[5]

Adjunctive treatment of increased intracranial pressure caused by cerebral edema (extra-label): 0.5 – 1 g/kg IV, IO over 15 to 20 minutes. If required, repeat boluses (usually ever 6 to 8 hours) may be administered; mannitol CRIs are not recommended for this indication.[6,7]

HORSES:

Oliguric acute kidney injury refractory to volume replacement (extra-label): 0.25 – 1 g/kg IV administered as a 20% solution over 15 to 20 minutes[8]

Increased intracranial pressure from traumatic brain injury (extra-label): 0.25 – 1 g/kg IV every 4 to 6 hours.[9] These effects are best accomplished with rapid mannitol bolus administration rather than continuous administration. The efficacy of mannitol wanes with repeated administration.[10]

Adjunctive treatment of hypoxic ischemic encephalopathy in foals (extra-label): 0.25 – 1 g/kg IV every 6 to 12 hours[11]

CATTLE, SWINE, SHEEP, GOATS:

Adjunctive treatment of cerebral edema (extra-label): 1 – 3 g/kg IV[12]

Diuretic for oliguric acute kidney injury (extra-label): 0.25 - 2 g/kg IV over 15 to 20 minutes[13]

FERRETS:

Increased intracranial pressure (extra-label): 0.5 – 1 g/kg IV administered over 20 minutes[14,15]

RABBITS/GUINEA PIGS/CHINCHILLAS:

Increased intracranial pressure (extra-label): 0.25 – 1 g/kg IV administered over 15 minutes[14,16]

Monitoring

- Serum electrolytes (especially sodium), serum osmolality (especially if multiple doses or CRIs are administered), acid-base status
- Serum BUN and creatinine
- Urine output
- Hydration status
- Blood pressure
- Central venous pressure, if possible
- Thoracic auscultation, respiratory rate and effort
- Neurologic status (eg, mentation, pupillary light reflex, pupil size and symmetry, Cushing reflex)

Client Information

- Mannitol should only be administered by professional staff in a setting where adequate monitoring can occur.

Chemistry/Synonyms

An osmotic diuretic, mannitol occurs as an odorless, sweet, white, crystalline powder with a melting range of 165°C to 168°C (329°F-334°F) and a pK_a of 3.4. One gram is soluble in ≈5.5 mL of water (at 25°C [77°F]); it is very slightly soluble in alcohol. The commercially available injectable products have a pH of ≈4.5 to 7.

Mannitol may also be known as cordycepic acid, E421, manita, manitol, manna sugar, mannite, mannitolum, or Eufusol M.

Storage/Stability

Mannitol solutions are recommended to be stored between 15°C and 30°C (59°F-86°F); avoid freezing.

Crystallization may occur at low temperatures in concentrations more than 15%. If crystals form, the solution can be gently heated to 60°C (140°F) to dissolve. Cool to body temperature before administering. If unsuccessful in dissolving the precipitate, discard. An in-line IV filter is recommended when administering concentrated mannitol solutions.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information. It is not recommended to mix mannitol with any other drugs. Use of PVC, other plastics, or rough glass may potentiate crystallization.

Drugs reported to be physically **compatible** with mannitol include amikacin sulfate, cefoxitin sodium, cimetidine HCl, dopamine HCl, gentamicin sulfate, metoclopramide HCl, tobramycin sulfate, and verapamil HCl.

Mannitol should NOT be added to whole blood products to be used for transfusion. If administration of mannitol via a separate line or at different times from the blood products cannot be avoided, pseudoagglutination can be prevented by adding at least 20 mEq/L of sodium chloride to mannitol prior to administering it with the whole blood product. Sodium or potassium chloride can cause mannitol to precipitate out of solution when mannitol concentrations are 20% or greater. Mannitol may be physically **incompatible** when mixed with strongly acidic or alkaline solutions.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Mannitol Injection: 20% (200 mg/mL; 1100 mOsm/L) in 100 mL single-dose vials; generic; (Rx). Labeled for use as an osmotic diuretic in dogs; products have not been FDA-approved.

HUMAN-LABELED PRODUCTS:

Mannitol Injection: 5% (50 mg/mL; 275 mOsm/L) in 1000 mL; *Osmitrol*®; (Rx)

Mannitol Injection: 10% (100 mg/mL; 550 mOsm/L) in 500 mL and 1000 mL; *Osmitrol*®; (Rx)

Mannitol Injection: 15% (150 mg/mL; 825 mOsm/L) in 500 mL; *Osmitrol*®, generic; (Rx)

Mannitol Injection: 20% (200 mg/mL; 1100 mOsm/L) in 250 mL and 500 mL; *Osmitrol*®, generic; (Rx)

Mannitol Injection: 25% (250 mg/mL; 1375 mOsm/L) in 50 mL single use vials (12.5 g/vial); generic; (Rx)

Marbofloxacin

(mar-boe-***flox***-a-sin) *Zeniquin®*

Fluoroquinolone Antibiotic

Prescriber Highlights

- ► Veterinary oral fluoroquinolone antibiotic effective against a variety of bacterial pathogens
- ► Contraindications include hypersensitivity to fluoroquinolones, cats younger than 12 months, and immature dogs during the rapid growth phase.
- ► May produce erosions of cartilage in weight-bearing joints and other signs of arthropathy in immature animals of various species
- ► Use with caution in patients with hepatic or renal insufficiency or dehydration, in those that are prone to seizures, and in immature dogs and cats during the rapid growth phase.
- ► Adverse effects include GI distress; marbofloxacin has not been proven to cause ocular toxicity in cats or predispose to *Streptococcus canis* necrotizing fasciitis.
- ► Many drug interactions
- ► Prohibited for extra-label use in food animals in the United States

Uses/Indications

Marbofloxacin is labeled for treatment of susceptible bacterial infections in dogs and cats. It is recommended that marbofloxacin be reserved for cases of bacterial cystitis with documented resistance to first-line agents (eg, amoxicillin, amoxicillin/clavulanic acid); however, it is a good first-line choice for pyelonephritis or prostatic infections.[1] Fluoroquinolones are considered second-tier drugs for treatment of bacterial folliculitis.[2] In dogs, marbofloxacin appears to have some efficacy for treating the clinical signs associated with canine leishmaniasis.[3] Broad-spectrum antibacterial coverage can be achieved by combining marbofloxacin with an antibiotic with gram-positive and anaerobic activity (eg, clindamycin, ampicillin/amoxicillin).

The World Health Organization (WHO) has designated fluoroquinolones as Critically Important, Highest Priority antimicrobials for human medicine.[4] The Office International des Epizooties (OIE) has designated second-generation quinolones as Veterinary Critically Important Antimicrobial (VCIA) Agents in avian, bovine, equine, lagomorph, and swine species.[5]

Pharmacology/Actions

Marbofloxacin is a third-generation, concentration-dependent, bactericidal fluoroquinolone. It acts by inhibiting bacterial DNA-gyrase (type-II topoisomerase), thus preventing DNA supercoiling and DNA synthesis, with susceptible bacteria cell death occurring within 20 to 30 minutes of exposure. Like other fluoroquinolones, marbofloxacin has demonstrated a significant postantibiotic effect for both gram-negative and gram-positive bacteria and is active in both stationary and growth phases of bacterial replication. Clinical efficacy is associated with achieving a peak marbofloxacin concentration 10 times greater than bacterial MIC.[6,7]

Marbofloxacin has a similar spectrum of activity as the other veterinary commercially available fluoroquinolones, although marbofloxacin is considered more active against *Pseudomonas aeruginosa* as compared with enrofloxacin.[8] Fluoroquinolone agents have good activity against many gram-negative bacilli and cocci, including most species and strains of *Pseudomonas aeruginosa*, *Klebsiella* spp, *Escherichia coli*, *Enterobacter* spp, *Campylobacter* spp, *Shigella* spp, *Salmonella* spp, *Aeromonas* spp, *Haemophilus* spp, *Pasteurella* spp, *Proteus* spp, *Yersinia* spp, *Serratia* spp, and *Vibrio* spp. Other organisms that are generally susceptible include *Brucella* spp, *Chlamydia trachomatis*, *Staphylococcus* spp (including penicillinase-producing and methicillin-resistant strains), *Mycoplasma* spp, and some *Mycobacterium* spp. *Bordetella bronchiseptica* was susceptible, and a significant postantibiotic effect was demonstrated ex vivo.[9]

Fluoroquinolones have variable activity against most streptococci and are not usually recommended to treat these infections. Marbofloxacin is ineffective in treating anaerobic infections. Fluoroquinolones are ineffective against viral, protozoal, or fungal infections.

Resistance can occur by mutation, particularly with *Pseudomonas aeruginosa, Klebsiella pneumoniae, Acinetobacter* spp, *Staphylococcus* spp, and enterococci, but plasmid-mediated resistance is thought to occur only rarely.

Marbofloxacin's leishmanicidal activity is via the TNF-alpha and nitric oxide synthase pathways.[3]

Pharmacokinetics

In dogs, marbofloxacin is rapidly absorbed after oral administration and has a bioavailability of 94%.[10] Mean peak plasma concentrations in dogs given 2.75 mg/kg or 5.5 mg/kg PO were 2 μg/mL and 4.2 μg/mL, respectively. Peak concentrations occur in ≈1.5 hours. Protein binding is low, and the apparent volume of distribution is 1.2 to 1.9 L/kg. Marbofloxacin is widely distributed in canine tissues, and relatively high concentrations can be found in prostatic fluid. Elimination half-life averages 9 to 12 hours.[11,12] The drug is eliminated unchanged in the urine (40%) and bile/feces.[11] Only ≈15% of a dose is metabolized in the liver. Mild to moderate renal impairment does not significantly alter dose requirements in dogs.[13]

In cats, absorption after oral administration is nearly complete and peak serum concentrations occur ≈1 to 2 hours post-administration.[10,14] Mean peak plasma concentrations in cats given 5.5 mg/kg PO were 4.8 μg/mL. Terminal elimination half-life is ≈13 hours, with ≈70% of a dose excreted in the urine mostly as unchanged drug.

In rabbits, 5 mg/kg PO every 24 hours produced a peak plasma concentration of 1.7 μg/mL 24 hours after the first administration and 2.6 μg/mL after the tenth daily dose. Elimination half-life was 4 to 8 hours.[15]

Contraindications/Precautions/Warnings

Marbofloxacin is contraindicated in patients hypersensitive to it or other fluoroquinolones. Fluoroquinolones may cause cartilage erosions in weight-bearing joints in immature animals; dogs appear to be more susceptible to this effect.[10] To avoid cartilage damage, marbofloxacin is contraindicated in immature dogs during the rapid growth phase (small- and medium-breed dogs up to 8 months of age, large breeds to 12 months of age, and giant breeds to 18 months of age). It is also contraindicated in cats younger than 12 months.

Marbofloxacin can (rarely) cause CNS stimulation and should be used with caution in patients with seizure disorders. Patients with severe renal or hepatic impairment may require dosage adjustments (eg, increased dosing interval) to prevent drug accumulation.

Fluoroquinolones may cause photosensitization, and prolonged exposure of bare skin (eg, nose) or thinly haired skin to direct sunlight should be avoided.[10]

The FDA has prohibited the extra-label use of this drug in food-producing animals.

Adverse Effects

With the exception of potential cartilage abnormalities in young animals (see ***Contraindications/Precautions/Warnings***), the adverse effect profile of marbofloxacin is usually limited to GI distress (eg, vomiting, anorexia, diarrhea) and decreased activity.

Other fluoroquinolones have, in rare incidences, caused elevated hepatic enzymes, ataxia, seizures, depression, lethargy, and nervous-

ness in dogs. Hypersensitivity reactions or crystalluria could occur.

Although unlikely to occur, the FDA's Adverse Drug Reaction database has received some reports of blindness associated with marbofloxacin. Unlike enrofloxacin, causal effect of ocular toxicity has not yet been proven with marbofloxacin, but higher dosages should be used carefully.

Induction of *Streptococcus canis* necrotizing fasciitis, which can be seen with enrofloxacin, does not appear to be a problem with marbofloxacin.

Reproductive/Nursing Safety

The safety of marbofloxacin in pregnant or lactating animals or those used for breeding purposes has not been demonstrated.[10] Fluoroquinolones should be used cautiously in pregnant animals due to their adverse effects on cartilage.

In cattle, marbofloxacin distributes into milk, attaining milk concentration similar to that of plasma.[16]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

It is unlikely that an acute overdose of marbofloxacin would result in signs more serious than either anorexia or vomiting, but the adverse effects noted previously could occur. Dogs receiving 55 mg/kg per day PO for 12 days have developed anorexia, vomiting, dehydration, tremors, red skin, facial swelling, lethargy, and weight loss.[10] All large-breed, 3- to 4-month-old puppies given 11 mg/kg/day developed marked lameness due to articular cartilage lesions. Increased salivation, vomiting, and redness of the pinnae occurred in cats given 27.5 – 55 mg/kg/day.[10] Macroscopic and microscopic cartilage changes were noted but without accompanying lameness.

Acute bilateral blindness occurred in a dog following an accidental overdose of 35 mg/kg/day for 3 days.[17]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving marbofloxacin or related fluoroquinolones and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Aluminum-, Calcium-, and Magnesium-Containing Oral Products**: May bind to marbofloxacin and prevent its absorption; separate doses of by at least 2 hours.
- **Antibiotics, Other** (eg, **aminoglycosides, third-generation cephalosporins, penicillins—extended-spectrum**): Synergism may occur but is not predictable against some bacteria (particularly *Pseudomonas aeruginosa*) with these compounds. Although marbofloxacin has minimal activity against anaerobes, in vitro synergy has been reported when it was used with clindamycin against strains of *Peptostreptococcus* spp, *Lactobacillus* spp, and *Bacteroides fragilis*.
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Concomitant use with fluoroquinolones may increase the risk for tendonitis and tendon rupture.
- **Cyclosporine** (**systemic**): Fluoroquinolones may exacerbate the nephrotoxicity and reduce the metabolism of cyclosporine when used systemically.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs,** eg, **flunixin**): Flunixin has been shown in dogs to increase the AUC and elimination half-life of enrofloxacin, and enrofloxacin increases the AUC and elimination half-life of flunixin; it is unknown if marbofloxacin also causes this effect, if other NSAIDs interact with marbofloxacin, or if this interaction applies to other species.
- **Iron** (**oral**): May decrease marbofloxacin absorption; doses should be separated by at least 2 hours after marbofloxacin.
- **Methotrexate (MTX)**: May increase MTX concentrations and risk for MTX toxicity
- **Nitrofurantoin**: May antagonize the antimicrobial activity of the fluoroquinolones; concomitant use is not recommended
- **Probenecid**: May block tubular secretion of ciprofloxacin; may increase the blood concentration and half-life of marbofloxacin
- **QT-Prolonging Agents** (eg, **cisapride, sotalol, quinidine, erythromycin, ondansetron**): In humans, fluoroquinolones may enhance the QT-prolonging effect of other drugs.
- **Sucralfate**: May inhibit absorption of marbofloxacin; administration of these drugs should be separated by at least 2 hours after marbofloxacin.
- **Theophylline, Aminophylline**: Marbofloxacin may increase theophylline blood concentrations; this interaction is more likely to occur with enrofloxacin than with marbofloxacin.[18]
- **Urine Acidifiers** (eg, **ammonium chloride**, **methionine**): Low urinary pH could have an inhibitory effect on the activity of marbofloxacin.
- **Warfarin**: Potential for increased warfarin effects; monitor prothrombin time (PT)
- **Zinc** (**oral**): May decrease marbofloxacin absorption; doses should be separated by at least 2 hours after marbofloxacin.

Laboratory Considerations

- In some humans, fluoroquinolones have caused increases in **liver enzymes**, **BUN**, and **creatinine** and decreases in **hematocrit**. The clinical relevance of these mild changes in veterinary medicine is not known.

Dosages

DOGS:

Skin and soft tissue infections:

- **Label dosage; FDA-approved**: 2.75 – 5.5 mg/kg PO once daily.[10] Give for 2 to 3 days beyond cessation of clinical signs to a maximum duration of 30 days.
- **Extra-label dosage**: 5.5 mg/kg PO once daily[19]

UTIs:

- **Label dosage; FDA-approved**: 2.75 – 5.5 mg/kg PO once daily for at least 10 days to a maximum duration of 30 days. **NOTE**: A shorter treatment duration (ie, 3 to 5 days) is adequate for most cases of bacterial cystitis.[1]
- **Extra-label dosage for sporadic bacterial cystitis**: 2.75 – 5.5 mg/kg PO once daily for 3 to 5 days.[1] **NOTE**: When treating *Pseudomonas* spp infections, most clinicians recommend using the higher end of the dose range.

Leishmaniasis (extra-label): 2 mg/kg PO once daily for 28 days. At the one-year follow-up, marbofloxacin has shown some efficacy in 70% of treated dogs. At 3 months, there was a 61% decrease in the sum of clinical scores. Though clinically improved, dogs remained parasitologically positive.[3,20,21]

CATS:

Skin and soft tissue infections:

- **Label dosage; FDA-approved**: 2.75 – 5.5 mg/kg PO once daily.[10] Give for 2 to 3 days beyond cessation of clinical signs to a

maximum duration of 30 days.

- **Extra-label dosage**: 5.5 mg/kg PO once daily[19]

UTIs:

- **Label dosage; FDA-approved**: 2.75 – 5.5 mg/kg PO once daily for at least 10 days to a maximum duration of 30 days. **NOTE**: a shorter treatment duration (ie, 3 to 5 days) is adequate for most cases of bacterial cystitis.[1]
- **Extra-label dosage for sporadic bacterial cystitis**: 2.75 – 5.5 mg/kg PO once daily for 3 to 5 days.[1] **NOTE**: When treating *Pseudomonas* spp infections, most clinicians recommend using the higher end of the dose range.

First-line treatment of feline mycobacterial infections (extra-label): If decision is made to treat localized cutaneous nontuberculous mycobacteria (NTM) infections; 2 mg/kg PO once daily in combination with rifampin and *either* azithromycin or clarithromycin for the initial 2 months, then continue with a combination of rifampin with either marbofloxacin or a macrolide for at least 4 months, with treatment continuing for at least 3 months beyond resolution of lesions and clinical signs.[22] Marbofloxacin is not effective against *M avium* complex (MAC) infection.

Hemotropic mycoplasma infections (extra-label): 2.75 mg/kg PO once daily for 14 to 28 days. Treatment up to 8 weeks with a goal to achieve a negative PCR has been suggested.[23,24] One protocol uses doxycycline 5 mg/kg PO twice daily for 28 days, and cats that remained PCR-positive or became positive again were treated with marbofloxacin 2 mg/kg PO once daily for 14 days.[25]

BIRDS:

Macaws (extra-label): From a single-dose pharmacokinetic study, 2.5 mg/kg PO every 24 hours may be considered.[26]

Mallard ducks (extra-label): 2 – 2.5 mg/kg PO or IV every 24 hours.[27,28] **NOTE**: Parenteral formulation is not available in the United States.

RABBITS:

Susceptible infections (extra-label): 5 mg/kg PO every 24 hours. 2 mg/kg IV, IM, or SC every 24 hours.[15,28,29] **NOTE**: Parenteral formulation is not available in the United States.

REPTILES:

Ball pythons (*Python regius*) (extra-label): 10 mg/kg PO at least every 48 hours. Dosage is based on a pharmacokinetic study; further studies are required to determine effective dosages and toxicity.[30]

Monitoring

- Fluoroquinolone use should be based on culture and susceptibility results.
- Clinical efficacy
- Adverse effects

Client Information

- Give this medicine to your animal as prescribed by your veterinarian. Do not stop the treatment even if your animal appears well.
- This medicine is best given without food on an empty stomach, but if your animal vomits or acts sick after receiving it, give it with food or small treat (no dairy products, antacids, or iron supplements). If vomiting continues, contact your veterinarian.
- Be sure to tell your veterinarian what medications (including vitamins, supplements, herbal therapies, and treats) you are giving your animal, including the amount and schedule of each. This medicine should not be given at the same time as some medications (eg, sucralfate) or vitamins that contain calcium, iron, or aluminum, as these can interfere with how well the medicine works.
- This medicine may cause bone and joint abnormalities if used in young animals or animals that are pregnant or nursing.
- The most common side effects are vomiting, nausea, or soft stool/diarrhea.
- For animals with thin hair coats, there may be a risk for sun sensitivity within a few hours of receiving fluoroquinolones.
- Your veterinarian will need to monitor your animal while it is taking this medicine. Do not miss important follow-up visits.

Chemistry/Synonyms

Marbofloxacin is a synthetic fluoroquinolone antibiotic that occurs as a light yellow, crystalline powder. It is soluble in water, but solubility decreases as pH increases.

Marbofloxacin may also be known as Ro 9-1168, *Aristos®*, *Boflox®*, *Efex®*, *Forcyl®*, *Kelacyl®*, *Marbocyl®*, *Marbocare®*, *Marbonor®*, *Marboquin®*, *Marbox®*, *Marfloquin®*, *Quiflor®*, or *Zeniquin®*.

Storage/Stability

Marbofloxacin tablets should be stored below 30°C (86°F).

Compatibility/Compounding Considerations

A marbofloxacin 20 mg/mL oral suspension was prepared by grinding twenty 100 mg tablets in a mortar with a pestle. The ground tablets were passed through a sieve to separate the powder from the tablet coating and returned to the mortar. The powder was wet with a small amount of glycerin. Equal amounts of *OraPlus®* and *OraSweet®* were added to form a smooth paste, and the liquid was transferred to an amber prescription liquid bottle and brought to 100 mL final volume with additional vehicle. Stability studies supported a beyond-use date (BUD) of 60 days when stored at controlled room temperature. The suspension should be shaken well prior to measuring a dose. **NOTE**: Use of *OraBlend®* resulted in a gritty suspension and a shorter BUD; *OraPlus®* and *OraSweet®* should be used separately.[31]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Marbofloxacin Oral Tablets: 25 mg, 50 mg, 100 mg, and 200 mg; *Zeniquin®*, *Marboquin®;* (Rx). FDA-approved for use in dogs and cats.

Extra-label use of fluoroquinolones is illegal in food animals in the United States.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Maropitant

(ma-**rahp**-it-ent) *Cerenia®*

Neurokinin-1 (NK-1) Receptor Antagonist, Antiemetic

Prescriber Highlights

- ► FDA-approved in dogs for the treatment of acute vomiting (SC injection), and for the prevention of acute vomiting (SC injection, oral tablets) and the prevention of vomiting due to motion sickness (tablets)
- ► The SC injection is also FDA-approved for the treatment of vomiting in cats.
- ► In animals that are actively vomiting, the injectable formulation is preferred to ensure the full dose is received.
- ► Because maropitant acts at the emetic center, it is effective for the treatment of emesis mediated via either peripheral or central mechanisms.
- ► SC injections may cause pain and swelling at the injection site. Refrigerating the injection may reduce pain.
- ► The PO dose is higher than the SC dose in dogs because of the decreased bioavailability of the oral tablet.
- ► Not for use in patients with suspected toxin ingestion

Uses/Indications

Maropitant tablets are indicated for the prevention of acute vomiting in dogs 2 months and older and vomiting due to motion sickness in dogs 4 months and older.[1]

Maropitant injectable solution is indicated for the prevention and treatment of acute vomiting in dogs 2 months and older and for the prevention of vomiting caused by emetogenic medication and chemotherapeutic agents in dogs 4 months and older.[2] Maropitant injectable solution also is approved for treatment of vomiting in cats 4 months or older.[2]

Maropitant has been effective for controlling vomiting secondary to a variety of stimuli, including xylazine (cats), hydromorphone (dogs),[3–6] morphine (dogs),[7–9] morphine with dexmedetomidine (cats),[10,11] cisplatin (dogs),[12–14] copper sulfate, apomorphine (dogs), brimonidine ophthalmic solution (cats),[15] tranexamic acid (dogs),[16] and parvovirus.[17–19] Maropitant demonstrated modest efficacy for controlling chemotherapy-induced nausea and ondansetron appeared to have a better effect.[14] In dogs hospitalized with parvoviral enteritis, maropitant was equally as effective as ondansetron in controlling clinical signs.[20] Maropitant reduced both nausea and vomiting when administered 2 hours before preoperative administration of hydromorphone, acepromazine, and glycopyrrolate[21]; however, preoperative maropitant does not appear to reduce perioperative gastroesophageal reflux.[22,23]

Maropitant appears to enhance the antinociceptive effect of other analgesic in dogs and cats[19,24–27] and has demonstrated a minimum alveolar concentration (MAC)-sparing effect (≈15% to 25% reduction) in dogs and cats maintained on inhalant anesthesia.[19,24,28–30]

Maropitant failed to improve clinical signs, airway hyperresponsiveness, or eosinophilia in experimental models of acute and chronic feline asthma.[31,32]

A 4-week treatment with oral maropitant seemed to be an effective, well-tolerated therapeutic option to control pruritus in cats with feline atopic skin condition.[33]

Pharmacology/Actions

Maropitant is a neurokinin-1 (NK-1) receptor antagonist that acts in the CNS by inhibiting the binding of substance P, which is the key neurotransmitter involved in vomiting. Maropitant can suppress both peripheral and centrally mediated emesis. Maropitant has been shown to reduce the MAC requirements of sevoflurane and to reduce visceral pain in dogs, as NK-1 receptors are stimulated by substance P.[28,30] Maropitant does not affect gastric emptying times or intestinal transit times, but it can decrease small intestine contraction pressure patterns.[34] Maropitant has been shown to possess anti-inflammatory activity in a mouse model of pancreatitis.[35]

Pharmacokinetics

In dogs, maropitant is rapidly absorbed after PO and SC administration. Peak plasma concentrations (C_{max}) are reached in less than 1 hour following 1 mg/kg SC administration and less than 2 hours following 2 or 8 mg/kg PO administration; C_{max} after IV administration is ≈3 times higher than the same dose given SC (297 ng/mL vs 103 ng/mL, respectively) and is ≈4 times higher than 2 mg/kg PO (81 ng/mL). After PO administration, bioavailability is 24% (2 mg/kg) and 37% (8 mg/kg), which suggests first-pass metabolism becomes saturated at the higher dose. Feeding status does not affect bioavailability. Bioavailability is 91% following SC administration of 1 mg/kg. An accumulation ratio of 1.5 occurs after use of maropitant every 24 hours for 5 consecutive days at 1 mg/kg SC or 2 mg/kg PO. Accumulation ratio is 2.18 after 2 consecutive days at 8 mg/kg PO daily. Accumulation ratios after 2 mg/kg and 8 mg/kg PO once daily for 14 days were 2.46 and 4.81 based on AUC, respectively, and 2.03 and 2.77 based on C_{max}.[36] However, no accumulation was demonstrated after administration of 2 mg/kg/day for 28 days.[37]

Maropitant is eliminated primarily by the liver. Hepatic metabolism of maropitant involves 2 cytochrome P450 enzymes: CYP2D15 (low capacity, high affinity) and CYP3A12 (high capacity, low affinity). The nonlinear kinetics at oral doses of 2 – 16 mg/kg may be due to saturation of the low-capacity enzyme and increased involvement of CYP3A12 at higher doses. Twenty-one metabolites have been identified and the major pharmacologically active metabolite is a product of hydroxylation. Plasma protein binding of maropitant is high (99.5%). Large interpatient PK variations have been observed. In dogs, the half-life is 8.8 hours (range: 6.07 to 17.7 hours) for 1 mg/kg SC, 6.9 hours for 1 mg/kg IV, and 4.03 hours (range: 2.58 to 7.09 hours) for 2 mg/kg PO. Urinary recovery of maropitant and its major metabolite is minimal (less than 1%).

In cats, bioavailability is ≈50% (PO) and 91% (SC). Protein plasma binding is high (99%). Maropitant displays linear kinetics when administered SC within the 0.25 – 3 mg/kg dose range. Terminal elimination half-life in cats is ≈15 hours. Feline isoforms of CYP1A and CYP3A enzymes are involved in the hepatic biotransformation of maropitant in cats. Less than 1% of a dose is excreted unchanged in urine or feces.[38,39]

There appears to be an age-related effect on pharmacokinetics, as puppies (10 weeks of age) and kittens (16 weeks of age) appear to have a faster clearance of maropitant than adults.[2]

Contraindications/Precautions/Warnings

Maropitant is most effective in preventing vomiting associated with chemotherapy if it is administered before the chemotherapeutic agent.[1,2] Safe use has not been evaluated in dogs or cats that have GI obstructions or ingested toxins. If vomiting persists despite treatment, reevaluation is needed to determine the cause.

Maropitant can cause prolongation of the QT interval because of cardiac potassium channel blockade. Safe use of maropitant has not been reported in patients with underlying cardiac disease when administered in combination with cardiac antiarrhythmic drugs.[40]

Caution is advised in patients with hepatic dysfunction, as maropitant is hepatically metabolized; the dose may need to be reduced by 50% if used in these patients.

Caution is also advised when administering the higher dose of maropitant to prevent vomiting due to motion sickness in puppies younger than 11 weeks. A higher frequency and greater severity of histologic evidence of bone marrow hypoplasia was seen in puppies treated with the higher dose of maropitant as compared with control

puppies. In puppies 16 weeks or older, bone marrow hypocellularity was not observed.[1,2]

In humans, topical exposure may elicit allergic skin reactions in some individuals. In the event of accidental skin exposure, skin should be washed with soap and water. In the event of accidental eye exposure, eyes should be flushed with water for 15 minutes and medical attention should be sought.[1,2]

Adverse Effects

Maropitant appears to be well tolerated in dogs and cats. Allergic reactions are possible but rare and typically resolve with supportive treatment within 48 hours after the drug is discontinued.

In dogs given the higher oral dose required for prevention of motion sickness, the 2 most common adverse effects are pretravel vomiting and hypersalivation. Swelling or pain at the injection site has been reported following SC administration of this drug. A study found that dogs had less pain at the injection site when the injection was refrigerated and immediately injected,[41] and a formulation preserved with benzyl alcohol was less painful than the metacresol-containing product that is currently available in the US.[42] Other adverse effects include depression and lethargy, anorexia, diarrhea, anaphylaxis/anaphylactoid reactions (including swelling of the head and face), ataxia, tremors, fever, dyspnea, collapse/loss of consciousness, sedation, and convulsions.[1,2]

In healthy dogs, IV maropitant further decreased arterial blood pressure caused by isoflurane anesthesia, and clinically significant hypotension occurred in dogs premedicated with acepromazine.[43]

In cats, adverse effects include depression and lethargy, anorexia, injection site pain, hypersalivation, dyspnea, ataxia, fever, recumbency, vomiting, panting, convulsion, and muscle tremors.[2]

Reproductive/Nursing Safety

Safe use of maropitant in dogs or cats used for breeding or in pregnant or lactating bitches or queens has not been evaluated.[1,2] Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Single-dose toxicity was studied in mice and rats after PO and IV administration.[44] No adverse effects were reported after PO administration of up to 30 mg/kg (mice) and 100 mg/kg (rats) and after IV administration of 6.5 mg/kg (mice) and 2.5 mg/kg (rats). Clinical signs of overdose in mice and rats included decreased activity, irregular or labored respiration, ataxia, and tremors. Excretion of reddish urine was observed in some mice and rats following IV administration.

In dogs, no serious adverse effects were noted when oral doses up to 24 mg/kg (3 times the highest recommended dose) were administered 3 times longer than the proposed maximum duration of treatment.

Oral toxicokinetic studies with the primary metabolite were conducted in mice, rats, rabbits, and dogs; it was demonstrated that the metabolite was well tolerated.[44]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

During field safety and efficacy studies, a number of medications were used concomitantly with maropitant. The most common concomitant medication was metronidazole. Other commonly used concomitant medications included dextrose/Ringer's solution IV, sodium chloride IV, amoxicillin, ampicillin, cefazolin, cephalexin, enrofloxacin, sulfamethoxazole/trimethoprim, famotidine, sucralfate, cimetidine, dexamethasone, ivermectin, ivermectin/pyrantel, pyrantel, lufenuron/milbemycin, milbemycin, moxidectin, vitamin B, and vaccines. No problems were observed with any of these drugs when used in conjunction with maropitant.

Drug interactions with maropitant have not been thoroughly investigated. Maropitant may be susceptible to interactions because it is biotransformed in the liver by CYP3A12 and CYP2D15 in dogs and by CYP1A- and CYP3A-related enzymes in cats and is highly bound to plasma proteins. The following drug interactions are theoretical in animals receiving maropitant and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**): The UK label states maropitant *Should not be used concomitantly with Ca-channel antagonists as maropitant has affinity to Ca-channels*.[45]
- **CYP3A Inhibitors** (eg, **amiodarone, diltiazem, cimetidine, erythromycin, ketoconazole, itraconazole**): May reduce maropitant metabolism
- **CYP2D Inhibitors** (eg, **cimetidine, fluoxetine, terbinafine**): May reduce maropitant metabolism
- **Highly Protein Bound Drugs** (eg, **valproic acid, oral anticoagulants [rivaroxaban, warfarin], NSAIDs, salicylates, sulfonamides, sulfonylurea antidiabetic agents**): Because maropitant is highly bound to plasma proteins (99.5%), it could theoretically displace other highly bound drugs, causing a transient increase in serum concentrations of each drug. These interactions are unlikely to be of clinical concern because free drug concentrations will equilibrate through increased clearance. Monitor for adverse effects of each drug when using this combination.
- **QT Prolonging Agents** (eg, **cisapride, domperidone, quinidine, sotalol**): Concurrent use may increase risk for QT prolongation and should be avoided.

Laboratory Considerations

- No specific concerns have been noted.

Dosages

NOTE: Refrigerating the injectable product may reduce the pain response associated with SC administration.

DOGS:

Label dosages (FDA-approved)[1,2]:

Indication	Dosage form	Minimum age for use	Dosage	Duration of therapy
Prevention and treatment of acute vomiting	Injection	2 months	1 mg/kg SC once daily	Up to 5 consecutive days
Prevention and treatment of acute vomiting	Injection	4 months	1 mg/kg SC or IV (over 1 to 2 minutes) once daily	Up to 5 consecutive days
Prevention of vomiting caused by emetogenic medications or chemotherapeutic agents	Injection	4 months	1 mg/kg SC or IV (over 1 to 2 minutes) once, 45 to 60 minutes prior to emetogenic medications or chemotherapeutic agents	Single injection

Indication	Dosage form	Minimum age for use	Dosage	Duration of therapy
Prevention of acute vomiting	Tablets	2 months	2 mg/kg PO once daily	5 days for dogs 2 to 7 months of age; until vomiting ceases in dogs older than 7 months
Prevention of vomiting due to motion sickness	Tablets	4 months	8 mg/kg PO once daily on an empty stomach or with a small amount of food; do not feed full meal prior to travel	Up to 2 consecutive days

Extra-label dosages:

Prevention of perioperative vomiting and improvement in recovery from general anesthesia after morphine use: 1 mg/kg SC or IV once daily more than 1 hour in advance of morphine administration; may be used for up to 5 consecutive days

Prevention and treatment of vomiting in dogs undergoing multiagent chemotherapy: 2 mg/kg PO once daily for 28 days[37]

Antitussive as part of a multimodal approach in dogs with airway disease: 2 mg/kg PO every 48 hours may be useful as an antitussive to break the cough cycle associated with tracheal collapse. A study showed that although cough was decreased in patients with chronic bronchitis, this dosage did not decrease airway inflammation.[46]

Analgesia/MAC-sparing effect during ovariohysterectomy:

a) 1 mg/kg SC at time of premedication. Maropitant also reduced postoperative nausea and vomiting and improved time to food intake.[9,24,29]

b) Intraoperatively, administration of 1 mg/kg IV followed by 0.03 mg/kg/hour CRI demonstrated an anesthetic sparing effect during visceral noxious stimulation of the ovarian ligament.[47] Higher doses (5 mg/kg IV followed by 0.15 mg/kg per hour CRI) have yielded marginally better results.[47,48] Doses involving continuous infusions do not appear to have superior MAC-sparing effects as compared with SC doses. Differences in study design make a direct comparison difficult.

CATS:

Treatment of vomiting in cats 4 months and older (label dosage; FDA-approved): 1 mg/kg SC or IV (over 1 to 2 minutes) once daily for up to 5 consecutive days[2]

Prevention of vomiting, including from motion sickness (extra-label): 1 mg/kg SC or PO.[45,49] A study reported that 8 mg/cat (NOT mg/kg) PO was effective in reducing emesis when administered as early as 18 hours before emetic medications.[11,50]

Prevention of vomiting associated with chronic kidney disease (CKD) (extra-label): 4 mg/cat (NOT mg/kg) PO every 24 hours for 2 weeks palliated vomiting associated with CKD.[51]

Analgesia/MAC-sparing effect during ovariohysterectomy (extra-label): In a proof-of-concept study, 1 mg/kg IV intraoperatively demonstrated an anesthetic sparing effect during visceral noxious stimulation of the ovarian ligament.[30] Alternatively, maropitant 1 mg/kg IV bolus followed maropitant 100 µg/kg/hour IV CRI experienced a lower heartrate and blood pressure during the procedure and required less analgesic rescue during the postoperative period compared to control cats.[52]

Feline atopic skin syndrome (extra-label): 2 mg/kg PO every 24 hours for 4 weeks seemed to be effective and well-tolerated.[33] NOTE: This dosage is from an open label, uncontrolled study, and further research to validate efficacy is warranted.

Monitoring

- Clinical efficacy as indicated by decreased episodes of vomiting
- Adverse effects

Client Information

- When using to prevent motion sickness, administer maropitant 2 hours before traveling with a small amount of food (not a full meal).
- Some dogs may vomit after taking this medication. Giving the drug with a small amount of food can help prevent vomiting.
- Do not wrap these pills tightly in food snacks, as this can prevent the drug from being released into the stomach.
- If giving your animal fractions (ie, half, quarter) of a tablet, wrap the remaining portion of the split tablet tightly in foil and store away from children and other animals.
- Do not give this medicine to puppies younger than 8 weeks, as bone marrow problems can occur.
- Side effects are uncommon. Contact your veterinarian if your animal experiences drooling, lethargy (ie, lack of energy), drowsiness/sleepiness, lack of appetite, or diarrhea.
- In humans, topical exposure may elicit allergic skin reactions in some individuals. In the event of accidental skin exposure, wash skin with soap and water. In the event of accidental eye exposure, flush the eye with water for 15 minutes and seek medical attention.

Chemistry/Synonyms

Commercial formulations containing maropitant citrate are classified as substituted quinuclidines and have a molecular weight of 678.81. Commercial formulations express drug potency or strength as milligrams of maropitant. The injection is a clear solution that may be colorless to light yellow and contains metacresol as a preservative.

Maropitant may also be known as CJ-11,972, *Cerenia®*, and *Prevomax®*.

Storage/Stability

The maropitant injectable solution contains a preservative and is designed for multidose use. The product label states the injectable solution should be stored at a controlled room temperature between 20°C and 25°C (68°F-77°F) with excursions between 15°C and 30°C (59°F-86°F) permitted. After the first vial puncture, the drug should be stored at a refrigerated temperature between 2°C and 8°C (36°F-46°F) and should be used within 90 days (56 days per UK label). The stopper may be punctured a maximum of 25 times.

Store maropitant tablets at room temperature 20°C to 25°C (68°F to 77°F) with excursions between 15°C to 30°C (59°F to 86°F). Maropitant tablets are packaged in foil to protect them from moisture uptake, which was observed in less protective packaging. A European stability study indicated that tablets removed from the blister pack and halved showed no loss of potency during the 48-hour testing period.

Compatibility/Compounding Considerations

Precipitation has been reported when maropitant and pantoprazole are coadministered in the same IV line. Given lack of compatibility information, consideration should be given to administering maropitant injections alone. The UK product label states that the maropitant injection *must not be mixed with other veterinary medicinal products in the same syringe*.[45] One study diluted maropitant in lactated Ringer's solution for use as an IV CRI, but the potency and stability of the admixture were not evaluated.[52]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Maropitant Citrate Injectable Solution: 10 mg/mL in 20 mL multidose vials; *Cerenia*®; (Rx). FDA-approved for use in dogs and cats. Licensed for use in other countries and available in a variety of vial sizes

Maropitant Citrate Oral Tablets: 16 mg, 24 mg, 60 mg, and 160 mg in blister packs (4 tablets per pack; carton of 10); *Cerenia*®; (Rx). Labeled for use in dogs

HUMAN-LABELED PRODUCTS: NONE

Mavacoxib

(mav-ah-***cox***-ib) *Trocoxil*®

Long-Acting NSAID

Prescriber Highlights

- ► Very long-acting NSAID for dogs; half-life averages 16 to 17 days. Not licensed/approved in the United States
- ► First 2 doses are given 14 days apart, then at 1 MONTH intervals for a maximum of 7 doses.
- ► Contraindications include pre-existing GI disorders, coagulopathies, impaired renal or hepatic function, cardiac insufficiency, or hypersensitivity to mavacoxib or sulfonamides.
- ► Adverse effect profile expected to be similar to other canine-approved NSAIDs: vomiting, diarrhea, loss of appetite, melena, and impairment of renal function.
- ► Primary benefit appears to be for patients whose owners have difficulty adhering to a daily oral dosing regimen.
- ► Although efficacy is long-lasting, adverse effects may persist and washout times to give other NSAIDs or glucocorticoids are prolonged.

Uses/Indications

Mavacoxib is a very long-acting oral NSAID licensed for use in dogs in the UK, Europe, and elsewhere. In the UK, it is labeled *for the treatment of pain and inflammation associated with degenerative joint disease in dogs aged 12 months or more in cases where continuous treatment exceeding 1 month is indicated*. Mavacoxib may be beneficial in cases in which long-term NSAID administration is indicated, but owners have difficulty adhering to a daily oral dosing regimen. However, because of its long half-life and duration of action, adverse effects could also persist for many weeks after the drug was last given.

In a study comparing the safety and efficacy of mavacoxib with carprofen in 124 dogs, the 2 were statistically equivalent, and each had a similar rate and profile of adverse effects.[1]

Pharmacology/Actions

In dogs, mavacoxib is a relatively selective inhibitor of cyclooxygenase-2 (COX-2) versus COX-1. At therapeutic dosages, this effect would inhibit the production of the prostaglandins that contribute to pain and inflammation (COX-2) and spare those that maintain normal GI and renal function (COX-1). However, COX-1 and COX-2 inhibition studies are done in vitro and do not necessarily correlate with clinical effects seen in patients.

Pharmacokinetics

Pharmacokinetic values for mavacoxib in dogs are widely patient variable. Average bioavailability after oral dosing is ≈46% when fasted but nearly doubles (87%) when given with food. Peak concentrations occur in ≈11 hours but range widely. In most dogs, blood concentrations are thought to be therapeutic, occurring ≈1 hour after dosing when given with food. The apparent volume of distribution at steady-state averaged 1.6 L/kg, and the drug is highly bound to canine plasma proteins (98%). Total body clearance was very low, 2.7 mL/hour/kg, and it is primarily cleared by biliary excretion. The average terminal half-life was 16.6 days (range: 8 to 39 days).[2] A population pharmacokinetic study in osteoarthritic dogs reported a typical elimination half-life of 44 days, but ≈5% of patients had Bayesian estimates greater than 80 days.[3]

Contraindications/Precautions/Warnings

Mavacoxib is contraindicated in dogs less than 12 months of age and/or less than 5 kg (11 lb) body weight, with GI disorders, including ulceration and bleeding, evidence of a hemorrhagic disorder, impaired renal or hepatic function, cardiac insufficiency, or with a history of hypersensitivity to the active substance, any of the excipients, or to sulfonamides.

Do not use concomitantly with glucocorticoids or other NSAIDs. Do not administer other NSAIDs within 1 month of the last administration of mavacoxib (washout period).

Avoid use in any dehydrated, hypovolemic, or hypotensive animal, as there is a potential risk for increased renal toxicity. Concurrent administration of potentially nephrotoxic medicinal products should be avoided.[4] Do not allow treated dogs to become dehydrated when receiving this or other NSAIDs.

Adverse Effects

Common adverse effects include vomiting and diarrhea, similar to other NSAIDs. Less common adverse effects include loss of appetite, hemorrhagic diarrhea, melena, and impaired renal function. GI ulceration can occur.

GI protectants and parenteral fluids may be required for dogs with GI or renal adverse effects.

Reproductive/Nursing Safety

The safety of mavacoxib has not been established during pregnancy and lactation. Per the UK label, do not use mavacoxib in pregnant, breeding, or lactating animals. Studies in pregnant rabbits receiving another coxib-class NSAID (eg, firocoxib) at dosages approximating those given to dogs demonstrated maternotoxic and fetotoxic effects.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In overdose safety studies performed in dogs, repeated doses (at the labeled frequency) of 5 mg/kg and 10 mg/kg did not demonstrate adverse effects, abnormal clinical chemistry, or significant histological abnormalities. At 15 mg/kg, vomiting, softened/mucoid feces, and increases in clinical chemistry parameters reflecting decreased renal function were noted. Doses of 25 mg/kg cause GI ulceration. In 1 study, a dog died from GI perforation and peritonitis at the 25 mg/kg dose.[5]

Oral acute overdoses of mavacoxib should be managed as with other NSAIDs toxicity, but because of the drug's long duration of effect, prolonged monitoring and treatment may be required; consulting a veterinary poison control center or the drug sponsor's hotline seems prudent until more experience has been gained with this agent.

As with any NSAID, overdoses can lead to GI and renal effects. The ASPCA Animal Poison Control Center (APCC) has not yet set a dosage level of concern for renal damage for dogs or cats. Decontamination with emetics and/or activated charcoal is appropriate. For doses at which GI effects are expected, the use of GI protectants is warranted. If renal effects are also expected, fluid diuresis is warranted.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

At the time of writing, no drug interactions have been reported with mavacoxib, but the manufacturer warns that use in conjunction with other **NSAIDs** or **corticosteroids** is contraindicated. It is also possible that mavacoxib could cause increased renal dysfunction if used with other drugs that can cause or contribute to **renal dysfunction** (eg, **diuretics, aminoglycosides**), but the clinical significance of this potential interaction is unclear. The following drug interactions are either expected or are theoretical in dogs receiving mavacoxib and may be of clinical significance:

- **ACE Inhibitors** (eg, **enalapril, benazepril**): Some NSAIDs can reduce effects on blood pressure. Because ACE inhibitors potentially can reduce renal blood flow, use with NSAIDs could increase the risk for renal injury. However, 1 study on dogs receiving tepoxalin did not show any adverse effects. It is unknown what effects, if any, occur if other NSAIDs and ACE inhibitors are used together in dogs.
- **Anticoagulants** (eg, **heparins, rivaroxaban, warfarin**): May increase the risk for bleeding
- **Aspirin**: May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea). Washout periods several weeks long are probably warranted when switching from mavacoxib to aspirin therapy in dogs.
- **Bisphosphonates** (eg, **alendronate**): May increase the risk for GI ulceration
- **Clopidogrel**: May increase the risk for bleeding
- **Glucocorticoids** (eg, **predniso(lo)ne**): May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea)
- **Digoxin**: NSAIDs may increase serum levels.
- **Fluconazole**: Administration has increased plasma concentrations of celecoxib in humans and potentially could also affect mavacoxib concentrations in dogs.
- **Furosemide**: NSAIDs may reduce saluretic and diuretic effects.
- **Methotrexate**: Serious toxicity has occurred when NSAIDs have been used concomitantly with methotrexate; use together with extreme caution.
- **Nephrotoxic Drugs** (eg, **furosemide**, **aminoglycosides**, **amphotericin B**): May enhance the risk for nephrotoxicity development
- **NSAIDs, Other** (eg, **carprofen, meloxicam**): May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea). The UK label states: *Should another NSAID be administered after Trocoxil® treatment, a treatment-free period of at least 1 MONTH should be ensured to avoid adverse effects.* Because of its long half-life (up to 39 days in 1 study dog),[6] however, mavacoxib may have a conservative washout time of 195 days.[7]

Laboratory Considerations

- None were identified.

Dosages

DOGS:

UK Label: **Treatment of pain and inflammation associated with degenerative joint disease in dogs aged 12 months or more in cases where continuous treatment exceeding 1 month is indicated** (extra-label in the United States): 2 mg/kg PO given immediately before or with the dog's main meal.[4] Care should be taken to ensure that the tablet is ingested. The treatment should be repeated 14 days later; thereafter, the dosing interval is 1 MONTH. A treatment cycle should not exceed 7 consecutive doses (6.5 months). **THIS IS NOT A DAILY NSAID**.

Monitoring

- Baseline and periodic CBC and serum chemistry (including BUN, serum creatinine, and liver function assessment)
- Baseline history and physical; repeat exam recommended 1 month after starting treatment with mavacoxib and prior to administering a third dose[4]
- Efficacy of therapy
- Adverse effects

Client Information

- Give doses exactly as directed by your veterinarian. Do not give extra doses or increase the dose without your veterinarian's guidance. Do NOT give this drug every day. After giving the first 2 doses 2 weeks apart, give this drug once a month for up to 5 doses, then an extra month off the drug is needed if you need to start the drug again.
- Do not administer steroids or other NSAIDs within 1 month of the last dose of mavacoxib (eg, carprofen, deracoxib, meloxicam).
- Give the medication with the dog's largest meal of the day. The drug is much better absorbed from the stomach if given with food.
- Contact your veterinarian if any of the following side effects persist or are severe: loss of appetite, vomiting, change in bowel movements (eg, stool color), change in behavior, or decrease in water consumption or urination; these could potentially occur many weeks after giving the last dose. Immediately report to your veterinarian if any of the following side effects occur: bloody stool/diarrhea, bloody vomiting, or allergic reaction (facial swelling, hives, red, itchy skin).
- Do not allow the dog to become dehydrated while receiving this drug. Ensure ready access to drinking water. Contact your veterinarian if your dog's fluid intake is reduced, or if your dog is losing bodily fluids (eg, vomiting, diarrhea).
- Dogs may find the chewable tablets' taste desirable; store the drug out of reach of animals and children.

Chemistry/Synonyms

Mavacoxib is structurally related to the human NSAID celecoxib and is a diaryl substituted pyrazole member of the sulphonamide group of coxibs. Mavacoxib's solubility in water is relatively low (0.006 mg/mL).

Mavacoxib may also be known as mavacoxibum; PHA 739,521; or UNII-YFT7X7SR77. A common trade name is *Trocoxil®*.

Storage/Stability

Store in the original packaging at room temperature, out of reach of pets and children.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None in the United States. In the UK and Europe: Mavacoxib Oral Chewable Tablets: 6 mg, 20 mg, 30 mg, 75 mg, and 95 mg; *Trocoxil®*; (Rx/POM-V)

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Mechlorethamine

(me-klor-***eth***-a-meen) *Mustargen®*

Antineoplastic

Prescriber Highlights

- ► Highly toxic agent; handle with extreme caution.
- ► Antineoplastic for lymphoreticular neoplasms
- ► Contraindications include pre-existing myelosuppression or infection, and hypersensitivity to mechlorethamine.
- ► Adverse effects include myelosuppression, GI effects (vomiting, nausea), ototoxicity (high dosages); potentially alopecia, hyperuricemia, hepatotoxicity, peripheral neuropathy, GI ulcers.
- ► Avoid extravasation; vesicant injuries may be severe.
- ► Carcinogenic, mutagenic, and teratogenic
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies mechlorethamine as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Mechlorethamine is used in dogs and cats as part of MOPP (mechlorethamine, vincristine, procarbazine, prednisone),[1,2] MPP (mechlorethamine, procarbazine, prednisone),[3] and MOMP (mechlorethamine, vincristine, melphalan, prednisone)[4] protocols to treat both naïve and relapse cases of lymphoma.

Pharmacology/Actions

Mechlorethamine is an alkylating agent, thereby interfering with DNA replication, RNA transcription, and protein synthesis. It is cell cycle–phase nonspecific.

Pharmacokinetics

Mechlorethamine is irritating to tissues and must be given IV for systemic use. It is incompletely absorbed after intracavitary administration. After injection, mechlorethamine combines with water and undergoes a rapid chemical transformation, resulting in no active drug within minutes of administration.

Contraindications/Precautions/Warnings

Mechlorethamine is contraindicated in patients with a known hypersensitivity to it or with known infections.

The risk versus benefits of therapy must be carefully considered in patients with pre-existing myelosuppression. Additive bone marrow depression may occur in patients undergoing concomitant radiation therapy. Therapy with mechlorethamine may increase the risk for a second malignant tumor, especially when combined with other antineoplastic agents or radiation therapy.[5] In humans, mechlorethamine can contribute to the rapid development of amyloidosis.

Only veterinarians with the experience and resources to monitor the toxicity of this agent should administer this drug.

Mechlorethamine is a severe vesicant; extravasation must be avoided. Mechlorethamine is highly toxic and must be handled with extreme caution in both powdered and liquid forms. Mechlorethamine is corrosive to skin and eyes, and is highly toxic by oral route. The drug is a respiratory tract irritant, and exposure to mechlorethamine dust or vapors must be avoided. It is carcinogenic, mutagenic, and teratogenic.

The National Institute for Occupational Safety and Health (NIOSH) classifies mechlorethamine as a hazardous drug; personal protective equipment (PPE, including respirators) and environmental controls should be used accordingly to minimize the risk for exposure. Clothing contaminated with mechlorethamine should be discarded.

Adverse Effects

Myelosuppression (leukopenia, thrombocytopenia) and GI effects (vomiting, nausea) are common and can be serious enough to halt therapy; pretreatment with antiemetics can be beneficial. In humans, it is preferred to administer at night if sedation for adverse effects is required; while this timing does not directly apply to veterinary patients, the severity of adverse effects should be closely monitored. Neutrophil and platelet nadir is ≈7 days.

Ototoxicity may occur with either high dosage. Hypersensitivity reactions have been reported in humans, including anaphylaxis.

Other potential effects include alopecia, hyperuricemia, hepatotoxicity, peripheral neuropathy, and GI ulcers.

Because it is often used in combination with other chemotherapy agents, myelosuppression and GI effects (hemorrhagic gastritis) may be enhanced.

Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, increased shedding, poor regrowth in shaved areas). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant alopecia.

Mechlorethamine is a moderate to severe vesicant, and perivascular extravasation may lead to tissue damage and sloughing. If extravasation occurs, sodium thiosulfate may be administered (IV and SC around the extravasation site) to reduce vesicant damage. Ice compresses should be applied for 15 minutes every 6 hours for 48 hours. Other reported supportive therapies include local application of DMSO and/or perivascular infusion of corticosteroids, sodium chloride, and hyaluronidase.

Reproductive/Nursing Safety

Mechlorethamine is a teratogen in lab animals and fetal malformations have been documented. Use only during pregnancy when the benefits to the mother outweigh the risks to the offspring. Mechlorethamine can suppress gonadal function.

For sexually intact patients, verify pregnancy status prior to administration.

Although it is not known whether mechlorethamine enters maternal milk, nursing puppies or kittens should receive milk replacer when the dam is receiving mechlorethamine.

Overdose/Acute Toxicity

Because of the great toxic potential of this agent, determine dosages carefully. The LD_{50} in mice and rats following IV administration is 2 mg/kg and 1.6 mg/kg, respectively.[2] The drug is not dialyzable, and treatment is supportive.

In humans, overdoses may lead to severe leukopenia, anemia, and thrombocytopenia that can result in delayed bleeding and ultimately death. The only treatment is repeated blood transfusions, antibiotic therapy, and supportive care.[5]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving mechlorethamine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medications may result in additive myelosuppression.

- **Vaccines** (live and inactivated): Mechlorethamine may diminish vaccine efficacy and enhance adverse effects of vaccines.

Laboratory Considerations

- Mechlorethamine may raise **serum uric acid** levels. Drugs such as allopurinol may be required to control hyperuricemia.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and since chemotherapy indications, treatment protocols, and monitoring and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[6–10] are strongly recommended.

DOGS:

Lymphoma, first-line (T-cell) or rescue (extra-label): When mechlorethamine is used, it is given as part of a protocol in combination with other antineoplastic agents (MOPP, MPP, MOMP protocols) and usually given at a dose of 3 mg/m^2 (**NOT** mg/kg) IV given on Days 1 and 7 of a 21- to 28-day protocol.[1–4]

CATS:

Lymphoma, rescue (extra-label): When mechlorethamine is used, it is given as part of a protocol in combination with other antineoplastic agents (MOPP protocol, MOMP rescue protocol[11]) and usually given at a dose of 3 mg/m^2 (**NOT** mg/kg) IV given on Days 1 and 7 of a 21- to 28-day protocol.

Monitoring

- Baseline and weekly CBC
- Hepatic enzymes; initially before starting treatment and then every 3 to 4 months
- Renal function
- Injection site for signs of extravasation

Client Information

- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH) because it may affect the reproductive ability of males or females actively trying to conceive, women who are pregnant or may become pregnant, and women who are breastfeeding. It is recommended that you wear gloves when administering this medication to your pet and wash your hands thoroughly afterwards. If you have questions about this medication's hazards, please speak with your veterinarian or pharmacist.
- On the day your animal gets the drug and then for ≈72 hours afterward, handle all bodily waste (urine, feces, litter), blood, or vomit only while wearing disposable gloves. Seal the waste in a plastic bag and then place both the bag and gloves in with the regular trash.
- Bone marrow suppression can occur. The greatest effects on bone marrow usually occur about 1 week after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal becomes tired easily, contact your veterinarian right away.
- Immediately report any signs associated with toxicity (eg, vomiting, GI upset, abnormal bleeding, bruising, urination, depression, infection, shortness of breath).
- While your animal is taking this medication, it is important to return to your veterinarian for laboratory work. Do not miss these important follow-up visits.

Chemistry/Synonyms

Mechlorethamine, a bifunctional alkylating agent, occurs as a hygroscopic, light-yellow brown, crystalline powder that is very soluble in water. After reconstitution with sterile water or sterile saline, the resultant solution is clear and has a pH of 3 to 5.

Mechlorethamine may also be known as nitrogen mustard, mustine, HN2, chlormethine hydrochloride, chlorethazine hydrochloride, HN2 (mustine [chlormethine]), mechlorethamine hydrochloride, mustine hydrochloride, nitrogen mustard (mustine [chlormethine]), NSC-762, WR-147650, *Caryolysine®*, *Mustargen®*, and *Onco-Cloramin®*.

Storage/Stability

Store the powder for injection between 15°C and 30°C (59°F and 86°F), protected from light and humidity.[5] Mechlorethamine solution are highly unstable and decompose upon standing; administer the drug immediately after preparation.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

When reconstituted, the solution should be clear and colorless. Do NOT use if the solution is discolored or if droplets of water are visible within the vial prior to reconstitution.[5] It is **NOT** recommended to mix mechlorethamine with any other medication or to dilute further beyond what is described in the package insert.

Drugs that have been reported to be **compatible** with mechlorethamine when given via an IV Y-site include aztreonam, filgrastim, granisetron, melphalan, and ondansetron.

Unused portions of the reconstituted drug must be neutralized; neutralization can be accomplished by mixing with equal volumes of 5% sodium thiosulfate and 5% sodium bicarbonate. Allow this solution to stand for 45 minutes and then discard appropriately. Empty mechlorethamine vials should be neutralized in this same manner.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Mechlorethamine Powder for Injection: 10 mg; *Mustargen®*; (Rx)

A Topical gel (*Valchlor®*) is also available.

For the complete list of references, see **wiley.com/go/budde/plumb**

Meclizine

(***mek***-li-zeen) *Antivert®*

Antihistamine, Antiemetic

Prescriber Highlights

- ► Antihistamine with sedative and antiemetic effects used primarily for motion sickness and vestibular disease
- ► Caution is advised in animals with prostatic hypertrophy, bladder neck obstruction, angle-closure glaucoma, or GI obstruction.
- ► Adverse effects include sedation; less frequently, anticholinergic effects (eg, dry mucous membranes, dry eyes, tachycardia) may be noted. Paradoxical CNS stimulation is possible.

Uses/Indications

Meclizine is principally used in small animal species as an antiemetic primarily for the treatment and prevention of motion sickness.

Pharmacology/Actions

Meclizine is an H_1 receptor blocking antihistamine agent with anticholinergic properties. This drug has antiemetic, CNS depressant, antispasmodic, and local anesthetic effects. The exact mechanisms

of action for the antiemetic and anti-motion–sickness effects are not completely understood, but it is thought that they are at least partially a result of the drug's central anticholinergic and CNS depressant activity. The antiemetic effect is likely mediated through the chemoreceptor trigger zone. In humans, meclizine is considered less sedating than dimenhydrinate.

Pharmacokinetics

Little information is available. In humans, meclizine is absorbed following oral administration. The drug is metabolized in the liver predominantly via CYP2D6 and has a serum half-life of ≈6 hours.[1]

Contraindications/Precautions/Warnings

Meclizine is contraindicated in animals hypersensitive to it. It should be used with caution in animals with prostatic hypertrophy, bladder neck obstruction, and other forms of urinary retention, angle-closure glaucoma, asthma, or GI obstruction. Theoretically, renal or hepatic impairment can lead to drug accumulation and increased risk for adverse effects.

Adverse Effects

The typical adverse effect noted is sedation; less frequently, anticholinergic effects (eg, dry mucous membranes, dry eyes, tachycardia) may be seen. Paradoxical CNS stimulation has also been reported. Cats may develop inappetence while receiving this medication.[2]

Reproductive/Nursing Safety

Meclizine is considered teratogenic at high doses in laboratory animals, and cleft palates have been noted in rats given oral doses as low as 25 mg/kg (≈2 to 4 times the maximum human dose based on body surface area). However, in humans, it has been suggested that meclizine possesses low risk for teratogenicity for antiemetic drugs and can be used to treat nausea and vomiting associated with pregnancy.

It is unknown if meclizine enters milk; its anticholinergic activity may inhibit lactation.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Moderate overdose may result in drowsiness alternating with hyperexcitability; tachycardia and vomiting may also be seen. Massive overdose may result in profound CNS depression, hallucinations, seizures, and other anticholinergic effects (eg, tachycardia, urine retention).

Treatment is supportive and based on clinical signs. Consider gastric decontamination when animals are presented soon after ingestion. Avoid respiratory depressant medications.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving meclizine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Drugs** (eg, **atropine**, **glycopyrrolate, oxybutynin**): Other anticholinergic drugs may cause additive anticholinergic effects.
- **CNS Depressants** (eg, **benzodiazepines, gabapentin, trazodone**): Use with other CNS depressants may cause additive sedation.
- **Digoxin**: Meclizine may increase digoxin absorption by slowing GI motility.
- **Fluoxetine**: May increase meclizine concentrations and effects by inhibiting metabolism
- **Opioids** (eg, **hydrocodone**, **morphine**): May have additive CNS depression and anticholinergic effects (eg, constipation, urinary retention)
- **Potassium Salts, Oral/Solid**: Solid dose oral forms of potassium salts can cause focal upper GI injury, which can be worsened by drugs that may slow GI motility.
- **Prokinetic Agents** (eg, **cisapride**, **metoclopramide**): Meclizine may diminish the efficacy of prokinetic agents by decreasing GI motility.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Other anticholinergic drugs may cause additive anticholinergic effects.

Laboratory Considerations

- **Intradermal allergy testing (IDT)**: As an antihistamine, meclizine may suppress IDT results. Discontinue meclizine 2 (minimum) to 7 days (preferred) before IDT.[3]

Dosages

DOGS:

Vestibular disease; prevention of motion sickness and vomiting (extra-label): No controlled studies supporting any dosage regimen were found. Anecdotally: 4 mg/kg PO once daily. Practically: 12.5 mg – 50 mg/dog (NOT mg/kg) PO once daily[4]

CATS:

Vestibular disease; prevention of motion sickness and vomiting (extra-label): No controlled studies supporting any dosage regimen were found. Anecdotally: 6.25 – 12.5 mg/cat (NOT mg/kg) PO once daily

RABBITS, RODENTS, SMALL MAMMALS:

Rabbits: **rolling, torticollis, motion sickness, head tilt** (extra-label):

a) 2 – 12 mg/kg PO once daily[5,6]

b) 12.5 mg/rabbit (NOT mg/kg) PO every 12 to 24 hours[7]

Monitoring

- Efficacy
- Adverse effects

Client Information

- This medicine may be given with or without food. Giving this medicine with a small amount of food or a treat may help prevent vomiting.
- When using this medication for motion sickness prevention, give it 30 to 60 minutes before travel.
- The most common side effect is sedation (ie, drowsiness, sleepiness).

Chemistry/Synonyms

Meclizine HCl is a piperazine derivative antiemetic antihistamine that is structurally similar to hydroxyzine. It occurs as a white or yellowish-white crystalline powder. It is slightly soluble in water and soluble in alcohol. Meclizine is hygroscopic.

Meclizine may also be known as meclizinium, meclozine, or parachloramine. *Antivert*® and *Bonine*® are common trade names.

Storage/Stability

Meclizine products should be stored in well-closed, light-resistant containers at room temperature 20°C to 25°C (68°F-77°F); excursions are permitted between 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Meclizine HCl Oral Tablets: 12.5 mg, 25 mg (plain and chewable), and 50 mg; *Antivert®*, *Dramamine® Less Drowsy Formula*, *Bonine®*, *Travel-Ease®*, generic; (Rx and OTC)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Medetomidine

(mee-de-***toe***-mi-deen) *Domitor®*

Alpha-2-Adrenergic Agonist

Prescriber Highlights

- ► Reversible sedative analgesic used primarily in dogs, cats, small mammals, and exotic species
- ► Contraindications include most forms of cardiac disease, respiratory disorders, shock, severe debilitation, or animals stressed due to heat, cold, or fatigue. Also contraindicated in liver or kidney disease, although some anesthesiologists consider those contraindications to be relative because medetomidine effects can be reversed.
- ► Use with caution in geriatric and pediatric animals.
- ► Adverse effects include bradycardia, occasional AV block, decreased respiratory rate, hypothermia, urination, vomiting, and hyperglycemia. Rarely, prolonged sedation, hypersensitivity, apnea, and death from circulatory failure may occur.
- ► Systemic and central effects may be reversed with atipamezole; however, analgesia will also be reversed, and additional analgesic agents may be required for adequate pain control.
- ► Do **NOT** confuse medetomidine with detomidine or dexmedetomidine.

Uses/Indications

Medetomidine is an alpha-2 agonist used as a sedative, premedication/anesthesia adjunct, and analgesic in dogs, cats, other small animal species, and in a wide variety of large animal species (eg, horses, cattle, camelids, small ruminants). Medetomidine is commonly used in combination with an opioid and/or ketamine to extend the depth and duration of action to minimize the need for redosing.

Pharmacology/Actions

An alpha-2 adrenergic receptor, medetomidine has an alpha-2:alpha-1 selectivity factor of 1620:1 and, as compared with xylazine, is reportedly 10 times more specific for alpha-2 receptors versus alpha-1 receptors. The pharmacologic effects of medetomidine include depression of CNS (sedation, anxiolysis), GI (nausea/vomiting, decreased secretions, varying effects on intestinal muscle tone), and endocrine functions; peripheral and cardiac vasoconstriction; bradycardia; respiratory depression; diuresis; hypothermia; analgesia (somatic and visceral); muscle relaxation; and blanched or cyanotic mucous membranes. Effects on blood pressure are variable, but medetomidine can cause hypertension for longer periods as compared with xylazine. Medetomidine also induces sedation for a longer period as compared with xylazine. Sedative effects persist longer than analgesic effects.

Pharmacokinetics

After IV or IM injection, onset of effect is rapid (5 minutes for IV; 10 to 15 minutes for IM). The drug is absorbed via the oral mucosa when administered sublingually in dogs, but efficacy at a given dose may be less than with IM dosing.

Contraindications/Precautions/Warnings

The label states that medetomidine is contraindicated in dogs having the following conditions: cardiac disease, respiratory disorders, liver or kidney disease, shock, severe debilitation, or dogs stressed due to heat, cold, or fatigue. However, not all forms of cardiac disease create a contraindication, for instance, medetomidine administered to cats with left ventricular outflow obstruction improved cardiac function secondary to slowed heart rate with subsequent increased ventricular filling.[1] Because medetomidine's effects are reversible, some anesthesiologists consider medetomidine contraindications to be relative, particularly in patients with hepatic or renal disease. Of note, reversal with atipamezole will counteract sedation, physiologic effects, and analgesia; additional analgesic agents may be required for adequate pain control.

Medetomidine should only be used in situations in which sufficient monitoring and patient-support capabilities (eg, intubation, ventilation) are available.

Dogs that are extremely agitated or excited may have a decreased response to medetomidine; the manufacturer suggests allowing these dogs to rest quietly before administration of the drug. Dogs not responding to medetomidine should not be redosed according to the label. Clinically, redose is common if a low dose was used initially and was not effective; however, the most effective process would be to combine medetomidine with an opioid and/or an anesthetic such as ketamine rather than to redose. Use medetomidine in pediatric or geriatric dogs should be done with caution.

Medetomidine reduces tear flow in dogs and cats.[2,3] Ophthalmic ointment should be used to protect eyes when using this drug.[4,5]

Do not confuse medetomidine with detomidine or dexmedetomidine. Do not interchange dexmedetomidine with medetomidine dosages. On a **mg**/kg basis, dexmedetomidine doses are ≈½ of the medetomidine dose since dexmedetomidine is more potent; however, dexmedetomidine is ½ the concentration of medetomidine so the doses are the same on a **mL**/kg basis.

Adverse Effects

The adverse effects reported with medetomidine are essentially extensions of its pharmacologic effects including bradycardia, occasional AV blocks, decreased respiratory rate, hypothermia, urination (particularly during recovery, 90 to 120 minutes following administration), vomiting, and hyperglycemia. Rare effects have also been reported, including prolonged sedation, paradoxical excitation[6] (particularly when combined with midazolam[7]), hypersensitivity, apnea, and death from circulatory failure.

Vomiting is common in cats and appears to be proportional to dose administered.[8–10]

Reduced tear flow has been documented in dogs[2] and cats.[3] However, in dogs, administration of medetomidine at 5, 10, 20, 40, and 80 µg/kg IM did not affect intraocular pressure except at the 80 µg/kg dose, which caused a decrease in intraocular pressure hours after administration.[11] In cats, even high doses (100 µg/kg) of medetomidine do not affect intraocular pressure.[12]

Reproductive/Nursing Safety

Medetomidine is not recommended for use in pregnant dogs or dogs used for breeding[6]; medetomidine induces maternal uterine contractions in pregnant dogs.[13] Medetomidine 0.007 mg/kg IV has been used with propofol and sevoflurane for cesarean sections in dogs with resultant safety for the bitch and high puppy vigor scores and survival rate.[14]

Medetomidine crosses the placenta of pregnant goats and ewes, with equivalent fetal and maternal medetomidine concentrations.[15,16] In sheep, medetomidine induced maternal uterine contractions[15]; decreases in fetal heart rate and increases in fetal blood pressure were also noted.

Information on medetomidine use in lactating animals was not located.

Because safety has not been established in animals, this drug should only be used in pregnant or nursing animals when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Single doses of medetomidine up to 5 times (IV) and 10 times (IM) the recommended dose were tolerated in dogs, but adverse effects can occur (see ***Adverse Effects***). Repeated doses may cause profound sedation, bradycardia, and reduced respiratory rate.[6] A single IV administration of 10 times the label dose may result in a prolonged anesthesia-like episode with muscle twitching. Death has occurred rarely in dogs (1 in 40,000) receiving 2 times the label dose.

Because of the potential of additional adverse effects occurring (heart block, PVCs, or tachycardia), treatment of medetomidine-induced bradycardia with anticholinergic agents (atropine or glycopyrrolate) is usually not recommended (see ***Drug Interactions***). Atipamezole is a safer choice to treat any medetomidine-induced effect provided reversal of analgesia or sedation is not contraindicated.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving medetomidine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate. **NOTE**: Before attempting combination therapy with medetomidine, it is strongly advised to consult veterinary anesthesia references or veterinary anesthesiologists familiar with the use of this drug.

- **Alfaxalone**: When alfaxalone is used after medetomidine, hypoxemia may occur secondary to respiratory depression. Oxygen delivery during induction or as soon as intubated is recommended. Dosages of alfaxalone should be adjusted based on the patient's level of sedation, ie, dose to effect.
- **Anticholinergic Agents** (eg, **atropine, butylscopolamine**, **glycopyrrolate**): The use of atropine or glycopyrrolate to prevent or treat medetomidine-caused bradycardia is controversial as tachycardia and hypertension may result. This is more important when using higher doses of medetomidine (more than 20 µg/kg) and concomitant use is discouraged. However, in anesthetized patients that received medetomidine as premedication and that become hypotensive, anticholinergic use is often recommended to increase heart rate and improve blood pressure without reversing the sedation. Reversal of sedation can cause sudden arousal of the patient. One study showed tachycardia and hypertension developed when butylscopolamine was administered IV or IM before medetomidine in horses.[17]
- **Opioids** (eg, **butorphanol, morphine**): Enhancement of sedation and analgesia occurs when medetomidine is used concurrently with all opioids; however, adverse effects (eg, bradycardia, hypoventilation) may be pronounced. Combination therapy of medetomidine with opioids is recommended for enhanced sedation and analgesia but reduced dosages (low end of the standard dosing range) of both drugs should be used and the patient should be observed for excessive sedation, bradyarrhythmias, and hypotension.
- **Propofol**: When propofol is used after medetomidine, hypoxemia may occur secondary to respiratory depression. Oxygen delivery during induction or as soon as intubated is recommended. Dosages of propofol should be adjusted based on the patient's level of sedation, ie, dose to effect.
- **Sympathomimetics** (eg, **dopamine, epinephrine**): Concurrent use contraindicated.[18] However, dopamine is often used in anesthetized patients that received medetomidine as premedication and that become hypotensive in spite of anticholinergic administration to normalize heart rate. Epinephrine is generally reserved for emergencies and is not contraindicated in a cardiovascular emergency.
- **Yohimbine**: May reverse the effects of medetomidine; but atipamezole is preferred for clinical use to reverse the drug's effects because atipamezole is more selective for the alpha receptors and is unlikely to cause hypotension, which is common following administration of yohimbine

Laboratory Considerations

- Medetomidine can inhibit ADP-induced **platelet aggregation** in cats, but this does not appear to be clinically significant.

Dosages

NOTES:

1. Medetomidine dosages depend on the combination of drugs used and the dosage(s) of the other drug(s). Dosage adjustments will also need to be made to account for the degree of desired sedation; type, duration, and pain level of the procedure, and patient temperament and body weight/size.
2. Dosing based on body surface area (BSA; or allometric scaling) is not common in clinical practice but decreases the variability in drug response between giant/large and small/toy breed dogs. See the United States label[1] for dosing based on BSA where, as an example, a 4 kg (8.8 lb) dog would receive ≈50 µg/kg IV versus a 40 kg (88 lb) dog would receive ≈20 µg/kg IV.
3. Premedication with medetomidine will significantly reduce the dose of the induction agent required and will reduce volatile anesthetic requirements for maintenance anesthesia. All anesthetic agents used for induction or maintenance of anesthesia should be administered to effect.
4. For all dosages, the low end of the dose range is generally appropriate for IV administration, whereas the mid-upper range is most appropriate for IM or SC administration. Higher dosages will provide more profound sedation and analgesia.
5. When SC administration is used, the speed of sedation is slower, and the level of sedation is lighter and inconsistent. For more predictable sedation, IM or IV administration is recommended.
6. The effects of medetomidine can be reversed with atipamezole. It is most often dosed by volume at ½ or same volume of medetomidine that was administered and given IM. See ***Atipamezole***.

DOGS:

Sedation/analgesia (label dosage; FDA-approved): 750 µg/m^2 (0.75 mg/m^2) IV or 1000 µg/m^2 (1 mg/m^2) IM.[6] For use in dogs over 12 weeks of age

Sedation/analgesia when medetomidine is used as sole agent (extra-label): Dosage ranges commonly used to achieve general sedation levels include:

a) **Light sedation (often also used for pre-anesthesia)**: 5 – 20 µg/kg IM, IV, SC[18]

b) **Moderate sedation (may be used for pre-anesthesia if deeper sedation is desired or the patient has a high energy or anxiety level)**: 20 – 40 µg/kg IM, IV, SC

c) **Deep sedation**: 30 – 80 µg/kg IM, IV, or SC[18]; repeat dose if necessary or consider using a combination protocol because these high doses can be dangerous.

Other routes of administration

a) Medetomidine can be administered oral transmucosally (OTM) but published papers are sparse. Based on the dexmedetomidine dose to sedate aggressive dogs by this route,[19] an average of ≈64 µg/kg OTM is suggested.

b) 40 µg/kg via nasal atomization produced sedation similar to IM administration; IN onset 7.2 minutes versus 6.3 minutes with IM.[20]

Sedation/analgesia when used in combination with other drugs (extra-label): More predictable sedation is obtained when medetomidine is administered in combination with other analgesic or sedative drugs. Use of medetomidine in combination with other sedatives allows for a reduced dose of medetomidine, which improves safety and, when used in combination with other analgesic agents, it enhances analgesia. Medetomidine has been combined with different opioids (eg, morphine, methadone, hydromorphone, buprenorphine, butorphanol, fentanyl) and induction agents (eg, propofol, alfaxalone, ketamine) to produce sedation/analgesia and decrease the amount of anesthesia maintenance drugs in healthy dogs with minimal adverse effects.[21–25] When combining medetomidine with other drugs, the low-mid range of the medetomidine dosage based on the desired level of sedation is generally adequate.

