Massive overdoses can lead to CNS and respiratory depression or hypotension. Gastric decontamination can be considered. Use of analeptic agents (eg, caffeine, doxapram) is generally not recommended. Flumazenil can be used to reverse respiratory depression or severe CNS depression. The half-life of flumazenil is short and the animal may require multiple doses of the drug. Flumazenil may precipitate seizures in epileptic patients or patients chronically receiving clonazepam antiseizure therapy.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving clonazepam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anesthetic Agents** (eg, **alfaxalone, dexmedetomidine, isoflurane, propofol**): Additive sedation or respiratory depression may occur.
- **Anticholinergic Agents** (eg, **atropine, glycopyrrolate**): Anticholinergic effects may be potentiated.
- **Antidepressants** (eg, **amitriptyline**, **clomipramine**, **mirtazapine**): Concurrent use may decrease the risk for CNS and/or respiratory depression.
- **Antihypertensive Agents** (eg, **amlodipine**, **benazepril**, **telmisartan**): Concurrent use may increase the risk for hypotension and orthostasis.
- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): May increase clonazepam levels
- **Cannabidiol:** Additive CNS depression may occur
- **Carbamazepine**: Concurrent use may result in decreased clonazepam concentrations.
- **Carbonic Anhydrase Inhibitors** (**CAIs**; eg, **acetazolamide, dichlorphenamide, methazolamide**): Clonazepam may interfere with the beneficial effects of CAIs by inhibiting responses to hypoxia.
- **Cimetidine**: May decrease metabolism of benzodiazepines
- **Danazol**: Danazol may increase clonazepam concentrations.
- **Digoxin**: Concurrent use may increase digoxin levels, increasing the risk for toxicity. Digoxin levels should be closely monitored and doses adjusted as indicated.
- **Diltiazem**: May increase levels of clonazepam. Monitor for overextension of pharmacologic effect.
- **Erythromycin**: May decrease the metabolism of benzodiazepines
- **Opioids** (eg, **buprenorphine, fentanyl, methadone, morphine, tramadol**): Concomitant use may result in profound sedation and respiratory depression.
- **Phenobarbital**: May decrease clonazepam concentrations. Additive CNS depression may occur.
- **Phenothiazines** (eg, **acepromazine**): Additive CNS depression may occur
- **Phenytoin**: May decrease clonazepam concentrations
- **Propantheline**: Concurrent propantheline use with orally disintegrating clonazepam tablets may decrease clonazepam concentrations.
- **Rifampin**: May induce hepatic microsomal enzymes and decrease the pharmacologic effects of benzodiazepines
- **Valproic Acid, Divalproex:** Concurrent use may increase risk of teratogenesis and may displace benzodiazepines from protein binding sites and inhibit metabolism. Monitor for excessive sedation and avoid combination in pregnancy.
- **Yohimbine:** May decrease therapeutic effects of anxiolytic drugs

Laboratory Considerations

- Benzodiazepines may decrease the thyroidal uptake of I^{123} or I^{131}.

Dosages

DOGS:

Anxiolytic (extra-label): Dosage recommendations vary considerably. Most range from 0.1 – 1 mg/kg PO up to 2 to 3 times per day, but up to 2.2 mg/kg every 6 hours has also been recommended.[5] In general, dosages are started near the low end and increased

if necessary. If discontinuing after long-term use, do so gradually.

Adjunctive treatment of seizures or sleep disorders (extra-label): Most dosage recommendations range from 0.5 – 1 mg/kg PO 2 to 3 times per day, but up to every 6 hours or dosages up to 2 mg/kg PO every 12 hours have also been recommended. In general, dosages are started near the low end and increased if necessary. If discontinuing after long-term use, do so gradually.

CATS:

Anxiolytic (extra-label): Dosage recommendations vary considerably. Most range from 0.02 – 0.25 mg/kg PO up to 2 times a day.[5] In general, dosages are started near the low end and increased if necessary. If discontinuing after long-term use, do so gradually.

Adjunctive treatment of seizures (extra-label): Dosage recommendations vary considerably. Most range from 0.02 – 0.5 mg/kg PO up to 2 times a day. In general, dosages are started near the low end and increased if necessary. If discontinuing after long-term use, do so gradually.

Monitoring

- Efficacy
- Adverse effects
- The therapeutic plasma concentration has been reported as 0.02 to 0.07 µg/mL in humans[6]; therapeutic drug monitoring is not routinely performed in veterinary patients.
- In cats, baseline and periodic liver panel

Client Information

- This drug is used to help control seizures and as a tranquilizer.
- Can cause sedation and/or disorientation, which may impair performance of working animals.
- When using for thunderstorm anxiety or other triggers (eg, owner separation) that upset your animal, try to give clonazepam ≈1 hour before the event or trigger. This medication works best for treating anxiety-related behaviors when given along with behavior therapy.
- When used to treat for seizures, it is very important to give doses regularly.
- May be given with or without food. Food or small treats may be given if your animal vomits or acts sick after receiving the medication on an empty stomach. Contact your veterinarian if vomiting continues.
- Contact your veterinarian immediately if you see yellowing of the skin, gums, or whites of the eyes.
- Sleepiness is the most common side effect, but this drug can change the animal's behavior (eg, hyperactivity, anxiety) in unexpected ways.
- This drug may increase appetite, especially in cats.
- Men or women who are actively trying to conceive, women who are pregnant or may become pregnant, and women who are breast feeding should consider wearing gloves while handling this drug and wash their hands after handling.
- Do not stop treatment abruptly. Contact your veterinarian if you feel the drug should be discontinued.
- Clonazepam is a schedule 4 (C-IV) controlled drug and requires a new written prescription for refills. Use of this medication in animals or humans other than those for whom they are prescribed is illegal.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Clonazepam, a benzodiazepine anticonvulsant, occurs as an off-white to light-yellow crystalline powder with a faint odor. It is insoluble in water and slightly soluble in alcohol.

Clonazepam may also be known as clonazepamum, Ro-5-4023, *Antelepsin®*, *Clonagin®*, *Clonapam®*, *Clonax®*, *Clonex®*, *Diocam®*, *Epitril®*, *Iktorivil®*, *Kenoket®*, *Klonopin®*, *Kriadex®*, *Neuryl®*, *Paxam®*, *Rivatril®*, *Rivotril®*, or *Solfidin®*.

Storage/Stability

Tablets should be stored in airtight, light-resistant containers at room temperature of 20°C to 25°C (68°F-77°F). For orally disintegrating tablets, excursions to 15°C to 30°C (59°F-86°F) are permitted.

Clonazepam is a schedule 4 (C-IV) controlled substance, clonazepam must be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

Compounded preparation stability: Clonazepam oral suspension compounded from commercially available tablets has been published.[7] Triturating 6 clonazepam 2 mg tablets with 60 mL of *Ora-Plus®* and qs ad to 120 mL with *Ora-Sweet®* (or *Ora-Sweet® SF*) yields a 0.1 mg/mL suspension that retains greater than 90% potency for 60 days stored at both 5°C (41°F) and 25°C (77°F). Compounded preparations of clonazepam should be protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Clonazepam Oral Tablets: 0.5 mg, 1 mg, and 2 mg; *KlonoPIN®*, generic; (Rx; C-IV)

Clonazepam Orally Dispersible (Disintegrating) Tablets: 0.125 mg, 0.25 mg, 0.5 mg, 1 mg, and 2 mg (with mannitol); generic; (Rx; C-IV). **NOTE:** May contain xylitol

Report dispensing to state monitoring programs where required.

Clonidine

(***klah***-nih-deen) *Catapres®*, *Duraclon®*

Alpha-2-Adrenergic Agonist

Prescriber Highlights

- ► Centrally acting alpha-adrenergic agonist used as a preanesthetic agent, an adjunct analgesia in epidurals, and an adjunctive treatment for some behavioral conditions
- ► Can be used in diagnostic agent testing for growth hormone deficiency or pheochromocytoma in dogs and as an antidiarrheal agent
- ► Limited experience in veterinary species for therapeutic or diagnostic purposes
- ► Potential adverse effects include transient hyperglycemia, dry mouth, constipation, sedation, aggressive behavior, hypotension, collapse, and bradycardia
- ► When discontinuing after prolonged use, reduce dosage over several days.

Uses/Indications

Clonidine may be useful as a preanesthetic medication and as an epidural adjunct, with or without opioids, in dogs[1-3] and cattle.[4]

The use of clonidine as an adjunctive treatment for certain behavioral conditions in dogs has been of interest, but limited evidence supporting its use is available. An open trial using clonidine on an as-needed basis for fear-based behavioral problems suggested that clonidine reduced phobic signs and aggression in most treated dogs.[5] Clonidine combined with fluoxetine appeared effective in dogs with behavioral disorders.[6]

Clonidine may be used as a diagnostic agent to determine growth hormone deficiency or pheochromocytoma in dogs. Clonidine has been used as an antidiarrheal agent in dogs and cats,[7] and as adjunctive treatment of diarrhea-predominant inflammatory bowel disease in dogs.[8]

Pharmacology/Actions

Clonidine acts in the brain stem, stimulating alpha-adrenergic receptors, and results in reduced sympathetic outflow from the CNS and decreased renal vascular resistance, peripheral resistance, cardiac rate, and blood pressure. Renal blood flow and glomerular filtration rates are not affected.

Clonidine causes growth hormone (GH, somatotropin) release from the pituitary gland by stimulating hypothalamic release of GHRH, but this effect does not persist with continued dosing. Clonidine reduces plasma renin activity and aldosterone excretion.

Clonidine possesses central analgesic effects most likely at presynaptic and postjunctional alpha$_2$-adrenoreceptors in the spinal cord, thereby blocking pain signal transmission to the brain. It may also increase seizure threshold, but the clinical significance of this effect is unclear. Clonidine acts on the GI tract to increase fluid and electrolyte absorption. Studies have shown that clonidine reduces renal sympathetic nerve activity, restores vascular sensitivity to phenylephrine and angiotensin II, and results in better preservation of arterial pressure during hypotensive sepsis in sheep.[9]

Pharmacokinetics

Limited information is available on the pharmacokinetics of clonidine in domestic animals. In cats, clonidine exhibits a 2-compartment open model and penetrates into tissues rapidly.

In humans, the drug is well absorbed after oral administration. Peak plasma concentrations occur ≈1 to 3 hours after oral administration. After epidural administration, maximal analgesia occurs within 30 to 60 minutes. Clonidine is apparently widely distributed into body tissues; tissue concentrations are higher than in plasma. Clonidine enters the CSF, but brain concentrations are low compared with other tissues. In humans with normal renal function, clonidine's half-life is 12 to 16 hours. Elimination may be prolonged with higher dosages (dose-dependent elimination kinetics) or in patients with renal dysfunction. Up to 60% of a dose is eliminated unchanged in the urine, but the remainder is metabolized in the liver; 1 active metabolite (p-hydroxyclonidine) has been identified.

Contraindications/Precautions/Warnings

Clonidine is contraindicated in patients known to be hypersensitive to it. It should be used with caution in patients with severe cardiovascular disease, including conduction disturbances or heart failure; lower dosages may be required in patients with renal insufficiency.

Abrupt cessation of oral clonidine use has produced withdrawal-like symptoms (eg, agitation, nervousness, tremor, elevated blood pressure) in humans.[10] Although the veterinary significance is unknown, gradual dose reduction over 2 to 4 days should be considered.

Do not confuse cloNIDine with cloNAZepam, KLONOpin, or QUINidine.

Adverse Effects

Bradycardia and hypotension have been observed following epidural[2,11] and IM[12] administration in dogs. Dogs receiving IV clonidine for the diagnosis of growth hormone deficiency have experienced adverse reactions including sedation, aggressive behavior, hypotension, collapse, and bradycardia (responsive to atropine) lasting for 15 to 60 minutes post-clonidine administration.[13] Marked sedation and ataxia occurred after epidural administration in horses.[14]

Long-term use in rats, but not in humans, has been associated with dose-dependent retinal degeneration.

Reproductive/Nursing Safety

Clonidine crosses the placenta. No teratogenic or embryotoxic effects were found in rabbits, but increased resorption occurred in rats and mice.[10] Because safety has not been established in animal species, this drug should only be used when the maternal benefits outweigh the potential fetal risks.

Clonidine enters human maternal milk and may reach concentrations exceeding that of maternal plasma; severe adverse effects in the nursing infant may occur. Use cautiously in nursing veterinary species or consider milk replacer.