Examples of combinations used in clinical practice

a) Medetomidine 5 µg/kg combined with butorphanol 0.3 mg/kg and given IM followed by 1 – 2.5 mg/kg alfaxalone IM provided anesthesia with minimal to no cardiorespiratory depression.[26]

b) Medetomidine 24 µg/kg combined with butorphanol 0.24 mg/kg and given IM allowed for lower sevoflurane requirements to maintain general anesthesia.[27]

c) Medetomidine 20 µg/kg combined with butorphanol 0.3 mg/kg and given IM provided adequate clinical sedation.[28]

d) Medetomidine 2.5 µg/kg combined with either morphine 0.3 mg/kg or methadone 0.3 mg/kg and given IV prior to anesthesia induction with propofol and maintained with isoflurane.[21] Isoflurane-sparing effect and enhanced analgesia are noted.

e) Medetomidine 2.5 µg/kg combined with alfaxalone 2.5 mg/kg and butorphanol 0.25 mg/kg and given IM produced lateral recumbency and allowed intubation in dogs, without causing severe cardiopulmonary depression.[22]

f) Medetomidine 2.5 µg/kg combined with butorphanol 0.4 mg/kg or methadone 0.4 mg/kg in the same syringe and given IM.[23] Maximum sedation occurred at 20 to 30 minutes postinjection; heart rate decreased in both groups.

Refractory seizures (extra-label): Medetomidine 0.016 µg/kg per minute IV CRI was used to treat refractory seizures in a dog following portosystemic shunt ligation.[29]

CATS:

Sedation/analgesia when medetomidine is used as a sole agent (extra-label): Dosage ranges commonly used to achieve general sedation levels include:

a) **Light sedation (often also used for pre-anesthesia)**: 5 – 30 µg/kg IV, IM, or SC

b) **Moderate sedation (may be used for pre-anesthesia if deeper sedation is desired or the patient has a high energy or anxiety level)**: 30 – 50 µg/kg IV, IM or SC

c) **Deep sedation**: 50 – 80 µg/kg IV, IM,[8,9] SC. Doses up to 100 µg/kg have been used and up to 150 µg/kg are listed on the label of some countries[18] but an upper dose of 80 µg/kg is generally sufficient for most cats. Doses this high (ie, 100 to 150 µg/kg) are often dangerous and a combination protocol should be considered.

Sedation/analgesia when used in combination with other drugs (extra-label): Medetomidine has been combined with different opioids (eg, morphine, methadone, hydromorphone, buprenorphine, butorphanol, fentanyl) and induction agents (eg, propofol, alfaxalone, ketamine) to produce sedation/analgesia and decrease the amount of maintenance drugs in healthy cats with minimal adverse effects. When combining with other drugs, the low-mid range of the dose for the desired level of sedation is generally adequate. For many of these protocols, the drugs are combined in the same syringe and administered IM.

Examples of combinations used in clinical practice for *light* sedation

a) Medetomidine 20 µg/kg combined in the same syringe with butorphanol 0.4 mg/kg IM prior to induction[30]

b) Medetomidine 20 µg/kg combined with methadone 0.5 mg/kg and given IM prior to induction[30]

c) Medetomidine 20 µg/kg combined with buprenorphine 20 µg/kg and given IM prior to induction[30]

Other routes of administration

a) Medetomidine can be administered oral transmucosally (OTM) but published papers are sparse. Based on the dexmedetomidine dose to sedate cats by this route, a recommended dosage is medetomidine 20 µg/kg combined with buprenorphine 20 µg/kg and administered oral transmucosally (OTM) to provide sedation, although the degree of sedation is lower and less predictable as compared with IM administration of the same drugs at the same doses.[31]

Example of combination used in clinical practice for *moderate* sedation

a) Medetomidine 50 µg/kg combined in the same syringe with butorphanol 0.4 mg/kg IM prior to induction[18]

Examples of combinations used in clinical practice for *heavy* sedation/anesthesia (extra-label):

a) Medetomidine 60 µg/kg combined in the same syringe with ketamine 10 mg/kg IM[32]

b) Medetomidine 60 µg/kg combined in the same syringe with ketamine 10 mg/kg and morphine 0.2 mg/kg IM[32]

c) Medetomidine 60 µg/kg combined in the same syringe with ketamine 10 mg/kg and tramadol 2 mg/kg IM (injectable tramadol is not available in the US)[32]

General anesthesia when used in combination with ketamine (extra-label): Medetomidine 80 µg/kg combined in the same syringe with ketamine 2.5 – 7.5 mg/kg and given IM or SC; anesthesia occurs within 3 to 4 minutes and persists for 20 to 50 minutes.[18]

General anesthesia when used in combination with ketamine and butorphanol or buprenorphine | "Kitty Magic" (extra-label):

a) Medetomidine 20 – 40 µg/kg with ketamine 2 – 4 mg/kg and *either* butorphanol 0.2 – 0.4 mg/kg or buprenorphine 0.006 (generally considered too low for adequate analgesia) to 0.012 mg/kg combined in one syringe and given IM.[33] **NOTE**: This combination can also be calculated by drug *volume* when using drug concentrations of medetomidine 1 mg/mL, ketamine 100 mg/mL, butorphanol 10 mg/mL, buprenorphine 0.3 mg/mL: use 0.02 - 0.04 mL/kg of each drug combined in one syringe and given IM. The low end of the volume provides deep sedation whereas the high end provides anesthesia.

b) Medetomidine 70 – 80 µg/kg combined with ketamine 5 mg/kg

and butorphanol 0.4 mg/kg OR buprenorphine 0.02 mg/kg in the same syringe and given IM[34]

General anesthesia when used in combination with alfaxalone (extra-label):

a) Medetomidine 40 µg/kg IM or SC followed 15 to 20 minutes later by alfaxalone 2.5 – 5 mg/kg IV

b) Medetomidine 20 µg/kg combined in the same syringe with butorphanol 0.2 mg/kg and alfaxalone 5 mg/kg and given IM; minimal cardiopulmonary effects expected but the cardiovascular effects of medetomidine are present. The mean time from induction to extubation was 114 minutes, from induction to standing 125 minutes (clinically prolonged), and analgesia lasted 55 minutes.[35] This protocol is limited to small patients due to the volume of injectate required. If 10 mg/mL butorphanol is used in this combination, the total volume of injectate at these dosages is a little over 2 mL IM.

HORSES:

Sedation/analgesia prior to general anesthesia or for short duration standing procedures (extra-label):

a) Medetomidine 5 – 7 µg/kg IV alone or in combination with butorphanol 0.02 mg/kg IV

b) Medetomidine 5 µg/kg IV bolus followed by medetomidine 1.25 – 3.5 µg/kg/hour IV CRI[36,37]

Total intravenous anesthesia (extra-label):

1. Premedication with medetomidine 7 µg/kg IV followed by anesthesia induction with ketamine 2.2 mg/kg IV and maintained by medetomidine 5 µg/kg/hour, ketamine 3 mg/kg per hour, and midazolam 0.1 mg/kg/hour IV CRI.[38]
2. Premedication with medetomidine 5 µg/kg combined with butorphanol 0.02 mg/kg IV; induce general anesthesia with guaifenesin 10 mg/kg IV, followed by either propofol 2 mg/kg IV or alfaxalone 1 mg/kg IV; anesthesia was maintained with IV CRI of either propofol 3 mg/kg/hour or alfaxalone 1.5 mg/kg/hour IV CRI in combination with medetomidine 3 µg/kg/hour and guaifenesin 80 mg/kg/hour IV CRI.[39]

CATTLE:

Sedation (extra-label): Calves were given medetomidine 8, 10, or 12 µg/kg IV. Onset of sedation was rapid and dose dependent. Duration of sedation ranged from 73 to 117 minutes with the longer duration seen at the higher dose.[40]

SHEEP/GOATS:

Analgesia (extra-label):

1. In sheep, medetomidine 2 µg/kg IV can provide analgesia for ≈20 minutes during surgery.[41]
2. In goats, medetomidine 10 µg/kg via lumbosacral subarachnoid administration produced mild sedation and moderate analgesia of the hind quarter, perineum, and flank for 158 minutes.[42]
3. In goats, medetomidine 20 µg/kg via lumbosacral epidural administration produced sedation and surgical analgesia; mean duration of lateral recumbency was 136 minutes.[43]

Sedation (extra-label):

1. In sheep, medetomidine 30 µg/kg IM[44]
2. In goats, medetomidine 20 µg/kg IV. Recumbency was observed 90 seconds after administration.[45] Doses as low as 4 – 6 µg/kg IV also resulted in sedation and analgesia.[46]
3. In goats, medetomidine 40 µg/kg IM. Recumbency lasted for 90 minutes.[47]

Heavy sedation/anesthesia (extra-label):

1. In sheep, medetomidine 10 µg/kg IV will produce recumbency.[48]
2. In sheep, medetomidine 2 µg/kg IV in combination with alfaxalone 2 mg/kg IV. Sheep showed minor excitatory effects, but those did not impact induction.[49]
3. In goats, medetomidine 15 µg/kg IM in combination with ketamine 5 mg/kg IM; surgical anesthesia was induced within ≈11 minutes and lasted ≈47 minutes with complete recovery at 121 minutes.[50]

CAMELIDS:

Sedation (extra-label): Medetomidine 10 µg/kg IM can produce standing sedation without analgesia.[48]

Heavy sedation (extra-label): Medetomidine 30 µg/kg IM; onset ≈7 minutes, duration ≈90 minutes[51]

BIRDS:

Sedation/analgesia (extra-label):

1. Medetomidine 75 – 100 µg/kg IM with ketamine 3 – 7 mg/kg IM[52]
2. Medetomidine 60 – 85 µg/kg IM with ketamine 1.5 – 2 mg/kg IM[53]

Anesthesia (extra-label): Medetomidine 50 - 200 µg/kg IM in combination with ketamine 3 – 10 mg/kg IM[54]

RABBITS:

Heavy sedation/ anesthesia (extra-label):

1. Medetomidine 250 µg/kg IM with atropine 0.5 mg/kg IM, midazolam 0.5 mg/kg IM followed 5 minutes later by propofol 2 mg/kg IV resulted in analgesia for 25 minutes; time from extubation to sternal recumbency was ≈27 minutes.[55]
2. Medetomidine 350 µg/kg IM followed by ketamine 5 mg/kg IV produced anesthesia of ≈19 minutes duration; medetomidine 350 µg/kg IM combined with propofol 3 mg/kg IV produced anesthesia for ≈11 minutes.[56]
3. Medetomidine 250 µg/kg with ketamine 15 mg/kg IM, SC.[57–59] Equivalent anesthetic effects were noted with either route of administration. **NOTE**: in one study all animals required supplemental oxygen.[58] SC administration appears to be better tolerated, but induction of anesthesia is faster with IM administration.[59,60] Another study determined that medetomidine 500 µg/kg and ketamine 25 mg/kg given SC offered reliable anesthesia and excellent muscle relaxation, but respiratory depression was noted.[61]
4. Medetomidine 250 µg/kg IM followed 5 minutes later by ketamine 60 mg/kg IM[62]
5. Medetomidine 200 µg/kg with ketamine 10 mg/kg administered intranasally to rabbits in sternal recumbency. 50% of the dose was repeated if swallowing occurred during intubation.[63]
6. Medetomidine 500 µg /kg IM, ketamine 35 mg/kg IM, and buprenorphine 0.03 mg/kg IM.[64] Another study administered buprenorphine 0.03 mg/kg SC one hour prior to medetomidine 250 µg/kg and ketamine 15 mg/kg SC, which prolonged the duration of analgesia and anesthesia.[65]
7. Medetomidine 200 µg/kg IM with morphine 1 – 2 mg/kg IM, followed by alfaxalone 10 mg/kg IV; anesthesia was suitable, but profound respiratory depression occurred.[66]

FERRETS:

Sedation/analgesia prior to general anesthesia (extra-label): 15 minutes prior to medetomidine, give atropine 0.05 mg/kg or glycopyrrolate 0.01 mg/kg IM or SC followed by medetomidine

60 – 80 µg/kg IM or SC.[8] Sedation lasts up to 3 hours. May be reversed with atipamezole 400 µg/kg IM

General anesthesia (extra-label):

1. Medetomidine 40 – 80 µg/kg in combination with butorphanol 0.1 – 0.4 mg/kg and ketamine 5 – 10 mg/kg and given IM[67]; may need to supplement with isoflurane 0.5% to 1.5% to maintain general anesthesia for abdominal surgery.
2. Medetomidine 20 µg/kg IM followed by alfaxalone 2.5 mg/kg IV provided anesthesia lasting ≈80 minutes.[68] **NOTE**: Alfaxalone used alone in the ferret produced unsatisfactory anesthetic results.

REPTILES:

Sedation/analgesia (extra-label): **NOTE**: Reversal of all dosages with atipamezole is 4 to 5 times the medetomidine dose.[69]

- **Medium to small land tortoises**: Medetomidine 100 to 150 µg/kg combined with ketamine 5 – 10 mg/kg and given IV or IM
- **Freshwater turtles**: Medetomidine 150 – 300 µg/kg combined with ketamine 10 – 20 mg/kg and given IV or IM
- **Giant land tortoises** (200 kg [440.9 lb] Aldabra tortoise): Medetomidine 40 µg/kg combined with ketamine 4 mg/kg and given IV or IM
- **Smaller Aldabra tortoises**: Medetomidine 40 – 80 µg/kg combined with ketamine 4 – 8 mg/kg and given IV or IM. Wait 30 to 40 minutes for peak effect.
- **Iguanas**: Medetomidine 100 – 150 µg/kg combined with ketamine 5 – 10 mg/kg and given IV or IM

Monitoring

- Level of sedation and analgesia; body temperature
- Heart rate and rhythm, blood pressure, respiratory depth and rate, $ETCO_2$, pulse oximetry, and body temperature should be considered in all patients, and mandatory in higher risk patients.

Client Information

- When given by injection (in the veterinary clinic), medetomidine should be used in a professionally supervised setting by individuals familiar with its properties.
- Withhold feed and water until the sedative effects of me detomidine have subsided.

Chemistry/Synonyms

An alpha-2-adrenergic agonist, medetomidine occurs as a white or off-white crystalline substance. It is soluble in water. Although the compound exists as 2 stereoisomers, only the D-isomer is active. 1 mg of medetomidine HCl is equivalent to 0.85 mg of medetomidine base. Dosages are expressed as medetomidine HCl.

Medetomidine HCl may also be known as MPV-785, *Domitor®*, *Dorbene®*, *Dormilan®*, and *Sedanorm®*.

Storage/Stability

The commercially available injection should be stored at room temperature (15°C-30°C [59°F-86°F]) and protected from freezing. Use within 28 days of first vial puncture.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

See ***Dosage*** section for acceptable combinations; more information may also be found in the ***Dexmedetomidine*** monograph.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

Medetomidine HCl for Injection: 1 mg/mL in 10 mL multidose vials; *Domitor®*, generic; (Rx). FDA-approved for use in dogs over 12 weeks of age.

HUMAN-LABELED PRODUCTS: NONE

Medetomidine/Vatinoxan

(mee-de-***toe***-mi-deen/va-te-***nox***-an) *Zenalpha®*

Alpha-2-Adrenergic Agonist/Peripheral Antagonist Combination

Prescriber Highlights

- ► Reversible sedative-analgesic combination product approved for use in dogs to facilitate examinations, clinical procedures, or minor surgical procedures; the addition of vatinoxan reduces the risk for medetomidine's negative cardiovascular effects.
- ► Duration of sedation from the combination is typically shorter than that achieved by use of an equivalent dose of alpha-2 agonist alone
- ► Contraindicated in patients hypersensitive to either agent, and in dogs with cardiac disease, respiratory disorders, shock, or severe debilitation; that have or are at risk for developing hypoglycemia; and dogs stressed due to heat, cold, or fatigue. Additionally, do not administer to dogs with pre-existing hypotension, hypoxia (hypoxemia), or bradycardia.
- ► Use with caution in diabetic, geriatric, and pediatric dogs, and in dogs with renal or hepatic disease.
- ► Significant hypotension has been observed in cats and horses.
- ► Adverse effects include diarrhea, muscle tremors, and colitis; hypothermia, bradycardia, and arrhythmias are possible.
- ► Sedation and cardiac effects can be reversed with atipamezole.

Uses/Indications

Medetomidine/vatinoxan is indicated for use in clinically healthy dogs as a sedative and analgesic to facilitate clinical examinations or minor procedures. In field studies, the onset and duration of sedation after IM administration were ≈14 minutes and 38 minutes, respectively. In healthy dogs, medetomidine/vatinoxan has been safely used in combination with butorphanol[1,2] and as a premedication prior to propofol induction and isoflurane anesthesia,[3] and during isoflurane anesthesia.[4]

Pharmacology/Actions

An alpha-2-adrenergic receptor agonist, medetomidine is ≈10 times more specific for alpha-2 receptors versus alpha-1 receptors as compared with xylazine. The desirable pharmacologic effects of medetomidine include CNS depression (sedation, anxiolysis) and somatic and visceral analgesia. Other effects include GI (eg, nausea/vomiting, decreased secretions, varying effects on intestinal muscle tone), and endocrine (hyperglycemia) functions; peripheral vasoconstriction and hypertension with subsequent baroreflex-mediated bradycardia and decreased cardiac output; respiratory depression; diuresis; hypothermia; muscle relaxation; and blanched or cyanotic mucous membranes. The sedative effects of medetomidine generally persist longer than the analgesic effects.

Vatinoxan is a peripherally acting alpha-2-adrenergic antagonist. Vatinoxan attenuates the hemodynamic effects of alpha-2-adrenergic receptor agonists that occur outside the CNS in dogs when a plas-

ma medetomidine:vatinoxan concentration ratio of 1:18 is reached or exceeded.[4] In dogs, the combination of medetomidine/vatinoxan resulted in higher heart rate and cardiac index, and lower mean arterial pressure and systemic vascular resistance as compared to medetomidine alone.[5,6] One study in dogs documented that IM vatinoxan did not prevent the initial hemodynamic changes (bradycardia, hypertension) caused by IM medetomidine, but vatinoxan resulted in the cardiovascular effects disappearing more rapidly.[7] Vatinoxan also prevented or abolished metabolic changes (eg, hyperglycemia, hypoinsulinemia, hyperlactatemia) induced by dexmedetomidine,[8] and mitigated the hypothermic effects of medetomidine and butorphanol combination.[9] Medetomidine/vatinoxan may decrease serum glucose in healthy dogs.[10]

Unlike atipamezole (a centrally and peripherally acting antagonist), vatinoxan appears to only minimally decrease the degree or depth of sedation caused by the alpha-2 agonist, and the difference does not appear to be clinically significant.[5,11–13] In dogs, the duration of sedation produced by medetomidine/vatinoxan is equivalent to its duration of analgesia; however, the duration of sedation from the combination is shorter than that achieved by medetomidine alone.[10,14] Vatinoxan did not diminish the visceral antinociceptive effects of medetomidine in healthy dogs, but vatinoxan's effect on somatic antinociception was variable.[15] Vatinoxan demonstrated a dose-related attenuation of the dexmedetomidine reduction of sevoflurane MAC in healthy dogs.[16] In horses, vatinoxan appeared to mitigate the reduced intestinal activity[17,18] and GI microperfusion[19] caused by alpha-2 agonists.

Pharmacokinetics

As a single agent, medetomidine is ≈90% bound to plasma proteins. In healthy dogs, its volume of distribution was 1.3 L/kg, clearance was 1.3 L/kg/hour, and terminal half-life was ≈1 hour.[20] Medetomidine is primarily oxidized in the liver and excreted renally.

Vatinoxan is ≈70% protein bound in canine plasma, and protein binding is not altered by the presence of medetomidine.[21] Vatinoxan only minimally distributes into the CNS; after IV administration, the CNS:plasma vatinoxan concentration ratio was ≈1:50.[22] Preliminary evidence suggests vatinoxan is not a substrate of P-gp.[23] Vatinoxan elimination has not been fully described, but less than 5% is excreted in the urine.

When a medetomidine and vatinoxan combination was administered IM to dogs as a 1:30 ratio (**NOTE**: The commercially available product contains a 1:20 ratio), peak plasma concentrations of dexmedetomidine (the active medetomidine isomer) and vatinoxan occurred ≈13 and 18 minutes after IM administration, respectively.[10] Vatinoxan decreased the apparent volume of distribution of dexmedetomidine,[24] and increased (more than doubled) the clearance of medetomidine and dexmedetomidine in dogs.[14] Vatinoxan reduced plasma concentrations of medetomidine and dexmedetomidine in dogs[14] but had variable effects in horses[25,26] and sheep.[27,28]

Contraindications/Precautions/Warnings

Medetomidine/vatinoxan is contraindicated in dogs that are hypersensitive to medetomidine or vatinoxan; dogs with cardiac disease, respiratory disorders, shock, or severe debilitation; that have or are at risk for developing hypoglycemia; and dogs that are stressed due to heat, cold, or fatigue.[10] Do not administer medetomidine/vatinoxan to patients with pre-existing hypotension, hypoxia (hypoxemia), or bradycardia. Use medetomidine/vatinoxan with caution in dogs with hepatic or renal disease, as the safe use in these conditions has not been evaluated.[10] Medetomidine/vatinoxan has not been evaluated in dogs younger than 4.5 months old. Because medetomidine's effects are reversible, some anesthesiologists consider these precautions to be relative, particularly in patients with hepatic or renal disease.

Medetomidine/vatinoxan should only be used in situations in which sufficient monitoring and patient-support capabilities (eg, intubation, oxygen administration, breathing support) are available.

Dogs that are extremely agitated, nervous, or excited may have a delayed or decreased response to medetomidine; the manufacturer suggests allowing these dogs to rest quietly for 10 to 15 minutes after administration of the drug. Repeat dosing of medetomidine/vatinoxan has not been evaluated by the manufacturer, but in one study, dogs that required additional sedation received a lower dose of medetomidine alone (ie, without vatinoxan).[2]

It is recommended that dogs fast for 4 to 6 hours prior to receiving medetomidine/vatinoxan.[29]

Medetomidine/vatinoxan use in cats[30–32] and horses[33] has been associated with significant hypotension, and the manufacturer states that medetomidine/vatinoxan is not intended for use in cats.[10]

Humans with cardiovascular disease and pregnant women should exercise caution when handling medetomidine/vatinoxan to avoid accidental exposure, as alpha-2 agonists cause changes to uterine contractility and blood flow which may result in fetal hypoxia and/or bradycardia.[10]

Do not confuse medetomidine/vatinoxan combination with medetomidine as a single agent, or with detomidine or dexmedetomidine.

Adverse Effects

Diarrhea, muscle tremors, and colitis were the most commonly reported adverse effects observed following IM use of medetomidine/vatinoxan during field studies, occurring in 2% to 4% of dogs.[10] Although decreased body temperature (ie, 99°F [37°C] or less) is common (52% of medetomidine/vatinoxan treated dogs), clinical hypothermia occurred only rarely and was of shorter duration and much less common in dogs receiving medetomidine/vatinoxan (0.9%) as compared with dogs receiving dexmedetomidine (11.5%); hypothermia may persist longer than sedation. Tachycardia occurring after recovery from sedation occurred rarely,[10] and may continue for up to 6 hours after administration.[29]

Medetomidine/vatinoxan use in cats has resulted in hypotension.[10]

Reproductive/Nursing Safety

Safe use of medetomidine/vatinoxan in dogs intended for breeding or pregnant or lactating bitches has not been established.[10] Extrapolating information from other alpha-2-adrenergic receptor agonists, medetomidine can induce uterine contractions in pregnant animals, and fetal bradycardia and hypoxia are possible.[34–36] Medetomidine crosses the placenta, with equivalent fetal and maternal medetomidine concentrations.[36,37]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Medetomidine/vatinoxan administered IV at doses 3 and 5 times the label IM dose resulted in sedation (4-to 8-hour duration), hypotension, hypothermia and an initial bradycardia followed later by sinus tachycardia during recovery.[10] Hypoglycemia occurred in 2 dogs receiving 5 times the label IM dose. Clinical signs included stool changes (eg, mucoid, soft, or watery), salivation, tremors, vocalization, defecation, vomiting, injected sclera, struggling after dosing, and skin that was cool to touch. Dogs returned to baseline physiologic state within 8 hours of administration.[10]

Atipamezole IM may be used to treat any medetomidine-induced effect provided reversal of analgesia or sedation is not contraindicated; reversal of sedation occurs within 5 to 10 minutes.[10]

For patients that have experienced or are suspected of having experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in provid-

ing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving medetomidine and/or vatinoxan and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate. **NOTE**: Before attempting combination therapy with medetomidine, it is strongly advised to consult veterinary anesthesia references or veterinary anesthesiologists familiar with the use of this drug.

- Analgesics, Sedatives, Tranquilizers, and/or Anesthetic Agents, Other (eg, **acepromazine**, **anesthetic agents** [**alfaxalone, isoflurane, ketamine, propofol**], **benzodiazepines** [eg, **midazolam**], **opioids** [eg, **fentanyl, morphine**]): When used in combination, lower dosages of medetomidine and/or other anesthetic or analgesic agents may be required. Additionally:
  a) Vatinoxan accelerated the time to peak midazolam concentration after IM administration.[38]
  b) Vatinoxan blocked the decrease in alfaxalone clearance caused by medetomidine.[39]
  c) Significant hypotension has been observed in studies using medetomidine/vatinoxan in combination with other anesthetic or analgesic drugs.[33,40]
- Anticholinergic Agents (eg, **atropine, butylscopolamine, glycopyrrolate**): Vatinoxan minimizes the risk for medetomidine-induced bradycardia, and the concurrent administration of glycopyrrolate appeared to provide no benefit in dogs that received medetomidine/vatinoxan.[6]
- Antihypertensive Agents/Vasodilators (eg, **amlodipine, enalapril, hydralazine, telmisartan**): Concurrent use may increase the risk for hypotension.
- Atipamezole: Atipamezole may be used to reverse the central effects of medetomidine when used in combination with vatinoxan[41]; reversal of sedation occurs within 5 to 10 minutes of IM atipamezole administration.[10]
- Hypoglycemic Agents (eg, **glipizide**, **insulin, metformin**): Medetomidine/vatinoxan may decrease serum glucose in healthy dogs.[10] Potentiation of hypoglycemic effect by medetomidine/vatinoxan was not observed in healthy dogs, but the study authors suggest using the combination cautiously in dogs at risk for hypoglycemia.[42]
- Sympathomimetics (eg, **dopamine, epinephrine**): Concurrent use with medetomidine is contraindicated[43]; however, dopamine is often used in anesthetized patients that received medetomidine as premedication and that become hypotensive in spite of anticholinergic administration to normalize heart rate. Epinephrine is generally reserved for emergencies and is not contraindicated in a cardiovascular emergency.

Laboratory Considerations

- Medetomidine can inhibit ADP-induced **platelet aggregation** in cats, but this does not appear to be clinically significant.

Dosages

NOTE: Watch units closely when calculating doses. Do not confuse mg/m^2 with mg/kg, µg/m^2, or µg/kg.

DOGS:

Sedation and analgesia to facilitate examinations, clinical procedures, or minor surgical procedures in dogs (label dosage, FDA-approved): Calculate the dose based on medetomidine 1 mg/m^2 (NOT mg/kg) IM [which provides vatinoxan 20 mg/m^2 (NOT mg/kg)], or use the dosing table found in the United States product label and replicated below. Note that the mg/kg dosage decreases as body weight increases. Allow the dog to rest quietly until evidence of sedation has occurred (5 to 15 minutes).

Body weight – kg (lb)	Dose volume (mL)
2-3 (4.4-7)	0.3
3.1- 4 (7.1-9)	0.4
4.1-5 (9.1-11)	0.6
5.1-10 (11.1-22)	0.8
10.1-13 (22.1-29)	1
13.1-15 (29.1-33)	1.2
15.1-20 (33.1-44)	1.4
20.1-25 (44.1-55)	1.6
25.1-30 (55.1-66)	1.8
30.1-33 (66.1-73)	2
33.1-37 (73.1-81)	2.2
37.1-45 (81.1-99)	2.4
45.1-50 (99.1-110)	2.6
50.1-55 (110.1-121)	2.8
55.1-60 (121.1-132)	3
60.1-65 (132.1-143)	3.2
65.1-70 (143.1-154)	3.4
70.1-80 (154.1-176)	3.6
Greater than 80 (176)	3.8

Sedation and analgesia to facilitate diagnostic imaging of dogs (extra-label): Medetomidine 0.5 mg/m^2 (NOT mg/kg) in combination with vatinoxan 10 mg/m^2 (NOT mg/kg) IM and butorphanol 0.1 mg/kg IM. Medetomidine (as a single agent) 0.25 mg/m^2 (NOT mg/kg) IM was administered when additional sedation was needed.[2]

HORSES:

Multimodal sedation protocol (extra-label): Medetomidine 7 µg/kg in combination with vatinoxan 140 µg/kg IV prior to medetomidine (as a single agent) 3.5 µg/kg/hour IV CRI[25]

SHEEP:

Multimodal sedation protocol (extra-label): Medetomidine 30 µg/kg in combination with vatinoxan 600 µg/kg IM and ketamine 1 mg/kg IM[27]

Monitoring

- Quality of sedation and analgesia
- Heart rate and rhythm
- Blood pressure
- Respiratory rate, tidal volume or size of breath, $ETCO_2$, pulse oximetry, and body temperature

Client Information

- Medetomidine/vatinoxan should be used in a professionally supervised setting by individuals familiar with its properties and equipped with sufficient monitoring and patient-support capabilities.

Chemistry/Synonyms

An alpha-2-adrenergic agonist, medetomidine hydrochloride occurs as a white or off-white crystalline substance. It is soluble in water.

Although the compound exists as 2 stereoisomers, only the d-isomer (dexmedetomidine) is active. Medetomidine may also be known as MPV-785.

Vatinoxan hydrochloride occurs as a white to pale-yellow crystalline substance that is sparingly soluble in water. Vatinoxan may also be known as MK-467 and L-659066.

Medetomidine/vatinoxan may also be known as *Zenalpha®*.

Storage/Stability

Store medetomidine/vatinoxan below 25°C (77°F), protected from light and freezing. Discard in-use vials after 3 months.[10]

Compatibility/Compounding Considerations

Do not mix medetomidine/vatinoxan with other agents, as compatibility studies have not been performed.[29]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Medetomidine and Vatinoxan Injection: medetomidine 0.5 mg/mL and vatinoxan 10 mg/mL in 10 mL vials; *Zenalpha®*; (Rx). FDA-approved for use in dogs. NADA# 141-551

The Association of Racing Commissioners International (ARCI) has designated medetomidine as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS: NONE

Medium Chain Triglycerides; (MCT) Oil

Nutritional

Prescriber Highlights

- ► Lipid sometimes used to provide calories and fatty acids to dogs with restricted fat intake from chronic infiltrative diseases of the small intestine or fat malabsorption syndromes; may have benefit in canine epilepsy
- ► Most clinicians use dietary therapy instead of MCT oil.
- ► Use with caution in animals with significant hepatic disease (eg, portacaval shunts, cirrhosis).
- ► Adverse effects include unpalatability (dogs), bloating, flatulence, and diarrhea; may be associated with hepatic lipidosis in cats.

Uses/Indications

Medium chain triglycerides (MCT) oil, as a separate compound (not as an ingredient in commercial foods), can offset caloric reduction when dietary long chain triglycerides are restricted. Fat-restricted disease states include chronic infiltrative diseases of the small intestine or fat malabsorption of any cause. Many clinicians bypass MCT oil due to expense and unpalatability to dogs. Commercially made prescription diets, that are highly digestible with low fat content, can be used. Alternatively, a veterinary nutritionist can prepare a recipe for clients to make a homemade, complete, and balanced diet for their animals.

MCT oil may be useful as a base-vehicle to administer drugs to cats. A study evaluating the acceptance of low-dose (0.1 mL/kg) MCT oil, gelatin capsules, or thin-film dissolving strips found that owner-perceived acceptability by cats of MCT oil and thin-film strips was significantly higher than that of gelatin capsules.[1]

Diets with MCT may play a supporting role in prevention or treating cognitive dysfunction syndromes in dogs and cats.[2]

When added to standard antiepileptic treatment, supplementation with MCT decreased seizure frequency and number of days with seizure activity in dogs with idiopathic epilepsy.[3–5]

Pharmacology/Actions

Medium chain triglycerides (MCT) are more readily hydrolyzed than conventional food fat. MCT can pass through intestinal membranes into venous blood circulation. Bile acids or pancreatic lipase are not required for their absorption into portal circulation. MCT are not a source for essential fatty acids.

MCT oil supplementation (as coconut oil) to the diet of cats did not cause food aversion or significant effects on lipid metabolism.[6]

In epileptic brains, decreased metabolism of glucose and increased energy requirements from increased electrical activity creates an energy deficit. MCTs release octranoic and decanoic acids, which are hepatically converted into ketone bodies that can be used for fuel in the brain.[7]

Pharmacokinetics

No specific information located; see ***Pharmacology/Actions***.

Contraindications/Precautions/Warnings

Use medium chain triglycerides (MCT) oil with caution in patients with significant hepatic disease (eg, portacaval shunts, cirrhosis). MCTs are rapidly absorbed via the portal vein and if hepatic clearance is impaired, significantly high systemic blood and cerebral spinal fluid levels of medium chain fatty acids can occur. This may precipitate or exacerbate hepatic coma.

Patients experiencing diabetic ketoacidosis (DKA) should avoid MCT until the DKA has resolved.

Adverse Effects

Adverse effects seen with medium chain triglycerides (MCT) oil in small animals include unpalatability, bloating, flatulence, and diarrhea. In cats, higher dosages of MCT oil may induce hepatic lipidosis. Adverse effects may be transient and minimized by starting with low doses and gradually increasing the dose. Fat-soluble vitamin supplementation (vitamins A, D, E, and K) using a commercial feline or canine vitamin-mineral supplement has been recommended.

Reproductive/Nursing Safety

No reproductive or nursing safety data were located. Although medium chain triglycerides (MCT) use is unlikely to cause problems in pregnant or nursing animals, because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose would likely exacerbate the GI adverse effects noted (see ***Adverse Effects***). Treat severe diarrhea supportively if necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

- ■ None listed. Medium chain triglycerides (MCT) oil could theoretically affect absorption of drugs that are dependent on fat for oral absorption (eg, griseofulvin, fat-soluble vitamins).

Dosages

DOGS:

Offset caloric reduction when dietary long chain triglycerides are restricted (extra-label): Most clinicians prefer to use dietary therapy with foods containing additional medium chain tri-

glycerides (MCT) in their formulation; but 0.5 – 2 mL/kg/day added to food is appropriate.

Adjunct to standard epilepsy treatment (extra-label): 6.5% – 9% of total caloric intake daily[3–5]

Monitoring
- Adverse effects (mostly GI-related)
- Efficacy (weight gain, improved seizure control)

Client Information
- Because of the unpalatability of the oil, it should be mixed with small quantities of food before offering to the animal.
- Contact your veterinarian if you notice side effects, including diarrhea or flatulence, or any other new problems.

Chemistry/Synonyms
Medium chain triglycerides (MCT) oil is a lipid fraction of coconut oil consisting principally of the triglycerides C8 (≈67%) and C10 (≈23%) saturated fatty acids. Each 15 mL contains 115 kCal (7.67 kCal/mL).

Medium chain triglycerides may also be known as triglycerida saturata media.

Storage/Stability
Unless otherwise noted by the manufacturer, store this product at room temperature in glass bottles, protected from light.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Medium Chain Triglycerides Oil: in quart bottles (946 mL); *MCT*®; (OTC).

Medroxyprogesterone
Medroxyprogesterone Acetate

(me-***drox***-ee-proe-***jess***-te-rone) *Provera*®

Progestin

Prescriber Highlights
- ► Used primarily to treat cats for sexually dimorphic behavior problems such as roaming, inter-male aggressive behaviors, spraying, and mounting; sometimes used to treat alopecia X in dogs
- ► Because of its serious adverse effect profile, particularly in small animal species, consider safer alternatives first.
- ► Contraindications include pre-pubescent dogs or cats, diabetes mellitus, pseudopregnancy in bitches, female patients in diestrus or with prolonged heat, and uterine hemorrhage or discharge.
- ► Adverse effects include increased thirst, increased appetite, weight gain, depression, lethargy, personality changes, adrenocortical depression, mammary changes (including enlargement, milk production, and neoplasms), diabetes mellitus, pyometra, and temporary inhibition of spermatogenesis.
- ► SC injection may cause permanent local alopecia or atrophy, and depigmentation may occur.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies medroxyprogesterone as a hazardous drug; use appropriate precautions when handling.

Uses/Indications
In cats, medroxyprogesterone has been used to treat sexually dimorphic behavior problems such as roaming, inter-male aggressive behaviors, spraying, and mounting when castration is either ineffective or undesirable.[1]

In dogs, medroxyprogesterone has been used to treat progestin-responsive dermatitis, aggressive behaviors,[1,2] long-term reproductive control, treatment of young German shepherd dwarfs, short-term treatment of benign prostatic hypertrophy, and luteal insufficiency. An open study in 8 Pomeranian dogs with alopecia X found that medroxyprogesterone administration resulted in partial hair regrowth in 3 and complete hair regrowth in 1 of the dogs treated.[3]

Progesterones have been used in horses for many purposes, including management of the spring transition period, prevention of estrus behavior, induction of estrous cycle synchrony, pregnancy maintenance, and modification of stallion behavior.[4] However, medroxyprogesterone does not appear to effectively suppress estrous behavior or follicular activity in normal cycling mares.[5]

In humans, parenteral medroxyprogesterone has been used as a long-acting contraceptive in women and as an antineoplastic agent for some carcinomas (see ***Pharmacology/Actions***). Oral medroxyprogesterone is used in women to treat secondary amenorrhea or abnormal uterine bleeding secondary to hormone imbalances.

Pharmacology/Actions
Progestins are primarily produced endogenously by the corpus luteum. They transform proliferative endometrium to secretory endometrium, enhance myometrium hypertrophy, and inhibit spontaneous uterine contraction. Progestins have a dose-dependent inhibitory effect on the secretion of pituitary gonadotropins and can have an anti-insulin effect. Medroxyprogesterone has exhibited a pronounced adrenocorticoid effect in animals (species not listed) and can suppress ACTH and cortisol release. Medroxyprogesterone is anti-estrogenic and will also decrease plasma testosterone levels in male humans and dogs.

Medroxyprogesterone has antineoplastic activity against endometrial carcinoma and renal carcinoma (efficacy in doubt) in humans.

Pharmacokinetics
No specific pharmacokinetic parameters in veterinary species were located for this drug. It has been reported that injectable MPA has an approximate duration of action of 30 days when used to treat behavior disorders in cats.[6] When administered IM to women, medroxyprogesterone has contraceptive activity for at least 3 months.[7] Single-dose half-life following oral administration in humans was ≈12 hours.[8]

Contraindications/Precautions/Warnings
When medroxyprogesterone is used for reproductive control, patients should 1) undergo a thorough reproductive history to rule out occurrence of estrus within the last 1 to 2 months (female patient in diestrus); 2) a complete physical examination; 3) palpation of mammary glands to rule out neoplasia; and 4) a vaginal cytology to rule out presence of estrus.[9]

This agent should not be used to treat bitches with pseudopregnancy. Female patients should not be treated during diestrus or if they have a uterine hemorrhage. Do not use medroxyprogesterone in female patients with prolonged heat unless cystic ovarian disease is confirmed and surgery, GNRH, or hCG are not viable options. Animals with diabetes mellitus should not receive medroxyprogesterone.

Do not use medroxyprogesterone prior to puberty in cats, as chronic, severe, mammary hypertrophy may result. Use in dogs before puberty may precipitate subclinical uterine or endocrine conditions (eg, cystic endometrial hyperplasia, pyometra, diabetes mellitus).

Because this drug can suppress adrenal function, exogenous ste-

roids may need to be administered if the patient is stressed (eg, surgery, trauma).

In humans, medroxyprogesterone is contraindicated in patients that are hypersensitive to it and in patients with liver dysfunction.[10] Progestogen therapy can cause serious adverse effects (eg, thromboembolic disease), and safer alternative treatments should be considered when possible. Weigh the potential risks versus benefits before instituting therapy. Many clinicians believe that progestogens are grossly overused.

The National Institute for Occupational Safety and Health (NIOSH) classifies medroxyprogesterone as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Adverse reactions that are possible in dogs and cats include increased appetite with weight gain, polyuria, polydipsia, depression, lethargy, personality changes, adrenocortical depression, mammary changes (including enlargement, milk production, and neoplasms), diabetes mellitus, hypothyroidism, pyometra, and temporary inhibition of spermatogenesis. In dogs, acromegaly and increased growth hormone levels have been seen when used in patients with diabetes mellitus.

SC administration may result in permanent local alopecia or atrophy, and depigmentation may occur. If injecting SC, it is recommended to use the inguinal area to avoid these manifestations.

Reproductive/Nursing Safety

In humans, progestins have caused congenital heart defects, limb reduction deformities, hypospadias in male fetuses, and mild virilization of the external genitalia of female fetuses, especially when administered to women during the first 4 months of pregnancy. Medroxyprogesterone is considered contraindicated in pregnant women. In general, medroxyprogesterone should be avoided in pregnant animals with some exceptions (eg, luteal deficiency); facial deformities were reported in 1 of 4 pups in a litter from a bitch treated with medroxyprogesterone for hypoluteoidism. In most instances, the potential benefits of progesterone treatment for hypoluteoidism during the second half of pregnancy outweigh the maternal and fetal risks.[11,12]

Medroxyprogesterone can be detected in maternal milk. Although no adverse effects have been noted in nursing infants, infant risk cannot be ruled out. Weigh the potential risks and benefits before using in nursing animals.

Overdose/Acute Toxicity

No reports or information were located on inadvertent overdoses with this agent. See ***Adverse Effects***.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving medroxyprogesterone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Corticosteroids**: May result in an increased risk for corticosteroid adverse effects
- **Cyclosporine**: May increase risk for cyclosporine toxicity
- **Felbamate**: May increase medroxyprogesterone metabolism
- **Rifampin**: A potential interaction exists with rifampin, which may decrease progestin activity if administered concomitantly. This is presumably due to microsomal enzyme induction with resultant increase in progestin metabolism. The clinical significance of this potential interaction is unknown.
- **Selegiline**: May result in an increase in selegiline oral bioavailability and an increased risk for selegiline adverse reactions
- **Theophylline**: May result in theophylline toxicity

Laboratory Considerations

- In humans, progestins, in combination with estrogens (eg, oral contraceptives), have been demonstrated to increase thyroxine-binding globulin (TBG) with resultant increases in total circulating thyroid hormone. Decreased T_3 resin uptake also occurs, but free T_4 concentrations are unaltered. Liver function tests may also be altered.
- The manufacturer recommends notifying the pathologist of patient medroxyprogesterone exposure when submitting relevant specimens.

Dosages

DOGS:

Luteal insufficiency in pregnant bitches (extra-label): 0.1 mg/kg PO once daily.[11,12] Treatment is discontinued several days prior to the expected due date to avoid prolonged gestation. See ***Reproductive/Nursing Safety***.

Long-term reproductive control (extra-label): 2.5 – 3 mg/kg IM every 5 months[9,13,14]

Alopecia X (extra-label): A study done in Pomeranians found that 5 or 10 mg/kg SC every 4 weeks for 4 treatments resulted in partial hair regrowth in 3 and complete hair regrowth in 1 of 8 dogs treated.[3] The authors concluded that prolonged treatment could result in improved success with careful monitoring for adverse effects.

CATS:

Behavioral disorders (eg, to reduce marking in neutered male cats when all other drugs have been unsuccessful; extra-label): 5 – 20 mg/kg SC or IM 3 to 4 times yearly[15]

Long-term reproductive control (extra-label): 2 mg/kg IM every 5 months[9,13,14]

HORSES:

Management of the spring transition period, prevention of estrus behavior, induction of estrous cycle synchrony, pregnancy maintenance, or modification of stallion behavior (extra-label): ≈500 – 800 mg IM. The interval between doses varies between horses. Most injections last 2 to 3 months. Medroxyprogesterone will not prevent pregnancy loss and does not stop cyclicity,[4] and it does not appear to effectively suppress estrous behavior or follicular activity in normal cycling mares.[5]

Monitoring

- Body weight
- Baseline and periodic blood glucose
- Mammary gland palpation and examination to detect development of neoplasia
- Adrenocortical function (ie, ACTH stimulation test) as indicated by clinical situation
- Efficacy

Client Information

- Give this medicine as directed by your veterinarian.
- Side effects in dogs and cats can include loss of hair/fur at the site of injection, increased appetite with weight gain, increased thirst, depression and lethargy, changes in behavior, mammary changes (including enlargement, milk production, and tumors), diabetes

mellitus, low thyroid hormone (*hypothyroidism*), uterine infection (females), and temporary inhibition of sperm production (males).

- Your veterinarian will need to monitor your animal while it is receiving this medicine. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

A synthetic progestin, medroxyprogesterone acetate occurs as an odorless, white to off-white, crystalline powder. It is insoluble in water and sparingly soluble in alcohol. It has a melting range of 200°C to 210°C (392°F-410°F).

Medroxyprogesterone acetate may also be known as MPA, MAP, acetoxymethylprogesterone, medroxyprogesteroni acetas, methylacetoxyprogesterone, metipregnone, and NSC-26386; many trade names are available.

Storage/Stability

Medroxyprogesterone acetate suspensions for injection should be stored at room temperature (15°C-30°C [59°F-86°F]); avoid freezing and temperatures above 40°C (104°F). Tablets should be stored in well-closed containers at room temperature.

Compatibility/Compounding Considerations

No specific information is noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

Megestrol

Megestrol Acetate

(me-***jess***-trole) *Ovaban®, Megace®*

Progestin

Prescriber Highlights

- ► Used in female dogs for postponement of estrus, in male dogs for benign prostatic hypertrophy, and in cats for many dermatologic and behavior-related conditions
- ► Contraindications include pregnant animals; animals with uterine disease, diabetes mellitus, or mammary neoplasias; and in female patients during diestrus or with uterine hemorrhage.
- ► Use with caution in patients with thrombophlebitis and pseudopregnancy; although indicated for alleviation of pseudopregnancy, it is no longer recommended for this indication.
- ► Adverse effects in dogs include increased appetite, weight gain, lethargy, change in behavior or hair color, mucometra, endometritis, cystic endometrial hyperplasia, mammary gland enlargement and neoplasia, acromegaly, adrenocortical suppression, or lactation (rare).
- ► Adverse effects in cats include profound adrenocortical suppression, adrenal atrophy, transient diabetes mellitus, polydipsia/polyuria, personality changes, weight gain, endometritis, cystic endometrial hyperplasia, mammary hypertrophy, neoplasias, and hepatotoxicity.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies megestrol as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Megestrol is FDA-approved for use in dogs for the postponement of estrus and the alleviation of pseudopregnancy; however, it has fallen out of favor for treatment of pseudopregnancy due to recurrence rates after drug withdrawal, adverse effects associated with its use, and availability of safer options (eg, cabergoline). In male dogs, it has also been used for benign prostatic hypertrophy. Megestrol has also been used clinically for many dermatologic and behavior-related conditions, primarily in cats. Low-dose megestrol may be an alternative to surgery for contraception in free-roaming cats, but safety, efficacy, regulatory pathways, and ethics remain questionable.[1]

Megestrol is indicated in humans for the palliative treatment of advanced carcinoma of the breast or endometrium.

Pharmacology/Actions

Megestrol possesses the pharmacologic actions expected of other progestational drugs (eg, medroxyprogesterone acetate). It has significant antiestrogen and glucocorticoid activity (with resultant adrenal suppression). It does not have anabolic or masculinizing effects on the developing fetus.

Pharmacokinetics

Megestrol is well absorbed from the GI tract and appears to be metabolized completely in the liver to conjugates and free steroids.

The half-life of megestrol acetate is reported to be 8 days in the dog.

Contraindications/Precautions/Warnings

Megestrol is contraindicated in pregnant animals or in animals with uterine disease, diabetes mellitus, or mammary neoplasias. Megestrol is not recommended in dogs prior to their first estrous cycle or for anestrus therapy in dogs with abnormal cycles. Prevent mating if estrus occurs within 30 days of cessation of megestrol therapy.[2]

Megestrol should not be used during pregnancy; it is no longer

recommended to treat bitches with pseudopregnancy despite its labeled indication for this use. Female patients with uterine hemorrhage or those in diestrus should not be treated. Do not use megestrol in female patients with prolonged estrus unless cystic ovarian disease is confirmed and surgery, GNRH, or hCG are not viable options.

For estrus control, the drug must be given for the full treatment regimen to be effective.[2] It should not be given for more than 2 consecutive treatments, but the reasons for this are unclear; some theriogenologists question the need for this precaution. When megestrol is used for reproductive control, it has been recommended that patients undergo a thorough reproductive history (to rule out occurrence of estrus within the last 1 to 2 months), a complete physical examination, palpation of mammary glands (to rule out mammary nodules), and a vaginal cytology (to rule out the presence of estrus).[3,4]

Because this drug can suppress adrenal function, exogenous steroids may need to be administered if the patient is stressed (eg, surgery, trauma).

In humans, megestrol should be used with caution in patients with thrombophlebitis.[5]

The National Institute for Occupational Safety and Health (NIOSH) classifies megestrol as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Adverse effects in dogs include increased appetite, weight gain, lethargy, change in behavior, change in hair color, mucometra, endometritis, pyometra, cystic endometrial hyperplasia, mammary enlargement and neoplasia, acromegaly, adrenocortical suppression, and, rarely, lactation. One dog reportedly developed diabetes mellitus after use.[6]

Adverse effects in cats include profound adrenocortical suppression and adrenal atrophy. Iatrogenic Addison syndrome can develop at standard dosages (2.5 – 5 mg every other day) within 1 to 2 weeks. After discontinuation, serum cortisol levels (both resting and ACTH-stimulated) will return to normal levels within a few weeks. Clinical signs of adrenocortical insufficiency (eg, vomiting, lethargy) are uncommon, but exogenous glucocorticoid support should be considered if the animal is stressed (eg, surgery, trauma). Cats may develop transient diabetes mellitus while receiving megestrol. Polydipsia/polyuria, personality changes, weight gain, endometritis, cystic endometrial hyperplasia, mammary hypertrophy, and neoplasias may also occur; however, increased appetite and weight gain are not consistently seen. Rarely, megestrol can cause hepatotoxicity in cats. Megestrol potentially can exacerbate latent viral infections (eg, FHV-1).

Limited clinical studies have suggested that megestrol may cause less cystic endometrial hyperplasia than other progestational agents, but cautious use and vigilant monitoring are still warranted.

Reproductive/Nursing Safety

No effects were noted in either the bitch or litter when pregnant dogs received megestrol 0.25 mg/kg PO daily for 32 days during the first half of pregnancy; however, reduced litter sizes and puppy survival were detected when the dose was given during the last half of pregnancy. Fetal hypospadias is possible if progestational agents are administered during pregnancy.

Detectable amounts of progestins enter the milk of mothers receiving these agents. Effects on nursing infants have not been established.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No information was located regarding acute megestrol overdoses. In humans, dosages of megestrol of up to 1600 mg/day caused no observable adverse reactions.[5]

Toxicity studies performed in dogs at dosages of 0.1 to 0.25 mg/kg/day PO for 36 months yielded no gross abnormalities in the study population. Histologically, cystic endometrial hyperplasia was noted at 36 months but resolved when therapy was discontinued. At dosages of 0.5 mg/kg/day PO for 5 months, reversible uterine hyperplasia was seen in treated dogs. Dosages of 2 mg/kg/day demonstrated early cystic endometritis in biopsies done on dogs at 64 days.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

- **Corticosteroids**: Megestrol used with corticosteroids (long-term) may exacerbate adrenocortical suppression and diabetes mellitus.
- **Rifampin**: May decrease progestin activity if administered concomitantly, presumably due to microsomal enzyme induction with a resultant increase in progestin metabolism. The clinical significance of this potential interaction is unknown.

Dosages

DOGS:

Postponement of estrus (label dosage; FDA-approved):

a) **During proestrus**: 2.2 mg/kg PO daily for 8 days during the first 3 days of proestrus[2]

b) **During anestrus**: 0.55 mg/kg PO daily for 32 days[2]

NOTE: If used properly during proestrus, physical manifestations of proestrus and estrus and breeding behavior will subside within days, and the bitch will not ovulate on that cycle. If used properly during anestrus, return to subsequent proestrus will be postponed for ≈3 months.[6]

Alleviation of clinical signs associated with false pregnancy (pseudopregnancy) (label dosage; FDA-approved): 2.2 mg/kg PO daily for 8 days.[2] **NOTE**: Despite this indication being listed on the label, the use of megestrol for alleviating clinical signs associated with pseudopregnancy are no longer recommended.[7]

Benign prostatic hypertrophy to maintain breeding potential for a short time prior to castration (extra-label): 0.1 – 0.5 mg/kg PO daily for 3 to 8 weeks[8]

Subinvolution of placental sites (SIPS) (extra-label): From a small non-blinded study in 9 dogs, 0.1 mg/kg PO once daily for the first week, then 0.05 mg/kg PO once daily for the second week.[9] Vaginal discharge ceased in all treated dogs within the treatment period, and 5 of 6 that were subsequently mated became pregnant.

CATS:

Postponement of estrus (extra-label):

a) **During proestrus**: 5 mg/cat (NOT mg/kg) PO daily for 4 days, then 5 mg/cat (NOT mg/kg) PO every 2 weeks[4,10]

b) **During anestrus**: 5 mg/cat (NOT mg/kg) PO every 2 weeks OR 2.5 mg/cat (NOT mg/kg) PO weekly, ideally divided into 2 doses given every 3.5 days

Alternative for treating feline atopy when standard treatments fail (extra-label): 2.5 – 5 mg/cat (NOT mg/kg) PO every 48 hours for 1 to 3 weeks may induce remission of clinical signs. Frequency can then be decreased to once weekly.[11]

Reduce marking in neutered male cats when all other drugs have been unsuccessful (extra-label): 2.5 – 10 mg/cat (NOT mg/kg) PO once daily for one week, then reduce to once or twice weekly[12]

Eosinophilic keratitis (extra-label): A compounded aqueous ophthalmic preparation of megestrol acetate 0.5% administered every 8 to 12 hours showed efficacy in one study, with 15 of 17 cats responding to treatment.[13]

Monitoring
- Body weight
- Baseline and periodic blood glucose
- Mammary gland development and appearance
- Adrenocortical function (ie, ACTH stimulation) with long-term treatment
- Liver enzymes if long-term treatment
- Efficacy

Client Information
- This medicine may be given with food or on an empty stomach but giving with food may help prevent vomiting.
- Megestrol can have many side effects; some of them are serious. Watch your animal for changes to the mammary glands/nipples or for any vaginal discharge.
- If you are pregnant, use caution when handling this medicine. Be sure to wear gloves and wash hands after handling any medication.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms
Megestrol acetate is a synthetic progestin that occurs as an essentially odorless, tasteless, white to creamy white, crystalline powder that is insoluble in water, sparingly soluble in alcohol, and slightly soluble in fixed oils. It has a melting range of 213°C to 219°C (415°F-426°F) over a 3° range and a specific rotation of +8° to +12°.

Megestrol acetate may also be known as BDH-1298, compound 5071, megestroli acetas, NSC-71423, SC-10363. *Megace*® and *Ovaban*® are common trade names.

Storage/Stability
Store megestrol tablets in well-closed containers at a temperature of less than 40°C (104°F). Tablets may be crushed and administered with food; however, appropriate precautions are needed due to hazardous properties. The veterinary manufacturer recommends storing the tablets from 2°C to 30°C (36°F-86°F).

Compatibility/Compounding Considerations
Those who compound with this drug should wear appropriate PPE, as megestrol is classified as a hazardous drug.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:

Megestrol Acetate Oral Tablets: 20 mg; *Ovaban*®; (Rx). FDA-approved for use in dogs only. **NOTE**: This product is still listed in the FDA's Green Book of approved animal drugs but may no longer be marketed in the United States.

HUMAN-LABELED PRODUCTS:

Megestrol Acetate Tablets: 20 and 40 mg; *Megace*®, generic; (Rx)

Megestrol Acetate Oral Suspension: 40 mg/mL and 125 mg/mL; *Megace*®, *Megace ES*®, generic (40 mg/mL); (Rx)

Meglumine Antimoniate

(***meg***-loo-meen an-tih-***mohne***-ee-ate) *Glucantime*®

Antiprotozoal

Prescriber Highlights
- ► Used for treating leishmaniasis (with or without allopurinol) in dogs
- ► Not available in the United States
- ► Extreme caution (relatively contraindicated) in patients with cardiac, hepatic, or renal insufficiency
- ► Primary adverse effects noted in dogs with meglumine antimoniate are injection site reactions, lethargy, and GI effects (eg, inappetence, vomiting).
- ► Resistance to treatment has been reported.
- ► Treatment is prolonged, and the cost may be substantial.

Uses/Indications
Meglumine antimoniate is used to treat leishmaniasis in dogs, and combination therapy with allopurinol appears to be the treatment of choice for dogs with confirmed infection. It is available commercially in some Mediterranean and South American countries but not in the United States. The combination of meglumine antimoniate with allopurinol appears to have better clinical efficacy than a miltefosine/allopurinol combination.[1]

Meglumine antimoniate may be useful for treating feline leishmaniasis, but more evidence for safety and efficacy is needed before suggesting its use.

Liposomal formulations of meglumine antimoniate has been an active area of research,[2–4] but commercial dosage forms are not yet available.

Pharmacology/Actions
Pentavalent antimony compounds, such as meglumine antimoniate and sodium stibogluconate, selectively inhibit the leishmanial enzymes required for glycolytic and fatty acid oxidation. Pentavalent antimony compounds rarely are successful in completely eradicating *Leishmania* spp organisms in infected dogs. When used with allopurinol, synergy for treating leishmaniasis and reduced risk for antimonial drug-resistance development can occur.

Pharmacokinetics
After SC or IM injections in dogs, systemic bioavailability is ≈92%; the highest tissue concentrations are found in the liver, spleen, and skin. The elimination half-life is relatively short (≈2 hours when given SC). Within 9 hours of dosing, 80% of the antimony is excreted in the urine. Reduced renal function can cause increased antimoniate half-lives.

Contraindications/Precautions/Warnings
Hypersensitivity reactions have been reported in people, and any patient with the previous hypersensitivity to meglumine antimoniate or sulfites should not receive the drug.

Patients with renal, hepatic, or cardiac failure are more likely to develop serious adverse effects with this agent; weigh the potential risks vs benefits carefully before treating. Decreased renal function, in particular, may lead to drug accumulation and an increased risk for toxicity. In dogs with severe renal failure (IRIS stages III-IV), the correction of fluid and acid-base imbalances prior to treatment with allopurinol alone has been recommended.[5]

In humans, a protein-rich diet is required during treatment, and it is recommended to correct iron deficiencies prior to treatment.[6]

Adverse Effects
Primary adverse effects noted in dogs are injection site reactions (cutaneous abscesses/cellulitis), lethargy, and GI effects (inappetence,

vomiting). Transient increases in liver enzymes have been reported.[7]

Potentially, the drug may be nephrotoxic in dogs, but this is difficult to evaluate in clinically infected dogs as renal dysfunction is one of the likely consequences of the infection. A study done in healthy dogs showed diffuse proximal tubule cell vacuolization and multifocal areas with coagulative necrosis under light microscopy. Electron microscopy showed reduced organellar content, loss or attenuation of brush border, cellular detachment from the basement membrane, apical blebbing, and individual cell necrosis. The authors concluded that meglumine antimoniate caused severe tubular damage.[8] A small study in dogs with leishmaniosis found that meglumine antimoniate 50 mg/kg SC every 12 hours for 28 days had no effects on glomerular filtration rate or urine specific gravity; urine protein to creatinine ratio was reduced following treatment.[9]

In a study in 28 dogs with clinical disease treated with meglumine antimoniate (75 mg/kg every 12 hours for 60 days), when compared pre-treatment and posttreatment (day 60), significant changes in serum cardiac troponin I concentrations or corrected QT intervals were not found.[10]

Drug resistance may occur. After several courses of treatment, decreased sensitivity of *Leishmania infantum* to meglumine antimoniate or antimonials has been reported.[11]

In humans, increased serum lipase, amylase, creatinine, urea nitrogen, and increased QT interval on ECG have been reported. Occasionally, decreases in white blood cell counts and hemoglobin have been reported in humans. Other adverse effects in humans include dyspnea, skin rash, facial edema, abdominal pain, elevated liver enzymes, and, rarely, pancreatitis.

Reproductive/Nursing Safety

There is limited information available. Pregnant rats given up to 300 mg/kg on days 6 to 15 of gestation caused increased fetal resorptions and increased rates of abnormalities of the atlas bone. A case report of a bitch that received meglumine antimoniate during pregnancy has been published.[12] Pregnancy and delivery were deemed normal. Three puppies died within 2 days of delivery, but the 2 surviving puppies were followed clinically, serologically, and with real-time PCR until 1 year of age. Neither puppy had clinical or serological evidence of *L. infantum* despite *L. infantum* DNA evidence being found in the uterine tissue of the bitch. The authors concluded that meglumine antimoniate may have prevented vertical transmission of leishmaniasis.

It is unknown if the drug enters maternal milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No specific overdose information was located. Depending on the dosage, a single overdose could potentially cause renal, hepatic, pancreatic, and hematologic effects, but GI effects (vomiting) and lethargy would be the most likely outcomes. It is recommended to observe the patient and contact an animal poison control center for further guidance with an overdose situation.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving meglumine antimoniate and may be of significance in veterinary patients (dogs):

- **Agents That Can Prolong QT Interval** (eg, **tricyclic antidepressants, disopyramide, quinidine, procainamide**): Meglumine antimoniate may prolong QT interval further with increased risk for arrhythmias.
- **Other Potentially Nephrotoxic Drugs** (eg, **amphotericin B, aminoglycosides**): Avoid or use with caution in dogs with clinical leishmaniasis and kidney disease being treated with meglumine antimoniate.[13]

Laboratory Considerations

- No specific laboratory interactions or considerations were noted.

Dosages

DOGS:

Leishmaniasis (extra-label): 100 mg/kg SC once daily for 4 weeks[14–16] is the most commonly reported treatment regimen. However, because of the short half-life, giving meglumine antimoniate 50 – 75 mg/kg SC twice daily[10,16,17] for 4 to 8 weeks could be more effective. Combining it with allopurinol (10 mg/kg PO twice daily for at least 6 months) may yield a longer period of clinical remission than if treated with either drug alone.[1,10,18,19] The addition of deslorelin 4.7 mg SC implant to a combination of meglumine antimoniate 50 mg/kg SC twice daily for 28 days and allopurinol 10 mg/kg PO twice daily improved clinical signs and antibody levels beyond that observed ion dogs that only received meglumine antimoniate and allopurinol.[20]

Monitoring

- CBC (baseline and periodic)[14]
- Serum chemistry profile, including giver enzymes; renal function tests (serum creatinine, BUN); serum lipase and amylase (baseline and periodic)[14]
- Urinalysis (baseline and periodic), including urine protein:creatinine ratio[14]
- Antibody titer (controversial)

Client Information

- Clients should understand that treatment with this drug can be prolonged and expensive and that a cure (complete eradication) is unlikely.

Chemistry/Synonyms

Meglumine antimoniate is 1-Deoxy-1-methylamino-D-glucitol antimoniate. It has a molecular weight of 366. One gram contains ≈272 mg of antimony.

Meglumine antimoniate may also be known as meglumine antimonate, N-methylglucamine antimoniate, RP-2168, antimony meglumine, Protostib, 1-Deoxy-1-methylamino-D-glucitol antimoniate, *Glucantime*®, and *Glucantim*®. The chemical symbol for antimony is Sb.

Storage/Stability

Unless otherwise specified by the manufacturer, store commercially available ampules below 40°C (104°F), preferably between 15°C and 30°C (59°F and 86°F); protect from freezing. Check the solution for particles before use. If small particles are present, shake the vial well before use. If particles persist after shaking, do not use the product. Meglumine antimoniate may deteriorate with prolonged storage. Must be used immediately after opening.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None in the United States. May be available via the CDC, see: http://www.cdc.gov/laboratory/drug-service.html

HUMAN-LABELED PRODUCTS: NONE IN THE UNITED STATES

Meglumine antimoniate may be available in several countries, including Brazil, Venezuela, and Europe; trade names include *Glucantime®* and *Glucantim®*. Commercially, it is available as a solution containing 1.5 g of meglumine antimoniate (425 mg pentavalent antimony) per 5 mL.

Melarsomine

(mee-***lar***-soe-meen) *Diroban®, Immiticide®*

Arsenical Antiparasitic

Prescriber Highlights

- ► Organic arsenical adulticide for heartworm disease in dogs. American Heartworm Society recommends a 3-dose protocol (except for dogs with caval syndrome) that includes prior treatment with doxycycline and a macrocyclic lactone.
- ► Contraindications include caval syndrome; weigh risk versus benefits in pregnant, lactating, or breeding dogs. Reportedly toxic in cats; melarsomine is not currently recommended for use in this species.
- ► Many adverse effects are possible. The most common adverse effects are injection site reactions, coughing, gagging, depression/lethargy, anorexia/inappetence, excessive salivation, fever, lung congestion, vomiting, and pulmonary thromboembolism.
- ► Calculate dosages very carefully. Correct IM injection technique and site are required. Do not give IV or SC.
- ► Strict cage rest after treatment is essential.

Uses/Indications

Melarsomine is indicated for the treatment of stabilized class 1 (mild), class 2 (moderate), and class 3 (severe) heartworm disease caused by immature (4-month-old juvenile adults) to mature adult infections of *Dirofilaria immitis* in dogs.

The American Heartworm Society recommends that a 3-dose melarsomine protocol should be used. Prior to melarsomine treatment, it is recommended to administer doxycycline for 4 weeks concomitantly with a monthly macrocyclic lactone (at heartworm preventive doses) for 2 months. Doxycycline helps to reduce subsequent microfilaremia by eliminating *Wolbachia pipientis*, a bacterium associated with embryogenesis in *D immitis*.[1] The macrocyclic lactone prevents new infections and eliminates existing susceptible larvae.[2]

Although not optimal, if unexpected delays in melarsomine treatment occur, melarsomine injections should begin within 1 year after doxycycline therapy.[1] A heartworm preventive should be continued until melarsomine injections can begin. A delay of up to 6 months between the first and second melarsomine injection is considered acceptable as long as a heartworm preventive is continued; however, the second and third melarsomine injections ***must*** still be given within the recommended 24-hour timeframe.

Melarsomine is not recommended for use in cats.[3,4] Melarsomine may be useful for treating ferrets with adult heartworm infections.[5]

Pharmacology/Actions

Although melarsomine is an arsenical compound, its exact mechanism of action is not known. Both laboratory and field studies have demonstrated that melarsomine is 90% to 99% effective in killing adult and L_5 larvae of *Dirofilaria immitis* in dogs at recommended dosages. The 2-dose method kills only ≈90% of adult worms whereas the 3-dose method kills 98%.[2,6]

Pharmacokinetics

Melarsomine is reportedly rapidly absorbed after IM injection in dogs; time to peak plasma concentration is ≈11 minutes. The apparent volume of distribution is ≈0.7 L/kg. Terminal half-life is ≈3 hours.

Contraindications/Precautions/Warnings

Melarsomine is contraindicated in dogs with class 4 (caval syndrome) heartworm disease. Caval syndrome is when adult heartworms are present in the venae cavae and right atrium. Do **NOT** give melarsomine IV or SC as significant toxicity or tissue damage may occur.[6] Administer only by deep IM injection into the lumbar (L3-L5) epaxial muscles; do not administer at any other site. Dogs older than 8 years may be more susceptible to adverse effects than younger dogs.[6] Although all dogs with heartworm disease are at risk for posttreatment pulmonary thromboembolism, those with severe pulmonary artery disease are at increased risk for posttreatment morbidity and mortality.

It is imperative to strictly adhere to the manufacturer's instructions for administration. Exercise restriction during the recovery period is essential for minimizing cardiopulmonary complications.[2] Cage rest is recommended, beginning at the time of the first injection and continuing for 6 to 8 weeks after the last injection (10 to 12 weeks total).[2] The cage rest should occur where the animal can be observed and kept calm (eg, veterinary clinic, at home). If cage rest and observation are not possible, owners should be advised that, unless the patient's exercise is restricted, thromboembolic events are more likely and can be fatal.

Melarsomine is reportedly very toxic to cats; it is currently not recommended in this species.[4]

Because of the seriousness of heartworm infection and the potential for morbidity and mortality associated with treatment, consider requiring clients to give informed consent before electing to treat the patient.

Avoid drug contact with animal's eyes; if exposed, wash with copious amounts of water. Avoid human exposure. Wash hands after use or wear gloves when administering the drug. If human exposure occurs, contact a physician.[6]

Adverse Effects

Approximately ⅓ of dogs show signs of injection site reactions (pain, swelling, tenderness, reluctance to move) after receiving melarsomine, typically occurring within the first week after injection. This can be minimized by ensuring the injection is deposited deep into the belly of the epaxial musculature, with a needle newly changed after the drug is drawn into the syringe and that is an appropriate length and gauge for the size of dog and body condition. Most injection site signs resolve within weeks, but, rarely, severe injection reactions can occur. Firm nodules at the injection site could persist indefinitely.[6] The most severe local reactions are usually seen if the drug leaks back from the injection site into subcutaneous tissues. Applying firm pressure to the injection site for 1 to 2 minutes after administration may reduce the risk for this problem.

Creatine kinase (CK) elevations, up to 25-fold, and AST, up to 7-fold, were noted to be related to muscle damage at sites of injection; 2-fold elevations in ALT were also seen.[6] In a separate study, elevations of CK and AST of the same magnitude were observed within 8 hours of injection. These values approached pretest measurements by 72 hours and diminished to within the normal range by 1 month postinjection.[6]

Other reactions reported in 5% or more of treated dogs included coughing/gagging (22%), depression/lethargy (15%), anorexia/inappetence (13%), fever (7%), lung congestion (6%), and vomiting (5%). There is significant interpatient variance in both the date of onset and duration for the above effects. Dogs may also exhibit excessive salivation after dosing. Coughing may be exacerbated by the lack of exercise restriction.[7]

There are many other adverse effects in dogs with reported incidences less than 3%, including paresis and paralysis. Refer to the product label for further details.[6]

Animals not exhibiting adverse effects after the first dose or course may demonstrate them after the second dose or course.

Reproductive/Nursing Safety

Safety has not been established for use in pregnant, lactating, or breeding dogs. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

There is a low margin of safety with melarsomine dosages. At 7.5 mg/kg (3 times the recommended dose) in healthy dogs, melarsomine has demonstrated respiratory inflammation and distress, excessive salivation, restlessness, panting, vomiting, edema, tremors, lethargy, ataxia, cyanosis, stupor, and death. Signs of diarrhea, excessive salivation, restlessness, panting, vomiting, and fever have been noted in infected dogs that have received inadvertent overdoses (2 times the recommended dose).

Treatment with dimercaprol (BAL in Oil) may be considered to treat melarsomine overdoses; however, clinical efficacy of melarsomine may be reduced.[6]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The manufacturer reports that during clinical field trials, melarsomine was given to dogs receiving anti-inflammatory agents, antibiotics, insecticides, heartworm prophylactic medications, and various other drugs commonly used to stabilize and support dogs with heartworm disease and that no adverse drug interactions were noted.

- **Aspirin**: Has been shown not to reduce adverse effects and may complicate therapy; use is not recommended.
- **CNS Depressant Drugs**: Drugs that have similar adverse effects (eg, depression caused by CNS depressant) may cause additive adverse effects or increase their incidence when used with melarsomine.

Laboratory Considerations

None noted

Dosages

CAUTION: **Because of the low margin of safety, calculate dosages very carefully.**

DOGS:

Refer to the most recent guidelines published by the American Heartworm Society at **www.heartwormsociety.org** for more information.

Treatment of heartworm disease (label dosage; FDA-approved): After diagnosis, determine the class (stage) of the disease. **NOTE**: The manufacturer provides worksheets that assist in determining the classification and treatment regimen. It is highly recommended to use these treatment records to avoid confusion and to document therapy. Recommended needle size for dogs 10 kg (22 lb) or less = 23 gauge x 1 inch; 10 kg (22 lb) or more = 22 gauge x 1.5 inch.

a) *Class 1 and 2*: melarsomine 2.5 mg/kg deep IM in the lumbar (L3-L5) epaxial muscles twice, 24 hours apart.[6] Use alternating sides with each administration. Based on response, the regimen may be repeated 4 months following the first treatment (2-dose protocol). **NOTE**: The 2-dose protocol is not recommended by the American Heartworm Society.

b) *Class 3 using the alternate dosing regimen*: In stabilized dogs, melarsomine 2.5 mg/kg deep IM once in the lumbar (L3-L5) epaxial muscles. One month later, give 2.5 mg/kg deep IM deep IM in the lumbar (L3-L5) epaxial muscles twice, 24 hours apart (3-dose protocol).[6]

Treatment of heartworm disease in both clinical (not caval syndrome) and subclinical dogs using the 3-dose protocol (extra-label): The American Heartworm Society (AHS) has a detailed management program table (including diagnostic, nursing, and monitoring guidelines) that can be accessed at **www.heartwormsociety.org**; the following is a summary.

1. Prior to melarsomine use, administer a macrocyclic lactone (eg, ivermectin, milbemycin, moxidectin, selamectin) at heartworm preventive doses for 2 months prior to melarsomine treatment (ie, Days 1, 30, 60) and doxycycline 10 mg/kg PO twice daily for 4 weeks (Days 1 to 28).[2] **NOTE**: Minocycline may be substituted for doxycycline, at the same dosage, but doxycycline is the antibiotic of choice.
   a) Dogs with clinical signs associated with the infection should begin treatment (Day 0) with oral prednisone 0.5 mg/kg twice daily for the first week, then 0.5 mg/kg once daily for the second week, followed by 0.5 mg/kg every other day for the third and fourth weeks.
   b) Dogs with microfilariae detected during the initial workup, should be treated (Day 1) with an antihistamine and a glucocorticoid (if not already on prednisone) to reduce the risk for anaphylaxis from macrocyclic lactone treatment.
2. Melarsomine 2.5 mg/kg deep IM in the lumbar (L3-L5) epaxial muscles on Day 61, followed by 2 doses of melarsomine 2.5 mg/kg deep IM in the lumbar (L3-L5) epaxial muscles administered 24 hours apart on Days 90 and 91.
3. To reduce the risk for thromboembolism after melarsomine treatment is started, a glucocorticoid should be used in dogs that are in highly endemic areas for heartworm, where they are more likely to have significant worm burdens. On days 61 and 90, begin oral prednisone 0.5 mg/kg twice daily for the first week, then 0.5 mg/kg once daily for the second week, followed by 0.5 mg/kg every other day for the third and fourth weeks.
4. Strict cage rest/confinement is required at the time of the first melarsomine injection and continuing for 6 to 8 weeks after the last melarsomine injection (10 to 12 weeks total).[2]

Abbreviated treatment of heartworm disease in clinical (not caval syndrome) and subclinical dogs (extra-label): On Day 0, ivermectin 6 **µg**/kg PO every 30 days ongoing, and doxycycline 10 mg/kg PO twice daily for 30 days. Melarsomine 2.5 mg/kg IM was administered on Days 30, 60, and 61. On Days 90 and 240, all dogs (n = 76) were confirmed to be free of microfilaria, and circulating antigen was not detected.[8] **NOTE**: This study was performed in a geographic region where *Dirofilaria immitis* is hyperendemic; protocol is not recommended by the American Heartworm Society, but current data about the susceptibility gap[9] support this shortened protocol.

Monitoring

- Adverse effects including signs of thromboembolism (eg, low-grade fever, cough, hemoptysis, exacerbation of right-sided heart failure)
- Cardiac biomarkers (cardiac troponin I, MB isoenzyme of creatine kinase, myoglobin) may be useful to monitor the effects of worms and adulticide treatment on the heart, but additional research is necessary to confirm utility and application.[10,11]
- Clinical efficacy

- Microfilaria testing: Test 30 days after last melarsomine dose (Day 120 of the American Heartworm Society 3-dose protocol)
- Antigen test: Test 9 months after last melarsomine dose (Day 365 of the American Heartworm Society 3-dose protocol)

Client Information

- Strict exercise restriction after dosing with melarsomine is required. Follow your veterinarian's instructions closely.
- Your veterinarian will need to monitor your dog closely before, during, and after treatment. Do not miss these important follow-up visits.

Chemistry/Synonyms

An organic trivalent arsenical compound, melarsomine dihydrochloride has a molecular weight of 501 and is freely soluble in water.

Melarsomine may also be known as Cymelarsan, *Diroban®*, or *Immiticide®*. Its CAS registry is 128470-15-5.

Storage/Stability

The powder should be stored upright at room temperature (15°C-25°C [59°F-77°F]). Once reconstituted, the solution should be kept in the original container and kept protected from light and refrigerated for up to 24 hours. Do not freeze. Do not mix with any other drug.

Compatibility/Compounding Considerations

Reconstitute with 2 mL of the diluent provided (sterile water for injection) with a resultant concentration of 25 mg/mL.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Melarsomine Dihydrochloride Powder for Injection: 50 mg/vial; *Immiticide®*, *Diroban®*; (Rx). FDA-approved for use in dogs

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Melatonin

(mel-ah-***tone***-in) *PrimeX®, Regulin®*

Hormone, Nutraceutical

Prescriber Highlights

- ► Oral and implantable pineal gland hormone
- ► FDA-approved to accelerate the fur priming cycle in mink. Other potential uses include as a reversible estrus suppression agent in cats; treatment of nonpruritic alopecia in dogs; treatment of sleep and behavior disorders in cats and dogs; adjusting seasonally controlled fertility in horses, sheep, and goats; and as adjunctive treatment for adrenal disease in ferrets.
- ► Adverse effects appear to be minimal; however, there are few data available for its use in veterinary medicine.
- ► Potential contraindications include pregnancy and liver dysfunction.

Uses/Indications

The only FDA-approved indication for melatonin is for SC implants in healthy male and female kits and adult female mink (*Mustela vison*) to accelerate the fur priming cycle. Although published evidence is weak to support clinical use of melatonin in animals, it has been proposed for many purposes. Many clinicians will use melatonin on a trial basis because the potential for adverse effects is very low.

In dogs, melatonin has been used anecdotally to treat alopecia-X in Nordic breeds (eg, Norwegian elkhound), canine pattern baldness, or canine recurrent flank alopecia, postclipping alopecia, and various follicular disorders such as follicular dysplasia.[1] The efficacy of melatonin on hair regrowth in dogs is variable and no published studies demonstrating efficacy were located; therefore, every effort to identify the underlying cause of alopecia should be made before starting therapy.[1] Melatonin has also been used for the treatment of sleep cycle disorders, cognitive dysfunction syndrome, idiopathic vacuolar hepatopathy,[2] phobias, and anxiety. Melatonin may have possible usefulness in reduction of anesthetic requirements[3] and postoperative phacoemulsification complications[4], promotion of sleep in hospitalized patients,[5] and for adjunctive treatment of canine mammary tumors,[6] hyperadrenocorticism,[7] and immune-mediated hemolytic anemia,[8] although clinical trials demonstrating efficacy for these indications are lacking.

In cats, melatonin has been used for the treatment of sleep cycle disorders. In queens, melatonin implants prolong the interestrus period by ≈60 to 120 days when they are placed during anovulatory interestrus.[9] In male cats, a melatonin implant reversibly reduced (but did not eliminate) sperm quantity and quality in male domestic cats for ≈120 days; spermatogenesis returned to baseline ≈140 days after implant.[10] The clinical utility of this finding in male cats is unclear.

Melatonin has been suggested for treating seasonal headshaking syndrome in horses.[11,12]

Supplementation of melatonin to the diets fed to late-gestation Holstein heifers resulted in calves with increased body weight and height at 8 weeks compared with the control group.[13]

In sheep and goats (and potentially in horses), melatonin implants are used to improve early breeding and ovulation rates.[14,15] Melatonin implants improved cashmere production and quality in adult goats.[16]

In ferrets, melatonin is widely used and appears to be effective in alleviating clinical signs associated with adrenal neoplasia, including alopecia, aggressive behavior, vulvar swelling, and prostatomegaly; however, it does not appear to alter tumor growth.[17]

Pharmacology/Actions

Melatonin is a tryptophan derivative. It is involved with the neuroendocrine control of photoperiod-dependent molting, hair growth, and pelage color. Melatonin stimulates winter coat growth and spring shedding occurs when melatonin decreases. The mechanism of how melatonin induces these effects is not well understood; however, it may be related to modulation of sex hormone concentrations, interference with cortisol production, blockage of estrogen receptors at the hair follicle concentration, or deficiency of melatonin. Melatonin may have direct effects on the hair follicle or alter the secretion of prolactin and/or melanocyte-stimulating hormone. In addition, melatonin's antiestrogenic properties seem to play an important role in tumor growth inhibition by reducing the mitogenic response in estrogen-dependent tumor cells.[6] Melatonin also increases serum prolactin concentrations, growth hormone, and the response to growth hormone-releasing hormone. Long-term use of melatonin may decrease luteinizing hormone concentrations. Melatonin is also ostensibly a free radical scavenger.

Pharmacokinetics

In cats, the calculated circulating shelf-life of orally administered melatonin was 45 minutes.[18]

In humans, melatonin has a short half-life (20-50 minutes); plasma concentrations return to baseline within 24 hours of a dose even after long-term dosing of less than 10 mg/day.

Contraindications/Precautions/Warnings

Melatonin is contraindicated in patients that are hypersensitive to it. Use melatonin implants cautiously in sexually immature animals. There are very specific times for melatonin administration, depending on indication for use, latitude, hemisphere, species, and breed. Animals that are pregnant or nursing may not benefit from implant therapy.[15]

In humans, melatonin is considered contraindicated in patients with hepatic insufficiency as it is cleared by the liver and should be used with caution in patients with renal impairment. Because of its CNS depressant qualities, caution is advised when using melatonin in patients with a history of cerebrovascular disease, depression, or neurologic disorders.

Adverse Effects

Melatonin appears to be quite safe in dogs and cats. Adverse effects in dogs are rare when melatonin is administered orally; it may cause sedation and affect sex hormone secretion and fertility. SC implants in dogs have been associated with sterile abscesses.

Adverse effects in ferrets are not commonly reported. Weight gain and/or lethargy could occur.

Adverse effects reported in humans include altered sleep patterns, hypothermia, sedation, tachycardia, confusion, headache, and pruritus. Increased blood glucose concentration has been reported, but the veterinary significance of this finding is unknown.[19]

Reproductive/Nursing Safety

Melatonin appears to cross the placenta. There are conflicting data from studies in rats: one study reported an inhibitory effect on the neuroendocrine reproductive axis in the offspring of pregnant rats that received 2.5 mg/kg SC daily throughout pregnancy, whereas another study using doses up to 200 mg/kg/day observed no maternal or fetal toxicity.[20] The melatonin implant labeled for mink states not to use it in breeding stock.[21]

Melatonin is excreted in breast milk; effects on nursing offspring are unknown. Melatonin implants in lactating cashmere goats had no impact on hair follicle development in the kids.[16]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Little information is available; however, melatonin is unlikely to cause significant morbidity after a single oral overdose.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving melatonin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Benzodiazepines**: Melatonin may potentiate the effects of benzodiazepines.
- **Cimetidine**: May increase melatonin concentration
- **Succinylcholine**: Melatonin may potentiate the effects of succinylcholine.
- **Warfarin**: May increase risk for bleeding

Laboratory Considerations

- Melatonin can reduce **cortisol, progesterone,** and **estradiol** concentrations.[22]
- Melatonin can decrease total T_3 and total T_4 concentrations in dogs; free T_3 and free T_4 are not affected.[23]

Dosages

DOGS:

Dermatologic conditions such as alopecia-X in Nordic breeds, canine pattern baldness, postclipping alopecia, various follicular disorders such as follicular dysplasia, color dilution alopecia, recurrent or seasonal flank alopecia (extra-label):

- Oral formulations: Treat for at least 2 months for canine seasonal flank alopecia and 4 months for alopecia X to evaluate for maximal response.[1]
  a) 3 – 12 mg/dog (NOT mg/kg) PO 2 to 3 times daily, depending on the dog's size[1,24]
  b) Alternatively, 1 mg/kg/day PO *divided* into 2 or 3 doses
- SC Implant doses are based on dog's size according to the table below.[1] Re-treatment may be necessary 1 to 2 times a year.

Body weight in kg (lb)	Amount of melatonin (mg)/implant	Number of implants to insert
Less than 9 (19.8)	8	1
9-18 (19.8-39.9)	12	1
More than 18 (39.9)	18	1

Sleep disorders (eg, **nocturnal activity), phobias** (extra-label): 0.1 mg/kg PO 1 to 3 times daily initially.[5] Practically, round dose up to the nearest 1 mg/dog (NOT mg/kg). A single dose from 1 – 9 mg/dog (NOT mg/kg), depending on dog's size ≈30 minutes before bedtime may be sufficient to help with night waking.

Stressful situations (extra-label):

a. **Pre-appointment calming**: Administered by body weight according to table below. As part of the "chill" protocol, give at least 2 hours prior to stressful event and use in combination with buccal (OTM) acepromazine and oral gabapentin ± trazodone.

Body weight in kg	Amount of melatonin to administer (mg/dog [NOT mg/kg])
Less than 5	1
5-15	1.5
15-50	3
More than 50	5

b. **Preoperative calming**: 5 mg/kg PO 2 hours prior to surgery. In dogs subjectively considered "trustful," melatonin reduced propofol requirements for anesthesia induction and endotracheal tube placement.[3]

Idiopathic vacuolar hepatopathy (extra-label): 3 mg/dog (NOT mg/kg) PO every 12 hours. Dogs over 15 kg (33.1 lb) may require a higher dose.[2]

CATS:

Sleep disorders | nocturnal activity (extra-label): Practically, 1.5 – 6 mg/cat (NOT mg/kg) PO before bedtime. Alternatively, 3 – 12 mg/cat (NOT mg/kg) PO every 12 to 24 hours[5]

Suppression of estrus (extra-label): 18 mg/cat (NOT mg/kg) implant administered SC suppressed estrus for 2 to 4 months.[9,25] Alternatively, 4 – 30 mg/cat (NOT mg/kg) PO once daily [9,18,26]

HORSES

Headshaking syndrome for seasonal headshakers that begin in spring and stop in late fall or winter (extra-label): Starting November 1 (Northern hemisphere), give 12 – 15 mg/horse (NOT mg/kg) PO once daily between 5 and 6 PM (1700 to 1800).[27,28] Administer this dose all year round; horse may not shed and may need body clipping.

SHEEP:

Stimulate early onset of reproductive activity in sexually mature ewes (extra-label): 18 mg/sheep (NOT mg/kg) implant administered SC near the base of ear 30 to 40 days prior to the

selected joining date.[15] Follow label instructions for breed-based time of year to administer and guidance on separating ewes and rams.

GOATS:

Stimulate testosterone secretion in bucks during nonbreeding season (extra-label): Following 2.5 months of long days, two 18 mg implants (36 mg total dose) administered SC near the base of ears resulted in higher peak testosterone concentrations, which occurred 2 months earlier than in the control group.[29]

FERRETS:

Adjunctive treatment of adrenal disease to help control clinical signs (extra-label):

a) Oral formulations: Anecdotally, 0.5 – 1 mg/ferret (NOT mg/kg) PO once daily 7 to 9 hours after sunrise[17,30]

b) Implant dosages: 2.7 mg/ferret (NOT mg/kg [under 600 g body weight]) or 5.4 mg/ferret (NOT mg/kg [over 600 g body weight]) SC every 3 to 4 months

MINK:

Accelerate fur priming cycle (label dosage; FDA-approved): 2.7 mg/mink (NOT mg/kg) implanted SC[21]

Monitoring

- Clinical efficacy (eg, depending on indication: hair regrowth, estrus suppression, improvement in sleep/unwanted behaviors)
- Adverse effects (eg, sedation, lethargy, weight gain, sterile abscesses [implants only])

Client Information

- For treatment of hair loss, efficacy of melatonin varies. A 4-month trial is necessary to see if the treatment is beneficial.
- The oral medicine may be given with or without food.
- This medicine is usually well tolerated; sleepiness may occur.

Chemistry/Synonyms

Melatonin is a naturally occurring hormone produced in the pineal gland. It occurs as a white to pale yellow, crystalline solid that is slightly soluble in water and has a molecular weight of 232. It can be derived from natural sources or by synthetic means.

Melatonin may also be known as n-acetyl-5-methoxytryptamine, MEL, MLT, or pineal hormone.

Storage/Stability

Unless otherwise labeled, store at room temperature in tight containers.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Melatonin implant 2.7 mg; *PrimeX*®; (OTC). FDA-approved for use in mink. NADA# 140-846. Although this product is still listed in FDA's Green Book of approved animal drugs, marketing status is uncertain.

The following products are marketed for ferret and dog use. Their FDA approval status is not known, and they are not listed in FDA's Green Book of approved animal drugs.

Melatonin Implant 2.7 mg and 5.4 mg; *Ferretonin*®; (OTC); marketed for ferrets

Melatonin Implant 8 mg, 12 mg, 18 mg, and 24 mg; *Dermatonin*®; (OTC); marketed for dogs, cats, sheep, goats, skunk, cattle, and horses.

An 18 mg implant for sustained SC release is available in a variety of countries. One trade name is *Regulin*®. It is labeled for use in sheep (UK and AUS/NZ) and goats (AUS/NZ) to improve early breeding and ovulation rates.

HUMAN-LABELED PRODUCTS:

Melatonin Capsules, Tablets, Chewable Tablets, Disintegrating Oral Tablets, Gummies, Extended-Release Tablets, Sublingual Tablets: 0.2 – 20 mg, although 1 – 10 mg are most common; (OTC). Because melatonin is considered a "nutraceutical," there is no official labeling or central quality control systems for it in the US. Purchase from reputable sources.

Melatonin Oral Solution: 0.25 mg/mL, 0.33 mg/mL, and 1 mg/mL; generic; (OTC)

Meloxicam

(mel-***ox***-i-kam) *Metacam*®

Nonsteroidal Anti-Inflammatory Drug (NSAID)

Prescriber Highlights

- ► COX-2–preferential NSAID used in many species
- ► Long-term use in cats is controversial.
- ► Available as both injectable and oral products
- ► Primary adverse effects are GI- and renal-related, but idiosyncratic hepatotoxicity has occurred in dogs (rare).

Uses/Indications

Meloxicam is FDA-approved for the treatment of pain, inflammation, and osteoarthritis in dogs.[1,2] Short-term use (eg, single-dose injectable, administered before surgery) of meloxicam is also FDA-approved in the United States in cats to control postoperative pain and inflammation associated with orthopedic surgery, ovariohysterectomy, and castration.[3] Meloxicam is licensed in several countries for long-term use (at lower doses) in cats.

Oral meloxicam may be a cost-effective agent for use during painful procedures such as castration or dehorning in calves[4]; however, meloxicam administration in calves prior to transportation did not affect movement or feeding or drinking behaviors[5] and did not mitigate leukocyte function or inflammatory markers.[6]

Metronomic cyclophosphamide and meloxicam successfully managed oral squamous cell carcinoma in a horse.[7]

Pharmacology/Actions

Like other NSAIDs, meloxicam exhibits analgesic, anti-inflammatory, and antipyretic activity, most likely through its inhibition of cyclooxygenase (COX) and prostaglandin synthesis. Meloxicam is considered COX-2 preferential (not COX-2 specific) because at higher doses, its COX-2 specificity is diminished.

Pharmacokinetics

In dogs, meloxicam is almost completely absorbed after PO and SC administration. The oral transmucosal spray product (not currently marketed in the United States) is bioequivalent to the canine-approved oral suspension.[8] Peak blood concentrations occur ≈4 to 8 hours after oral administration and 2.5 hours after SC administration.[1,3,9,10] The volume of distribution in dogs is 0.3 L/kg and ≈97% is bound to plasma proteins. Meloxicam is extensively biotransformed to several different metabolites in the liver; none of these appear to have pharmacologic activity. The majority of these metabolites (and unchanged drug) are eliminated in the feces. A significant amount of enterohepatic recirculation occurs. Elimination half-life is species-specific. The elimination half-life in dogs averages 24 hours (range, 12 to 36 hours).

In cats, SC injection is nearly completely absorbed. Peak concentrations occur ≈1.5 hours after injection. Meloxicam is relatively highly bound to feline plasma proteins (97%), and volume of distribution is ≈0.27 L/kg. After a single dose, total systemic clearance is

≈130 mL/hour/kg, and elimination half-life is ≈15 hours. The major pathway for biotransformation is oxidation, and the major elimination route is fecal.

In horses, oral meloxicam tablets appear to be well absorbed, regardless of feeding status.[11] Elimination half-life in horses given 0.6 mg/kg IV toward the end of laparotomy for colic syndrome was 6.9 hours[12] and 5 hours in horses given 0.6 mg/kg PO once daily for 14 days.[13] Absorption was similar in foals younger than 6 weeks of age, but elimination half-life was 2.5 hours.[14]

In ruminant calves (≈3 months of age), meloxicam 1 mg/kg PO was well absorbed and had an elimination half-life of ≈24 hours.[4] Half-life was 25.7 hours in 4- to 6-month-old beef calves given 0.5 mg/kg PO every 24 hours for 4 days, and meloxicam tissue concentrations were below the concentration of quantification 15 days after treatment.[15] In 6-month-old Holstein steers given 1 mg/kg PO, the terminal half-life was 16.7 hours, and mean residence time (MRT) was 34 hours.[16] In adult cows given a single 1 mg/kg PO dose, elimination half-life was 10 to 13 hours.[15,17] MRT was 30.3 hours in postpartum cows as compared with 22.3 hours in mid-lactation cows. Meloxicam was detected in the milk of postpartum cows up to 144 hours after administration, as compared with 96 hours in mid-lactation cows, and the authors suggest that a 96-hour milk withdrawal period may be insufficient in postpartum cows to avoid a violative residue.[18]

In lactating goats, meloxicam 0.5 mg/kg IM was completely absorbed, and elimination half-life was 10.8 hours.[19] Administration once every 24 hours was predicted to provide an analgesic plasma concentration. Meloxicam was quantifiable in milk up to 48 hours after IM administration.

Elimination half-life was 15.4 hours in healthy sheep given 0.5 mg/kg IV or 1 mg/kg PO; oral bioavailability was 72%, and time to peak concentration was 19 hours.[20]

Meloxicam was well absorbed (bioavailability, ≈90%) in mature swine given 0.5 mg/kg IV and PO, and elimination half-life was ≈6 hours.[21]

In African gray parrots given 1 mg/kg IV, IM, and PO as a single dose, peak drug concentrations were reached 30 minutes and 13 hours after IM and PO administration, respectively. Bioavailability was 78% (IM) and 38% (PO) as compared with IV administration. Elimination half-life with IV administration was 31 hours.[22] Plasma accumulation ratios of 2 (IM) and 2.4 (PO) were noted with meloxicam dosages of 1 mg/kg PO or IM every 24 hours for 7 (IM) or 12 (PO) days.[23] In Hispaniolan parrots, peak meloxicam concentration occurred at 15 minutes, with 100% bioavailability after IM administration, while peak concentrations occurred 6 hours after oral administration with 50% to 75% bioavailability. Elimination half-life was ≈15 hours regardless of the route of administration.[24]

In healthy white leghorn hens, a single dose of meloxicam 1 mg/kg PO produced peak concentrations after 2 hours, and the plasma elimination half-life was 2.8 hours. Meloxicam was not detected after 4 days in egg whites and after 8 days in egg yolks.[25]

Contraindications/Precautions/Warnings

Meloxicam is contraindicated in animals that are hypersensitive to it. The European and United Kingdom labels state that safe use has not been evaluated in dogs younger than 6 weeks of age[9,10]; the United States FDA label states that safe use has not been established in dogs younger than 6 months of age.[1] The drug should not be used or should be used with extreme caution in dogs with active GI ulceration or bleeding or in dogs receiving glucocorticoids.[10,26] To avoid accidental overdosing, dogs weighing less than 4.5 kg (10 lb) should have meloxicam doses carefully measured and applied on food only, never directly into the mouth.[2]

Meloxicam, like all NSAIDs, should be used with caution in animals with impaired hepatic, cardiac, or renal function and animals with hemorrhagic disorders. Hypotension, high doses, hypovolemia, sodium depletion, and inhalant anesthesia all appear to increase risk for NSAID renal toxicity.[27]

Concurrent use with other anti-inflammatory drugs may result in additional or increased adverse effects; therefore, a treatment-free period from all other anti-inflammatories should be observed for at least 24 hours before beginning treatment with meloxicam. The treatment-free period, however, should take into account the pharmacokinetic properties of the products used previously. Use meloxicam under strict veterinary monitoring in animals with a risk for GI ulcers, or if the animal previously displayed intolerance to other NSAIDs.

The manufacturer warns that additional doses of meloxicam or other NSAIDs are contraindicated in cats, as no safe dose for repeated NSAID administration has been established, and the United States product labels contain a boxed warning stating that repeated use of meloxicam in cats has been associated with acute renal failure and death.[3] Safe use in cats younger than 4 months of age has not been established. Preoperative use in cats undergoing major surgery, in which hypotensive episodes are possible, may result in a higher risk for renal damage.

The human label states that no dose adjustment is necessary in patients with mild to moderate hepatic or renal impairment.

The veterinary oral suspension comes with a dosing syringe that is marked in pounds. If providing dosing directions in mL, make sure to supply an appropriately marked dosing syringe.

Adverse Effects

Experience in Europe and Canada has demonstrated a relatively safe adverse effect profile for meloxicam at labeled doses in healthy dogs.[26] GI distress is the most commonly reported adverse effect, and in United States field trials, vomiting, soft stools, diarrhea, and inappetence were the most common adverse effects. Renal toxicity appears to be quite low in animals with normal renal blood flow. Adverse effects reported postapproval have included GI effects (eg, vomiting, anorexia, diarrhea, melena, ulceration), elevated liver enzymes/hepatotoxicity, pruritus, azotemia, elevated creatinine, and renal failure. When NSAIDs are used long term in dogs, gastroprotectant drugs (eg, proton pump inhibitors [PPIs], H_2 blockers, misoprostol) have been used in an attempt to prevent or limit GI adverse effects, but the benefits of these drugs have not been proven.[28]

Like other COX-2 NSAIDs, meloxicam may have effects on platelet function, although no effect was demonstrated in healthy dogs in a small study.[29] A case report of a dog developing vasculitis with ulcers, vesicles, and erosions has been published.[30] In cats, single doses of meloxicam appear relatively safe. In field trials, some cats developed elevated BUN, posttreatment anemia, and residual pain at the injection site (rare). In other studies, meloxicam has caused GI effects (eg, vomiting, diarrhea, inappetence), behavior changes, and lethargy. Repeated use of meloxicam in cats is controversial, as repeated doses have been associated with renal failure and death. The FDA warns against repeated doses in cats; however, low-dose long-term use is licensed in some countries, and guidelines for long-term NSAID use in cats suggest the benefits of treatment often outweigh the risks.[31]

Acute dosing studies in dogs have not demonstrated any hepatic toxicity.[1,3] Administration to piglets for ≈2 months demonstrated no adverse effects on trabecular bone or growth plates.[32]

Meloxicam is relatively safe in other species (eg, horses, cattle, camelids, swine, rabbits, small ruminants) when used at recommended doses.

Reproductive/Nursing Safety

Safe use has not been established in dogs or cats used for breeding

or in pregnant or lactating animals. Meloxicam had a positive effect on pregnancy rates after embryo transfer in heifers.[33,34] Meloxicam reduced deslorelin-induced ovulation and induced intrafollicular hemorrhage and luteinization of anovulatory follicles in mares.[35]

Most NSAIDs are excreted in milk. Because safety has not been established, this drug should only be used when the maternal benefits outweigh the potential fetal risks.

Overdose/Acute Toxicity

GI effects (eg, vomiting, diarrhea) and renomegaly with minimal degeneration and necrosis were noted in dogs given 3 and 5 times the label dosage during 6-week safety studies. Overdoses should be treated supportively based on clinical signs. Therapeutic plasma exchange was successful in the overdose management of one dog.[36]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center that specializes in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

In humans, meloxicam is a CYP2C9 substrate. The following drug interactions have either been reported or are theoretical in humans or animals receiving meloxicam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**): NSAIDs can reduce effects on blood pressure.
- **Amiodarone**: May increase meloxicam concentrations
- **Amlodipine**: Some NSAIDs can reduce effects on blood pressure.
- **Anesthetics, Inhalant** (eg, **isoflurane, sevoflurane**): May increase risk for renal hypotension and NSAID renal toxicity
- **Angiotensin-II Receptor Blockers** (**ARBs**; eg, **telmisartan**): Some NSAIDs can reduce effects on blood pressure.
- **Anticoagulants** (eg, **heparins, rivaroxaban, warfarin**): Increased chance for bleeding
- **Bisphosphonates** (eg, **alendronate**): May increase risk for GI ulceration
- **Clopidogrel**: Increased chance for bleeding
- **Corticosteroids** (eg, **dexamethasone**, **prednis(ol)one**): May increase risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea); avoid use with NSAIDs
- **Cyclosporine** (**systemic**): Concurrent use may result in increased risk for cyclosporine nephrotoxicity.
- **Digoxin**: NSAIDs may increase serum concentrations.
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Concurrent use may result in reduced diuretic efficacy and possible nephrotoxicity.
- **Fluconazole**: Administration has increased plasma concentrations of celecoxib in humans and could also affect meloxicam concentrations in dogs.
- **Fluoroquinolones** (eg, **enrofloxacin, marbofloxacin**): Meloxicam may increase fluoroquinolone concentrations, increasing risk for CNS toxicity.
- **Leflunomide**: May increase meloxicam exposure; risk for leflunomide hepatotoxicity may be increased
- **Methotrexate**: Concomitant NSAID use with methotrexate may increase risk for myelosuppression, nephropathy, hepatotoxicity, and GI toxicity; use together with extreme caution.
- **Nephrotoxic Drugs** (eg, **aminoglycosides, amphotericin B, furosemide**): May enhance risk for nephrotoxicity
- **NSAIDs** (eg, **carprofen**): May increase risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea)
- **Pentoxifylline**: May increase risk for bleeding
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**): Concurrent use may increase risk for GI toxicity and bleeding.
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine**): Concurrent use may result in an increased risk for bleeding.
- **Sulfonamides** (eg, **sulfamethoxazole**): May inhibit meloxicam metabolism, increasing meloxicam exposure and risk for toxicity
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Concurrent use may increase risk for bleeding.

Dosages

When doses are listed in drops, use with caution; drug concentration per drop may be different in products marketed in different countries.

DOGS:

Control of pain and inflammation associated with osteoarthritis (label dosage; FDA-approved): 0.2 mg/kg PO, IV, or SC on the first day of treatment; subsequent doses of 0.1 mg/kg PO every 24 hours.[1–3] For dogs weighing less than 4.5 kg (10 lb), administer drops on food only, never directly into the mouth; for dogs weighing more than 4.5 kg (10 lb), drops can be placed in food or directly into the mouth. Consult product labels for additional oral dosing instructions for dogs weighing less than 2.3 kg (5 lb).[2] Use the lowest effective dose for the shortest duration consistent with individual response.

CATS:

Control of postoperative pain and inflammation associated with orthopedic surgery, ovariohysterectomy, and castration (label dosage; FDA-approved): 0.3 mg/kg SC once; should not be followed by additional doses of meloxicam or other NSAIDs.[3]

NOTE: The following dosages for cats are extra-label in the United States, and in 2010, the drug sponsor and the FDA issued the following: *WARNING: Repeated use of meloxicam in cats has been associated with acute renal failure and death. Do not administer additional doses of injectable or oral meloxicam to cats.*[1] See ***Contraindications/Precautions/Warnings***. However, the ISFM and AAFP Consensus Guidelines: Long-Term Use of NSAIDs in Cats include the following statements:

It is only recently that NSAIDs have become licensed for long-term use in cats in some countries. The panel believe that these drugs have a major role to play in the management of chronic pain in cats, but at present only limited feline-specific data are available. To date published studies of the medium- to long-term use of the COX-1 sparing drug meloxicam in older cats and cats with chronic kidney disease provide encouraging data that these drugs can be used safely and should be used to relieve pain when needed. While further data are needed and would undoubtedly lead to refinement of the guidelines presented here, the panel hope that these recommendations will encourage rational and safe long-term use of NSAIDs in cats, thereby improving patients' quality of life in the face of painful disease conditions.[31]

Prevention of mild to moderate postoperative pain and inflammation following surgical procedures: 0.2 mg/kg SC once before surgery. To continue treatment for up to 5 days, the initial dose may be followed 24 hours later by administration of oral suspension at 0.05 mg/kg PO every 24 hours for a total of up to 4 oral doses. For cats not receiving additional oral doses, a single injec-

tion of meloxicam 0.3 mg/kg SC has also been shown to be safe and effective.[37]

Alleviation of pain and inflammation associated with acute or chronic musculoskeletal disorders: On the first day of treatment, 0.1 – 0.2 mg/kg PO once for acute disorders or 0.1 mg/kg PO once for chronic disorders.[38–40] Thereafter, maintenance treatment should be 0.05 mg/kg PO every 24 hours. A clinical response is normally seen within 7 days. Treatment should be discontinued after 14 days if no clinical improvement is apparent.[38,41] Many cats may experience pain relief at even lower doses given every 2 to 3 days. Titrating to the lowest effective dose may help avoid adverse effects.[42,43]

HORSES:

Inflammation and pain associated with musculoskeletal disorders or colic pain (extra-label):

a) **IV**: 0.6 mg/kg IV once; oral dose may be given after 24 hours.

b) **Oral**: 0.6 mg/kg PO either mixed with food or given directly in the mouth every 24 hours, for up to 14 days. When administering this product with food, add to a small quantity of feed to be fed before providing full meal.[44,45]

Pain and inflammation (extra-label):

a) **Foals**: In a pharmacokinetic study in healthy foals, the authors concluded 0.6 mg/kg PO every 12 hours would likely be therapeutic in foals younger than 7 weeks of age.[14]

b) **Adults**: 0.6 mg/kg PO every 24 hours was effective in a lipopolysaccharide-induced synovitis model of pain.[46]

CATTLE:

Acute respiratory infection with appropriate antibiotic therapy to reduce clinical signs in cattle; diarrhea, in combination with oral rehydration therapy, to reduce clinical signs in calves older than 1 week of age and young nonlactating cattle; as adjunctive therapy in the treatment of acute mastitis, in combination with antibiotic therapy (extra-label): 0.5 mg/kg SC, IV, or IM once[47]

Analgesia for surgical pain (extra-label):

a) **Oral**: 0.5 – 1 mg/kg PO every 24 to 48 hours.[48] Single doses appear effective for dehorning.[16]

b) **Buccal**: 0.5 mg/kg buccal meloxicam gel reduced pain and inflammation related to castration[49] and dehorning[50] in unweaned beef calves.

Lameness (extra-label): 0.5 mg/kg PO once daily for 4 days alone or in combination with gabapentin (15 mg/kg PO once daily) was effective in experimentally induced lameness in 4- to 6-month-old beef calves.[51]

SMALL RUMINANTS:

Pain and inflammation (extra-label):

a) **Sheep**: 0.5 mg/kg IV every 12 hours. 2 mg/kg PO on first day and then 1 mg/kg PO every 24 hours. A single 1 mg/kg SC injection provided analgesia in an experimental pain model.[52,53]

b) **Goats**: 0.5 mg/kg IV every 8 hours; 0.5 mg/kg IM or PO every 24 hours.[54] 1 mg/kg of buccal meloxicam was shown to be effective when given to lambs immediately before marking[55] or surgical mulesing and hot-knife tail docking.[56]

CAMELIDS:

Pain and inflammation (extra-label): 0.5 mg/kg IV; 1 mg/kg PO every third day[54]

SWINE:

Noninfectious locomotor disorders to reduce the clinical signs of lameness and inflammation; for adjunctive therapy in the treatment of puerperal septicemia and toxemia (mastitis-metritis-agalactia syndrome) with appropriate antibiotic therapy (extra-label): 0.4 mg/kg IM once. If required, a second administration of meloxicam can be given after 24 hours.

BIRDS:

Analgesic (extra-label): 0.5 mg/kg IM once is also commonly used in birds and may be the safest of the NSAID analgesics for avian species. Because the adverse effects of all analgesics have not been studied in birds, these drugs should be used carefully in avian patients.[57] Another source states, *Injectable forms of meloxicam and carprofen will cause myositis/muscle necrosis and therefore oral formulations are recommended . . . however oral bioavailability of NSAIDs varies greatly between avian species. Therefore, it is critical to monitor response to dosage and frequency of NSAID treatment for each avian patient*.[58]

FERRETS:

Anti-inflammatory/analgesic for postsurgical pain (extra-label): 0.2 mg/kg PO or SC once[59,60]

SMALL MAMMALS:

Pain and inflammation (extra-label):

a) **Rabbits**: Pharmacokinetic studies in healthy rabbits receiving 1 mg/kg PO every 24 hours for 5 to 29 days concluded that meloxicam at this dose and treatment duration may be safe and effective.[61,62]

b) **Rats**: 1 mg/kg PO or SC every 12 to 24 hours[63]

c) **Guinea pigs**:

i. 0.2 mg/kg PO as a single presurgical dose, followed by 0.1 mg/kg PO every 24 hours for postoperative days 2 and 3. Dose may be titrated up to 0.5 mg/kg in individual cases; do not exceed 0.6 mg/kg per dose.[38]

ii. 0.1 – 0.3 mg/kg PO or SC every 24 hours has also been recommended.[63]

REPTILES:

Pain and inflammation (extra-label): 0.2 mg/kg PO every 24 hours for 5 days. Subsequent administration should be 0.2 mg/kg every 48 hours. A study in ball pythons failed to demonstrate analgesic effects when meloxicam was used at 0.3 mg/kg.[64]

Monitoring

- Clinical efficacy
- Adverse effects, especially GI effects in dogs
- Baseline and periodic serum renal and hepatic chemistry panels when used chronically. One recommendation is to perform baseline renal and hepatic panels; repeat within the first 2 weeks and periodically thereafter.[27] When liver enzymes are elevated and concern for liver function is present, liver function tests (eg, serum bile acids) should be performed.[65]

Client Information

- If using the oral liquid, shake the bottle well before using, and carefully measure the dose. Do not confuse the markings on the syringe (provided by the manufacturer). Give with food. For dogs weighing less than 4.5 kg (10 lb), it is safest to carefully measure the amount of medicine to give and apply it directly to a small amount of food. Do not give this medicine directly in the mouth.
- Most animals tolerate meloxicam well, but ulcers or serious kidney and liver problems can develop (rare), especially in cats. Contact your veterinarian if your animal develops side effects such as eating less than normal, vomiting, changes in bowel movements, changes in behavior or activity (ie, more or less active than normal), weakness (eg, stumbling, clumsiness), seizures (ie, convulsions), aggression (ie, threatening behavior/actions), changes in drinking habits (ie, frequency, amount consumed), changes in urination habits (ie, frequency, color, or smell), and/or yellowing of gums, skin, or whites of the eyes (ie, jaundice).

- Store this medicine well out of reach of animals and children, especially the honey-flavored oral liquid.
- Periodic laboratory tests to check for liver and kidney side effects are required.

Chemistry/Synonyms

Meloxicam is a COX-2–preferential NSAID that occurs as a pale-yellow powder. It is in the oxicam class, related to piroxicam.

Meloxicam may also be known as UH-AC-62 and/or UH-AC-62XX; many trade names are available, including *Alloxate®, Inflacam®, Loxicom®, M-eloxyn®, Meloxadin®, Meloxidolor®, Meloxidyl®, Meloximed®, Metacam®, Ostilox® Recocam®, Rheumocam®, and Zeleris®*.

Storage/Stability

Unless otherwise labeled, store the injection and oral liquid at controlled room temperature (20°C to 25°C [68°F-77°F]), with excursions permitted between 15°C to 30°C (59°F-86°F) for the oral suspension. The oral suspension labeled for use in the United Kingdom has a 6-month shelf life after the immediate package is first opened.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Meloxicam Oral Suspension: 0.5 mg/mL (0.02 mg/drop) and 1.5 mg/mL (0.05 mg/drop) in a honey-flavored base: 10 mL, 32 mL, 100 mL, and 180 mL dropper bottles with measuring syringe (marked in 5-lb body weight increments); *Metacam®*, generic; (Rx). FDA-approved for use in dogs. NADA# 141-213

Meloxicam 5 mg/mL for Injection: 10 mL vial; *Metacam®*, generic; (Rx). FDA-approved for use in dogs and cats. NADA# 141-219

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

Suggested withdrawal periods for extra-label use; always consult with local regulatory agencies prior to prescribing:

Horses: meat/offal, 5 days[44,45]

Cattle: Conservative 21- to 30-day meat withdrawal and 5-day milk withdrawal times have been recommended.[66,67] United Kingdom withdrawal periods: 15-day meat withdrawal; milk: 120 hours[47]

Swine: meat/offal, 5 days[45]

Sheep and goats: 15-day meat withdrawal time has been recommended.[67]

HUMAN-LABELED PRODUCTS:

Meloxicam Tablets: 7.5 mg and 15 mg; *Mobic®*, generic; (Rx)

Meloxicam Capsules: 5 mg and 10 mg; *Vivlodex®*; (Rx)

Meloxicam Oral Suspension: 7.5 mg/5 mL in 100 mL bottle; *Mobic®*, generic; (Rx)

Melphalan

(***mel***-fa-lan) *Alkeran®, Evomela®*

Antineoplastic

Prescriber Highlights

- ► Alkylating antineoplastic agent primarily used for multiple myeloma, resistant leukemia or lymphoma, and various other neoplasms
- ► Use with caution in patients with anemia, leukopenia, thrombocytopenia, previous chemotherapy or radiotherapy, impaired hepatic or renal function, or in those for whom immunosuppression may be dangerous (eg, infection).
- ► Adverse effects include chronic bone marrow suppression (eg, anemia, thrombocytopenia, leukopenia), GI effects (eg, anorexia, vomiting, diarrhea), and pulmonary infiltrates or fibrosis.
- ► Potentially teratogenic and fetotoxic
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies melphalan as a hazardous drug; use appropriate precautions when handling it.

Uses/Indications

Melphalan may be useful in the treatment of a variety of neoplastic diseases, including lymphoreticular neoplasms particularly of plasma cell neoplasms, osteosarcoma, and mammary or pulmonary neoplasms. When combined with prednisone, it is considered the drug of choice for treating multiple myeloma. Melphalan can be used for treating primary (essential) thrombocythemia in dogs or cats. It has been used with some success in a variety of rescue protocols, including dexamethasone, melphalan, dactinomycin, and cytarabine (DMAC) for relapsed multicentric lymphoma in dogs and cats,[1–4] and mechlorethamine, vincristine, melphalan, and prednisolone (MOMP) for relapsed canine lymphoma[5] and resistant feline lymphoma.[6] Melphalan has been used successfully in combination with prednisone for canine cutaneous plasmacytosis.[7]

Pharmacology/Actions

Melphalan is a bifunctional alkylating agent and interferes with RNA transcription and DNA replication, thereby disrupting nucleic acid function. Because it is bifunctional, it has effects on both dividing and resting cells. Melphalan does not require activation by the liver (unlike cyclophosphamide).

Pharmacokinetics

Melphalan absorption is variable and often incomplete. It is distributed throughout the body water, but it is unknown whether it crosses the placenta, blood–brain barrier, or enters maternal milk. Melphalan is eliminated principally by hydrolysis. In humans, protein binding varies from 50% to 92%, and terminal half-lives are ≈75 minutes following IV administration.

Contraindications/Precautions/Warnings

Melphalan should not be used in patients with a history of hypersensitivity and should be used with caution in the following conditions: anemia, bone marrow depression, current infection, impaired hepatic or renal function, tumor cell infiltration of bone marrow, or patients that have received previous chemotherapy or radiotherapy. Severe bone marrow suppression resulting in infection or bleeding can occur in humans. Melphalan is considered an irritant, and care should be taken to avoid extravasation.

In humans with impaired renal function receiving IV melphalan, a 50% dose reduction is suggested.[8]

The National Institute for Occupational Safety and Health (NIOSH) classifies melphalan as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Melphalan hydrochloride for injection is available in 2 formulations, which have different storage and preparation instructions. Melphalan flufenamide is a prodrug of melphalan and should not be interchanged with melphalan hydrochloride.

Adverse Effects

The most serious adverse effect likely with melphalan is bone marrow depression (eg, anemia, thrombocytopenia, leukopenia); the onset of, and recovery from, leukopenia can be delayed. Other potential adverse effects include GI effects (eg, anorexia, vomiting, diarrhea), pulmonary infiltrates or fibrosis, or neurotoxic effects. Prophylactic antiemetics are recommended in humans. Hepatotoxicity, secondary malignancies, and skin hypersensitivity reactions[9] have also been reported in humans.

Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant alopecia.

Reproductive/Nursing Safety

Safe use of melphalan during pregnancy has not been established. Other alkylating agents are known teratogens, and melphalan is considered potentially mutagenic in humans. Melphalan should only be used during pregnancy when the benefits to the mother outweigh the risks to the offspring. Melphalan can suppress gonadal function. For sexually intact patients, verify pregnancy status prior to administration.

Although it is unknown whether melphalan enters maternal milk, nursing is generally not recommended when dams are receiving the drug.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Because of the toxic potential of this agent, overdoses must be avoided. Determine dosages carefully. The reported lowest lethal dose (LD_{Lo}) following IV administration in a dog is 3 mg/kg, with the dog exhibiting diarrhea, somnolence, and anemia. The drug is not considered dialyzable, and the recommended treatment is supportive.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving melphalan and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Cyclosporine**: There are anecdotal reports of melphalan causing increased nephrotoxicity associated with systemic cyclosporine use in humans.
- **Immunosuppressants** (eg, **cyclosporine, leflunomide, tacrolimus**): May increase the immunosuppressive effect and decrease cyclosporine concentration
- **Myelosuppressive Agents** (eg, **azathioprine**, **chloramphenicol**): May increase the risk for neutropenia or other hematologic effects
- **Vaccines, Live**: Melphalan may diminish vaccine efficacy.

Laboratory Considerations

- Melphalan may raise serum **uric acid** levels. Drugs such as allopurinol may be required to control hyperuricemia.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and since chemotherapy indications, treatment protocols, and monitoring and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[10–14] are strongly recommended.

DOGS:

Melphalan dosages for dogs vary depending on the source, the disease treated, and the protocol being used. As a general guide, it is usually dosed from 1.5 – 2 mg/m^2 (NOT mg/kg) or 0.1 – 0.2 mg/kg in dogs, but higher dosages have been used.[8,9] Dosage frequencies range from daily to every other day to pulse dosing (eg, daily for 5 days, then 16 days off). The following are examples:

Multiple myeloma (extra-label): Several dosing schedules have been developed to treat canine multiple myeloma with melphalan. One recommended dosing regimen is 0.1 mg/kg PO every 24 hours for 10 days, followed by 0.05 mg/kg PO every 48 hours thereafter. Another source recommends 0.25 mg/kg/day PO for 4 days and 2 – 4 mg/day PO maintenance. Pulse therapy is another reported option: 7 mg/m^2 (NOT mg/kg) PO every 24 hours for 5 days every 21 days.[15] One retrospective study reported similar efficacy and adverse effect profiles for daily and pulse dosing protocols, although pulse dosing allows for fewer days of handling chemotherapy and reduces hazardous waste exposure.

Anecdotally, the human dosage 16 mg/m^2 (NOT mg/kg) IV every 2 weeks has been used in dogs. A 50% dose reduction is recommended for animals with pre-existing renal insufficiency. Clinical response can be assessed by improved clinical signs and reduced serum immunoglobulin. Melphalan should be administered indefinitely until clinical relapse, which may involve worsened bone pain, recurrence of bleeding diathesis, funduscopic changes, or elevated serum immunoglobulins.[16] **NOTE**: Melphalan flufenamide (*Pepaxto*®) is not interchangeable with melphalan hydrochloride.

Rescue protocol (DMAC) to treat relapsed multicentric lymphoma (extra-label): Dactinomycin 0.75 mg/m^2 (NOT mg/kg) IV with cytarabine 300 mg/m^2 (NOT mg/kg) IV over 4 hours or SC and dexamethasone 1 mg/kg PO on Day 0, then melphalan 20 mg/m^2 (NOT mg/kg) PO and dexamethasone (1 mg/kg PO) on Day 7. The cycle was repeated continuously every 2 weeks as long as a complete or partial remission is achieved. After 4 cycles, chlorambucil was substituted for melphalan at the same dose. If complete remission was achieved, the protocol was discontinued after 5 to 8 cycles, and maintenance therapy with the LMP (chlorambucil, methotrexate, prednisone) or lomustine/prednisone protocols was instituted. If dogs developed grades 3 or 4 toxicosis, DMAC was discontinued, and maintenance protocol was started.[1,17]

CATS:

Melphalan dosages for cats vary depending on the source, the disease treated, and the protocol being used. As a general guide, it is usually dosed from 1.5 – 2 mg/m^2 (NOT mg/kg) or 0.5 mg/cat (NOT mg/kg) PO. Dosage frequencies range from daily to every other day to pulse dosing (eg, daily for 7 to 10 days, then 3 weeks off). The following listed indication and dosage is an example:

Chronic lymphocytic leukemia (extra-label): 2 mg/m^2 (NOT mg/kg) PO every other day with or without prednisone at 20 mg/m^2 (NOT mg/kg) PO every other day[18]

Monitoring

- CBC with platelets at least every week for 2 weeks and then monthly thereafter. Significant myelosuppression requires an alteration in dose or frequency of administration.

Client Information

- Wear gloves when handling the medication and give it with food.
- Melphalan is a chemotherapy (cancer) drug. The drug and its by-products can be hazardous to other animals and people that come in contact with it. On the day your animal gets the drug and then for a few days afterward, handle all bodily waste (ie, urine, feces, litter), blood, or vomit only while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in with the regular trash.
- Bone marrow suppression can occur. The greatest effects on bone marrow usually occur within a few weeks after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal becomes tired easily, contact your veterinarian right away.
- Give melphalan as your veterinarian has directed; immediately report any signs associated with toxicity (eg, abnormal bleeding, bruising, urination, depression, infection, shortness of breath).
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Melphalan is a nitrogen mustard derivative that occurs as an off-white to buff-colored powder that is practically insoluble in water.

Melphalan may also be known as CB-3025, NSC-8806, PAM, L-PAM, L-phenylalanine mustard, phenylalanine mustard, phenylalanine nitrogen mustard, L-sarcolysine, WR-19813, *Alkeran*®, or *Alkerana*®.

Storage/Stability

Store melphalan tablets in well-closed, light-resistant glass containers in the refrigerator (2°C-8°C [36°F-46°F]).

Store intact powder vials between 15°C and 30°C (59°F-86°F), protected from light. Complete administration within 60 minutes of reconstitution. Once reconstituted, the injectable product should not be refrigerated, or a precipitate may form. For IV administration of *Alkeran*® and the generic, the reconstituted solution should be further diluted with sterile 0.9% sodium chloride to a concentration of not more than 0.45 mg/mL.[15] Further dilution or refrigeration of the solution increases the stability of certain products; check package insert of the specific product used.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Melphalan has **variable compatibility** with 0.9% sodium chloride; concentration should not exceed 0.45 mg/mL.

Melphalan is **incompatible** with 5% dextrose in water and lactated Ringer's solution.

Melphalan is also **incompatible** with amphotericin B, chlorpromazine, and pantoprazole for Y-site administration.

Compounded oral formulations have been shown to have variable stability and potency.[19] The risks vs benefits of using a compounded formulation should be carefully considered.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Melphalan Oral Tablets: 2 mg; *Alkeran*®; (Rx)

Melphalan Powder for Injection (lyophilized): 50 mg in single-use vials; *Alkeran*®, *Evomela*®, generic; (Rx). Melphalan flufenamide (*Pepaxto*®) is not interchangeable with melphalan hydrochloride.

Meperidine

Pethidine

(me-***per***-i-deen) *Demerol*®

Opioid Agonist

Prescriber Highlights

- ► Infrequently used due to short duration of analgesia and potential for more adverse effects than other commonly used injectable opioids
- ► Contraindicated in patients hypersensitive to it, patients with diarrhea caused by a toxic ingestion, and patients taking MAOIs
- ► Use with extreme caution in patients with head injuries, respiratory disease, acute respiratory dysfunction, or acute abdominal conditions (eg, colic).
- ► Use with caution in patients with hypothyroidism, adrenocortical insufficiency, seizures, renal/hepatic impairment, or in geriatric or severely debilitated patients.
- ► Adverse effects include respiratory depression, histamine release, bronchoconstriction, central nervous system (CNS) depression, and GI effects (eg, nausea, vomiting, decreased intestinal peristalsis). Mydriasis can be seen in dogs, and salivation can occur, especially in cats. Horses may also experience tachycardia with premature or polymorphic ventricular contractions (PVCs), profuse sweating, or hyperpnea. Meperidine may potentiate intestinal obstruction secondary to reduced intestinal motility.
- ► Must be administered slowly if given IV; may be irritating when given SC
- ► Overdoses can cause CNS excitatory effects (eg, agitation, seizures); naloxone may enhance rather than reverse these effects.
- ► DEA Schedule II (C-II) controlled substance

Uses/Indications

Meperidine has been used as a sedative/analgesic in small animal species for both postoperative pain and medical conditions, such as acute pancreatitis and thermal burns; however, other opioids are usually preferred as meperidine has a short analgesic duration and can cause significant histamine release. Meperidine is occasionally used in horses and other large animal species for pain control; however, when meperidine is used a single agent, it does not provide much restraint in large animal species.

Pharmacology/Actions

Meperidine is an opioid agonist with activity at the mu-OP_3 receptor. It has ≈20% to 25% the potency of morphine. Receptors for opioid analgesics are found in high concentrations in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain. The GI tract, urinary tract, and other smooth muscle tissues also contain opioid receptors.

The morphine-like agonists (morphine, meperidine, oxymorphone, hydromorphone, fentanyl) have primary activity at the mu-opioid receptors. The primary pharmacologic effects of these agents include analgesia, antitussive activity, respiratory depression, sedation, emesis, physical dependence, and intestinal effects (constipation/defecation). Secondary pharmacologic effects include effects on the central nervous system (euphoria and confusion), cardiovascular system (bradycardia due to central vagal stimulation, depressed alpha-adrenergic receptors resulting in peripheral vasodilation, decreased peripheral resistance, and baroreceptor inhibition, possible

orthostatic hypotension and syncope), and urinary effects (increased bladder sphincter tone and resulting urinary retention).

Meperidine produces equivalent respiratory depression at equianalgesic doses as morphine. Like morphine, it can cause histamine release. Meperidine does not have antitussive activity at doses lower than those causing analgesia. Meperidine is the only used opioid that has vagolytic (can cause tachycardia) and negative inotropic properties at clinically used doses. One study in ponies demonstrated changes in jejunal activity after meperidine administration, but no effects on transit time or colonic electrical activity were noted.

Pharmacokinetics

Although meperidine is generally well absorbed after oral administration, a marked first-pass effect limits oral effectiveness. Therefore, meperidine is rarely used orally in the clinical setting. Oral bioavailability in dogs (beagles; $n = 3$) ranged from 3% to 25%. After IM or SC injection, peak analgesic effects occur between 30 and 60 minutes, with the IM route having a slightly faster onset. Duration of action is variable, with effects generally lasting from 1 to 6 hours in most species. In dogs and cats, analgesic duration is less than 2 hours and often less than 1 hour at clinically used doses. The drug is metabolized primarily in the liver (mostly hydrolysis with some conjugation), and ≈5% is excreted unchanged in the urine. One metabolite is normeperidine, which is active with ≈50% of the analgesic effects of the parent compound. Accumulation of normeperidine is associated with central nervous system excitatory effects that appear to be mediated by other than mu-opioid receptors and are not amenable to reversal by naloxone or other mu antagonists.

In horses, IM and SC administration resulted in low plasma concentrations.[1]

Contraindications/Precautions/Warnings

Meperidine is contraindicated in patients that are hypersensitive to narcotic analgesics and in patients currently receiving or that have received monoamine oxidase inhibitors (MAOIs) within 14 days. Avoid use in patients with diarrhea caused by toxic ingestion until the toxin is eliminated from the gastric tract.

Use meperidine with extreme caution in patients with head injuries, increased intracranial pressure, and acute abdominal conditions (eg, colic) as it may obscure the diagnosis or clinical course of these conditions. Use with extreme caution in patients suffering from respiratory disease or acute respiratory dysfunction (eg, pulmonary edema secondary to smoke inhalation). In humans, meperidine is contraindicated in patients with acute or severe bronchial asthma.[2]

Meperidine should be used with caution in patients with hypothyroidism, hypoadrenocorticism (Addison's disease), prostatic hypertrophy, urethral stricture, and geriatric or severely debilitated patients. Use with caution in patients with renal or hepatic impairment, as meperidine and its active metabolite, normeperidine, may accumulate.[2] Use caution in patients with biliary tract impairment, including pancreatitis, as Sphincter of Oddi constriction may occur. Consider using an alternate analgesic in patients with seizure disorders, as normeperidine can cause central nervous system excitement and precipitate anxiety, tremors, and seizures. Hypotension may occur with meperidine. Use caution in patients with cardiovascular disease and in those that are hypovolemic. Use caution in patients with tachycardia due to potential increased ventricular response rate.

Use meperidine with caution in cats. Some recommend avoiding meperidine use in feline patients.

Many clinicians recommend meperidine not be administered IV. If meperidine must be given IV, it must be given very slowly to prevent severe hypotension. In humans, it should only be given IV when necessary and should preferably be administered in a diluted solution, as rapid injection can increase incidence of adverse effects.[2]

Although naloxone will reverse respiratory depression associated with meperidine overdoses, it will not reverse CNS excitement mediated by normeperidine and may exacerbate CNS excitement and seizures.[3]

Opioid analgesics are contraindicated in patients that have been stung by the scorpion species *Centruroides sculpturatus Ewing* and *Centruroides gertschi Stahnke* as opioids may potentiate their venoms. Meperidine should not be used for pain secondary to envenomations from Gila monsters or Mexican beaded lizards.[4]

In humans, the American Pain Society and Institute for Safe Medication Practices do not recommend meperidine use due to neurotoxicity related to meperidine's metabolite, normeperidine. If using meperidine, it is generally not recommended to use it for longer than 48 hours.

Adverse Effects

Meperidine may be irritating when administered SC. Severe hypotension can occur with rapid IV administration. Meperidine can cause pronounced histamine release, particularly with IV administration. At usual doses, the primary concern is the effect meperidine has on respiratory function. Decreased tidal volume, depressed cough reflex, and the drying of respiratory secretions may all have a detrimental effect on susceptible patients. Bronchoconstriction following IV doses has been noted in dogs. GI effects may include nausea, vomiting, and decreased intestinal peristalsis. In dogs, meperidine causes mydriasis (unlike morphine). If given orally, meperidine may be irritating to the buccal mucosa and cause salivation; this is of particular concern in cats. Chronic administration can lead to physical dependence.

In horses undergoing general anesthesia, meperidine has been associated with a reaction that manifests as tachycardia with premature ventricular contractions, profuse sweating, and hyperpnea. Urticaria induced by IV meperidine is presumably due to histamine release.

Cutaneous eruptions and localized sweating have been reported after SC administration in horses.[5] Meperidine can reduce colonic activity and increase the risk for postanesthetic colic. Doses greater than 2 mg/kg may induce locomotor activity; 5 mg/kg initially causes incoordination, shaking, and immobility, followed by a substantial locomotor response.[6]

Reproductive/Nursing Safety

Meperidine is more lipophilic than several other opioids (eg, morphine, hydromorphone) and can more readily cross the placenta. Meperidine is generally not recommended for use in pregnant animals.

Most opioids are excreted into milk. Meperidine enters human breast milk. Central nervous system and respiratory depression may occur in nursing human infants. Use in breastfeeding humans is not recommended, and either breastfeeding or meperidine should be discontinued.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses may produce profound respiratory and/or central nervous system (CNS) depression in most species. Other effects include cardiovascular collapse, hypothermia, and skeletal muscle hypotonia. A metabolite of meperidine, normeperidine, can have CNS excitatory effects (eg, agitation, hyperreflexia, seizures), and these effects can predominate in meperidine overdoses. While naloxone (at low doses) can be used for treating profound respiratory depression when ventilator support is unavailable, it is not recommended when treating suspected normeperidine-induced CNS excitotoxicity.[7] Benzodiazepines or barbiturates may be considered if treatment of CNS excitement is needed. Use caution as additive respiratory depression can occur.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving meperidine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acyclovir**: May increase plasma concentrations of meperidine and normeperidine[2]
- **Anticholinergic Agents**: Medications with anticholinergic properties may increase the risk for urinary retention and constipation when combined with opioids.
- **Antihypertensive Agents/Vasodilators** (eg, **amlodipine, enalapril, hydralazine, prazosin, sildenafil**): Concurrent use may increase the risk for hypotension and other adverse effects.
- **Butorphanol, Nalbuphine, Naltrexone, Naloxone**: Opioid antagonists and partial agonists may contribute to central nervous system (CNS) excitatory effects of normeperidine (see ***Overdose/Acute Toxicity***). In cases where normeperidine excitotoxicity is suspected, avoid the use of naloxone or butorphanol unless severe respiratory depression is present without a method of ventilatory support.[7]
- **Central Nervous System Depressants, Other** (eg, **anesthetic agents, antihistamines, barbiturates, benzodiazepines,[2] ethanol, phenothiazines**): May cause increased central nervous system or respiratory depression when used with meperidine
- **Cimetidine**: Serum concentrations of meperidine may be increased when given concurrently.
- **Desmopressin**: Opioids may increase the risk for water intoxication or hyponatremia when combined with desmopressin**.**
- **Gastrointestinal Agents, Prokinetic** (eg, **metoclopramide, cisapride**): Opioids may antagonize the GI motility effects of these agents.
- **Diuretics**: Opioids may decrease efficacy in congestive heart failure patients.
- **Iohexol**: Meperidine may lower the seizure threshold, increasing the risk for seizure and potential adverse/toxic effects from iohexol. Discontinue meperidine 2 days prior to iohexol use and wait 24 hours after iohexol administration to restart meperidine.
- **Isoniazid**: Meperidine may enhance isoniazid's adverse effects.
- **Minocycline**: IV minocycline therapy may enhance the central nervous system depressant effects of meperidine.
- **Monoamine Oxidase Inhibitors** (**MAOIs;** eg, **amitraz**, **linezolid**, **methylene blue,** possibly **selegiline**): Meperidine is contraindicated in patients receiving MAOIs and for at least 14 days after receiving MAOIs in humans. Some human patients have exhibited signs of opioid overdose after receiving therapeutic doses of meperidine while taking MAO inhibitors.
- **Muscle Relaxants, Skeletal**: Meperidine may enhance neuromuscular blockade, and additive CNS depression may be seen.
- **Succinylcholine**: Opioids, combined with succinylcholine, may enhance the bradycardic effects of opioids.
- **Serotonin Modulators** (eg**, metoclopramide, mirtazapine, ondansetron, SSRIs [eg, fluoxetine], trazodone**): Opioids may enhance the serotonergic effect of other serotonin modulators, potentially causing serotonin syndrome.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): Meperidine may exacerbate the effects of tricyclic antidepressants.
- **Warfarin**: Opioids may potentiate anticoagulant activity.

Laboratory Considerations

- Opioids may increase biliary tract pressure, resulting in increased **plasma amylase** and **lipase** values up to 24 hours following opioid administration.
- Increased **bromosulfophthalein (BSP)** retention.
- Increased **creatine kinase (CK)** with IM injections.

Dosages

DOGS:

Analgesic (extra-label): Dosage recommendations vary but generally are 3 – 5 mg/kg (up to 11 mg/kg has been noted) IM or SC. Analgesic duration in dogs usually lasts 30 minutes to 2 hours.

Analgesic for anesthetic premedication (extra-label):

a) One study recommended atropine 0.04 mg/kg IM 20 minutes before administering meperidine 2 mg/kg IM with propofol to effect until loss of pedal reflexes.[8]

b) 3 – 4 mg/kg IM have been used to pre-medicate dogs undergoing pacemaker placement due to the potential positive chronotropic effects of meperidine.[9]

c) 2 mg/kg administered as premedication reduced the dose of propofol required to induce general anesthesia, but muscle twitching and defecation were noted.

CATS:

NOTE: Meperidine is generally not recommended for use in cats.

Analgesic for perioperative pain (extra-label): Dosage recommendations vary but generally are 2 – 5 mg/kg IM or SC. Analgesic duration of in cats lasts 30 minutes to greater than 1 hour. A premedication dose of meperidine 6 mg/kg IM was reported to be inferior to tramadol 2 – 4 mg/kg IM to control postoperative pain in cats undergoing ovariohysterectomy.[10]

HORSES:

Analgesic (extra-label): 1 – 2 mg/kg IM or 0.3 – 0.6 mg/kg slow IV. A study comparing meperidine 1 mg/kg IM vs placebo for treating pain associated with experimental laminitis found meperidine was more effective, but analgesic effects only lasted 2 to 3.7 hours. The authors concluded that it could be used as an alternative analgesic for acute foot pain, with efficacy lasting 2 to 3 hours.[11] **NOTE**: Meperidine may cause central nervous system excitement or ataxia in horses. Some clinicians recommend pretreatment with acepromazine 0.02 – 0.04 mg/kg IV or xylazine 0.3 – 0.5 mg/kg IV to reduce drug-induced behavioral changes. **WARNING**: Narcotic analgesics can mask behavioral and cardiovascular signs associated with mild colic.

CATTLE:

Perioperative analgesic (extra-label): 3.3 – 4.4 mg/kg IM or SC[12]

FERRETS:

Analgesic (extra-label): 5 – 10 mg/kg IM or SC every 2 to 3 hours[13]

RABBITS:

Analgesic for moderate pain (extra-label): 5 – 10 mg/kg IM or SC every 2 to 3 hours. Use banana flavored oral syrup: 0.2 mg/mL in drinking water[14]

SMALL MAMMALS (RODENTS):

Analgesic (extra-label): 5 – 10 mg/kg IM, IV, or SC every 2 to 4 hours[13]

Monitoring

- Respiratory rate and depth; $ETCO_2$; pulse oximetry (SpO_2)
- Heart rate
- CNS level of depression/excitation

- Blood pressure (especially with IV use)
- Analgesic efficacy
- Body temperature

Client Information

- Give this medicine to your animal as directed by your veterinarian.
- Oral formulations of this medicine may cause mouth irritation.
- Meperidine is classified as a Schedule II controlled drug by the federal Drug Enforcement Agency (DEA) and requires a new written prescription for every refill. The use of this medication in animals or humans without a prescription is illegal.

Chemistry/Synonyms

Meperidine HCl, a synthetic opioid analgesic, is a fine, white, crystalline, odorless powder that is very soluble in water, sparingly soluble in ether, and soluble in alcohol. Meperidine has a pK_a of 7.7 to 8.15 and a melting range of 186°C to 189°C (367°F-372°F). The pH of the commercially available injectable preparation is between 3.5 and 6.

Meperidine HCl may also be known as pethidine HCl, isonipecaine, meperidine hydrochloride, pethidini hydrochloridum, or *Demerol®*.

Storage/Stability

Meperidine is a DEA Schedule II controlled substance. It should be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding the disposal of unused or wasted controlled drugs.

Meperidine is stable at room temperature. Avoid freezing the injectable solution and protect from light during storage. Meperidine has not exhibited significant adsorption to polyvinyl chloride (PVC) IV bags or tubing in studies to date.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Meperidine is reported to be physically **compatible** with the following fluids and drugs: 0.45% and 0.9% sodium chloride; Ringer's injection; lactated Ringer's; 2.5%, 5%, and 10% dextrose for injection; dextrose/sodium chloride combinations; dextrose/lactated Ringer's solutions; atropine, butorphanol, chlorpromazine, dimenhydrinate, diphenhydramine HCl, dobutamine, fentanyl citrate, glycopyrrolate, metoclopramide, pentazocine lactate, promazine HCl, succinylcholine, verapamil HCl as well as other drugs. Consult a specialized reference for additional information.

Meperidine is reported to have **variable compatibility** when admixed with sodium bicarbonate and when mixed in a syringe with atropine and promethazine. Meperidine is reported to have **variable compatibility at Y-sites** with the following agents: acyclovir, ampicillin, ampicillin-sulbactam, cefotetan, chloramphenicol, dexamethasone, doxorubicin, furosemide, haloperidol, heparin, hydralazine, hydrocortisone sodium succinate, imipenem, magnesium sulfate, methylprednisolone sodium succinate, minocycline, oxacillin, and sulfamethoxazoletrimethoprim.

Meperidine is reported to be **incompatible** when admixed with the following agents: aminophylline, heparin sodium, morphine sulfate, pentobarbital sodium, phenobarbital sodium, phenytoin sodium, and thiopental. It is reported to be **incompatible** when mixed in a syringe with the following agents: heparin sodium, morphine sulfate, pantoprazole, pentobarbital sodium, and thiopental. Meperidine is reported to be **incompatible at Y-sites** with the following agents: allopurinol, amphotericin B, azathioprine, cefepime, cefoperazone, dantrolene, diazepam, diazoxide, idarubicin, lorazepam, pantoprazole, pentobarbital, phenobarbital, phenytoin, sodium bicarbonate, and thiopental.

Dosage Forms/Regulatory Status

Mepivacaine

(me-***piv***-a-kane) *Carbocaine®-V, Isocaine®*

Local Anesthetic

Prescriber Highlights

- ► Amide-type local anesthetic with a quick onset (5 to 10 minutes) and intermediate duration of action (2 to 3 hours) compared with others in its class
- ► FDA-approved for infiltration, nerve block, intra-articular, and epidural anesthesia in horses
- ► Local anesthetics are absorbed from the site of administration and may have systemic effects.
- ► Adverse effects are usually minimal when used correctly, but local anesthetic systemic toxicity, including cardiac and CNS effects, may occur.
- ► Use should be limited to clinicians experienced in the diagnosis and management of local anesthetic systemic toxicity; resources for treating acute emergencies must be readily available.

Uses/Indications

Mepivacaine is indicated for infiltration, nerve block, intra-articular and epidural anesthesia, and anesthesia of the laryngeal mucosa prior to ventriculectomy for horses. Perineural analgesic duration during lameness evaluations may be shorter than observed for soft-tissue analgesia.[1] Adding mepivacaine to an IV regional limb perfusion with amikacin provided analgesia without altering amikacin's antimicrobial activity under experimental conditions.[2] Combination with triamcinolone acetonide for intra-articular injection into the metacarpophalangeal joints of horses did not alter the potency or duration of triamcinolone's action.[3] Topical ocular administration decreased corneal sensitivity immediately, and this persisted for 35 minutes.[4] When used in dogs intra-articularly before elbow arthroscopy, mepivacaine blunts the hemodynamic response and reduces interventional analgesia requirement.[5] Similarly, intra-articular mepivacaine prior to carpal arthroscopy in horses resulted in fewer detectable reactions to surgical stimulation, with similar recovery scores and blood pressure support requirements.[6]

The duration of analgesia from local anesthetics can be extended when combined with opioids. Mepivacaine can have a MAC-sparing effect on general anesthesia in dogs and horses,[7,8] and leads to better postoperative recovery.[9]

Intra-articular mepivacaine facilitated diagnostic evaluations of canine elbows, although false negative results were observed.[10] Intra-articular mepivacaine combined with iohexol was determined to be safe and reliable when used in a diagnostic test for identifying and

confirming the source of pain in dogs with shoulder joint lameness.[11]

Mepivacaine has been used to provide local or epidural anesthesia in a variety of other species, including cattle, small ruminants, and swine.

Pharmacology/Actions

Local anesthetics block sodium ion channels on the nerve cell membrane, thereby altering electrical excitability, depolarization, and action potential propagation. They block the generation and conduction of impulses in motor, sensory, and autonomic nerve fibers around the site of application. Nerve fiber diameter, conduction velocity, and myelination determine loss of nerve function. Clinically, the progressive loss of nerve function occurs in the following order: pain, temperature, touch, proprioception, and skeletal muscle tone. Anesthetic effect is lost in reverse order.

Mepivacaine produces analgesia typically within 3 to 20 minutes of administration, and this persists for 2 to 2.5 hours. Mepivacaine has a slower onset of analgesia than lidocaine but is more rapid than bupivacaine. Its duration of action is longer than lidocaine but shorter than bupivacaine. However, after palmar digital nerve block in horses, desensitization of the skin was observed for ≈107 minutes as compared with only 25 and 53 minutes with lidocaine and bupivacaine, respectively.[12] The duration of action after IV regional perfusion is ≈150 minutes.[13]

Pharmacokinetics

Local anesthetics are absorbed from their site of administration into systemic circulation. The rate and extent of systemic absorption increases with the dose and volume given, repeated administration, administration in the head and neck region, and administration into highly vascularized sites.

Mepivacaine may diffuse into surrounding tissue after intrasynovial[14–17] and perineural[18,19] administration. The extent of tissue diffusion may be dependent on administration volume and injection approach.[20]

Pharmacokinetic information was not found for veterinary species. In humans, peak concentrations occur ≈3 to 20 minutes after administration. Systemically absorbed drug distributes into all tissues, including the CNS, placenta, and into breast milk. Protein binding is ≈75%. Mepivacaine is hepatically metabolized and undergoes enterohepatic recirculation but is predominantly excreted in the urine as metabolites. Elimination half-life in humans is ≈2 to 3 hours in adults and ≈9 hours in neonates.

Epinephrine (at a very low concentration) may be added to mepivacaine products to cause vasoconstriction at the site of administration, thereby reducing the rate of systemic absorption. Epinephrine prolongs the duration of action at the site of administration, as well as minimizes systemic mepivacaine toxicity. Dexmedetomidine also prolongs the duration of mepivacaine anesthesia at the palmar digital nerves of horses.[21]

Contraindications/Precautions/Warnings

Mepivacaine is contraindicated in patients with a known hypersensitivity to it or to other amide-type local anesthetic agents. Injections should be administered aseptically, aspirating frequently and relocating the needle if blood is aspirated. Ensure adequacy of local anesthesia prior to starting painful procedures. Care should be taken when administering epidural anesthesia to avoid injecting the local anesthetic into the subarachnoid space. Local anesthetics with preservatives should not be used for epidural or intrathecal anesthesia. Epidural injections should be administered incrementally, with aspiration prior to each dose to avoid intravascular injection.

To reduce potential toxicoses, high doses should be used with caution in patients with hepatic or renal disease or impaired cardiovascular function. Chondrolysis has occurred in humans receiving intra-articular infusions. Mepivacaine maintained equine chondrocyte viability to a greater extent than lidocaine or bupivacaine, and mepivacaine was less toxic to equine chondrocytes than bupivacaine in in vitro studies.[22,23]

Mepivacaine products that contain epinephrine should be used with caution, or not at all, in patients with hypertension, if the integrity of the nerve is compromised (it might cause nerve ischemic injury), or to block extremities without collateral circulation (eg, digits, ears, nose, or penis), as it may cause tissue necrosis.

Adverse Effects

Local anesthetics are generally well tolerated when administered correctly. Adverse effects (ie, local anesthetic systemic toxicity) are related to high plasma concentrations, which may result from the dosage or mepivacaine concentration used, rapid absorption from the injection site, and unintentional intravascular or subarachnoid injection.

Adverse cardiovascular effects include bradycardia, AV block, and decreased cardiac output; hypotension may occur but is less likely with mepivacaine than other amide-class anesthetics. Either CNS excitation (eg, restlessness, tremors) or depression (eg, drowsiness, loss of consciousness) may occur. Nausea and vomiting may occur in species with the ability to vomit. Other local anesthetics have caused methemoglobinemia, but this has not been reported with mepivacaine.

Reproductive/Nursing Safety

Local anesthetics readily cross the placenta; however, animal reproductive studies have not been conducted with mepivacaine. Use during labor and delivery may cause fetal and neonatal toxicity, including cardiovascular and CNS effects.

The extent to which mepivacaine is excreted in milk is unknown; use with caution during lactation.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Toxic blood concentrations are most likely to occur after unintended intravascular administration. Toxic effects may occur rapidly and simultaneously. Cardiac conduction and excitability are depressed, which may lead to AV block, ventricular arrhythmias, and cardiac arrest; arrhythmias may be refractory to treatment. In addition, myocardial contractility is depressed, and peripheral vasodilation occurs, leading to decreased cardiac output and arterial blood pressure. CNS stimulation (eg, restlessness, tremors, and shivering progressing to convulsions) may precede CNS depression, coma, and respiratory arrest. The mean dosage that induced seizures in rhesus monkeys was 18.8 mg/kg. The LD_{50} in mice was 23 to 35 mg/kg IV.

Management must begin with delivery of oxygen via a patent airway. Benzodiazepines or barbiturates can be used for seizure management but may cause further CNS depression. Cardiovascular support should be provided and may include IV fluids and vasopressor drugs (eg, epinephrine); use of lidocaine, calcium channel blockers, and beta blockers should generally be avoided. Prolonged resuscitative efforts may be required. IV lipid emulsion therapy may be beneficial.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving mepivacaine and may be of significance in veterinary patients. Unless otherwise noted, use

together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Propranolol**: May increase mepivacaine concentration and risk for toxicity

Severe, prolonged hypertension may result when using mepivacaine/epinephrine combination products with the following:

- **Ergot Alkaloids**
- **Monoamine Oxidase Inhibitors** (eg, **selegiline, linezolid, amitraz**)
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**)
- **Vasopressors** (eg, **dobutamine**, **norepinephrine**)

Laboratory Considerations

- Mepivacaine may increase **(99m) Technetium hydroxymethylene diphosphonate** tissue uptake following peroneal nerve block in horses.[24]

Dosages

NOTE: Mepivacaine product concentration, administration volume, site of administration, administration technique, and underlying patient condition(s) are important interrelated factors that determine mepivacaine's safe and effective use. Local anesthetics should only be used by clinicians well versed in correct administration technique, diagnosis, and management of local anesthetic toxicity, and who have completed resuscitative resources immediately available. All dosages are for a 2% solution unless otherwise stated.

DOGS:

Local analgesia (extra-label): 1 – 5 mg/kg [25,26]

Epidural analgesia and anesthesia (extra-label): 3 – 4.5 mg/kg[27]

CATS:

Local analgesia (extra-label): 0.5 – 2.5 mg/kg[25]

Epidural analgesia and anesthesia (extra-label): 1 – 1.5 mg/kg[27]

HORSES:

The following FDA-approved dosages are a general guide[28]:

Nerve block (diagnosis of lameness, firing, pain relief in osteoarthritis, navicular disease): 3 – 15 mL total dose (NOT mg/kg)

Epidural anesthesia (animal standing): 5 – 20 mL total dose (NOT mg/kg)

Intra-articular anesthesia (removal of fracture chips, bone and bog spavin, arthritis): 10 – 15 mL total dose (NOT mg/kg)

Infiltration (alone or in combination with nerve block or intra-articular anesthesia): As required

Anesthesia of the laryngeal mucosa prior to ventriculectomy: Administer topically, or by infiltration, or by a combination of the 2. For topical application, a total of 25 – 40 mL applied by spray (3 mL per application) is usually adequate. For infiltration, 20 to 50 mL will suffice.

Diagnostic analgesia of the foot (extra-label): The following doses use a mepivacaine 2% solution.[29]

a) **Palmar/plantar digital nerve**: 1.5 mL over each nerve
b) **Abaxial sesamoid nerve**: 2.5 mL over each nerve; a larger volume may anesthetize the fetlock.
c) **DIP joint**: 5 – 6 mL administered into the joint will also anesthetize the navicular apparatus. 10 mL may anesthetize the entire sole.

Retrobulbar block (extra-label): 10 – 12 mL total dose (NOT mg/kg) injected into the retrobulbar space[30]

Stifle joint anesthesia and analgesia (extra-label): 20 mL total dose (NOT mg/kg) injected into each stifle joint synovial compartment.[31]

Local block (extra-label): Less than 4 mg/kg[8]

Epidural analgesia and anesthesia for urogenital surgery (extra-label): 5 – 7 mL total dose (NOT mg/kg) alone or in combination with 0.1 mg/kg morphine[32]

IV regional limb perfusion (extra-label): Mepivacaine 500 mg was added to 1 gallon amikacin, diluted with saline to 60 mL final volume, and administered by cephalic vein for 30-minute duration.[2]

CATTLE:

Local analgesia (extra-label): 5 mg/kg[33]

SHEEP/GOATS:

Local analgesia (extra-label): 6 mg/kg. Dilute to 1% solution when administering to lambs or kids.[33]

Caudal epidural analgesia and anesthesia (extra-label): 2 – 4 mL total dose (NOT mg/kg) in the sacrocaudal or the first intercoccygeal space should anesthetize the perineum and vagina without interfering with motor function.[34]

SWINE:

Analgesia during castration (extra-label): 0.5 mL total dose (NOT mg/kg) injected intratesticularly and 0.5 mL total dose (NOT mg/kg) injected subscrotally[35]

Monitoring

- Adequacy of analgesia and anesthesia
- Cardiovascular and respiratory function as well as state of consciousness, after each injection

Client Information

- This drug should only be used by professionals familiar with its use and in a setting where adequate patient monitoring can be performed.
- This medication causes temporary loss of feeling. The area where it was injected may not have usual function for several hours.

Chemistry/Synonyms

Mepivacaine hydrochloride is an amide-class local anesthetic. It occurs as a white, odorless crystalline powder and is freely soluble in water and alcohol.

Mepivacaine hydrochloride is also known as mepivacaini hydrochloridum, *Carbocaine®*, and *Isocaine®*.

Storage/Stability

Mepivacaine should be stored at controlled room temperatures of 20°C to 25°C (68°F-77°F). Mepivacaine stored under field conditions for equine use was found to maintain pH and potency without microbial contamination in a variety of storage conditions and with repeated vial use over 12 months.[36]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Mepivacaine HCl is **compatible** with 0.9% sodium chloride solutions, epinephrine, and gentamicin. Mepivacaine HCl is reported to be **variably compatible** with sodium bicarbonate, and to be **incompatible** with bupivacaine. Mepivacaine solutions to which sodium bicarbonate have been added (to reduce pain on infiltration) should be used immediately and promptly discarded.

The recommended final concentration of epinephrine for combined use with mepivacaine is 5 µg/mL. To reach this concentration, add 0.1 mL of epinephrine 1 mg/mL to 20 mL of local anesthetic.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Mepivacaine Hydrochloride Injection: 2% (20 mg/mL) in 50 mL

multidose vials; *Carbocaine®-V*; (Rx). FDA-approved for use in horses not intended for human consumption. NADA# 100-703

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN -LABELED PRODUCTS:
Mepivacaine Hydrochloride Injection: 1%, 1.5%, and 2% in 20 mL or 30 mL single-dose vials, and 50 mL multidose vials; *Carbocaine®*, *Isocaine®*, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Meropenem

(mare-oh-***pen***-ehm) *Merrem IV®*
Carbapenem Antibiotic

Prescriber Highlights

- ► Broad-spectrum parenteral antibiotic
- ► Can be administered more rapidly and with less volume than imipenem
- ► Adverse effects are uncommon; drug is usually well tolerated
- ► Use in veterinary medicine is controversial because of the drug's importance in human medicine. Veterinary infectious disease specialists should be consulted prior to treatment. Use should be reserved for infections with confirmed susceptibility that are resistant to lower-tier options.