Overdose/Acute Toxicity

Clonidine has a narrow margin of safety. Common clinical signs associated with an overdose mirror the adverse effect profile in dogs and cats and include lethargy/sedation, bradycardia, ataxia, vomiting, and hypotension. In humans, seizures or respiratory depression are rarely seen. The LD_{50} values reported for oral clonidine in rats and mice are 465 mg/kg and 206 mg/kg, respectively.[10]

Treatment for overdoses associated with clinical signs includes GI decontamination using standard protocols. Use of emetics should be considered carefully, as level of consciousness may deteriorate rapidly. Treatment of systemic effects is primarily based on clinical signs and is supportive. Hypotensive effects may be treated, if necessary, using fluids or pressors (eg, dopamine); bradycardia may be treated with IV atropine, if required. Atipamezole or yohimbine may also be used to help reverse the cardiovascular effects, but multiple doses may be required as clinical signs can last up to 48 hours, depending on clonidine dosage.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving clonidine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antihypertensive Drugs** (eg, **amlodipine, enalapril, hydralazine, sildenafil, telmisartan**): Possible additive hypotensive effects
- **Beta-Adrenergic Antagonists** (eg, **propranolol**): May enhance bradycardia when given with clonidine. If clonidine is to be discontinued in patients concurrently receiving clonidine and beta-adrenergic antagonists, the beta-adrenergic antagonist should be discontinued prior to clonidine and clonidine gradually discontinued; otherwise, rebound hypertension may occur.
- **Calcium Channel Blockers** (eg, **diltiazem, verapamil,** but not **amlodipine**): Increased risk of sinus bradycardia and complete AV block; blood pressure and heart rate should be closely monitored.
- **CNS Depressant Drugs** (eg, **barbiturates, opioids**): Clonidine may exacerbate the actions of other CNS depressant drugs.

- **Digoxin**: Possible additive bradycardia. Blood pressure and heart rate should be closely monitored.
- **Glucocorticoids** (eg, **dexamethasone, prednis(ol)one**): May decrease the antihypertensive effects of clonidine by causing fluid and sodium retention
- **Prazosin**: May decrease the antihypertensive effects of clonidine
- **Stimulants** (eg, **doxapram**): Concurrent use may increase risk of hypertension and tachycardia. Monitor pulse and blood pressure.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): May block the antihypertensive effects of clonidine and increase risk of severe hypertension. Risk of corneal opacities is increased. Combination should be avoided if possible. If use together is necessary, monitor blood pressure diligently. Withdrawal of either drug should be done gradually.

Laboratory Considerations

- False-positive **Coombs test** has been reported.[10]

Dosages

DOGS:

Adjunctive treatment (with other medications and behavioral therapy) for situational fears, phobias, and separation anxiety (extra-label): 0.01 – 0.05 mg/kg PO up to twice daily; median effective dosage was 0.017 – 0.026 mg/kg PO up to twice daily. The same dose may be used on an as-needed basis ≈1.5 to 2 hours prior to the triggering event.[5]

Epidural analgesia (extra-label):

1. 150 µg/dog (NOT µg/kg) administered immediately after anesthetic induction[1,11]
2. 5 µg/kg with 2.5 mg/kg lidocaine (1%). **NOTE**: Supplemental isoflurane was required.[3]

Premedicant prior to anesthesia (extra-label): 6 – 10 µg/kg IV prior to etomidate/halothane anesthesia[2]

Diagnosing growth hormone deficiency (hyposomatotropism; extra-label): Dosage may vary depending on the laboratory's protocol. Contact laboratory prior to test to determine protocol and sample handling instructions. Usual dose is 10 µg/kg IV.[13] Obtain plasma for growth hormone (GH) concentrations prior to clonidine dosing and again at 15, 30, 45, 60, and 120 minutes. Healthy dogs should demonstrate GH concentrations of 10 ng/mL after clonidine administration.[15]

Adjunctive antidiarrheal therapy for refractory cases of inflammatory bowel disease (extra-label): 5 – 10 µg/kg PO or SC 2 to 3 times daily[7]; can activate alpha-2-receptors in the chemoreceptor trigger zone (CRTZ) and cause vomiting[8,16]

CATS:

Adjunctive antidiarrheal therapy for refractory cases of inflammatory bowel disease (extra-label): As fourth-line therapy after prostaglandin synthetase inhibitors (ie, sulfasalazine, bismuth subsalicylate), opioid agonists (ie, loperamide), and 5-HT_3 serotonergic antagonists (ie, ondansetron) are being used: clonidine 5 – 10 µg/kg 2 to 3 times daily, SC or PO[7,8]

CATTLE:

Epidural analgesia/analgesia (extra-label): 2 – 3 µg/kg diluted to 8 mL with sterile normal saline epidurally. Onset/duration of analgesia is 19 minutes/192 minutes respectively, with a 2 µg/kg dosage. Onset/duration of analgesia is 9 minutes/311 minutes respectively, with a 3 µg/kg dosage. Peak analgesic effects with both dosages occurs at 60 to 180 minutes.[4]

Monitoring

- Baseline and periodic blood pressure, and heart rate and rhythm with chronic use. **NOTE**: Cardiovascular effects usually only persist for 1 hour after dose.
- Clinical efficacy

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after receiving this medicine on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Experience with this drug in dogs or cats is limited. Sleepiness and lowered blood pressure (eg, weakness, collapse) are the most likely side effects. Report unusual effects to your veterinarian.
- When used to treat fear-based behavioral problems, clonidine is usually given 90 minutes to 2 hours before the event. Dosages are started low and then gradually increased, depending on side effects and effectiveness. Sometimes this medicine is used longer term on a regular basis (up to twice daily).
- This medicine is best used with behavioral modification training for fear-based problems.
- When used daily, do not change or skip doses, or discontinue treatment, without your veterinarian's advice.

Chemistry/Synonyms

An imidazoline derivative, clonidine HCl is a centrally acting alpha-adrenergic agonist that occurs as an odorless, bitter, white or almost white crystalline powder. It is soluble in water and alcohol and is considered highly lipid soluble. The commercially available injection for epidural use has an adjusted pH between 5 and 7.

Clonidine may also be known as ST-155 or clonidini hydrochloridum; *Catapres*® and *Duraclon*® are common trade names.

Storage/Stability

Clonidine tablets should be stored in tight, light-resistant containers at room temperature, 25°C (77°F); excursions from 15°C to 30°C (59°F-86°F) are permitted. The preservative-free injection for epidural use should be stored at controlled room temperature, 20°C to 25°C (68°F-77°F). Because it contains no preservative, unused portions of the injection should be discarded.

Compatibility/Compounding Considerations

Clonidine is reportedly **compatible** with 0.9% sodium chloride, and in the same syringe with bupivacaine, fentanyl, heparin, ketamine, lidocaine, and morphine.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Clonidine HCl Injection for epidural use: 100 µg/mL and 500 µg/mL (must be diluted before use) preservative-free in 10 mL vials; *Duraclon*®, generic; (Rx)

Clonidine HCl Oral Tablets: 0.1 mg, 0.2 mg, and 0.3 mg; *Catapres*®, generic; (Rx)

Clonidine extended-release tablets and transdermal patches also are available.

For the complete list of references, see **wiley.com/go/budde/plumb**

Clopidogrel

(kloe-***pid***-oh-grel) *Plavix®*

Platelet Aggregation Inhibitor

Prescriber Highlights

- Oral, once-daily platelet aggregation inhibitor that may be useful in the treatment of dogs, cats, and horses with hypercoagulable conditions and in the prevention of thromboembolic disease
- Inhibits platelet function for the lifespan of the platelet; clinically normal platelet function gradually returns 3 to 7 days after discontinuation of the medication as new platelets are released
- Appears to be well tolerated, but can potentially cause vomiting or bleeding

Uses/Indications

Clopidogrel, a platelet aggregation inhibitor, may be useful for the prevention of thromboembolic disease in cats and dogs.[1] Clopidogrel appears to reduce recurrent cardiogenic arterial thromboembolism and mortality in cats when administered after arterial thromboembolism.[2] Although aspirin and clopidogrel have historically (and in humans, are commonly) been used together, evidence supporting the combination of these drugs in veterinary patients is scarce.[3,4] Clopidogrel may also improve pelvic limb circulation in cats after a cardiogenic embolic event via a vasomodulating effect secondary to inhibition of serotonin release from platelets.[5]

Clopidogrel has been suggested as a treatment to decrease the chances of arterial thromboembolism in dogs with hypercoagulable conditions, although evidence supporting this recommendation is limited.[4,6] Thromboprophylaxis is recommended in all dogs with immune-mediated hemolytic anemia (IMHA), except those with severe thrombocytopenia (ie, platelet count less than 30,000/µL), in which clopidogrel is preferred to aspirin for antiplatelet therapy.[7]

Clopidogrel inhibits platelet function in healthy adult horses[8–11] but failed to attenuate the clinicopathologic effects of endotoxin infusion or ex vivo equine herpesvirus (EHV)-1-induced platelet activation.[12,13]

Pharmacology/Actions

Clopidogrel is a prodrug and must be hepatically metabolized to form an active, highly unstable thiol compound (commonly referred to as clopidogrel active metabolite [CAM]). This compound binds selectively to the platelet surface adenosine diphosphate (ADP) receptor, $P2Y_{12}$, and irreversibly alters the ADP receptor for the lifespan of the platelet.[14] This receptor alteration reduces activation of the platelet by ADP and inhibits full activation of the glycoprotein GPIIb/IIIa complex (which is responsible for platelet binding to fibrinogen and integration into clots).[15]

In a pharmacodynamic study in healthy dogs, most dogs had significant inhibition of platelet function within 3 hours after the initial oral dose of clopidogrel; inhibition lasted at least 24 hours.[16] In cats, a daily oral dosage of clopidogrel 18.75 mg/cat (NOT mg/kg), inhibited platelet function within 1 day, whereas a lower daily oral dosage of 10 mg/cat (NOT mg/kg) had a delayed effect.[17] Clinically apparent decreases in platelet aggregation persist for 3 to 7 days in dogs and cats.[16–20] Generic clopidogrel had antiplatelet effects comparable with *Plavix®* in cats.[21] Desmopressin acetate (DDAVP) is not effective for reversing the antiplatelet effects of clopidogrel in healthy dogs.[22] In healthy dogs, the combination of clopidogrel and prednisone did not change platelet aggregation responses as compared with dogs receiving clopidogrel alone.[23]

In horses, antiplatelet effects were seen after 3 to 5 days of treatment and lasted for 5 days after discontinuation of the medication.[10]

Pharmacokinetics

Because clopidogrel inactivates platelets for their lifespan, the drug's biological action is not explained by its pharmacokinetic profile.[20]

In dogs, clopidogrel's pharmacokinetics have not been fully elucidated, but onset of clinical effects on platelets may range from 3 hours to 2 days.[16,18] Concentrations of an inactive metabolite peaked between 1 to 2 hours after a single oral dose.[16] The variable time to full inhibition may provide justification for a loading dose when initiating therapy.[18]

In a pilot pharmacokinetic study of clopidogrel in 2 cats, time to peak clopidogrel active metabolite (CAM) concentration was 1.5 to 2 hours, and the elimination half-life was 2.8 to 4.9 hours. An almost 2-fold difference was noted in total CAM exposure (as measured by area under the curve [AUC]).[24] High interindividual variation in CAM formation was determined to be due primarily to genetic polymorphism in CYP2C; however, males were associated with reduced CAM formation.[25] Variability in the *P2RY1* gene may alter the pharmacodynamics of clopidogrel in cats (and likely other species) and may explain the interpatient differences in response to therapy.[26]

In horses, clopidogrel decreased ADP-induced platelet aggregation, but the time to onset and total required dose in horses was greater than in other species.[10] A loading dose inhibited platelet function within hours; platelet function returned to baseline 6 days after cessation of therapy.[8]

In humans, clopidogrel is rapidly absorbed with a bioavailability of ≈50%; food does not alter its absorption. Clopidogrel is highly bound to plasma proteins. It is rapidly and predominantly hydrolyzed to an inactive carboxylic acid derivative (SR 26334) that is excreted via the urine and feces. A small fraction of a dose is transformed to the active intermediate compound (see ***Pharmacology/Actions***), which has a half-life of 30 minutes. Two percent of the administered drug is covalently bound to platelets and has an elimination half-life of ≈11 days.[14]

Contraindications/Precautions/Warnings

Clopidogrel is contraindicated in patients hypersensitive to it or those with active pathologic bleeding or inherited thrombocytopathias. Clopidogrel is relatively contraindicated in patients with thrombocytopenia or coagulopathies, depending on the underlying cause.