Uses/Indications

Meropenem is a carbapenem that is used to provide broad coverage for both gram-positive and gram-negative infections, but it is especially useful in infections caused by extended-spectrum beta-lactamase–producing Enterobacterales or *Pseudomonas aeruginosa*.[1] Because this antibiotic is used for multidrug-resistant infections in humans, its use in veterinary medicine should be reserved for confirmed infections where culture and susceptibility testing demonstrates resistance to all other options, the infection is considered treatable, and consultation with an infectious disease expert has concluded that meropenem is a viable and reasonable treatment.[1-3]

Parenteral administration of meropenem is required. Meropenem can be used judiciously for outpatient treatment of stable patients, as it is amenable for SC administration; however, it is not intended for home management of critical patients (eg, sepsis).

The World Health Organization (WHO) classifies meropenem as a Critically Important, High Priority antibiotic for human use.[4]

Pharmacology/Actions

Meropenem has a broad antibacterial spectrum similar to that of imipenem, but meropenem is more active against Enterobacterales and less so against gram-positive bacteria. Synergy against *Pseudomonas aeruginosa* could occur when meropenem is used with aminoglycosides. Meropenem resistance is currently rare in dogs and cats, but carbapenemase-producing bacteria are a serious and increasing problem in humans and sporadic carbapenem-resistant infections in animals have been reported.[5-7] Methicillin-resistant *Staphylococcus* spp are resistant to carbapenems. Meropenem has demonstrated in vitro or in vivo activity against the following bacteria: *Enterococcus faecalis*, *Staphylococcus aureus, Staphylococcus epidermidis* (methicillin-susceptible isolates only), *Streptococcus* spp, *Escherichia coli, Haemophilus influenzae, Klebsiella pneumoniae, Klebsiella oxytoca, Neisseria meningitides, Pseudomonas aeruginosa, Proteus mirabilis, Aeromonas hydrophila, Campylobacter jejuni, Citrobacter koseri, Citrobacter freundii, Enterobacter cloacae, Hafnia alvei, Moraxella catarrhalis, Morganella morganii, Pasteurella multocida, Proteus vulgaris, Bacteroides* spp, *Peptostreptococcus* spp, *Clostridium difficile, Clostridium perfringens, Eubacterium lentum, Fusobacterium* spp, *Prevotella* spp, and *Porphyromonas asaccharolytica*.

Because meropenem is more resistant to renal dehydropeptidase-I than imipenem is, meropenem does not require the addition of cilastatin to inhibit that enzyme.

Pharmacokinetics

Meropenem is a time-dependent antibacterial that must be administered parenterally.

After SC injection in dogs, bioavailability is 84%.[8] After IV injection in dogs, the volume of distribution is ≈0.37 L/kg, protein binding is ≈12%, half-life is ≈40 minutes, and clearance is ≈6.5 mL/minute/kg. Concentrations of total and unbound drug in tissue or interstitial fluid and plasma are similar.[8,9] In dogs receiving intermittent hemodialysis, the extraction ratio was 0.46 and dialysis clearance was 71 mL/hour/kg.[10]

After IV injection in cats, peak concentration was 101 µg/mL, volume of distribution was 0.21 L/kg, and the drug was minimally protein bound (1.54% to 9.38%).[11] Half-life was ≈1.35 hours and clearance was ≈0.11 L/hour/kg. Following SC and IM administration in cats, bioavailability was 96.5% and 99.6%, respectively. Absorption was significantly faster after IM administration compared with SC (0.5 vs 1.7 hours). Half-life was ≈2.2 hours following either SC or IM administration.

Following a single IV injection in horses, peak concentration (77 µg/mL) was reached in ≈1 hour, the volume of distribution was 136 mL/kg, and protein binding was 7% to 11%.[2] Half-life was 0.8 hours and clearance was 165 mL/hour/kg. Meropenem penetrated into synovial fluid, reaching peak concentration of 7.5 µg/mL 1 hour after IV administration, and the half-life in synovial fluid was 2.4 hours. Following IV regional limb perfusion, the concentration of meropenem in synovial fluid remained above 1 µg/mL for 3 hours.[12]

In ewes, after IM injection meropenem was rapidly absorbed and had a bioavailability equal to that of IV dosing.[13] Volume of distribution at steady state was 0.06 L/kg and protein binding was ≈43%; elimination half-life was ≈43 minutes. After IM injection, 91% of the drug was recovered in the urine over 24 hours.

Pharmacokinetic data for humans include wide distribution in body tissues and fluids, including into the CSF and bile and very low protein binding.[3] In patients with normal renal function, elimination half-life is ≈1 hour. One inactive metabolite has been identified, but the majority of the drug is eliminated via renal mechanisms (tubular secretions and glomerular filtration) and 70% of a dose is recovered unchanged in the urine over 12 hours.

Contraindications/Precautions/Warnings

Meropenem is contraindicated in patients that are hypersensitive to it or other carbapenems and in patients that have developed anaphylaxis after receiving any beta-lactam antibiotic.[3]

In humans, carbapenems have been associated with CNS toxicities, including seizures.[3] Meropenem has less associated seizure risk than other carbapenems,[14-16] but it should be used cautiously in patients with a history of seizure disorders or with renal impairment, as accumulation may increase risk for CNS toxicity.[3]

Adverse Effects

Meropenem is usually well tolerated. Anecdotally, animals receiving the drug SC may show changes in fur color or slight fur loss over injection sites. In human patients receiving meropenem, GI effects (nausea, vomiting, diarrhea, constipation), headache, and skin rashes have been reported to occur in more than 1% of patients.[3] Mero-

penem use in humans is associated with a low risk of seizures, but the risk of meropenem-induced seizures in clinically ill veterinary patients has not been described.[15]

Reproductive/Nursing Safety

Meropenem has not demonstrated fetal toxicity or malformations in laboratory animals.[3,17]

Meropenem is found in the breast milk of humans,[3] but as meropenem is not orally absorbed, it is likely safe to use during lactation. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring. As meropenem is used for serious infections only, the potential benefits of treatment likely outweigh the risks.

Overdose/Acute Toxicity

Overdoses of meropenem are unlikely to occur in patients that have normal renal function. In mice and rats, large IV doses of meropenem (2200 mg/kg – 4000 mg/kg) have been associated with ataxia, dyspnea, convulsions, and mortalities.[3] In human trials, doses of 2 g every 8 hours failed to demonstrate any significant adversity. If an overdose occurs, the drug can be discontinued, or the next dose could be delayed by a few hours. Meropenem can be removed via hemodialysis when necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving meropenem and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides**: The combination of aminoglycosides and meropenem can be synergistic against some isolates of *Pseudomonas aeruginosa.*
- **Probenecid**: May increase serum concentrations and elimination half-life of meropenem

Laboratory Considerations

- No specific laboratory interactions noted

Dosages

NOTES:

1. Meropenem susceptibility and resistance to first-line antibacterial drugs should be confirmed prior to using the drug.
2. Consultation with a veterinary infectious disease specialist or veterinary pharmacologist prior to use is recommended.[1]
3. Concurrent aminoglycoside therapy is indicated for infections caused by *Pseudomonas aeruginosa*.
4. De-escalate therapy to a lower-tier antibiotic class if culture and susceptibility results indicate an antibacterial agent with a narrower spectrum would be effective.
5. Usually administered IV over 15 to 30 minutes, although low volumes can be given over 3 to 5 minutes

DOGS:

Documented multidrug-resistant UTIs, particularly those caused by multidrug-resistant Enterobacterales *or P aeruginosa* (extra-label): 8.5 mg/kg SC every 12 hours or slowly IV every 8 hours[1]

Documented multidrug-resistant systemic or soft tissue infections caused by Enterobacterales (extra-label): 8.5 mg/kg SC every 12 hours or 24 mg/kg IV every 12 hours[8,18]

Documented multidrug-resistant systemic or soft tissue infections caused by *P aeruginosa* or other similar organisms with MIC values near 1 µg/mL (extra-label): 12 mg/kg SC every 8 hours or 25 mg/kg IV every 8 hours.[8,19] A pharmacokinetic study has determined that a loading dose of 0.37 mg/kg IV bolus followed by 0.38 mg/kg/hour IV CRI could maintain plasma meropenem concentration of 1 µg/mL.[9]

***Escherichia coli*-associated granulomatous colitis** (extra-label): 10 mg/kg SC every 12 hours for at least 6 weeks[20]

CATS:

Documented multidrug-resistant UTIs, particularly those caused by multidrug-resistant Enterobacteriaceae *or P aeruginosa* (extra-label): 10 mg/kg IV, SC, or IM every 12 hours[1]

Documented multidrug-resistant systemic or soft tissue infections, specifically caused by Enterobacteriaceae (extra-label): 10 mg/kg SC, IM, or IV every 12 hours[19]

HORSES:

Documented multidrug-resistant systemic or soft tissue infections (extra-label): Based on a pharmacokinetic study, 5 mg/kg IV every 8 hours or 0.5 mg/kg/hour as a CRI should maintain meropenem concentration above the MIC target of 1 µg/mL for an adequate time.[2]

Monitoring

- Clinical efficacy: resolution of clinical signs associated with UTI or other systemic infection[1]
- Recheck urinalysis (for UTI) and aerobic bacterial culture and susceptibility 5 to 7 days after cessation of antimicrobials[1]

Client Information

- Meropenem must be injected in the vein or under the skin of your animal; it does not work if given by mouth.
- Your animal's fur may become thinner or change color over the injection site.
- It is important to give this medication exactly as prescribed, to complete the full course of therapy, and to follow up with your veterinarian as instructed, even if your animal seems better. Missing doses, stopping treatment early, or failing to perform recommended recheck testing may result in treatment failure.
- Your veterinarian will need to monitor your animal closely during treatment. Do not miss these important follow-up appointments.

Chemistry/Synonyms

Meropenem is a synthetic carbapenem antibiotic that occurs as a clear to white to pale yellow powder or crystals. It is very slightly soluble in water or hydrated alcohol and practically insoluble in acetone or ether. When the commercially available injection is reconstituted, the resulting pH is between 7.3 and 8.3.

Meropenem may also be known as ICI-194660, SM-7338, *Meronem®, Meropen®, Merrem®, Optinem®,* or *Zeropenem®*.

Storage/Stability

The powder for injection should be stored at controlled room temperature (20°C-25°C [69°F-77°F]). When the commercially available powder for injection is reconstituted with sterile water for injection (up to a concentration of 50 mg/mL), it is labeled as stable (per the manufacturer) for up to 3 hours at room temperature and up to 13 hours when refrigerated. When reconstituted with normal saline in concentrations ranging from 1 to 20 mg/mL, it is stable per the manufacturer for up to 1 hour at temperatures up to 25°C (77°F) and up to 15 hours at temperatures up to 5°C (41°F). When reconstituted with dextrose injection 5%, the solution should be used immediately.

When the dry meropenem powder is reconstituted with sterile water and further diluted to a concentration of 20 mg/mL with sodium chloride 0.9%, the solution is stable for up to 5 days if kept refrigerated

(5°C [41°F]) and protected from light.[21] Once the refrigerated solution is brought back to room temperature, it should be used within 1 hour.[17]

Meropenem and sodium chloride injection solution in DUPLEX containers should be stored at controlled room temperature (20°C-25°C [69°F-77°F]). Reconstituted solution should be used within 1 hour but may be stored under refrigeration for up to 15 hours. Administer only if solution is clear and free from particulates.

The manufacturer recommends that solutions of meropenem should not be frozen.[17] Additionally, one study noted the formation of a precipitate after thawing of a frozen meropenem solution.[22]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Meropenem has been reported **compatible** with vancomycin, ranitidine, morphine sulfate, metoclopramide, heparin, gentamicin, furosemide, dopamine, dobutamine, dexamethasone sodium phosphate, atropine, and aminophylline.

Additives should not be added to meropenem and sodium chloride injection solution in DUPLEX containers.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Meropenem Powder for solution for Injection: 500 mg and 1 g in 20 mL, and 30 mL vials; *Merrem® IV*, generic; (Rx)

Meropenem and Sodium Chloride Injection Solution: 500 mg and 1 g in DUPLEX containers with 50 mL 0.9% NaCl; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Metergoline

(meh-***tir***-goe-leen) *Contralac®, Liserdol®*

Serotonin Antagonist; Prolactin Inhibitor

Prescriber Highlights

- ► Serotonin antagonist prolactin inhibitor used primarily for pseudopregnancy in dogs
- ► Primary adverse effects are GI (especially vomiting) and behavior related
- ► Not commercially available in the United States
- ► Metergoline should be handled as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Metergoline is used to treat pseudopregnancy in dogs. It is available as a veterinary product in several European and South American countries. Metergoline has been investigated as an abortifacient in dogs at high doses (0.4 – 0.6 mg/kg); however, similar to other ergot prolactin inhibitors, it can only be used reliably for this effect during the last 3 weeks of gestation.[1] Metergoline could potentially be used to induce estrus or treat pyometra in bitches.

In humans, metergoline has been used for hyperprolactinemia, prolactinomas, and migraine prophylaxis.

Pharmacology/Actions

Metergoline reduces prolactin primarily via its serotonin antagonism effects. It differs from cabergoline and bromocriptine in that it has both strong central and peripheral antiserotonin effects, and only weak direct dopamine-2-agonist effects. Like those drugs, it also is an antagonist at dopamine-1 receptors. Potentially, metergoline could be used to induce estrus or treat pyometra in bitches.

Pharmacokinetics

Limited pharmacokinetic information is available for dogs. The half-life of metergoline is reportedly short (≈4 hours), and twice-daily dosing is required.

In humans, metergoline oral bioavailability is ≈25% and volume of distribution is 0.8 L/kg. It is metabolized in the liver to at least 1 active metabolite (1-desmethylmetergoline), which attains plasma concentrations higher than that of the parent drug. Elimination half-life is ≈50 minutes for the parent drug and 80 to 100 minutes for 1-desmethylmetergoline.

Contraindications/Precautions/Warnings

Metergoline is contraindicated in dogs and cats that are pregnant unless abortion is desired. It should not be used in patients who are hypersensitive to ergot derivatives. Patients that do not tolerate cabergoline or bromocriptine may or may not tolerate metergoline. Use metergoline with caution in patients with significantly impaired liver function; lower doses may be required.

The National Institute for Occupational Safety and Health (NIOSH) classifies cabergoline, a related drug, as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure. Women who are pregnant or of child-bearing age should avoid contact with or wear disposable gloves when administering metergoline.

Adverse Effects

Reported adverse effects for metergoline in dogs include behavior-related effects (eg, anxiety, aggressiveness, depression, hyperexcitation, whining, escaping) and GI effects (eg, anorexia, vomiting, nausea).[2]

Reproductive/Nursing Safety

Metergoline is contraindicated in dogs and cats that are pregnant unless abortion is desired. Because it suppresses prolactin, metergoline should not be used in nursing mothers.

Overdose/Acute Toxicity

Limited information is available. Vomiting is the most likely effect after an overdose of metergoline.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving metergoline and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Bromocriptine, Cabergoline**: May cause additive effects if used with metergoline
- **Cyproheptadine**: May cause additive effects if used with metergoline
- **Metoclopramide**: May reduce the efficacy of both drugs and should be avoided.
- **Selective Serotonergic Receptor Inhibitors (SSRIs**; eg, **fluoxetine**, **paroxetine**, **sertraline**): May reduce the efficacy of each drug

Laboratory Considerations

- No particular laboratory interactions or considerations were located for this drug.

Dosages

DOGS:

Pseudopregnancy or to halt lactation (extra-label): 0.5 mg/kg PO twice daily for 4 to 5 days is effective for the treatment of most bitches. Treatment failures can be managed by repeating the treatment protocol and extending the duration to 8 to 10 days, or by using joint protocols of cabergoline plus metergoline or cabergoline plus bromocriptine.[2]

Pregnancy termination (extra-label): 0.4 – 0.5 mg/kg PO once daily for 5 days[3]

Induce estrus (extra-label): Cabergoline and bromocriptine have consistently given positive results, while metergoline's results have been more variable depending on dosage. Using low dose metergoline 0.1 mg/kg PO twice a day, the commercial oral formulation (administered from 100 days after ovulation until the following proestrus) caused the interestrus interval to be significantly shortened.[4]

CATS:

Pseudopregnancy or to halt lactation (extra-label): 0.125 mg/kg PO twice a day for 4 to 8 days[5]

Monitoring

- Efficacy
- Adverse effects

Client Information

- Give this medicine with food. Contact your veterinarian if your animal has vomiting that does not stop.
- Keep this medication and all other medications away from animals.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Metergoline is an ergot derivative and has the chemical name benzyl (8S,10S)-(1,6-dimethylergolin-8-ylmethyl)carbamate.

Metergoline may also be known as FI-6337, MCE, Metergoliini, Metergolin, Metergolina, Métergoline, Metergolinum, or Methergoline. Common trade names are *Contralac*® (veterinary) and *Liserdol*® (human).

Storage/Stability

Metergoline tablets should be stored at room temperature and protected from light.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None in the United States. Metergoline 0.5 mg and 2 mg oral tablets are available in some European and South American countries; *Contralac*®

HUMAN-LABELED PRODUCTS:

None in the United States. Metergoline 4 mg tablets are available in some countries.

Metformin

(met-***fore***-min) *Glucophage*®

Antihyperglycemic

Prescriber Highlights

- ► Oral anti-hyperglycemic agent that could be useful in the adjunctive treatment of noninsulin-dependent diabetes (NIDDM) in dogs and cats or in equine metabolic syndrome; however, its use is controversial
- ► Contraindications include patients hypersensitive to it, patients with renal dysfunction or metabolic acidosis, or temporarily when iodinated contrast agents are required.
- ► Adverse effects may include lethargy, inappetence, vomiting, and weight loss.
- ► Potentially significant drug interactions
- ► Human dosage forms may be difficult to accurately dose in cats; compounded formulations may be required.

Uses/Indications

Metformin may be useful in the adjunctive treatment of noninsulin-dependent diabetes mellitus (NIDDM) in cats. Limited trials of the drug have been performed in cats, with only limited success when the drug is used alone. Currently, metformin should only be used in cats with functional beta cells known to have type 2 diabetes mellitus.[1] Studies comparing its safety and efficacy with other oral antihyperglycemics (eg, glipizide or insulin) were not located.

Metformin may also be useful in dogs with NIDDM; however, evidence is limited, and incidence of NIDDM is rare in canines.[2]

There has been some research evaluating metformin for treating insulin resistance associated with equine metabolic syndrome in horses, but data conflict regarding its efficacy.[3,4] Because of the drug's low cost and low adverse effect profile, further investigation of its clinical usefulness is warranted.

Pharmacology/Actions

Metformin's actions are multifaceted. At usual dosages, it increases insulin's ability to transport glucose across cell membranes in skeletal muscle without increasing lactate production and inhibits the formation of advanced glycosylation end-products. Metformin decreases hepatic glucose production and may decrease intestinal absorption of glucose. It does not stimulate insulin production or release from the pancreas and therefore does not cause hypoglycemia.

In horses, metformin has poor oral bioavailability (around 5%) and is not likely to act systemically; however, there is some indication that metformin may act locally and limit gut glucose uptake. A recently published study in 7 normal horses found that metformin at 30 mg/kg via NG tube 1 hour prior to an oral glucose challenge test (dextrose powder 0.5 g/kg PO in feed) reduced glycemic and insulinemic responses. Further work is required to determine whether these effects may translate into clinical benefits in horses with equine metabolic syndrome and hyperinsulinemia.[4]

In a study evaluating the whole blood of 4 horses, metformin displayed anti-inflammatory properties by reducing TNF-alpha production. Further studies are warranted to determine whether or not these properties have a role in the treatment of equine endotoxemia or other infections.[5]

Pharmacokinetics

A pharmacokinetic study done in cats showed that metformin is variably absorbed (35% to 67%) after oral administration.[6] In cats, the steady-state volume of distribution was 0.55 L/kg, the elimination half-life was ≈12 hours, and total clearance was 0.15 L/hour/kg. Metformin is primarily eliminated via the kidneys. The authors concluded that the drug's pharmacokinetics are similar to those seen in

humans, and that a dosage of 2 mg/kg twice daily would give plasma concentrations known to be effective in humans.

In a small (4 subjects) pharmacokinetic study in horses, metformin demonstrated very low oral bioavailability (4% fed, 7% fasted).[7] Maximum blood concentrations were around 0.4 µg/mL. The elimination half-life after IV dosing was ≈25 minutes.

Contraindications/Precautions/Warnings

In humans (and presumably cats), metformin is contraindicated in patients that are hypersensitive to it, patients with severe renal dysfunction, and patients with metabolic acidosis. It is also temporarily contraindicated when iodinated contrast agents are to be used (see ***Drug Interactions***).

In humans, metformin rarely can cause lactic acidosis that may lead to death. The onset can be subtle with nonspecific symptoms, including malaise, myalgia, respiratory distress, somnolence, and abdominal pain.[8] Risk factors for lactic acidosis include renal impairment, old age, hypoxic states (eg, acute congestive heart failure), and hepatic impairment.

In a study evaluating metformin in 5 diabetic cats, 1 cat died unexpectedly 11 days after receiving metformin.[9] As the cause of death was undetermined, metformin could not be ruled out as a causative factor.

Adverse Effects

Metformin caused adverse GI effects (eg, diarrhea, inappetence, vomiting) in ≈40% of dogs, which were managed with dose reduction and weekly dose increases.

In cats, metformin may cause lethargy, inappetence, vomiting, and weight loss. Hypoglycemia would not be an expected adverse effect when metformin is used as a single agent.

Reproductive/Nursing Safety

Metformin is excreted in maternal milk in levels equivalent to those found in plasma. Although adverse effects in nursing kittens would be unlikely, use with caution in lactating queens.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In small animals, hypoglycemia is not commonly seen in overdoses with metformin alone, but it has a narrow margin of safety regarding GI upset. Vomiting commonly occurs with ingestion of metformin in small animals. Another common clinical sign associated with overdose is lethargy.

Massive overdoses in humans (100 g) caused hypoglycemia only 10% of the time, but lactic acidosis has occurred. Lactic acidosis has been seen in human overdoses of 7 and 20 g (total dose). It is unknown at what dose acidosis may occur in domestic animals. Ingestion of up to 1700 mg by children is not usually associated with significant toxicity. Enhancement of metformin elimination may be amenable to dialysis.

In 2 case reports in dogs, lactic acidosis and hypoglycemia were reported after ingestion of 198 to 291 mg/kg of metformin.[10,11] Treatment included fluids, dextrose, and sodium bicarbonate, and clinical signs resolved within 24 to 34 hours.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving metformin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors**: May increase the risk for hypoglycemia
- **Carbonic acid inhibitors** (eg, **acetazolamide, zonisamide**): May increase the risk for lactic acidosis, as carbonic acid inhibitors frequently cause decreased serum bicarbonate.
- **Cimetidine**: In humans, cimetidine can cause a 60% increase in peak metformin plasma levels and a 40% increase in AUC.
- **Corticosteroids** (eg, **dexamethasone, predniso(lo)ne**): May reduce metformin efficacy
- **Diuretics, Thiazide**: May reduce hypoglycemic efficacy
- **Fluoroquinolones** (eg, **enrofloxacin**): May increase the risk for hyperglycemia or hypoglycemia. If the combination is necessary, monitor blood glucose closely.
- **Furosemide**: Can increase the AUC and plasma levels of metformin by 22% in humans; metformin can decrease the peak plasma concentrations and AUC of furosemide.
- **Iodinated Contrast Agents, Parenteral**: May cause acute renal failure and lactic acidosis if used within 48 hours of a metformin dose
- **Isoniazid**: May reduce hypoglycemic efficacy
- **Sympathomimetic Agents** (eg, **phenylpropanolamine**): May reduce hypoglycemic efficacy

Laboratory Considerations

- No specific laboratory interactions or considerations were noted.

Dosages

CATS:

Noninsulin-dependent diabetes mellitus (patients with detectable concentrations of insulin) (extra-label): 2 mg/kg PO twice daily,[6] which generally equals 25 – 50 mg/cat (NOT mg/kg) PO twice daily.[1] If using tablets, must be compounded. No information on the use of the oral liquid (100 mg/mL) or extended-release tablets for use in cats was noted. One 14-day study found the maximum tolerated dose in cats to be 10 mg/kg.[12]

HORSES:

Adjunctive treatment of equine metabolic syndrome (extra-label): **NOTE**: Use is controversial, and evidence for efficacy conflicts. Reserve metformin treatment for horses and ponies with markedly increased oral sugar test (OST; corn syrup-based) insulin concentrations, even after the loss of body fat mass and dietary management. Current recommendations are metformin 30 mg/kg PO every 8 to 12 hours, preferably 30 to 60 minutes before the horse is fed.[4,13]

Monitoring

- Efficacy: Standard methods of monitoring efficacy for diabetes treatment should be followed (eg, blood glucose, appetite, attitude, body condition, PU/PD resolution, and perhaps serum fructosamine and/or glycosylated hemoglobin levels).
- Renal function (baseline and annually)
- Adverse effects

Client Information

- Monitor your animal for vomiting, decrease in appetite, diarrhea, lethargy, or any other new problems and report them to your veterinarian.
- While your animal is taking this medication, it is important to return to your veterinarian for physical examinations and laboratory work. Do not miss these important follow-up visits.

Chemistry/Synonyms

Metformin HCl is a biguanide oral anti-hyperglycemic agent that oc-

curs as white to off-white crystals that are slightly soluble in alcohol and freely soluble in water. It is a weak base—a 1% aqueous solution of metformin HCl has a pK_a of 6.68, and a metformin base has a pK_a of 12.4.

Metformin HCl may also be known as dimethylbiguanide HCl or metforimini hydrochloridium. There are many proprietary names outside of the United States for this drug.

Storage/Stability

Store metformin HCl oral products (tablets, sustained-release tablets) protected from light at a controlled room temperature of 20°C to 25°C (68°F-77°F). Excursions permitted to 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Metformin HCl Oral Tablets: 500 mg, 850 mg, and 1000 mg; *Glucophage®*, generic; (Rx)

Metformin HCl Extended-Release Oral Tablets: 500 mg, 750 mg, and 1000 mg; *Glucophage XR®*, *Glumetza®*, *Fortamet®*, generic; (Rx)

Metformin HCl Oral Solution: 500 mg/5 mL (100 mg/mL) in 118 mL and 473 mL; *Riomet®*; (Rx)

There are also fixed-dose oral tablet combination products available containing metformin and glyburide or glipizide.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Methadone

(***meth***-a-done) *Dolophine®, Methadose®*

Opioid Agonist

Prescriber Highlights

- ► Opioid mu-receptor agonist with NMDA blocking properties used in dogs, cats, and horses
- ► Can be used for sedation, as premedication before anesthesia, and for analgesia
- ► Adverse effects include panting, vomiting, vocalization, defecation postinjection, bradycardia, and respiratory depression.
- ► Many possible drug interactions
- ► DEA Schedule II (C-II) controlled substance in the United States
- ► Effects can be reversed with naloxone.

Uses/Indications

Methadone may be used as an opioid sedative, preanesthetic, or analgesic agent. Methadone use as a premedication reduces MAC requirements.[1] Methadone has demonstrated an analgesic effect after epidural use in horses.[2] Poor bioavailability precludes oral administration in dogs.[3]

Pharmacology/Actions

In small animal species, methadone acts similarly to morphine with regard to its degree of analgesia and duration of action. Methadone is a synthetic mu-receptor agonist that is supplied as a racemic mixture; the L-isomer is up to 50 times more potent as a μ-agonist than the D-isomer. Agonism of the mu-opioid receptor (a g-protein coupled receptor) on both pre- and postsynaptic neurons results in decreased transmission and modulation of pain. Presynaptically, binding of the mu-opioid receptor results in closure of calcium ion channels and reduction of neurotransmitter release. Postsynaptically, agonism will open potassium channels, resulting in hyperpolarization and inhibition of postsynaptic neurons.[4] Both methadone isomers are noncompetitive inhibitors of NMDA (N-methyl-D-aspartate) receptors[5] and can reduce reuptake of norepinephrine,[6] which may also contribute to its analgesic effects, especially in patients tolerant to other opioids[7,8]; however, the therapeutic application of this is unknown.

Methadone's depression of the medullary respiratory center results in respiratory depression, and stimulation at the vagal center can cause bradycardia. Methadone is more lipid-soluble than morphine and is therefore more potent due to having more favorable pharmacokinetics. IV administration of methadone has potential for histamine release, but studies have shown no resulting hemodynamic instability[9]; histamine release following administration of methadone by other routes is unknown but possible.

Pharmacokinetics

In dogs, methadone has poor oral bioavailability due to extensive first-pass metabolism.[3,10] Coadministration of multiple CYP450 inhibitors (eg, ketoconazole, fluconazole, fluoxetine, trimethoprim, chloramphenicol) presumably affects different isoenzymes in dogs and has been shown to significantly increase oral absorption, area under the curve (AUC), and plasma concentrations of methadone.[3,11] Methadone absorption after oral transmucosal administration is slower and reduced as compared with methadone given IM.[12] SC administration has a bioavailability of ≈80%, with peak concentrations occurring ≈1 hour after administration. Bioavailability is ≈90% after IM administration,[6] with peak concentrations occurring within 5 to 15 minutes. Vd_{SS} is ≈5 to 6 L/kg, and protein binding is 60% to 90%.[6] Terminal elimination half-life after IV administration is ≈1.75 to 4 hours; clearance is ≈25 to 50 mL/kg/minute.[13,14] After SC and IM administration, half-life is ≈11 hours and ≈1 to 2 hours, respectively; however, there is wide interpatient variation.[6,14]

In cats, bioavailability of buccal (ie, oral transmucosal [OTM]) methadone is 44%.[15] After administration of methadone 0.3 mg/kg IV or 0.6 mg/kg via OTM administration, peak concentrations occurred at 10 minutes (IV) and 2 hours (OTM).[16] A 0.6 mg/kg IM dose provides 4 hours of analgesia and reaches plasma concentration between 40 to 124 ng/mL. T_{max} and clearance were 20 minutes and 9.1 mL/kg/minute, respectively.[17]

In horses, methadone given PO appears to be well absorbed, but bioavailability is ≈3 times lower when administered intragastrically. P-glycoprotein may play a role in the poor intestinal absorption of methadone in vivo. Elimination half-life is ≈1 to 2 hours, and clearance is 5 to 8 mL/kg/minute.[18,19]

In goats, methadone has a high bioavailability and volume of distribution (7 L/kg) after SC administration, with a half-life of ≈3.6 hours. IV administration resulted in a terminal half-life of ≈1.5 hours.[20] Elimination half-life after IM administration was ≈1.4 hours.[21]

In humans, methadone is well absorbed from the GI tract via PO administration and after parenteral injection (SC or IM). Methadone is widely distributed and extensively bound to plasma proteins (60% to 90%, principally $alpha_1$-acid glycoprotein). Methadone is metabolized in the liver to inactive metabolites primarily by the CYPP450, CYP3A, and CYP2B6 isoenzymes, but other isoenzymes also play metabolic roles. Methadone's half-life in humans is widely variable (15 to 60 hours). Elimination half-lives of methadone may be extended if giving multiple doses.

Contraindications/Precautions/Warnings

Methadone is contraindicated in animals hypersensitive to narcotic analgesics and in animals with any condition associated with respiratory depression, acute respiratory dysfunction, advanced respiratory failure, and severe hepatic or renal dysfunction, as well as during parturition.[6,22,23]

Use methadone with extreme caution in patients with head injuries, increased intracranial pressure, or acute abdominal conditions (eg, colic), as it may obscure the diagnosis or clinical course of these conditions.

Use opioids with caution in patients with hypothyroidism and hypoadrenocorticism (ie, Addison's disease), as well as geriatric and severely debilitated patients. Neonatal, debilitated, and geriatric patients or patients with severe hepatic disease may be more susceptible to the effects of methadone, may require lower doses, and should be monitored closely. Greyhounds may require higher doses than other breeds.[24]

Methadone can cause bradycardia and therefore should be used cautiously in patients with pre-existing bradyarrhythmia. Hypotension may occur and result in decreased cardiac output and blood pressure.

Because vomiting may occur, methadone as a preanesthetic in animals with suspected gastric dilatation-volvulus or intestinal obstruction is usually not recommended.

Opioid analgesics are contraindicated in patients stung by scorpions (eg, *Centruroides* spp) as it may potentiate venom effects.[25]

Some dosage forms may contain benzylalcohol as a preservative. In human newborns, benzylalcohol and derivatives can potentially displace bilirubin from protein binding sites; caution in human neonates is advised. There is an FDA black-box warning regarding the risk for misuse and abuse, respiratory depression, QT prolongation, neonatal withdrawal syndrome, accidental ingestion, and addiction treatment when prescribing methadone for humans. QT intervals may be prolonged in patients taking methadone, which can result in life-threatening arrhythmia. Use caution in patients with prolonged QT intervals or those receiving medications that can further prolong QT intervals. See ***Drug Interactions***.

Extreme care should be taken when administering methadone; spillage onto the skin can result in respiratory depression. If methadone comes in contact with skin, wash the area thoroughly and seek medical advice.

Adverse Effects

In dogs, adverse effects can include panting,[26] whining/vocalization,[14] dysphoria, sedation, anorexia,[27] emesis, urination and/or defecation (shortly after injection), constipation or paralytic ileus, reduced body temperature,[3] bradycardia, and respiratory depression or apnea. Systemic vascular resistance may increase.[28,29] Adverse effects appear to be dose-related.[1,30] Methadone tends to cause less sedation or vomiting than morphine.[31] Methadone has a greater cardiodepressant effect than morphine.[32]

In cats, methadone appears to cause less excitation (eg, lip licking, salivation, tremors, urination, vocalization) and vomiting than some other mu-agonists, but these effects can occur. Pupil dilation persists after analgesia in cats.[6] Hyperalgesia has also been reported in cats.

In horses, methadone 0.1 mg/kg IV or greater has caused pronounced CNS excitement. Gut sounds may be diminished.[33] Mean arterial pressure may be increased when administered in combination with detomidine.[34]

In sheep, methadone 0.5 mg/kg IV may result in drooling, bruxism, mydriasis, nystagmus, vocalization, and tremors. Rumination was inhibited in goats receiving SC methadone.[20]

Reproductive/Nursing Safety

Effects on the hypothalamic–pituitary–gonadal axis may cause testicular regression, decreased testosterone concentrations, and reduced sexual activity in males. Administration to animals from the time of organogenesis through lactation has resulted in increased neonate mortality, decreased litter size, neural tube defects, and lifelong behavior alterations.[35]

In humans, methadone is relatively safe to use at low doses for short periods during the first 2 trimesters of pregnancy; methadone administered late in term has caused significant respiratory depression and increased stillbirths.

Epidural administration results in lower umbilical cord methadone concentration than IV methadone.[36] Some veterinary-approved product labels outside of the United States state that methadone is contraindicated for use in animals during parturition.[23]

Methadone has been found in breast milk and there are subsequently low plasma concentrations in nursing human infants.

Although methadone enters maternal milk, it is considered compatible with breastfeeding in women.[37]

Overdose/Acute Toxicity

Overdose may produce profound respiratory and/or CNS depression in most species. Newborn animals may be more susceptible to these effects than adults. In dogs, a lethal dose of 50% (LD_{50}) is reported to be 29 mg/kg.[38] A dose of 4 mg/kg can be fatal in cats.[6] Other toxic effects can include cardiovascular collapse, hypothermia, and skeletal muscle hypotonia. Seizures may occur at very high doses (ie, 10 times the therapeutic dose).[22,23]

Naloxone, an opioid antagonist, is the agent of choice in treating respiratory depression. Naloxone may need to be readministered in cases of larger overdoses. Patients given naloxone must be observed closely because naloxone's effects may diminish before subtoxic concentrations of methadone are reached. Mechanical respiratory support should be considered in cases of severe respiratory depression. Dialysis, charcoal hemoperfusion, and forced diuresis do not appear to be beneficial in treating methadone overdose.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methadone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate. In humans, the FDA-approved product has a black-box warning regarding the risk for fatal respiratory depression when methadone is administered with other CYP inhibitors.

- **Alpha$_2$-Receptor Agonists** (eg, **detomidine**, **dexmedetomidine, xylazine**): Although methadone combinations with alpha$_2$-receptoragonists are generally safe and effective,[39] severe hypoxemia was seen in dogs breathing room air in one study using methadone/medetomidine combination.[40] Detomidine may reduce methadone clearance in horses[41]
- **Antiarrhythmics, Class I and III** (eg, **amiodarone, lidocaine, procainamide, quinidine**): Use with methadone may increase the risk for arrhythmia, including QT prolongation.
- **Anticholinergic Agents** (eg, **atropine, clomipramine, diphenhydramine, hyoscyamine, procainamide**): Medications with anticholinergic properties may increase the risk for urinary retention and constipation when combined with opioids.
- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): May increase methadone plasma concentrations. Methadone is contraindicated with ketoconazole in humans. In dogs, ketoconazole did not appreciably increase methadone absorption following oral administration in one study[10] but appeared to increase oral methadone absorption, peak methadone concentration, and total drug exposure (AUC) in another study.[3] Fluconazole appears to increase oral methadone absorption, peak

methadone concentration, and exposure in dogs.[11]

- **Benzodiazepines** (eg, **alprazolam, diazepam, midazolam**): May potentiate the CNS and respiratory depressant effects of methadone
- **Calcium Channel Blockers**: Use with methadone may increase the risk for arrhythmias.
- **Central Nervous System Depressants, Other** (eg, **anesthetic agents, antihistamines, , ethanol, methocarbamol, phenothiazines**): May cause increased CNS or respiratory depression when used with methadone
- **Chloramphenicol**: May increase methadone concentrations. Chloramphenicol given to greyhounds that had also received methadone resulted in increased peak drug concentrations, total drug exposure (AUC), and persistence of drug concentrations. Coadministration of chloramphenicol with methadone may result in exaggerated and prolonged effects of methadone if methadone doses are not adjusted.[26]
- **Cimetidine**: May reduce methadone metabolism
- **Corticosteroids With Mineralocorticoid Activity** (eg, **desoxycorticosterone pivalate [DOCP], fludrocortisone**): Use with methadone may increase potential for electrolyte abnormalities.
- **Desmopressin**: Opioids may increase the risk for water intoxication or hyponatremia when combined with desmopressin.
- **Diuretics** (eg, **furosemide**): Opioids may decrease diuretic efficacy in patients with congestive heart failure and increase the adverse effects of diuretics.
- **Interferon Alfa**: May increase methadone concentrations
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May inhibit metabolism of methadone and increase methadone concentrations
- **Magnesium Sulfate**: The CNS effects of methadone may be increased; this is more likely with higher magnesium doses or IV magnesium therapy.
- **Minocycline**: IV minocycline therapy may enhance the CNS depressant effects of methadone.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): Methadone may enhance the serotonergic effect of MAOIs and lead to possible serotonin syndrome; avoid concurrent use.
- **Naloxone**: Used clinically to reverse opioid CNS and respiratory depression.
- **Opioid Agonist/Antagonist** (eg, **buprenorphine**, **butorphanol**, **nalbuphine**): Combined use could antagonize opioid effects.
- **Phenobarbital, Primidone**: May decrease methadone concentrations; additive CNS or respiratory depression is possible
- **QT Prolongation** (eg, **cisapride, fluoxetine, metronidazole, ondansetron**): Methadone may prolong QT intervals in humans; this effect may be increased with agents that also prolong QT intervals. In dogs, methadone does not appear to prolong the QT interval.[30] Use with caution with other QT-prolonging agents.
- **Rifampin**: May decrease methadone concentrations, but potentially not in dogs
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs;** eg, **fluoxetine, sertraline**): Concurrent fluoxetine increases oral methadone absorption, peak methadone concentration, and exposure in dogs.[3] May have additive serotonergic effects. Monitor for serotonin syndrome.
- **Serotonin Modulators** (eg, **metoclopramide, mirtazapine, ondansetron, tramadol, trazodone**): Serotonin effects may be enhanced when serotonin modulators are given concomitantly with methadone. Monitor for serotonin syndrome.
- **St John's Wort**: May decrease methadone concentrations
- **Succinylcholine**: Opioids combined with succinylcholine may enhance the bradycardic effects of opioids.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Methadone may exacerbate the CNS depressant effects of tricyclic antidepressants; serotonin effects may be enhanced.
- **Trimethoprim**: Concurrent use appears to increase oral methadone absorption, peak methadone concentration, and exposure in dogs.[3]
- **Zidovudine**: Methadone may increase zidovudine concentrations.

Laboratory Considerations

- Opioids may increase biliary tract pressure, resulting in increased plasma **amylase** and **lipase** values up to 24 hours following their administration.
- The following drugs can reportedly cause false positive results on **urine screening tests for methadone**: chlorpromazine, clomipramine, diphenhydramine, doxylamine, quetiapine, quinolones, thioridazine, and verapamil.

Dosages

NOTE: All listed dosages are based on the methadone HCl salt formulation (10 mg methadone HCl is equivalent to ≈8.9 mg of methadone). Most products are labeled with methadone HCl strength but check before administering to patients.

DOGS:

Perioperative pain control (extra-label):

IM: Methadone 0.5 mg/kg IM and acepromazine 0.03 mg/kg IM as a premedication prior to orthopedic surgery and meloxicam 0.2 mg/kg at induction produced superior analgesia to buprenorphine for 8 hours postoperatively.[42] Methadone 0.3 mg/kg combined with acepromazine 0.05 mg/kg or medetomidine 10 µg/kg and given IM as premedication for ovariohysterectomy produced superior analgesia to buprenorphine for 8 hours postoperatively.[43]

IV: Methadone 0.2 mg/kg IV; dexmedetomidine 1 µg/kg IV preceded[44]

Epidural: Methadone 0.1 mg/kg at induction; may combine this dose with ropivacaine 1.65 mg/kg.[45] Methadone 0.5 mg/kg lumbosacrally has also been used[46]; isoflurane MAC can be reduced by up to 30% with this higher methadone dose.

Analgesia (extra-label):

Continuous rate infusion (CRI): Methadone 0.1 – 0.2 mg/kg IV as a loading dose followed by methadone 0.12 mg/kg/hour IV CRI. Practically, add methadone 60 mg (6 mL of the 10 mg/mL injection) to 500 mL IV fluid (eg, 0.9% NaCl, Ringer's, 5% dextrose) at 1 mL/kg/hour. May be combined with ketamine and/or lidocaine[47]

Intermittent dosing:

1. Dosage recommendations vary but range from methadone 0.1 – 1 mg/kg IV,[45] SC, or IM every 4 to 8 hours.[6,22]
2. Methadone 0.2 mg/kg IV every 4 hours provided analgesia equivalent to fentanyl CRI following spinal surgery.[48]
3. Methadone 0.7 mg/kg IM provides sedation and analgesia as a premedication prior to orthopedic surgery.[49]
4. Methadone 0.5 mg/kg combined with acepromazine 0.02 mg/kg and given IM decreases isoflurane MAC.[50]
5. Methadone 0.3 mg/kg IV after medetomidine 2.5 µg/kg IV enhances sedation and provides postoperative analgesia.[51]

Premedication to general anesthesia (extra-label):

IM:

1. Methadone 0.2 – 0.3 mg/kg IM[52]

2. Methadone 0.2 mg/kg combined with acepromazine 0.02 mg/kg and given IM[53]
3. Methadone 0.2 mg/kg combined with dexmedetomidine 2 µg/kg and given IM prior to brachycephalic obstructive airway syndrome surgery[54]
4. Methadone 0.2 – 0.3 mg/kg combined with dexmedetomidine 5 µg/kg and given IM[55]
5. Methadone 0.2 – 0.3 mg/kg combined with dexmedetomidine 5 µg/kg and midazolam 0.3 mg/kg and given IM[56]
6. Methadone 0.2 – 0.3 mg/kg combined with medetomidine 20 µg/kg and given IM[57]

IV:

1. Methadone 0.2 mg/kg IV was used as a premedication, followed by isoflurane for anesthesia in a study of 32 dogs undergoing orthopedic surgery.[55]
2. Methadone 0.2 – 0.3 mg/kg IV with acepromazine 0.05 mg/kg IV[58]

SC: Methadone 1.1 mg/kg SC[22]

Extradural: Methadone 0.3 mg/kg diluted with saline to 0.2 mL/kg; acepromazine 0.05 mg/kg IV was used as a preanesthetic agent[58]

Sedative combinations (extra-label):

IM:

1. Methadone 0.25 – 0.75 mg/kg combined with acepromazine 0.05 mg/kg and given IM. For shorter sedation requirements (30 to 90 minutes), use methadone 0.25 mg/kg; for longer sedation requirements (up to 120 minutes), use methadone 0.5 – 0.75 mg/kg IM. Peak effect is achieved within 30 minutes.[39,59]
2. Methadone 0.5 mg/kg IM; can be combined with dexmedetomidine 10 µg/kg[60] or xylazine 0.5 mg/kg and given IM[39]
3. Methadone 0.4 mg/kg combined with medetomidine 2.5 µg/kg and given IM enhances sedation; bradycardia and panting may occur.[61]

IV: Methadone 0.2 mg/kg IV with dexmedetomidine 2 µg/kg IV[62]

CATS:

Perioperative pain control (extra-label):

IM combinations:

1. Methadone 0.5 mg/kg IM combined with medetomidine 20 µg/kg IM[63] or acepromazine 0.05 mg/kg IM[64]
2. Methadone 0.3 mg/kg IM, dexmedetomidine 15 µg/kg IM, and either alfaxalone 3 mg/kg IM or ketamine 3 mg/kg IM provided adequate analgesia and anesthesia and smooth recoveries for cats undergoing ovariectomy.[65]
3. **QUAD protocol**: methadone 5 mg/m^2 (NOT mg/kg), medetomidine 600 µg/m^2 (NOT µg/kg), ketamine 60 mg/m^2 (NOT mg/kg), midazolam 3 mg/m^2 (NOT mg/kg) mixed in the same syringe and given IM 10 minutes prior to anesthesia[66]

SC: Methadone 0.6 mg/kg with acepromazine 0.02 mg/kg SC as preoperative combination provided effective analgesia for 6 hours following ovariohysterectomy in most cats.[67]

Epidural:

1. In cats undergoing ovariohysterectomy, lumbosacral epidural combination of lidocaine 2% 4 mg/kg with methadone 0.3 mg/kg resulted in adequate surgical analgesia and prolonged (ie, greater than 18 hours) postoperative analgesia.[68]
2. Under maintenance anesthesia, methadone 0.2 mg/kg epidural reduced and delayed the need for postoperative rescue analgesia.[69]

Analgesia (extra-label):

Continuous rate infusion (CRI): Loading dose of 0.1 – 0.2 mg/kg IV; followed by 0.12 mg/kg/hour IV CRI. Practically, add methadone HCl 60 mg (6 mL of the 10 mg/mL injection) to 500 mL IV fluid and run at 1 mL/kg/hour IV CRI. May combine with ketamine and/or lidocaine[47]

Intermittent dosing:

1. Dosage recommendations vary but range from methadone 0.05 – 0.5 mg/kg IV, SC, or IM every 4 to 6 hours.
2. Methadone 0.2 – 0.6 mg/kg SC[17,70–72]; may repeat at 3 time points at 5 hour intervals.[22]
3. Methadone 0.5 mg/kg IM with ketamine 0.3 mg/kg IM 20 minutes before induction of anesthesia[73]
4. Methadone 0.75 mg/kg oral transmucosal provided transient antinociception under experimental conditions.[72]

Anesthesia premedication (extra-label): Methadone 0.1 – 0.6 mg/kg IV, IM, or SC[70,74]

IM combinations:

1. Methadone 0.2 mg/kg combined with acepromazine 0.05 mg/kg and given IM[75]
2. Methadone 0.2 mg/kg combined with dexmedetomidine 5 µg/kg and given IM[76]
3. Methadone 0.2 mg/kg combined with tiletamine/zolazepam 3 mg/kg and given IM[77]
4. Methadone 0.3 mg/kg combined with dexmedetomidine 3 – 4 µg/kg and given IM[78,79]

HORSES:

Analgesia (extra-label): 0.22 mg/kg IM or SC[23]

IV combination: Methadone 0.2 – 0.5 mg/kg IV. Can be combined with detomidine 10 µg/kg IV or acepromazine 0.05 mg/kg IV and given IV.[80–82] In one study, more pronounced antinociception occurred with the methadone/detomidine combination as compared with methadone/acepromazine.[81] Use of methadone 0.5 mg/kg IV provided better analgesia but more adverse effects.[80]

Continuous rate infusion (CRI):

1. Methadone 0.2 mg/kg combined with detomidine 5 µg/kg and given IV as a loading dose followed by methadone 0.05 mg/kg per hour and detomidine 12.5 µg/kg/hour IV CRI.[83,84] Decreased gut sounds occurred.

Epidural (extra-label): Methadone 0.1 mg/kg in the first intercoccygeal space (ie, Co1-Co2) diluted with sterile 0.9% sodium chloride solution to a total volume of 20 mL and administered at a rate of 1 mL/second; analgesia was attained 15 minutes after administration and lasted 5 hours.[2]

Restraint (extra-label): Methadone 0.11 mg/kg combined with acepromazine 0.055 mg/kg and given IV[23]

Premedication (extra-label): Methadone 0.1 mg/kg combined with romifidine 80 µg/kg and given IV; combination administered 30 to 120 minutes after acepromazine 0.02 mg/kg IM[85]

SHEEP:

Sedation (extra-label): Methadone 0.5 mg/kg IV combined with *either* xylazine 0.1 mg/kg *or* acepromazine 0.05 mg/kg IV[87,88]

Lumbosacral epidural (extra-label):

1. Methadone 0.15 – 0.3 mg/kg combined with bupivacaine 0.25 – 0.5 mg/kg[89,90,68]

Monitoring

- Analgesic or preanesthetic effect
- Respiratory depression at higher doses

Client Information

- Methadone should only be used in the clinic or with direct professional supervision when given as an injection.
- Methadone is a C-II controlled drug and requires a new written prescription for refills. Use of this medication in animals or humans other than those for whom they are prescribed is illegal.

Chemistry/Synonyms

Methadone HCl, a synthetic diphenylheptane-derivative narcotic agonist, occurs as an odorless, white crystalline powder. Methadone is freely soluble in water, chloroform, and alcohol and practically insoluble in ether or glycerol. The pH of a 1% solution in water is between 4.5 to 6.5. The commercially available injection has a pH from 3 to 6.5. Methadone is typically supplied as methadone hydrochloride (HCl) salt and doses are based on the concentration of the salt formulation (ie, 10 mg methadone HCl is equivalent to 8.9 mg methadone). The dispersible tablet formulation (ie, *Diskets*®) contains insoluble ingredients that deter their use for injection. Methadone injectable products and oral suspensions should be protected from light.[6]

Methadone may also be known as amidine HCl, amidone HCl, methadoni hydrochloridum, Phenadone, *Adolan*®, *Biodone*®, *Cloro Nona*®, *Comfortan*®, *Dolmed*®, *Eptadone*®, *Gobbidona*®, *Heptadon*®, *Ketalgine*®, *Metadol*®, *Metasedin*®, *Methaddict*®, *Methadose*®, *Methatabs*®, *Methex*®, *Methodyne*®, *Methone*®, *Pallidone*®, *Phymet*®, *Physeptone*®, *Pinadone*®, *Sedo*®, *Symoron*®, *Synastone*®, or *Synthadon*®.

Storage/Stability

Methadone injection should be stored at room temperature of 20°C to 25°C (68°F-77°F) and protected from light. Store vials in the manufacturer's carton until ready for use.

Methadone is a schedule II (C-II) controlled substance. In accordance with DEA regulations, it must be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Methadone injection is reportedly stable when mixed in a syringe with acepromazine and compatible with propofol and alfaxalone.

Methadone is **compatible** in solution with 0.9% sodium chloride, and appears **Y-site compatible** with the following drugs (partial list): ampicillin/sulbactam, calcium chloride/gluconate, cefazolin, dexamethasone sodium phosphate, dexmedetomidine, diazepam, dobutamine, dopamine, esmolol, esomeprazole, famotidine, hydrocortisone sodium succinate, magnesium sulfate, methylprednisolone sodium succinate, metoclopramide, midazolam, pantoprazole, phenobarbital, potassium chloride, and sodium bicarbonate.

Methadone injection is reportedly **incompatible** at Y-sites with acyclovir, allopurinol, amphotericin B conventional, dantrolene, fluorouracil, meloxicam, methohexital, pentobarbital, piperacillin-tazobactam, sulfamethoxazole-trimethoprim, and thiopental.

Methadone has reported **variable compatibility** at Y-sites with furosemide.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES

Methadone HCl Injection: (10 mg/mL) is approved for veterinary use in some countries (ie, United Kingdom, Australia).

The Association of Racing Commissioners International (ARCI) has designated this drug as a Class 1 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Methadone HCl Injection: 10 mg/mL in 20 mL multidose vials; generic; (Rx, C-II)

Methadone HCl Oral Tablets: 5 and 10 mg; *Dolophine*®; generic; (Rx, C-II)

Methadone HCl Dispersible Tablet: 40 mg; *Methadose*®; generic; (Rx, C-II)

Methadone HCl Oral Solution: 1 mg/mL and 2 mg/mL in 500 mL bottles; *Methadose*®; generic; (Rx, C-II)

Methadone HCl Oral Liquid Concentrate: 10 mg/mL in 30 mL (with calibrated dropper) and 1000 mL bottles; *Methadose*®, *Intensol*®; generic; (Rx, C-II)

Report dispensing to state monitoring programs where required.

Methazolamide

(meth-a-***zoe***-la-mide) *Neptazane*®

Carbonic Anhydrase Inhibitor

Prescriber Highlights

- ► Oral carbonic anhydrase inhibitor used primarily for open angle glaucoma; reportedly is becoming difficult to obtain at an affordable cost
- ► Contraindications include patients with significant hepatic, renal, or pulmonary disease, hyponatremia, hypokalemia, hypoadrenocorticism, hyperchloremic acidosis, or electrolyte imbalance.
- ► Primary adverse effects include GI (eg, vomiting, diarrhea, inappetence), hypokalemia, and metabolic acidosis. Cats may be more susceptible to developing adverse effects.
- ► Give oral doses with food if GI adverse effects occur.
- ► Monitor with tonometry for glaucoma; check electrolytes

Uses/Indications

Orally administered methazolamide is used for the medical treatment of glaucoma. Topical carbonic anhydrase inhibitors (eg, dorzolamide) are more commonly used today, as they can lower intraocular pressure as effectively as systemic drugs and have fewer adverse effects.

Pharmacology/Actions

The carbonic anhydrase inhibitors are noncompetitive, reversible inhibitors of carbonic anhydrase. Inhibition of carbonic anhydrase results in a reduction of the formation of hydrogen and bicarbonate ions from carbon dioxide and decreases the availability of these ions for active transport into body secretions.

Pharmacologic effects of the carbonic anhydrase inhibitors include decreased formation of aqueous humor, thereby reducing intraocular pressure; increased renal tubular secretion of sodium and potassium and, to a greater extent, bicarbonate, leading to increased urine alkalinity and volume; and anticonvulsant activity, which is independent of its diuretic effects (mechanism not fully understood, but may be due to carbonic anhydrase or a metabolic acidosis effect).

Pharmacokinetics

Little information is available. Methazolamide is absorbed from the GI tract, albeit more slowly than acetazolamide. It is distributed throughout the body, including the CSF and aqueous humor. Methazolamide is at least partially metabolized in the liver.

Contraindications/Precautions/Warnings

Carbonic anhydrase inhibitors are contraindicated in patients with significant hepatic disease (may precipitate hepatic coma), renal or adrenocortical insufficiency, hyponatremia, hypokalemia, hyperchloremic acidosis, or electrolyte imbalance. They should not be used in patients with severe pulmonary obstruction unable to increase alveolar ventilation (may precipitate acidosis) or in those that are hypersensitive to them. Long-term use of carbonic anhydrase inhibitors is contraindicated in patients with chronic, noncongestive, angle-closure glaucoma, as angle closure may occur, and the drug may mask the condition by lowering intraocular pressure.

Methazolamide is a sulfonamide derivative and has the potential to cause severe reactions. Stevens-Johnson syndrome, toxic epidermal necrolysis, and aplastic anemia have been reported in humans.[1]

Do not confuse methaZOLAMIDE with methIMAZOLE, or methENAMINE.

Adverse Effects

Adverse effects may include GI disturbances (eg, vomiting, diarrhea, inappetence), metabolic acidosis (with heavy panting), CNS effects (eg, sedation, depression, disorientation, excitement), hypokalemia, hematologic effects (eg, bone marrow depression, thrombocytopenia), renal effects (eg, crystalluria, dysuria, renal colic, polyuria, polydipsia), hyperglycemia, hyponatremia, hyperuricemia, hepatic insufficiency, dermatologic effects (eg, rash), and hypersensitivity reactions. Electrolyte imbalances may manifest as weakness or cardiac arrhythmias.

Cats may be more prone to developing adverse effects than are dogs.

Combining methazolamide (oral dosing) with topical (ophthalmic) dorzolamide does not apparently yield additive reductions in intraocular pressure and may cause increased adverse effects.

Reproductive/Nursing Safety

Methazolamide is teratogenic in rats at high doses. Safety for use of methazolamide during nursing has not been established, but a related compound, acetazolamide, is excreted in milk in concentrations that are unlikely to have pharmacologic effect.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Information regarding overdoses of this drug is not readily available. It is suggested to monitor serum electrolytes, blood gases, volume status, and CNS status during an acute overdose. Treat overdoses symptomatically and supportively.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methazolamide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antidepressants, Tricyclic**: Alkaline urine caused by methazolamide may decrease excretion.
- **Aspirin (or Other Salicylates)**: Increased risk for methazolamide accumulation and toxicity and metabolic acidosis; methazolamide increases salicylate excretion.
- **Digoxin**: As methazolamide may cause hypokalemia, there is increased risk for toxicity.
- **Insulin**: Rarely, carbonic anhydrase inhibitors interfere with the hypoglycemic effects of insulin.
- **Metformin**: Increased risk for lactic acidosis
- **Methenamine Compounds**: Methazolamide may negate effects in the urine.
- **Potassium And Drugs Affecting Potassium** (eg, **corticosteroids, amphotericin B, corticotropin, or other diuretics**): Concomitant use may exacerbate potassium depletion.
- **Phenobarbital, Primidone**: May increase urinary excretion and reduce phenobarbital levels
- **Quinidine**: Alkaline urine caused by methazolamide may decrease excretion.

Laboratory Considerations

- By alkalinizing the urine, carbonic anhydrase inhibitors may cause false positive results in determining **urine protein** using bromphenol blue reagent (*Albustix®*, *Albutest®*, *Labstix®*), sulfosalicylic acid (*Bumintest®*, *Exton's® Test Reagent*), nitric acid ring test, or heat and acetic acid test methods.
- Carbonic anhydrase inhibitors may **decrease iodine uptake** by the thyroid gland in hyperthyroid or euthyroid patients.

Dosages

DOGS:

Open-angle glaucoma (extra-label): Dosages usually range from 2 – 5 mg/kg PO 2 to 3 times a day.

CATS:

Open-angle glaucoma (extra-label): Dosages usually range from 1 – 4 mg/kg PO 2 to 3 times a day.

Monitoring

- Intraocular pressure/tonometry
- Serum electrolytes; pH. May need to supplement potassium.
- Baseline CBC with differential and periodic retests if using long term
- Adverse effects including GI disturbances, altered CNS status, and dermatologic abnormalities

Client Information

- This medicine must be given 2 to 3 times a day.
- If gastrointestinal upset (eg, vomiting, lack of appetite) occurs, give the medicine with food.
- Notify your veterinarian if abnormal bleeding or bruising occurs, or if your animal develops tremors or a rash.
- While your animal is taking this medication, it is important to return to your veterinarian for physical examinations and laboratory work. Do not miss these important follow-up visits.

Chemistry/Synonyms

A carbonic anhydrase inhibitor similar to dichlorphenamide, methazolamide occurs as a white to slightly yellow crystalline powder. It is very slightly soluble in water.

Methazolamide may also be known as *GlaucTabs®*, *Glaumetax®*, *MZM®*, and *Neptazane®*.

Storage/Stability

Methazolamide tablets should be stored in tightly closed containers at room temperature (20°C-25°C [68°F-77°F]), with excursions permitted to 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations

No specific information is noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The American Racing Commissioners International (ARCI) has des-

ignated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:
Methazolamide Tablets: 25 and 50 mg; *Neptazane®*; generic; (Rx)

Methenamine

(meth-***en***-a-meen) *Hiprex®, Urex®*
Urinary Antiseptic

Prescriber Highlights

- ► Urinary antiseptic used for recurrent UTIs in dogs and cats, but efficacy is questionable and no evidence supports its use
- ► Contraindications include metabolic acidosis, hypersensitivity to methenamine, concurrent treatment with sulfonamides, renal insufficiency, severe hepatic impairment (due to ammonia production), or severe dehydration.
- ► Adverse effects include GI irritation; dysuria is possible if used long term.
- ► Urine pH must be less than or equal to 6 (ideally less than 5.5) to be effective.

Uses/Indications

Methenamine is used as an antimicrobial agent for prophylaxis of recurrent UTIs. It is not commonly used in veterinary medicine and little good evidence is available to confirm its efficacy in dogs or cats.[1]

Pharmacology/Actions

In an acidic urinary environment (pH less than 6.5), methenamine is converted to formaldehyde. Formaldehyde is a nonspecific antibacterial agent that exerts a bactericidal effect. It can have activity against a variety of bacteria, including both gram-positive (*Staphylococcus aureus, Staphylococcus epidermidis, Enterococcus* spp) and gram-negative organisms (*Escherichia coli, Enterobacter* spp, *Klebsiella* spp, *Proteus* spp, and *Pseudomonas aeruginosa*), but may be less effective against those bacteria that produce urease (and increase urine pH). Reportedly, methenamine has activity against fungal UTIs.

Hippuric acid or mandelic acid is added primarily to help acidify the urine, but it also has some nonspecific antibacterial activity. Bacterial resistance to formaldehyde or hippuric acid does not usually occur.

Pharmacokinetics

Human data: Although methenamine and its salts are well absorbed from the GI tract, up to 30% of a dose may be hydrolyzed by gastric acid to ammonia and formaldehyde. With enteric-coated tablets, the amount hydrolyzed in the gut is reduced. While absorbed, plasma concentrations of both formaldehyde and methenamine are very low and have negligible systemic antibacterial activity. Methenamine does cross the placenta and is distributed into milk.

Within 24 hours, 70% to 90% of a dose is excreted unchanged into the urine.[2] In acidic urine, conversion to ammonia and formaldehyde takes place. Peak formaldehyde concentrations occur in the urine at ≈2 hours postdose (3 to 8 hours with enteric-coated tablets).

Contraindications/Precautions/Warnings

Methenamine and its salts are contraindicated in patients with known hypersensitivity to it, renal insufficiency, metabolic acidosis, severe hepatic impairment (due to ammonia production), or severe dehydration.

Because methenamine requires acidic urine to be beneficial, urine pH should ideally be kept at or below 5.5. Some urea-splitting bacteria (eg, *Proteus* spp and some strains of staphylococci, *Enterobacter* spp, and *Pseudomonas* spp) may increase urine pH. Addition of a urinary acidification program may be required using dietary modification and acidifying drugs (eg, ascorbic acid, methionine, sodium biphosphate, ammonium chloride).

Do not confuse meTHENAMine with meTHIOnine.

Adverse Effects

The most likely adverse effect noted is GI upset, with nausea, vomiting, and anorexia predominant. Some patients may develop dysuria, likely secondary to irritation due to high formaldehyde concentrations. Cats reportedly do not tolerate methenamine as well as dogs. Potentially, systemic acidosis could occur.

In humans, increased liver enzymes, pruritus, and rashes have rarely been reported, and large doses have caused bladder irritation, albuminuria, and hematuria. Lipoid pneumonitis has been reported in some humans that receive prolonged therapy with the suspension.

Reproductive/Nursing Safety

Methenamine crosses the placenta. Although laboratory animal studies have not demonstrated any teratogenic effects, it should be used with caution during pregnancy. Administration to pregnant dogs has been reported to cause a slight increase in stillborn rate and slight impairment of weight gain and survival in offspring.[2]

Methenamine enters milk; in humans, it is recommended to discontinue nursing or discontinue methenamine.[2]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Dogs have received single IV dosages of up to 600 mg/kg of methenamine hippurate without overt toxic effects. Large oral overdoses should be handled using established GI decontamination protocols, maintaining hydration status, and supportive care as required.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methenamine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Carbonic Anhydrase Inhibitors** (eg, **acetazolamide, methazolamide**): Use of drugs that alkalinize the urine may reduce the efficacy of the methenamine.
- ■ **Salicylates** (eg, **aspirin, bismuth subsalicylate**): Acidified urine may reduce salicylate excretion and increase salicylate concentrations.
- ■ **Sulfonamides** (eg, **sulfa-/trimethoprim, zonisamide**): Use of methenamine with sulfonamides is not recommended. An insoluble precipitate may form in urine.
- ■ **Thiazide Diuretics** (eg, **hydrochlorothiazide**): Use of drugs that alkalinize the urine may reduce the efficacy of the methenamine.
- ■ **Urine Alkalinizing Drugs** (eg, **calcium or magnesium containing antacids, citrates, sodium bicarbonate**): Use of urinary

alkalinizing drugs may reduce the efficacy of the methenamine.

Laboratory Considerations

- Urinary values of the following compounds may be falsely elevated: **catecholamines, vanillylmandelic acid (VMA),** and **17-hydrocorticosteroid.**
- Falsely decreased urinary values of **estriol** or **5-HIAA** may occur.
- Methenamine may cause false-positive **urine glucose determinations** when using cupric sulfate solution (Benedict's Solution, *Clinitest®*) and false-negative tests utilizing the glucose oxidase (*Tes-Tape®*, *Clinistix®*) method.

Dosages

DOGS/CATS:

Recurrent UTI (extra-label): No prospective studies supporting any dosage protocol were noted, and there is little evidence to support clinical use, but it theoretically could be effective. Recommended anecdotal dosages usually range from 10 – 20 mg/kg PO every 8 to 12 hours or 500 mg/dog (NOT mg/kg) every 12 hours or 250 mg/cat (NOT mg/kg) every 12 hours.[3] Practically, this is rounded off to the nearest 250 mg (as usually only available in 1 gram tablets). Requires acidic urine (pH less than or equal to 6; optimally less than 5.5) for efficacy and an acidifying diet and/or urinary acidifiers may be required. It reportedly is not tolerated well in cats.

Monitoring

- Urine pH
- Liver function tests periodically in patients with hepatic impairment[2]
- Efficacy (decreased frequency of UTI; monitor for clinical symptoms of UTI and urine culture periodically)

Client Information

- Give this medication with food to prevent stomach upset. Tablets are large but can be split.
- Vomiting, nausea (acting "sick"), and reduced appetite are common. Cats may not tolerate the drug as well as dogs.
- Requires urine to be acidic to work properly. Your veterinarian may recommend other drugs (eg, vitamin C, methionine) or dietary changes to increase urine acidity.
- While your animal is taking this medication, it is important to return to your veterinarian for physical examinations and laboratory work. Do not miss these important follow-up visits.

Chemistry/Synonyms

Methenamine is chemically unrelated to other anti-infective agents. It is commercially available as methenamine hippurate or methenamine mandelate. Methenamine mandelate occurs as a white crystalline powder and contains ≈48% methenamine and 52% mandelic acid. It is very soluble in water. Methenamine hippurate occurs as a white crystalline powder with a sour taste and contains ≈44% methenamine and 56% hippuric acid. It is freely soluble in water.

Methenamine may also be known as hexamine amygdalate, hexamine mandelate, mandelato de metenamina, *Aci-Steril®*, *Mandelamine®*, *Hiprex®*, *Reflux®*, *Urocedulamin®*, and *Urex®*.

Storage/Stability

Commercially available methenamine products should be stored at 15°C to 30°C (59°F-86°F). Because acids hydrolyze methenamine to formaldehyde and ammonia, do not mix with acidic vehicles before administering.

Compatibility/Compounding Considerations

Methenamine is physically **incompatible** when mixed with most alkaloids and metallic salts (eg, ferric, mercuric, or silver salts). Ammonium salts or alkalis will darken methenamine.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Methenamine Hippurate Oral Tablets: 1 g; generic; (Rx)

Methenamine Mandelate Tablets: 0.5 g and 1 g; generic; (Rx). These products are available but are not listed as an FDA-approved drug.

For the complete list of references, see **wiley.com/go/budde/plumb**

Methimazole

Thiamazole

(meth-***im***-a-zole) *Felimazole®, Tapazole®*

Antithyroid

Prescriber Highlights

- ► FDA-approved for treatment of feline hyperthyroidism
- ► The sugar coating on the veterinary-approved product masks the bitter taste that is noticed with uncoated human products.
- ► Transdermal methimazole gels can be considered in cats that do not tolerate oral administration.
- ► Review ***Contraindications/Precautions/Warnings*** before prescribing.
- ► Adverse GI effects occur most commonly in the first 3 months of therapy and are usually transient. Adverse hematologic or hepatic effects and facial excoriations may require discontinuation of therapy.
- ► Nursing should not be allowed for queens receiving methimazole; kittens should be placed on a milk replacer.
- ► Blood samples for monitoring thyroid hormone concentrations can be collected at any time of the day.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies methimazole as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Methimazole is considered by most clinicians in North America to be the drug of choice to treat feline hyperthyroidism. More than 90% of cats that tolerate methimazole respond to the drug.[1] In a retrospective case series, iodine 131 was more effective than methimazole in the treatment of hyperthyroid cats, and cats treated with iodine 131 had a survival time of 4 years as compared with 2 years for those treated with methimazole and 5.3 years in those that received methimazole followed by radioiodine.[2]

Transdermal methimazole (in pluronic lecithin organogel [PLO]) has been used with some therapeutic success in cats that cannot tolerate oral administration.[3–5] Four or more weeks of therapy may be required for the drug to reach efficacy. Orally administered methimazole is more effective than transdermal methimazole.[4]

Pharmacology/Actions

Methimazole inhibits thyroid peroxidase and interferes with iodine incorporation into tyrosyl residues of thyroglobulin, thereby inhibiting thyroid hormone synthesis. It also inhibits iodinated tyrosyl residues from coupling to form iodothyronine. Methimazole has no effect on the release or activity of thyroid hormones already formed or in general circulation. Significant reductions in serum thyroxine (T_4) usually occur within 2 to 3 weeks of therapy.[1,6]

Pharmacokinetics

In a study of healthy cats, peak drug concentration occurred 30 to 60 minutes after oral administration.[7–9] Average oral bioavailability was 80%, and elimination half-life was 5.1 to 6.6 hours, with wide inter-

patient variability (≈2 to 15 hours).[8,9] Administration in a fasted state increases absorption.[6] Protein binding is minimal. Absorption and steady-state volume of distribution (1.1 L/kg) are similar in normal and hyperthyroid cats, but elimination half-life is shorter (2.5 hours) in hyperthyroid cats.[9] The drug is renally eliminated.[10]

Drug absorption using compounded (pluronic lecithin organogel [PLO]-base) transdermal methimazole can be highly variable; in a study, methimazole was detectable in only 2 of 6 cats given a 5 mg dose.[11] However, in another study[12] in cats receiving methimazole PLO (either 2.5 mg/cat [NOT mg/kg] twice daily or 5 mg/cat [NOT mg/kg] once daily), at 1 and 3 weeks after starting treatment, all cats showed sustained suppression of T_4 concentration 10 hours after administration. In both groups, T_4 concentrations measured immediately before the next methimazole treatment were not significantly different as compared with measurements at any time point after application.[12] An alternative non-PLO–based transdermal methimazole formulation applied to the pinnae of healthy cats demonstrated more reliable absorption after a 10 mg/cat (NOT mg/kg) dose as compared with a 5 mg/cat (NOT mg/kg) dose.[13]

In dogs, methimazole has a serum half-life of 8 to 9 hours. Methimazole apparently concentrates in canine thyroid tissue.

Contraindications/Precautions/Warnings

Methimazole is contraindicated in patients that are hypersensitive to it, carbimazole, or the excipient, polyethylene glycol. The US veterinary label states that methimazole is contraindicated in cats with autoimmune disease, primary liver disease, renal failure, or hematologic disorders (ie, anemia, neutropenia, lymphopenia, thrombocytopenia) or coagulopathies[6]; the UK veterinary label also states, *Do not use in cats suffering from systemic disease such as primary liver disease or diabetes mellitus.*[10] Cats with liver disease can potentially receive the drug at lower doses with dose titration and liver function tests intensely monitored.

Treatment of hyperthyroid cats with methimazole can unmask underlying renal disease because lowering thyroid hormone concentrations decreases glomerular filtration rates.[14] An estimated 40% of hyperthyroid cats also have chronic kidney disease.[15] As such, the cat's renal parameters should be monitored closely during treatment (see ***Monitoring***). A significant reduction in serum creatinine was noted after restoration of euthyroidism in cats with iatrogenic hypothyroidism caused by methimazole or carbimazole.[16] Appropriate dose adjustments to avoid iatrogenic hypothyroidism are important, as cats with iatrogenic hypothyroidism are at an increased risk for azotemia.

An increasing prevalence of moderate-to-severe thyroid disease (eg, large thyroid tumors, multifocal disease, intrathoracic thyroid masses) was associated with an increased duration of methimazole treatment, which the study authors speculated may indicate a progressive nature of feline hyperthyroidism that is not stopped by maintaining euthyroidism with methimazole.[17]

Methimazole has antivitamin K activity, which may increase risk for bleeding.[6]

The National Institute for Occupational Safety and Health (NIOSH) classifies methimazole as a hazardous drug representing an occupational hazard to healthcare workers; wash hands after handling and use personal protective equipment (PPE) accordingly to minimize the risk for exposure.[18]

MethIMAzole should not be confused with meTAMizole (dipyrone), methazolamide, or metOLazone.

Adverse Effects

Most adverse effects associated with methimazole use in cats occur within the first 3 months of therapy, with vomiting, anorexia, depression/lethargy, and abnormal vocalization occurring most frequently.[6,19] GI effects occur in ≈10% of treated cats and may be related to the drug's bitter taste or direct gastric irritation and are usually transient. Cats that cannot tolerate GI adverse effects may tolerate transdermal methimazole. Other systemic adverse effects occur at similar rates when comparing oral with transdermal methimazole, although skin reactions (eg, erythema) may occur at the transdermal application site.[3]

Eosinophilia, leukopenia, thrombocytopenia, and lymphocytosis may be noted in ≈15% of cats in the first 8 weeks of therapy[19]; these hematologic effects usually resolve within a week of drug withdrawal.[1] Blood dyscrasias (eg, severe thrombocytopenia, bleeding, neutropenia, agranulocytosis) can occur in ≈4% of cats and typically occurs within the first 1 to 2 months of treatment.[19] Methimazole use should be discontinued in these patients, and prophylactic antibiotic therapy and other supportive measures can be considered.[10] Methimazole rechallenge can cause recurrence of adverse effects.[20]

Methimazole-treated cats can develop pruritus and facial excoriations. Incidence of these effects has been reported to be 2% to 3%, with most cases occurring within the first 3 weeks of treatment,[20] although an incidence rate of up to 15% has been reported.[21] Discontinuation of methimazole is warranted in these cases.

Increased ALT may occur early in therapy and normalize with continued therapy. Other serious but rare adverse effects include hepatopathy (1.5% of cases) and a positive direct antiglobulin test result (1.9% of cases).[19] Methimazole and carbimazole are thought to be potential triggers for immune-mediated hemolytic anemia and/or immune-mediated thrombocytopenia in cats[22]; in such cases, drug withdrawal is generally required. If methimazole must be discontinued due to adverse effects, alternative therapies (eg, radioiodine, antithyroid diet) should be considered.

Up to 20% of cats receiving methimazole chronically (longer than 6 months) will develop a dose-dependent positive antinuclear antibody result and require dose reduction.[6,19]

Rarely, cats can develop an acquired myasthenia gravis that requires drug withdrawal or concomitant glucocorticoid therapy. Pyogranulomatous mural folliculitis[23] and lymphadenomegaly[24] have been reported.

Reproductive/Nursing Safety

Delayed testes maturation was noted in a 12-week safety study.[6] High concentrations of methimazole cross the placenta and may induce hypothyroidism in kittens born of queens receiving the drug. The drug is contraindicated in pregnant or lactating queens, as laboratory studies in mice and rats have shown evidence of teratogenic and embryotoxic effects.

Methimazole concentrations higher than those found in plasma have been detected in human breast milk, so it has been suggested that queens not allow kittens to nurse; kittens should be placed on a milk replacer after receiving colostrum from a queen on methimazole.

Overdose/Acute Toxicity

Signs of acute toxicity that may be seen with overdoses include those listed in ***Adverse Effects***. Agranulocytosis, hepatopathy, immune-mediated hemolytic anemia, and thrombocytopenia are likely the most serious effects that may be seen. Treatment of overdose/toxicity consists of following standard protocols for handling an oral ingestion (eg, empty stomach, administer charcoal if not contraindicated) and treat supportively and based on clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Hyperthyroidism increases glomerular filtration rate (GFR). Methimazole restores euthyroidism, thereby reducing GFR,[14] which may alter the pharmacokinetics of drugs that rely on GFR for elimination from the body. The following drug interactions have either been reported or are theoretical in humans or animals receiving methimazole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Anticoagulants** (eg, **heparin, rivaroxaban**): Methimazole may potentiate anticoagulant activity.
- **Benzimidazole Antiparasitics** (eg, **albendazole**, **fenbendazole**, **thiabendazole**): Concurrent methimazole use can reduce hepatic oxidation of benzimidazoles and increase blood concentrations of the parent drug or its metabolites.[6,25–27]
- **Beta-Blockers** (eg, **atenolol, propranolol**): Reduction in the beta-blocker dose may be needed when the patient becomes euthyroid.[6]
- **Chloramphenicol**: Combination may increase the risk for myelosuppression.
- **Digoxin**: Correction to euthyroidism reduces digoxin clearance, resulting in increased digoxin exposure and risk for toxicity. A reduction in the digoxin dose may be needed when the patient becomes euthyroid.[6]
- **Dipyrone**: Combination may increase the risk for myelosuppression.
- **Iodine 131**: Methimazole does not appear to have a significant impact on radioiodine efficacy and discontinuing methimazole prior to radioiodine does not appear necessary.[1]
- **Phenobarbital**: Concurrent use of phenobarbital may reduce the clinical effectiveness of methimazole.[6]
- **Prednis(ol)one**: A reduction in dose may be needed when the patient becomes euthyroid.
- **Technetium-99m Pertechnetate**: Thyroid scintigraphy has not been shown to be significantly altered by methimazole in hyperthyroid cats.[28]
- **Theophylline**: A reduction in the theophylline dose may be needed when the patient becomes euthyroid.[6]
- **Warfarin**: In humans with hyperthyroidism, the metabolism of vitamin K clotting factors is increased, resulting in increased sensitivity to oral anticoagulants. By reducing the effects of hyperthyroidism, methimazole may decrease clotting factor metabolism, thus reducing the effects of warfarin. However, patients that are euthyroid on methimazole and receiving warfarin may develop hypoprothrombinemia if methimazole is stopped and they become thyrotoxic again. Methimazole also has antivitamin K activity, and the veterinary label states that anticoagulants may be potentiated by methimazole.[6] Recommendation: If methimazole and warfarin are used together, increased monitoring of anticoagulant effect is warranted.

Laboratory Considerations

None were noted.

Dosages

CATS:

Hyperthyroidism (label dosage; FDA-approved): Starting dose is 2.5 mg/cat (NOT mg/kg) PO every 12 hours.[6] After 3 weeks of treatment, the dose should be titrated to effect based on individual serum total T_4 (TT_4) concentrations and clinical response. Dose adjustments should be made in 2.5 mg increments. The maximum total dose is 20 mg per day divided, not to exceed 10 mg as a single administration. In an extended-use field study, the average maintenance dose was 2.5 mg/cat (NOT mg/kg) twice daily, with a range of 2.5 – 15 mg/cat (NOT mg/kg) per day.

Hyperthyroidism (extra-label):

Oral: An initial methimazole dose of 1.25 – 2.5 mg/cat (NOT mg/kg) PO twice a day; in cases of extremely elevated TT_4, an initial dose of 5 mg/cat (NOT mg/kg) PO twice a day can be used. TT_4 should be evaluated 2 to 3 weeks after starting therapy or after any treatment adjustment(s) until euthyroidism is achieved; most cats will become euthyroid after this time. Doses are titrated in 2.5 mg/day increments to obtain and maintain circulating TT_4 concentrations in the lower half of the reference interval. Once euthyroidism is achieved, once-daily dosing can be considered.[1,15,29]

Transdermal: Methimazole (50 mg/mL; 5 mg/0.1 mL) in pluronic lecithin organogel (PLO) for transdermal administration: 2.5 – 5 mg/cat (NOT mg/kg) to inner pinna every 12 hours; alternate ear with each application.[3,4,12] See ***Compatibility/Compounding Considerations***. Gloves or finger cots should be worn when applying the medication. Convenience of administration must be weighed against somewhat lower efficacy than the oral form (67% vs 82% euthyroid at 4 weeks).[4] Lower incidence of GI effects with transdermal as compared with the oral form (4% vs 24%). No difference in facial excoriation, neutropenia, hepatotoxicity, or thrombocytopenia between the transdermal and oral form has been reported. Drawbacks of transdermal administration include erythema at the application site (alternating application site location helps prevent this), increased cost, and stability of compounded medication (guaranteed stable for 2 weeks).[30] Considering these drawbacks, topical preparations are a good alternative in cats intolerant of administration of oral dose forms.[29]

SMALL MAMMALS:

Hyperthyroidism in guinea pigs (from a case report of 3 animals treated medically[31]): Initial dose was methimazole 1 – 1.4 mg/kg PO once daily. Maintenance dosages were 2 – 3 mg/kg PO once daily for 2 animals, and 2.5 mg/kg PO every 8 hours in the third animal. All 3 animals showed improvement of clinical signs during therapy but not until the dose or frequency of administration was increased. Therefore, regular monitoring of circulating TT_4 concentrations may be required to determine appropriate dosage.[31]

Monitoring

Published guidelines recommend the following[20]:

- Owners should be counseled to monitor for lethargy, vomiting, inappetence, jaundice, or pruritus.
- The drug should be stopped at the first potential sign of adverse effects.
- The cat should be evaluated as soon as possible by performing a physical examination for skin excoriations, ruling out blood dyscrasia (CBC), ruling out hepatotoxicity (ALT, bilirubin, ALP) and comparing values with pretreatment liver enzymes (often reversibly increased in hyperthyroid cats), evaluating for renal decompensation (BUN, creatinine), and checking serum TT_4.
- If simple GI upset (ie, blood work is normal): A dose reduction should be initiated or the animal switched to transdermal methimazole, which has a lower incidence of GI upset than oral methimazole.

During the first 3 months of therapy (baseline values and after 3 and 6 weeks of treatment)[6]:

NOTE: Cats receiving daily doses that exceed 10 mg should be monitored more frequently.

- CBC with platelet count
- Serum chemistry profile

- Serum TT_4: Blood samples can be collected at any time and do not need to be collected at a prescribed time after methimazole treatment.
- Antinuclear antibody (ANA) testing, if indicated by clinical signs

After stabilization (at least 3 months of therapy)[6]:
- TT_4 at 3- to 6-month intervals
- Other diagnostic tests as indicated by adverse effects

Client Information
- Although this medicine decreases excessive thyroid hormones, it does not cure the condition. Give this medicine as directed by your veterinarian. It may take several weeks before your cat shows clinical improvement.
- Most side effects, including vomiting, decreased appetite, or lethargy (eg, tiredness, lack of energy), occur in the first 3 months of therapy.
- This medicine is available in different dosage forms, including a compounded topical gel that can be applied to your animal's skin.
- Wear gloves when the transdermal/topical formulation is applied to your animal's skin. Wash hands with soap and water after handling the medicine (even if gloves are worn) and when cleaning waste from the litter box.
- Pregnant women, women who may become pregnant, and nursing mothers should wear gloves when handling this medicine, litter, or bodily fluids of treated cats.
- Do not use the transdermal gel if it appears visibly separated (ie, not uniform in appearance).
- Crusted material that forms on your cat's ear can be removed with moistened gauze or cotton ball prior to the next dose. Alternate ears with each application.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms
Methimazole, a thioimidazole-derivative (thioureylene) antithyroid drug, occurs as a white to pale-buff crystalline powder and has a faint characteristic odor and a melting point of 144°C to 147°C (291.2°F-296.6°F). It is freely soluble (1 gram in 5 mL) in water or alcohol.

Methimazole may also be known as thiamazole, mercazolylum, methylmercaptoimidazole, thiamazolum, tiamazol, *Felimazole®*, and *Tapazole®*.

Storage/Stability
Methimazole tablets should be stored in well-closed, light-resistant containers at room temperature 25°C (77°F) with excursions between 15°C and 30°C (59°F-86°F) permitted; protect from moisture.

Compatibility/Compounding Considerations
Compounded transdermal formulations of methimazole in a pluronic lecithin organogel (PLO) vehicle have been investigated,[3,4,11,12] and, although another proprietary formulation has been reported,[13,32] studies validating other common compounding vehicles (eg, *Lipoderm®*) were not located.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:
Methimazole Tablets (sugar-coated): 2.5 mg and 5 mg; *Felimazole®*; (Rx). FDA-approved for use in cats. NADA #141-292. 1.25 mg tablets are available in the UK, in addition to 2.5 mg and 5 mg (POM-V).

HUMAN-LABELED PRODUCTS:
Methimazole Tablets (plain and scored): 5 mg and 10 mg; *Tapazole®*, generic; (Rx)

Methionine
DL-Methionine
Racemethionine

(me-***thye***-oh-neen) *Methio-Form®*
Urinary Acidifier, Nutritional

Prescriber Highlights
- ► Used primarily as a urinary acidifier; may be useful in managing struvite urolithiasis
- ► Contraindications include renal failure, pancreatic disease, hepatic insufficiency, pre-existing acidosis, and oxalate or urate calculi. Not recommended for kittens
- ► Adverse effects include GI distress (food may alleviate) and Heinz-body hemolytic anemia (cats).

Uses/Indications
In small animal species, methionine has been used primarily for its urine acidification effect in the treatment and prevention of certain types of urolith formation (eg, struvite) and to reduce ammoniacal urine odor. Use of methionine is generally not recommended unless urine pH is more than 6.5. Feeding of acidifying commercial feline diets can successfully minimize or dissolve struvite urolith formation,[1,2] and methionine can be considered for cats for which these diets are contraindicated or that cannot be fed.

In food animal species, methionine has been used as a nutritional supplement in swine and poultry feed and in the treatment of ketosis in cattle. It has been suggested as a treatment for laminitis in horses and cattle (purportedly provides a disulfide bond substrate to maintain the hoof-pedal bone bond), but definitive studies demonstrating its effectiveness for this indication are lacking. A small study in male goats (wethers) concluded that methionine may be a more palatable alternative for urine acidification in small ruminants.[3]

Pharmacology/Actions
Methionine has several pharmacologic effects. It is an essential amino acid (l-form) and nutrient, a lipotrope (prevents or corrects fatty liver in choline deficiency), and a urine acidifier. Two molecules of methionine can be converted to one molecule of cysteine. Methionine supplies both sulfhydryl and methyl groups to the liver for metabolic processes. Choline is formed when methionine supplies a methyl group to ethanolamine. After methionine is metabolized, sulfate is excreted in the urine as sulfuric acid, thereby acidifying the urine.

Pharmacokinetics
No information is available on the pharmacokinetics of this agent in veterinary species or humans.

Contraindications/Precautions/Warnings
Methionine (at pharmacologic doses) is contraindicated in patients with severe renal or pancreatic disease.[4] If used in patients with severe hepatic disease, methionine can cause increased production of mercaptan-like compounds and intensify the signs of hepatic encephalopathy or coma. Methionine should not be given to animals with pre-existing acidosis (eg, diabetic ketoacidosis) or with oxalate or urate calculi. It is not recommended for use in kittens, as excess dietary methionine has been shown to alter growth.[5]

Use of methionine in combination with a urinary acidifying diet is not recommended.

Do not confuse methionine with methenamine or S-adenosyl-L-methionine (SAMe).

Adverse Effects

At recommended dosages, GI distress can occur; give with food or divide into multiple meals to alleviate this effect.[4] Methionine may cause Heinz-body hemolytic anemia in cats. See ***Overdose/Acute Toxicity*** (below) for other potential adverse effects.

Unmonitored use of methionine with an acidifying diet may increase the risk for adverse effects or acute toxicity.

Reproductive/Nursing Safety

No specific information was located. Methionine administration to the dam could cause fetal acidosis.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Vomiting and ataxia are the most common clinical signs of overdose in dogs. Vomiting may occur at doses as low as 22.5 mg/kg. At higher doses (300 mg/kg), vocalization, tremors, hypermetria, tremors, and disorientation may occur. Methionine may be toxic to kittens that consume food in which methionine has been added. When methionine was administered at a dose of 2 g/kg PO daily to mature cats, anorexia, methemoglobinemia, Heinz-body formation (with resultant hemolytic anemia), ataxia, and cyanosis were noted. An ingestion of 20 grams/cat (NOT mg/kg) is likely to be fatal without treatment.[4] Metabolic acidosis may occur with overdoses in any species, particularly in combination with an acidifying diet.

Treatment can include GI decontamination (if the ingestion occurred within 2 to 4 hours prior to presentation), supportive therapy, and correction of acid/base abnormalities. Clinical signs generally resolve within 24 to 48 hours.[6]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methionine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides** (eg, **amikacin, gentamicin**): Aminoglycosides are more effective in an alkaline medium; urine acidification may diminish the effectiveness of these drugs in treating bacterial UTIs.
- **Antiarrhythmic Agents** (**lidocaine, mexiletine, procainamide, quinidine**): Urine acidification may increase excretion of these antiarrhythmic agents, potentially reducing their efficacy.
- **Carbonic Anhydrase Inhibitors** (eg, **acetazolamide, methazolamide**): May negate the effect of each drug on urine pH. Avoid combination.
- **Citrate, Potassium**: May negate the effect of each drug on urine pH. Avoid combination.
- **Colchicine**: Urine acidification may increase colchicine excretion, potentially reducing its efficacy.
- **Ephedrine**: Urine acidification may increase ephedrine excretion, potentially reducing its efficacy.
- **Erythromycin**: Erythromycin is more effective in an alkaline medium; urine acidification may diminish the effectiveness of erythromycin in treating bacterial UTIs.
- **Phenylpropanolamine (PPA)**: Urine acidification may increase PPA excretion, potentially reducing its efficacy.
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**): Urine acidification may decrease salicylate excretion and increase plasma salicylate concentration.
- **Zonisamide**: May reduce the ability of methionine to acidfy the urine.

Laboratory Considerations

- No known laboratory considerations

Dosages

DOGS:

Urine acidification (label dosage; not FDA-approved): 150 – 300 mg (2 – 4 mEq)/kg PO daily.[3] Practically, small breeds (less than 7 kg [15 lb]): ½ – 4 tablets PO daily; medium breeds (7 to 15 kg [15 to 33 lb]): 2 – 7 tablets PO daily; large breeds (15 to 30 kg [33 to 66 lb]): 4 – 13 tablets PO daily. Once-daily dosing is appropriate, but daily dose may be administered in 2 or 3 divided doses. **NOTE**: Tablets can be crushed and sprinkled over the food.

Urine acidification; infection-induced struvite dissolution (extra-label): 75 – 100 mg/kg PO every 12 hours in combination with an appropriate antibiotic microbial agent and without using a struvite dissolution diet. Continue antibiotic until urolith is dissolved. Reconsider diagnosis and/or choice of antibiotic if uroliths have not decreased in size by 50% within one month of treatment initiation.[7]

CATS:

Urine acidification (label dosage; not FDA-approved): 188 – 375 mg (2.5 – 5 mEq)/kg PO daily.[3] Practically, ½ – 1 tablet/1 to 1.5 kg (2.5 to 3 lb) body weight; average-sized cats typically receive 1-½ – 3 tablets (10 – 20 mEq) PO daily. Once-daily dosing is appropriate, but daily dose may be administered in 2 or 3 divided doses. **NOTE**: Tablets can be crushed and sprinkled over the food.

Urine acidification (extra-label): 1000 – 1500 mg/cat (NOT mg/kg) PO daily given in the food once daily[8] if diet and antimicrobials do not reduce urine pH.[9]

SMALL RUMINANTS:

Urine acidification (extra-label): 200 mg/kg PO daily in feed.

Monitoring

- Urine pH (urine pH of less than or equal to 6.5 has been recommended as goal of therapy)
- Blood pH if signs of toxicity are present
- CBC in cats exhibiting signs of toxicity
- If attempting medical dissolution of struvite uroliths, monthly monitoring of abdominal radiographs and/or ultrasonography monthly until calculi are no longer visible

Client Information

- Give with meals or mixed in food, unless otherwise instructed by your veterinarian.
- Do not use in combination with a urinary acidifying diet unless directed to do so by a veterinarian.
- Discontinue use and contact your veterinarian if your animal starts vomiting, has difficulty walking, or develops any new signs.
- While your animal is taking this medication, it is important to return to your veterinarian for urine and other testing. Do not miss these important follow-up visits.

Chemistry/Synonyms

A sulfur-containing amino acid, methionine occurs as a white, crystalline powder with a characteristic odor. One gram is soluble in ≈30 mL of water and it is very slightly soluble in alcohol. 74.6 mg is equivalent to 1 mEq of methionine.

Methionine may also be known as dl-methionine, racemethionine, M, s-methionine, l-methionine, methioninum, *Ammonil®*, *Methigel®*, *Methio-Form®*, *Pedameth®*, and *Uracid®*.

Storage/Stability
Methionine should be stored at room temperature.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:
Methionine is labeled for use in dogs, cats, and horses in pharmaceutical dosage forms; however, there are no methionine products listed in the FDA's Green Book of approved products. Products labeled as nutritional supplements may be approved for use in other species. Depending on the product, methionine may be available without prescription. Methionine is an ingredient found in many other nutritional products.

Methionine Tablets: 200 mg and 500 mg; *Ammonil® Tablets*, generic; (Rx). Labeled for use in cats and dogs

Methionine Tablets Chewable: 500 mg; *Methio-Form®*; (Rx). Labeled for use in cats and dogs

Methionine Powder (concentration varies with product); may also be called d-l-Methionine Powder. Labeled for use in dogs and cats

Methionine Gel: 480 mg/6 g (8%) in 120.5 g tubes; *Methigel®*; (OTC). Labeled for use in cats and dogs

HUMAN-LABELED PRODUCTS:
Methionine Capsules: 200 mg and 500 mg; (OTC, Rx)

Methionine Tablets: 500 mg; generic; (OTC, Rx)

Methionine Oral Powder 100 mg/packet; generic; (OTC)

Topical ointments, cream, lotion, pads, and powder available

For the complete list of references, see **wiley.com/go/budde/plumb**

Methocarbamol
(meth-oh-***kar***-ba-mole) *Robaxin®*
Muscle Relaxant

Prescriber Highlights
- ► Oral and injectable centrally acting muscle relaxant; appears useful in treating muscle tremors associated with toxic agents
- ► Contraindications include food animals, animals with renal disease (injectable only), and animals with a hypersensitivity to methocarbamol.
- ► Adverse effects include sedation, salivation, emesis, lethargy, weakness, and ataxia.
- ► IV administration should be slow, not to exceed 2 mL/minute in dogs and cats. Avoid extravasation. May be given IM but not SC
- ► Use caution when using with other CNS depressant drugs, as additive CNS and respiratory depression can occur.

Uses/Indications
Methocarbamol is FDA-approved for oral and IV use in dogs and cats as an adjunctive treatment for acute inflammatory and traumatic conditions of skeletal muscle and for reduction of muscular spasms.[1] Methocarbamol has been effective in treating skeletal muscle hyperactivity due to intervertebral disc syndrome, myelitis, spinal cord injury (where cord remains intact), sprains and strains, and myositis/bursitis/synovitis. It has also been used for muscular spasms prior to or following surgical procedures and to maintain muscle relaxation in tetanus. Methocarbamol has also been found useful in treating tremors and muscle fasciculations associated with various toxicities (eg, metaldehyde, pyrethroids, strychnine, CNS stimulants [eg, caffeine, amphetamines, guarana], SSRIs, tremorgenic mycotoxins, compost ingestions) in dogs and cats. One retrospective study in cats found that after permethrin toxicity, cats that received methocarbamol had a shorter duration of hospitalization compared with cats that did not receive methocarbamol.[2]

In horses, methocarbamol is FDA-approved for IV use as an adjunctive therapy for acute inflammatory and traumatic conditions of the skeletal muscle to reduce muscular spasms and affect striated muscle relaxation.[1] Efficacy has been demonstrated for sprains and strains, myositis/fibrositis/bursitis/synovitis, and tying-up syndrome. It has also been used for muscular spasms prior to or following surgical procedures and to maintain muscle relaxation in tetanus.

Pharmacology/Actions
Methocarbamol is a central nervous system depressant with sedative and musculoskeletal relaxant properties.[3] The exact mechanism for causing skeletal muscle relaxation is uncertain, but it is thought to work centrally on the internuncial neurons. Its prolonged blocking effect on polysynaptic neurons reduces skeletal muscle hyperactivity. Methocarbamol has no direct relaxant effects on striated muscle, nerve fibers, or the motor endplate.[4] It will not directly relax contracted skeletal muscles. The drug has a secondary sedative effect at higher doses.

Pharmacokinetics
Methocarbamol is readily absorbed orally in dogs, with peak concentrations at 2 hours and a dose-dependent half-life of 0.6 to 2 hours. Methocarbamol and its metabolites are extensively conjugated before excretion in urine. There is limited excretion (ie, 2%) in feces, and most methocarbamol is eliminated within 24 hours.[5]

In horses, oral paste bioavailability is ≈50%[6]; the volume of distribution is 1.6 L/kg, clearance is 6 to 9 mL/kg/minute, and elimination halflife is 3 to 4 hours.[7] In a study,[7] the elimination half-life for single 5 g and 15 g oral (paste) doses were 32 and 3.7 hours, respectively, and there was no significant difference between the single dose of 15 g and multiple doses of 15 g (4.1 hours). The majority of horses given a single oral dose or multiple oral doses of 15 g were above the regulatory threshold set by the Association of Racing Commissioners International (ARCI) at the recommended withdrawal time. The study concluded that, because of the similarities between absorption and elimination half-lives, the difference in the time above the regulatory threshold with a 15 g oral dose (as compared with a 5 g dose) is likely due to higher drug exposure rather than lower clearance.

In humans, methocarbamol has an onset of action ≈30 minutes after oral administration. Peak concentrations occur ≈2 hours after administration, and plasma protein binding is ≈50%. The serum half-life is ≈1 to 2 hours. The drug is metabolized, and the inactive metabolites are excreted into the urine and the feces (small amounts).

Guaifenesin is a minor metabolite of methocarbamol and was quantifiable after oral administration, which may have regulatory ramifications in racing; however, it probably has little clinical effect.

Contraindications/Precautions/Warnings
Methocarbamol should not be used in patients that are hypersensitive to it or in food animals.

Methocarbamol should not be administered SC, and extravasation should be avoided, as the injection is hypertonic; IV administration should not exceed 2 mL/minute in dogs and cats.[4]

Because the injectable product contains polyethylene glycol (PEG) 300, the manufacturer lists known or suspected renal pathology as a contraindication to injectable methocarbamol therapy.[3] PEG 300 has been noted to increase pre-existing acidosis and urea retention in

humans with renal impairment. In addition, drug clearance is reduced with severe renal impairment or severe hepatic impairment; dosage reduction may be necessary. Use methocarbamol with caution in patients with known or suspected seizure disorders. In humans, IV administration rate should not exceed 3 mL/minute due to the risk for bradycardia and hypotension attributable to PEG 300.[3]

Adverse Effects

Adverse effects can include sedation, salivation, emesis, lethargy, weakness, loss of righting reflex, and ataxia in dogs and cats. These effects appear to be related to dose and rate of injection. Sedation and ataxia are possible in horses. Because of its CNS depressant effects, methocarbamol may impair the abilities of working animals.

In humans, serious adverse effects include anaphylactic reactions and seizures.[3] Onset of convulsive seizures during IV administration of methocarbamol has been reported in patients with seizure disorders.

Reproductive/Nursing Safety

It is unknown whether methocarbamol crosses the placenta and what the effects are, if any, on the developing fetus. It should be used with caution during pregnancy, as studies demonstrating its safety during pregnancy are lacking.

Methocarbamol or its metabolites are excreted in the milk in dogs.[8] In humans, the Briggs breastfeeding recommendation states that methocarbamol is likely compatible with breastfeeding. Caution should be used in nursing dams.[9]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The reported oral LD_{50} in rats and dogs is 1.32 g/kg and 2 g/kg, respectively.[10] Overdose is generally characterized by CNS depressant effects (eg, loss of righting reflex, prostration). In dogs and cats, excessive doses may cause emesis, salivation, weakness, and ataxia.

GI decontamination protocols may be indicated if the patient presents within 2 to 3 hours of a toxic ingestion. Emesis should not be induced if the patient's continued consciousness cannot be assured. Severe clinical signs should be treated supportively, including maintenance of an adequate airway and administration of IV fluids if necessary.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methocarbamol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antihistamines** (eg, **diphenhydramine**): Increased risk for CNS depression
- **Benzodiazepines** (eg, **diazepam, midazolam**): Increased risk for CNS depression
- **Buprenorphine**: Methocarbamol may enhance the CNS depressant effect of buprenorphine.
- **CNS Depressants** (eg, **acepromazine, baclofen, dexmedetomidine, trazodone**): Additive depression may occur when methocarbamol is given with other CNS depressant agents.
- **Gabapentin**: Concurrent use may result in respiratory depression.
- **Metoclopramide**: Increased risk for CNS depression
- **Mirtazapine**: Methocarbamol may enhance the CNS depressant effect of mirtazapine.
- **Opioids** (eg, **buprenorphine, morphine, tramadol**): Increased risk for CNS depression
- **Phenobarbital**: May result in additive respiratory depression
- **Pyridostigmine**: Methocarbamol may diminish the therapeutic effect of pyridostigmine.
- **Selective Serotonin Reuptake Inhibitors (SSRIs;** eg, **fluoxetine, paroxetine)**: Methocarbamol may enhance the adverse/toxic effects of SSRIs.

Laboratory Considerations

- Methocarbamol may cause color interference in certain screening tests for **5-hydroxyindoleacetic acid** using nitrosonaphthol reagent and in screening tests for urinary **vanillylmandelic acid** using the Gitlow method.

Dosages

DOGS/CATS:

Reducing muscle spasms from acute inflammatory and traumatic conditions of the skeletal muscle (label dosage; FDA-approved):

a) **Injectable**:

i. For relief of moderate conditions: 44 mg/kg IV initial dose[4]

ii. For controlling severe effects of strychnine and tetanus: 55 – 220 mg/kg IV initial dose.[4] Rapidly administer 1/2 of the total dosage, allow muscle relaxation to occur, then administer the remainder of the dosage. Additional doses may be needed to relieve residual effects or prevent a recurrence. The total cumulative dose should not exceed 330 mg/kg.[4] Administer IV at a rate no faster than 2 mL/minute.

b) **Oral (tablets)**: 132 mg/kg PO on Day 1 in 2 or 3 equally divided doses (ie, every 8 to 12 hours), then 66 – 132 mg/kg/day PO divided every 8 to 12 hours.[11] Discontinue therapy if there is no response within 5 days.[12]

Adjunctive treatment of toxicities associated with muscle tremors (extra-label): Although there are no controlled studies documenting efficacy in animals, consider using an initial IV bolus, followed by a CRI or multiple (if required) IV boluses. Initially, 40 – 50 mg/kg IV slowly over 3 to 5 minutes to clinical effect (ie, resolution or near-resolution of clinical signs). Repeat as necessary or follow with a CRI at an initial rate of 10 mg/kg/hour IV. Titrate the bolus dose/frequency or CRI administration rate to clinical effect. There are 3 case reports of this method being used successfully for pyrethroid intoxication, and IV CRI rates of 8.8, 11.6, and 12.2 mg/kg/hour were used.[13] The labeled maximum dose of 330 mg/kg/day can be exceeded if necessary, but the patient must be monitored for profound CNS depression, seizures, and hypotension.[14] The IV CRI can be administered with a syringe pump or with the drug added to a fluid bag (eg, 0.9% NaCl). If the parenteral product is not available and the oral route is not appropriate, tablets can be crushed and given rectally.

Muscle relaxant for the adjunctive treatment of intervertebral disk disease in dogs (extra-label): Anecdotal dosages of 15 – 20 mg/kg PO every 8 hours are usually noted.

HORSES:

Reducing muscle spasms from acute inflammatory and traumatic conditions of the skeletal muscle (label dosage; FDA-approved):

a) For moderate conditions: 4.4 – 22 mg/kg IV to effect[1]

b) For severe conditions (tetanus): 22 – 55 mg/kg IV[1]

Monitoring
- Level of muscle relaxation/sedation
- Adverse effects (eg, salivation, emesis, ataxia, CNS depression)

Client Information
- May be given with or without food
- Drowsiness/sedation is the most common side effect.
- May cause dark or blue–green urine, but this is not clinically significant

Chemistry/Synonyms
Methocarbamol, a centrally acting muscle relaxant related structurally to guaifenesin, occurs as a fine white powder with a characteristic odor. In water, it has a solubility of 25 mg/mL. The commercial injection is hypertonic, and the pH is ≈3.5 to 6.

Methocarbamol may also be known as guaiphenesin carbamate, *Robinax®*, and *Robaxin®*.

Storage/Stability
Store methocarbamol tablets at 20°C to 25°C (68°F-77°F), protected from light and moisture. Store the injection at 20°C to 25°C (68°F-77°F), with excursions permitted to 15°C to 30°C (59°F-86°F); do not freeze. Do not refrigerate solutions prepared for IV infusion, as a precipitate may form. Because a haze or precipitate may form, physically inspect all diluted IV solutions before administration.

Compatibility/Compounding Considerations
Methocarbamol solutions diluted to 4 mg/mL in 5% dextrose or 0.9% sodium chloride are stable for 6 days at room temperature.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:

NOTE: Although these products are still listed in the FDA Green Book of approved animal drugs, they may no longer be commercially available in the United States.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

Methocarbamol Tablets: 500 mg; *Robaxin®-V*; (Rx). FDA-approved for use in dogs and cats. NADA# 045-715

Methocarbamol Injection: 100 mg/mL in vials of 20 mL and 100 mL; *Robaxin®-V*; (Rx). FDA-approved for use in dogs, cats, and horses not intended for food. NADA 038-838

HUMAN-LABELED PRODUCTS:

Methocarbamol Tablets: 500 mg and 750 mg; *Robaxin®*, *Robaxin®-750*, generic; (Rx)

Methocarbamol Injection: 100 mg/mL in 10 mL vials; *Robaxin®*; (Rx)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Methotrexate
Methotrexate Sodium
(meth-oh-***trex***-ate)

Antineoplastic, Immunosuppressive

Prescriber Highlights
- ► Used primarily for lymphoma in dogs and cats
- ► Contraindications include pre-existing myelosuppression, severe hepatic or renal insufficiency, or known hypersensitivity to methotrexate.
- ► Common adverse effects include inappetence, vomiting, and diarrhea.
- ► Many potential drug interactions
- ► Teratogenic; may affect spermatogenesis. The National Institute for Occupational Safety and Health (NIOSH) classifies methotrexate as a hazardous drug; use appropriate precautions when handling it.

Uses/Indications
Methotrexate was used in original multiagent protocols for the treatment of lymphoproliferative diseases in dogs and cats; however, as less toxic and more potent agents became available, methotrexate has fallen out of favor and is now rarely used in veterinary oncology protocols. Methotrexate has been suggested as part of a possible rescue therapy combination with lomustine and cytarabine for relapsed feline lymphoma, failing more standardized multiagent protocols (COP and CHOP), but strong evidence of efficacy is lacking.[1]

Although there is little clinical experience with methotrexate as an immunomodulating drug in animals, low-dose methotrexate has been used as an alternate immunosuppressive agent when other drugs (eg, prednisone, azathioprine) have not been effective, or as an add-on drug to enhance efficacy and/or allow dosage reductions of other drugs.

Pharmacology/Actions
Methotrexate is an S-phase specific antimetabolite antineoplastic agent that competitively inhibits folic acid reductase, preventing the reduction of dihydrofolate to tetrahydrofolate and affecting the production of purines and pyrimidines. Rapidly proliferating cells (eg, neoplasms, bone marrow, GI tract epithelium, fetal cells) are most sensitive to the drug's effects.

Dihydrofolate reductase has a much greater affinity for methotrexate than either folic acid or dihydrofolic acid, and coadministration of folic acid will not reduce methotrexate's effects. Leucovorin calcium (a derivative of tetrahydrofolic acid) can block the effects of methotrexate.

Methotrexate also has immunosuppressive activity, possibly due to its effects on lymphocyte replication. Neoplastic cells have been noted to develop resistance to methotrexate, possibly due to decreased cellular uptake of the drug. One study demonstrated that the 50% inhibitory concentration for methotrexate was higher in histiocytic sarcoma lines than in lymphoma.[2]

Pharmacokinetics
In a pharmacokinetic study in dogs, the oral bioavailability of low-dose methotrexate (≈0.5 mg/kg) was 30%, but inter-individual variability was high. SC bioavailability was much higher at ≈93% and was more consistent. The half-life was ≈2 to 3 hours.[3]

In one pharmacokinetic study in horses, oral bioavailability was less than 1%, but SC bioavailability was 73%. The half-life was ≈2 to 2.5 hours.[4]

In humans, oral absorption is dose-dependent, and the absorption rate appears to decrease with the increasing dose. After oral administration of dosages less than 30 mg/m^2, the average bioavail-

ability of methotrexate was ≈60%. Peak concentrations occur within 4 hours after oral dosing and between 30 minutes and 2 hours after IM injection.

Methotrexate is widely distributed in the body and is actively transported across cell membranes. The highest concentrations are found in the kidneys, spleen, gallbladder, liver, and skin. When given orally or parenterally, methotrexate does not reach therapeutic concentrations in the CSF. When given intrathecally, methotrexate attains therapeutic concentrations in the CSF and also passes into the systemic circulation. In humans, methotrexate is ≈50% bound to plasma proteins and crosses the placenta. Methotrexate is excreted almost entirely by the kidneys via both glomerular filtration and active transport. Serum half-life is between 3 and 10 hours.

Contraindications/Precautions/Warnings

Methotrexate is contraindicated in patients with pre-existing bone marrow depression, severe hepatic or renal insufficiency, or hypersensitivity to the drug. It should be used with caution in patients that are susceptible to or have pre-existing clinical signs associated with the adverse reactions associated with this drug (see ***Adverse Effects***).

Unexpected and severe myelosuppression has been reported in humans. Respiratory clinical signs, especially coughing, may indicate a severe methotrexate-induced interstitial pneumonitis and should prompt further investigation. Diarrhea and stomatitis require interruption of therapy in humans, as there is a risk for fatal hemorrhagic enteritis and intestinal perforation. Severe skin reactions have been reported in humans. Hepatotoxicity is possible but typically only after prolonged use. Although acute increases in liver enzymes are often seen, they are usually transient. Methotrexate may cause renal damage that can lead to acute renal failure. Potentially fatal opportunistic infections are possible. Elimination is reduced in patients with ascites or pleural effusion.[5]

In human medicine, methotrexate is considered a high-alert medication (medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Some formulations contain benzyl alcohol.

The National Institute for Occupational Safety and Health (NIOSH) classifies methotrexate as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

In dogs and cats, GI adverse effects are most prevalent, including diarrhea, nausea, inappetence (especially cats), and vomiting (especially dogs). Leukopenia, thrombocytopenia, temporary alopecia, depigmentation, or oral lesions can occur but are uncommon. Transient elevations in liver enzymes are possible, including with low dosages in dogs and horses.[3,4] Higher doses may lead to nephrotoxicity due to the precipitation of the drug in the renal tubules. CNS toxicity (encephalopathy) may be noted if methotrexate is given intrathecally; however, a retrospective evaluation of 112 dogs and 8 cats receiving cytosine arabinoside alone or in combination with methotrexate found that only 1 patient developed generalized tonic-clonic seizure activity after intrathecal administration of this drug combination.[6] From this evaluation, it was concluded that intrathecal administration of cytosine arabinoside alone or in combination with methotrexate is a safe procedure in dogs and cats. Anaphylaxis has rarely been seen. One case of granulomatous mural folliculitis has been reported in a dog receiving cyclosporine and methotrexate.[7]

Reproductive/Nursing Safety

Methotrexate is teratogenic, embryotoxic, and may affect spermatogenesis in male animals.

For sexually intact patients, verify pregnancy status prior to administration.

Methotrexate is contraindicated in nursing mothers. It is excreted in breast milk in low concentrations with a milk:plasma ratio of 0.08:1. Nursing offspring should be switched to milk replacer if the dam requires methotrexate.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The oral LD_{50} for single doses of methotrexate in mice and rats is 146 mg/kg and 135 mg/kg, respectively. The LD_{50} for single IV doses in mice and rats is 65 mg/kg and 14 mg/kg, respectively. Acute overdoses in dogs are associated with exacerbations of the adverse effects outlined above, particularly myelosuppression and acute renal failure. Acute tubular necrosis is secondary to drug precipitation in the tubules. In dogs, the maximum tolerated dose is reported to be 0.12 mg/kg once daily for 5 days; 10 mg/kg is considered a lethal dose if leucovorin rescue is not performed.

Treatment of acute oral overdoses includes GI decontamination and prevention of drug absorption using standard protocols if the ingestion is recent. Additionally, oral neomycin has been suggested to help prevent the absorption of methotrexate from the GI tract. In order to minimize renal damage, forced alkaline diuresis should be considered. Urine pH should be maintained between 7.5 and 8 by the addition of sodium bicarbonate 0.5 – 1 mEq/kg per 500 mL of IV fluid. One case of successful serial use of charcoal hemoperfusion and hemodialysis following a methotrexate overdose in a dog has been reported.[8]

Leucovorin calcium is specific therapy for methotrexate overdoses. It should be given as soon as possible, preferably within the first hour and within 48 hours. Doses of leucovorin required are dependent on the methotrexate serum concentration. See ***Leucovorin***.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Methotrexate has been shown to be a substrate of the drug transporter ABCG-2, and there are potentially many interactions with other drugs that may be clinically significant. The following drug interactions have either been reported or are theoretical in humans or animals receiving methotrexate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: May increase the risk for methotrexate toxicity
- **Asparaginase**: May decrease the antineoplastic activity of methotrexate, as asparaginase inhibits cell replication that is required for methotrexate activity
- **Chloramphenicol**: May decrease methotrexate efficacy
- **Ciprofloxacin**: May increase methotrexate concentrations
- **Cyclosporine**: May increase methotrexate levels; consider therapy modification.
- **Doxycycline**: May increase the risk for methotrexate toxicity
- **Hepatotoxic Drugs** (eg, **halothane, ketoconazole, valproic acid, phenobarbital, primidone**): Methotrexate should be used cautiously with other drugs that can cause hepatotoxicity.
- **Hydrochlorothiazide**: May increase methotrexate exposure and increase the risk for myelosuppression
- **Immunosuppressive Drugs** (eg, **azathioprine, cyclophosphamide, corticosteroids**): Use with other immunosuppressant drugs may increase the risk for infection.

- **Leflunomide**: May result in increased methotrexate exposure and increased risk for hepatotoxicity and bone marrow toxicity
- **Levetiracetam**: May increase methotrexate exposure and toxicity
- **Loop Diuretics** (eg, **furosemide**): Methotrexate may decrease the efficacy of loop diuretics; consider therapy modification.
- **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medications may result in additive myelosuppression; avoid combination when possible.
- **Neomycin** (**oral**): Oral neomycin may decrease the absorption of oral methotrexate if given concomitantly.
- **nonsteroidal anti-inflammatory drugs (NSAIDs), Salicylates**: In humans, severe hematologic and GI toxicity has resulted in patients receiving both methotrexate and NSAIDs; avoid or use very cautiously in dogs on methotrexate.
- **Proton Pump Inhibitors** (eg, **omeprazole, pantoprazole**): May increase concentrations of methotrexate and its metabolite; increased risk for methotrexate toxicity
- **Penicillins**: Penicillins may interfere with the excretion of methotrexate and increase the risk for methotrexate toxicity. Avoid concurrent use. If the combination cannot be avoided, consider decreasing the methotrexate dose and monitoring closely for adverse effects.
- **Probenecid**: May inhibit the tubular secretion of methotrexate and increase its half-life
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**): May displace methotrexate from plasma proteins, increasing the risk for toxicity
- **Theophylline**: May increase theophylline exposure
- **Vaccines** (live and inactivated): Methotrexate may diminish vaccine efficacy and enhance adverse effects of vaccines.
- **Warfarin**: May cause prolonged bleeding times and increased risk for bleeding

Laboratory Considerations

- Methotrexate may cause invalid **vitamin B_{12}** results.
- Methotrexate may interfere with the microbiologic assay for **folic acid**.

Dosages

NOTE: Dosages and dosage forms of methotrexate sodium are expressed in terms of methotrexate. Because of the potential toxicity of methotrexate, when used at antineoplastic dosages, to patients, veterinary personnel, and clients, and since chemotherapy indications, treatment protocols, monitoring, and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[9–13] are strongly recommended. It is not recommended to crush, split, or formulate oral tablets into liquid, as this practice increases the risk for environmental contamination, and personal and/or occupational exposure to chemotherapy. Dosages are commonly listed as mg/m^2. Do not confuse with mg/kg dosages.

DOGS:

Susceptible neoplastic diseases (usually as part of a multi-drug protocol) (extra-label):

a) As part of the LMP protocol for maintenance of canine lymphoma: Chlorambucil 20 mg/m^2 (NOT mg/kg) PO every 15 days; methotrexate 2.5 – 5 mg/m^2 (NOT mg/kg) PO twice a week; prednisone 20 mg/m^2 (NOT mg/kg) PO every other day. Vincristine can be added to this protocol at a dosage of 0.5 – 0.7 mg/m2 (NOT mg/kg) IV given every 15 days, alternating weeks with chlorambucil.[14]

b) Combining with other antineoplastics (per protocol): methotrexate 5 mg/m^2 (NOT mg/kg) PO twice weekly or 0.8 mg/kg IV every 21 days; alternatively, 2.5 mg/m^2 (NOT mg/kg) PO daily[15]

As an immunosuppressive agent (extra-label): There is not much experience using methotrexate as an immunosuppressant agent in animals. Anecdotal dosages noted include 2.5 mg/m^2 (NOT mg/kg) PO every 24 hours.

CATS:

Susceptible neoplastic diseases (usually as part of a multi-drug protocol); (extra-label): 2.5 mg/m^2 (NOT mg/kg) PO 2 to 3 times weekly; 0.3 – 0.8 mg/m^2 (NOT mg/kg) IV every 7 days.[16] A study evaluating the combination of alternating lomustine, cytarabine, and methotrexate used a target methotrexate dosage of 0.5 – 0.6 mg/m^2 (NOT mg/kg) IV.[1]

Immunosuppressive agent (extra-label): One dosage recommendation for treating rheumatoid arthritis with leflunomide is: Initially, 10 mg of leflunomide per cat (NOT mg/kg) PO once daily with 2.5 mg of methotrexate per cat (NOT mg/kg) PO 3 times on 1 day per week (ie, 7.5 mg of methotrexate per cat [NOT mg/kg] is divided and given as 3 separate 2.5 mg doses over a single day). When significant improvement occurs, reduce doses to 10 mg of leflunomide per cat (NOT mg/kg) PO twice weekly and 2.5 mg of methotrexate (NOT mg/kg) PO once weekly.[17,18]

HORSES:

Immunomodulatory agent (extra-label): 0.2 mg/kg SC weekly was suggested based on a pharmacokinetic study, further studies are warranted to verify efficacy and safety.[4]

Monitoring

- Efficacy: serial lymph node measurements by physical caliper measurements and/or radiologic methods (thoracic and abdominal radiographs and ultrasound)
- Baseline CBC, serum chemistry profile, and urinalysis:
  - CBCs should be performed weekly early in therapy and eventually every 4 to 6 weeks when stabilized. If absolute neutrophil count is less than 2500/µL or platelet count is less than 75,000/µL, therapy should be delayed until these values return to normal. The chemistry panel should be evaluated monthly while on therapy or more frequently if abnormalities are noted at baseline.
  - Frequency of CBC and serum chemistry profile monitoring depends on the protocol employed. Consultation with a veterinary oncologist is recommended.
- Monitor for clinical signs of toxicity, including vomiting, diarrhea, inappetence, and fever.

Client Information

- It is important to follow your veterinarian's directions when giving this medication to your animal to minimize the risks for side effects.
- Methotrexate is a chemotherapy (anticancer) drug. It can be hazardous to other animals and humans that come in contact with it.
- Wear gloves when handling this medication. On the day your animal gets the drug and then for a few days afterward, handle all bodily waste (ie, urine, feces, litter), blood, or vomit only while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in with the regular trash.
- Give this medicine with food.
- This medicine can affect your animal's ability to fight infection (bone marrow suppression). The greatest effects on bone marrow usually occur within a few weeks after treatment.

- Methotrexate can be toxic to the gastrointestinal tract and cause vomiting and gastrointestinal upset.
- Contact your veterinarian immediately if you see bleeding, bruising, shortness of breath, vomiting, diarrhea, lack of an appetite, fever (indicating an infection), or if your animal becomes very tired easily.
- While your animal is taking this medication, it is important to return to your veterinarian for physical examinations and laboratory work. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Methotrexate is a folic acid antagonist that is available commercially as sodium salt. It occurs as a yellow powder that is soluble in water. Methotrexate sodium injection has a pH of 7.5 to 9.

Methotrexate and methotrexate sodium may also be known as MTX, amethopterin, 4-Amino-4-deoxy-10-methylpteroyl-L-glutamic acid, 4-Amino-10-methylfolic acid, CL-14377, alpha-methopterin, methotrexatum, metotrexato, NSC-740, WR-19039; there are many trade names available.

Storage/Stability

Store methotrexate tablets and injectables between 20°C and 25°C (68°F-77°F) in well-closed containers and protect from light.

Store methotrexate oral solution in the original container with tightly closed lid and refrigerated (2°C-8°C [36°F-46°F]); may store at room temperature for up to 60 days. Avoid freezing and excessive heat.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Methotrexate sodium is reportedly physically **compatible** with the following IV solutions and drugs: Amino acids 4.25%/dextrose 25%, D_5W, sodium bicarbonate 0.05 M, cytarabine, mercaptopurine sodium, sodium bicarbonate, and vincristine sulfate. In syringes, methotrexate is physically **compatible** with bleomycin sulfate, cyclophosphamide, doxorubicin HCl, fluorouracil, furosemide, leucovorin calcium, mitomycin, vinblastine sulfate, and vincristine sulfate.

Methotrexate sodium **compatibility information conflicts** or is dependent on diluent or concentration factors with the following drugs or solutions: heparin sodium and metoclopramide HCl.

Methotrexate sodium is reportedly physically **incompatible** when mixed with the following solutions or drugs: bleomycin sulfate (as an IV additive only; **compatible** in syringes and Y-lines), fluorouracil (as an IV additive only; **compatible** in syringes and Y-lines), prednisolone sodium phosphate, and ranitidine HCl.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Methotrexate Tablets: 2.5 mg, 5 mg, 7.5 mg, 10 mg, and 15 mg; *Trexall*®, generic (2.5 mg only); (Rx)

Methotrexate Oral Solution: 2.5 mg/mL in 120 mL bottles; *Xatmep*®; (Rx)

Methotrexate Injection for SC use; available in numerous strengths and configurations:

- 7.5 mg, 10 mg, 12.5 mg, 15 mg, 17.5 mg, 20 mg, 22.5 mg, and 25 mg in 0.4 mL auto-injectors (concentration varies); *Otrexup*®; (Rx)
- 7.5 mg, 10 mg, 12.5 mg, 15 mg, 17.5 mg, 20 mg, 22.5 mg, 25 mg, 27.5 mg, and 30 mg auto-injectors as 50 mg/mL solution (injection volume varies); *Rasuvo*®(Rx)
- 7.5 mg, 10 mg, 12.5 mg, 15 mg, 17.5 mg, 20 mg, 22.5 mg, and 25 mg pre-filled syringes as a 25 mg/mL solution (injection volume varies); *Reditrex*®; (Rx)

Methotrexate Sodium Injection: 25 mg/mL preservative-free in 2 mL, 10 mL, 20 mL, and 40 mL singleuse vials; generic; (Rx)

Methotrexate Powder for Injection, lyophilized: 1 g preservative-free in single-use vials; generic; (Rx)

Methylene Blue

(***meth***-i-leen ***bloo***) *ProvayBlue*®

Antidote

Prescriber Highlights

- ► Thiazine dye primarily used to treat methemoglobinemia in ruminants; can be used in dogs and horses, but considered relatively ineffective in horses
- ► Contraindications include lactating dairy animals, renal insufficiency, and hypersensitivity to methylene blue. It is generally considered contraindicated for use in cats. Not for intrathecal use.
- ► Adverse effects include Heinz body anemia or other red cell morphological changes, methemoglobinemia, and decreased red cell life spans; cats are particularly sensitive to these effects.

Uses/Indications

Methylene blue is used primarily in ruminants for treating methemoglobinemia secondary to oxidative agents[1] (eg, nitrates, nitrites, chlorates) and occasionally as an adjunctive or alternative therapy for cyanide toxicity.

In dogs, methylene blue may be considered for treating methemoglobinemia secondary to drugs or toxins (eg, phenol, mothballs, hydroxyurea, phenazopyridine[2]). It can also be used intra-operatively to preferentially stain islet-cell tumors of the pancreas in order to aid in their surgical removal or in determining the prognosis[3]; however, IV methylene blue is rarely used for this purpose due to its adverse effects and delayed effect of colorizing pancreatic cells.

Although it has been used for treatment of methemoglobinemia in horses caused by chlorate toxicity, methylene blue is considered relatively ineffective for this purpose.

In humans, methylene blue has been used to treat histamine-induced vasodilation. It may be an option in the future to treat anaphylactic shock in animals; however, further studies are needed.[4]

Pharmacology/Actions

Methylene blue is rapidly converted to leucomethylene blue in tissues. This compound serves as a reducing agent that helps to convert methemoglobin (Fe^{+++}) to hemoglobin (Fe^{++}). Methylene blue is an oxidating agent and may actually cause methemoglobinemia if high doses are administered (species-dependent).

Methylene blue also has antimicrobial activity. Methylene blue is a potent guanylyl cyclase inhibitor and blocks the release of cyclic guanosine monophosphate (cGMP), thereby preventing vascular smooth muscle relaxation. It is used in human medicine to improve hypotension associated with various clinical states (eg, vasoplegic shock, septic shock).

Pharmacokinetics

Oral absorption of methylene blue is species dependent. It is well absorbed from the GI tract of humans but poorly absorbed when given orally to dogs.[5] Therefore, it is usually administered parenterally in veterinary medicine. Methylene blue is excreted in the urine and bile, primarily in the colorless form, but some unchanged drug may be also excreted.

Contraindications/Precautions/Warnings

Methylene blue is contraindicated in patients with renal insufficiency and in patients that are hypersensitive to it. It cannot be given as an intrathecal injection.

Methylene blue is generally considered contraindicated in cats, as it can result in Heinz body anemia and methemoglobinemia. Although the number of cells with Heinz bodies increased after two doses of methylene blue, no increase was seen after a single dose.[6]

Methylene blue has the potential to cause severe serotonin syndrome when used in combination with other serotonergic drugs.

Adverse Effects

The greatest concerns with methylene blue therapy are the development of Heinz body anemia or other erythrocyte morphological changes, methemoglobinemia, and decreased erythrocyte life spans. Cats tend to be very sensitive to these effects and it is generally considered contraindicated in feline patients; however, dogs and horses can also develop hematologic adverse effects at relatively low doses.

Necrotic abscesses may develop if injected SC or extravasation occurs during IV administration.

Adverse effects in humans include pain in extremity, discoloration of skin, nausea, and dizziness.[7]

Reproductive/Nursing Safety

Safe use of this agent during pregnancy has not been demonstrated. Human data suggest risk to the fetus when administered to women in the second and third trimesters.[7,8]

No information on lactation safety in animals was found. In humans, it is recommended to discontinue nursing during treatment and for up to 8 days after.[7]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In sheep, the IV LD_{50} for 3% methylene blue is ≈42.3 mg/kg.[9]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methylene blue and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Serotonergic Drugs** (eg, **linezolid**, **monoamine oxidase inhibitors** [eg, **selegiline**], **selective serotonin reuptake inhibitors** [eg, **fluoxetine, paroxetine**], **tricyclic antidepressants** [eg, **amitriptyline, clomipramine**], **tramadol**): Methylene blue used in combination with drugs that increase serotonin levels may increase the risk for severe serotonin syndrome; combination is considered contraindicated in humans.

Laboratory Considerations

- Methylene blue can cause a green-blue color in urine and may affect the accuracy of **urinalysis**.
- **Pulse oximetry**. Methemoglobinemia optically interferes with the accuracy of pulse oximeters.

Dosages

DOGS:

Preferential staining of islet-cell tumors of the pancreas (extra-label): 3 mg/kg diluted in a total fluid volume of 250 mL and administered IV over 30 to 40 minutes intraoperatively.[3] **NOTE**: Dextrose 5% is recommended for dilution as sodium-chloride may reduce the solubility of methylene blue. Initial tumor staining occurs ≈20 minutes after infusion initiation and is maximal at ≈25 to 35 minutes after start of infusion. Tumors generally appear to be reddish-violet in color as opposed to the dusky blue color of the background staining.

Severe methemoglobinemia secondary to toxic exposures (eg, **phenol**, **mothballs**, **hydroxyurea**; extra-label): Using a 1% solution, 1 – 1.5 mg/kg given IV slowly over several minutes. A dramatic response should occur during the first 30 minutes after treatment. Dose may be repeated if necessary, but should be done cautiously as Heinz body anemia can result. Measure hematocrit for 3 days after treatment.[10]

Severe methemoglobinemia due to toxic phenazopyridine exposure (extra-label): 4 mg/kg IV was used in one case report.[2]

CATS:

NOTE: Use methylene blue with extreme caution in cats. Methylene blue is often considered contraindicated; however, single doses have been tolerated.[6]

Severe methemoglobinemia (extra-label): A single dose of 1 – 1.5 mg/kg IV infused slowly over several minutes

HORSES:

Methemoglobinemia secondary to chlorate toxicity (extra-label): Although generally considered ineffective, using a 1% solution, 4.4 mg/kg IV has been used; dose may be repeated after 15 to 30 minutes if clinical response is not obtained.[11]

RUMINANTS:

Methemoglobinemia due to toxins (eg, **nitrites, nitrates, chlorates**; extra-label): Using a 1% solution, 4 – 15 mg/kg IV every 6 hours.[1] See ***Dosage Forms/Regulatory Status***.

Monitoring

- Methemoglobinemia using co-oximetry or multi-wavelength pulse oximetry; pulse oximetry is not reliable
- Erythrocyte morphology, indices (eg, MCV, MCHC), hematocrit, hemoglobin

Client Information

- Because of the potential toxicity of this agent and the seriousness of methemoglobin-related intoxications, this medicine should be used with close professional supervision only.
- Methylene blue will stain clothing and skin. Removal may be accomplished using hypochlorite solutions (bleach).

Chemistry/Synonyms

A thiazine dye, methylene blue occurs as hygroscopic, dark-green crystals or crystalline powder that has a bronze-like luster. It may have a slight odor and is soluble in water and sparingly soluble in

alcohol. When dissolved, a dark blue solution results. Commercially available methylene blue injection (human-labeled) has a pH from 3 to 4.5.

Methylene blue may also be known as methylthioninium chloride, azul de metileno, blu di metilene, CI basic blue 9, colour index no. 52015, methylenii caeruleum, methylthioninii chloridum, schultz no. 1038, tetramethylthionine chloride trihydrate, *Azul Metile®*, *Collubleu®*, *Desmoidpillen®*, *Vitableu®*, *Urolene Blue®* and *Zumetil®*.

Storage/Stability

Unless otherwise instructed by the manufacturer, store methylene blue at room temperature.

Compatibility/Compounding Considerations

Methylene blue is reportedly physically **incompatible** when mixed with caustic alkalis, dichromates, iodides, and oxidizing or reducing agents.

ProvayBlue® may be diluted with 50 mL of dextrose 5% in water. Do NOT dilute with sodium chloride 0.9% due to a decrease in solubility of the methylene blue.[7]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

No FDA-approved products as pharmaceuticals for internal use. A non-sterile 1% (10 mg/mL) methylene blue solution is labeled for animal use as a dye, laboratory indicator, and reagent. It is available in pint and gallon bottles. Methylene Blue, USP powder may be available from chemical supply houses.

The recommended minimum milk withdrawal is 4 days and minimum meat withdrawal is an extremely conservative 180 days due to carcinogenicity concerns; however, available data suggest that a much shorter withdrawal time of 14 days may be sufficient.[12]

HUMAN-LABELED PRODUCTS:

Methylene Blue Injection: 1% (10 mg/mL) in 1 mL and 10 mL vials; generic; (Rx; not FDA-approved)[13]

Methylene Blue Injection: 5 mg/mL in 10 mL amp; *ProvayBlue®*; (Rx)

Methylphenidate

(meth-ill-***fen***-i-date) *Concerta®, Ritalin®*

CNS Stimulant

Prescriber Highlights

- ► Amphetamine-like drug that may be useful for treating cataplexy/narcolepsy or hyperkinesis/hyperactivity in dogs
- ► Contraindicated in patients receiving monoamine oxidase inhibitors or within 14 days after their discontinuation
- ► Use with caution in dogs with seizure disorders, cardiac disease, hypertension, or in aggressive animals.
- ► Adverse effects are primarily related to CNS stimulation.
- ► DEA Schedule II (C-II) controlled substance

Uses/Indications

Methylphenidate may be useful for diagnosing and treating cataplexy/narcolepsy or hyperactivity in dogs.

Pharmacology/Actions

Methylphenidate has stimulating effects on the central nervous and respiratory systems similar to that of amphetamine. It also has weak sympathomimetic activity and, at normal dosages, has little effect on peripheral circulation.

Pharmacokinetics

There is limited pharmacokinetic information available for methylphenidate in dogs. Single PO doses of immediate-release 20 mg tablets to 7 to 19 kg (15 to 42 lb) beagles resulted in peak concentrations of ≈60 µg/mL in ≈15 minutes after dosing. Clearance was ≈0.27 L/hour and elimination half-life was ≈1 hour. Interpatient variability was much higher with 20 mg sustained-release tablets; serum concentrations peaked ≈30 minutes after dosing, and peak concentrations were much lower than immediate-release tablets at 19 µg/mL. Clearance was ≈0.97 L/hour and elimination half-life was ≈40 minutes. Therapeutic plasma concentrations of methylphenidate are thought to be between 1 and 10 µg/mL.[1]

In humans, methylphenidate immediate-release tablets are rapidly and well absorbed from the GI tract. Food in the GI tract may increase the rate but not the extent of drug absorbed. Peak concentrations occur ≈2 hours postdose. Methylphenidate undergoes extensive first-pass metabolism; protein binding is low. Terminal elimination half-life is ≈3 hours; less than 1% is excreted unchanged in the urine.

Contraindications/Precautions/Warnings

Methylphenidate is contraindicated in patients receiving monoamine oxidase inhibitors or within 14 days of discontinuing them.[2] The risks associated with methylphenidate should be carefully considered before using this drug in dogs with seizure disorders, cardiac disease, hypertension, or aggressive behaviors.

Hypersensitivity reactions including angioedema and anaphylaxis have been reported in humans.[2]

Be alert for drug-seeking individuals as methylphenidate is a DEA Schedule II controlled drug in the United States. A written prescription (typically limited to a maximum of a 30-day supply) is required each time the drug is dispensed by a pharmacy.

Adverse Effects

The most likely adverse effects of methylphenidate are increased heart and respiratory rates, anorexia, tremors, and hyperthermia, particularly exercise-induced hyperthermia. CNS stimulation can occur (see ***Overdose/Acute Toxicity***).

Reproductive/Nursing Safety

Methylphenidate was associated with teratogenic effects in rabbits at massive dosages (200 mg/kg/day; ≈40 times the maximum recommended human dose).[2]

It is unknown if methylphenidate enters maternal milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In dogs, even relatively low doses can cause serious toxicosis. Methylphenidate doses of 1 mg/kg or less have caused toxic reactions. One fatality has been reported after a dog ingested 3.1 mg/kg[3]; however, research dogs have survived doses of 20 mg/kg/day for 90 days. Expected signs associated with an overdose in dogs are generally CNS overstimulation and excessive sympathomimetic effects, including hyperactivity, salivation, diarrhea, head bobbing, agitation, tachycardia, hypertension, tremors, seizures, and hyperthermia. Consider the dosage form (extended-release vs regular tablets) when considering treatment options and expected onset and duration of effects; extended-release formulations are associated with more severe clinical signs.

In one cat, given methylphenidate 5 mg PO developed tremors, agitation, mydriasis, tachycardia, tachypnea, and hypertension; signs resolved 25 hours postingestion with supportive care (eg, dark cage, diazepam, fluids).[4]

Typical GI decontamination protocols can be considered, but

emetics should be used with caution as CNS signs can occur rapidly. Treatment is supportive and aimed at controlling signs associated with toxicity. Phenothiazines (eg, acepromazine, chlorpromazine) may be useful in controlling agitation. Benzodiazepines (eg, diazepam) potentially could increase the severity of agitation and are typically avoided. Seizures may be controlled with propofol, followed by barbiturates if necessary. Additional treatments that may be considered include injectable methocarbamol for tremors; beta-blockers for tachycardia; prazosin, amlodipine, nitroprusside, or hydralazine for hypertension; external cooling for hyperthermia; and cyproheptadine to help prevent serotonin syndrome.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving methylphenidate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticonvulsants** (eg, **phenobarbital, primidone**): Methylphenidate may increase anticonvulsant serum concentrations.
- **Antihypertensive Drugs**: Methylphenidate may reduce effects.
- **Clonidine**: Methylphenidate may enhance toxic effects of clonidine. Historically, serious adverse events including death were reported with combination use in humans; however, more recent safety studies have found no evidence of adverse events from this combination.[5,6]
- **Inhalant Anesthetic Agents** (eg, **isoflurane, sevoflurane**): Concurrent use with methylphenidate may increase risk for interoperative hypertension, tachycardia, and arrhythmias; it is recommended to withhold methylphenidate on day of surgery.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): Concurrent therapy may lead to hypertensive crisis; combination is contraindicated.
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, sertraline**): Methylphenidate may inhibit metabolism and increase SSRI concentrations.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): Methylphenidate may inhibit metabolism and increase TCA concentrations.
- **Warfarin**: Methylphenidate may inhibit warfarin metabolism and prolong coagulation times.

Laboratory Considerations

- No specific laboratory interactions were noted for this drug.

Dosages

DOGS:

NOTES:

1. It is assumed that the following dosages are for the use of the immediate-release formulation of methylphenidate; dosages may not apply to extended-release formulations.
2. **Dosages listed below are anecdotal and widely variable**. It is recommended to start with the low end of the dosing range and titrate up as the patient's condition requires for clinical control.

Adjunctive treatment of narcolepsy/cataplexy (extra-label): 0.25 – 0.5 mg/kg PO or 5 – 10 mg/dog (NOT mg/kg) PO every 12 to 24 hours[7]

Diagnosis and treatment of hyperkinesis/hyperactivity (extra-label):

a) For diagnosis, doses of 5 – 20 mg/dog (NOT mg/kg), depending on the size of the dog, are given PO every 8 to 12 hours for 3 days, and the patient is assessed for improvement of target behaviors (anxiety, overactivity, learning ability).[8,9] If effective, treatment can be started at a lower dose given 1 to 2 times daily, then increased if necessary. Treatment is accompanied by training and behavior modification therapy. Breaks from therapy (drug holidays) can occur on days when the dog's behavior is less important.[8,10]

b) 0.25 – 4 mg/kg PO every 24 hours[11]

Monitoring

- Clinical efficacy
- Baseline and periodic physical exam to monitor vital signs and body weight (especially in young, growing puppies)
- Baseline and periodic blood pressure

Client Information

- A common side effect of this medicine is a decreased appetite.
- Be sure to let your veterinarian know if your animal has worn a flea or tick collar in the past 2 weeks. Do not use one of these collars on your animal while it is taking this medicine without first talking to your veterinarian.
- Contact your veterinarian immediately if your animal has a seizure while taking this medicine.
- Methylphenidate has significant potential for abuse by humans and should be kept secure.
- If using an extended-release product, do not crush the tablet or capsule.
- The Federal Drug Enforcement Agency (DEA) classifies methylphenidate as a schedule II (C-II) controlled drug, and it requires a new written prescription for refills. The use of this medication in animals or humans other than those for whom they are prescribed is illegal.

Chemistry/Synonyms

Methylphenidate HCl is a CNS stimulant related to amphetamine and occurs as a fine white odorless, crystalline powder. It is freely soluble in water and soluble in alcohol.

Methylphenidate may also be known as *Attenta®, Daytrana®, Equasym®, Focalin®, Metadate ER®, Methylin®, Rilatine®, Riphenidate®, Ritalina®, Ritalin®, Ritaphen®, Rubifen®,* or *Tranquilyn®*.

Storage/Stability

Unless otherwise noted on the label, store methylphenidate tablets and extended-release tablets and capsules in tight, light-resistant containers at room temperature.

Methylphenidate is a DEA schedule II (C-II) controlled substance. Store it in a substantially constructed and securely locked area. Follow applicable local, state, and federal rules regarding the disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The American Racing Commissioners International (ARCI) has designated this drug as a class 1 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:
Methylphenidate Oral Tablets (immediate release): 5 mg, 10 mg, and 20 mg; *Ritalin®*, generic; (Rx; C-II).

Methylphenidate Oral Chewable Tablets (immediate release): 2.5 mg, 5 mg, and 10 mg; *Methylin®*, generic; (Rx; C-II).

A wide variety of extended-release tablets, suspensions and transdermal formulations are also available; do not confuse these formulations.

For the complete list of references, see **wiley.com/go/budde/plumb**

Methylprednisolone
Methylprednisolone Acetate
Methylprednisolone Sodium Succinate

(meth-ill-pred-***niss***-oh-lone)

Medrol®, Depo-Medrol®, Solu-Medrol®

Glucocorticoid

For more information, see ***Glucocorticoid Agents, General Information***

Prescriber Highlights

- ► Oral and parenteral glucocorticoid that is 4 to 5 times more potent than hydrocortisone; no appreciable mineralocorticoid activity
- ► Relatively contraindicated with systemic fungal infections
- ► Use with caution in animals with active bacterial or viral infections, peptic ulcer, corneal ulcer, hyperadrenocorticism, diabetes mellitus, osteoporosis, predisposition to thrombophlebitis, hypertension, CHF, and renal insufficiency.
- ► Acetate form can cause marked HPA axis suppression. In cats, extracellular hyperglycemia can cause volume expansion and may predispose cats to diabetes mellitus and congestive heart failure. IM administration is generally reserved for when owners cannot adhere to oral treatment regimens.
- ► Goal of therapy should be to use the lowest dose possible for the least amount of time to treat and control patient's condition.
- ► Primary adverse effects are related to iatrogenic hyperadrenocorticism with sustained use.
- ► Many potential drug and laboratory interactions

Uses/Indications

Methylprednisolone is similar to prednisone or prednisolone but is slightly more potent. Methylprednisolone is effective in dogs with atopic dermatitis[1–3] and cats with allergies[4] or hypersensitivity dermatitis.[5] The drug did not show benefit in dogs with thoracolumbar intervertebral disk herniation.[6–8]

Although glucocorticoids have been used to treat many conditions in humans and animals, methylprednisolone has 4 primary uses with accompanying dosage ranges: 1) replacement or supplementation for glucocorticoid deficiency secondary to hypoadrenocorticism or relative adrenal insufficiency (eg, septic shock) for glucocorticoid deficiency secondary to hypoadrenocorticism, 2) anti-inflammatory agent, 3) immunosuppressive, and 4) antineoplastic agent. High-dose use is not supported for hemorrhagic or hypovolemic shock, head trauma, spinal cord trauma,[9] or sepsis. In general, when administering glucocorticoids, the following principles should be followed:

- A specific diagnosis is needed before glucocorticoids are administered, as they can mask disease.
- A course of treatment should be determined prior to treatment.
- A therapeutic endpoint should be determined prior to treatment.
- The least potent glucocorticoid should be used at the lowest dose for a minimal amount of time.
- It is important to understand when glucocorticoid use is inappropriate (eg, acute infection, diabetes mellitus).[10]

See ***Glucocorticoid Agents, General Information***

Pharmacology/Actions

Methylprednisolone may be administered orally or parenterally (sodium succinate, IV and IM; acetate, IM only). Its relative anti-inflammatory potency is ≈5 times that of cortisol. It has negligible to very slight mineralocorticoid activity. Once in the systemic circulation, it has an approximate duration of activity of 12 to 36 hours.

For further information, see ***Glucocorticoid Agents, General Information***

Pharmacokinetics

Methylprednisolone administered orally is relatively well absorbed and extensively distributed. The liver is the primary site for metabolism (oxidation); most of the drug is excreted renally as metabolites. The pharmacokinetics of methylprednisolone do not translate into pharmacologic effect, and duration of activity is independent of elimination half-life. Methylprednisolone is an intermediate-acting corticosteroid with a biologic half-life of ≈12 to 36 hours.

Methylprednisolone sodium succinate IV injection is water soluble and considered fast acting.

Methylprednisolone acetate IM injection is absorbed slowly and can have a duration of effect of weeks to months. Intra-articular (IA) or intrasynovial injection of methylprednisolone acetate in horses results in systemic methylprednisolone exposure.[11–16] In horses receiving methylprednisolone acetate 100 mg or 200 mg IA, the last quantifiable plasma concentration was measured at 7 days (100 mg) and 18 days (200 mg).[14]

Contraindications/Precautions/Warnings

Methylprednisolone acetate is contraindicated for IM administration in animals with arrested tuberculosis, peptic ulcer, and hyperadrenocorticism. Use with caution in patients with diabetes mellitus, osteoporosis, predisposition to thrombophlebitis, hypertension, CHF, renal insufficiency, and active tuberculosis.[17,18] Epidural use of glucocorticoids is associated with severe adverse CNS reactions (eg, blindness, paralysis, seizures).

Do not administer methylprednisolone acetate IV. When injected locally (eg, intrasynovially, intratendinously), methylprednisolone acetate is contraindicated in the presence of acute infections. If pain or further loss of joint mobility occurs with fever following intrasynovial or intratendon injection, immediate appropriate antibiotic therapy is warranted, as sepsis may be present.

Systemic glucocorticoids suppress adrenal function. Unless very short-term burst therapy is used, patients that have received systemic glucocorticoids systemically should be tapered off the drug. Tapering should be gradual if the patient has been receiving a glucocorticoid chronically, as endogenous ACTH and corticosteroid function may return slowly. Should the animal undergo a stressful event (eg, surgery, trauma, illness) during the tapering process and/or until normal adrenal and pituitary functions resume, additional glucocorticoids should be administered.

Corticosteroids may mask signs of infection and delay wound healing. Systemic use of glucocorticoids is generally considered contraindicated in patients with ocular herpetic or systemic fungal infections (unless used for replacement therapy in Addison's disease), when administered IM in patients with idiopathic thrombocytopenia, and in patients with hypersensitivities to glucocorticoids. Animals, particularly cats, at risk for diabetes mellitus or with concurrent cardiovascular disease should receive glucocorticoids with

caution because of the potent hyperglycemic effect of these agents.

Sustained-release injectable glucocorticoids are contraindicated for chronic corticosteroid therapy of systemic diseases because of their long duration of action and the increased risks for adverse effects. Most clinicians do not recommend use of methylprednisolone acetate IM when alternate day oral glucocorticoid therapy could be used. In difficult-to-pill cats, however, it may be a viable alternative to oral glucocorticoids. A study in cats ($n = 8$) with feline herpesvirus 1 (FHV-1) administered 5 mg/kg methylprednisolone acetate IM on day 0 and day 21 reported that clinical signs of activated FHV-1 occurred in some cats, but in most it was mild and self-limited.[19]

Do not confuse methylPREDNISolone with medroxyPROGESTERone or methylTESTOSTERone.

Adverse Effects

Adverse effects are generally associated with long-term administration of these drugs, especially if the drugs are administered at high doses or not on an alternate-day regimen. Effects typically manifest as clinical signs of hyperadrenocorticism. A complete listing of potential effects is outlined in ***Glucocorticoid Agents, General Information***.

In dogs, polyuria (PU), polydipsia (PD), and polyphagia (PP) may occur during short-term burst therapy and on days when the drug is administered during alternate-day maintenance therapy. Adverse effects in dogs can include dull/dry coat, bilaterally asymmetrical alopecia, weight gain, panting, vomiting, diarrhea, elevated liver enzymes, pancreatitis, GI ulceration (especially with high parenteral or oral doses); hypercoagulability; hyperlipidemia, activation or worsening of diabetes mellitus, muscle wasting, and/or behavior changes (eg, depression, lethargy, aggression). Glucocorticoids have been known to delay growth in young animals. Discontinuation of the drug may be necessary; changing to an alternate steroid may also alleviate adverse effects. Adverse effects associated with anti-inflammatory therapy are relatively uncommon, with the exception of PU, PD, and PP. Adverse effects associated with immunosuppressive dosages are more common and potentially more severe.

Cats generally require higher glucocorticoid doses than dogs for clinical effect but tend to develop fewer adverse effects. Occasionally, PD, PU, PP with weight gain, diarrhea, or depression can be seen. Long-term high-dose therapy can lead to effects related to hyperadrenocorticism. A study in 12 cats receiving the long-acting acetate salt demonstrated that methylprednisolone causes extracellular hyperglycemia leading to volume expansion and may predispose patients to diabetes mellitus and congestive heart failure.[20]

Rapid IV administration of methylprednisolone sodium succinate may cause vomiting; high doses may also reduce blood pressure.

Experimental data in sheep support the osteoporosis-inducing effects of glucocorticoids in animals.[21]

In humans, corticosteroid-related diabetes mellitus may be related to increased urinary excretion of chromium and potentially could respond to chromium supplementation.[22–25] Significance in animals is unknown.

Reproductive/Nursing Safety

Excessive glucocorticoid doses early in pregnancy may lead to teratogenic effects. When administered in the latter stages of pregnancy, exogenous steroid administration may induce parturition, including premature parturition followed by dystocia, fetal death retained placenta and metritis. Cleft palate, foreleg deformities, phocomelia, and anasarca have occurred in offspring of dogs that received corticosteroids during pregnancy.[18]

Use with caution in nursing animals. Glucocorticoids unbound to plasma proteins will enter milk. High doses or prolonged administration to mothers may inhibit growth, interfere with endogenous corticosteroid production, or cause other unwanted effects in nursing offspring. However, in humans, several studies suggest that amounts excreted in breast milk are negligible when methylprednisolone doses are less than or equal to 8 mg/day. Larger doses for short periods may not harm the infant.

Overdose/Acute Toxicity

The oral LD_{50} for methylprednisolone in mice is 450 mg/kg and in rats is greater than 4 g/kg.[26] Overdoses of glucocorticoids used alone are unlikely to cause harmful effects; GI effects (eg, vomiting, diarrhea), that are sometimes severe, can be seen in dogs. One incidence of a dog developing acute CNS effects after accidental ingestion of glucocorticoids has been reported. Consider GI decontamination for recent oral ingestion. If clinical signs occur, use supportive treatment if required.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have been reported or are theoretical in humans or animals receiving methylprednisolone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Concomitant administration with glucocorticoids may cause hypokalemia; in humans, CHF and cardiomegaly have been reported after methylprednisolone was used to treat amphotericin B adverse effects.
- **Analgesics, Opioids and/or Local Anesthetics (Epidural)**: Combination with glucocorticoids in epidural injections has caused serious CNS injuries and death; use only very small intrathecal test doses of these agents with glucocorticoids.
- **Anticholinesterase Agents** (eg, **pyridostigmine, neostigmine**): In patients with myasthenia gravis, concomitant glucocorticoid and anticholinesterase agent administration may lead to profound muscle weakness. If possible, discontinue anticholinesterase medication at least 24 hours prior to corticosteroid administration.
- **Antidiabetic Agents, Oral** (eg, **glimepiride, glipizide, glyburide, metformin**): Glucocorticoids may worsen glycemic control.
- **Aspirin**: Glucocorticoids may reduce salicylate blood concentrations. Combination may increase risk for GI ulceration.
- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): May decrease the metabolism of glucocorticoids and increase methylprednisolone blood concentrations; ketoconazole may induce adrenal insufficiency when glucocorticoids are withdrawn by inhibiting adrenal corticosteroid synthesis.
- **Cholestyramine**: May reduce methylprednisolone absorption
- **Cyclophosphamide**: Glucocorticoids may inhibit the hepatic metabolism of cyclophosphamide; dosage adjustments may be required.
- **Cyclosporine**: Concomitant administration of glucocorticoids and cyclosporine may increase the blood concentration of each drug by mutually inhibiting each drug's hepatic metabolism; the clinical significance of this interaction is not clear.
- **Desmopressin (DDAVP)**: Concomitant administration of DDAVP and glucocorticoids may increase the risk for hyponatremia.
- **Digoxin**: When glucocorticoids are used concurrently with digitalis glycosides, an increased chance of digitalis toxicity may oc-

cur should hypokalemia develop; diligent monitoring of potassium and digitalis glycoside concentrations is recommended.
- **Diltiazem**: Concurrent use may increase plasma concentrations of methylprednisolone.
- **Diuretics, Potassium-Depleting** (eg, **furosemide, thiazides**): Concurrent use increases the risk for hypokalemia.
- **Ephedrine**: May reduce methylprednisolone blood concentrations
- **Estrogens**: The effects of methylprednisolone, and possibly other glucocorticoids may be potentiated by concomitant administration with estrogens.
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**): Concurrent use may increase risk for tendinitis and tendon rupture.
- **Immunosuppressive Agents** (eg, **azathioprine, hydroxychloroquine, mycophenolate**): Additive immunosuppressive effects possible.
- **Insulin**: Insulin requirements may increase in patients receiving glucocorticoids.
- **Leflunomide**: Increased risk for pancytopenia, agranulocytosis, thrombocytopenia, and infection
- **Macrolide Antibiotics** (eg, **erythromycin, clarithromycin**): May decrease the metabolism of glucocorticoids and increase methylprednisolone blood concentrations
- **Mitotane**: May alter the metabolism of steroids; higher than usual doses of steroids may be necessary to treat mitotane-induced adrenal insufficiency.
- **Nonsteroidal Anti-Inflammatory Drugs** (eg, **carprofen, flunixin, meloxicam**): Administration of ulcerogenic drugs with glucocorticoids may increase the risk for GI ulceration.
- **Phenobarbital**: May increase the metabolism of glucocorticoids and decrease methylprednisolone blood concentrations
- **Rifampin**: May increase the metabolism of glucocorticoids and decrease methylprednisolone blood concentrations
- **Theophylline, Aminophylline**: Concomitant use can alter the pharmacologic effects of both drugs.
- **Vaccines**: Patients receiving corticosteroids at immunosuppressive dosages should generally not receive live attenuated-virus vaccines, as virus replication may be augmented; a diminished immune response may occur after vaccine, toxoid, or bacterin administration in patients receiving glucocorticoids.
- **Warfarin**: Methylprednisolone may affect clotting times; monitor prothrombin times.