In dogs, platelet function does not return to normal until ≈7 days after stopping administration of clopidogrel.[18] Consideration must be taken to assess the patient's risk for thrombosis versus the risk for bleeding during surgical procedures.[27] In dogs and cats at high risk for thrombosis, it is recommended to continue antiplatelet therapy through surgery unless animals are receiving more than one anticoagulant. For dogs and cats at low to moderate risk for thrombosis, it is recommended to discontinue antiplatelet agents 5 to 7 days prior to an elective procedure.[27]

In humans undergoing elective surgery with a major risk for bleeding, it is recommended to withhold clopidogrel 5 days prior to surgery to reduce the antiplatelet effect; platelet transfusion prior to surgery may be considered if clopidogrel withdrawal is not indicated.[14]

Adverse Effects

Clopidogrel appears to be well tolerated in dogs, cats, and horses. Vomiting (dogs and cats), anorexia, or diarrhea may occur; giving the drug with food may alleviate these effects in dogs and cats. Nonregenerative anemia has been reported in some cats receiving long-term clopidogrel treatment.

Clopidogrel alone did not cause GI bleeding or ulceration in dogs and did not appear to increase the incidence of GI ulceration when given in combination with prednisone.[28]

In humans, primary adverse effects have been related to bleeding. Major bleeding events occur in 3.7% of humans receiving clopidogrel and aspirin combination therapy, versus 2.7% incidence with clopidogrel alone.[14] Minor bleeding occurs in 5.1% of patients receiving both clopidogrel and aspirin, versus 2.4% in those receiving aspirin alone.[14] Rashes and GI effects (eg, diarrhea) have also been reported. Thrombotic thrombocytopenic purpura and aplastic anemia are rarely reported.

Reproductive/Nursing Safety

In pregnant rats, doses ≈65 times, and in rabbits doses 78 times, that of the human recommended dose (compared on an mg/m^2 basis) caused no teratogenic effects.[14]

In rats, clopidogrel and its metabolites are distributed into maternal milk.[14]

Because safety of clopidogrel has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available. Reported lethal oral doses in mice and rats were 1500 mg/kg and 2000 mg/kg (460 times the human adult dose on an mg/m^2 basis), respectively.[14] Acute toxic signs may include bleeding or vomiting. Because clopidogrel irreversibly inhibits its platelet function for the lifespan of the platelet, toxic effects may persist for several days. Platelet transfusions have been suggested if rapid reversal is required. Clopidogrel is unlikely to be dialyzable.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

In humans, clopidogrel is a substrate and inhibitor of CYP2C19 and a strong inhibitor of CYP2C8. The following drug interactions have either been reported or are theoretical in humans or animals receiving clopidogrel and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aspirin**: Concurrent use may increase the risk for bleeding; however, simultaneous use in humans is common.
- **Azole Antifungals** (eg, **fluconazole, ketoconazole**): Concurrent use may result in decreased efficacy of clopidogrel.
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**): Concurrent use may result in decreased efficacy of clopidogrel and increased risk for thrombosis.
- **Chloramphenicol**: Concurrent use may decrease efficacy of clopidogrel.
- **Cimetidine**: May decrease the effects of clopidogrel[29]
- **Cyclosporine**: A study in dogs showed that cyclosporine can increase clopidogrel peak concentration, but drug exposure was the same as compared with clopidogrel alone.[30]
- **Heparin; Low Molecular Weight Heparins** (eg, **dalteparin, enoxaparin**): Clopidogrel appears safe to use with heparin (both unfractionated and low molecular weight).
- **Isoniazid:** Concurrent use may reduce formation of the clopidogrel active metabolite.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, robenacoxib**): Concurrent use may increase the risk for bleeding; clopidogrel may interfere with NSAID metabolism.
- **Opioids** (eg, **hydromorphone**, **morphine**): Opioid use may delay and reduce formation of the clopidogrel active metabolite and the drug's antiplatelet effect, possibly by reducing GI motility and drug absorption.
- **Proton Pump Inhibitors** (**PPIs**; eg, **esomeprazole, omeprazole**): In humans, concurrent use of omeprazole and esomeprazole (but not other PPIs) may decrease the efficacy of clopidogrel and increase the risk for thrombosis; however, a study in dogs found omeprazole combined with clopidogrel did not alter antiplatelet effects in healthy dogs.[31]
- **Rifampin:** May increase the effects of clopidogrel by increasing formation of the clopidogrel active metabolite[29]
- **Rivaroxaban:** Concurrent use may increase the risk for bleeding.
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, paroxetine**): Concurrent use may increase the risk for bleeding.
- **Telmisartan**: Concurrent telmisartan use did not alter formation of the inactive clopidogrel metabolite.[30]
- **Torsemide**: Clopidogrel may interfere with metabolism.
- **Warfarin**: Concurrent use may increase the risk for bleeding; clopidogrel may interfere with metabolism of warfarin.

Laboratory Considerations

- None noted

Dosages

NOTE: Because of the drug's extreme bitterness, administering the medication in a gelatin capsule may be considered.

DOGS:

Antiplatelet agent (extra-label): 1 – 4 mg/kg PO once daily.[4,6,16,18,32] A loading dose of 4 – 10 mg/kg PO on the first day of treatment can be considered.[32,33] Experimental evidence suggests efficacy in prevention of arterial thromboembolism, but data are lacking for venous thromboembolism.[33]

CATS:

Aortic thromboembolism (extra-label): Loading dose: 37.5 – 75 mg/cat (NOT mg/kg) PO once after diagnosis.[5,33] Maintenance dose: 18.75 mg/cat (NOT mg/kg) PO every 24 hours

Thrombus prevention; antiplatelet agent (extra-label): 18.75 mg/cat (NOT mg/kg) PO once daily.[2,33] Experimentally in healthy cats, 10 mg/cat (NOT mg/kg) PO once daily had a similar antiplatelet effect as 18.75 mg/cat (NOT mg/kg) PO once daily, although the lower dosage required 2 days for onset of antiplatelet activity as compared with 1 day for the higher dosage.[17]

HORSES:

Antiplatelet agent (extra-label): From experimental studies, loading dose of 4 – 6.5 mg/kg PO once on the first day of treatment[8,11]; maintenance dose: 1.2 – 4 mg/kg PO once daily[8–10]

Monitoring

- Clinical efficacy
- Current guidelines do not provide recommendations for objective monitoring of clopidogrel therapy due to lack of data and the safety of clopidogrel when administered at recommended dosages.[34]
- Platelet aggregometry and modified thromboelastography have been used to evaluate clopidogrel effects in dogs, cats, and horses under experimental conditions.[16,19,20,31,35,36]
- Adverse effects (eg, vomiting, bleeding)

Client Information

- Bleeding is not likely but can occur. If your animal shows any signs of bleeding; bruising; difficulty breathing; blood in vomit (looks like coffee grounds); blood in urine; or black, tarry stools, consult your veterinarian immediately.

- This medicine may be given with or without food, but if vomiting occurs, give with food.

Chemistry/Synonyms
Clopidogrel bisulfate, a thienopyridine, occurs as a white to off-white powder that is practically insoluble in water at a pH of 7 but is freely soluble at a pH of 1.

Clopidogrel may also be known as SR-259990C, PCR-4099, or clopedogreli. A common trade name is *Plavix®*.

Storage/Stability
Clopidogrel tablets should be stored at 25°C (77°F), with excursions permitted to 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations
Compounded preparation stability: Clopidogrel oral suspension compounded from commercially available tablets has been published.[37] Triturating 4 clopidogrel 75 mg tablets with 30 mL of *Ora-Plus®* and qs ad to 60 mL with *Ora-Sweet®* (or *Ora-Sweet® SF*) yields a 5 mg/mL oral suspension that retains greater than 90% potency for 60 days stored at both 5°C (41°F) and 25°C (77°F). Compounded preparations of clopidogrel should be protected from light and may retain a bitter taste.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Clopidogrel Bisulfate Tablets: 75 mg and 300 mg; *Plavix®*, generic; (Rx)

Cloprostenol
(kloe-**pros**-te-nol) *Estrumate®*
Prostaglandin $F_{2\text{-alpha}}$

Prescriber Highlights
- ► Synthetic prostaglandin used in many large and small animal species to induce luteolysis and abortion and to treat pyometra and endometritis
- ► Contraindications include pregnancy (when abortion or induced parturition is not desired).
- ► Can cause cholinergic-like adverse effects in dogs
- ► Do not administer IV.
- ► Wear gloves when handling. Pregnant women should not handle the drug and those with asthma and women of childbearing age should handle with caution.

Uses/Indications
Cloprostenol (racemic) is FDA-approved for use in beef or dairy cows and replacement beef and dairy heifers for unobserved or undetected estrus; for the treatment of pyometra, chronic endometritis, or luteal cysts; expulsion of a mummified fetus; to induce abortions; and for estrus synchronization. It is also approved for use with gonadorelin to synchronize estrous cycles for artificial insemination in lactating dairy cows.[1]

Cloprostenol has been used in dogs for pregnancy termination and in dogs and cats for treatment of open pyometra. Cloprostenol has been shown to be ineffective for inducing abortion in cats[2]; however, it has been used successfully in cats for the treatment of open pyometra.[3]

In horses, cloprostenol has been used for luteolysis, inducing abortion, and stimulating uterine contractions.

Cloprostenol has been used in sows to induce farrowing; in sheep and goats for estrus synchronization, inducing parturition, and for pseudopregnancy; and in camelids for luteolysis.

Pharmacology/Actions
Prostaglandin F_{2alpha} and its analogues, cloprostenol and fluprostenol, are powerful luteolytic agents. They cause rapid regression of the corpus luteum to arrest its secretory activity. These prostaglandins also cause uterine smooth muscle contraction with relaxation of the cervix.

In normally cycling animals, estrus generally occurs 2 to 5 days after treatment. In pregnant cattle treated between 10 and 150 days of gestation, abortion will usually occur 2 to 3 days after cloprostenol injection.

Pharmacokinetics
In cows, cloprostenol peaks in the blood within the first hour following IM administration and falls to undetectable levels by 24 hours. The half-life of cloprostenol has been reported to be ≈3 hours, much longer than that of dinoprost tromethamine (9 minutes).

Contraindications/Precautions/Warnings
Should not be administered to pregnant animals unless abortion is the desired outcome.

Wear gloves when handling; cloprostenol is readily absorbed through the skin and must be washed off immediately with soap and water. Women of childbearing age and persons with asthma or other respiratory diseases should use extreme caution when handling cloprostenol, as the drug may induce abortion or acute bronchoconstriction.

Do not administer IV.

Adverse Effects
The manufacturer does not list any adverse effects for this product when used as labeled. If used after the fifth month of gestation, there is an increased risk for dystocia and decreased efficacy.

In dogs, cloprostenol can cause increased salivation, tachycardia, increased urination and defecation, gagging, vomiting, ataxia, and mild depression. Pretreatment with an anticholinergic drug (eg, atropine) may reduce the severity of these effects.

In cats, cloprostenol has been noted to cause diarrhea, vomiting, and vocalization.

In horses, cloprostenol causes uterine contractions for ≈5 hours postdose; higher doses of cloprostenol can cause sweating, cramping, and loose stools, but the incidence of adverse effects is less than with dinoprost tromethamine.

Reproductive/Nursing Safety
Cloprostenol is contraindicated in pregnant animals unless abortion or induced parturition is desired.

Cloprostenol is approved for use in lactating dairy cows.

Overdose/Acute Toxicity
The manufacturer states that at 50 and 100 times the recommended dosages of cloprostenol, cattle may show signs of uneasiness, slight frothing, and milk ejection. In cattle, 200 times the dose of cloprostenol sodium caused only mild and transient diarrhea.

Overdoses of cloprostenol or other synthetic prostaglandin F_{2alpha} analogues in small animals can reportedly result in shock and death.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions
The following drug interactions have either been reported or are theoretical in humans or animals receiving cloprostenol and may be of significance in veterinary patients. Unless otherwise noted, use

together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Oxytocin and Related Agents**: Activity of ecbolic agents may be enhanced by cloprostenol.

Laboratory Considerations

None noted

Dosages

DOGS:

Adjunctive treatment of pyometra[4] (extra-label): Cloprostenol 1 µg/kg SC in combination with cabergoline 5 µg/kg PO once daily for 7 days with oral antibiotic therapy and supportive hydration. If no response to treatment, cloprostenol (without cabergoline), along with supportive treatment, can be continued for another 7 days.

Abortifacient (extra-label):

NOTE: Multiple protocols have been published. Combination protocols minimize adverse GI effects associated with the use of cloprostenol as a single agent.

a) 1 – 2.5 µg/kg SC once daily for 4 to 7 days has been successful in terminating pregnancy in dogs after 30 days gestation.[5]

b) 1 – 2.5 µg/kg SC every 48 hours for 3 doses. Higher doses (2.5 µg/kg) appear to be effective starting at 30 days of pregnancy. Anticholinergic drug administration (eg, atropine) 15 minutes prior to dosing appears to lessen adverse effects.

c) Between gestation days 35 and 45: cloprostenol 1 µg/kg SC (after a tenfold dilution with physiologic saline) on days 1 and 3 given at least 8 hours after food, in combination with cabergoline 5 µg/kg PO once daily with food for 7 days.[6] If pregnancy is not terminated by day 8, continue cabergoline (at same dose) until day 12.