Laboratory Considerations

- Methylprednisolone can cross-react with cortisol when measuring cortisol for adrenal function testing with a **cortisol assay**, and spurious results can occur. Dexamethasone does not interfere with the assay for cortisol.
- Reactions to **intradermal allergy skin tests** may be suppressed by glucocorticoids. Suggested methylprednisolone withdrawal time prior to testing is 3 to 4 weeks for oral formulations and 8 weeks for IM methylprednisolone acetate.
- False-negative results of the **nitroblue tetrazolium** test for systemic bacterial infections may be induced by glucocorticoids.
- Glucocorticoids may increase **serum cholesterol.**
- Glucocorticoids may increase **serum and urine glucose**.
- Glucocorticoids may decrease **serum potassium.**
- Glucocorticoids can suppress the release of thyroid stimulating hormone (TSH) and reduce **total T_3** and **total T_4** values. Thyroid gland atrophy has been reported after chronic glucocorticoid administration. Uptake of **I^{131}** by the thyroid may be decreased by glucocorticoids.
- Glucocorticoids may cause **neutrophilia** within 4 to 8 hours after dosing and return to baseline within 24 to 48 hours after drug discontinuation.
- In dogs, glucocorticoids can cause **lymphopenia** that can persist for weeks after drug discontinuation.

Dosages

NOTES:

1) If using methylprednisolone tablets orally or methylprednisolone sodium succinate for IV injection, refer to the ***Prednisolone/Prednisone Dosages*** section to determine an appropriate dose for the condition treated. A near equivalent dose for methylprednisolone can be determined by dividing the dose of prednis(ol)one by 1.25 (eg, if the prednis(ol)one dose is 5 mg, the methylprednisolone dose is 4 mg).
2) If given daily, therapy for longer than 1 to 2 weeks will suppress the hypothalamic-pituitary-adrenal (HPA) axis, and recovery will take longer than 1 week. Therefore, if corticosteroids are used for longer than a few days, the dosage must be tapered using alternate-day therapy. Many glucocorticoid responsive diseases can be managed with chronic alternate-day therapy. If possible, it is suggested to avoid giving doses greater than 1 mg/kg (prednisolone equivalent) every other day; larger doses saturate a dog's ability to fully metabolize the last dose before the next dose is given and can negate the benefits of alternate-day therapy. However, to induce remission of clinical signs or manage their recurrence initially requires daily therapy at an appropriate dose to control clinical signs, then tapering the drug to reach a minimum daily dose that will control clinical signs, followed by alternate-day therapy to manage the disease. Animals vary greatly in their response to the therapeutic and adverse effects of glucocorticoids, and qualitative differences may exist between the effects of different glucocorticoids in the same animal.[27]

DOGS:

Label indications (FDA-approved):

NOTE: Label dosages are listed as mg/dog (NOT mg/kg).

1. Oral: Dogs weighing 2.3 to 6.8 kg (5-15 lb): 2 mg/dog (NOT mg/kg); dogs weighing 6.8 to 18.1 kg (15-40 lb): 2 – 4 mg/dog (NOT mg/kg); dogs weighing 18.1 to 36.3 kg (40-80 lb): 4 – 8 mg/dog (NOT mg/kg); these are average total daily doses, which should be divided into 2 equal doses and given 6 to 10 hours apart. Once clinical response has been obtained, gradually reduce dosage until treatment is terminated or the lowest effective dose has been achieved.[18]
2. IM (methylprednisolone *acetate*): 2 – 120 mg/dog (NOT mg/kg) IM (average 20 mg/dog; NOT mg/kg); depending on breed (ie, 2 mg/dog [NOT mg/kg] in miniature breeds; 40 mg/dog [NOT mg/kg] in medium breed; as high as 120 mg/dog [NOT mg/kg] in extremely large breeds or dogs with severe involvement), severity of condition, and response. May repeat at weekly intervals or in accordance with the severity of the condition and the response.[17] The manufacturer has specific directions for use of the drug intrasynovially.

Adjunctive treatment of canine atopic dermatitis (extra-label): Initial dosage of ≈0.4 – 0.8 mg/kg PO once to twice daily to be tapered as needed.[28,29]

Adjunctive treatment of anaphylaxis (extra-label): Methylprednisolone *sodium succinate* (NOT acetate) 2 – 6 mg/kg IV, not a substitute for epinephrine. Pre-treatment does NOT prevent anaphylaxis.[30] Infuse at no faster than 1 – 2 mg/kg/minute.[31]

CATS:

Label indications (FDA-approved):

NOTE: Labeled dosages are listed as mg/cat (NOT mg/kg.)

1. Oral: Cats weighing 2.3 to 6.8 kg (5-15 lb): 2 mg/cat (NOT mg/kg); Cats weighing more than 6.8 kg (15 lb): 2 – 4 mg/cat (NOT mg/kg). These are average total daily doses which should be divided into 2 equal doses and given 6 to 10 hours apart. Once clinical response has been obtained, gradually reduce the dose until treatment is terminated or the lowest effective dose has been achieved.[18]
2. Intramuscularly (methylprednisolone acetate): The average dose is 10 mg/cat (NOT mg/kg) IM with a range up to 20 mg/cat (NOT mg/kg); depending on breed (size), severity of condition, and response. May repeat at weekly intervals or in accordance with the severity of the condition and the response.[17]

Adjunctive treatment for allergic cats (extra-label):

a) Pruritus: Initial induction dosage was 4 mg/cat (NOT mg/kg) PO once daily for cats weighing less than or equal to 5 kg (11 lb), and 6 mg/cat (NOT mg/kg) PO once daily for cats more than 5 kg (11 lb). Cats that did not achieve remission by day 7 had their once daily induction dose doubled for the next 7 days. Mean dose required for induction of remission was 1.41 mg/kg (range 0.8 – 2.2 mg/kg) PO once daily, and 88% of treated cats achieved remission by the end of the second week. Dosages used to achieve remission were then given every other day and tapered (from 100% to 25% of induction dose in 25% increments) to the lowest every other day dosage that maintained remission. Sixty-seven percent of cats that achieved remission were maintained at 25% of the induction dose given every other day.[4]

b) Feline atopic dermatitis, as part of a multimodal treatment protocol: 1 – 2 mg/kg PO once daily for 7 days and then taper to the lowest effective dose.[32]

Adjunctive treatment of anaphylaxis (extra-label): Methylprednisolone *sodium succinate* (NOT acetate) 2 – 6 mg/kg IV. Not a substitute for epinephrine. Pre-treatment does NOT prevent anaphylaxis.[30] Infuse no faster than 1 – 2 mg/kg/minute.[31]

HORSES:

Anti-inflammatory (glucocorticoid effects); (label dosage; FDA-approved): Methylprednisolone acetate 200 mg IM repeated as necessary.[17] The manufacturer has specific directions for use of the drug intrasynovially.

Intra-articular use (extra-label): Methylprednisolone acetate 100 mg IA[33]

Monitoring

Monitoring of glucocorticoid therapy is dependent on the reason for use, dosage used, agent used (amount of mineralocorticoid activity), duration of therapy, and animal's age and condition. The following list may not be appropriate or complete for all animals; use clinical assessment and judgment should adverse effects be noted:

- Weight, appetite, signs of edema
- Serum and/or urine electrolytes
- Total plasma proteins, albumin
- Blood glucose
- Growth and development in young animals
- ACTH stimulation test if necessary (**NOTE**: Methylprednisolone can interfere with cortisol assay.)

Client Information

- Give oral products with food.
- Goal is to find the lowest dose possible and use for the shortest period.
- Many side effects are possible, especially when the medication is used long term. Most common side effects are increased panting, appetite, thirst, and need to urinate.
- In dogs, stomach or intestinal ulcers, perforation, or bleeding can occur. If your animal stops eating, or you notice a high fever, black tarry stools, or bloody vomit, contact your veterinarian right away.
- Do not stop therapy abruptly without a veterinarian's guidance as serious side effects could occur.

Chemistry/Synonyms

Methylprednisolone is a synthetically produced glucocorticoid. Both the free alcohol and the acetate ester occur as an odorless, white or practically white, crystalline powder. The powder is practically insoluble in water and sparingly soluble in alcohol.

Methylprednisolone sodium succinate occurs as an odorless, white or nearly white, hygroscopic, amorphous solid. It is very soluble in both water and alcohol. Methylprednisolone sodium succinate has equivalent biologic activity as methylprednisolone.

Methylprednisolone may also be known as 6α-methylprednisolone, methylprednisolonum, NSC-19987, *A-Methapred®*, *Depo-Medrol®*, *Medrol®* or *Solu-Medrol®*, *Medrone® V, Solu-Medrone® V*, and *Depo-Medrone® V.*

Storage/Stability

Commercially available products of methylprednisolone should be stored at room temperature (20°C to 25°C [68°F-77°F]); avoid freezing the acetate injection. Vial contents should be used within 12 weeks of first vial puncture or discarded. After reconstituting the sodium succinate injection, store at room temperature and use within 48 hours; only use solutions that are clear.

Compatibility/Compounding Considerations

Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Methylprednisolone sodium succinate injection is reportedly **Y-site compatible** with the following fluids and drugs: amino acids 4.25%/dextrose 25%, amphotericin B (limited amounts), butorphanol, cefazolin, chloramphenicol sodium succinate, cimetidine, clindamycin phosphate, dobutamine, dopamine, epinephrine, furosemide, heparin sodium, lactated Ringer's solution, metoclopramide, morphine, norepinephrine, parenteral nutrition (3-in-1 and 2-in-1), penicillin G potassium, piperacillin/tazobactam, polymyxin B, and verapamil.

The following drugs and fluids have been reported to be physically **incompatible** when mixed with methylprednisolone sodium succinate, compatible dependent upon concentration, or the data are conflicting: dextrose 5%/sodium chloride 0.45%, dextrose 5%/sodium chloride 0.9% (80 mg/L reported compatible), dextrose 5% (up to 5 g/L reported compatible), lactated Ringer's (up to 80 mg/L reported compatible), sodium chloride 0.9% (some reports of up to 60 g/L compatible), ampicillin, calcium gluconate, diazepam, famotidine, glycopyrrolate, insulin, pantoprazole, potassium chloride, and tetracycline HCl.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Methylprednisolone Tablets: 1 mg, 2 mg, and 4 mg tablets, *Medrol®*, generic; (Rx). FDA-approved for use in dogs and cats. NADA# 011-403

Methylprednisolone Acetate Injection: 20 mg/mL in 20 mL vials and 40 mg/mL in 5 mL vials; *Depo-Medrol®*, generic; (Rx). FDA-approved for IM injection in dogs, cats, and horses; intrasynovial injection in dogs and horses. The veterinary label states that the drug is not to be

used in horses intended for human consumption. NADA# 012-204

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Methylprednisolone Oral Tablets: 2 mg, 4 mg, 8 mg, 16 mg, and 32 mg; *Medrol*®, generic; (Rx)

Methylprednisolone Acetate Injection: 20 mg/mL, 40 mg/mL, and 80 mg/mL suspension in 1 mL (40 and 80 mg only), 5 mL, and 10 mL vials; *Depo-Medrol*®, generic; (Rx)

Methylprednisolone Sodium Succinate Powder for Injection: 40 mg, 125 mg, 500 mg, 1 gram, and 2 gram vials for reconstitution; *Solu-Medrol*®, *A-Methapred*®, generic; (Rx)

Metoclopramide

(met-oh-***kloe***-pra-mide) *Reglan*®, *Emeprid*®

GI Prokinetic Agent; Antiemetic

Prescriber Highlights

- ► Stimulates upper GI motility and has antiemetic properties
- ► In dogs, it is more potent as an antiemetic than a prokinetic agent; may be a poor antiemetic in cats
- ► May work best when used as an IV CRI
- ► Contraindications include GI hemorrhage, obstruction, perforation, and hypersensitivity. Relative contraindications include seizure disorders and pheochromocytoma.
- ► In dogs, adverse effects include changes in mentation and behavior and constipation. In cats, adverse effects include signs of frenzied behavior or disorientation, and constipation. When given IV in horses, adverse effects include severe CNS effects, behavior changes, and abdominal pain; adverse effects are less common in foals.
- ► Several potentially serious drug interactions

Uses/Indications

Metoclopramide has been used in animals for both its GI prokinetic and antiemetic properties. It has been used clinically for gastric stasis disorders, gastroesophageal reflux, intubation of the small intestine, and as an antiemetic for parvoviral enteritis, bilious vomiting syndrome, uremic gastritis, and to prevent or treat chemotherapy-induced vomiting. Although metoclopramide is widely accepted as an antiemetic in dogs, other drugs (eg, maropitant, ondansetron) are more effective and appear to be better tolerated.[1–4]

Distinct differences between antiemetic and prokinetic effects can be seen in different species. Antiemetic effects appear more pronounced in dogs than in cats; distal esophageal motility effects are greater in cats. Metoclopramide has gastric prokinetic effects in both species; however, in dogs, metoclopramide did not facilitate duodenal passage of a flexible endoscope[5,6] or promote gastric emptying following gastric dilatation and volvulus.[7] Breed and dose may influence prokinetic response.[8]

Pharmacology/Actions

The primary pharmacologic effects of metoclopramide are associated with the GI tract and the CNS. Metoclopramide stimulates motility of the upper GI tract without stimulating gastric, pancreatic, or biliary secretions. Although the exact mechanisms for these actions are unknown, it appears that metoclopramide sensitizes upper GI smooth muscle to the effects of acetylcholine. Intact vagal innervation is not necessary for enhanced motility, but anticholinergic drugs negate metoclopramide's effects. GI effects seen after metoclopramide administration include increased tone and amplitude of gastric contractions, relaxed pyloric sphincter, and increased duodenal and jejunal peristalsis. Gastric emptying and intestinal transit times can be significantly reduced. There is little or no effect on colon motility. In addition, metoclopramide may increase lower esophageal sphincter (LES) pressure and reduce gastroesophageal reflux; however, one study showed no significant change in LES pressure after metoclopramide administration in dogs.[9] The drug did not reduce gastroesophageal reflux in dogs undergoing anesthesia with acepromazine, propofol, and isoflurane[10] or the incidence of aspiration pneumonia in dogs with idiopathic laryngeal paralysis undergoing unilateral arytenoid lateralization.[11,12] A protocol involving metoclopramide and famotidine in brachycephalic dogs undergoing airway surgery was associated with a decreased incidence of postoperative regurgitation.[13] The drug ameliorated delayed gastric emptying caused by endotoxin administration in horses.[14]

The stimulatory effect of metoclopramide on distal esophageal peristalsis is species specific, with more effect seen in humans, cats, and guinea pigs and less effect seen in dogs.

In the CNS, metoclopramide apparently antagonizes dopamine (D_2) at receptor sites. It is also a weak inhibitor of serotonin 5-HT_3 receptors and an agonist for serotonin 5-HT_4 receptors. These actions help explain its sedative, central antiemetic, extrapyramidal, and prolactin secretion stimulation effects.

Antiemetic effects of metoclopramide are secondary to both central and peripheral (local) effects. Cats reportedly have few CNS dopamine receptors; therefore, metoclopramide may be a poor antiemetic choice in this species.[15] Nevertheless, metoclopramide delayed time to onset of vomiting and reduced the number of vomiting episodes following xylazine administration in cats by 50% to 88%.[16,17] Metoclopramide 0.5 mg/kg IV every 8 hours decreased the severity and frequency of vomiting in dogs hospitalized with parvoviral enteritis.[18] Another study showed that metoclopramide given at 0.5 mg/kg SC 45 minutes before morphine administration decreased incidence of emesis in dogs by 53%, and animals had a lower incidence of injection site pain as compared with maropitant.[4]

In humans, metoclopramide can induce transient increases in aldosterone concentrations, which increase sodium and fluid retention[19]; this effect was not found to occur in dogs or rabbits.[20] In cats and horses, there are no data pertaining to the effects of metoclopramide on aldosterone secretion.

In a study in horses comparing the effects of certain prokinetic drugs (eg, metoclopramide, cisapride, mosapride) on gastric emptying and small intestinal and cecal motility, metoclopramide promoted jejunal motility but did not significantly affect gastric emptying or cecal motility.[21] In a different study in healthy Arabian horses comparing the effects of neostigmine and metoclopramide on GI motility via ultrasound evaluation, metoclopramide improved cecal and colonic contractions compared to control, but not duodenal contractions.[22]

Pharmacokinetics

In dogs and cats, metoclopramide is almost completely absorbed; it is metabolized in the liver and 65% of the dose is eliminated in the urine. The elimination half-life is ≈0.9 hours.[3] Metoclopramide formulated for and used as a nasal spray has been shown to have a higher bioavailability and shorter T_{MAX} as compared to oral tablets.[23]

In goats given metoclopramide IV, volume of distribution was 1.34 L/kg and elimination half-life was 0.6 hours; the drug was un-

detectable in serum 120 minutes after administration. With IM administration, biologic half-life was 1 hour.[24]

In rabbits, bioavailability of metoclopramide was shown in a study to be 96% and 112% when administered at 2 mg/kg IM and SC, respectively; bioavailability was poor when administered per rectum (13% at a dose of 4 mg/kg). Terminal half-lives were 0.81 hours (IM), 0.89 hours (SC), and 1.68 hours (per rectum). Peak drug concentration occurred at ≈0.2 hours when given IM and SC.[25]

In humans, metoclopramide is well absorbed after oral administration, but a significant first-pass effect in some patients may reduce systemic bioavailability to 30%. Apparently, there is a great deal of interpatient variation with this effect. Bioavailability after IM administration is 74% to 96%. After oral administration, peak plasma concentrations generally occur within 2 hours. Metoclopramide is well distributed throughout the body and enters the CNS. Up to 30% of the drug is protein-bound.[19,26]

In humans, metoclopramide is primarily excreted in urine, and ≈20% to 25% of the drug is excreted unchanged. The remaining drug is primarily metabolized to glucuronidated or sulfated conjugate forms and then excreted in the urine. Approximately 5% is excreted in the feces. Elimination half-life is 5 to 6 hours.

Contraindications/Precautions/Warnings

Metoclopramide is contraindicated in animals with GI hemorrhage, obstruction, or perforation and in animals hypersensitive to it. It is relatively (some say absolutely) contraindicated in animals with seizure disorders. Catecholamine release may occur following IV injection, and the drug is contraindicated in animals with pheochromocytoma, as it may induce a hypertensive crisis. In humans, it is recommended to use metoclopramide with caution in patients with hypertension.[27]

Metoclopramide has a black box warning regarding the risk for development of tardive dyskinesia in humans; it is recommended that the drug not be used for longer than 12 weeks. Use should be avoided in animals with tardive dyskinesia or a history of dystonic reactions.

Metoclopramide has been associated with cases of neuroleptic malignant syndrome in humans.

Because of its effects on aldosterone in humans, metoclopramide should be used with caution in animals with congestive heart failure.[19]

A dose adjustment may be required when metoclopramide is used as a CRI in animals with renal failure. Anecdotal experience in a study suggests reducing the CRI to 25% to 50% of the standard dose.[28] Dose reduction should also be considered in animals with moderate to severe hepatic impairment.

Adverse Effects

In dogs, the most common (although infrequent) adverse effects are changes in mentation and behavior (eg, motor restlessness, involuntary spasms, aggression, vocalization, hyperactivity, drowsiness, depression). Metoclopramide can increase detrusor muscle contractility and reduce bladder capacity. Tremors may occur, particularly in dogs with renal insufficiency.[29] Extrapyramidal signs (head tremors, dystonia of the dorsal back and lateral thorax muscles) were observed in a dog after it received metoclopramide via IV bolus.[30]

Cats may exhibit signs of frenzied behavior or disorientation. Cats and dogs can develop constipation.

In adult horses, IV metoclopramide administration has been associated with the development of severe CNS effects.[31] Alternating periods of sedation and excitement, behavior changes, and abdominal pain have been noted. These effects appear to be less common in foals.

Other adverse effects that have been reported in humans and are plausible in animals include extrapyramidal effects (eg, dyskinesia, dystonia, akathisia), nausea, diarrhea, transient hypertension, and elevated prolactin concentrations.

Reproductive/Nursing Safety

Studies in laboratory animals have not produced any evidence of teratogenic or fetotoxic effects. Metoclopramide may elevate prolactin concentrations, which may lead to galactorrhea, gynecomastia, impotence, and anestrus; use should be avoided in dogs with pseudopregnancy.[32]

Metoclopramide is excreted into milk and may concentrate at approximately twice the plasma concentration; breastfed infants exposed to metoclopramide in milk have experienced adverse GI effects. Metoclopramide-induced hyperprolactinemia stimulated milk production in postpartum healthy bitches, but the effect on their offspring was not assessed.[33] Caution is advised when using in nursing animals.

Overdose/Acute Toxicity

The oral LD_{50} doses of metoclopramide in mice, rats, and rabbits are 465 mg/kg, 760 mg/kg, and 870 mg/kg, respectively. Because of the high doses required for lethality, it is unlikely an oral overdose will cause death in a veterinary patient. Clinical signs of an overdose include sedation, ataxia, agitation, extrapyramidal effects, nausea, vomiting, and constipation. Serotonin syndrome is possible.

There is no specific antidotal therapy for metoclopramide intoxication. If an oral ingestion was recent, standard GI decontamination protocols can be employed. Metoclopramide may reduce the efficacy of emetics (eg, ropinirole, apomorphine). Anticholinergic agents (eg, diphenhydramine, 2.2 mg/kg IV) that enter the CNS may be helpful in controlling extrapyramidal effects. Peritoneal dialysis or hemodialysis is not thought to be effective in removal of this drug.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving oral metoclopramide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Acetaminophen**: In overdose situations in humans, metoclopramide has enhanced absorption of these agents.
- **Alpha-2 Adrenergic Receptor Agonists** (eg, **dexmedetomidine, xylazine**): In cats, metoclopramide may reduce the emetic effects of alpha-2 agonists.[34]
- **Anesthetics**: Acute hypotension has been reported when metoclopramide is used concurrently IV.
- **Anticholinergic agents** (eg, **atropine, dimenhydrinate, diphenhydramine, glycopyrrolate, meclizine, oxybutynin**): May antagonize the GI motility effects of metoclopramide
- **Apomorphine**: Metoclopramide may negate the emetic effects of apomorphine.
- **Aspirin**: In overdose situations in humans, metoclopramide has enhanced absorption of these agents.
- **Butyrophenones** (eg, **azaperone, droperidol**): May potentiate the extrapyramidal effects of metoclopramide[35,36]
- **Cephalexin**: In dogs, oral metoclopramide was shown to increase cephalexin peak plasma concentrations and area under the curve (AUC). No dosage adjustments are required.[37]
- **Cholinergic Drugs** (eg, **bethanechol**): May enhance metoclopramide's GI effects

- **CNS Depressants** (eg, **anesthetic agents**, **antihistamines, anxiolytics**, **barbiturates, phenothiazines**, **sedatives**, **tranquilizers**): Metoclopramide may enhance CNS depressant effects.
- **Cyclosporine**: Metoclopramide can potentially increase the rate and extent of GI absorption of cyclosporine; however, this does not appear to be an issue in dogs.[38]
- **Dopamine and Dopaminergic Drugs** (eg, **bromocriptine, cabergoline**): Metoclopramide could theoretically antagonize dopamine or dopaminergic drugs, and vice versa, but clinical significance has not been established.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): May cause hypertension
- **Mirtazapine**: Increased risk for extrapyramidal adverse effects; use together is contraindicated in humans
- **Opioid Analgesics** (eg, **fentanyl, hydromorphone, morphine**): May antagonize the GI motility effects of metoclopramide and enhance metoclopramide's CNS depressant effects; combination may also reduce the emetic effects of hydromorphone.
- **Phenothiazines** (eg, **acepromazine**, **chlorpromazine**): May potentiate the extrapyramidal effects of metoclopramide[35,36]
- **Posaconazole**: May reduce posaconazole concentrations
- **Propofol**: In humans, metoclopramide reduces induction requirements of propofol by 20% to 25%.
- **Quinidine**: May inhibit metoclopramide metabolism
- **Ropinirole**: Metoclopramide may negate the emetic effects of ropinirole.
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, paroxetine, sertraline,**): Potential for enhanced extrapyramidal effects or neuroleptic malignant syndrome. In addition, SSRIs may inhibit metoclopramide metabolism and increase the risk for toxicity.
- **Tetracyclines**: Metoclopramide can increase the rate and extent of GI absorption.
- **Tramadol**: Use together may increase risk for seizures
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Potential for enhanced extrapyramidal effects or neuroleptic malignant syndrome

Laboratory Considerations

- Metoclopramide may induce secretion of **vasopressin** and alter fluid and electrolyte values.
- Metoclopramide may induce secretion of **prolactin**.

Dosages

DOGS:

Antiemetic and gastric prokinetic (extra-label):

Intermittent doses: Most published studies used a dose of 0.5 mg/kg IV or SC; historically, 0.2 – 0.5 mg/kg every 6 to 8 hours PO, SC, IV, or IM has been used.[39] When used as a prokinetic, administer 30 to 60 minutes before a meal. A higher dose (eg, 1 mg/kg SC, IM) may be required when used as an antiemetic for chemotherapy-induced emesis.

Constant rate infusion (CRI): 0.04 – 0.09 mg/kg/hour (1 – 2 mg/kg/day) IV[39]

Reduction of morphine-induced nausea and vomiting: 0.2 – 0.5 mg/kg SC 30 to 45 minutes prior to morphine administration[4,40]

Reduction of reflux or aspiration associated with surgery for laryngeal paralysis (extra-label): 1 mg/kg IV loading dose followed by 1 mg/kg/hour IV CRI during surgery. Postoperatively, rate was reduced to 0.083 mg/kg/hour IV CRI for a total treatment duration of 24 hours.[11]

Treatment for vomiting and reduced GI motility associated with gastritis, pyloric spasm, chronic nephritis, and digestive intolerance to some drugs (extra-label): 0.25 – 0.5 mg/kg twice daily or 0.17 – 0.33 mg/kg three times daily PO, IV, IM, or SC. Doses may be given up to every 6 hours.[35,36]

Induction of milk letdown reflex for secondary agalactia (extra-label): Oxytocin 0.25 – 1 unit (total dose; NOT units/kg) SC every 2 hours. Neonates are removed for 30 minutes postinjection and then encouraged to suckle or gentle stripping of the glands is performed. Metoclopramide 0.1 – 0.2 mg/kg SC every 12 hours can be used to promote milk production. Therapy is usually successful within 24 hours.[41]

Reduction of regurgitation and respiratory complications in brachycephalic dogs undergoing airway surgery (extra-label): 0.5 mg/kg SC in combination with famotidine 1 mg/kg IV or SC given either shortly before or as part of premedication.[13] In patients with no history of regurgitation or vomiting, this protocol was followed with no additional medications preoperatively. For non-emergent procedures in patients with a history of regurgitation or vomiting, patients were treated with oral metoclopramide and a proton pump inhibitor for one week prior to surgery, and the injectable protocol followed as described above. Implementation of this protocol decreased the incidence of postoperative regurgitation in brachycephalic dogs undergoing anesthesia.

CATS:

Antiemetic (extra-label): Other antiemetics (eg, ondansetron, maropitant) and prokinetic agents (eg, cisapride) are typically used, but metoclopramide dosages in dogs can be tried. 0.2 – 1 mg/kg IM delayed or reduced xylazine-induced emesis[16,17]

Gastric prokinetic (extra-label): 0.5 mg/kg SC every 8 hours[42]

Treatment for vomiting and reduced GI motility associated with gastritis, pyloric spasm, chronic nephritis, and digestive intolerance to some drugs (extra-label): 0.25 – 0.5 mg/kg twice daily or 0.17 – 0.33 mg/kg three times daily PO, IV, IM, or SC. Doses may be given up to every 6 hours.[35,36]

HORSES:

GI prokinetic (extra label):

a) 0.2 mg/kg SC improved jejunal motility[21]

b) 0.04 mg/kg/hour IV CRI reduced ileus following small intestinal resection and anastamosis[43]

c) 0.25 mg/kg IM improved cecal and colonic contractions, but not duodenal contractions, when evaluated by ultrasound in healthy Arabian horses[22]

RABBITS/RODENTS/SMALL MAMMALS:

a) Anecdotal dosages of 0.2 – 1 mg/kg PO, IM, or SC every 8 to 24 hours have been noted.

b) In a pharmacokinetic study, single doses of 2 mg/kg were used intra-arterial, IM, and SC in rabbits with no apparent adverse effects.[25]

c) Gastric dilation in rabbits (extra-label): 0.5 mg/kg SC three times daily[44]

Monitoring

- Clinical efficacy
- Adverse effects, including monitoring for tremors

Client Information

- When administering this medicine orally, it may be given ≈15 to 30 minutes before feeding or on an empty stomach. If your animal vomits or acts sick after receiving this medicine on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.

- If vomiting occurs after giving your animal the oral liquid solution, do not repeat the dose. Give the next dose at the next scheduled time and continue the regular schedule of administration.
- This medicine may be injected under the skin, especially when vomiting in small animals is being treated or prevented. Your veterinarian will instruct you on how to give the injections. Do not give the oral liquid as an injection.
- There are no specific precautions required when handling this medication unless you are allergic to it.
- This medicine is typically well tolerated in dogs and cats. Contact your veterinarian if your animal develops severe restlessness, hyperactivity, rigid posture, spasms, aggression, or severe drowsiness/depression. Your animal may need to urinate more often while taking this medicine.
- Cats may show signs of frenzied behavior or disorientation.
- Dogs and cats can become constipated when taking this medicine.

Chemistry/Synonyms

Metoclopramide HCl, a derivative of para-aminobenzoic acid, occurs as an odorless, white, crystalline powder with pK_as of 0.6 and 9.3. One gram is soluble in ≈0.7 mL of water or ≈3 mL of alcohol. The injectable product has a pH of 2.5 to 6.5. Dosage form potency is expressed in mg of metoclopramide base.

Metoclopramide HCl may also be known as AHR-3070-C, DEL-1267, metoclopramidi hydrochloridum, and MK-745; many trade names are available.

Storage/Stability

Metoclopramide is photosensitive and must be stored in light-resistant containers at room temperatures of 20°C to 25°C (68°F-77°F), with excursions permitted between 15°C to 30°C (59°F-86°F) for the injectable solution. Metoclopramide tablets should be kept in tight containers.

The injectable solution is reportedly stable in solutions with a pH range between 2 and 9 and with the following IV solutions: 5% dextrose, 0.9% sodium chloride, 5% dextrose/0.45% sodium chloride, Ringer's, and lactated Ringer's injection.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The following drugs have been stated to be physically **compatible** with metoclopramide for at least 24 hours: aminophylline, ascorbic acid, atropine sulfate, chlorpromazine HCl, cimetidine HCl, clindamycin phosphate, cyclophosphamide, cytarabine, dexamethasone sodium phosphate, dimenhydrinate, diphenhydramine HCl, doxorubicin HCl, fentanyl citrate, heparin sodium, hydrocortisone sodium phosphate, hydroxyzine HCl, insulin (regular), lidocaine HCl, magnesium sulfate, mannitol, meperidine HCl, methylprednisolone sodium succinate, morphine sulfate, multivitamin infusion (MVI), pentazocine lactate, potassium acetate/chloride/phosphate, prochlorperazine edisylate, ranitidine, TPN solution (25% dextrose with 4.25% *Travasol*®, with or without electrolytes), verapamil, and vitamin B complex with vitamin C.

Metoclopramide is reported to be physically **incompatible** when mixed with the following drugs: ampicillin sodium, calcium gluconate, chloramphenicol sodium succinate, cisplatin, erythromycin lactobionate, methotrexate sodium, penicillin G potassium, sodium bicarbonate, and tetracycline.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES

The Association or Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

All are expressed in terms of metoclopramide monohydrate:

Metoclopramide HCl Oral Tablets: 5 mg and 10 mg; *Reglan*®, generic; (Rx)

Metoclopramide Oral Dispersible Tablets (ODT): 5 mg; *Metozolv*®, generic; (Rx)

Metoclopramide HCl Oral Syrup: 1 mg/mL in 473 mL bottles; generic; (Rx)

Metoclopramide HCl Injection Solution: 5 mg/mL in 2, 10, and 30 mL single-use vials; generic; (Rx)

Metoprolol
Metoprolol Succinate
Metoprolol Tartrate

(me-***toe***-pro-lole) *Lopressor®, Toprol XL®*

Beta-Adrenergic Blocker

Prescriber Highlights

- ► Used in dogs for supraventricular tachyarrhythmias, premature ventricular contractions (PVCs), and systemic hypertension, and in cats for treatment of hypertrophic cardiomyopathy
- ► Due to its selectivity for beta-1 over beta-2, metoprolol is likely safer than propranolol in animals with bronchoconstrictive disease.
- ► Contraindications include overt or unstable heart failure, hypersensitivity to any beta-blocker, atrioventricular block greater than first-degree, and sinus bradycardia.
- ► Use with caution in animals with significant hepatic insufficiency, bronchospastic lung disease, stable CHF, pheochromocytoma, hyperthyroidism, diabetes mellitus, and sinus node dysfunction.
- ► Adverse effects include bradycardia, lethargy and depression, impaired AV conduction, worsening of heart failure, hypotension, hypoglycemia, bronchoconstriction, syncope, and diarrhea.
- ► Adverse effects are more likely in geriatric animals or animals with acute decompensating heart disease.
- ► Metoprolol should be gradually tapered when discontinuing after chronic use.

Uses/Indications

Metoprolol may be effective in treating dogs with supraventricular tachyarrhythmias, premature ventricular contractions (PVCs), and systemic hypertension. It may also be effective for treating cats with hypertrophic cardiomyopathy. Because metoprolol is relatively safe to use in animals with bronchospastic disease, it is often chosen over propranolol.

One retrospective study showed increased survival times when dogs were given metoprolol; however, no prospective studies documenting increased survival with beta-blockers in dogs with heart failure have been reported. Beta-blockers are generally not recommended for treatment of congestive heart failure (CHF) associated with myxomatous mitral valve disease (MMVD) except as potential adjunct treatment for heart rate control in atrial fibrillation.[1,2] Be-

ta-blockers should be used cautiously due to negative inotropic effects and should not be used in dogs with active signs of CHF.

Pharmacology/Actions

Metoprolol is a relatively selective beta-1-blocker and is sometimes characterized as a second-generation beta-blocker. At higher doses, nonselective beta-1 and beta-2-blockade can occur. Metoprolol does not possess any intrinsic sympathomimetic activity like pindolol, nor does it possess membrane-stabilizing activity like pindolol or propranolol. Metoprolol has negative inotropic and chronotropic actions, resulting in a decreased sinus heart rate, slowed AV conduction, diminished cardiac output at rest and during exercise, decreased myocardial oxygen demand, and reduced blood pressure.

Pharmacokinetics

No information on the pharmacokinetics of metoprolol succinate was located for dogs or cats. When a sustained-release tablet containing metoprolol 50 mg and felodipine 5 mg was administered orally to beagle dogs, the maximum plasma concentration of metoprolol was 532 µg/mL and occurred after 3.8 hours. The plasma half-life, clearance, and volume of distribution were 9.1 hours, 1.2 L/hour/kg, and 16.4 L/kg, respectively.[3]

In humans, metoprolol tartrate is rapidly and completely absorbed from the GI tract; however, bioavailability is only ≈50% due to high first-pass metabolism.[4] Metoprolol is only ≈5% to 15% bound to plasma proteins and is distributed well into most tissues. It crosses the blood-brain barrier, and CSF concentrations are ≈78% of those found in the plasma. It also crosses the placenta, and concentrations in milk are 3 to 4 times higher than those found in plasma. Metoprolol is extensively metabolized in the liver, and both unchanged drug and metabolites are excreted in the urine. The half-life in humans varies depending on CYP2D6 polymorphisms, and ranges from 3 to 4 hours in extensive metabolizers to 7 to 9 hours in poor metabolizers. Reported half-life of metoprolol tartrate in dogs is 1.7 hours; reported half-life in cats is 1.3 hours.

Contraindications/Precautions/Warnings

Metoprolol is contraindicated in patients with overt or unstable heart failure, hypersensitivity to any beta-blocker, atrioventricular block greater than firstdegree, or sinus bradycardia. In humans, metoprolol is contraindicated in patients with severe peripheral arterial circulatory disorders and pheochromocytoma. Nonselective beta-blockers are contraindicated in patients with bronchospastic lung disease; however, because metoprolol is relatively selective for beta-2 receptors, it can be used with extreme caution in patients with bronchospastic disease.

Metoprolol should be used cautiously in patients with history of cardiac failure as beta-blockade depresses myocardial contractility and can lead to failure over time.[4] It should also be used with caution in patients with significant hepatic insufficiency or sinus node dysfunction. At high doses, metoprolol can mask the clinical signs associated with hypoglycemia. It can also cause hypoglycemia or hyperglycemia and, therefore, should be used cautiously in labile diabetic patients. Metoprolol can also mask some clinical signs associated with thyrotoxicosis, but it may be used clinically to treat the clinical signs associated with this condition (eg, tachycardia, hypertension).

When discontinuing metoprolol after chronic administration, the dose should be gradually tapered.[4]

Do not confuse metoprolol succinate (extended-release) with metoprolol tartrate (immediate-release).

Adverse Effects

Adverse effects of metoprolol include bradycardia, lethargy, weakness, depression, impaired AV-node conduction, CHF or worsening of heart failure, hypotension, and hypoglycemia. Bronchoconstriction is possible, but less likely with beta-1 selective drugs like metoprolol. Syncope and diarrhea have also been reported in canine patients with beta-blockers. Cats with hypertrophic cardiomyopathy may be at an increased risk for pulmonary edema. It is reported that adverse effects most commonly occur in geriatric animals or those that have acute decompensating heart disease.

Exacerbation of clinical signs has been reported following abrupt cessation of beta-blockers in humans. Gradual discontinuation of therapy is recommended in patients that have been receiving metoprolol chronically.

Reproductive/Nursing Safety

Metoprolol crosses the placenta. No teratogenic effects have been reported, but safe use during pregnancy has not been established.

Metoprolol is excreted in milk in very small quantities. Use with caution in nursing animals and monitor offspring for adverse effects.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

There is limited information available on metoprolol overdoses. The predominant clinical signs of an overdose of other beta-blockers (eg, propranolol) include hypotension and bradycardia. Other possible effects include CNS (eg, depressed consciousness, seizures), bronchospasm, hypoglycemia, hyperkalemia, respiratory depression, pulmonary edema, other arrhythmias (especially AV block), and asystole.

If overdose is secondary to recent oral ingestion, GI decontamination protocols may be considered; however, use caution inducing emesis as coma and seizures may develop rapidly. Monitor ECG, blood glucose, potassium, and blood pressure. Treatment of the cardiovascular effects is based on clinical signs; fluids and pressor agents can be used to treat hypotension, and bradycardia may be treated with atropine. If atropine fails, isoproterenol, given cautiously, has been recommended. Use of a transvenous pacemaker may be necessary. Heart failure can be treated with digitalis glycosides, diuretics, and oxygen. Glucagon 5 – 10 mg IV may increase heart rate and blood pressure and reduce the cardiodepressant effects of metoprolol. Intravenous lipid emulsion (ILE) infusions are likely not beneficial for metoprolol intoxication.

Humans have reportedly survived doses of up to 5 g.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving metoprolol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anesthetics Agents, Inhalant** (eg, **halothane**): Increased risk for heart failure and hypotension
- **Antidiabetic Agents** (eg, **glipizide, insulin**): May result in hypoglycemia or hyperglycemia; metoprolol may mask signs of hypoglycemia
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**): Increased risk for hypotension, bradycardia, and AV node disturbances. Concurrent use of beta-blockers with calcium channel blockers (or other negative inotropics) should be done with caution, particularly in patients with pre-existing cardiomyopathy or CHF.

- **Digoxin**: May increase negative effects on SA or AV node conduction
- **Diuretics** (eg, **furosemide, thiazides**): May increase hypotensive effect of metoprolol
- **Hydralazine**: May increase the risks for pulmonary hypertension in uremic patients
- **Lidocaine, Systemic**: May result in lidocaine toxicity including myocardial depression and cardiac arrest
- **Methimazole**: Change from hyperthyroid to euthyroid state may alter metoprolol metabolism; metoprolol dose adjustment may be required
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam, robenacoxib**): May result in increased blood pressure
- **Phenobarbital**: May reduce metoprolol efficacy
- **Quinidine**: May increase metoprolol plasma concentrations
- **Reserpine**: Potential for additive hypotension and bradycardia
- **Rifampin**: May reduce metoprolol efficacy
- **Selective Serotonin Receptor Inhibitors** (**SSRIs**; eg, **fluoxetine, paroxetine, sertraline**): May increase metoprolol plasma concentrations
- **Sympathomimetics** (eg, **epinephrine, phenylpropanolamine, terbutaline**): Use together may reduce the efficacy of both agents
- **Terbinafine**: May increase metoprolol plasma concentrations

Dosages

DOGS:

Adjunctive treatment for heart rate control in atrial fibrillation (extra-label): Using metoprolol tartrate (immediate-release tablets), doses are typically started low at ≈0.2 mg/kg PO every 12 hours and slowly titrated upwards every 2 to 3 weeks as tolerated. Practically, 6.25 mg (1/4 of a 25 mg tablet) is the minimum dose using commercial tablets. Commonly, dosages of 0.4 – 1 mg/kg PO every 8 to 12 hours are used, but dosages as high as 6.6 mg/kg PO 3 times daily have been noted; however, many dogs will not tolerate upward dose titration. Extended-release metoprolol succinate tablets could be considered, but pharmacokinetic data supporting their use in dogs are not available.

CATS:

Beta-blockade (extra-label): Anecdotal dosages of 2 – 15 mg/cat (NOT mg/kg) PO every 8 hours have been noted. Compounded products may be necessary for small doses.

Monitoring

- Baseline and periodic physical exam, including heart rate, pulse, and pulse quality
- Baseline and periodic ECG as necessary
- Baseline and periodic blood pressure
- Echocardiography as clinically indicated
- Signs of toxicity (see ***Adverse Effects*** and ***Overdose/Acute Toxicity***)

Client Information

- This medicine may be given with or without food.
- The most common side effects are related to drops in heart rate and blood pressure and may include tiredness, lack of energy, and weakness. Contact your veterinarian if these signs occur.
- Notify your veterinarian if your animal becomes exercise intolerant, has shortness of breath or cough, or develops a change in behavior or attitude.
- When starting this medicine, your veterinarian may start with a low dose and gradually increase it over time to see how your animal reacts to it. Do not administer more than your veterinarian prescribes at one time.
- Your veterinarian will need to monitor your animal closely while it is taking this medicine. Do not miss these important follow-up visits.
- It is very important to not suddenly stop giving this medicine without your veterinarian's guidance.

Chemistry/Synonyms

Metoprolol tartrate, a beta-1 selective adrenergic blocker, occurs as a white, crystalline powder having a bitter taste. It is very soluble in water. Metoprolol succinate occurs as a white, crystalline powder and is freely soluble in water.

Metoprolol may also be known as CGP-2175E, H-93/26, and metoprolol; many trade names are available.

Storage/Stability

Protect metoprolol products from light. Store tablets in tight, light-resistant containers at room temperature. Avoid freezing the injection.

Compatibility/Compounding Considerations

The injection is **compatible** with D_5W and normal saline and at Y-sites with morphine sulfate.

Compounded preparation stability: Metoprolol oral suspension compounded from the commercially available tablets has been published.[5] Triturating twelve (12) metoprolol tartrate 100 mg tablets with 60 mL of *Ora-Plus*® and *qs ad* to 120 mL with *Ora-Sweet*® or *Ora-Sweet SF*® yields a 10 mg/mL metoprolol tartrate oral suspension that retains greater than 95% potency for 60 days when stored at both 4°C (39°F) and 25°C (77°F) and protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Metoprolol Tartrate Oral Tablets: 25 mg, 37.5 mg, 50 mg, 75 mg, and 100 mg; *Lopressor*®, generic; (Rx)

Metoprolol Succinate Extended-Release Tablets: 25 mg, 50 mg, 100 mg, and 200 mg; *Toprol XL*®, generic; (Rx)

Metoprolol Tartrate Injection: 1 mg/mL; *Lopressor*®, generic; (Rx)

Metronidazole

(me-troe-***ni***-da-zole) *Flagyl*®

Antibiotic, Antiparasitic

Prescriber Highlights

- ► Injectable and oral antibacterial (anaerobes) and antiprotozoal agent
- ► Prohibited by the FDA for use in food animals
- ► Contraindications include hypersensitivity to it or other nitroimidazole derivatives.
- ► Use with extreme caution in patients that are severely debilitated, pregnant, nursing, or that have hepatic dysfunction. Metronidazole may be a teratogen, especially in early pregnancy.
- ► Adverse effects include neurologic disorders, lethargy, weakness, neutropenia, hepatotoxicity, hematuria, anorexia, nausea, vomiting, and diarrhea.
- ► Very bitter taste; metronidazole benzoate may be more palatable when compounded.

Uses/Indications

Metronidazole has been used extensively in the treatment of *Giardia* spp in both dogs and cats, although it is not the drug of choice. It is also used clinically in small animal species for the treatment of other parasites (*Trichomonas* spp and *Balantidium coli*), as well as for treating both enteric and systemic anaerobic infections. It is sometimes used as a perioperative surgical prophylaxis antibiotic where anaerobes are likely (eg, colorectal surgery).

Although metronidazole is frequently used for acute nonspecific diarrhea in dogs, there is little evidence to support this use. One small study found that metronidazole shortened the duration of acute nonspecific diarrhea by ≈1.5 days compared with placebo.[1] Another study found no statistically significant difference in time to acceptable fecal consistency between metronidazole, probiotics, or placebo.[2] Metronidazole should not be used indiscriminately, as its use may have a significant and potentially sustained impact on the GI microbiota.[3,4]

In the United Kingdom, metronidazole is approved in dogs and cats for the treatment of GI tract infections caused by *Giardia* spp and *Clostridium* spp and for the treatment of infections of the urogenital tract, oral cavity, throat, and skin caused by obligate anaerobic bacteria susceptible to metronidazole.[5]

In horses, metronidazole has been used clinically for the treatment of systemic and enteric anaerobic infections.

The World Health Organization (WHO) has designated metronidazole as an Important antimicrobial for human medicine.[6]

Pharmacology/Actions

Metronidazole is a concentration-dependent bactericidal agent against susceptible bacteria. Metronidazole diffuses across the cell membranes of anaerobic bacteria where it interacts with DNA to cause strand breaks, resulting in inhibition of protein synthesis and cell death. Metronidazole has activity against most obligate anaerobes, including *Bacteroides* spp (including *Bacteroides fragilis*), *Eubacterium* spp, *Fusobacterium* spp, *Veillonella* spp, *Clostridium* spp, *Peptococcus* spp, *Peptostreptococcus* spp, and *Prevotella* spp. Resistance to metronidazole appears to be rare, although *Actinomyces* spp are frequently resistant.

Metronidazole is also trichomonacidal and amoebicidal. The mechanism of action for its antiprotozoal activity is not understood. It has therapeutic activity against *Entamoeba histolytica*, *Trichomonas* spp, *Giardia* spp, and *Balantidium coli*. It acts primarily against the trophozoite forms of Entamoeba rather than encysted forms.

Metronidazole has some inhibitive actions on cell-mediated immunity that may play a role in its use for treating inflammatory bowel disease; however, the clinical relevance of these properties is unclear.

Pharmacokinetics

Metronidazole is well absorbed after oral administration. It is lipophilic and is rapidly and widely distributed to most body tissues and fluids, including bone, abscesses, CSF, and seminal fluid. Metronidazole is less than 20% bound to plasma proteins in humans. Metronidazole is primarily metabolized in the liver via several pathways. Both the metabolites and unchanged drug are eliminated in the urine and feces.

The oral bioavailability of metronidazole in dogs is high, but there is interpatient variability, with ranges from 50% to 100% reported. If the drug is given with food, absorption is enhanced in dogs but delayed in humans. Peak concentrations occur ≈1 hour after oral administration.

In a single-dose study in cats, the oral bioavailability of metronidazole benzoate was variable but averaged ≈65%.[7] Peak concentrations after oral administration appear to be highly variable in cats (ranging from 1 to 8 hours), and peak serum concentrations are somewhat lower in cats than in dogs or humans. Mean systemic clearance is slower in cats than in dogs (cats, 1.53 mL/kg/minute; dogs, 2.49 mL/kg/minute). Despite the concern that glucuronidation is a metabolic pathway for metronidazole, terminal elimination half-life is only slightly (not significantly) longer (5 to 6 hours) in cats.

The oral bioavailability of the drug in horses averages ≈80% (range, 57% to 100%). In neonatal foals (1 to 2.5 days of age), volume of distribution (Vd) was 0.87 L/kg and elimination half-life (t½) was 11.8 hours; in the same foals at 10 to 12 days of age, t½ was 9 hours and Vd was unchanged. Oral bioavailability was 100%.[8] In adult horses, food does not appreciably alter oral absorption.[9] Metronidazole accumulation in pleural fluid after oral administration may be sufficient for targeting *Bacteroides* spp pneumonia or pleuropneumonia.[10] If the drug is administered rectally to horses, bioavailability is decreased by ≈50%. Manually evacuating the rectal contents prior to rectal administration improves metronidazole absorption only slightly and appears unnecessary.[11] Elimination half-life in horses is ≈2.9 to 4.3 hours. After IV regional limb perfusion (IVRLP) with metronidazole in standing horses, concentrations in the distal interphalangeal joint of the thoracic limb were high but rapidly declined below the MIC of target pathogens.[12] Studies are needed to determine if IVRLP with metronidazole is a plausible treatment for synovial anaerobic infections.

Contraindications/Precautions/Warnings

Metronidazole is prohibited for use in food animals by the FDA.

Metronidazole is contraindicated in animals that are hypersensitive to it or nitroimidazole derivatives. Metronidazole should be used with caution in animals with hepatic dysfunction. If the drug must be used in animals with significant liver impairment, the total daily dose should be reduced to ⅓ of the standard anti-anaerobe dose and administered once daily.[13] Hepatic disorders are listed as a contraindication in the United Kingdom product label.[5]

Neurotoxicity is a concern, particularly at high doses. In dogs, total daily doses of metronidazole should not exceed 60 mg/kg.[14] However, the median dosage identified in a more recent retrospective study of 26 dogs with metronidazole neurotoxicity was 21 mg/kg every 12 hours.[15] The primary clinical signs were cerebellovestibular ataxia (85%) and pathologic nystagmus (50%), and the median time to resolution was 3 days after metronidazole discontinuation. In a separate case report, neurologic status improved rapidly within 72 hours after discontinuation of high-dose (65 mg/kg/day) oral metronidazole.[16]

Metronidazole use (25 mg/kg PO twice daily) resulted in degradation in the ability to detect odors in 50% of explosives detection dogs.

Further studies are required to determine if a lower metronidazole dosage would have the same effect.[17]

Metronidazole tablets have a sharp, metallic taste that animals find unpleasant. Placing in capsules, using compounded oral suspensions, or hiding in pungent food may help alleviate avoidance.

Do not confuse metronidazole with metformin, mebendazole, or metoclopramide.

Adverse Effects

Adverse effects reported in dogs include neurologic disorders, lethargy, weakness, neutropenia, hepatotoxicity, hematuria, anorexia, nausea, vomiting, and diarrhea. Rare cases of cutaneous vasculitis associated with metronidazole have been reported. Neurologic toxicity in dogs may occur after acute high dosages or, more likely, with long-term moderate to high-dose therapy. See ***Overdose/Acute Toxicity***.

In cats, vomiting, inappetence, hepatotoxicity, and, rarely, CNS toxicity can occur with metronidazole therapy.[18] Genotoxicity was detected in peripheral blood mononuclear cells collected from cats after 7 days of oral metronidazole but resolved within 6 days of discontinuation of the drug. Clinical significance, particularly with long-term therapy, is yet to be determined.[7]

In horses, metronidazole may occasionally cause anorexia, ataxia, and depression, particularly when used at higher dosages. There have been reported cases of *Clostridium difficile* and *Clostridium perfringens* diarrhea and death after use of metronidazole.

In humans, convulsive seizures and peripheral neuropathy have been reported.[19]

Reproductive/Nursing Safety

Metronidazole has not demonstrated impairment of fertility or reproductive performance in mice or rats. Metronidazole's potential for teratogenicity is somewhat controversial; some references state that it has been teratogenic in some laboratory animal studies,[20,21] but others state that it has not. However, unless the benefits to the mother outweigh the risks for the fetus(es), it should not be used during pregnancy, particularly during the first 3 weeks of gestation. In humans, metronidazole is contraindicated in the first trimester of pregnancy.[14]

Metronidazole is present in human milk at concentrations similar to maternal serum concentrations. According to the American Academy of Pediatrics, metronidazole has unknown effects and may be of concern during breastfeeding. Because of the potential for tumorigenicity, using an alternative therapy or switching to milk replacer for nursing patients should be considered.

Overdose/Acute Toxicity

Signs of intoxication associated with metronidazole in dogs and cats include anorexia and/or vomiting, depression, mydriasis, nystagmus, ataxia, head tilt, deficits of proprioception, joint knuckling, disorientation, tremors, seizures, bradycardia, rigidity, and stiffness. These effects may be seen with acute overdoses, doses in dogs above 60 mg/kg per day, or in some animals on long-term therapy when using older recommended dosages (eg, 30 mg/kg/day).

In dogs, common signs of metronidazole toxicity include generalized ataxia with a rapid positional nystagmus. Most often, dogs have neurologic deficits localized to the central vestibular system and/or cerebellum. Dogs with mild to moderate clinical signs usually improve rapidly within 1 to 2 days, once metronidazole has been discontinued.[22]

Diazepam has been used successfully to decrease the CNS effects associated with metronidazole toxicity, but it has not been evaluated in a controlled manner.[15,23] See ***Diazepam*** for more information.

Acute overdoses should be handled by attempting to limit the absorption of the drug using standard protocols. Extreme caution should be used before attempting to induce vomiting in patients demonstrating CNS effects or aspiration may result. If acute toxicity is seen after long-term therapy, the drug should be discontinued. Neurologic clinical signs may require several days before showing signs of resolving. Patient management should consist of treatment of clinical signs and supportive therapy.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving metronidazole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Busulfan**: May result in increased busulfan concentrations and toxicity
- **Cimetidine**: May decrease the metabolism of metronidazole and increase the likelihood of dose-related adverse effects
- **Cyclosporine**: Use with metronidazole may increase cyclosporine concentrations.
- **Ethanol**: May induce a disulfiram-like reaction (eg, nausea, vomiting, cramps) when given with metronidazole
- **Fluorouracil (5-FU)**: May result in increased fluorouracil levels and toxicity
- **Mycophenolate**: Metronidazole may reduce formation of the active mycophenolate metabolite.
- **Phenobarbital, Primidone**: May increase the metabolism of metronidazole, thereby decreasing blood concentrations
- **QT Prolongation Drugs** (eg, **amiodarone, cisapride, procainamide, quinidine, sotalol**): May increase risk for QT prolongation
- **Warfarin**: Metronidazole may prolong PT in patients receiving warfarin or other coumarin anticoagulants. Concurrent use should be avoided if possible; otherwise, monitoring with prothrombin times should be intensified.

Laboratory Considerations

- Metronidazole can cause falsely decreased readings of **AST** and **ALT** when determined using methods measuring decreases in ultraviolet absorbance when NADH is reduced to NAD.
- Metronidazole can interfere with measurement of serum **triglycerides**.

Dosages

NOTES:

1. Dosages are for metronidazole base unless otherwise noted. If metronidazole benzoate is being used, dosages should be adjusted unless provided by pharmacy as "mg/mL of the base." One mg of metronidazole base = 1.6 mg of metronidazole benzoate. For example, if the calculated metronidazole dose is 200 mg (of the base), the corresponding dose using metronidazole benzoate would be 320 mg (metronidazole benzoate).
2. Because of the drug's extreme bitterness, using a flavored, compounded metronidazole benzoate or putting quartered tablets in an empty gelatin capsule may be considered.

DOGS:

Giardiasis (extra-label):

a) 25 mg/kg PO twice daily in combination with fenbendazole 50 mg/kg PO once daily for 5 days.[24] **NOTE**: The Companion

Animal Parasite Council (CAPC) recommends monotherapy with fenbendazole 50 mg/kg PO once daily for 5 days as its first choice, but combination therapy may result in better resolution of clinical disease and cyst shedding. If treatment, combined with bathing, does not eliminate infection, as evidenced by testing feces for persistence of cysts, treatment with either fenbendazole alone or in combination with metronidazole may be extended for another 10 days. All dogs in the household should be treated. Repeated courses of treatment are not indicated in dogs without clinical signs.

b) 50 mg/kg PO once daily for 5 to 7 days; dose may be divided equally for twice-daily administration[5]

Other protozoal infections (eg, *Entamoeba histolytica* or *Pentatrichomonas hominis*) (extra-label): 25 mg/kg PO every 12 hours for 8 days[25]

Perioperative surgical prophylaxis (eg, colorectal surgery) (extra-label): There is no consensus for dosages in veterinary medicine, but anecdotally, metronidazole 15 mg/kg IV over 30 to 60 minutes and completed ≈1 hour before surgery may be considered. Usually used in conjunction with cefazolin.

Anaerobic infections (extra-label):

a) For less severe anaerobic infections: 10 – 15 mg/kg PO every 8 to 12 hours

b) Severe infections (ie, sepsis): 15 mg/kg IV every 12 hours

Clostridial enteritis (extra-label):

a) 10 – 15 mg/kg PO every 8 to 12 hours for 5 days.

b) 15 mg/kg IV every 12 hours for 5 days can be used if PO is not an option

c) 50 mg/kg PO every 24 hours for 5 to 7 days; dose may be divided equally for twice-daily administration[5]

Adjunctive therapy of inflammatory GI conditions (IBD) (extra-label): 10 – 15 mg/kg PO twice daily. Dosage can be reduced to 7.5 – 10 mg/kg PO twice daily in patients with concomitant hepatic disease. Long-term therapy has potential risks for neurotoxicosis and hepatotoxicosis.

Confirmed *Helicobacter* spp gastritis infections in dogs showing clinical signs (extra-label):

a) Metronidazole 15.4 mg/kg PO every 8 hours in combination with amoxicillin 11 mg/kg PO every 8 hours and bismuth subsalicylate (original *Pepto-Bismol*®) 0.22 mL/kg PO every 4 to 6 hours for 3 weeks[26]

b) Metronidazole 10 mg/kg PO every 12 hours in combination with amoxicillin 15 mg/kg PO every 12 hours and bismuth subsalicylate 262 mg tablets given based on body weight (less than 5 kg [11 lb] = 0.25 tablet; 5 to 9.9 kg [11 to 21.8 lb] = 0.5 tablet; 10 to 24.9 kg [22 to 54.8 lb] = 1 tablet; greater than 25 kg [55 lb] = 2 tablets) PO every 12 hours for 2 weeks.[27]

c) Metronidazole 11 – 15 mg/kg PO every 12 hours in combination with amoxicillin 22 mg/kg PO every 12 hours and bismuth subsalicylate suspension 0.22 mL/kg (3.85 mg/kg) PO every 6 to 8 hours for 3 weeks[28]

Alternative treatment for *Babesia gibsoni* after atovaquone and azithromycin failed to eliminate infection on PCR test: Metronidazole 15 mg/kg PO twice daily in combination with clindamycin 25 mg/kg PO twice daily and doxycycline 5 mg/kg PO once daily for 30 to 90 days[29]

Hepatic encephalopathy (extra-label): 7.5 mg/kg PO every 8 to 12 hours[30]

CATS:

Giardiasis (extra-label):

a) 25 mg/kg PO twice daily for 5 days.[31] The CAPC states: Data on treatment of cats with Giardia are lacking. However, cats may be treated with either fenbendazole 50 mg/kg PO once daily for 5 days or metronidazole 25 mg/kg PO twice daily for 5 days, or a combination of the two as described for dogs. There is anecdotal evidence that metronidazole benzoate is tolerated better in cats than metronidazole (USP). If other pets live with an infected dog or cat, all those of the same species may also be treated with a single course of antigiardial therapy. Repeated courses of treatment are not indicated in dogs or cats without clinical signs.[24]

b) 50 mg/kg/day for 5 to 7 days; dose may be divided equally for twice-daily administration[5]

Trichomoniasis (*Tritrichomonas foetus,* most prevalent; *Pentatrichomonas hominis*); (extra-label): 30 – 50 mg/kg PO twice daily for 3 to 14 days has been used in the past for *T foetus*, but clearance of infections appears less common than when ronidazole is used.[32]

Perioperative surgical prophylaxis (colorectal surgery) (extra-label): There is no consensus for dosages in veterinary medicine, but metronidazole 15 mg/kg IV over 30 to 60 minutes and completed ≈1 hour before surgery may be considered. Usually used in conjunction with cefazolin.

Confirmed *Helicobacter* spp gastritis infections in cats showing clinical signs (extra-label):

a) Metronidazole 10 – 15 mg/kg PO twice daily in combination with clarithromycin 7.5 mg/kg PO twice daily and amoxicillin 20 mg/kg PO twice daily for 14 days[33]

b) Metronidazole 11 – 15.4 mg/kg PO every 8 – 12 hours in combination with amoxicillin 11 – 22 mg/kg PO every 8 hours and bismuth subsalicylate suspension (original *Pepto-Bismol*®) 0.22 mL/kg (3.85 mg/kg) PO every 4 to 8 hours and for 3 weeks[28,34]

c) Metronidazole 10 mg/kg PO twice daily in combination with amoxicillin 10 – 20 mg/kg PO 3 times daily and bismuth subsalicylate (262 mg tablets; *Pepto-Bismol*®) ¼ tablet/cat (total dose) PO twice daily, ± H_2 blocker (eg, famotidine) or omeprazole for 2 weeks.[27]

Anaerobic infections (extra-label):

a) For less severe anaerobic infections: 10 – 15 mg/kg PO every 12 hours or 15 – 25 mg/kg PO once daily can be considered. Practically, ¼ of a 250 mg tablet (62.5 mg) per cat is often chosen for a PO dose.

b) Severe infections (ie, sepsis): 15 mg/kg IV every 12 hours

Clostridial enteritis (extra-label):

a) 62.5 mg/cat (NOT mg/kg) PO every 12 hours for 5 days

b) 50 mg/kg PO daily for 5 to 7 days; dose may be divided equally for twice-daily administration[5]

Adjunctive therapy of inflammatory GI conditions (IBD) (extra-label): 10 – 15 mg/kg PO twice daily. Long-term therapy has potential risks for neurotoxicity and hepatotoxicity.[35] Practically, ¼ of a 250 mg tablet (62.5 mg) per cat is often chosen for a PO dose.

Hepatic encephalopathy (extra-label): 7.5 mg/kg PO every 8 to 12 hours[30]

HORSES:

Clostridial enterocolitis (extra-label): Dosage recommendations vary, but 15 mg/kg PO every 8 to 12 hours appears reasonable. IV route can be used if PO is not possible. Consider lower dosages

(ie, 10 mg/kg IV every 12 hours) in newborn (ie, less than 5 days old) foals.

Metritis secondary to *Bacteroides fragilis* (extra-label): 15 – 25 mg/kg PO every 12 hours[36]

Periodontal disease (extra-label): Metronidazole tablets were cut into 1 to 2 mm pieces and filled into mandibular periodontal pockets to the level of the gingiva.[37]

BIRDS:

Susceptible infections (anaerobes; *Giardia* spp) (extra-label): 10 – 50 mg/kg PO every 12 hours[38]

FERRETS:

***Helicobacter mustelae* gastritis infections** (extra-label): Metronidazole 20 mg/kg PO every 8 hours in combination with *either* amoxicillin 30 mg/kg PO every 8 hours OR clarithromycin 12.5 mg/kg PO every 12 hours for 21 to 28 days; the addition of bismuth subsalicylate 7.5 mg/kg PO every 8 hours to the combination is optional.[39,40]

Anaerobic infections (extra-label): 10 – 30 mg/kg PO 1 to 2 times daily

Inflammatory bowel disease (extra-label): 50 mg/kg PO once daily[39]

RABBITS, RODENTS, SMALL MAMMALS:

Anaerobic infections (extra-label):

a) **Rabbits**:
   i. 20 mg/kg PO every 12 hours for 3 to 5 days[41]
   ii. 40 mg/kg PO once daily[41]
   iii. 5 mg/kg slow IV every 12 hours[41]
b) **Mice**:
   i 3.5 mg/mL in water for 5 days[42]
   ii. ***Spironucleus muris:*** 10 – 40 mg/kg PO twice, 5 days apart[43]
c) **Rats**: 10 – 40 mg/rat (NOT mg/kg) PO once daily[42]
d) **Chinchillas, guinea pigs**: 10 – 40 mg/kg PO once daily[42]
e) **Gerbils, hamsters**: 7.5 mg/70 to 90 g body weight PO every 8 hours[42]

REPTILES/AMPHIBIANS:

Treatment of amoebae, flagellates, and ciliates in reptiles and amphibians (extra-label): Typically, metronidazole 100 mg/kg PO repeated in 2 weeks or 50 mg/kg PO once daily for 3 to 5 days; repeat treatment as needed.[44]

Anaerobic respiratory infections in reptiles (extra-label): 20 mg/kg PO every 48 hours[45]

Monitoring

- Clinical efficacy
- Adverse effects; clients should report any neurologic signs

Client Information

- Give this medication with food.
- This medicine can cause nervous system side effects, especially when administered at higher doses. Tell your veterinarian about any changes in your animal's behavior or coordination.
- Do not give this medicine to pregnant or nursing animals.
- Metronidazole is banned for use in animals that are used for food (including egg-laying chickens and dairy animals).
- Pregnant women and people who are allergic to this drug should be very careful not to accidentally take it.

Chemistry/Synonyms

Metronidazole is a synthetic, nitroimidazole antibacterial and antiprotozoal agent. It occurs as white to pale-yellow crystalline powder or crystals with a pK_a of 2.6. It is sparingly soluble in water or alcohol. Metronidazole base is commercially available as tablets or solution for IV injection. The hydrochloride is very soluble in water.

Metronidazole benzoate is the benzoic ester of metronidazole. It occurs as a white to slightly yellow crystalline powder that is practically insoluble in water, slightly soluble in alcohol, and soluble in acetone. Because it is less soluble in aqueous solutions as compared with the base, it does not taste as bad. Based on the molecular weights of metronidazole (171.1 g/mol) and metronidazole benzoate (275.3 g/mol), 1.6 mg metronidazole benzoate contains 1 mg metronidazole.

Metronidazole may also be known as Bayer-5360, metronidazolum, SC-32642, NSC-50364, RP-8823, and SC-10295; many trade names are available.

Storage/Stability

Metronidazole tablets and solution for injection should be stored at temperatures less than 30°C (86°F) and protected from light. The shelf life of divided tablets is 3 days.[5]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The manufacturer states that metronidazole should not be mixed with other drugs, and other IV infusions should be discontinued, when possible, while metronidazole is being infused. The following drugs and solutions are reportedly physically **Y-site compatible** with metronidazole ready-to-use solutions for injection: amikacin sulfate, aminophylline, ampicillin, cefazolin sodium, cefotaxime sodium, cefoxitin sodium, cefuroxime sodium, chloramphenicol sodium succinate, clindamycin phosphate, dexamethasone sodium phosphate, gentamicin sulfate, heparin sodium, hydrocortisone sodium succinate, hydromorphone HCl, ketamine, magnesium sulfate, metoclopramide, morphine sulfate, multi-electrolyte concentrate, multivitamins, penicillin G sodium, and tobramycin sulfate.

The following drugs and solutions are reportedly physically **incompatible** (or compatibility data conflict) with metronidazole ready-to-use solutions for injection: amphotericin B (all formulations), aztreonam, cefamandole naftate, diazepam, dopamine HCl, pantoprazole, and propofol.

Metronidazole hydrochloride is bitter tasting and, even with taste-masking or flavoring agents, is universally unpalatable to veterinary patients. Although not commercially available in the United States, the metronidazole ester of benzoic acid, metronidazole benzoate, is relatively palatable to animal patients and is often used in extemporaneously compounded suspensions, particularly in cats to reduce the drug's bitterness. If metronidazole benzoate is being used, dosages should be adjusted from those used for the base unless provided by the pharmacy as "mg/mL of the base." One mg of metronidazole base = ≈1.6 mg of metronidazole benzoate. Crystallization and sedimentation can occur in aqueous metronidazole benzoate suspensions when conversion from the anhydrous to the monohydrate form occurs.

Compounded preparation stability: One method for compounding a metronidazole benzoate suspension (80 mg/mL; equivalent to 50 mg/mL metronidazole hydrochloride) that is stable (when protected from light and kept at an ambient temperature) for at least a year has been published.[46] To make 750 mL of an 80 mg/mL suspension: 60 grams metronidazole benzoate powder is placed in a suitable mortar then triturated with 1.25 grams of Propylene Glycol, NF, to a smooth paste; increasing amounts of *SyrSpend® SF* are then added until the suspension is pourable. The liquid suspension is then transferred to a suitable graduated container and the mortar rinsed with 3 small aliquots of *SyrSpend® SF*, which are added to the suspension. Additional *SyrSpend® SF* is added to bring the suspension to the final volume of 750 mL. The suspension should be stored in light-re-

sistant containers and kept refrigerated or at room temperature.

Another published method is to triturate 9.6 g (9600 mg) of metronidazole benzoate powder with 60 mL of *Ora-Plus*® and *qs ad* to 120 mL with *Ora-Sweet*® or *Ora-Sweet*® *SF*® to yield a 80 mg/mL metronidazole benzoate oral suspension (equivalent to 50 mg/mL metronidazole hydrochloride) that retains greater than 90% potency for 90 days when stored at both 4°C (39.2°F) and 25°C (77°F) and protected from light.[47]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES.
VETERINARY TABLETS AND ORAL SUSPENSIONS ARE AVAILABLE IN OTHER COUNTRIES FOR DOGS AND CATS.
Metronidazole is prohibited for use in food animals by the FDA.

HUMAN-LABELED PRODUCTS:
Metronidazole Oral Tablets: 250 mg and 500 mg; *Flagyl*®, generic; (Rx)

Metronidazole Oral Capsules: 375 mg; *Flagyl 375*®, generic; (Rx)

Metronidazole Oral Suspension: 50 mg/mL in 150 mL (grape); generic; (Rx)

Metronidazole Injection 500 mg pre-mixed in 100 mL sodium chloride; generic; (Rx)

Metronidazole is available in combination with other medications (eg, bismuth, tetracycline) for treatment of *H pylori*. Lotions, gels, creams, and vaginal products are also available.

Metyrapone

(me-***teer***-a-pone) *Metopirone*®
Adrenal Steroid Inhibitor

Prescriber Highlights

- ► Primarily used in cats with hyperadrenocorticism; may be most useful for short-term treatment to stabilize patient before adrenalectomy
- ► Well tolerated in cats at recommended dosages
- ► May alter insulin requirements; monitor blood glucose closely.
- ► Inconsistent availability

Uses/Indications

Metyrapone may be useful to treat cats with hyperadrenocorticism, though it is not considered a first-line therapy. Effectiveness appears variable and may be transient, so it may be best used short-term in an attempt to stabilize the patient prior to adrenalectomy.[1,2] Metyrapone may potentially be useful in treating hyperadrenocorticism in ferrets and small mammals (eg, hamsters), but there is little, if any, information available on its use in these species.[2]

In humans, an overnight metyrapone test may be used in conjunction with other dynamic tests in the diagnosis of specific hypothalamic/pituitary/adrenal disorders.

Pharmacology/Actions

Metyrapone reduces cortisol and corticosterone production by inhibiting 11-beta-hydroxlase; this converts 11-deoxycortisol to cortisol within the adrenal cortex. ACTH production can subsequently increase as negative feedback is lost. With time, this effect may override the effects of metyrapone on the adrenal gland. Metyrapone can also suppress synthesis of aldosterone and cause a mild natriuresis. Mineralocorticoid deficiency does not usually occur with long-term metyrapone therapy because inhibition of the 11-beta-hydroxylation reaction increases production of 11-desoxycorticosterone; this has a mineralocorticoid effect and has been associated with hypertension in patients receiving long-term metyrapone therapy.

Pharmacokinetics

No information on the pharmacokinetics of metyrapone is available for cats. In humans, metyrapone is well absorbed after oral administration. Peak concentrations occur in ≈ 1 hour; however, pharmacological response to metyrapone does not occur immediately. It is rapidly cleared from the plasma and has an average elimination half-life of around 2 hours. Metyrapone's major metabolite, metyrapol, is active and formed via reduction; its half-life is about twice as long as that of metyrapone. Both metyrapol and metyrapone are conjugated with glucuronide in humans. As cats are unable to effectively glucuronidate, it is unclear what metabolic path(s) metyrapone takes in this species.

Contraindications/Precautions/Warnings

Metyrapone should not be used in animals that are hypersensitive to it or have adrenal cortical insufficiency. Metyrapone may induce acute adrenal insufficiency in patients that have reduced adrenal secretory capacity.[3]

Use cautiously in cats with concurrent diabetes mellitus; monitor blood glucose closely in these patients, as insulin requirements in may decrease.[1]

Adverse Effects

Metyrapone appears to be relatively well-tolerated in cats. Dosages ranging from 195 – 500 mg/cat/day (divided) have been used in cats with hyperadrenocorticism without observed toxicity.[4] Some cats may experience vomiting and anorexia.[5]

In humans, reported adverse effects include headache, dizziness, sedation, allergic rash, nausea, vomiting, and abdominal pain.[3] Rarely, metyrapone can cause myelosuppression.

Reproductive/Nursing Safety

Animal reproduction studies have not been conducted with metyrapone. In humans, metyrapone has been shown to cross the placenta.[6] In women given the drug in the 2nd and 3rd trimesters, evidence of fetal pituitary response to the enzymatic block was detected; a subnormal response to metyrapone may also occur during pregnancy.[3]

Metyrapone's safety in lactating animals and their offspring is not known. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The oral LD_{50} in rats (mg/kg) was 521 mg/kg. Metyrapone overdoses likely would cause GI effects and, possibly, acute adrenocortical insufficiency. Other effects that may be seen include hypoglycemia, hyponatremia, hypochloremia, hyperkalemia, cardiac arrhythmias, hypotension, dehydration, and impairment of consciousness. There is no specific antidote. Standard decontamination protocols should be considered with IV hydrocortisone, saline, and glucose. Monitoring and support for several days may be required.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving metyrapone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetaminophen (do NOT use in cats)**: In humans, there is an increased risk for acetaminophen toxicity.
- **Corticosteroids**: Decrease the efficacy of metyrapone

Laboratory Considerations

- In humans, the following drugs have been reported to interfere with the results of the metyrapone test: antidepressants (eg, amitriptyline), antithyroid drugs, phenothiazines, barbiturates, corticosteroids, cyproheptadine, and hormones such as estrogens and progesterone.
- The metyrapone test may not be reliable in humans with hyper- or hypothyroidism.

Dosages

CATS:

Hyperadrenocorticism (extra-label): Metyrapone has been used to successfully treat hyperadrenocorticism in the cat, but results are variable:

a) 30 – 70 mg/kg PO twice daily. Begin with the lower end of the range for the first 2 to 4 weeks.[1,7] Increase dose in small increments as indicated by clinical signs and ACTH stimulation testing.

b) 250 – 500 mg/cat (NOT mg/kg) PO daily.[4] If effective, results are generally noted within 5 days.

Monitoring

- Blood glucose should be closely monitored in cats with diabetes mellitus, as insulin requirements may change.
- Clinical signs associated with hyperadrenocorticism or hypoadrenocorticism should prompt dose adjustment.
- Adrenocorticotropic hormone (ACTH) stimulation tests may be used to assess adrenal function.

Client Information

- Do not stop giving this medicine to your animal unless instructed to do so by your veterinarian. Serious side effects can occur if the medicine is stopped suddenly.
- This medicine may be given with or without food but giving with food may reduce the likelihood of vomiting.
- This medicine is usually well tolerated. Side effects (eg, increased panting, appetite, thirst, and need to urinate) are possible, especially when the medicine is used long-term.
- Cats with diabetes will need their blood glucose monitored carefully while receiving this medicine. Do not miss these important follow-up visits.

Chemistry/Synonyms

Metyrapone occurs as a white to light amber, fine, crystalline powder, with a characteristic odor. It is sparingly soluble in water, soluble in chloroform and methyl alcohol.

Metyrapone may also be known as SU-4885, metirapon, metirapona, or metyraponum. A common trade name is *Metopirone®*.

Storage/Stability

Store metyrapone at room temperature (15°C-25°C [59°F-77°F]) in a well-closed, light-resistant container.[3] Protect from moisture.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Metyrapone Oral Capsules: 250 mg; *Metopirone®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Mexiletine

(mex-***ill***-i-teen) *Mexitil®*

Oral Antiarrhythmic

Prescriber Highlights

- ► Oral antiarrhythmic with similar effects to lidocaine
- ► Used for ventricular tachycardia, premature ventricular contractions (PVCs)
- ► Strict dosing frequency (every 8 hours) may be a barrier to clinical use; may be used in combination with sotalol to allow for less frequent dosing.
- ► Use with extreme caution in patients with pre-existing second- or third-degree AV block (without pacemaker) or in patients with cardiogenic shock.
- ► Use with caution in patients with severe congestive heart failure or acute myocardial infarction, hepatic function impairment, hypotension, sinus node dysfunction, seizure disorder, or sensitivity to the drug.
- ► Adverse effects include GI distress (eg, vomiting, inappetence); give with meals to alleviate.