CATS:

Adjunctive treatment of open pyometra (extra-label): Cloprostenol 5 µg/kg SC once daily for 3 days in addition to appropriate antibiotic therapy.

CATTLE:

Labeled indications in beef or dairy cows and replacement beef and dairy heifers using cloprostenol as a single agent (label dosage; FDA-approved)[1]:

a) **Unobserved or undetected estrus; treatment of pyometra, chronic endometritis, or luteal cysts; expulsion of a mummified fetus; induced abortions**: cloprostenol 500 µg/cow (NOT µg/kg) IM once.[1] When used for unobserved or non-detected estrus, cows can be inseminated at the usual time after detection of estrus, or twice at ≈72 and 96 hours after injection.

b) **Estrus synchronization**:

NOTE: Controlled breeding programs should be completed by observing animals and re-inseminating, hand mating after returning to estrus, or turning in clean-up bull(s) 5 to 7 days after the last cloprostenol injection to cover any animals returning to estrus.

Single injection method: Use only for animals with a mature corpus luteum. Complete rectal examination to determine corpus luteum maturity, anatomic normality, and lack of pregnancy. Give cloprostenol 500 µg/cow (NOT µg/kg) IM. Estrus should occur in 2 to 5 days. Inseminate at usual time after detecting estrus or inseminate 72 hours after cloprostenol injection; consider repeating insemination 96 hours after injection.

Double injection method: Complete rectal examination to determine corpus luteum maturity, anatomic normality, and lack of pregnancy. Give cloprostenol 500 µg/cow (NOT µg/kg) IM. Repeat dose 11 days later. Estrus should occur in 2 to 5 days after second injection. Inseminate at usual time after detecting estrus or inseminate 72 hours after second cloprostenol injection; consider repeating insemination 96 hours after second injection.

In combination with gonadorelin to synchronize estrous cycles for fixed time artificial insemination in lactating dairy cows (label dosage; FDA-approved)**:** Gonadorelin 86 µg/cow (NOT µg/kg) IM on Day 0, then give cloprostenol 500 µg/cow (NOT µg/kg) IM 6 to 8 days later, then repeat gonadorelin 86 µg/cow (NOT µg/kg) IM 30 to 72 hours after cloprostenol.[7] Inseminate cows 8 to 24 hours after the second gonadorelin injection or using standard herd practices.

HORSES:

Abortifacient (extra-label):

a) For mismating, cloprostenol 100 – 250 µg/mare (NOT µg/kg) IM may be administered as a single injection beginning at day 5 or 6 postovulation.

b) For pregnancy termination, cloprostenol 100 – 250 µg/mare (NOT µg/kg) IM may be administered as a single injection until day 35 of gestation. From day 35 until 100 days of gestation, serial daily injections may be needed to effectively terminate pregnancy.

Luteolysis and to stimulate uterine contractions (extra-label):

a) Cloprostenol 250 µg/horse (NOT µg/kg) IM once. Research has shown that 10% of a dose (25 µg) can cause luteolysis; if this dose is given once or on two consecutive days, adverse effects can be avoided.[8]

b) As an ecbolic: 250 µg /horse (NOT µg/kg) IM every 24 hours. Cloprostenol should not be used more than one day after ovulation because it can affect normal luteal function and risk pregnancy maintenance.

SWINE:

Induce parturition in sows (extra-label): Cloprostenol 175 µg/pig (NOT µg/kg) IM; give 2 days or less before anticipated date of farrowing. Farrowing generally occurs ≈36 hours after injection.[9]

SHEEP/GOATS:

Estrus synchronization (extra-label): During the breeding period, cloprostenol 125 µg/female (NOT µg/kg) IM or SC twice 9 to 10 days apart. Males can be reintroduced 48 hours after the second injection.

Induce parturition in does (extra-label):

a) Cloprostenol 62.5 – 125 µg/female (NOT µg/kg) IM at 144 days of gestation in early morning. Deliveries will peak at 30 to 35 hours after injection. Maintain goat in usual surroundings and minimize disturbances.

b) Toxemia in does: If there is only a partial response to medical therapy, induction of parturition with cloprostenol 250 µg/female (NOT µg/kg) IM can be attempted. Kidding or abortion typically occurs in 30 to 36 hours. A cesarean section may be needed if the animal does not respond quickly to therapy.[10]

Pseudopregnancy |hydrometra | mucometra (extra-label): Cloprostenol 125 µg/female (NOT µg/kg) IM once

CAMELIDS:

Luteolysis (extra-label): *Alpacas:* Cloprostenol 100 to 175 µg/alpaca (NOT µg/kg) IM once. *Llamas:* Cloprostenol 250 µg/llama (NOT µg/kg) IM. Give once or twice 24 hours apart. Luteolysis and abortion can be induced at any stage of pregnancy with 2 to 4 injections of cloprostenol.[11]

Monitoring
- Adverse effects
- Abdominal ultrasound to confirm pregnancy and/or termination of pregnancy

Client Information
- Cloprostenol should only be used by individuals familiar with its use and precautions.
- Pregnant women should not handle this medicine. Asthmatics or persons with other lung conditions should handle this product with extreme caution.
- Wear disposable gloves when handling and any accidental skin exposure should be washed off immediately.

Chemistry/Synonyms
A synthetic prostaglandin of the F class, cloprostenol sodium occurs as a white to off- or almost white, amorphous, hygroscopic powder. It is freely soluble in water and alcohol. Potency of the commercially available product is expressed in terms of cloprostenol.

Cloprostenol sodium may also be known as ICI-80996, *Estrumate®*, or *estroPLAN®*.

Storage/Stability
Cloprostenol sodium should be stored at room temperature (15°C-30°C [59°F-86°F]); protect from light. Use vial within 28 days of first puncture.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:

Cloprostenol Sodium Injection equivalent to 250 µg/mL cloprostenol in 20 mL vials; *Estrumate®*, *estroPLAN Injection*; (Rx). FDA-approved for use in beef and dairy cattle. No preslaughter or milk withdrawal is required when used at labeled dosages; no specific tolerances for cloprostenol residues have been published.

HUMAN-LABELED PRODUCTS: NONE

Clorazepate
(klor-***az***-e-pate) *Tranxene®*

Benzodiazepine

Prescriber Highlights
- ► Benzodiazepine anxiolytic, sedative-hypnotic, and anticonvulsant used in dogs and cats
- ► Contraindications include hypersensitivity to benzodiazepines, closed-angle glaucoma, or significant liver disease.
- ► Use with caution in aggressive animals (especially those with fear-induced aggression).
- ► Most prevalent adverse effects include sedation and ataxia
- ► DEA Schedule IV (C-IV) controlled substance

Uses/Indications
Clorazepate has been used in dogs both as an adjunctive anticonvulsant (often in conjunction with phenobarbital) and in the treatment of behavior disorders (primarily those that are anxiety or phobia related). It may be used chronically, or for short-term bridging until steady state is reached with primary, long-term therapies (eg, phenobarbital or bromides for seizure control or fluoxetine for anxiety) Clorazepate, along with fluoxetine and behavior modification, was shown to be most effective in treating nonaggressive dogs with anxiety-related disorders; aggressive dogs were less likely to improve or to show worsening of their undesired behavior.[1] Dogs have been reported to develop tolerance to the anticonvulsant effects of clorazepate less rapidly than to clonazepam or diazepam.[2]

Clorazepate has also been used as an anxiolytic or anticonvulsant agent in cats; however, there is little published on its use in this species.

Pharmacology/Actions
The subcortical levels (primarily limbic, thalamic, and hypothalamic) of the CNS are depressed by clorazepate and other benzodiazepines, thus producing the anxiolytic, sedative, skeletal muscle relaxant, and anticonvulsant effects seen. The exact mechanism of action is unknown, but postulated mechanisms include antagonism of serotonin, increased release of and/or facilitation of gamma-aminobutyric acid (GABA) activity, and diminished release or turnover of acetylcholine in the CNS. Benzodiazepine-specific receptors have been located in the mammalian brain, kidney, liver, lungs and heart. In all species studied, receptors are lacking in the white matter.

Pharmacokinetics
In dogs, clorazepate peak serum concentrations generally occur within 1 to 2 hours. Oral volume of distribution is ≈1.8 L/kg after multiple doses.[3] Clorazepate is metabolized to nordiazepam (also a metabolite of diazepam) and other metabolites in humans and dogs.[4] Nordiazepam is active and has a very long half-life (in humans, up to 100 hours), although the nordiazepam half-life after diazepam administration is only 2 to 10 hours.[5-7].

Contraindications/Precautions/Warnings
Clorazepate is contraindicated in patients with acute closed-angle glaucoma and in those that are hypersensitive to it or other benzodiazepines. Benzodiazepines, including clorazepate, should be used cautiously, if at all, in aggressive and fearful patients, as it may disinhibit the anxiety that may help prevent aggressive behavior in these animals.[1] Benzodiazepines have been reported to exacerbate myasthenia gravis. Patients with renal or hepatic dysfunction may require a reduced dosage, closer observation, or both. Because benzodiazepines increase the risk for respiratory depression, they should be used with caution in patients with respiratory disease.

The effect, if any, of clorazepate on the performance of working dogs is unknown. Physical dependence has been demonstrated in dogs and rabbits, and abrupt withdrawal of clorazepate has caused irritability and nervousness in humans and seizures in animals.[8] Withdrawal seizures have been observed in dogs one day after cessation of treatment and was lethal in one dog.[2]

Because the metabolism of clorazepate in cats has not been fully elucidated, cats should be monitored for potential development of acute hepatic necrosis that has been documented in cats receiving diazepam.[4] (See ***Diazepam***)

Do not confuse clorazepate with clonazepam. Consider writing orders and prescriptions using tall man letters: clorazePATE.

Adverse Effects
In dogs, the most commonly seen adverse effects include sedation and ataxia; similar effects may occur in cats. These effects occur infrequently and are mild and usually transient.

Reproductive/Nursing Safety
Nordiazepam, a metabolite of clorazepate, crosses the placenta. No fetal toxicity was noted after oral administration to rabbits given up to 15 mg/kg or rats given up to 150 mg/kg[8]; however, teratogenic effects of similar benzodiazepines have been noted in rabbits and rats. In humans, other benzodiazepines have been implicated in causing congenital abnormalities when administered during the first trimester of pregnancy. Signs of withdrawal have occurred in infants whose mothers chronically took benzodiazepines during pregnancy. The veterinary significance of these effects is unclear, but these agents should only be used during the first trimester of pregnancy, when the

benefits clearly outweigh the risks associated with their use.

Benzodiazepines and their metabolites, including nordiazepam, are distributed into milk and may cause CNS effects in nursing neonates. Use with caution in nursing veterinary patients.

Overdose/Acute Toxicity

The oral LD_{50} in rats is 1320 mg/kg.[8] Dogs have tolerated doses up to 75 mg/kg. When clorazepate is used alone, overdoses are generally limited to significant CNS depression (eg, confusion, coma, decreased reflexes). Treatment of significant oral overdoses consists of standard protocols for GI decontamination and supportive systemic measures. Flumazenil may be considered for more serious overdoses; repeated flumazenil doses may be needed. The use of analeptic agents (CNS stimulants such as caffeine, amphetamines) is generally not recommended.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving clorazepate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: Concurrent use may increase bioavailability and pharmacologic effects of benzodiazepines. Monitor for adverse effects and adjust benzodiazepine dose accordingly.
- **Antacids, Oral** (eg, **calcium carbonate, aluminum/magnesium combinations**): May slow the rate, but not the extent, of oral absorption; administer 2 hours apart to avoid this potential interaction.
- **Antihypertensive Agents** (eg, **atenolol**, **amlodipine**, **lisinopril**): Concurrent use may increase risk for hypotension and orthostasis. Monitor blood pressure.
- **Carbonic Anhydrase Inhibitors** (**CAIs**; eg, **dichlorphenamide**, **methazolamide**): Benzodiazepines may interfere with the beneficial effects of CAIs by inhibiting respiratory responses to hypoxia. Avoid combination.
- **CNS Depressant Agents** (eg, **acepromazine, anesthetic agents, cannabidiol**): Combination may increase the risk of CNS and/or respiratory depression. Monitor and adjust doses accordingly.
- **Digoxin**: Serum digoxin concentrations may be increased with concurrent administration; monitor serum digoxin levels and for clinical signs of toxicity.
- **Flumazenil:** Flumazenil reduces the effects of clorazepate by competing for benzodiazepine receptors. **NOTE**: This action is an expected outcome when flumazenil is used as a reversal agent.
- **Fluoxetine, Fluvoxamine**: Decreased clorazepate metabolism is possible.
- **Hepatic Enzyme Inducers** (eg, **dexamethasone**, **carbamazepine, rifampin**): Concurrent use may increase benzodiazepine metabolism. Monitor clinical response and adjust doses accordingly.
- **Hepatic Enzyme Inhibitors** (eg, **cimetidine, erythromycin, isoniazid, ketoconazole, itraconazole**): Metabolism of clorazepate may be decreased, and excessive sedation may occur. Cimetidine reduced nordiazepam half-life by 37%.[9]
- **Ifosfamide:** Concurrent use may increase the risk for ifosfamide-induced neurotoxic effects. Carefully monitor patients and discontinue both drugs if signs of encephalopathy occur.
- **Non-Depolarizing Neuromuscular Blockers** (eg, **atracurium**, **pancuronium**): Concurrent use of benzodiazepines may potentiate, attenuate, or have no effect on nondepolarizing neuromuscular blockers.
- **Opioids** (eg, **buprenorphine, fentanyl, morphine, tramadol**)**:** Concurrent use may increase the risk for respiratory and/or CNS depression.
- **Phenobarbital:** Concurrent phenobarbital may reduce concentration of clorazepate's active metabolite, nordiazepam.[10] Concurrent use may increase risk for respiratory and/or CNS depression.
- **Theophylline/Aminophylline:** Concurrent use may decrease the levels and effectiveness of benzodiazepines. Withdrawing theophylline from a stable patient may increase risk of benzodiazepine toxicity.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine, imipramine**): Clorazepate may increase plasma concentrations of these drugs; clinical significance is not known. However, concurrent use may increase the risk of CNS and/or respiratory depression. Anticholinergic effects may be additive.
- **Valproic Acid/Divalproex:** Concurrent use may increase risk for teratogenesis and may displace benzodiazepines from protein binding sites and inhibit benzodiazepine metabolism. Monitor for over sedation and avoid combination in pregnancy.
- **Yohimbine:** Limited data indicate that yohimbine may decrease therapeutic effects of anxiolytic drugs.