Uses/Indications

Mexiletine is used to treat some ventricular arrhythmias, including premature ventricular contractions (PVCs) and ventricular tachycardia in dogs. Ventricular tachycardias that have responded to lidocaine may respond to mexiletine. There is some evidence for efficacy for arrhythmogenic right ventricular cardiomyopathy in boxers,[1,2] and other breeds,[3] as well as for inherited ventricular arrhythmias in German shepherd dogs but the drug's dosing frequency may be challenging. See ***Pharmacokinetics***.

Mexiletine may be useful for treating certain myopathies in dogs such as myotonia congenita (most studied in miniature schnauzers[4] and chow chows) and myokymia in Jack Russell terriers.[5–7]

Pharmacology/Actions

Mexiletine is considered a class IB antiarrhythmic agent and is similar to lidocaine in its mechanism of antiarrhythmic activity. It inhibits the inward sodium current (fast sodium channel), thereby reducing the rate of rise of the action potential, Phase 0. In cardiomyocytes, automaticity is decreased and action potential duration is shortened; however, the effective refractory period is minimally affected. Usually conduction is unaffected but may be slowed in patients with pre-existing conduction abnormalities. No effect on sinus automaticity has been noted clinically.

Pharmacokinetics

There is limited information available for dogs. Mexiletine is relatively well absorbed from the GI tract and has a low first-pass effect. A preliminary report of a study in 6 healthy dogs (4 beagles, 2 hounds) reported that sotalol 2.5 mg/kg PO twice daily, combined with mexiletine 8 to 10 mg/kg PO twice daily for 10 days, resulted in mexiletine serum concentrations within the described therapeutic range (for humans) for the 12 hour postdose period in the 3 dogs weighing more than 10 kg (22 lb).[8] There are no published studies evaluating the pharmacokinetics of mexiletine in cats.

In humans, mexiletine is moderately bound to plasma proteins (60% to 75%) and is metabolized in the liver to inactive metabolites with an elimination half-life of ≈10 to 12 hours. Half-lives may be significantly increased in patients with moderate to severe hepatic disease,[9] or in those having severely reduced cardiac output. Half-lives may be slightly prolonged in patients with severe renal disease or after acute myocardial infarction.

Contraindications/Precautions/Warnings

Mexiletine should be used with extreme caution, if at all, in patients

with pre-existing second- or third-degree AV block (without pacemaker), or with cardiogenic shock.[9] It should only be used when the benefits of therapy outweigh the risks when the following medical conditions exist: severe congestive heart failure or acute myocardial infarction, hepatic function impairment, hypotension, intraventricular conduction abnormalities, sinus node function impairment, seizure disorder, or sensitivity to the drug.

A single case report of a collie with the *MDR1* genetic mutation (also known as *ABCB1-1delta*) was reported to have developed mexiletine toxicity with a standard dosage.[10,11] Although mexiletine is not known to be a P-glycoprotein substrate, consider testing for the mutation in susceptible breeds before treatment or if toxicity develops.

It is anecdotally reported that cats are more sensitive than dogs to mexiletine's adverse effects.

Do not confuse mexiletine with meclizine.

Adverse Effects

The most likely adverse effect noted in animals is GI distress, including vomiting and inappetence; giving with meals may alleviate GI effects.[9] Cats administered a wide range of dosages for 24 hours were noted to have anorexia, tremors, and incoordination with these signs most evident at 20 mg/kg and 40 mg/kg.[12] Trembling, dizziness, depression, chest pain, and, rarely, seizures and severe liver injury have been reported in humans.[9] In some humans (1% to 3%), AST values increased by as much as 3 times or more above the upper limit of normal. AST elevations were reportedly transient with no elevations in bilirubin; patients were asymptomatic and did not require discontinuation of therapy.[9]

Reproductive/Nursing Safety

Laboratory animal studies have not demonstrated teratogenicity.[9] Because mexiletine is secreted into maternal milk, it has been recommended to use milk replacer if the dam is receiving this drug. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Toxicity associated with a mexiletine overdose may be significant. A small series of healthy cats receiving doses of 4 – 40 mg/kg developed neurologic and GI signs, most commonly at a dose over 20 mg/kg.[12] Case reports in humans have noted that CNS signs always preceded cardiovascular signs. Treatment should consist of GI decontamination protocols when indicated, acidification of the urine to enhance urinary excretion, and supportive therapy. Atropine or pressor agents may be useful if bradycardia or hypotension occur.[9]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving mexiletine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: Concurrent use may increase mexiletine blood concentrations.
- **Antacids, Aluminum-Magnesium**: May slow the absorption of mexiletine
- **Atropine**: May reduce the rate of oral absorption
- **Bupropion**: Concurrent use may increase mexiletine blood concentrations.
- **Cimetidine**: May increase or decrease mexiletine blood concentrations
- **Clozapine**: Concurrent use may increase clozapine exposure and risk for adverse effects.
- **Griseofulvin**: May accelerate the metabolism of mexiletine
- **Lidocaine**: May cause additive adverse effects
- **Metoclopramide**: May accelerate the absorption of mexiletine
- **Opioids**: May slow the absorption of mexiletine
- **Paroxetine**: Concurrent use may increase mexiletine blood concentrations.
- **Phenobarbital, Primidone, Phenytoin**: May accelerate the metabolism of mexiletine
- **Propranolol**: Concurrent use may result in increased propranolol blood concentrations.
- **Quinidine**: Concurrent use may increase mexiletine bioavailability and risk for cardiotoxicity.
- **Rifampin**: May accelerate the metabolism of mexiletine
- **Sotalol**: May increase mexiletine plasma concentrations.[13] This may be used for therapeutic effect but could also increase potential for adverse effects.
- **Theophylline, Aminophylline**: Metabolism may be reduced by mexiletine, thereby leading to theophylline toxicity
- **Urinary Acidifying Drugs** (eg, **ammonium chloride, methionine, potassium phosphate, sodium phosphate**): May accelerate the renal excretion of mexiletine
- **Urinary Alkalinizing Drugs** (eg, **bicarb, carbonic anhydrase inhibitors, citrates**): May reduce the urinary excretion of mexiletine

Laboratory Considerations

- None noted

Dosages

DOGS:

Ventricular arrhythmias (extra-label): 4 – 6 mg/kg PO every 8 hours.[14,15] Higher dosages of 5 – 8 mg/kg PO every 8 hours have also been described.[1,13] Twice-daily dosing at 8 – 10 mg/kg PO every 12 hours has been described as yielding therapeutic concentrations of mexiletine when sotalol was concomitantly administered at 2.5 mg/kg PO every 12 hours,[8] though this dosage is not commonly administered in practice.

Myotonia congenita in chow chows and miniature schnauzers (extra-label): 8.3 mg/kg PO every 8 hours[16]

Myokymia in Jack Russell terriers (extra-label): 4 mg/kg PO every 12 hours has been suggested to decrease frequency of attacks.[5–7]

CATS:

Ventricular arrhythmias (extra-label): Anecdotal reports describe use of mexiletine in cats at similar dosages to that used in dogs, 4 – 6 mg/kg PO every 8 hours.[12]

Monitoring

- In humans, therapeutic plasma concentrations are 0.5 – 2 µg/mL; toxicity may be noted at therapeutic concentrations.
- ECG and 24-hour Holter monitoring
- Adverse effects (eg, vomiting, inappetence)

Client Information

- This medicine needs to be given 3 times a day (every 8 hours; even through the night) in order to work.
- Give with food to reduce the risk for vomiting or nausea.
- Vomiting is the most likely side effect; contact your veterinarian if it worsens or does not stop.

Chemistry/Synonyms

A class IB antiarrhythmic, mexiletine HCl occurs as a white or almost white, odorless, crystalline powder. It is freely soluble in water.

Mexiletine may also be known as Ko-1173, mexiletini hydrochloridum, *Mexilen®*, *Mexitil®*, *Mexitilen®*, *Myovek®*, and *Ritalmex®*.

Storage/Stability

Mexiletine capsules should be stored at controlled room temperature (20°C-25°C [68°F-77°F]) in a tight, light-resistant container with a child-resistant closure (as required).[9]

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Mexiletine Oral Capsules: 150 mg, 200 mg, and 250 mg; generic; (Rx)

Midazolam

(mih-***day***-zoe-lam) *Versed®*

Benzodiazepine

Prescriber Highlights

- ► Injectable benzodiazepine used primarily as a preoperative and co-induction medication and, unlike diazepam, may be given IM and can be used intranasally for seizures
- ► Contraindications include hypersensitivity to benzodiazepines and acute narrow-angle glaucoma.
- ► Caution is advised with hepatic or renal disease, open-angle glaucoma, debilitated or geriatric animals, significant respiratory depression, and animals in a coma or shock.
- ► The adverse effect of most concern is the potential for respiratory depression. Cats may develop excited behaviors; this drug should be used with sedatives/tranquilizers in this species.
- ► DEA Schedule IV (C-IV) controlled substance
- ► Effects are reversible with flumazenil.

Uses/Indications

Midazolam is principally used for its sedative, anxiolytic, and muscle relaxant properties as a premedication and co-induction agent (combined with other drugs) prior to induction of general anesthesia. When midazolam is used alone, sedation may be adequate in ruminants, camelids, swine, rabbits, ferrets, and some birds; it does not appear to provide predictable sedation in dogs, cats, or horses, as they may become sedated or dysphoric and excited. Cats may be more prone to developing an excited effect/disinhibition as compared with dogs. When used in combination with other drugs (eg, opioids, ketamine, acepromazine, dexmedetomidine), midazolam provides more reliable sedation.

Midazolam IV, IM, or intranasal (but not per rectum) may be used to treat status epilepticus. Midazolam given intranasally controlled status epilepticus in ≈70% to 75% of dogs, was more effective than rectal diazepam, and controlled seizures faster than midazolam IV.[1,2]

Pharmacology/Actions

Midazolam exhibits similar pharmacologic actions as other benzodiazepines; subcortical levels (primarily limbic, thalamic, and hypothalamic) of the CNS are depressed, which produces anxiolytic, sedative, skeletal muscle relaxant, and anticonvulsant effects. The exact mechanism of action is unknown, but postulated mechanisms include antagonism of serotonin, increased release of and/or facilitation of gamma-aminobutyric acid (GABA) activity, and diminished release or turnover of acetylcholine in the CNS.

Benzodiazepine-specific receptors have been located in the mammalian brain, kidney, liver, lungs, and heart. In all species studied, receptors are lacking in white matter.

Midazolam has unique solubility characteristics (eg, water-soluble injection formulation but lipid-soluble at pH greater than 4) that provide a rapid onset of action after injection. As compared with diazepam, midazolam has ≈2 times the affinity for benzodiazepine receptors, is nearly 3 times as potent, and has a faster onset of action and a shorter duration of effect.

Pharmacokinetics

After IM administration in healthy dogs, bioavailability was ≈47%, and peak plasma concentrations occurred ≈7 to 8 minutes postinjection.[3] The authors concluded that midazolam IM may be useful in treating seizures in dogs when venous access is unavailable but higher doses may be necessary. In dogs, midazolam is absorbed when the commercially available injection is administered intranasally, and peak plasma concentrations following intranasal administration are higher than when the drug is administered rectally. In dogs, a 50 mg/mL compounded gel (0.2% hydroxypropyl methylcellulose) demonstrated significantly higher peak plasma concentrations after intranasal administration as compared with the injectable formulation administered rectally or intranasally.[4] Buccal administration of midazolam 0.6 mg/kg using a 20 mg/mL hydroxypropyl methylcellulose gel resulted in a peak plasma concentration of 187 ng/mL.[5] The average midazolam elimination halflife is 77 minutes in dogs. Midazolam is metabolized in the liver via the cytochrome P450 enzyme 3A12, 3A26 (minor), and 2B11 isoenzymes[6]; this is in contrast to humans, in which CYP3A4 and CYP3A5 are largely responsible for the metabolism of midazolam.

In horses given midazolam 0.05 or 0.1 mg/kg IV, total clearance was ≈10.5 mL/minute/kg (median), volume of distribution (V_d) at steady state was 2 to 3 L/kg, and terminal half-life varied widely and ranged from 120 to 924 minutes (medians, 216 minutes after 0.05 mg/kg, 408 minutes after 0.1 mg/kg). Cardiorespiratory parameters and sedation scores did not change; however, agitation, postural sway, and weakness were noted, and a horse became recumbent after receiving a 0.1 mg/kg dose.[7]

In alpacas given midazolam 0.05 mg/kg IM or IV, IM bioavailability was 92%, and peak plasma concentrations were ≈3 times lower than after IV administration. Mean elimination half-lives were 98 minutes (IV) and 234 minutes (IM). The authors concluded that midazolam appears to provide a short duration of action with moderate levels of sedation and minimal cardiovascular or behavioral adverse effects in alpacas.[8]

In sheep receiving midazolam 0.5 mg IV, V_d was 0.84 L/kg, and the elimination half-life was 0.79 hours. After IM administration at 0.5 mg/kg, the total drug exposure as calculated by the area under the curve (AUC) was 3.3 times higher than with IV administration.[9] Time to peak plasma concentration following IM injection was ≈28 minutes.

In humans, the onset of action following IV administration is rapid due to the high lipophilicity of the agent, and loss of the lash reflex or counting occurs within 30 to 97 seconds after administration. Following IM injection, midazolam is rapidly and almost completely

(91%) absorbed. The drug is well absorbed after oral administration, but bioavailability suffers (≈36% in pediatric animals) because of a rapid first-pass effect.

Midazolam is highly protein-bound (ie, 94% to 97%) and rapidly crosses the blood–brain barrier. Changes in plasma protein concentrations and resultant protein binding may significantly alter the response to a given dose because only unbound drugs cross into the CNS. The serum halflife and duration of activity of midazolam in humans are shorter than diazepam. Midazolam is eliminated almost entirely by renal mechanisms as conjugates of hydroxylated metabolites. Elimination half-life in humans is ≈2 hours (diazepam is ≈30 hours) and is almost doubled in patients with significant hepatic impairment. The active metabolite alpha-hydroxymidazolam has a pharmacologic activity that contributes to midazolam's clinical effects. Alpha-hydroxymidazolam has a half-life of ≈1 to 1.5 hours, which is prolonged in patients with renal impairment.

Contraindications/Precautions/Warnings

In humans, hypersensitivity to benzodiazepines and acute narrow-angle glaucoma are contraindications. Intracarotid or other intra-arterial injections should also be avoided.

Caution should be used in animals with hepatic or renal disease and debilitated or geriatric animals. Animals with congestive heart failure or hepatic dysfunction may eliminate the drug more slowly, and prolonged effects can occur. This drug should be administered cautiously in animals in a coma or in shock and in animals with significant respiratory depression or open-angle glaucoma (contraindicated if untreated).

When used alone, midazolam does not possess significant effects on cardiorespiratory function; however, cardiorespiratory effects may be noted when it is used in combination with other agents. Increased heart rate and blood pressure may be noted when this drug is used with ketamine. Effects may be diminished if this combination is used after an opioid has been administered.

Midazolam given in combination with opioids can cause less cardiovascular depression but greater respiratory depression as compared with acepromazine given in combination with opioids. Midazolam in combination with butorphanol may cause anxiousness, aggressiveness, and restraint difficulties in some cats and is best reserved for geriatric or very ill cats.[10]

Midazolam given with etomidate should be used with caution in dogs undergoing ocular surgery. A study found this combination caused clinically relevant miosis; significantly increased intraocular pressure; and commonly induced ptyalism, gagging, and abdominal heaving. Midazolam given with propofol caused only a minor decrease in pupil diameter.[11]

Adverse Effects

At usual doses, midazolam is well tolerated in veterinary patients. Midazolam IV CRIs may cause thrombophlebitis less often than diazepam CRIs.

In dogs, after morphine and acepromazine are given prior to surgery, midazolam given 0.2 mg/kg IV prior to propofol anesthesia caused excitement in some dogs.[12,13] Hypothermia was noted in dogs premedicated with buprenorphine 0.02 mg/kg and acepromazine 0.05 mg/kg IM prior to induction with midazolam or diazepam 0.25 mg/kg IV combined with either ketamine 5 mg/kg IV or propofol 4 mg/kg IV and maintained on isoflurane for ovariohysterectomy. All dogs became hypothermic within 5 minutes of induction. Dogs receiving a combination of benzodiazepine and propofol had a greater temperature decrease and longer interval to the restoration of normothermia.[14] A combination of midazolam and medetomidine premedication resulted in a high incidence of paradoxical behavior in healthy dogs; the authors did not recommend this combination.[15] In healthy dogs undergoing ovariohysterectomy or castration following a combination of acepromazine and meperidine prior to surgery, midazolam 0.25 mg/kg administered IV prior to propofol anesthesia resulted in a significantly longer time to standing, an increased incidence of hypotension, and an overall negative effect on recovery as compared with dogs that did not receive midazolam. Pigmenturia occurred in dogs premedicated with hydromorphone and induced with midazolam followed by etomidate.[16]

In horses, midazolam administered as a sole agent at 0.05 and 0.1 mg/kg IV produces agitation and ataxia but not sedation.[7]

In humans receiving midazolam, effects on respiratory rate, heart rate, and blood pressure have been most frequently reported.[17] Respiratory depression has been reported in patients receiving narcotics or that have chronic obstructive pulmonary disease (COPD). Between 1% and 5% of patients receiving midazolam had pain on injection, local irritation, headache, nausea, vomiting, and/or hiccups. Midazolam impairs memory recall for several hours after administration; it is unclear whether this occurs in veterinary patients.

Reproductive/Nursing Safety

Although midazolam has not been demonstrated to cause fetal abnormalities, in humans, other benzodiazepines have been implicated in causing congenital abnormalities when administered during the first trimester of pregnancy. Anesthetic agents administered to animals during the third trimester of pregnancy (and during other periods of rapid brain growth) may adversely affect the developing brain. Infants born to mothers given large doses of benzodiazepines shortly before delivery have been reported to suffer from apnea, impaired metabolic response to cold stress, difficulty feeding, hyperbilirubinemia, and hypotonia. Signs of withdrawal have occurred in infants whose mothers chronically took benzodiazepines during pregnancy. The veterinary significance of these effects is unclear, but these agents should only be used during the first trimester of pregnancy when the benefits clearly outweigh the risks associated with their use.

Midazolam and alpha-hydroxymidazolam are excreted in milk and may cause CNS effects in nursing neonates. Caution should be used when administering this drug to a nursing mother.

Overdose/Acute Toxicity

The IV LD_{50} has been reported to be 50 mg/kg in mice and 75 mg/kg in rats.[18] It is suggested that accidental overdoses should be managed with supportive therapy (eg, cardiopulmonary support, IV fluids). In addition, flumazenil can be used to antagonize midazolam effects; however, supportive therapy may be more suitable in all but the largest overdoses because midazolam has a short duration of effect.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

Although midazolam is a CYP3A4 substrate in humans, it is a CYP3A12 and CYP2B11 substrate in dogs. Caution should be used when extrapolating midazolam human drug interactions to veterinary species. The following drug interactions have either been reported or are theoretical in humans or animals receiving midazolam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- Anesthetic Agents (eg, **alfaxolone**,[19,20] **etomidate**,[21] **isoflurane**,[22] **propofol**[13,20,23]): Midazolam reduces anesthetic requirements.
- Antihypertensive Agents (eg, **amlodipine, enalapril, telmisartan**): Concurrent use may increase the risk for hypotension

and orthostasis. Blood pressure should be monitored.

- **Azole Antifungals** (eg, **itraconazole, ketoconazole, voriconazole**): May increase midazolam concentration; excessive sedation may occur. In healthy dogs given oral fluconazole, clearance of IV midazolam and ketamine was ≈50% slower, and the duration of the sedative effect was increased.[24]
- **Carbonic Anhydrase Inhibitors** (CAIs; eg, **dichlorphenamide, methazolamide**): Benzodiazepines may interfere with the beneficial effects of CAIs by inhibiting respiratory responses to hypoxia; this combination should be avoided.
- **CNS Depressant Agents** (eg, **buspirone, cannabidiol, gabapentin, methocarbamol, trazodone**): Combination may increase the risk for CNS depression; monitoring and adjustment of doses are needed.
- **Hepatic Enzyme Inhibitors** (eg, **cimetidine, erythromycin, isoniazid**): Metabolism of midazolam may be decreased, and excessive sedation may occur.
- **Ifosfamide**: Concurrent use may increase the risk for ifosfamide-induced neurotoxic effects. Careful monitoring is needed, and discontinuation of both drugs may be necessary if signs of encephalopathy occur.
- **Nondepolarizing Neuromuscular Blockers** (eg, **atracurium, rocuronium**): Concurrent use may potentiate, attenuate, or have no effect; respiratory status should be monitored.
- **Opioids** (eg, **butorphanol**, **fentanyl, hydromorphone**): Combination may increase the risk for CNS and/or respiratory depression.
- **Phenobarbital, Primidone**: May induce hepatic microsomal enzymes and decrease the pharmacologic effects of benzodiazepines; additive CNS depression is possible.
- **Rifampin**: May induce hepatic microsomal enzymes and decrease the pharmacologic effects of benzodiazepines
- **Theophylline, Aminophylline**: Concurrent use may decrease the levels and effectiveness of benzodiazepines. Withdrawing theophylline from a stable patient may increase the risk for benzodiazepine toxicity.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine, imipramine**): Midazolam may increase the levels of these drugs; clinical significance is not known. Concurrent use may increase the risk for CNS and/or respiratory depression.
- **Yohimbine**: May decrease therapeutic effects of anxiolytic drugs

Laboratory Considerations

- Benzodiazepines may decrease the thyroidal uptake of I^{123} or I^{131}.

Dosages

NOTE: There are many potential combinations that have been suggested; the following are examples and not inclusive. For additional information, refer to other anesthesia-specific references.[25]

DOGS:

Preoperative agent (extra-label): Used in combination with other premedications or co-induction agents (eg, ketamine, acepromazine, opioids, alpha-2 agonists), 0.1 – 0.3 mg/kg SC, IM, IV

a) Dogs were premedicated with acepromazine 0.02 mg/kg and morphine 0.4 mg/kg IM and induced with midazolam 0.25 mg/kg IV followed by propofol 1 mg/kg IV or induced first with propofol 1 mg/kg IV followed by midazolam 0.25 mg/kg IV.[26] If intubation was not possible, propofol was titrated to effect until intubation was achieved. Dogs given midazolam before propofol had mild to moderate excitement. The total dose of propofol for intubation was decreased with the use of midazolam.

b) Dogs were sedated with fentanyl 7 µg/kg IV and induced with either propofol or alfaxalone with or without midazolam 0.3 mg/kg IV.[20] The addition of midazolam reduced the induction doses of both propofol and alfaxalone.

c) Dogs premedicated with acepromazine 0.025 mg/kg and morphine 0.25 mg/kg IM were induced with midazolam 0.2 mg/kg IV followed by propofol IV titrated until intubation was possible.[13] After midazolam administration, some dogs had excitement (eg, paddling, myoclonic twitching) that resolved after induction. Midazolam significantly decreased the amount of propofol needed for induction.

d) Dogs can be premedicated with midazolam 0.5 mg/kg and morphine 0.5 mg/kg IM, or they can be premedicated with midazolam 0.5 mg/kg, morphine 0.5 mg/kg, and acepromazine 0.05 mg/kg mixed in the same syringe and given IM.[27]

e) Dogs receiving butorphanol 0.2 mg/kg combined with midazolam 0.2 mg/kg IV followed by alfaxalone 2 mg/kg IV had an excellent quality of induction and recovery.[28] Premedication with acepromazine 0.02 mg/kg and hydromorphone 0.1 mg/kg mixed in the same syringe and administered IM with midazolam 0.3 mg/kg IV significantly reduced the alfaxalone dose required for intubation.[29]

f) Dogs were premedicated with buprenorphine 0.02 mg/kg and acepromazine 0.05 mg/kg IM prior to induction with midazolam or diazepam 0.25 mg/kg IV combined with either ketamine 5 mg/kg IV or propofol 4 mg/kg IV and maintained on isoflurane for ovariohysterectomy.[14] All dogs became hypothermic within 5 minutes of induction. Dogs receiving a combination of benzodiazepine and propofol had a greater temperature decrease and longer interval to the restoration of normothermia.

g) Dogs can be premedicated with a combination of alfaxalone 5 mg/kg, morphine 0.4 mg/kg, and midazolam 1 mg/kg IM prior to induction with alfaxalone IV and maintenance on sevoflurane.[30]

h) Midazolam 0.1 mg/kg IV with butorphanol 0.2 mg/kg IV did not cause significant influence on duodenal contrast-enhanced ultrasonography parameters in dogs.[31]

i) Following premedication with acepromazine 0.02 mg/kg and methadone 0.3 mg/kg IM, the addition of midazolam 0.4 mg/kg to induction protocol significantly reduced the total alfaxalone dose required for intubation (ie, 0.65 mg/kg vs 0.94 mg/kg) with no significant changes to heart rate or blood pressure; however, the incidence of apnea was increased.[32]

Status epilepticus (extra-label): Dose recommendations vary, and there is no evidence that supports a specific dosing protocol is better than others.

IV or IM: Most clinicians recommend 0.1 – 0.3 mg/kg, but doses can range from 0.07 – 0.5 mg/kg IM or IV; IM doses may need to be higher than IV doses. Doses up to 0.5 mg/kg may be repeated twice if no response is noted. If seizures recur, rebolus and consider a CRI.

Intranasal: 0.2 mg/kg intranasal; readminister dose as above. Midazolam was delivered via a nasal adaptor attached to the end of a syringe. In a study, the median time to seizure cessation was 33 to 47 seconds, and seizures were controlled in 70% to 75% of dogs.[1,2]

Continuous rate IV infusion: 0.25 – 0.4 mg/kg/hour IV CRI (range 0.1 – 2.5 mg/kg/hour); seizures were controlled in 77% of dogs.[33] In general, the dose should be started at the low end, and the rate should be increased until seizures are controlled.

CATS:

Preoperative agent (extra-label): Used in combination with other premedications (eg, ketamine, acepromazine, opioids, alpha-2 agonists); 0.1 – 0.3 mg/kg SC, IM, IV. **NOTE**: Midazolam in combination with butorphanol may cause anxiousness, aggressiveness,

and restraint difficulties in some cats and is best reserved for geriatric or very ill cats.[10]

a) Cats were premedicated with acepromazine 0.01 mg/kg and methadone 0.2 mg/kg IV. Induction was achieved with propofol 2 mg/kg IV followed by midazolam at 0.2 mg/kg, 0.3 mg/kg, 0.4 mg/kg, and 0.5 mg/kg IV; additional propofol was given as needed for intubation.[34] All doses of midazolam decreased the amount of propofol needed for induction.
b) Cats were sedated with dexmedetomidine 3 µg/kg and methadone 0.3 mg/kg IM.[35] Optimal induction was achieved with alfaxalone 0.25 mg/kg IV over 60 seconds followed 1 minute later by midazolam 0.08 mg/kg IV.
c) Cats were given ketamine 14 mg/kg and midazolam 0.5 mg/kg IM or intranasally by dropping the solution into both nostrils.[36] This drug combination was diluted with saline to a volume of 1 mL. Cats vocalized with the IM administration and sneezed or snorted with the intranasal administration. With both techniques, the onset was 3 minutes, and the duration of sedation was 23 (nasal) to 33 (IM) minutes.
d) Cats can be sedated with medetomidine 0.05 mg/kg and midazolam 0.5 mg/kg combined and given IM followed by ketamine 10 mg/kg IM.[37] This drug combination can cause hyperglycemia and decreases in epinephrine, norepinephrine, cortisol, and nonesterified fatty acids. These effects can be reversed with atipamezole 0.2 mg/kg IV.

Opioid-free injectable protocol for cats undergoing ovariohysterectomy (extra-label): Midazolam 0.25 mg/kg IM in combination with ketamine 5 – 7 mg/kg IM, dexmedetomidine 40 µg/kg IM, bupivacaine 2 mg/kg intraperitoneal, and meloxicam 0.2 mg/kg SC postoperatively.[38] Most adult cats in the study required an opioid for postoperative pain relief.

Placement of IV catheter (extra-label): Midazolam 0.2 mg/kg combined in the same syringe with alfaxalone 1.5 mg/kg and hydromorphone 0.1 mg/kg and administered IM in the epaxial muscles.[39] Combination may be beneficial when prolonged sedation is required.

EQUINE:

Preoperative agent/total IV anesthesia (TIVA) (extra-label): Midazolam may be used or substituted for diazepam in protocols in combination with ketamine ± xylazine. See ***Ketamine*** and ***Diazepam*** for more information.

a) Medetomidine 6 µg/kg and midazolam 20 µg/kg IV in the same syringe prior to induction[40]
b) **Castration in the field** can be done in ponies with premedication of xylazine 1.1 mg/kg IM or detomidine 20 – 30 µg/kg IV, along with or followed by either midazolam or diazepam 0.05 – 0.06 mg/kg in combination with ketamine 2.2 mg/kg IV in the same syringe.[41,42]
c) **TIVA for field castration**: Premedicate with acepromazine 0.01 – 0.02 mg/kg IV, medetomidine 7 µg/kg IV, and methadone 0.1 mg/kg IV; induce anesthesia with ketamine 2.2 mg/kg IV and midazolam 0.06 mg/kg IV; maintain anesthesia with IV infusion of ketamine 3 mg/kg/hour, medetomidine 5 µg/kg/hour, and midazolam 0.1 mg/kg/hour.[43]
d) Ponies can be premedicated with romifidine 80 µg/kg IV and induced with midazolam 0.06 mg/kg and ketamine 2.5 mg/kg IV.[44] General anesthesia was maintained with romifidine 120 µg/kg/hour, midazolam 0.09 mg/kg/hour, and ketamine 3.3 mg/kg/hour given IV as a CRI. Oxygen supplementation is recommended. Recovery was uneventful.
e) Premedicate with acepromazine 0.03 mg/kg IM followed 15 minutes later by either xylazine 0.5 mg/kg IV or dexmedetomidine 3.5 µg/kg IV and induced with ketamine 2.2 mg/kg and midazolam 0.05 mg/kg IV.[45] The TIVA protocol included ketamine 3 – 5 mg/kg/hour, midazolam 0.1 mg/kg/hour, and either xylazine 1 mg/kg/hour or dexmedetomidine 7 µg/kg/hour IV. TIVA was discontinued after 120 minutes; 20 minutes later, flumazenil 0.01 mg/kg IV was given, and recovery was good to excellent.
f) **Horses**: Midazolam 25 mg, ketamine 650 mg, and xylazine 325 mg were admixed into a 500 mL bag of 0.9% sodium chloride.[46] The average IV infusion rate was 0.04 mL/kg/minute, which provided midazolam 0.002 mg/kg/minute, ketamine 0.048 mg/kg/minute, and xylazine 0.024 mg/kg/minute. Premedication included the use of an alpha-2 agonist alone or with an additional agent (eg, butorphanol, acepromazine). Anesthesia induction was achieved with midazolam 0.05 mg/kg and ketamine 2.2 mg/kg IV. Times to extubation and standing were 18 and 33 minutes, respectively. A combination of ketamine, midazolam, and medetomidine also produced adequate anesthesia but better recovery than a combination of ketamine, medetomidine, and guaifenesin.[47] A combination of ketamine, midazolam, and xylazine was inferior to a combination of ketamine, xylazine, and propofol.[48]
g) Thoroughbreds received medetomidine 6 µg/kg and midazolam 0.02 mg/kg (the route was not specified, but IV is assumed) premedication prior to anesthesia with alfaxalone, ketamine, or thiopental. All horses were well sedated prior to induction.[40]
h) **Dental extractions**: an initial bolus of romifidine 0.03 mg/kg combined with midazolam 0.02 mg/kg IV followed by romifidine 0.05 mg/kg/hour with midazolam 0.06 mg/kg/hour IV CRI had improved sedation and surgical condition as compared with horses that received only romifidine.[49]
i) **Donkeys** that were premedicated with xylazine 0.5 mg/kg IM followed 3 minutes later by midazolam 0.05 mg/kg IV and either alfaxalone 1 mg/kg IV or ketamine 2.2 mg/kg IV had a smooth anesthesia induction and average recumbency of ≈1 hour (alfaxalone) or ≈0.5 hours (ketamine).[50] Time to recumbency was somewhat shorter with alfaxalone (29 seconds) than with ketamine (51 seconds).

Seizure control in foals (extra-label): 2 – 5 mg (NOT mg/kg) for a 50 kg (110 lb) foal IV, IM.[51,52] Rapid IV administration may result in apnea and hypotension. Repeat as necessary. An IV CRI may be used at 1 – 3 mg/hour (NOT mg/kg/hour) for a 50 kg (110 lb) foal.

RUMINANTS:

a) **Calves** (extra-label): Induced general anesthesia with xylazine 0.05 mg/kg IV followed by ketamine 2 mg/kg and midazolam 0.1 mg/kg IV, which allows endotracheal intubation.[53]
b) **Goats** (extra-label): Premedicate with midazolam 0.3 mg/kg IM or midazolam 0.3 mg/kg and butorphanol 0.1 mg/kg IM.[54] This premedication decreases the induction dose of alfaxalone.

BIRDS:

Intranasal sedative/restraining agent (extra-label):

a) A study in Hispaniolan Amazon parrots given midazolam 2 mg/kg intranasally (IN) 15 minutes prior to manual restraint; sedation occurred within 3 minutes of administration, and vocalization, flight, and defense responses were significantly reduced.[55] Flumazenil antagonized the effects of midazolam within 10 minutes. A study in pigeons found that midazolam 5 mg/kg IN with dexmedetomidine 80 µg/kg IN was effective.[56] In cockatiels, midazolam 3 mg/kg IN with butorphanol 3 mg/kg IN provided sedation within ≈90 seconds.[57]
b) **Intranasal** midazolam 5 mg/kg mixed with dexmedetomidine 80 µg/kg slowly dripped into the nares provided short-term immobilization of 20 to 30 minutes in pigeons.[56] Atipa-

mezole 250 µg/kg dripped into the nares resulted in decreased sedation but not full responsiveness. Intranasal midazolam 3 mg/kg used alone or with butorphanol 3 mg/kg provided safe and effective sedation in cockatiels.[57]

Parenteral sedative/restraining agent (extra-label): In budgerigars, midazolam 3 mg/kg IM in combination with dexmedetomidine 10 – 40 µg/kg IM.[58] Reverse with atipamezole and flumazenil.

Premedication for anxious or easily stressed birds (eg, macaws, African greys, raptors, wild birds) (extra-label): 1 mg/kg IM.[59] This causes mild sedation and relaxation. Doses as high as 6 mg/kg have been reported to result in considerable sedation.

Part of an injectable anesthetic regimen (extra-label): Injectable anesthetics are only occasionally used in birds for short procedures or in situations where inhalant anesthetics are not available.[59] Ketamine 10 – 30 mg/kg and midazolam 2 – 6 mg/kg can be used. Midazolam can be reversed with flumazenil 0.1 mg/kg if necessary. Butorphanol 1 – 2 mg/kg can be added for analgesia.

Psittacid species (extra-label): Midazolam 0.5 mg/kg in combination with butorphanol 1 mg/kg and given IM in the pectoral muscle provided good anesthetic premedication prior to isoflurane.[60] This combination improved the quality and time of induction without adverse effects on cardiorespiratory parameters.

RABBITS, RODENTS, SMALL MAMMALS:

Hamsters, Gerbils, Mice, Rats, Guinea pigs, Chinchillas (extra-label): 1 – 2 mg/kg IM

a) **Preanesthetic agent for rodents** (extra-label): 3 – 5 mg/kg IM or IV; often beneficial to minimize stress and anxiety. If needed, reversal is possible with flumazenil 0.1 mg/kg IV, but it may precipitate seizures.[61]
b) **Rodents** (extra-label): Midazolam 5 mg/kg in combination with ketamine 100 mg/kg and buprenorphine 0.05 mg/kg intraperitoneal
c) **Rats** (extra-label): Midazolam 2.5 mg/kg in combination with butorphanol 2 mg/kg intraperitoneal prior to isoflurane anesthesia can provide smooth induction and can attenuate the respiratory depression of isoflurane.[62]

Rabbits:

Preanesthetic agent (extra-label): 0.5 – 5 mg/kg IM or IV

Combination Dosages:

a) Midazolam 2 mg/kg in combination with dexmedetomidine 0.1 mg/kg and butorphanol 0.4 mg/kg mixed in the same syringe and delivered via transnasal catheter to the nasopharyngeal mucosa. Loss of righting reflex, sedation, and analgesia occurred within 1 to 2 minutes with a duration of 45 minutes.[63] Blood pressure decreased, and hypoventilation with hypoxemia occurred; close monitoring and oxygen supplementation are recommended.
b) Midazolam 0.2 mg/kg in combination with ketamine 30 mg/kg IM OR midazolam 0.2 mg/kg in combination with dexmedetomidine 25 µg/kg IM. Deeper sedation occurred with the combination of dexmedetomidine and midazolam.[64]

Induction agent:

a) Midazolam 0.05 – 0.5 mg/kg IV (typically via a marginal ear vein). The low end of the dose range is usually given and topped up as necessary. In nonsedated animals, prior preparation of the area with topical local anesthetics may be useful. Midazolam IV leads to further sedation of the animal, which is sufficient to allow intubation but may also induce apnea. This, together with fentanyl's respiratory depression, can potentially compound the possibility of hypoxia. It is therefore important that midazolam is given to effect and that preoxygenation is performed. Intubation is considered essential when using this protocol. **NOTE**: Not all animals require midazolam induction for purposes of intubation.[65] An assessment of the animal can be made in the first 10 minutes after premedication delivery. Some rabbits may be sufficiently sedated to allow intubation at this point.
b) A combination of midazolam 3 mg/kg and ketamine 25 mg/kg IM followed by isoflurane was superior to using midazolam alone or a combination of midazolam and ketamine.[66]

Injectable anesthesia: Premedication with medetomidine 0.1 mg/kg SC, sufentanil 2.5 µg/mL, and midazolam 0.45 mg/mL administered at 0.3 mL/kg/hour IV CRI for induction with 0.1 mL of the mixture given every 20 seconds until the righting reflex was lost.[67] Following endotracheal intubation, the infusion rate was adjusted to suppress the pedal withdrawal reflex. Although induction and recovery were smooth, this drug combination caused marked hypotension and respiratory depression that required intubation and ventilation.

Monitoring

- Signs of sedation or paradoxical excitement
- Baseline and periodic blood pressure
- Respiratory rate, $ETCO_2$, and pulse oximetry
- Horses should be observed carefully for ataxia.
- Clinical response to treatment

Client Information

- Do not give this medicine as an injection at home, as it requires special medical monitoring for safe use.
- If giving this medicine into the nose to stop a seizure in dogs, follow your veterinarian's instructions exactly and contact your veterinarian immediately for further instruction.

Chemistry/Synonyms

Midazolam HCl is a benzodiazepine that occurs as a white or yellowish crystalline powder. It is soluble in alcohol, but solubility in water is dependent on pH. At a pH of 3.4 (≈ the pH of the commercial injection and syrup), 10.3 mg are soluble in 1 mL of water.

Midazolam HCl may also be known as Ro-21-3981/003 or *Versed*®.

Storage/Stability

Store midazolam injection at room temperature (15°C-30°C [59°F-86°F]) and protected from light. After being frozen for 3 days and allowed to thaw at room temperature, the injectable product is physically stable. Midazolam is stable at a pH range of 3 to 3.6.

Midazolam is a DEA Schedule IV (C-IV) controlled substance. Store it in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding the disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Midazolam is reportedly physically **compatible** when mixed with the following products: D_5W, normal saline, lactated Ringer's, atracurium, atropine sulfate, buprenorphine, butorphanol, calcium chloride/gluconate, cefazolin, cefuroxime, chlorpromazine, ciprofloxacin, fentanyl citrate, gentamicin, glycopyrrolate, fluconazole, hydromorphone, hydroxyzine, ketamine, lidocaine, mannitol, meperidine, metoclopramide, morphine sulfate (not in a syringe; compatibility appears to be concentration-dependent), nalbuphine, ondansetron, penicillin G potassium/sodium, promethazine HCl, potassium chloride, sufentanil citrate, and scopolamine HBr.

Midazolam is physically **incompatible** with amphotericin B, ampicillin sodium, ceftazidime, dexamethasone sodium phosphate, dimenhydrinate, esomeprazole, furosemide, heparin, hydrocortisone

sodium succinate, pantoprazole, pentobarbital, phenobarbital, piperacillin/tazobactam, ranitidine, and sodium bicarbonate.

A midazolam hydrochloride oral suspension compounded from the commercially available injectable solution has been published.[68] Diluting midazolam 5 mg/mL injection in a 1:1 ratio with *Syrpalta®* yields a 2.5 mg/mL midazolam hydrochloride oral solution that retains more than 90% potency for 56 days when stored at 7°C (44.6°F), 20°C (68°F), or 40°C (104°F) and protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Midazolam HCl Injection: 1 mg (as HCl)/mL; 5 mg (as HCl)/mL; generic; (Rx, C-IV)

Midazolam HCl Syrup: 2 mg/mL; generic; (Rx, C-IV)

Midazolam HCl Nasal Spray: packaged in 5 mg units, 2 units per box; *Nayzilam®*; (Rx)

Report dispensing to state monitoring programs where required.

Prescriber Highlights

- ► Used as a heartworm preventive and for the removal and/or control of hookworms, roundworms, and whipworms in dogs and puppies
- ► Available in combination with other anthelmintics or insecticides
- ► Prevents heartworm disease and removes adult roundworms and hookworms in cats and kittens
- ► No absolute contraindications
- ► Animals with a high number of circulating microfilariae may develop a transient shock-like syndrome.
- ► Adverse effects appear unlikely at labeled dosages; at higher doses, neurologic signs become more likely.

Uses/Indications

Milbemycin tablets for dogs and puppies are labeled as a monthly heartworm preventive (*Dirofilaria immitis)*, for hookworm control (*Ancylostoma caninum*), and for control and removal of adult roundworms (*Toxocara canis, Toxascaris leonina*) and whipworms (*Trichuris vulpis*).[1] It can also be used extra-label for treatment of infestations of *Demodex canis, Demodex injai*, and *Sarcoptes scabiei* var. *canis*. In a systematic review of published clinical trials, the optimal determined treatments for demodicosis were daily oral milbemycin and weekly[2,3] or monthly[4–6] topical moxidectin (± imidacloprid); however, isoxazolines (eg, fluralaner, sarolaner) are as effective as the moxidectin/imidacloprid combination and have supplanted macrolide antiparasitics for the treatment of demodicosis.[3–5]

In cats, milbemycin tablets are labeled as a monthly heartworm preventive (*D. immitis)* and for removal of adult hookworms (*Ancylostoma tubaeforme*) and roundworms (*Toxocara cati*).

Pharmacology/Actions

The primary mode of action of milbemycins is binding to glutamate-gated chloride ion channels in the nervous system of nematodes and arthropods. Cell membrane permeability to chloride ions is increased, inhibiting the electrical activity of nerve cells in nematodes and muscle cells in arthropods and causing paralysis and death of the parasites.

Milbemycins also enhance the release of Gamma-aminobutyric acid (GABA) at presynaptic neurons. GABA acts as an inhibitory neurotransmitter and blocks postsynaptic stimulation of the adjacent neuron in nematodes or the muscle fiber in arthropods.

Milbemycins are generally not toxic to mammals, as mammals do not have glutamate-gated chloride channels and because these compounds do not readily cross the blood–brain barrier and therefore cannot reach the mammalian GABA receptors.

Pharmacokinetics

No specific information was located. At labeled doses, milbemycin is considered effective for at least 45 days after infection by *D immitis* larvae.

Contraindications/Precautions/Warnings

Manufacturers do not list any absolute contraindications to milbemycin use. Because some dogs with a high number of circulating microfilariae will develop a transient, shock-like syndrome after receiving milbemycin, the manufacturer recommends testing for pre-existing heartworm infections and treating infected dogs to remove adult heartworms and microfilariae prior to initiating milbemycin.

If using milbemycin at doses greater than labeled in breeds susceptible to the *MDR1* gene mutation (also known as *ABCB1*-1delta), genetic testing is recommended before initiating milbemycin.

The manufacturer states to only use the product (*Interceptor®*) in dogs 4 weeks of age or older and weighing at least 0.9 kg (2 lb) and in cats and kittens 6 weeks of age and older and weighing at least 0.7 kg (1.5 lb). Age and weight restrictions vary slightly for combination products labelled for use in dogs and puppies; consult specific product labels for further information.

Adverse Effects

At label dosages, adverse effects appear to be infrequent in microfilaria-free dogs, including breeds susceptible to neurologic toxicity (see ***Overdose/Acute Toxicity***). Lethargy, vomiting, ataxia, anorexia, diarrhea, convulsions, and weakness have been reported in dogs.

In a study of dog breeds susceptible to the *MDR1* mutation, milbemycin was given at dosages of 1 – 2.2 mg/kg PO daily for the treatment of demodicosis. All *MDR1* mutant/mutant dogs exhibited signs of CNS toxicity, whereas no *MDR1* wild-type/wild-type or *MDR1* mutant/wild-type dogs exhibited signs of toxicity.[7]

Reproductive/Nursing Safety

Studies in pregnant dogs at daily doses 3 times those labeled showed no adverse effects to offspring or bitch.[1] In cats, safety in breeding, pregnant, and lactating queens and breeding toms has not been established.

Milbemycin enters maternal milk. At labeled doses, no adverse effects have been noted in nursing puppies.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Eight-week-old puppies receiving 2.5 mg/kg (5 times the label dose) for 3 consecutive days showed no clinical signs after the first day, but after the second or third consecutive dose, showed some ataxia and trembling.

Beagles have tolerated a single oral dose of 200 mg/kg (400 times the label dose). Rough-coated collies have tolerated doses of 10 mg/kg (20 times the label dose) without adversity (label information; *Interceptor®*). Avermectin-sensitive collies tolerated 10 mg/kg milbemycin when combined with 300 mg/kg spinosad.[8] Toxic doses can cause mydriasis, ptyalism, lethargy, ataxia, pyrexia, seizures, coma, and death. Intravenous lipid emulsion (ILE) has been recommended for management of macrocyclic lactone toxicity,[9] and ILE was used to manage milbemycin toxicity in one dog[10] and one cat.[11] Supportive therapy is recommended.

Safety studies were conducted in young cats and kittens and doses of 1, 3, and 5 times the minimum recommended dose of 2 mg/kg demonstrated no drug-related effects. Tolerability studies at 10 times the label dose also demonstrated no drug-related adverse effects in kittens and young adult cats.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The manufacturer states that milbemycin was used safely during testing in dogs and cats receiving other frequently used veterinary products, including vaccines, anthelmintics, antibiotics, steroids, flea collars, shampoos, and dips. The following drug interactions have either been reported or are theoretical in humans or animals receiving GABA agonists and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Benzodiazepines**: Effects may be potentiated by milbemycin; use together not advised in humans

Caution is advised if using milbemycin with other drugs that can inhibit **p-glycoprotein**, particularly in those dogs at risk for *MDR1* genetic mutation (collies, Australian shepherds, shelties, long-haired whippet, "white feet" breeds), unless tested normal. Drugs and drug classes involved include:

- **Amiodarone**
- **Carvedilol**
- **Clarithromycin**
- **Cyclosporine**
- **Diltiazem**
- **Erythromycin**
- **Itraconazole**
- **Ketoconazole**
- **Quinidine**
- **Spironolactone**
- **Verapamil**

Laboratory Considerations

None noted

Dosages

DOGS:

Parasiticide for labeled indications using milbemycin as a single agent (label dosages; FDA-approved): Appropriate dose is based on body weight and given orally, once a month, at the recommended minimum dosage of 0.5 mg/kg (0.23 mg/lb body weight).

Recommended Dosage Schedule for Dogs

Body weight	INTERCEPTOR® Flavor Tabs
0.9-4.5 kg (2-10 lb)	One tablet (2.3 mg)
5-11.3 kg (11-25 lb)	One tablet (5.75 mg)
11.8-22.7 kg (26-50 lb)	One tablet (11.5 mg)
23.2-45.5kg (51-100 lb)	One tablet (23.0 mg)

Dogs over 45.5 kg (100 lb) are provided the appropriate combination of tablets (Label information; *Interceptor®*)

Treatment of canine demodicosis (extra-label):

a) 0.5 – 1.6 mg/kg/day (mean dose 0.75 mg/kg/d) PO for 1 to 6 months and/or until skin scrape is negative. Cure more likely with juvenile-onset patients[12]

b) 1 – 2 mg/kg/day PO[13,14]

Treatment of canine sarcoptic mange (extra-label):

a) 0.75 mg/kg/day PO for 30 days[15]

b) 2 mg/kg PO once weekly for 3 treatments[16]

Prevention of *Angiostrongylus vasorum* infection (extra-label): milbemycin oxime/spinosad combination tablet at 0.75 – 1 mg/kg and 45 – 60 mg/kg PO, respectively. From a laboratory study, monthly doses would be expected to be effective.[17]

CATS:

Parasiticide for labeled indications using milbemycin as a single agent (label dosages; FDA-approved): Appropriate dose is based on body weight and given orally, once a month, at the recommended minimum dosage of 2 mg/kg (0.9 mg/lb body weight).

Recommended Dosage Schedule for Cats

Body weight	INTERCEPTOR® Flavor Tabs
0.7-2.7 kg (1.5-6 lb)	One tablet (5.75 mg)
2.8-5.5 kg (6.1-12 lb)	One tablet (11.5 mg)
5.4-11.4 kg (12.1-25 lb)	One tablet (23.0 mg)

Cats over 11.4 kg (25 lb) are provided the appropriate combination of tablets. (Label information; *Interceptor®*)

Treatment of Lungworm infections (extra-label): milbemycin 2 mg/kg with praziquantel 5 mg/kg PO every 15 days for 3 doses[18]

Monitoring

- Efficacy based on clinical signs and diagnostic testing (eg, fecal flotation, heartworm antigen testing, external parasite elimination)
- For demodicosis, clinical signs and monthly skin scraping; continue treatment for 4 weeks beyond 2 negative monthly skin scrapings.[14]
- Adverse effects

Client Information

- Used monthly in dogs to control heartworm and hookworms and to control and remove roundworms and whipworms.
- Used monthly in cats to control heartworm and to control and remove hookworms.
- Appears very safe when used at recommended dosages for prevention of heartworm, even in dogs with the *MDR1* genetic mutation.
- Store flavored tablets out of reach of children and animals. This medicine may be toxic to wildlife so dispose of unused tablets responsibly.

- When using milbemycin for heartworm prevention it is important to administer each monthly dose on schedule, as a late or missed dose may allow a heartworm infection to become established. Be certain that your pet fully consumes each dose.
- It is recommended to administer heartworm preventives year-round. If being administered seasonally, the first dose should be given within one month of the first mosquito exposure and continued monthly thereafter until the end of the mosquito season.

Chemistry/Synonyms

Milbemycin oxime consists of ≈80% of the A_4 derivatives and 20% of the A_3 derivatives of 5-didehydromilbemycin. Milbemycin is considered to be a macrolide antibiotic structurally. Milbemycin oxime occurs as a white to yellow powder.

Milbemycin may also be known as CGA-179246, *Interceptor®*, *Milbeguard®*, and *Milbehart®*.

Storage/Stability

Store milbemycin oxime tablets at room temperature between 15°C and 25°C (59°F-77°F).

Compatibility/Compounding Considerations

An analysis of aqueous milbemycin suspensions compounded by two national compounding pharmacies found that potency varied from 67.5% to 135% of labeled strength, and that potency decreased by ≈20% over the 3-week study period.[19]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Milbemycin Oxime Oral Tablets for dogs: 0.9 to 4.5 kg (2 to 10 lb): 2.3 mg; 5 to 11.4 kg (11 to 25 lb): 5.75 mg; 11.8 to 22.7 kg (26 to 50 lb): 11.5 mg; 23.2 to 45.5 kg (51 to 100 lb): 23 mg; dogs more than 45.5 kg (100 lb) are provided the appropriate combination of tablets; *Interceptor® Flavor Tabs,* generic (Rx). FDA-approved for use in dogs and puppies older than 4 weeks of age and at least 0.9 kg (2 lb).

Milbemycin Oxime Oral Tablets for cats: 0.7 to 2.7 kg (1.5 to 6 lb): 5.75 mg; 2.8 to 5.5 kg (6.1 to 12 lb): 11.5 mg; 5.5 to 11.4 kg (12.1 to 25 lb): 23 mg; *Interceptor® Flavor Tabs,* generic; (Rx). FDA-approved for cats and kittens older than 6 weeks of age and at least 0.7 kg (1.5 lb).

Milbemycin/Lufenuron Oral Tablets for dogs: 0.9 to 4.5 kg (2 to 10 lb): 2.3 mg/46 mg; 5 to 11.4 kg (11 to 25 lb): 5.75 mg/115 mg; 11.8 to 22.7 kg (26 to 50 lb): 11.5 mg/230 mg; 23.2 to 45.5 kg (51 to 100 lb): 23 mg/460 mg milbemycin/lufenuron; *Sentinel® Flavor Tabs*; (Rx). FDA-approved for use in dogs and puppies older than 4 weeks of age and at least 0.9 kg (2 lb). Also available with nitenpyram *(Capstar®)*.

Milbemycin/Praziquantel Chewable Oral Tablets for dogs: 0.9 to 3.6 kg (2 to 8 lb): 2.3 mg/22.8 mg; 3.7 to 11.4 kg (8.1 to 25 lb): 5.75 mg/57 mg; 11.4 to 22.7 kg (25.1 to 50 lb): 11.5 mg/114 mg; 22.7 to 45.5 kg (50.1 to 100 lb): 23 mg/228 mg; *Interceptor® Plus* (Rx). FDA-approved for use in dogs and puppies 6 weeks of age or older and at least 0.9 kg (2 lb).

Milbemycin/Lufenuron/Praziquantel Chewable Oral Tablets for dogs: 0.9 to 3.6 kg (2 to 8 lb): 2.3 mg/46 mg/22.8 mg; 3.7 to 11.4 kg (8.1 to 25 lb): 5.75 mg/115 mg/57 mg; 11.4 to 22.7 kg (25.1 to 50 lb): 11.5 mg/230 mg/114 mg; 22.7 to 45.5 kg (50.1 to 100 lb): 23 mg/460 mg/228 mg; *Sentinel® Spectrum®*; (Rx). FDA-approved for use in dogs and puppies older than 6 weeks of age and at least 0.9 kg (2 lb).

Milbemycin/Spinosad Chewable Oral Tablets for dogs: 2.3 to 4.5 kg (5 to 10 lb): 2.3 mg/140 mg; 4.5 to 9.1 kg (10.1 to 20 lb): 4.5 mg/270 mg; 9.1 to 18.2 kg (20.1 to 40 lb): 9.3 mg/560 mg; 18.2 to 27.3 kg (40.1 to 60 lb): 13.5 mg/810 mg; 27.3 to 54.5 kg (60.1 to 120 lb): 27 mg/1620 mg; *Trifexis®*, *Comboguard®*; (Rx). FDA-approved for use in dogs and puppies 8 weeks of age or older and at least 2.2 kg (5 lb).

Milbemycin 0.1% otic solution (*Milbemite®*) available for treatment of ear mite (*Otodectes cynotis*) infestations in cats and kittens 4 weeks of age and older.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Miltefosine

(mil-***tef***-oh-seen) *Milteforan®, Impavido®*

Antileishmanial

Prescriber Highlights

- ► Oral treatment for canine leishmaniasis; improves clinical status but is unlikely to fully clear the organism
- ► Appears to be more effective when used with allopurinol
- ► Contraindicated in patients hypersensitive to it, in pregnant or lactating animals, and in breeding animals
- ► Use caution in animals with hepatic dysfunction or cardiac insufficiency.
- ► Adverse effects include vomiting and diarrhea.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies miltefosine as a hazardous drug; use appropriate precautions when handling and do not handle if pregnant.

Uses/Indications

Originally developed as an antineoplastic agent, miltefosine can be used alone or with allopurinol to treat canine leishmaniasis. Like other drugs, it does not completely clear the organism in dogs, but can substantially reduce the parasitic load.[1,2] Clinical efficacy is improved when used with allopurinol.[1] Clinical signs decrease substantially immediately after beginning treatment and are significantly reduced after 2 weeks.[3] The combination of meglumine antimoniate with allopurinol appears to have better clinical efficacy than a miltefosine-allopurinol combination.[4]

One case report demonstrates efficacy of miltefosin and allopurinol combination therapy for leishmaniasis in a ferret.[5]

Pharmacology/Actions

Although the exact mechanism of action for miltefosine against *Leishmania infantum* is not understood, it is thought that it inhibits the penetration of the organism into macrophages by interacting with glycosomes and glycosylphosphatidyl-inositol anchors that are essential for the survival of *Leishmania* organisms intracellularly. Also, by inhibiting phospholipase, miltefosine disrupts *Leishmania* membrane signal transduction. Other possible mechanisms include inhibition of mitochondrial function and cell death from an apoptosis-like effect. Miltefosine has antineoplastic, immunomodulatory, anti-amebic, and antiviral activity.

Pharmacokinetics

After oral administration in dogs, miltefosine has a bioavailability of 94% with peak plasma concentrations occurring around 5 hours postdose. The drug is distributed throughout the major organs, including the brain. Intravascularly, it is nearly evenly distributed between plasma and erythrocytes. Miltefosine undergoes phospholipase D-like cleavage in the liver; it is mainly eliminated via the feces, with ≈10% of a dose eliminated unchanged. Renal elimination appears negligible. Miltefosine has a long half-life of around 6.5 days.

Contraindications/Precautions/Warnings

Miltefosine is labeled as contraindicated in patients hypersensitive to it and in pregnant, lactating, or breeding animals.

Use with caution in patients with severe hepatic dysfunction or cardiac impairment. Do not underdose as it may increase the risk for drug resistance to occur.

The National Institute for Occupational Safety and Health (NIOSH) classifies miltefosine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Clinical signs of GI distress (eg, vomiting, diarrhea, inappetence) are the most common adverse effects seen in dogs.[6] In clinical studies, these adverse effects occurred on average within 5 to 7 days of starting treatment and lasted for 1 to 2 days, but may last longer in some animals. Giving with food may reduce GI signs.[3] Miltefosine potentially may cause nephrotoxicity and/or hepatotoxicity, but as leishmaniasis can cause kidney and liver damage, it is difficult to ascribe any specific risk for these potential adverse effects in dogs. One study in healthy beagles found that miltefosine 2 mg/kg/day PO in 8 dogs did not cause renal tubular damage, but meglumine antimoniate 100 mg/kg/day SC caused severe tubular damage (cell necrosis and apoptosis).[7]

In humans, the most common (>10%) adverse effects are abdominal pain, nausea, vomiting, diarrhea, reduced appetite, and an increase in liver enzymes.[8] Nephrotoxicity and thrombocytopenia have also been reported in humans.

Reproductive/Nursing Safety

Miltefosine is contraindicated during pregnancy in humans[8] and should be considered contraindicated in pregnant, lactating, and breeding animals. When pregnant rats were dosed at 1.2 mg/kg/day and higher during the early embryonic development (up to day 7 of pregnancy), an increased risk for embryotoxic, fetotoxic, and teratogenic effects was determined. In pregnant rabbits given 2.4 mg/kg/day and higher during the organogenesis phase, embryotoxic and fetotoxic effects were also seen.

Male rats given miltefosine 8.25 mg/kg daily showed testicular atrophy and impaired fertility; this was at least partially reversible within 10 weeks.

It is not known if miltefosine is excreted into milk. The canine and human labels state that it should not be used in nursing mothers.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses can result in uncontrollable vomiting.[3] Potentially, hepatic, renal, and retinal toxicity are possible in large overdoses. A specific antidote for miltefosine overdose is not known.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

No drug interactions have been reported for miltefosine.

Laboratory Considerations

- No specific concerns noted

Dosages

DOGS:

Canine leishmaniasis (extra-label):

a) 2 mg/kg PO, poured onto food, with a full or partial meal once a day for 28 days[2,3,9]

b) As an alternative treatment to meglumine antimoniate and allopurinol: miltefosine 2 mg/kg PO once daily for 28 days with allopurinol 5 – 20 mg/kg PO every 12 hours, for at least 6 months[1,10–12]

c) Miltefosine 1.5 mg/kg PO once daily for 5 days, then 2.5 mg/kg PO once daily for 25 days; used in combination with allopurinol 10 mg/kg PO twice daily, for at least 6 months[4,9]

FERRETS:

Leishmaniosis (extra-label): From a case report: miltefosine 2 mg/kg PO once daily for 28 days with allopurinol 10 mg/kg PO every 12 hours[5]

Monitoring

- Baseline and periodic renal function and hepatic enzymes
- Adverse effects (especially vomiting)
- Body weight

Client Information

- Give with food to help reduce the chance for vomiting.
- If vomiting or severe diarrhea occurs, contact your veterinarian.
- Because this drug has caused birth defects, it should not be handled by pregnant women.
- Do not allow treated dogs to lick persons immediately after intake of the veterinary liquid form of the medication.
- If using a veterinary oral solution (imported), wear disposable gloves when administering this product as it has caused skin reactions.
- To avoid foaming, do not shake the vial of the veterinary oral solution (imported).
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Miltefosine is a phospholipid derivative (alkylphosphocholine) that is structurally related to the phospholipid components of cell membranes. It occurs as a white powder freely soluble in water or ethanol. The commercially available canine product (*Milteforan®*) is a clear, colorless, viscous solution containing 20 mg/mL of miltefosine. Excipients in the solution include hydroxypropylcellulose, propylene glycol, and water.

Miltefosine may also be known as D-18506, HDPC, hexadecilfosfocolina, hexadecylphosphocholine, miltefosiini, miltefosina, miltéfosine, or miltefosinum. Trade names include *Milteforan®*, *Miltex®*, and *Impavido®*.

Storage/Stability

Miltefosine capsules should be protected from moisture and stored at 20°C to 25°C (68°F-77°F); excursions permitted from 15°C to 30°C (59°F-86°F). Avoid freezing. Veterinary liquid should be discarded 1 month after first opening the container.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None in the United States. Elsewhere, a canine licensed product may be available. Miltefosine Oral Solution: 20 mg/mL in 30 mL, 60 mL, and 90 mL vials; *Milteforan®*; (Rx)

HUMAN-LABELED PRODUCTS:

Miltefosine capsules: 50 mg; *Impavido®*; (Rx). Approved as an orphan drug by FDA. For availability, see www.impavido.com

Mineral Oil

Liquid Paraffin

Lubricant Laxative

Prescriber Highlights

- ► Laxative used mainly in horses to treat constipation and fecal impaction
- ► Use with caution in debilitated or pregnant patients, patients with hiatal hernia, dysphagia, or esophageal or gastric retention.
- ► Use caution when administering by tube to avoid aspiration.
- ► Adverse effects include lipid pneumonitis if aspirated, granulomatous reactions in liver if significant amounts are absorbed from gut, and oil leakage from the anus.
- ► Long-term use may lead to decreased absorption of fat-soluble vitamins (A, D, E, K).

Uses/Indications

Mineral oil is commonly used in horses to treat constipation and fecal impactions. Mineral oil has also been administered after ingestion of lipid-soluble toxins (eg, kerosene, metaldehyde) to delay the absorption of these toxins through its laxative and solubility properties.

Mineral oil products containing petrolatum (eg, *Laxatone*®) may be used in dogs and cats as a laxative or to prevent and reduce hairballs in cats. Mineral oil has been used with some success to treat gastric impaction in certain raptor species.[1]

Pharmacology/Actions

Mineral oil acts as a laxative by lubricating fecal material and the intestinal mucosa. It also reduces reabsorption of water from the GI tract, thereby increasing fecal bulk and decreasing intestinal transit time.

Pharmacokinetics

It has been reported that after oral administration, emulsions of mineral oil may be up to 60% absorbed, but most reports state that mineral oil preparations are only minimally absorbed from the gut.

Contraindications/Precautions/Warnings

No specific contraindications were noted with regard to veterinary patients. In humans, orally administered mineral oil is considered contraindicated in patients less than 6 years of age; debilitated or pregnant patients; and patients with hiatal hernia, dysphagia, or esophageal or gastric retention.

Use caution when administering mineral oil by nasogastric tube to avoid aspiration, especially in debilitated or recalcitrant animals. To avoid aspiration in small animal species, oral administration of mineral oil should not be attempted when there is a pre-existing difficulty with swallowing or if there is an increased risk for vomiting or regurgitation. Many clinicians believe that mineral oil should not be administered orally to small animal species due to the risk for aspiration and should be administered rectally when used as a laxative.

In horses, administration of mineral oil is contraindicated to remove an esophageal blockage, as aspiration can occur.

Adverse Effects

When used on a short-term basis and at recommended doses, mineral oil should cause minimal adverse effects. The most serious effect that could be encountered is aspiration of the oil with resultant lipid pneumonitis. This effect can be prevented by using mineral oil only in appropriate cases when the risk for aspiration is minimal and by ensuring that the tube is in the stomach when administering via tube, and by administering the oil at a reasonable rate.

Granulomatous reactions have occurred in the liver, spleen, and mesenteric lymph nodes when significant quantities of mineral oil are absorbed from the gut. Oil leakage from the anus may occur and be of concern in animals with rectal lesions or house pets. Long-term administration of mineral oil may lead to decreased absorption of fat-soluble vitamins (A, D, E, K). No reports were found documenting clinically significant hypovitaminosis in cats receiving long-term petrolatum therapy, however.

Reproductive/Nursing Safety

Oral mineral oil should be safe to use during nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No specific information was located regarding overdoses of mineral oil; but it would be expected that with the exception of aspiration, the effects would be self-limiting. See ***Adverse Effects*** for more information.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving mineral oil and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Docusate**: Theoretically, mineral oil should not be given with docusate (DSS), as enhanced absorption of the mineral oil could occur; however, this does not appear to be of significant clinical concern with large animal species.
- **Vitamins A, D, E, K**: Long-term administration of mineral oil may affect absorption of fat-soluble vitamins (A, D, E, K). It has been recommended to administer mineral oil products between meals to minimize this problem.

Dosages

DOGS/CATS:

Lubricant laxative (extra-label): Because of the risk for aspiration, liquid mineral oil is rarely recommended for oral administration. Occasionally, some clinicians administer liquid mineral oil rectally at 5 – 30 mL/dog (NOT mL/kg) and 5 – 10 mL/cat (NOT mL/kg). Cat laxative (petrolatum-based) products are sometimes recommended at 1 – 5 mL/cat (NOT mL/kg) PO daily.

Preventing hairballs (label dosage; NOT FDA-approved): ½ – 1 teaspoonful PO daily for 2 to 3 days, then ¼ – ½ teaspoonful 2 to 3 times per week.[2]

HORSES:

Laxative (extra-label):

a) **Large colon impactions**:
   i. Adults: 2 – 4 liters/horse via nasogastric (NG) tube; may be repeated every 12 hours
   ii. Foals: 60 – 240 mL/foal (NOT mL/kg). Not recommended for foals less than 24 hours old

b) **Sand colic**: In one experimental study, 0.5 kg psyllium was mixed with 1 liter of mash and given twice daily. Two liters of mineral oil via NG tube were administered once daily. This combination was more effective (measured ash content of feces) than giving mineral oil alone.[3]

CATTLE:

Laxative (extra-label):

a) Adults: 0.5 – 4 liters/animal via stomach tube

b) Calves: 60 – 120 mL (NOT mL/kg) via stomach tube

SHEEP & GOATS:

Laxative (extra-label): 100 – 500 mL/animal (NOT mL/kg) via stomach tube[4]

SWINE:

Laxative (extra-label): 50 – 100 mL/animal (NOT mL/kg) via stomach tube[4]

BIRDS:

Laxative and to aid in the removal of lead from the gizzard (extra-label): 1 – 3 drops/30 grams of body weight or 5 mL/kg PO once. Repeat as necessary. Give via tube or give slowly to avoid aspiration.[5]

RABBITS, RODENTS, SMALL MAMMALS:

Laxative or to remove hairballs in rabbits (extra-label): Using a feline laxative product: 1 – 2 mL/rabbit (NOT mL/kg) PO per day for 3 to 5 days[6]

Monitoring

- Clinical efficacy (eg, stool consistency and frequency)
- If aspiration is suspected, auscultate and perform thoracic radiographs.

Client Information

- Follow your veterinarian's instructions or label directions for cat laxative products.
- Do not increase the amount you are giving your animal or prolong treatment beyond your veterinarian's recommendations.

Chemistry/Synonyms

Mineral oil, also known as liquid petrolatum, liquid paraffin, or white mineral oil, occurs as a tasteless, odorless (when cold), transparent, colorless, oily liquid that is insoluble in both water and alcohol. It is a mixture of complex hydrocarbons and is derived from crude petroleum. For pharmaceutical purposes, heavy mineral oil is recommended over light mineral oil, as it is believed to have a lesser tendency to be absorbed in the gut or aspirated after oral administration.

White petrolatum, also known as white petroleum jelly or white soft paraffin, occurs as a white or faintly yellow unctuous mass. It is insoluble in water and almost insoluble in alcohol. White petrolatum differs from petrolatum only in that it is further refined to remove more of the yellow color.

Mineral oil may also be known as liquid paraffin, 905 (mineral hydrocarbons), dickflussiges paraffin, heavy liquid petrolatum, huile de vaseline epaisse, liquid petrolatum, oleum petrolei, oleum vaselini, paraffinum liquidum, paraffin oil, paraffinum subliquidum, vaselinol, vaselinum liquidum, and white mineral oil; many trade names are available.

Storage/Stability

Mineral oil products should be stored at room temperature between 10°C and 30°C (50°F-86°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Mineral oil products have not been formally FDA-approved for use in animals. These products and preparations are available without a prescription (OTC).

Mineral Oil Oral Preparations:

Liquid Mineral Oil: Available in gallons or 55 gallon drums

Cat Laxative Products: Products may vary in actual composition; some contain liquid petrolatum in place of white petrolatum and may have various flavors (eg, tuna, caviar, malt). There are many proprietary products marketed.

HUMAN-LABELED PRODUCTS:

Mineral Oil Liquid: in 180 mL and 473 mL; generic; (OTC)

Mineral Oil Emulsions: There are several products available that are emulsions of mineral oil and may be more palatable for oral administration. Trade names include: *Kondremul® Plain*; (OTC). Various generic products are available.

For the complete list of references, see **wiley.com/go/budde/plumb**

Minocycline

(mi-noe-***sye***-kleen) *Minocin®, Solodyn®*

Tetracycline Antibiotic

Prescriber Highlights

- ► Oral and parenteral tetracycline antibiotic; potential alternative to doxycycline
- ► Less likely to cause bone and teeth abnormalities than other tetracyclines, but use in pregnant and/or young animals should be avoided when possible
- ► May be used in patients with mild to moderate renal insufficiency without dosage adjustment
- ► Administration on an empty stomach is preferred.
- ► Adverse effects are most commonly GI-related (eg, nausea, vomiting).

Uses/Indications

Minocycline is a tetracycline-derived antibiotic used for the treatment of a variety of bacterial infections, particularly when doxycycline is unavailable. It can be effective against some doxycycline-resistant staphylococci.[1] Minocycline is not recommended for the treatment of bacterial cystitis or prostatitis,[2] as it does not reach adequate concentrations in these sites.[3,4] Minocycline may be used instead of doxycycline as part of the American Heartworm Society's recommended canine heartworm treatment protocol.[5]

Minocycline is effective in the treatment of periodontitis in dogs when applied locally after scaling and root planing were performed.[6,7] Minocycline purportedly has antiangiogenic effects but was ineffective as adjuvant therapy when given to dogs with hemangiosarcoma treated with standard chemotherapy[8]; however, concerns have been expressed about the use of antimicrobials for nonantimicrobial effects.[9]

Minocycline has been suggested as a potential alternative to doxycycline in the treatment of Lyme disease (ie, *Borrelia burgdorferi* infection) in horses, although minocycline may not attain MIC concentrations.[10,11] Minocycline is a preferred choice for the treament of Lyme borreliosis in dogs.[12]

The World Health Organization (WHO) has designated minocycline as a Highly Important antimicrobial in human medicine.[13] The World Organization for Animal Health (OIE) has designated tetracyclines as a Veterinary Critically Important Antimicrobial Agent.[14]

Pharmacology/Actions

Tetracyclines are time-dependent, bacteriostatic antibiotics. In susceptible organisms, tetracyclines inhibit bacterial protein synthesis by reversibly binding to the bacterial 30S ribosomal subunits, thus

preventing aminoacyl tRNA attachment to the ribosome. Tetracyclines also alter cytoplasmic membrane permeability in susceptible organisms. At high concentrations, tetracyclines inhibit protein synthesis in mammalian cells.

A study in 6 beagles reported a mean oral bioavailability of ≈50%, but bioavailability ranged from 28% to 74%. This study concluded that minocycline at a dosage of 5 mg/kg PO twice daily is sufficient for inhibiting *Staphylococcus pseudintermedius* isolates with MICs less than or equal to 0.25 µg/mL.[15] A small pharmacokinetic/drug interaction study in 5 healthy greyhounds found that a dose of 7.5 mg/kg PO every 12 hours achieved the pharmacodynamic index for a bacterial MIC of 0.25 µg/mL (AUC:MIC greater than or equal to 33.9), but the authors cautioned that this was not an efficacy study and that further studies are required.[16] Staphylococcal resistance to tetracyclines occurs via the *tet*(K) and *tet*(M) genes. *tet*(K) confers resistance to tetracycline but not doxycycline or minocycline, whereas *tet*(M) confers resistance to all 3. These findings indicate that minocycline can be a useful second-tier drug in the treatment of canine infections caused by some strains of MRSP (eg, ST71) and other multidrug- and doxycycline-resistant strains harboring the tetracycline-resistance gene *tet*(K).[15] Minocycline susceptibility testing should be performed to determine whether minocycline is a valid choice in the treatment of MRSP.

Although doxycycline and minocycline are sometimes considered interchangeable, they have differences in pharmacokinetics and antibacterial activity. Human interpretive breakpoints may overreport minocycline susceptibility, potentially leading to treatment failure; thus, a lower canine-specific breakpoint (ie, susceptibility less than or equal to 0.25 µg/mL as compared with the human breakpoint of 4 µg/mL) has been recommended.[17] A retrospective review of MRSP found that of the 107 isolates tested, 36% were susceptible to tetracycline, 38% to doxycycline, and 65% to minocycline.[1] In the treatment of MRSP, minocycline susceptibility testing should be performed if doxycycline resistance is reported. Resistance to minocycline is indicative of presence of the *tet*(M) gene, whereas susceptibility to minocycline but resistance to doxycycline can occur with presence of the *tet*(K) gene.[18] Therefore, some doxycycline-resistant staphylococci will be susceptible to minocycline. A small prospective study determined that minocycline is an acceptable alternative to doxycycline in the treatment of *Ehrlichia canis* infection in dogs.[19]

As a class, tetracyclines have activity against most *Mycoplasma* spp, spirochetes (including *Borrelia burgdorferi*), *Chlamydia* spp, and *Rickettsia* spp. Against gram-positive bacteria, tetracyclines have inherent activity against staphylococci and streptococci, but resistance in these organisms to tetracyclines is increasing.[1] Gram-positive bacteria usually covered by tetracyclines include *Actinomyces* spp, *Bacillus anthracis*, *Clostridium perfringens*, *Clostridium tetani*, *Listeria monocytogenes*, and *Nocardia* spp. Among gram-negative bacteria, tetracyclines usually have in vitro and in vivo activity against *Bordetella* spp, *Brucella* spp, *Bartonella* spp, *Haemophilus* spp, *Pasteurella multocida*, *Shigella* spp, and *Yersinia pestis*. Many or most strains of *Escherichia coli*, *Klebsiella* spp, *Bacteroides* spp, *Enterobacter* spp, *Proteus* spp, and *Pseudomonas aeruginosa* are resistant to tetracyclines.[20]

Minocycline and doxycycline have significant inhibitory properties against the activity of matrix metalloproteinases (eg, collagenase, gelatinase) and can act as a disease-modifying agent for osteoarthritis. The clinical benefits of this approach are unclear, and concern has been expressed about the use of antimicrobials for nonantimicrobial properties.[21]

Pharmacokinetics

Minocycline is highly lipid-soluble and distributed widely throughout the body. In dogs, minocycline appears to be cleared more rapidly than doxycycline. Therapeutic concentrations can be found in CSF (whether meninges are inflamed or not), saliva, and eyes. Minocycline is extensively metabolized in the liver and excreted primarily as inactive metabolites in the feces and urine. Less than 20% is excreted unchanged in the urine. The half-life in dogs after an oral dose is ≈4 hours.[15] In dogs, administration without food has been recommended due to the impact of food on drug pharmacokinetics. In a study, administration of minocycline with a meal to hounds reduced the peak concentration as compared with fasted dogs, with the overall extent of absorption reduced but not considered significant.[22]

In cats, a dose of minocycline at 5 mg/kg IV resulted in a mean volume of distribution at steady-state (Vdss) of 1.5 L/kg. Plasma protein binding was 60%, total body clearance was 2.9 mL/kg/minute, and elimination half-life was 6.7 hours. An oral dose of minocycline at 50 mg/cat (NOT mg/kg) (mean, 13.9 mg/kg) resulted in a mean oral bioavailability of 62%, and elimination half-life was 6.3 hours.[23]

In a study of adult horses given a single dose of minocycline (2.2 mg/kg IV), mean Vdss was 1.53 L/kg, total body clearance was 0.16 L/hour/kg, and elimination half-life was ≈8 hours. Plasma protein-binding was 68%, and concentration of free minocycline was 0.12 µg/mL at 12 hours.[24] In studies of healthy horses given minocycline at 4 mg/kg PO every 12 hours, time to maximum concentration was 1 to 1.3 hours, maximum serum concentration was 1.6 to 2.3 µg/mL, and steady-state elimination half-life was 8.6 to 12 hours.[25–27] Oral bioavailability was more than doubled (39% vs 16%) when horses underwent a 12 hour fast prior to drug administration and access to hay was delayed for 2 hours after administration.[28] Minocycline pharmacokinetics in foals are similar to pharmacokinetics in adult horses, except oral bioavailability in foals was ≈58%.[27] Minocycline has been detected 1 to 3 hours after administration in pulmonary epithelial lining fluid,[27] brain tissue,[24] CSF,[24,25] tear fluid,[29] synovial fluid, and aqueous humor.[25] Minocycline concentrations in plasma, CSF, and synovial fluid exceeded MIC_{90} for many gram-positive equine pathogens.[25] However, tear fluid levels were inconsistent and oral administration may not be effective in the treatment of ocular infections.[29]

Contraindications/Precautions/Warnings

Minocycline is contraindicated in patients that are hypersensitive to tetracyclines and should be used with caution in patients that are pregnant, nursing, or younger than 6 months due to the potential for enamel hypoplasia or permanent discoloration of the teeth.[30,31] Minocycline is much less likely to cause dental abnormalities than other more water-soluble tetracyclines (eg, oxytetracycline, tetracycline). Unlike either oxytetracycline or tetracycline, minocycline can be used in patients with moderate renal insufficiency without dosage adjustment; however, patients with oliguric renal failure may require dosage adjustment or use of an alternative antibiotic.