Laboratory Considerations

- Benzodiazepines may decrease the thyroidal uptake of I^{123} or I^{131}.
- Clorazepate may increase **serum alkaline phosphatase** and **serum cholesterol** levels; clinical significance is unclear.

Dosages

DOGS:

Adjunctive treatment of epilepsy (extra-label): Dosing recommendations vary but consider: 0.5 – 1.5 mg/kg PO every 8 hours or 1 – 2.5 mg/kg PO every 12 hours; generally used in conjunction with phenobarbital (see ***Drug Interactions***).

Adjunctive therapy for treatment of fears and phobias (extra-label):

a) 1 mg/kg PO every 24 hours combined with fluoxetine 1 mg/kg PO once daily and behavior modification therapy[1]; clorazepate was discontinued after 4 weeks.

b) 0.55 – 2.2 mg/kg PO up to every 8 hours

CATS:

Anxiolytic or for treatment of compulsive behaviors (extra-label): 0.2 – 0.5 mg/kg PO every 12 to 24 hours[11]

Alternative drug to phenobarbital for seizures (extra-label): 3.75 – 7.5 mg/cat (NOT mg/kg) PO once to twice daily[4]

Monitoring

- Efficacy based on indication for use (eg, seizure control, improvement in desired behavior)
- Adverse effects (eg, sedation, ataxia)
- Cats: baseline and periodic (eg, after 1 week of treatment and again within one month) liver enzyme measurements[4]

Client Information

- This medicine can be used to prevent fear and anxiety in dogs and cats.
- This medicine may increase appetite, especially in cats.
- When using this medicine for thunderstorm phobias or other triggers (eg, separation anxiety) that upset your animal, give the

clorazepate about an hour before the event or trigger.

- Clorazepate can be given with or without food. If your animal vomits or acts sick after receiving the medicine on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- If your cat stops eating or if you see yellowing of the whites of the eyes, gums, or skin (jaundice), contact your veterinarian immediately.
- Sleepiness is the most common side effect, but sometimes the drug can change behavior or work in a way that's opposite from what is expected.
- Clorazepate is classified as a Schedule IV (C-IV) controlled drug by the federal Drug Enforcement Agency (DEA). Use of this medication in animals or humans other than those for whom they are prescribed is illegal.

Chemistry/Synonyms

A benzodiazepine anxiolytic, sedative-hypnotic, and anticonvulsant, clorazepate dipotassium occurs as a light yellow, fine powder that is very soluble in water and slightly soluble in alcohol.

Clorazepate dipotassium may also be known as Abbott-35616, AH-3232, 4306-CB, clorazepic acid, dipotassium clorazepate, dikalii clorazepas, or potassium clorazepate; many trade names are available.

Storage/Stability

Store clorazepate tablets at room temperature (20˚C-25˚C [68˚F-77˚F) and protected from light and moisture.

Clorazepate dipotassium is unstable in the presence of water. Consider keeping the desiccant packets in with the original container and adding a desiccant packet to the prescription vial when dispensing large quantities of tablets to the client.

Follow applicable local, state, and federal rules regarding controlled drug storage, waste, and disposal.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Clorazepate Dipotassium Tablets: 3.75 mg, 7.5 mg, and 15 mg; *Tranxene® T-tab*, generic; (Rx DEA C-IV). Report prescribing and/or dispensing to state monitoring programs where required.

Cloxacillin
Cloxacillin Benzathine
Cloxacillin Sodium

(klox-a-***sill***-in) *Dariclox®, Orbenin-DC®, Dry-Clox®*

Anti-Staphylococcal Penicillin

Prescriber Highlights

- ► Intramammary isoxazolyl (anti-staphylococcal) penicillin
- ► Contraindications include hypersensitivity to penicillins
- ► Oral dosage forms of cloxacillin (human) no longer marketed in the United States
- ► Rarely used systemically in veterinary medicine

Uses/Indications

Cloxacillin is used via intramammary infusion in dry and lactating dairy cattle.

The World Health Organization (WHO) has designated cloxacillin as a Highly Important antimicrobial for human medicine.[1] The Office International des Epizooties (OIE) has designated cloxacillin as a Veterinary Critically Important Antimicrobial (VCIA) Agent in bovine, caprine, equine, ovine, and swine species.[2]

Pharmacology/Actions

Cloxacillin, dicloxacillin, and oxacillin have nearly identical spectrums of activity and can be considered therapeutically equivalent when comparing their in vitro activity. These penicillinase-resistant penicillins have a narrower spectrum of activity than the natural penicillins. Their antimicrobial efficacy is aimed directly against penicillinase-producing strains of gram-positive cocci, particularly staphylococcal species, and they are sometimes called anti-staphylococcal penicillins. Cloxacillin is not destroyed by the enzyme penicillinase, and therefore it is active against penicillin-resistant strains of *Staphylococcus aureus*. It is also active against non-penicillinase–producing *Staphylococcus aureus* as well as *Streptococcus agalactiae*. Although this class of penicillins has activity against some other gram-positive and gram-negative aerobes and anaerobes, other antibiotics (penicillins and otherwise) are usually better choices. The penicillinase-resistant penicillins are *not* effective against methicillin-resistant staphylococci, *Rickettsia* spp, mycobacteria, fungi, *Mycoplasma* spp, and viruses.

Pharmacokinetics

Cloxacillin is only available in intramammary dosage forms in the United States. In the nonlactating mammary gland, cloxacillin benzathine provides bactericidal cloxacillin levels for a prolonged period. This prolonged activity is due to the low solubility of the cloxacillin benzathine and to the slow-release oil-gel base. This prolonged contact between the antibiotic and the pathogenic organism enhances the probability of a bacteriologic cure.

Contraindications/Precautions/Warnings

Penicillins are contraindicated in patients with a history of hypersensitivity to them. Use penicillins cautiously in patients that are documented to be hypersensitive to other beta-lactam antibiotics (eg, cephalosporins, cefamycins, carbapenems) because there may be cross-reactivity.

Adverse Effects

Adverse effects with the penicillins are usually not serious and have a relatively low frequency of occurrence.

Hypersensitivity reactions, unrelated to dose, can occur with these agents and can manifest as rashes, fever, eosinophilia, neutropenia, agranulocytosis, thrombocytopenia, leukopenia, anemias, lymphadenopathy, or anaphylaxis. In humans, it is estimated that up to 15% of patients that are hypersensitive to cephalosporins will also

be hypersensitive to penicillins.[3] The incidence of cross-reactivity in veterinary patients is unknown.

Reproductive/Nursing Safety

Penicillins have been shown to cross the placenta. Safe use of these drugs during pregnancy has not been firmly established, but neither have there been any documented teratogenic problems associated with these drugs. This class of drugs is likely safe when used via the intramammary route.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose of intramammary infusions is unlikely to pose much risk to the patient but may prolong withdrawal times.

Drug Interactions

- No significant interactions are likely when intramammary dosage forms are used as labeled.

Laboratory Considerations

- No specific concerns were noted.

Dosages

CATTLE:

Mastitis (treatment or prophylaxis) caused by susceptible organisms (Label dosage; FDA-approved):

a) Lactating cows (using lactating cow formula; sodium cloxacillin): After milking out completely, clean and disinfect teat(s), then instill contents of one syringe into each affected quarter; massage. Repeat every 12 hours for 3 total doses.[4]

b) Dry (nonlactating) cows (using dry cow formula; cloxacillin benzathine): After last milking (or early in the dry period), clean and disinfect teats, then instill contents of one syringe into each quarter; massage.[5,6]

Monitoring

- Because penicillins usually have minimal toxicity associated with their use, monitoring for efficacy is usually all that is required unless toxic signs develop. Serum levels and therapeutic drug monitoring are not routinely done with these agents.

Client Information

- Prior to administration, be sure to follow all product instructions for milking, cleaning, and disinfecting the udder and teats.
- After administration, gently massage the affected quarter(s) to distribute the medicine
- Lactating cow product (sodium cloxacillin; *Dariclox*®) withdrawal times after last treatment, when used as labeled: milk withdrawal = 48 hours; slaughter withdrawal = 10 days
- Dry cow products (benzathine; *Orbenin-DC*®, *Dry-Clox*®) slaughter withdrawal is 28 or 30 days depending on product used.

Chemistry/Synonyms

Cloxacillin sodium, an isoxazolyl-penicillin, is a semisynthetic, penicillinase-resistant penicillin. It is available commercially as the monohydrate sodium salt that occurs as an odorless, bitter-tasting, white, crystalline powder. It is freely soluble in water and soluble in alcohol and has a pK_a of 2.7. One milligram of cloxacillin sodium contains not less than 825 µg of cloxacillin.

Cloxacillin benzathine occurs as a white or almost white powder that is slightly soluble in water and alcohol. A 1% (10 mg/mL) suspension has a pH from 3 to 6.5.

Cloxacillin sodium may also be known as BRL-1621, sodium cloxacillin, chlorphenylmethyl isoxazolyl penicillin sodium, methylchlorophenyl isoxazolyl penicillin sodium, cloxacilina sodica, cloxacillinum natricum, or P-25; many trade names are available.

Storage/Stability

Unless otherwise instructed by the manufacturer, store cloxacillin benzathine or cloxacillin sodium mastitis syringes at temperatures less than 25°C (77°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Cloxacillin Benzathine 500 mg (of cloxacillin) in a peanut-oil gel; 10 mL syringe for intramammary infusion: *Orbenin-DC*®, *Dry-Clox*; (Rx). FDA-approved for use in dairy cows during the dry period (immediately after last milking or early in the dry period). Do not use *Dry-Clox*® within 30 days prior to calving; (28 days for *Orbenin-DC*®). Slaughter withdrawal for *Dry-Clox*® = 30 days; *Orbenin*®-DC = 28 days

Cloxacillin Sodium 200 mg (of cloxacillin) in vegetable oils; 10 mL syringe for intramammary infusion: *Dariclox*®; (Rx). FDA-approved for use in lactating dairy cows. When the drug is used as labeled, milk withdrawal = 48 hours; slaughter withdrawal = 10 days

HUMAN-LABELED PRODUCTS: NONE

Cobalamin

Cyanocobalamin, Hydroxocobalamin, Methylcobalamin, Vitamin B_{12}

(koe-***bal***-a-min)

Vitamin

Prescriber Highlights

- ► Used for oral (eg, cyanocobalamin, methylcobalamin) and parenteral (eg, cyanocobalamin, hydroxocobalamin) treatment of cobalamin (ie, vitamin B_{12}) deficiency
- ► Safe to use
- ► Cyanocobalamin and hydroxocobalamin have equivalent biologic activity in humans; there are no data available in animals.
- ► Hydroxocobalamin at very high (mg/kg, NOT µg/kg) doses can be used as a cyanide antidote.