Because urine concentrations are low, minocycline is not recommended in the treatment of bacterial cystitis.

For oral use of minocycline, the doxycycline recommendations for administration should be followed to reduce the risk for oroesophageal erosions, particularly in cats. In the use of oral tablets or capsules, pilling should be followed by a bolus of water or food (at least 6 mL for cats).[32] Dry pilling should not be performed.

Adverse Effects

The most commonly reported adverse effects of oral minocycline in dogs and cats are nausea and vomiting. To alleviate these effects, the drug could be given with food although this may impair drug absorption. Dental or bone staining can occur when minocycline exposure occurs in utero or early in life. More rarely, increases in hepatic enzymes and/or ototoxicity are possible. Two research cats (50%) became lethargic and tachypneic after IV administration, and vomiting occurred in 3 (≈30%) cats.[23]

Similar to doxycycline, oral minocycline can cause esophagitis

and esophageal strictures, particularly in cats. See ***Contraindications/Precautions/Warnings*** for more information.

IV injections of minocycline in dogs have caused urticaria, shivering, hypotension, dyspnea, cardiac arrhythmias, and shock when given rapidly[15]; IV administration should be done slowly over a minimum of 10 minutes,[33,34] although 60 minutes is recommended for humans.[31]

Tetracycline therapy—especially long-term—may result in overgrowth (eg, superinfections) of nonsusceptible bacteria or fungi.[30,31]

In humans, minocycline (or other tetracyclines) has also been associated with photosensitivity reactions and, rarely, hepatotoxicity or blood dyscrasias. CNS effects (eg, dizziness, lightheadedness) are commonly reported in humans taking minocycline. A blue-gray pigmentation of skin and mucous membranes may occur.[30,31] Erythema multiforme and Stevens-Johnson syndrome have also been reported in humans; significance in veterinary medicine is unknown.[30,31]

Reproductive/Nursing Safety

Because tetracyclines can delay fetal skeletal development and discolor deciduous teeth, they should only be used in the last half of pregnancy when the benefits outweigh the fetal risks. Minocycline is much less likely to cause these abnormalities than other more water-soluble tetracyclines (eg, oxytetracycline, tetracycline). Minocycline has been shown to impair fertility in male rats.[30,31]

Tetracyclines are excreted in milk. Milk:plasma ratios vary between 0.25 and 1.5. In humans, minocycline may alter milk production or composition. Although minocycline probably has less effect on teeth and bones than other tetracyclines, its use should be avoided during nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral overdoses of minocycline would most likely be associated with GI disturbances (eg, vomiting, anorexia, diarrhea). Although this drug is less vulnerable to chelation with cations than other tetracyclines, oral administration of divalent or trivalent cation antacids may bind some of the drug and reduce GI distress. Treatment is supportive based on clinical signs. If patients develop severe emesis or diarrhea, hydration and electrolytes should be monitored and corrected if necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving minocycline and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Antacids, Aluminum-, Calcium-, and Magnesium Containing**: When orally administered, tetracyclines can chelate divalent or trivalent cations and decrease the absorption of the tetracycline or another drug if it contains these cations. Minocycline has a relatively low affinity for divalent or trivalent cations, but it is recommended that all oral tetracyclines be given at least 1 to 2 hours before or after the cation-containing product.
- **Bismuth Subsalicylate, Kaolin, Pectin**: May reduce absorption of minocycline
- **Digoxin**: Concurrent use with minocycline may cause digoxin toxicity. These effects may persist for months after discontinuation of the tetracycline.
- **Iron, Oral**: Oral iron products are associated with decreased tetracycline absorption, and iron salts should preferably be given 3 hours before or 2 hours after the tetracycline dose.
- **Kaolin/Pectin**: Decreased minocycline absorption is possible; administer oral tetracyclines at least 1 to 2 hours before or after kaolin/pectin.
- **Penicillins**: Bacteriostatic drugs (eg, tetracyclines including minocycline) may interfere with the bactericidal activity of penicillins, cephalosporins, and aminoglycosides; however, there is a fair amount of controversy regarding the actual clinical significance of this interaction.
- **Rifampin**: Synergistic activity against *Rhodococcus equi* in foals may occur.
- **Sevoflurane**: In a study of rats, minocycline reduced sevoflurane MAC requirement by 23%.[35]
- **Sucralfate**: Significantly decreases the oral bioavailability of minocycline in healthy dogs. Administration 2 hours after minocycline did not have a significant impact on absorption of minocycline.[16]
- **Vitamin A**: May result in an increased risk for pseudotumor cerebri
- **Warfarin**: Tetracyclines may depress plasma prothrombin activity; patients on anticoagulant therapy may need dosage adjustment.
- **Zinc, Oral**: Decreased minocycline absorption is possible; administer oral tetracyclines at least 1 to 2 hours before or after oral zinc preparations.

Laboratory Considerations

- Tetracyclines can reportedly cause false-positive **urine glucose** results if the cupric sulfate method of determination (eg, Benedict's reagent, *Clinitest®*) is used, but this may be the result of ascorbic acid that is found in some parenteral formulations of tetracyclines.
- Tetracyclines have reportedly caused false-negative results in determining **urine glucose** when the glucose oxidase method (eg, *Clinistix®, Tes-Tape®*) is used.
- Minocycline may interfere with the fluorescence test for **urinary catecholamines**, causing falsely elevated values.

Dosages

NOTE: No clinical studies using IV minocycline were located. Considering minocycline's bioavailability, use of IV dosages at the lower end of the oral range appears to be reasonable. Doses administered IV should be given over at least 10 minutes.[33,34] Immediate-release formulations are used for oral dosages.

DOGS:

Susceptible infections (extra-label): Dosage information is derived from pharmacokinetic studies rather than clinical trials.[15,16,22,36] 5 – 10 mg/kg PO every 12 hours without food has been suggested. Practically, doses are rounded to the nearest 25 mg if using commercially available, solid, immediate-release dosage forms. 5 mg/kg PO every 12 hours has been recommended for dogs with respiratory disease.[37]

***E canis* infection** (extra-label): 5 – 10 mg/kg PO twice daily for 28 days[19,38]

Adjunctive treatment of canine heartworm disease (extra-label): If doxycycline is unavailable, use minocycline 10 mg/kg PO twice daily for 4 weeks (days 1 through 28 of the American Heartworm Society protocol) along with an approved heartworm preventive.[5,39]

Lyme borreliosis (extra-label): 10 mg/kg IV or PO once or twice daily for 30 days[12]

CATS:

Susceptible infections including respiratory tract infections (extra-label): Based on a pharmacokinetic study and typical bacterial MIC, 8.8 mg/kg PO every 24 hours.[23,37] Anecdotal dosing recommendations range from 5 – 25 mg/kg PO twice daily, whereas 5 – 12.5 mg/kg PO twice daily is commonly noted. Practically, 50 mg/cat (NOT mg/kg) PO every 24 hours is recommended.

HORSES:

Susceptible (MIC less than or equal to 0.25 µg/mL) nonocular infections (extra-label): Based on pharmacokinetic data, 4 mg/kg PO every 12 hours.[25,40] Oral absorption is improved if hay is withheld for 2 hours after administration.[28]

Monitoring

- Clinical efficacy: resolving signs of infection; culture and susceptibility testing if indicated
- Adverse effects (eg, nausea, vomiting)

Client Information

- Oral minocycline works best when given without food. If your animal vomits or acts sick after receiving the medicine on an empty stomach, try giving the next dose with a small amount of food or a treat.
- Do not give as a dry pill. Give this medicine with a moist treat or small amount of liquid to be sure it reaches the stomach. This is especially important in cats as minocycline may cause ulcers in the throat and esophagus if the pill gets stuck there before it reaches the stomach. If your animal has trouble swallowing or eating, contact your veterinarian immediately.
- Do not give antacids, including sucralfate, oral iron, and antidiarrheal medicine, within 2 hours before or after giving minocycline. These other medications will reduce the effectiveness of this antibiotic.
- This drug may make your animal's skin more sensitive to sunlight and increase the risk for sunburn on hairless areas (eg, nose, abdomen, around the eyelids and ears). Tell your veterinarian if you notice any reddening/sunburn on the skin while your animal is on this medication.
- For this medication to work, give it exactly as your veterinarian has prescribed. Always check the prescription label to be sure you are giving the drug correctly. Avoid missing doses and give the full course of medication as directed by your veterinarian even if your animal seems to be back to normal.
- Your veterinarian will need to monitor your animal while it is taking this medicine. Do not miss these important follow-up visits.

Chemistry/Synonyms

Minocycline HCl is a semisynthetic tetracycline that occurs as a yellow crystalline powder. It is soluble in water and slightly soluble in alcohol. Commercial minocycline dosage forms contain minocycline hydrochloride.

Minocycline may also be known as minocyclini hydrochloridum, *Arestin®*, *Minocin®*, or *Solodyn®*; many other trade names are available.

Storage/Stability

Store oral preparations at room temperature in tight containers. Do not freeze oral suspensions. The injectable should be stored at room temperature (20°C-25°C [68°F-77°F]) and protected from light, moisture, and excessive heat. After reconstitution with sterile water for injection, solutions with a concentration of 20 mg/mL are stable for 4 hours at room temperature or for 24 hours if refrigerated.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Minocycline lyophilized powder for injection should be reconstituted with 5 mL sterile water for injection and immediately further diluted with sodium chloride injection USP, dextrose injection USP, dextrose and sodium chloride injection USP, Ringer's injection USP, or lactated Ringer's injection USP. Minocycline is **incompatible** with most medications. If the same IV line is being used for sequential drug administration, the line should be flushed with saline before and after minocycline infusion.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Minocycline HCl Oral Tablets: 50 mg, 75 mg, and 100 mg; generic; (Rx)

Minocycline Extended-Release Tablets: 45 mg, 55 mg, 65 mg, 80 mg, 90 mg, 105 mg, 115 mg, and 135 mg; *Solodyn®*, generic; (Rx)

Minocycline HCl Oral Capsules: 50 mg, 75 mg, and 100 mg; generic; (Rx)

Minocycline HCl Pellet-Filled Oral Capsules: 50 mg and 100 mg; *Minocin®*; (Rx)

Minocycline HCl Powder for Injection: 100 mg in vials; *Minocin®*; (Rx)

Minocycline HCl Powdered Microspheres, Extended-Release, Dental: 1 mg; *Arestin®*; (Rx)

Mirtazapine

(mir-***taz***-ah-peen) *Remeron®, Miratаz®*

Tetracyclic Antidepressant; 5-HT_3 Antagonist

Prescriber Highlights

- ► Transdermal formulation is labeled for management of weight loss in cats. Also used in tablet form as an appetite stimulant and antiemetic in dogs and cats with chronic kidney disease (CKD).
- ► It can be used in conjunction with other antiemetics.
- ► Primary adverse effect is sedation. In cats, vocalization and increased affection can be noted. Serotonin syndrome is possible; check for drug interactions when administering with other medications.
- ► The lowest effective dose should be used to reduce sedative properties. Doses should not exceed 30 mg/day in dogs when using it for appetite stimulation.
- ► Gloves should be worn when handling transdermal mirtazapine. Humans and other animals in the household should avoid contact with the treated cat for at least 2 hours after transdermal administration.

Uses/Indications

Transdermal mirtazapine is indicated in the management of weight loss in cats[1]; the average weight gain in cats was 3.9% of body weight after a 2-week course of therapy.[2] Mirtazapine is an effective appetite stimulant and has antiemetic activity in cats with CKD.[3] Cats receiving mirtazapine tablets ingested significantly more food as compared with placebo. Food ingestion did not correlate with mirtazapine dose, but high doses (ie, 3.75 mg/cat [NOT mg/kg]) of mirtazapine were associated with noticeable behavior changes.[4] In cats with stage 2 or 3 chronic kidney disease, administration of compounded trans-

dermal mirtazapine demonstrated an increased appetite and weight gain; this formulation may benefit cats in countries where the commercial product is not available.[5]

In a study of healthy dogs, mirtazapine accelerated gastric emptying and colonic transit without having an effect on small intestine transit.[6] Mirtazapine can also be used for the treatment of chemotherapy-induced nausea and vomiting.[7]

Pharmacology/Actions

The antidepressant activity of mirtazapine appears to be mediated by antagonism at central presynaptic alpha-2 receptors, which normally act as a negative feedback mechanism, inhibiting further norepinephrine (NE) release. By blocking these receptors, mirtazapine overcomes the negative feedback loop and causes a net increase in NE. This mechanism may also contribute to the appetitestimulating effects of the medication, as NE acts at other α receptors to increase appetite. In addition, mirtazapine antagonizes several serotonin (5-HT) receptor subtypes. The drug is a potent inhibitor of the 5-HT_2, 5-HT_3, and histamine (H_1) receptors. Antagonism at 5-HT_3 receptors accounts for the antinausea and antiemetic effects of the drug, and its action at H_1 receptors produces prominent sedative effects. It is a moderate peripheral α_1-adrenergic antagonist, a property that may explain the occasional orthostatic hypotension associated with its use; it is also a moderate antagonist of muscarinic receptors, which may explain the relatively low incidence of anticholinergic effects.

Pharmacokinetics

In a pilot study in healthy beagles, the mean clearance of mirtazapine was 1193 mL/kg/hour and the mean half-life was 6.17 hours after 20 mg/dog PO.[8]

After administration of oral mirtazapine at either 1.88 mg (low dose [LD]) or 3.75 mg (high dose [HD]) in a study of healthy cats, median elimination half-lives were 9.2 hours and 15.9 hours, respectively. Mean clearance was 10.5 mL/kg/minute (LD) and 18 mL/kg/minute (HD). A single LD of mirtazapine was well tolerated, and the half-life (9 hours) was compatible with 24-hour dose intervals in healthy cats. Mirtazapine does not appear to have linear kinetics in cats.[4] A study in cats with CKD (n = 6) found that the mean half-life was 15.2 hours and the mean oral clearance was 0.6 L/hour/kg.[9] The authors concluded that the results were compatible with administration every 48 hours in cats with CKD.[9] Liver disease delays time to peak concentration (4 hours vs 1 hour) and prolongs elimination half-life (14 hours vs 7 hours) in cats.[10]

Transdermal mirtazapine bioavailability in cats is ≈65%, and peak drug concentration is reached ≈16 hours after administration of a single dose and ≈2 hours after repeated administration.[11] Half-life is 21 to 27 hours,[11] although a shorter half-life (10 to 11 hours) may reflect both topical and oral (ie, grooming) exposure. In healthy cats, transdermal mirtazapine has been shown to reach a steady-state within 14 days. Transdermal time to maximum concentration is 6 hours, with a peak plasma concentration (C_{max}) of 32.1 ng/mL.

After a single PO dose of mirtazapine 2 mg/kg (fasted or fed) in horses, peak concentrations occurred at 2.2 hours (fasted) and 1.3 hours (fed) after administration. The mean residence time of mirtazapine was 6 to 7 hours, and elimination half-life was ≈4 to 5 hours. The authors concluded that mirtazapine might be amenable for long-term oral administration but obtaining additional information concerning safety and efficacy before it is used clinically is critical.[12]

Following oral administration in humans, mirtazapine is rapidly and completely absorbed, but oral bioavailability is ≈50%. C_{max} is reached within ≈2 hours after oral administration. Food has minimal effects on both the rate and extent of absorption and does not require dose adjustment. Plasma protein binding (PPB) for mirtazapine appears to be ≈70% to 72% in mice, rats, and dogs, whereas in humans and rabbits, it is ≈85%. Despite the interspecies differences in PPB, no displacement interactions or dose adjustments for mirtazapine are expected because of its large therapeutic window and nonspecific, relatively low affinity for plasma proteins. Mirtazapine is metabolized via multiple pathways and varies by species. In all species tested (ie, humans and laboratory animals), the drug is metabolized via the following mechanisms: 8-hydroxylation followed by conjugation, *N*-oxidation, and demethylation followed by conjugation. Humans and guinea pigs also produce metabolites via N^+-glucuronidation, whereas mice are the only species that have been found to use demethylation followed by CO_2 addition and conjugation and 13-hydroxylation followed by conjugation as methods of mirtazapine breakdown. These processes are conducted primarily by CYP2D6, CYP1A2, and CYP3A4, but mirtazapine exerts minimal inhibition on these cytochromes. Several metabolic pathways of mirtazapine involve conjugation with glucuronide (glucuronidation). Because cats have a limited capacity for glucuronidation, mirtazapine is cleared less rapidly from the system; therefore, extended dosing intervals may be required.

In humans, elimination occurs via urine (75%) and feces (15%). Renal impairment may reduce elimination by 30% to 50% as compared with normal subjects, and hepatic impairment may reduce clearance by up to 30%. The elimination half-life of mirtazapine ranges from 20 to 40 hours across age and gender subgroups, so dose increases should occur no more frequently than every 7 to 14 days. Females (both human and animal) of all ages exhibit significantly longer elimination half-lives than males (in humans, mean half-life of 37 hours for females versus 26 hours for males).

Contraindications/Precautions/Warnings

Mirtazapine is contraindicated in patients hypersensitive to it and in those that have received monoamine oxidase inhibitors (eg, selegiline) in the past 14 days. Transdermal mirtazapine should not be administered orally or in the eye.

Mirtazapine has been associated with orthostatic hypotension in humans and should, therefore, be used with caution in patients with known cardiac disease or cerebrovascular disease that could be exacerbated by hypotension. Patients with renal impairment, renal failure, or hepatic disease may require lower doses of mirtazapine and should be closely monitored while receiving mirtazapine. Mirtazapine has rarely been associated with hyponatremia in humans; caution should be used in patients receiving a diuretic or other medication that could decrease sodium levels.

In humans, abrupt discontinuation of mirtazapine after long-term administration has resulted in withdrawal symptoms, (eg, nausea, headache, malaise). In general, antidepressants may affect blood glucose concentrations because of their indirect effects on the endocrine system; caution should be used in patients with diabetes mellitus.

Mirtazapine exhibits very weak anticholinergic activity; consequently, vigilance should be used in patients that might be more susceptible to these effects (eg, those with urinary retention; prostatic hypertrophy; acute, untreated closed-angle glaucoma, or increased intraocular pressure; GI obstruction or ileus). Effects of mirtazapine may also be additive to anticholinergic medications.

Extra care should be taken in active animals, as mirtazapine may impair concentration and alertness. Although extremely rare, mirtazapine has been associated with blood dyscrasias in humans and should be used cautiously in patients with the pre-existing hematologic disease, especially leukopenia, neutropenia, and/or thrombocytopenia. Prolongation of the QT interval has been reported, and risk may increase with other QT-prolonging drugs.

Adverse Effects

Mirtazapine appears to be well tolerated in both dogs and cats at the appropriately prescribed dosages. In a study evaluating the adverse

effects of mirtazapine in cats, the 10 most common adverse effects seen (listed from most frequent to least frequent) were vocalization (56%), agitation (31%), vomiting (26.2%), abnormal gait/ataxia (16.7%), restlessness (14.3%), tremors/trembling (14.3%), hypersalivation (13%), tachypnea (11.9%), tachycardia (10.7%), and lethargy (10.7%).[13] Only 1 cat that received a dose of 1.88 mg/cat (NOT mg/kg) dose had adverse effects, whereas 25 cats that received a dose of 3.75 mg/cat (NOT mg/kg) displayed adverse effects. Other adverse effects reported during the study included anorexia, disorientation, dyspnea, hypothermia, mouth breathing/panting, mydriasis, behavior changes, depression/sedation, fasciculations, hyperactivity, hypertension, pacing, dysphoria, inappropriate elimination, polyphagia, circling, discomfort, hiding, inappetence, seizures, and weakness.[13] Increases in liver enzymes have been reported in some cats receiving mirtazapine. Cats experienced more behavioral effects (vocalization, interactions) with 3.75 mg doses as compared with 1.88 mg doses.

Transdermal mirtazapine may cause application site reactions (eg, erythema, crusting/scabbing, residue) in ≈10% of cats.

Reproductive/Nursing Safety

Reproductive studies in rats, rabbits, and dogs have shown no evidence of teratogenicity. Additional studies in hamsters, rabbits, and rats have shown no evidence of fetal genetic mutation or reduction in parental fertility, although there were increases in postimplantation losses and pup deaths, as well as decreases in birth weight.

Mirtazapine is distributed in human breast milk and can be detected in the serum of breastfed infants; caution should be used in nursing dams.

Overdose/Acute Toxicity

Clinical signs associated with mirtazapine overdose include agitation, lethargy, vocalization, panting, and tremors; cats may also develop tachycardia and ataxia.

In humans, mirtazapine ingestion upwards of 10 times the therapeutic dose exhibits minimal toxicity, requiring no acute intervention and only 6 hours of observation. Similar effects were seen in patients receiving up to 30 times the recommended dose. However, serotonin syndrome is possible, and the package insert for mirtazapine recommends that activated charcoal be administered in addition to other standard monitoring activities in an overdose situation.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Mirtazapine is a substrate for several hepatic cytochrome P450 isoenzymes, including 2D6, 1A2, and 3A4. The following drug interactions have either been reported or are theoretical in humans or animals receiving mirtazapine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Benzodiazepines** (eg, **diazepam, midazolam**): Concurrent use has minimal effects on mirtazapine blood levels, but use together may cause additive impairment of motor skills.
- **Buprenorphine**: Concurrent use with mirtazapine may increase the risk for serotonin syndrome.
- **Butorphanol**: Concurrent use with mirtazapine may increase the risk for serotonin syndrome.
- **Cimetidine**: May increase mirtazapine exposure
- **Clonidine**: Concurrent use with mirtazapine may cause increases in blood pressure.
- **CNS Depressants** (eg, **acepromazine, antihistamines**, **gabapentin**): Concurrent use with mirtazapine may increase the risk for sedation and CNS depression.
- **Cyproheptadine**: May negate the effects of mirtazapine
- **Diuretics** (eg, **furosemide**): May increase the risk for hyponatremia
- **Erythromycin**: May increase mirtazapine exposure
- **Ketoconazole**: May increase mirtazapine exposure
- **Monoamine Oxidase Inhibitors (MAOIs;** eg, **amitraz, linezolid, methylene blue, selegiline**): Increased risk for serotonin syndrome when used concurrently with mirtazapine. Concurrent use or use within 14 days is contraindicated.
- **Opioids** (eg, **morphine**): May increase the risk for hyponatremia, sedation, and CNS depression
- **Serotonergic Agents, Miscellaneous** (eg, **buspirone, metoclopramide, ondansetron, trazodone**): Concurrent use with mirtazapine increases the risk for serotonin syndrome.
- **Selective Serotonin Reuptake Inhibitors (SSRIs;** eg, **fluoxetine, fluvoxamine**): Concurrent use with mirtazapine increases the risk for serotonin syndrome.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Concurrent use with mirtazapine increases the risk for serotonin syndrome.
- **Tramadol**: Increased risk for serotonin syndrome when used concurrently with mirtazapine
- **Warfarin**: May prolong prothrombin time (PT) when used concurrently with mirtazapine

Laboratory Considerations

- No specific concerns were noted.

Dosages

DOGS:

Appetite stimulant and/or antiemetic (extra-label): There is little data on mirtazapine pharmacokinetics or efficacy in dogs. Anecdotal dosages ranging from 3.75 – 30 mg/dog (depending on dog size; NOT mg/kg) PO every 24 hours have been suggested. Alternatively, 1.1 – 1.3 mg/kg PO every 24 hours.[14] Doses should not exceed 30 mg/dog (NOT mg/kg) PO once daily.

Chemotherapy-induced anorexia: 0.5 mg/kg PO every 24 hours[7]

CATS:

Management of weight loss (label dosage; FDA-approved): Using the transdermal formulation, apply 1.5-inch ribbon (≈2 mg/cat) to the inner pinna of the cat's ear every 24 hours for 14 days.[1] The person applying medication should wear gloves. Alternate application of ointment between the left and right inner pinnae of the ears.

Appetite stimulant and/or antiemetic (extra-label): **NOTE**: Higher initial doses are not more effective and have more adverse effects.

a) **Healthy cats**: 1.88 mg/cat (NOT mg/kg) PO every 24 hours.[4] Practically, ¼ of a 7.5 mg tablet or ⅛ of a 15 mg tablet PO every 24 hours

b) **Cats with chronic kidney or hepatic disease**: 1.88 mg/cat (NOT mg/kg) PO every 48 hours.[3,10] Practically, ¼ of a 7.5 mg tablet or ⅛ of a 15 mg tablet PO every 48 hours

Chemotherapy-induced anorexia: 0.5 mg/kg PO every 24 to 72 hours[7]

Monitoring

- Clinical efficacy measured by the following parameters: increased appetite, decreased episodes of vomiting, and weight gain
- Liver enzymes in cats
- Adverse effects (eg, behavior, sedation) and signs of serotonin

syndrome (eg, sedation, GI signs, vocalization, agitation, tremors, difficulty breathing, hyperactivity, hyperthermia)

Client Information

- This medicine may be given with or without food. If your animal vomits after receiving the medication on an empty stomach, give it with food or a small treat. If vomiting continues, contact your veterinarian.
- Mirtazapine is usually tolerated well in dogs. Contact your veterinarian if your cat develops side effects as the dose may need to be adjusted. Common side effects include vocalization, behavior changes, and tremors/shaking. Report excessive drowsiness or vocalization to your veterinarian.
- If your animal is receiving orally disintegrating tablets, make sure your hands are dry before handling the tablet. Place the tablet under the animal's tongue and hold the animal's mouth closed for several seconds to allow it to dissolve (should occur quickly). After the tablet has melted, offer the animal water.
- You should wear gloves when handling the transdermal formulation and dispose of them afterward in the regular trash. Be sure you understand how to give this medicine to your animal. Apply the medicine to the inner side of the ear flap and not into the ear canal. After applying the medication, wash your hands with soap and water. Caregivers should avoid contact with the treated area for 2 hours after administration, as the medicine can be absorbed through the skin.

Chemistry/Synonyms

Mirtazapine, a member of the piperazinoazepine group of compounds, is classified as an atypical tetracyclic antidepressant and is not chemically related to other antidepressants. Mirtazapine occurs as a white to creamy white crystalline powder that is slightly soluble in water.

Mirtazapine may also be known as 6-azamianserin, Org-3770, mepirzapine, and *Remeron*®; many trade names for international products are available.

Storage/Stability

Store mirtazapine transdermal ointment at 25°C (77°F) and use it within 30 days after opening.

Store the coated tablets and orally disintegrating tablets between 20°C and 25°C (68°F and 77°F), with excursions permitted between 15°C and 30°C (59°F and 86°F). Protect from light and moisture. The orally disintegrating tablets must be used immediately upon removal from the tablet blister and cannot be stored.

Compatibility/Compounding Considerations

Compounded preparation stability: Mirtazapine 10 mg/mL oral suspension can be compounded from commercially available tablets. Triturate 10 mirtazapine 30 mg tablets with 15 mL of *Ora-Plus*® and qs ad to 30 mL with *Ora-Sweet*®. The resulting suspension retains 90% potency for 90 days stored at both 5°C (41°F) and 25°C (77°F). Compounded mirtazapine suspensions should be protected from light and shaken well before use.[15]

Mirtazapine powder compounded into a transdermal *Lipoderm*® gel at concentrations of 1.88 mg/0.1 mL and 3.75 mg/0.1 mL did not reliably meet compendial standards for potency, as mirtazapine concentration within the gel varied by greater than 10% of target despite concerted efforts of the compounding staff.[5] Transdermal mirtazapine gel prepared by commercial compounding pharmacies have also demonstrated significant variation from the intended product concentration.[16]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Mirtazapine Transdermal Ointment: 100 mg/tube in 5 g tube (20 mg/1 g); *Miratаz*®, (Rx)

HUMAN-LABELED PRODUCTS:

Mirtazapine Oral Tablets: 7.5 mg, 15 mg, 30 mg, and 45 mg; *Remeron*®, generic; (Rx)

Mirtazapine Orally Disintegrating Tablets (ODT): 15 mg, 30 mg, and 45 mg; *Remeron SolTab*®, generic; (Rx). **NOTE**: Some generic ODTs may contain xylitol (unknown quantity).

Misoprostol

(mye-soe-***prost***-ole) *Cytotec*®

Prostaglandin Analogue

Prescriber Highlights

- ► Prostaglandin E1 analogue for treatment or prevention of GI lesions, especially those associated with aspirin therapy; may also be useful for reproductive purposes. Appears ineffective in prevention of glucocorticoid-induced lesions
- ► Contraindications include pregnant animals (but has been used in horses mid-gestation and intravaginally for cervical ripening) and nursing dams (diarrhea in the nursing offspring).
- ► Caution is advised in patients sensitive to prostaglandins or prostaglandin analogues.
- ► Adverse effects include GI distress (eg, diarrhea, abdominal pain, vomiting, flatulence) and potentially uterine contractions and vaginal bleeding in female dogs.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies misoprostol as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Misoprostol may be useful as primary or adjunctive therapy in *preventing* gastroduodenal ulceration in dogs, especially when caused or aggravated by NSAIDs.[1] Although misoprostol can be used for *treatment* of gastric ulcers, other drugs may be equally effective and better tolerated; it does not appear to be effective in reduction of gastric ulceration secondary to glucocorticoid therapy.[2-6] Misoprostol reduces basal gastric acid secretion in horses.[7]

There is limited evidence of efficacy for misoprostol in the treatment of atopic dermatitis in dogs.[8]

Misoprostol's effects on uterine contractility and cervical ripening make it effective as an adjunct treatment for reproductive indications (eg, abortifacient, pyometra) in multiple species.

Pharmacology/Actions

Misoprostol is a synthetic prostaglandin E_1 analogue. It has 2 main pharmacologic effects that make it a potentially useful agent in prevention of upper GI ulceration. It acts via direct action on parietal cells to inhibit basal and nocturnal gastric acid secretion as well as gastric acid secretions stimulated by food, pentagastrin, or histamine—pepsin secretion is decreased under basal conditions, but not when stimulated by histamine. Misoprostol also has a cytoprotective effect on gastric mucosa, likely by increasing production of gastric mucosa and bicarbonate and increasing turnover and blood supply of gastric mucosal cells. Misoprostol enhances mucosal defense mechanisms and healing in response to acid-related injuries.

Other pharmacologic effects include increased amplitude and frequency of uterine contractions, cervical thinning and relaxation, stimulation of uterine bleeding, and total or partial expulsion of uterine contents in pregnant animals.

Pharmacokinetics

Approximately 88% of an oral dose of misoprostol is rapidly absorbed from the GI tract in humans, but a significant amount is me-

tabolized via the first-pass effect. The presence of food and antacids will delay the absorption of the drug. Misoprostol is rapidly de-esterified to misoprostol acid, which is the primary active metabolite. Misoprostol and misoprostol acid are equal in their effects on gastric mucosa.[9] Plasma protein binding of both misoprostol and the acid metabolite is between 81% and 89%.[10]

Misoprostol acid is further biotransformed via oxidative mechanisms to pharmacologically inactive metabolites. These metabolites, free acid, and small amounts of unchanged drug are principally excreted into the urine. In humans, the serum half-life of misoprostol is ≈30 minutes and its duration of pharmacologic effects is ≈3 to 6 hours.

Contraindications/Precautions/Warnings

Misoprostol is contraindicated in patients hypersensitive to it and during pregnancy. The misoprostol product label has a black-box warning against administration in pregnant women due to risk for abortion, premature birth, uterine rupture, or birth defects[11]; this drug should be used with caution in female veterinary patients with reproductive potential that may become pregnant.

Do not confuse miSOPROstol with miFEPRIStone.

The National Institute for Occupational Safety and Health (NIOSH) classifies misoprostol as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[12]

Adverse Effects

In humans, the most prevalent adverse effect seen with misoprostol is GI distress, which usually manifests as diarrhea, abdominal pain, vomiting, and flatulence.[11] Adverse effects are often transient and resolve over several days or may be minimized by dosage adjustment or giving doses with food. Potentially, uterine contractions and vaginal bleeding could occur in female dogs. See ***Contraindications/Precautions/Warnings*** and ***Reproductive/Nursing Safety***.

Reproductive/Nursing Safety

Misoprostol may cause abortion, premature birth, uterine rupture, or birth defects (eg, skull and limb defects, facial malformations) and is contraindicated during pregnancy. However, in humans, it is used intravaginally for cervical ripening to induce labor when spontaneous labor and vaginal delivery is indicated. Misoprostol may impair fertility as pre- and postimplantation losses, and a significant decrease in the number of live pups were noted when high doses were given to male and female breeding rats.

In horses, a study[13] in midgestational pregnant mares given a 5-day course of oral misoprostol 5 µg/kg PO twice daily as a GI mucosal cytoprotectant during colic found that pregnancy was not disrupted and no adverse effects were noted. Cervical tone, ultrasonographic characteristics of the uterus, cervix and conceptus, and progesterone and estrone sulfate concentrations were similar before misoprostol treatment. The authors concluded that additional investigation of treatment at earlier and later stages of gestation, for longer term treatment, and evaluating neonates for developmental disturbances would add further information on safety of misoprostol during gestation.

Misoprostol acid is excreted in milk. Misoprostol is not recommended for lactating dams, as it could potentially cause significant diarrhea in nursing offspring.

Overdose/Acute Toxicity

There is limited information available. Overdoses in laboratory animals have produced diarrhea, GI lesions, emesis, tremors, focal cardiac, hepatic, or renal tubular necrosis, dyspnea, abdominal pain, sedation, tremors, fever, seizures, bradycardia, and hypotension.[11] GI distress (eg, vomiting, diarrhea, abdominal pain) is the most common clinical sign seen in dogs.

Overdoses should be treated seriously, and standard GI decontamination techniques should be employed when applicable. Resultant toxicity should be treated supportively and based on clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving misoprostol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antacids, Magnesium-Containing**: Magnesium-containing antacids may aggravate misoprostol-induced diarrhea. If an antacid is required, an aluminum-only antacid may be a better choice. Antacids and food reduce the rate of misoprostol absorption and may reduce the systemic availability, but these probably do not affect therapeutic efficacy.
- **Oxytocin**: Misoprostol may enhance effects.
- **Phenylbutazone**: Concurrent use may result in neurosensory effects (eg, dizziness, ataxia).

Dosages

DOGS:

Prevention of aspirin-induced gastric injury (extra-label): 3 µg/kg PO every 8 to 12 hours. Efficacy appears similar with dosing intervals of every 8 hours and every 12 hours.[14,15]

Prevention of gastric injury caused by other NSAIDs (extra-label): No controlled studies documenting safety and efficacy were located and no clear evidence currently is available that supports any dosage in dogs.[5] Anecdotal dosage recommendations usually range from 2 – 5 µg/kg PO every 8 to 12 hours, although some have suggested that longer times between doses may be effective and that dosages above 3 µg/kg may be associated with more GI adverse effects.

Adjunctive therapy as an abortifacient (extra-label):

a) Aglepristone 10 mg/kg SC every 24 hours on 2 consecutive days and misoprostol 200 µg/bitch (NOT µg/kg) for bitches weighing less than or equal to 20 kg (44 lb) or 400 µg/bitch (NOT µg/kg) for bitches weighing more than 20 kg (44 lb) intravaginally once daily until completion of abortion. In a study, all bitches in the treatment group aborted within 6 days.[16]

b) Misoprostol 1 – 3 µg/kg administered as a vaginal suppository once daily to promote cervical dilation. This allows for a reduced dinoprost (PGF2alpha) dose of 0.1 mg/kg SC every 8 hours for 2 days, then 0.2 mg/kg SC every 8 hours to effect. Abortion usually occurs after 5 days.[17]

Pyometra and metritis (extra-label): Give aglepristone 10 mg/kg SC on days 1, 2, 8, 15, and 29. Give misoprostol 10 µg/kg PO twice daily on days 3 through 12. Approximately 75% of cases showed significant clinical improvement without developing the adverse effects associated with the prostaglandins (PGF2alpha, cloprostenol).[18]

Adjunctive therapy for atopic dermatitis (extra-label): Target dosage of 5 µg/kg PO 3 times daily. Modest improvement in clinical signs.[19] **NOTE**: This is not recommended as a first-choice therapy, and efficacy is questionable.

CATS:

GI adverse effects associated with NSAID use (extra-label): No controlled studies documenting safety or efficacy in cats were

located. When adverse GI effects are observed in cats receiving NSAIDs, NSAID therapy should be withheld and appropriate supportive therapy introduced until any mucosal lesions have healed.[20] If NSAID therapy is reinstituted, it should be done so at the lowest effective dose, with consideration given to the concomitant use of misoprostol 5 µg/kg PO every 8 hours or omeprazole 0.7 – 1 mg/kg PO once daily and/or a different NSAID where licensing/approval permits.[20]

Adjunctive therapy as an abortifacient (extra-label): Aglepristone 10 mg/kg SC every 24 hours on 2 consecutive days and misoprostol 200 µg/queen (NOT mg/kg) PO every 12 hours until the start of abortion. In a study, treatments began on the same day; abortion began within ≈3 to 6 days of beginning treatment and were completed within ≈5 to 7 days of beginning treatment.[21] Misoprostol as a single agent was ineffective as an abortifacient.

HORSES:

GI mucosal cytoprotectant (extra-label): 5 µg/kg PO every 8 to 12 hours[7,13]

Equine glandular disease (extra-label): 5 µg/kg PO every 12 hours, 1 hour prior to feeding[22]

Inducing cervical relaxation (extra-label): From a case report of postbreeding endometritis in a maiden mare in which the cervix remained closed during estrus and acted as a barrier to uterine clearance[23]: After uterus was lavaged and catheter removed, misoprostol 1000 µg/mare (NOT µg/kg) as a compounded cream was applied to the caudal os and lumen of the cervix. Oxytocin 20 Units/mare (NOT µg/kg) IM was administered immediately following lavage and again every 6 hours until the following morning. Separately, a study using misoprostol 1000 µg/mare (NOT µg/kg) in 1.5 g of a compounded cream applied to the external cervical os failed to induce a measurable degree of cervical relaxation.[24]

Unexplained infertility (extra-label): 200 µg (total amount; NOT µg/kg) diluted in 3 mL sterile water and applied deep in the uterine horn, as close as possible to the papilla of the uterine tube; perform in each horn[25]

COWS:

Induction of parturition (extra-label): 200 – 400 µg/cow (NOT µg/kg) intravaginally every 6 hours to a maximum of 6 doses. Misoprostol tablets were moistened with drops of water prior to insertion.[26]

SHEEP:

Cervical relaxation (extra-label): May improve depth of cervical penetration when nonsurgical access to the uterus is needed.

a) 200 µg/ewe (NOT µg/kg) diluted in 1.5 mL 0.9% NaCl and applied directly to the cervix 5 hours prior to the procedure (eg, artificial insemination, embryo collection/transfer). **NOTE**: Ewes were also given cloprostenol 37.5 µg/ewe (NOT µg/kg) IM 12 hours prior to the procedure. Degree of cervical dilation improved when treatment was also combined with a compounded formulation of estradiol benzoate 100 µg/ewe (NOT µg/kg; diluted with 2.5 mL 0.9% NaCl and 2.5 mL ethanol) IV 12 hours prior and oxytocin 100 Units/ewe (NOT Units/kg) IV 15 minutes prior to cervical transposition.[27]

b) Misoprostol 1000 µg/ewe (NOT µg/kg) and terbutaline 5 mg/ewe (NOT mg/kg) combined and dissolved in 4 mL glycerol. The resulting mixture was filtered and applied vaginally near the cervix 6 hours prior to artificial insemination.[28]

Monitoring

- Efficacy based on indication for use
- Adverse effects (eg, vomiting, diarrhea, flatulence)
- Absence of pregnancy prior to initiating misoprostol therapy when it is being used for non-abortifacient indications.

Client Information

- Give this medicine with food if stomach upset occurs or to prevent stomach upset.
- Common side effects include diarrhea, abdominal/stomach pain, vomiting, and flatulence (ie, gas). These effects may only last a few days, and giving the drug with food may help, but if any of these effects are severe, get worse, or continue to be a problem, contact your veterinarian.
- This medicine is considered to be a hazardous drug because it may affect the reproductive ability of males or females actively trying to conceive, women who are pregnant or may become pregnant, as it can cause miscarriage, and women who are breastfeeding. It is recommended that you wear gloves when administering this medicine to your animal and wash your hands thoroughly afterwards. If you have questions about this medicine's hazards, please speak with your veterinarian or pharmacist.

Chemistry/Synonyms

Misoprostol, a synthetic prostaglandin E_1 analogue, occurs as a yellow, viscous liquid with a musty odor.

Misoprostol may also be known as SC-29333, *Arthrotec*®, or *Cytotec*®.

Storage/Stability

Misoprostol tablets should be stored in well-closed containers at room temperature of 25°C (77°F) or less.

Compatibility/Compounding Considerations

Misoprostol has been compounded into a variety of vehicles (eg, sterile water,[25] sterile saline solution,[27] glycerol,[28] gum acacia[29]) for inducing cervical relaxation. As stability and potency were not validated, these formulations should be prepared at the time of administration for 'immediate-use' only.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 5 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Misoprostol Tablets: 100 and 200 µg; *Cytotec*®, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Mitotane

(***mye***-toe-tane) *Lysodren®, o,p'-DDD*

Antineoplastic

Prescriber Highlights

- ► Adrenal cytotoxic agent used for medical treatment of pituitary-dependent hyperadrenocorticism in dogs and ferrets
- ► Caution with pregnancy, diabetes mellitus, and pre-existing renal or hepatic disease
- ► Adverse effects include lethargy, ataxia, weakness, anorexia, vomiting, and/or diarrhea; liver changes possible
- ► Relapses are not uncommon.
- ► All dogs receiving mitotane therapy should receive additional glucocorticoid supplementation if undergoing stress (eg, surgery, trauma, acute illness).
- ► Monitoring is mandatory.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies mitotane as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

In veterinary medicine, mitotane is used primarily for the medical treatment of pituitary-dependent hyperadrenocorticism (PDH) when there are clinical signs present (eg, polyuria, polydipsia, polyphagia) that are consistent with this condition. Mitotane has also been used for the palliative treatment of adrenal carcinoma in humans and dogs.[1]

Approximately 80% of dogs with PDH respond to mitotane treatment.[1] However, trilostane is the preferred treatment of PDH, as retrospective studies[2-4] found no qualitative or statistical difference in survival times in dogs treated with mitotane or trilostane, and mitotane typically causes more adverse effects than trilostane.

In cats, mitotane is not recommended, as it is ineffective and may be poorly tolerated.[5]

Pharmacology/Actions

Although mitotane is considered an adrenal cytotoxic agent, it apparently can also inhibit adrenocortical function without causing cell destruction. The exact mechanisms of action for these effects are not clearly understood. Mitotane also inhibits several enzymes responsible for corticosteroid production.

In dogs with PDH, mitotane has been demonstrated to cause severe, progressive necrosis of the zona fasciculata and zona reticularis. These effects occur quite rapidly (usually within 5-10 days of starting therapy). It has been stated that mitotane spares the zona glomerulosa and therefore aldosterone synthesis is unaffected; however, this is only partially true as the zona glomerulosa may also be affected by mitotane therapy although it is uncommon for clinically significant effects on aldosterone production to be noted with therapy. Additionally, dogs with PDH that are treated with mitotane demonstrate decreased aldosterone secretion 30 and 60 minutes after ACTH stimulation compared to healthy controls.[6]

Pharmacokinetics

In dogs, the systemic bioavailability of mitotane is poor. Oral absorption can be enhanced by giving the drug with food (especially food high in oil/fat). In humans, ≈40% of an oral dose of mitotane is absorbed after dosing, with peak serum concentrations occurring ≈3 to 5 hours after a single dose. Distribution of the drug occurs to virtually all tissues in the body. The drug is stored in the fat and does not accumulate in the adrenal glands. A small amount may enter the CSF.

Mitotane has a very long plasma half-life in humans, ranging from 18 to 159 days. Serum half-lives may increase in a given patient with continued dosing, perhaps due to a depot effect from adipose tissue releasing the drug. The drug is metabolized in the liver and is excreted as metabolites in the urine and bile. Within 24 hours of dosing, ≈15% of an oral dose is excreted in the bile and 10% in the urine.

Contraindications/Precautions/Warnings

Mitotane is contraindicated in patients known to be hypersensitive to it. Mitotane should only be used to treat patients that have clinical signs *and* laboratory testing consistent with hyperadrenocorticism; it should never be administered to sick patients (eg, lethargy, inappetence).

Hepatic impairment may interfere with mitotane metabolism. Dogs with pre-existing renal or hepatic disease should receive the drug with caution and with more intense monitoring.

Patients with concurrent diabetes mellitus may have rapidly changing insulin requirements during the initial treatment period; closely monitor insulin requirements to avoid insulin overdose until effects of hyperadrenocorticism are controlled.

Some clinicians recommend giving prednis(ol)one at 0.2 mg/kg/day (0.4 mg/kg/day to diabetic dogs) PO during the induction treatment period to reduce the potential for adverse effects from acute endogenous steroid withdrawal.[7] Other clinicians have argued that routinely administering glucocorticoids masks the clinical markers that signify when the endpoint of therapy has been reached and that steroids must be withdrawn 2 to 3 days before ACTH stimulation tests can be done. The benefits of routine glucocorticoid administration may not be warranted because, in adequately observed patients, adverse effects requiring glucocorticoid therapy may only be necessary in 5% of patients.

When mitotane is prescribed, owners should always be provided a small supply of predniso(lo)ne or dexamethasone tablets so that they can initiate emergency treatment for Addisonian crisis if this occurs. Dexamethasone is the preferred corticosteroid for treatment, as it will not interfere with the ACTH stimulation test. If prednisone or prednisolone are used, an ACTH stimulation test cannot be accurately performed for at least 24 hours after administration because of cross reactivity of these drugs in cortisol assays.

The National Institute for Occupational Safety and Health (NIOSH) classifies mitotane as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[8]

Adverse Effects

The most common adverse effects seen with initial therapy in dogs include lethargy, ataxia, weakness, anorexia, vomiting, and/or diarrhea. Neurologic signs can be seen but are not common. Adverse effects are commonly associated with plasma cortisol concentrations of less than 1 µg/dL or a too rapid decrease of plasma cortisol concentrations into the normal range. Adverse effects may also be more commonly seen in dogs weighing less than 5 kg, which may be due to the inability to accurately dose mitotane because of limited tablet size availability. The incidence of one or more of these effects is ≈25%, and they are usually mild. If mild adverse effects are noted, it is recommended to halt mitotane therapy. If moderate to severe signs are noted (especially GI in nature; moderate to severe vomiting, and/or diarrhea), halt mitotane therapy and supplement with glucocorticoid therapy.

Mitotane decreases aldosterone secretory reserve.[9] Rarely, an Addisonian crisis can occur during therapy. Owners should be warned about this life-threatening complication and counseled on the clinical signs of an Addisonian crisis. If such signs occur, owners need to discontinue mitotane therapy, administer glucocorticoid replacement therapy, and seek veterinary care immediately.

Liver changes (congestion, centrilobular atrophy, and moderate to severe fatty degeneration) have been noted in dogs given mitotane.

Although not commonly associated with clinical signs, these effects may be more pronounced with long-term therapy or in dogs with pre-existing liver disease.

In ≈5% of dogs treated, long-term glucocorticoid and sometimes mineralocorticoid replacement therapy may be required. All dogs receiving mitotane therapy should receive additional glucocorticoid supplementation if undergoing a stressful event (eg, surgery, trauma, acute illness).

Relapses are not uncommon in dogs receiving mitotane for hyperadrenocorticism.

Reasons for treatment failure include misdiagnosis, adrenal tumors unresponsive to mitotane, loss of drug potency, administration of drugs that interfere with mitotane metabolism (eg, phenobarbital), or inadequate mitotane dose for that particular patient.

Reproductive/Nursing Safety

Mitotane crosses the placenta and is known to have caused preterm births and early pregnancy loss in humans.

Mitotane is excreted in human maternal milk and nursing is not recommended during mitotane therapy.

Overdose/Acute Toxicity

There are no specific recommendations regarding overdoses of mitotane. Because of the drug's toxicity and long half-life, emptying the stomach and administering charcoal and a cathartic should be considered after a recent ingestion. It is recommended that the patient be closely monitored; clinical signs associated with hypoadrenocorticism may require treatment with corticosteroids, mineralocorticoids, and IV fluids.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

In humans, mitotane induces the CYP3A4 enzyme and may increase the metabolism of other drugs that are substrates of this cytochrome P450 enzyme system. The following drug interactions have either been reported or are theoretical in humans or animals receiving mitotane and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **CNS Depressant Drugs** (eg, **acepromazine, methocarbamol**): If mitotane is used concomitantly with drugs that cause CNS depression, additive depressant effects may be seen.
- **Dexamethasone**: Mitotane may reduce dexamethasone concentration.
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**): Mitotane may reduce estrogen concentration.
- **Fentanyl**: Mitotane may increase fentanyl metabolism.
- **Insulin**: Diabetic dogs receiving insulin may have decreased insulin requirements after starting mitotane therapy.
- **Itraconazole**: Mitotane may reduce itraconazole concentration; it is recommended to avoid this combination in humans.
- **Midazolam**: Mitotane may increase midazolam metabolism.
- **Phenobarbital**: Phenobarbital can induce enzymes and reduce the efficacy of mitotane; conversely mitotane can induce hepatic microsomal enzymes and increase the metabolism of phenobarbital.
- **Praziquantel**: Mitotane may reduce praziquantel concentration; it is recommended to avoid this combination in humans.
- **Rivaroxaban**: Mitotane may reduce rivaroxaban concentration; it is recommended to avoid this combination in humans.
- **Selegiline**: Mitotane may increase selegiline metabolism and result in loss of efficacy.
- **Spironolactone**: In dogs, spironolactone has been demonstrated to block the action of mitotane; it is recommended to use an alternate diuretic if possible.
- **Warfarin**: Mitotane may increase warfarin metabolism.

Laboratory Considerations

- Mitotane will bind competitively to thyroxine-binding globulin and decreases the amount of serum protein-bound iodine. Serum **total thyroxine (tT_4)** concentrations may be unchanged or slightly decreased, but free thyroxine (fT_4) concentrations remain in the normal range. Mitotane does not affect the results of the resin triiodothyronine uptake test.
- Mitotane can reduce the amount of measurable **17-OHCS** in the urine, which may or may not reflect a decrease in serum cortisol levels or adrenal secretion.

Dosages

DOGS:

Medical treatment of pituitary-dependent hyperadrenocorticism (bilateral adrenal hyperplasia) (extra-label): **NOTE**: Treatment with mitotane can be very complex and potentially serious adverse effects can occur. Use requires vigilance by the veterinarian and pet owner for monitoring therapy. The reader is advised to refer to the original references for more detail or to the review by Reine.[1] The following are synopses of published dosing protocols; choose one ONLY:

a) Induction phase: Mitotane 30 – 50 mg/kg/day PO with a meal once daily or divided every 12 hours for 7 to 10 days. If adverse effects (lethargy, vomiting, weakness, diarrhea) occur, discontinue mitotane and give glucocorticoids (prednis(ol) one at 0.15 – 0.25 mg/kg/day) until dog can be evaluated. If decreased appetite occurs, discontinue mitotane and evaluate with an ACTH stimulation test. Perform ACTH stimulation test at end of 10-day period or sooner if adverse effects occur. Goal is to have basal and post-ACTH cortisol between 1 and 5 µg/dL (normal basal level for most labs). If basal and post-ACTH cortisol falls below 1 µg/dL, temporarily suspend mitotane and supplement with glucocorticoids until circulating cortisol normalizes (usually 2 to 4 weeks, but may take several weeks to months). If basal or post-ACTH cortisol is above normal, continue daily mitotane and recheck ACTH stimulation tests at 5 to 10 days intervals until serum cortisol falls within normal resting range. Begin maintenance dose when desired cortisol concentrations are documented by ACTH stimulation testing. Mitotane given initially at 35 – 50 mg/kg per week in 2 to 3 divided doses. If adverse effects occur, discontinue mitotane and supplement with glucocorticoids until dog can be evaluated by serum electrolytes and ACTH stimulation test. If ACTH stimulation tests are above desired range, the maintenance dose can be cautiously increased. If dose increase fails to normalize clinical signs and cortisol levels, induction can be repeated.[10]

b) Initial dose: Mitotane 50 mg/kg divided every 12 hours. Glucocorticoids are not usually administered concurrently, but a small supply of prednis(ol)one should be made available to the owner for emergencies. Continue until water consumption decreases to less than 100 mL/kg/day, or until a decreased appetite, depression, diarrhea, or vomiting are observed. The time for clinical response is quite variable but most dogs respond within 3 to 7 days. At this point the dog should be re-evaluated and an ACTH stimulation test performed. Prednis(ol)

one treatment (0.2 mg/kg/day) should be initiated in patients that are showing clinical signs of hypocortisolemia, until the results of the ACTH stimulation test are known. In patients that are not polydipsic prior to therapy, where water consumption cannot be monitored, and whose polydipsia is due to another cause (eg, diabetes mellitus), mitotane should be administered for a maximum of 5 to 7 days prior to ACTH stimulation testing. The goal of treatment is to have both the pre- and post-cortisol measurement in the normal resting range (2 - 6 µg/dL). Maintenance therapy: Mitotane 50 mg/kg every 7 to 10 days divided over multiple days is started once the ACTH stimulation test shows adequate suppression and prednis(ol)one therapy (if necessary) has been discontinued. Failure to use maintenance therapy will result in regrowth of the adrenal cortex and recurrence of clinical signs. Efficacy of maintenance therapy is monitored by an ACTH stimulation test after 1 month of maintenance treatment and then every 3 months. The dose of mitotane required for long-term maintenance is variable: 26 – 330 mg/kg/week.[11]

c) Intentionally causing complete destruction of the adrenal cortex as an alternative to the traditional mitotane treatment: Mitotane 75 – 100 mg/kg/day for 25 consecutive days, given in 3 to 4 doses per day with food. Lifelong prednisone at 0.1 – 0.5 mg/kg PO twice daily initially and mineralocorticoid therapy is begun at the start of mitotane therapy. Prednisone dose is tapered after completion of the 25 day protocol. Relapse is common and periodic ACTH stimulation testing is necessary. May be considerably more expensive than traditional therapy because of the expense associated with treating Addisonian dogs.[12]

d) Total adrenal ablation for management of Cushing's disease: Mitotane 100 mg/kg/day divided twice daily for 30 days. Supplemental cortisone acetate 2 mg/kg/day divided twice daily and fludrocortisone acetate 0.1 mg/4.5 kg (10 lb) of body weight PO once daily are begun on day 1 of mitotane therapy. Diet is supplemented with 1 – 5 g of sodium chloride per day. One week after induction phase with mitotane, cortisone acetate is reduced to 1 mg/kg/day. Electrolytes and ACTH stimulation test are performed at end of induction, every 6 months thereafter, and at any time the patient demonstrates signs of either hypo- or hyperadrenocorticism. This form of management requires close patient monitoring and lifelong daily therapy. Close attention during stress and nonadrenal illnesses required.[13]

Palliative medical treatment of adrenal carcinomas or medical treatment of adrenal adenomas (extra-label):

a) Mitotane 50 – 75 mg/kg PO in daily divided doses for 5 days then every other day for over 40 days. Smaller dog breeds may require up to 100 mg/kg/day. Beginning on the third day of treatment, supplement with predniso(lo)ne 0.4 mg/kg/day, fludrocortisone 0.0125 mg/kg/day, and salt 0.1 g/kg/day. If adverse effects occur, stop mitotane (but not supplemental corticosteroids) therapy and evaluate dog. After day 45, assess treatment by withholding the evening doses of prednis(ol)one and fludrocortisone and the re-evaluate the following morning. After initial therapy, continue mitotane 50 – 75 mg/kg PO once per week and predniso(lo)ne 0.1 – 0.2 mg/kg/day, fludrocortisone 0.0125 mg/kg/day, and salt for at least 6 months.[14]

b) Initially, mitotane 50 – 75 mg/kg PO in daily divided doses for 10 to 14 days.[15,16] May supplement with predniso(lo)ne 0.2 mg/kg/day. Stop therapy and evaluate dog if adverse effects occur. After initial therapy, run ACTH stimulation test (do not give prednis(ol)one the morning of the test). If basal or post-ACTH serum cortisol values are decreased, but still above the therapeutic end-point (less than 1 µg/dL), repeat therapy for an additional 7 to 14 days and repeat testing. If post-ACTH serum cortisol values remain greatly elevated or unchanged, increase mitotane to 100 mg/kg/day and repeat ACTH stimulation test at 7- to 14-day intervals. If ACTH continues to remain elevated, increase dosage by 50 mg/kg/day every 7 to 14 days until response occurs or drug intolerance ensues. Adjust dosage as necessary as patient tolerates or ACTH-responsive dictates. Once undetectable or low-normal post-ACTH cortisol levels are attained, continue mitotane 100 – 200 mg/kg/week in divided doses with glucocorticoid supplementation (predniso(lo)ne 0.2 mg/kg/day). Repeat ACTH stimulation test in 1 to 2 months. Continue at present dose if cortisol remains below 1 µg/dL. If cortisol increases to 1 – 4 µg/dL, increase maintenance dose by 50%. If basal or post-ACTH cortisol goes above 4 µg/dL, restart daily treatment of mitotane 50 to 100 mg/kg/day as outlined above. Once patient is stabilized, repeat ACTH stimulation tests at 3 to 6 month intervals.[17]

FERRETS:

Medical treatment of hyperadrenocorticism where surgery has not been performed or tumor has not been fully resected (extra-label): 50 mg per ferret (NOT mg/kg) PO once daily for 1 week, then 50 mg per ferret (NOT mg/kg) PO 2 to 3 times per week. Have a compounding pharmacy make 50 mg capsules. Capsules can be easily administered if coated with a substance such as *Nutrical*.[18,19] This treatment may no longer be recommended.

Monitoring

Initially and as needed (see ***Dosages***):

- Physical examination and history (including water and food consumption, weight)
- Reduction of clinical signs related to hyperadrenocorticism
- Adverse effects. A life-threatening adverse effect of mitotane therapy can be an Addisonian crisis (eg, vomiting, diarrhea, collapse, shock). Monitor closely during therapy for this potential complication; daily communication with the pet owner during the induction period of mitotane therapy (ie, the first 7 to 10 days) is recommended.
- ACTH stimulation testing: See ***Dosages*** for monitoring during induction phase of treatment. Once maintenance therapy is started, perform ACTH stimulation test after 1, 3, and 6 months; repeat every 3 months to monitor level of control (sooner if dog develops clinical signs). See ***Cosyntropin***.
- Periodic CBC and serum chemistry profile with electrolytes
- Blood pressure

Client Information

- Mitotane treatment requires intensive monitoring and close supervision by your veterinarian. Keep in close contact with your veterinarian while your animal is on this medication and report any concerns you may have as soon as possible. **Contact your veterinarian immediately if you notice any vomiting, diarrhea, poor appetite, low energy level, weakness, or stumbling.**
- The drug should be given with food.
- You will usually see positive effects (ie, animal eats, drinks, and urinates less) in 5 to 14 days after starting this medicine. Contact your veterinarian when this occurs so that your animal can be tested for completion of the initial phase of treatment.
- Your animal will need to be monitored closely while on this medication. Do not miss important follow-up visits.
- If your animal requires surgery or has been injured, be sure to tell your veterinarian that your animal has been taking this medication. Mitotane can decrease the body's ability to handle stress,

and medications such as prednisone may be needed during these times.

- Pregnant women should not handle this drug; others should wear disposable gloves whenever handling the drug.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Mitotane, also commonly known in veterinary medicine as o,p'-DDD, is structurally related to the infamous insecticide, chlorophenothane (DDT). It occurs as a white, crystalline powder with a slightly aromatic odor. It is practically insoluble in water and soluble in alcohol.

Mitotane may also be known as CB-313, o,p'DDD, NSC-38721, WR-13045, *Lysodren®*, or *Lisodren®*.

Storage/Stability

Mitotane tablets should be stored at room temperature (15°C-30°C [59°F-86°F]) in tight, light-resistant containers.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Mitoxantrone

(mye-toe-***zan***-trone) *Novantrone®*
Antineoplastic

Prescriber Highlights

- ► Used to treat a variety of neoplastic diseases in dogs and cats
- ► Less risk for nephrotoxicity and less cardiotoxic than doxorubicin, but more myelosuppressive than doxorubicin
- ► Contraindications include hypersensitivity to the drug.
- ► Use with caution in patients with myelosuppression, concurrent infection, hyperuricemia or hyperuricuria, hepatic dysfunction, and in patients that have received prior cytotoxic drug or radiation exposure.
- ► Adverse effects include dose-dependent GI distress (eg, vomiting, diarrhea, anorexia), myelosuppression (primarily neutropenia), lethargy, and seizures (in cats).
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies mitoxantrone as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Mitoxantrone may be used in the treatment of several neoplastic diseases in dogs and cats, including lymphoma, mammary adenocarcinoma, squamous cell carcinoma, renal adenocarcinoma, fibrosarcoma, thyroid or prostate carcinoma, anal sac adenocarcinoma, and hemangiopericytoma. When used with piroxicam, mitoxantrone has shown efficacy for treating transitional cell bladder carcinoma in dogs.[1–3] Mitoxantrone is commonly used in veterinary medicine as an alternative to doxorubicin in the presence of cardiac dysfunction, and may be a reasonable substitution in a CHOP protocol.[4,5] In dogs, mitoxantrone has limited value when used as a single agent for treatment of the first relapse of lymphoma[6]; however, it may be useful as part of a rescue protocol when combined with dacarbazine for resistant lymphoma.[7]

Mitoxantrone is less nephrotoxic than doxorubicin and may be a safer option in cats with renal insufficiency.

Pharmacology/Actions

Mitoxantrone is a DNA-reactive agent that binds in between DNA base pairs, causing crosslinks and strand breaks. Mitoxantrone also interferes with RNA synthesis and is a potent topoisomerase II inhibitor. Mitoxantrone is not cell cycle phase-specific but appears to be most active during the S phase.

Pharmacokinetics

Mitoxantrone is rapidly and extensively distributed after IV infusion. The highest concentrations of the drug are found in the liver, heart, thyroid, and red blood cells. Penetration into the CNS is low. In humans, it is ≈78% bound to plasma proteins. Mitoxantrone metabolism is poorly understood, but the drug's clearance is reduced in patients with hepatic impairment. Roughly 10% of the drug is excreted in the urine, and ≈25% in the feces. In humans, half-life is based on a 3-compartment model, and the drug can be detected for ≈5 days following administration secondary to the drug being taken up, bound, and then slowly released by tissues.

Contraindications/Precautions/Warnings

Mitoxantrone is contraindicated in patients with a history of hypersensitivity and should be used with caution in patients with myelosuppression, concurrent infection, hyperuricemia or hyperuricuria, or those that have received prior cytotoxic drug or radiation exposure. Use mitoxantrone with caution in patients with hepatic impairment and dose adjustment may be required.

One study in dogs receiving their first dose of mitoxantrone 5 mg/m^2 found that dogs weighing 10 kg (22 lb) or less were significantly more likely to develop grade 3 or grade 4 neutropenia than dogs over 10 kg (22 lb); a reduction of the initial dose can be considered for dogs weighing less than 10 kg (22 lb).[8]

Mitoxantrone is not for intrathecal use; severe injury can occur. In humans, congestive heart failure can occur during or long after therapy with mitoxantrone; cardiotoxicity risk increases with increasing cumulative dose.[9]

Mitoxantrone is considered an irritant (rarely, a vesicant) and care should be taken to avoid extravasation.[9]

The National Institute for Occupational Safety and Health (NIOSH) classifies mitoxantrone HCl as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Mitoxantrone is considered a high-alert medication (medications that require special safeguards to reduce the risk for errors). Consider instituting practices such as redundant drug dosage and volume checking, and special alert labels.

Adverse Effects

In dogs and cats, adverse effects include dose-dependent GI distress (eg, nausea, vomiting, anorexia, diarrhea) and myelosuppression, which can lead to infection and sepsis. Neutropenia has been established as the dose-limiting toxicity in dogs.[8,10,11] Nonregenerative anemias may be detected, and white cell nadirs generally occur on day 7 to 10. Some evidence exists that by giving recombinant granulocyte-colony stimulating factor, myelosuppression severity and duration may be reduced.[12] Lethargy may also be noticed. Some cats receiving this drug have developed seizures. Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or Old English sheepdogs) are more likely to experience significant alopecia.

Unlike doxorubicin, cardiotoxicity has not yet been reported in dogs and rarely occurs in humans. Other adverse effects less frequently or rarely noted in humans and possible in dogs include conjunctivitis, jaundice, renal failure, seizures, allergic reactions, cough or dyspnea, thrombocytopenia, bleeding or bruising, and irritation or phlebitis at the injection site. Tissue necrosis associated with extravasation has only been reported in a few human cases.

Reproductive/Nursing Safety

In humans, mitoxantrone is excreted in maternal milk and significant concentrations (18 ng/mL) have been reported for 28 days after the last administration.[9] Because of the potential for serious adverse effects in offspring, it is recommended to use milk replacer if mitoxantrone is administered. For sexually intact patients, verify pregnancy status prior to administration.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The LD_{50} following IV administration to mice is 66 mg/kg. Because of the potential serious toxicity associated with this agent, dosage determinations must be made carefully. No specific antidote is known; treatment is supportive. Reported effects after an overdose in dogs include neutropenia, thrombocytopenia, anemia, diarrhea, anorexia, vomiting, lethargy, nausea, and death.[13]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Mitoxantrone is a substrate for ABCB1 (P-glycoprotein) and ABCG2 and it is likely that there are other interacting drugs yet to be identified. The following drug interactions have either been reported or are theoretical in humans or animals receiving mitoxantrone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Cyclosporine**: May increase mitoxantrone's toxic effects
- **Doxorubicin**, **Daunorubicin**, or **Radiation Therapy**: Cardiotoxicity risks may be enhanced in patients that have previously received doxorubicin, daunorubicin, or radiation therapy to the mediastinum.
- **Immunosuppressive Drugs** (eg, **azathioprine, cyclophosphamide, corticosteroids**): Use with other immunosuppressant drugs may increase the risk for infection.
- **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other myelosuppressive drugs may result in additive myelosuppression; avoid combination when possible.
- **Vaccines** (live and inactivated): Mitoxantrone may diminish vaccine efficacy and enhance adverse effects of vaccines.

Laboratory Considerations

- Mitoxantrone may raise serum **uric acid** concentrations. Drugs such as allopurinol may be required to control hyperuricemia.
- **Liver function tests** may become abnormal, indicating hepatotoxicity.
- Mitoxantrone may discolor **urine** to a green-blue color.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and because chemotherapy indications, treatment protocols, monitoring and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[14–18] are strongly recommended.

DOGS:

Treatment of susceptible neoplastic diseases (extra-label): Used in chemotherapy protocols with other chemotherapeutic agents; commonly dosed at 5 – 6 mg/m^2 (NOT mg/kg) IV once every 21 days.[4–7,19–21] Must be diluted in 0.9% sodium chloride or 5% dextrose prior to administration and should be infused over a minimum of 5 minutes. Consider using a lower first dose for dogs weighing 10 kg (22 lb) or less due to increased risk for severe neutropenia.[8]

CATS:

Treatment of neoplastic diseases (extra-label): 5.5 – 6.5 mg/m^2 (NOT mg/kg) IV once every 21 days.[22] Must be diluted in 0.9% sodium chloride or 5% dextrose prior to administration, and should be infused over a minimum of 5 minutes

Monitoring

- Efficacy: tumor or lymph node measurements, thoracic or abdominal imaging
- Baseline and periodic CBC, serum chemistry profile, and urinalysis:
  - CBCs should be performed weekly early in therapy and eventually every 4 to 6 weeks when stabilized.
  - Frequency of CBC and serum chemistry profile monitoring depends on protocol employed. Consultation with a veterinary oncologist is recommended.
  - Consider serum uric acid concentrations for susceptible patients
- Monitor for clinical signs of toxicity (eg, vomiting, diarrhea, inappetence, fever)

Client Information

- Mitoxantrone is a chemotherapy (anticancer) medicine. It can be harmful to other animals and people that come in contact with it. This medicine may be detected in urine up to 6 days, and in feces up to 7 days after your animal receives it. On the day your animal gets the medicine and then for a few days afterward, all bodily waste (ie, urine, feces, litter), blood, or vomit should only be handled while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in with the regular trash.
- A blue-green color urine or a bluish color to the whites of the eyes can be seen but is not a problem.
- This medicine can affect your animal's ability to fight infection (bone marrow suppression). The greatest effects on the bone marrow usually occur within a few weeks after treatment. Your veterinarian will need to do blood tests on your animal while it is taking this medicine. Do not miss these important follow-up visits.
- Mitoxantrone can be toxic to the gastrointestinal tract and cause vomiting and gastrointestinal upset. Contact your veterinarian immediately if your animal has any bleeding, bruising, shortness of breath, vomiting, diarrhea, lack of an appetite, fever (indicating an infection), or if your animal becomes very tired easily.
- This medicine is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the safe handling of this medicine.

Chemistry/Synonyms

Mitoxantrone HCl is a synthetic anthracenedione antineoplastic. It occurs as a dark-blue powder that is sparingly soluble in water, prac-

tically insoluble in acetone, acetonitrile, and chloroform, and slightly soluble in methyl alcohol.

Mitoxantrone may also be known as: L-232315, DHAD, dihydroxyanthracenedione dihydrochloride, mitoxantroni hydrochloridum, NSC-301739, or *Novantrone®*.

Storage/Stability

Mitoxantrone HCl should be stored between 20°C and 25°C (68°F-77°F). Store multidose vials no longer than 7 days at room temperature and no longer than 14 days under refrigeration.[9] Although the manufacturer recommends not to freeze this drug, one study demonstrated that the drug maintained its cytotoxic effects when frozen and thawed at various intervals over a 12-month period.[23] Do not mix or use the same IV line with heparin infusions (precipitate may form). It is not recommended to mix this drug with other IV drugs.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Compatible for dilution with 0.9% sodium chloride or 5% dextrose. Do not mix or use the same IV line with heparin infusions (precipitate may form). It is recommended to not mix with other IV drugs.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Mitoxantrone HCl for Injection Solution Concentrate: 2 mg/mL, preservative-free in 10 mL, 12.5 mL, and 15 mL multi-dose vials; generic; (Rx)

Choline Tetrathiomolybdate
Sodium Molybdate

(moe-***lib***-dates) Molypen®

Copper Toxicosis Treatment

Prescriber Highlights

- ► Used primarily to treat copper toxicosis in food animals (especially sheep)
- ► May be useful in the treatment of copper-associated chronic hepatopathy in dogs
- ► Consider contacting FDA Center for Veterinary Medicine (CVM) for guidance in treating food animals

Uses/Indications

Molybdates are used for the investigational or compassionate treatment of copper toxicosis in food animals, primarily sheep.[1,2] A 12-week study demonstrated that oral administration of ammonium tetrathiomolybdate (TTM) to dogs with copper-associated chronic hepatopathy can effectively lower hepatic copper concentrations[3]; however, further investigation is needed to determine the long-term safety and efficacy of this treatment as compared with established therapies (eg, d-penicillamine).

Pharmacology/Actions

Molybdates are chelating agents that irreversibly bind and promote the excretion of copper. They also prevent intestinal copper absorption by binding copper in the GI tract.[4]

Pharmacokinetics

A study on ammonium tetrathiomolybdate (TTM) reported the following pharmacokinetic information after single IV and oral dosing of 1 mg/kg in dogs: oral bioavailability was 21 ± 22%, Vdss was 1 L/kg, and half-life was ≈27 hours.[5] TTM has high affinity for hepatocytes in other species and a high first-pass effect may be responsible for the low relative drug exposures in the study. Elimination characteristics described in the study suggested that a long dosing interval may be appropriate. The study also found that pretreatment with maropitant to dogs that had a history of vomiting with TTM treatment might have resulted in an increase in the bioavailability of TTM and could prove useful in preventing emesis and improving TTM efficacy. Both maropitant and TTM are highly protein-bound substances and are hepatically metabolized and eliminated. The study authors concluded that the increased serum copper concentrations observed in response to TTM were suggestive of mobilization of tissue copper stores, but more investigation is needed.

One study of TTM in sheep found a volume of distribution of 0.8 L/kg and serum elimination half-life of ≈7 hours.[6]

Adverse Effects

After apparent successful treatment for copper toxicosis with ammonium tetrathiomolybdate (TTM), a flock of sheep became infertile and progressively unthrifty and died 2 to 3 years later. The authors concluded the TTM was retained in the CNS, pituitary glands, and adrenal glands and caused a toxic endocrinopathy.[7] Increased AST was observed in dairy goats with copper toxicosis that were treated with ammonium molybdate, penicillamine, and sodium thiosulfate.[8]

Molybates are usually well tolerated by dogs; vomiting is the most common adverse effect seen.[5] One dog developed anorexia, lethargy, and presumed immune-mediated hemolytic anemia (IMHA) and thrombocytopenia during the 11th week of TTM treatment, but it remains undetermined whether IMHA was a direct result of TTM use.[3] Substantial hepatic molybdenum accumulation occurs with treatment in dogs, although the clinical significance of this finding is unknown.[3]

Reproductive/Nursing Safety

Ammonium molybdate is secreted in the breast milk in substantial amounts in humans.[9] Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Dosages

DOGS:

Copper-associated chronic hepatopathy (extra-label):

Ammonium tetrathiomolybdate (TTM): ≈0.5 mg/kg PO 4 times daily; from a 12-week safety and efficacy study, the administered dose was between 0.4 – 0.7 mg/kg.[3]

FOOD ANIMALS:

Copper toxicosis (extra-label):

Ammonium molybdate:

a) 50 – 500 mg/animal (NOT mg/kg) PO once daily in combination with sodium thiosulfate 300 – 1000 mg/animal (NOT mg/kg) PO once daily for 3 weeks[10,11]
b) 500 mg/animal (NOT mg/kg) PO once daily in combination with sodium thiosulfate 1000 mg/animal (NOT mg/kg) PO once daily for 5 days[12]
c) 200 mg/animal (NOT mg/kg) PO once daily for 3 weeks[13]

Ammonium tetrathiomolybdate (TTM):

a) 235 mg/calf (≈1 mg/kg) in 7 mL 0.9% sodium chloride SC every other day for 3 doses[14]
b) 2 – 15 mg/kg IV every 24 hours for 3 to 6 days.[15] **NOTE**: Until more is known about the significance of TTM cuproenzyme

inhibition, it is recommended that it be used conservatively (eg, 1 mg/kg IV once). Dose could be repeated if there is recurrence of prehemolytic copper toxicosis. Reduction in available copper in dietary supply is necessary. Zinc 150 mg/kg (route not stated) may be useful along with the antagonists, molybdate, and sulfate.[16]

Sodium molybdate: 200 mg/animal (NOT mg/kg) per day PO in combination with removal of copper-containing supplements[17]

SHEEP:

Copper toxicosis (extra-label):

Ammonium molybdate: 3.4 mg/kg SC every other day (ie, every 48 hours) for 3 doses[1]

Ammonium tetrathiomolybdate (TTM): 1.7 – 3.4 mg/kg SC every other day (ie, every 48 hours) for 3 doses[16]

GOATS:

Copper toxicosis (extra-label):

Ammonium molybdate: 300 mg/animal (NOT mg/kg) PO every 24 hours in combination with penicillamine 50 mg/kg and sodium thiosulfate 300 mg/animal (NOT mg/kg) PO every 24 hours[8]

Monitoring

- Baseline and periodic liver enzymes
- Copper concentration: serum, hepatic (requires biopsy)

Chemistry/Synonyms

Ammonium molybdate is an inorganic salt that occurs as odorless white crystals. Ammonium tetrathiomolybdate (TTM) occurs as a red crystalline powder. Specific solubility information was not located, but anecdotally, ammonium molybdate is more water-soluble than is TTM.

Ammonium molybdate may also be known as *Molybdene*® or *Molypen*®. Ammonium tetrathiomolybdate may also be known as TTM and tiomolibdate diammonium.