Uses/Indications

Cyanocobalamin is used for the treatment of cobalamin (ie, vitamin B_{12}) deficiencies secondary to GI tract disease or exocrine pancreatic insufficiency (EPI). It is also used for dietary chromium deficiencies (in ruminants) that can be associated with cobalamin dietary deficiencies. As there appears to be a high percentage of dogs and cats with EPI or GI disease that are deficient in cobalamin, there is considerable interest in evaluating serum cobalamin in these patients. Cobalamin supplementation appears to improve overall EPI treatment response.[1] Beagles, border collies, and komondors have a genetic defect (ie, Imerslund-Gräsbeck syndrome) that affects the location of the cobalamin-intrinsic factor receptor, causing cobalamin deficiency.[2–4] Chinese shar-peis in the United States are an overrepresented breed for cobalamin deficiency of undetermined etiology that is likely related to abnormal cobalamin metabolism.[5] Other breeds (eg, giant schnauzers, Australian shepherd dogs)[6,7] have been associated with cobalamin deficiency, but these breeds generally do not have a higher incidence of cobalamin deficiency as compared with other breeds. Dogs with EPI or chronic enteropathy also commonly develop cobalamin deficiency. Hypocobalaminemia at the time of diagnosis has been associated with reduced survival in dogs with

EPI.[8] Oral and parenteral cobalamin supplementation both appear to be effective in dogs[9] and cats.[10]

Hydroxocobalamin may have potential use in dogs with cyanide poisoning.[11] Hydroxocobalamin has shown promise in experimental models of hydrogen sulfide exposure[12] and anecdotally in dogs with smoke inhalation.

Pharmacology/Actions

Cobalamin, a cobalt-containing water-soluble vitamin, serves as an important cofactor for many enzymatic reactions in mammals that are required for normal cell growth, function, and reproduction; nucleoprotein and myelin synthesis; amino acid synthesis; carbohydrate and fat metabolism; and erythropoiesis. Cobalamin is required for folate utilization; cobalamin deficiency can cause functional folate deficiency. Unlike in humans, macrocytic anemias do not appear to be a significant component for cobalamin deficiency in dogs or cats.[13]

In ruminants, cobalamin appears to be synthesized by rumen microbiota and requires dietary cobalt to be present for its formation.

Hydroxocobalamin can be used interchangeably with cyanocobalamin for cobalamin supplementation.[14]

Hydroxocobalamin is used as a cyanide antidote by binding to cyanide and forming cyanocobalamin, which is excreted in the urine.

Pharmacokinetics

After food is consumed in monogastric mammals, gastric proteolytic enzymes cleave cobalamin from dietary proteins. Cobalamin then binds to haptocorrin in the stomach. The haptocorrin–cobalamin complex becomes hydrolyzed by pancreatic proteases in the duodenum. After being separated from the complex, cobalamin binds to intrinsic factor (IF), a protein produced in the stomach in humans and in the exocrine pancreas in dogs and cats.[14] The cobalamin–IF complex is absorbed in the small intestine and binds to cubulin, which facilitates its entry into the portal circulation. Transcobalamin 2 (TCII), a protein, then binds to cobalamin, allowing its entry into target cells. Some cobalamin is rapidly excreted into the bile where enterohepatic recirculation occurs.

In healthy cats, the circulating half-life of cobalamin is ≈13 days; however, in 2 cats with inflammatory bowel disease, the circulating half-life was only 5 days.[15]

After a hydroxocobalamin bolus at 70 mg/kg (NOT µg/kg) IV was given to dogs, the volume of distribution was 0.49 L/kg, clearance was 0.58 L/hour, and elimination half-life was 7.4 hours.[16]

In humans, IM hydroxocobalamin is more slowly absorbed from the injection site and produces a more sustained rise in cobalamin concentrations than cyanocobalamin. Hydroxocobalamin is stored in the liver and undergoes some enterohepatic recirculation. Hydroxocobalamin is excreted in the urine more slowly than cyanocobalamin.

Contraindications/Precautions/Warnings

No contraindications are documented for injectable or oral use in domestic animals. In humans, cyanocobalamin is contraindicated in patients hypersensitive to it, hydroxocobalamin, or cobalt.

In humans, administration by the IV route results in almost all of the dose being lost in the urine.

Do not use cyanocobalamin to treat cyanide toxicity.

Adverse Effects

Cyanocobalamin appears to be very well tolerated when used parenterally in animals. In humans, anaphylaxis has rarely been reported after parenteral use. Pain at the injection site is uncommon with cyanocobalamin but may be more problematic with hydroxocobalamin, as the latter has a lower pH. Skin discoloration, hypotension, and bradycardia may occur when hydroxocobalamin is used at high doses as a cyanide antidote.[17]

Reproductive/Nursing Safety

Serum cobalamin decreases in late pregnancy; it is unclear what, if any, adverse effects result.[18] Cobalamin crosses the placenta. Studies documenting safety during pregnancy have apparently not been done in humans or animals, but cobalamin is likely safe to use. Vitamin B_{12} deficiencies are thought to cause teratogenic effects.

Although cobalamin can be excreted into milk, it is safe for use while nursing.

Overdose/Acute Toxicity

Overdose has not been reported with cyanocobalamin.[19] Hydroxocobalamin LD_{50} is 50 mg/kg when given IV to mice.[20]

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving cobalamin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Chloramphenicol:** Concurrent use may result in decreased hematologic response.
- **Proton Pump Inhibitors** (**PPIs**; eg, **omeprazole, pantoprazole**): Long-term use of PPIs may reduce cobalamin absorption in humans; veterinary significance is unknown. Cobalamin deficiency was not detected after 60 days of twice-daily omeprazole administration in 6 healthy cats.[21]

Laboratory Considerations

- Serum samples to be analyzed for cobalamin and/or folate should be protected from bright light and excessive heat.

Dosages

NOTE: Cyanocobalamin and hydroxocobalamin have equivalent biologic activity in humans. Although cost and availability may be obstacles, hydroxocobalamin can be a substitution for veterinary patients that do not readily respond to cyanocobalamin.[14] All dosages are for cyanocobalamin unless otherwise noted.

DOGS:

Cobalamin (ie, vitamin B_{12}) deficiency:

Cyanocobalamin (extra-label):

a) **Injectable**: 25 µg/kg SC, or practically, if body weight is less than 5 kg (11 lb), 250 µg/dog (NOT µg/kg); 5 to 10 kg (11 to 22 lb), 400 µg/dog (NOT µg/kg); 10 to 20 kg (22 to 44 lb), 600 µg/dog (NOT µg/kg); 20 to 30 kg (44 to 66 lb), 800 µg/dog (NOT µg/kg); 30 to 40 kg (66 to 88 lb), 1000 µg/dog (NOT µg/kg); 40 to 50 kg (88 to 110 lb), 1200 µg/dog (NOT µg/kg); greater than 50 kg (110 lb), 1500 µg/dog (NOT µg/kg) once weekly for 4 to 6 weeks, then once monthly. If serum cobalamin concentrations are low after monthly administration, consider reducing dosing interval to every 2 weeks.[14,22]

b) **Oral**: Body weight 1 to 10 kg (2.2 to 22 lb), 250 µg/dog (NOT µg/kg); 10 to 20 kg (22 to 44 lb), 500 µg/dog (NOT µg/kg); greater than 20 kg (44 lb), 1000 µg/dog (NOT µg/kg) PO every 24 hours.[23] Alternatively, dogs less than 20 kg (44 lb), 250 µg/dog (NOT µg/kg); greater than 20 kg (44 lb), 1000 µg/dog (NOT µg/kg) PO every 24 hours.[24] Cyanocobalamin at 1000 µg PO once daily maintained normal clinical status and cellular markers in 3 beagles with Imerslund-Gräsbeck syndrome.[25]

Hydroxocobalamin for chronic enteropathy (extra-label): 0.25 – 1 mg/dog (NOT mg/kg) IM. Administration of hydroxocobalamin at 1 mg/dog (NOT mg/kg) IM every other month controlled clinical signs and laboratory parameters in beagles with Imerslund-Gräsbeck syndrome.[26]

Adjunctive treatment for cyanide poisoning, including sodium nitroprusside toxicity or smoke inhalation (extra-label):

NOTE: Cyanocobalamin should *not* be used for this indication. **Hydroxocobalamin** 75 – 150 mg/kg (NOT µg/kg) IV infusion over 7.5 minutes.[11,17] Intraosseous infusion may be considered.[27]

CATS:

Cobalamin (ie, vitamin B_{12}) deficiency (extra-label):

a) **Injectable**: 250 µg/cat (NOT µg/kg) SC once weekly for 6 weeks, then once every 1 to 2 months based on cobalamin levels

b) **Oral**: 250 µg/cat (NOT µg/kg) PO every 24 hours for 12 weeks[22]; 0.91 mg/m^2 (NOT mg/kg) PO once daily has been reported[10]

HORSES:

Vitamin B_{12} nutritional supplement (label dosage; not FDA-approved): 1000 – 6000 µg/horse (NOT µg/kg) IM or SC; dose may be repeated every 1 to 2 weeks depending on condition and response to treatment.[19,28]

CATTLE, SHEEP:

Vitamin B_{12} nutritional supplement (label dosage; not FDA approved): 1000 – 6000 µg/animal (NOT µg/kg) IM or SC; dose may be repeated every 1 to 2 weeks depending on condition and response to treatment[19,28]

Cobalamin (ie, vitamin B_{12}) deficiency associated with cobalt deficiency in sheep (extra-label):

a) **Adult sheep**: 300 – 1000 µg/sheep (NOT µg/kg) IM or SC once weekly[29]

b) **Lambs**: 100 µg/lamb (NOT µg/kg) IM or SC[29]

Cobalamin (ie, vitamin B_{12}) deficiency in lambs (extra-label): 2000 µg/lamb (NOT µg/kg) SC once; may be repeated every 60 days[30,31]

SWINE:

Vitamin B_{12} nutritional supplement (label dosage; not FDA-approved): 1000 – 6000 µg/pig (NOT µg/kg) IM or SC; dose may be repeated every 1 to 2 weeks depending on condition and response to treatment[19,28]

RABBITS:

Deep vein thrombosis (extra-label): cyanocobalamin (vitamin B_{12}) 500 µg /rabbit (NOT µg/kg) once daily in addition to folic acid (vitamin B_9) 15 mg/rabbit (NOT mg/kg) PO daily.[32] High levels of cobalamin (vitamin B_{12}) and folic acid (vitamin B_9) can improve plasma hyperhomocysteinemia, coagulation indexes, and some pathologic changes seen in deep vein thrombosis of the lower extremity.

Monitoring

- Cobalamin levels (serum cobalamin concentration) are improved by 1 month after initial loading therapy (either daily oral doses or weekly injections) is complete.[9] If the cobalamin concentration is low then increase dosing frequency from weekly to twice weekly.[14]
- In small animal species, folate status (before and after treatment with cyanocobalamin)
- Improvement of clinical signs associated with deficiency
- Baseline and periodic CBC if/when indicated by clinical condition
- Serum methylmalonic acid may be useful for diagnosis of cobalamin deficiency and monitoring treatment response.[24,33,34]

Client Information

- This medication is a vitamin injected under the skin to treat vitamin B_{12} (ie, cobalamin) deficiency. Treatment may be needed for the rest of your animal's life.
- Improvement is often seen after the first 1 to 2 weeks of treatment.
- This medication is very safe; injections may sting on administration.
- Dispose of needles and syringes safely in a sharps container provided by your veterinarian.

Chemistry/Synonyms

Cyanocobalamin occurs as dark red crystals or a crystalline powder. Hydroxocobalamin appears as dark red orthorhombic needles or as an amorphous or crystalline red powder. Cyanocobalamin is sparingly soluble in water and soluble in alcohol, and hydroxocobalamin is moderately water soluble. In the anhydrous form, cyanocobalamin and hydroxocobalamin are very hygroscopic and can absorb substantial amounts of water from the air. The pH range of commercial cyanocobalamin for injection is 4.5 to 7; the pH of hydroxocobalamin for injection is 3.5 to 5. Cyanocobalamin and hydroxocobalamin have equivalent biologic activity in humans.

Vitamin B_{12} may also be known as cobalamin. Cyanocobalamin may also be known as cianocobalamina, cianokobalaminas, cobamin, cyanocobalamine, cyanocobalaminum, or cycobemin; there are many internationally registered trade names.

Storage/Stability

Cyanocobalamin injection should be stored below 40°C (104°F) and protected from light and freezing.

Hydroxocobalamin for injection should be stored protected from light and moisture at controlled room temperature 20°C to 25°C (59°F-77°F). Cyanide antidote kits may experience excursions up to 60°C (140°F) for up to 4 days and freeze/thaw cycles for up to 15 days.

Compatibility/Compounding Considerations

Cyanocobalamin, a USP active pharmaceutical ingredient powder, is magenta in color and often used as a tracer instead of azo dyes when compounding capsules for cats or other patients that cannot tolerate azo dyes found in food colors.

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information

Cyanocobalamin injection is reportedly **compatible** with all commonly used IV fluids; it is reported to be **incompatible** with chlorpromazine hydrochloride, phytonadione, prochlorperazine edisylate, warfarin sodium, ascorbic acid, dextrose, heavy metals, oxidizing or reducing agents, and alkaline or strongly acidic solutions.

Hydroxocobalamin is reportedly **incompatible** with ascorbic acid, diazepam, dobutamine, fentanyl, nitroglycerin, pentobarbital, propofol, sodium nitrite, sodium thiosulfate, and thiopental.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Cyanocobalamin Chewable Tablets: 250 µg and 1000 µg tablets; *Cobalequin*®; (OTC); also contains methyltetrahydrofolate. Flavored with hydrolyzed chicken

Cyanocobalamin (Vitamin B_{12}) Injection: 1000, 3000, and 5000 µg/mL in 100 mL, 250 mL, and 500 mL multidose vials depending on source; generic; (Rx). Products may be labeled as cyanocobalamin or vitamin B_{12} and be labeled for use in dogs, cats, cattle, horses, sheep, or swine.

There are many combination products, both oral and injectable, that contain cyanocobalamin as an ingredient. These formulations are not recommended for use when cobalamin deficiency exists.

HUMAN-LABELED PRODUCTS:

Cyanocobalamin (crystalline, Vitamin B_{12}) Injection: 100 µg (0.1 mg)/mL and 1000 µg (1 mg)/mL, vial sizes range from 1 mL single use to 10 mL and 30 mL multidose; generic; (Rx). In addition to generic-labeled products, there are several products available with a variety of trade names, including *Crystamine*®, *Crysti*®, *Cyanoject*®, and *Rubesol*®.

Cyanocobalamin (Vitamin B_{12}) Oral Tablets: 100 µg, 250 µg, 500 µg, 1000 µg, 2000 ug, and 5000 ug; generic; (OTC)

Hydroxocobalamin Injection: 1000 µg/mL in 10 mL vials; generic; (Rx). Hydroxocobalamin is also available as a 2.5 g cyanide antidote kit (*Cyanokit®*).

A nasally administered product, oral lozenges, sustained-release tablets, and oral sublingual tablets are marketed, but there is little to no information regarding their use in dogs or cats. Limited information has shown these formulations to be ineffective in veterinary species.

Codeine

(***koe***-deen)

Opioid, Antitussive

Prescriber Highlights

- ► Opioid used for analgesia and cough in dogs and cats
- ► Oral bioavailability in dogs is very low (high first-pass effect), and analgesic efficacy is unknown.
- ► Use is often in combination products with acetaminophen; these combination products are *not* for use in cats or ferrets.
- ► Common adverse effects include sedation, constipation, and respiratory depression (when administered in high doses). Cats may also show CNS stimulation.
- ► DEA controlled substance. Schedule varies by product used: C-II when used as a sole agent; combination products are either C-III or C-V.

Uses/Indications

In small animal medicine, codeine is potentially useful as an oral analgesic for mild pain or as an antitussive, and possibly as an antidiarrheal agent. Its pharmacokinetic profile raises questions of codeine's efficacy in dogs. Codeine did not provide antinociceptive effects in experimental studies in dogs[1] or cats.[2] A pharmacokinetic study[3] concluded that future studies are needed to assess the antinociceptive effects of oral codeine in dogs to determine if the drug can be effectively used. To date, there are no studies that definitively prove the efficacy of oral codeine formulations for antitussive or antidiarrheal effects in veterinary patients.

In dogs with experimentally induced lameness, carprofen was more effective than acetaminophen/codeine at improving lameness scores.[4] In a different study, acetaminophen/codeine and meloxicam were equally effective as perioperative analgesic in dogs undergoing surgery.[5]

Hydrocodone is more potent than codeine, and commercially available dosage forms of hydrocodone are combined with homatropine to prevent abuse, which is why many clinicians prefer a hydrocodone/homatropine combination versus codeine for use as an antitussive in dogs.

Pharmacology/Actions

Codeine possesses mu-opioid activity similar to other opioids. Codeine's pharmacokinetics and metabolic fate—and hence its efficacy—can vary widely between species. In humans, codeine is an effective antitussive and a mild analgesic that produces similar respiratory depression as compared with morphine at equianalgesic dosages. Although the major metabolite in dogs (ie, codeine-6-glucuronide) has opioid activity, it is not clear how much antinociceptive, antitussive, or antidiarrheal activity it possesses.[3] Codeine, like other opioids, can have immunosuppressive effects, but it is not clear if this is clinically significant.[6]

Pharmacokinetics

In dogs, oral codeine is well absorbed, but its bioavailability is ≈4% to 6%, as it appears to undergo extensive first-pass metabolism (primarily to codeine-6-glucuronide). The volume of distribution is 3.2 L/kg, and the elimination half-life is ≈1.5 hours.[1,3,7] Codeine is metabolized predominantly to codeine-6-glucuronide, and only negligible amounts of morphine are formed.[1,3]

In horses, the time to peak codeine concentration is ≈0.44 hours, and its elimination half-life is 2 hours.[8] The drug undergoes extensive biotransformation, with the primary metabolite being morphine-3-glucuronide; morphine-6-glucuronide and morphine were formed but to lesser extents.

In humans, codeine salts are rapidly absorbed after oral administration. Codeine is about ⅔ as effective after oral administration when compared with parenteral administration. After oral administration, the onset of action is usually within 30 minutes, and analgesic effects persist for 4 to 6 hours. Codeine is metabolized in the liver, primarily by glucuronidation and demethylation, and morphine is an active metabolite. Codeine and metabolites are eliminated in the urine.

Contraindications/Precautions/Warnings

Do not use the combination product containing acetaminophen in cats or ferrets; use caution with the combination product in dogs with hepatic insufficiency. Codeine is contraindicated in patients that are hypersensitive to it or other narcotic analgesics; in patients with significant respiratory depression, a known or suspected GI obstruction, or diarrhea caused by toxic ingestion (until the toxin is eliminated from the GI tract); and in patients that are receiving or are within 14 days of receiving monoamine oxidase inhibitors (MAOIs).[9] It should not be used repeatedly in patients with severe inflammatory bowel disease.

All opioids should be used with caution in patients with hypothyroidism, severe renal insufficiency, and hypoadrenocorticism (ie, Addison disease), as well as in geriatric or severely debilitated patients. Because it may obscure the diagnosis or clinical course of these conditions, codeine should be used with caution in patients with head injuries or increased intracranial pressure, seizure disorders, and acute abdominal conditions (eg, colic). Use codeine with extreme caution in patients suffering from respiratory disease or acute respiratory dysfunction (eg, pulmonary edema secondary to smoke inhalation). Dogs experiencing respiratory depression may not be able to efficiently pant and cool themselves in warmer climates.

Opioid analgesics are contraindicated in patients that have been stung by the scorpion species *Centruroides sculpturatus Ewing* or *Centruroides gertschi Stahnke,* as venom may be potentiated.[10] Respiratory depressants should not be used in coral snake envenomation in dogs or cats.[11]

Abrupt discontinuation of codeine after long-term use may lead to clinical signs of withdrawal; gradual tapering of the drug is suggested.

Although other opioids, such as butorphanol, are known to be problematic in dogs with multidrug resistance-1 gene (*MDR1* gene, also known as *ABCB1* gene) polymorphisms, codeine appears to be well tolerated in these dogs.

Some humans have a CYP2D6 genotype that can lead to ultra-rapid metabolism of codeine and the formation of a greater amount of morphine, increasing the risk for respiratory depression. Codeine has a high abuse potential in humans, and diversion from its intended use is possible.

Adverse Effects

Codeine is generally well tolerated, but typical opioid adverse effects are possible, particularly at higher doses or with repeated use. Sedation is the most likely adverse effect. Potential adverse GI effects

include anorexia, vomiting, constipation, ileus, and biliary and pancreatic duct spasms. Respiratory depression is generally not noted unless the patient receives high doses or is at an increased risk (see ***Contraindications/Precautions/Warnings***).

In cats, opioids may cause CNS stimulation with hyperexcitability, tremors, and/or seizures.

Reproductive/Nursing Safety

Opioids cross the placenta. Very high doses in mice have caused delayed ossification, and embryo- and fetotoxic effects have occurred in other laboratory animals.[9] Neonatal opioid withdrawal syndrome may occur in humans. Use during pregnancy only when the benefits outweigh the risks, particularly with chronic use. Long-term opioid use may cause reduced fertility.

Codeine enters maternal milk. Breastfeeding is not recommended in women taking codeine-containing products. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Opioid overdose may produce profound respiratory and/or CNS depression in most species, and airway management is crucial. Other effects can include cardiovascular collapse, hypothermia, and skeletal muscle hypotonia. If an oral overdose occurs, gastric decontamination using standard protocols should be performed. Because rapid changes in CNS status may occur, inducing emesis should be attempted with caution. Naloxone should be used to treat respiratory depression. In cases of massive overdoses, the naloxone dose may need to be repeated, and animals should be closely observed because naloxone's effects may diminish before subtoxic levels of codeine are attained. Mechanical respiratory support should also be considered in cases of severe respiratory depression. Serious overdoses involving opioids should be closely monitored.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving codeine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Drugs** (eg, **atropine, glycopyrrolate, oxybutynin**): Use with codeine may increase the chances of developing constipation.
- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): May increase codeine exposure and morphine formation
- **Cannabidiol:** May potentiate CNS depression
- **Clopidogrel:** Opioid use may delay and reduce formation of the clopidogrel-active metabolite and the drug's antiplatelet effect, possibly by reducing GI motility and drug absorption.
- **CNS depressants, Other** (eg, **anesthetic agents, antihistamines, barbiturates, benzodiazepines, muscle relaxants, phenothiazines**): May cause increased CNS or respiratory depression when used with codeine
- **Desmopressin (DDAVP):** Increased risk for hyponatremia
- **Dexamethasone:** May reduce codeine exposure and morphine formation
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**): Opioids may reduce diuretic efficacy by releasing an antidiuretic hormone.
- **Macrolide Antibiotics** (eg, **clarithromycin**, **erythromycin**): May increase codeine exposure and morphine formation
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): May potentiate CNS effects; concurrent use or use within 14 days of stopping MAOIs is contraindicated.
- **Naloxone**: Antagonizes opioid effects. **NOTE**: This action is an expected outcome when naloxone is used as a reversal agent.
- **Prokinetic Agents** (eg, **cisapride, metoclopramide**): Opioids may decrease the effectiveness of GI prokinetic agents
- **Quinidine:** May increase codeine exposure and morphine formation
- **Serotonergic Drugs, Other** (eg, **mirtazapine, trazodone**): May increase the risk for serotonin syndrome
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine, paroxetine, sertraline**): May increase codeine exposure and morphine formation; there is an increased risk for serotonin syndrome.
- **Terbinafine:** May increase codeine exposure and morphine formation
- **Tricyclic Antidepressants** (**eg, amitriptyline, clomipramine**): May increase the risk for serotonin syndrome[12,13]

Laboratory Considerations

- Opioids may increase biliary tract pressure, leading to increased plasma **amylase** and **lipase** values up to 24 hours following opioid administration.

Dosages

DOGS:

Antitussive (extra-label): Codeine 1 – 2 mg/kg PO every 6 to 12 hours

Analgesic (extra-label):

a) **When used alone**: Anecdotal analgesic dosages for codeine are usually 1 – 2 mg/kg PO every 4 to 6 hours, but it has been suggested that doses up to 4 mg/kg may be required. Codeine's pharmacokinetics in dogs may be problematic as it undergoes a high first-pass effect, and it is not clear how much analgesic efficacy the primary metabolite possesses.

b) **When used with the acetaminophen combination products** (eg, *Tylenol® #3*): Calculate the dose to provide acetaminophen 10 – 15 mg/kg PO every 8 hours (every 12 hours if using long-term), then choose the tablet size (eg, *Tylenol® #3 or #4*) to provide codeine 1 – 2 mg/kg. Codeine dosage may be cautiously increased, provided the acetaminophen dose does not exceed 15 mg/kg. For example, the dose when giving 1 tablet of *Tylenol® #4* (acetaminophen 300 mg/codeine 60 mg) PO every 8 hours to a 20 kg (44 lb) dog would be acetaminophen 15 mg/kg and codeine 3 mg/kg. When giving *Tylenol®* #3 (acetaminophen 300 mg/codeine 30 mg) to the same dog, the codeine dose would be 1.5 mg/kg.

CATS:

NOTE: Do *not* use the combination product that contains acetaminophen in cats.

Analgesic (extra-label): 0.5 – 2 mg/kg PO every 6 to 8 hours

RABBITS:

Analgesic (extra-label): Using the acetaminophen and codeine elixir, 1 mL in 10 to 20 mL of drinking water (add dextrose to enhance palatability)[14]

Monitoring

- Efficacy
- Adverse effects

Client Information

- This medicine may be given with food or on an empty stomach.

- Sedation (drowsiness) and constipation are the most common side effects. Slowed breathing can occur with higher doses.
- Cats may become overly excited after receiving this medicine.
- **Do not use combination products that contain acetaminophen (eg, *Tylenol® #3* or *Tylenol® #4*) in cats or ferrets.**
- Codeine (alone) is a C-II controlled drug and requires a new written prescription for refills. The use of this medication in animals or humans other than those for whom they are prescribed is illegal.
- Keep this medicine out of reach of children and animals.
- Report any significant changes in behavior, activity level, breathing rate, or gastrointestinal effects (eg, constipation, lack of appetite, vomiting) to your veterinarian.

Chemistry/Synonyms

Codeine, a phenanthrene-derivative opioid agonist, is available as the base and 2 separate salts. Codeine base is slightly soluble in water and freely soluble in alcohol. Codeine phosphate occurs as fine, white, needle-like crystals or as a white, crystalline powder. It is freely soluble in water. Codeine sulfate's appearance resembles codeine phosphate, but it is soluble in water.

Codeine may also be known as codeini or codeinii; many trade names are available.

Storage/Stability

Store codeine sulfate tablets in light-resistant, well-closed containers at room temperature 15°C to 30°C (59°F-86°F).

Codeine is a controlled substance. In accordance with DEA regulations, store it in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding the disposal of unused or wasted controlled drugs. Report dispensing to state monitoring programs where required.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Codeine phosphate 3 mg/mL compounded oral suspension has been reported to be stable for 98 days at controlled room temperature (20°C to 25°C [68°F-77°F]) when protected from light.[15] Codeine phosphate injection is reportedly **compatible** with glycopyrrolate or hydroxyzine HCl. It is reportedly **incompatible** with aminophylline, ammonium chloride, heparin sodium, pentobarbital sodium, phenobarbital sodium, phenytoin sodium, sodium bicarbonate, and sodium iodide.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 1 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

There are many products available containing codeine. The following is a partial listing:

Codeine Sulfate Tablets: 15 mg, 30 mg, and 60 mg; generic; (Rx, C-II)

Codeine Phosphate 7.5 mg (#1), 15 mg (#2), 30 mg (#3), and 60 mg (#4) with Acetaminophen 300 mg tablets; *Tylenol® with Codeine #s 1, 2, 3, 4;* generic; (Rx, C-III); **WARNING**: Do not use in cats or ferrets.

Codeine and Acetaminophen Oral Solution: codeine 12 mg and acetaminophen 120 mg/5 mL (2.4 mg and 24 mg/mL) in 118 mL and 473 mL bottles; generic; (Rx, C-V). Contains 7% alcohol. **WARNING**: Do not use in cats or ferrets

NOTE: Codeine-only products are C-II controlled substances. Combination products with aspirin or acetaminophen are C-III. Codeine-containing cough syrups are either C-III or C-V, depending on the state. Report prescribing and/or dispensing to state monitoring programs where required.

Colchicine

(***kol***-chi-seen) *Colcrys®*

Anti-inflammatory

Prescriber Highlights

- ► Unique anti-inflammatory that has been used for shar-pei fever; occasionally used in dogs for hepatic cirrhosis/fibrosis
- ► Contraindications include serious GI or cardiac dysfunction and in those with severe renal or hepatic disease that are also receiving certain concomitant drugs.
- ► Use with caution in geriatric or debilitated patients and in those with renal or hepatic insufficiency
- ► The most likely adverse effects include GI distress (diarrhea, vomiting; may be an early sign of toxicity), but several serious effects are possible, including myelosuppression.
- ► Teratogenic; reduces spermatogenesis
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies colchicine as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Colchicine has been proposed as a treatment in small animal species for amyloidosis and shar-pei fever; however, it must be given early in the course of the disease, and it is ineffective once renal insufficiency has occurred. No conclusive evidence currently exists for its efficacy for these or any other indication in dogs.

Colchicine has also been proposed for treating chronic hepatic fibrosis, presumably by decreasing the formation and increasing the breakdown of collagen, but its efficacy is in question. Because of the lack of proven efficacy and common occurrence of adverse effects, some veterinary specialists do not recommend the use of colchicine in dogs.[1]

A case report[2] using colchicine to treat endotracheal stent granulation stenosis in a dog has been published, and the drug may find a place in therapy for this indication after further investigation.

Colchicine possibly may be beneficial to reduce hyperuricemia in birds with renal disease or amyloidosis, or to reduce renal or hepatic fibrosis. No controlled studies were located to document efficacy for any of these potential uses.

Pharmacology/Actions

Colchicine inhibits cell division during metaphase by interfering with the sol-gel formation and the mitotic spindle. The mechanism for its antifibrotic activity is believed to be secondary to collagenase activity stimulation.

Colchicine apparently blocks the synthesis and secretion of serum amyloid A (SAA; an acute-phase reactant protein) by hepatocytes, thereby preventing the formation of amyloid-enhancing factors and preventing amyloid disposition.

Colchicine is best known in human medicine for its anti-gout activity. The mechanism for this effect is not fully understood, but it is likely related to the drug's ability to reduce the inflammatory response to the disposition of monosodium urate crystals.

Pharmacokinetics

No information was located specifically for domestic animals. The

following information is human and laboratory animal data unless otherwise noted. After oral administration, colchicine is absorbed from the GI tract. Some of the absorbed drug is metabolized in the liver (first-pass effect). These metabolites and unchanged drug are re-secreted into the GI tract via biliary secretions where it is reabsorbed. This recycling phenomena may explain the intestinal manifestations noted with colchicine toxicity. Colchicine is distributed into several tissues but is concentrated in leukocytes. The plasma half-life is about 20 minutes, but the leukocyte half-life is ≈60 hours.

Colchicine is deacetylated in the liver and metabolized in other tissues. Although most of a dose (as colchicine and metabolites) is excreted in the feces, some is excreted in the urine. More of the dose may be excreted in the urine of patients with hepatic disease. Patients with severe renal disease may have prolonged half-lives.

Contraindications/Precautions/Warnings

Colchicine is contraindicated in patients with serious GI or cardiac dysfunction. In humans with severe renal or hepatic impairment, colchicine is contraindicated when combined with strong inhibitors of CYP3A and/or P-glycoprotein (see ***Drug Interactions***). Colchicine should be used with caution in geriatric or debilitated patients and in those with renal or hepatic insufficiency; a dose reduction may be warranted.

Colchicine use in veterinary medicine is somewhat controversial, as safety and efficacy have not been well documented.

The National Institute for Occupational Safety and Health (NIOSH) classifies colchicine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[3]

Adverse Effects

There has been only marginal experience with colchicine in domestic animals. Colchicine can cause nausea, vomiting, and diarrhea in dogs, particularly at higher dosages. Rarely, myelosuppression (neutropenia), renal toxicity, and peripheral neuropathy can occur.

In humans, GI effects (eg, abdominal pain, anorexia, vomiting, diarrhea) have been noted and can be an early indication of toxicity; it is recommended to discontinue therapy (in humans) should these occur. Prolonged administration has caused myelosuppression. Colchicine may impair cobalamin (vitamin B_{12}) absorption.

Reproductive/Nursing Safety

Because colchicine has been demonstrated to be teratogenic in laboratory animals (mice and hamsters), it should be used during pregnancy only when its potential benefits outweigh its risks. Colchicine may decrease spermatogenesis.

Colchicine enters maternal milk; use it cautiously in nursing mothers.[4]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Colchicine can be a very toxic drug after relatively small overdoses. GI manifestations are usually the presenting signs seen. These can range from anorexia and vomiting to bloody diarrhea or paralytic ileus. Renal insufficiency, hepatotoxicity, pancytopenia, paralysis, shock, and vascular collapse may also occur.[5] In humans, colchicine doses of 0.5 – 0.8 mg/kg presented with significant GI symptoms and myelosuppression[4] ; doses exceeding 0.8 mg/kg were uniformly fatal.

There is no specific antidote to colchicine. GI decontamination should be employed when applicable. Because of extensive enterohepatic recycling of the drug, repeated doses of activated charcoal and a saline cathartic may reduce systemic absorption. Other treatment is supportive and based on clinical signs. Dialysis (peritoneal) may be of benefit. One case report in a dog describes successful treatment of a significant colchicine overdose (≈10 times the recommended dose), using aggressive supportive care including activated charcoal, IV lipid emulsion therapy, and N-acetylcysteine.[6]

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving colchicine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B:** May increase risk for nephrotoxicity
- **Azole antifungals** (eg, **itraconazole, ketoconazole**)**:** Concurrent use may result in increased colchicine plasma concentrations and increased risk for toxicity.[7] The combination is contraindicated in humans.
- **Calcium Channel Blockers** (eg, **diltiazem, verapamil** [not amlodipine])**:** Concurrent use may result in increased colchicine plasma concentration and increased risk for toxicity. The combination is contraindicated in humans with severe renal or hepatic impairment.
- **Chloramphenicol:** May cause additive myelosuppression or GI effects
- **Cyclosporine:** May increase risk for nephrotoxicity or myelosuppression. The combination is contraindicated in humans with severe renal or hepatic impairment.
- **Digoxin:** May increase the risk for rhabdomyolysis
- **Fenofibrate/Gemfibrozil:** Concurrent use may increase the risk for myopathy or rhabdomyolysis.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**)**:** May increase colchicine concentrations and risk for toxicity. The combination is contraindicated in humans with severe renal or hepatic impairment.
- **Myelosuppressive Agents** (eg, **antineoplastics, azathioprine**)**:** May cause additive myelosuppression or GI effects when used with colchicine
- **P-Glycoprotein Inhibitors** (eg, **amiodarone, doxorubicin, spironolactone**): May increase colchicine concentrations and risk for toxicity

Laboratory Considerations

- Colchicine may cause false-positive results when testing for **erythrocytes or hemoglobin in urine**.
- Colchicine may interfere with **17-hydroxycorticosteroid** determinations in urine if using the Reddy, Jenkins, and Thorn procedure.
- Colchicine may cause increased serum values of **alkaline phosphatase** (**ALP**).

Dosages

DOGS:

Adjunctive treatment of hepatic cirrhosis/fibrosis, shar-pei fever, amyloidosis (extra-label): Most clinicians recommend 0.03 mg/kg PO once daily. Some clinicians suggest starting at a lower initial dose to determine if the dog will tolerate it (GI adverse effects). As an example, for an adult shar-pei, using the commercially available 0.6 mg tablets: start with ½ tablet (0.3 mg) PO once daily and increase the dose in 0.3 mg increments every 4 to 5 days as tolerated until a target dose of up to 0.6 mg/dog (NOT mg/kg) PO twice daily is reached. In dogs that cannot tolerate a given dose, the dose is reduced, or the drug is temporarily discontinued and restarted at a lower dose.

BIRDS:

Adjunctive treatment of hepatic fibrosis, amyloidosis, or hyperuricemia (extra-label): Recommended anecdotal doses can

vary widely from 0.01 – 0.2 mg/kg PO every 12 hours. It is recommended to start at the lower end of the dosage range and increase the dosage gradually.

Monitoring
- Efficacy
- Adverse effects (eg, vomiting, diarrhea, myelosuppression)
- Baseline and periodic CBC, chemistry panel, and urinalysis
- Consider checking cobalamin levels when using colchicine long term

Client Information
- There is limited experience using this medicine in animals; side effects are not well known. Report any suspected side effects to your veterinarian.
- This medicine may be given with or without food.
- Pregnant women should avoid exposure to this medicine or to the waste (eg, urine, feces) of animals receiving it.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms
Colchicine is an anti-gout drug that possesses many other pharmacologic effects. It occurs as a pale yellow, amorphous powder or scales. It is soluble in water and freely soluble in alcohol.

Colchicine may also be known as colchicinum or *Colcrys®*, *Gloperba®*, or *Mitigare®*.

Storage/Stability
Store colchicine tablets in tight, light-resistant containers.

Compatibility/Compounding Considerations
No specific information was noted.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Colchicine Oral Capsules and Tablets: 0.6 mg (1/100 gr); *Colcrys®*, *Mitigare®*, generic; (Rx)

Colchicine Solution: 0.12 mg/mL (0.6 mg/5 mL); *Gloperba®*; (Rx)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Corticotropin

(kor-ti-koe-***troe***-pin) *Acthar®*

Hormonal Diagnostic Agent

See also ***Cosyntropin***

Prescriber Highlights
- ► Cosyntropin is more commonly used.
- ► Stimulates cortisol release; used primarily to test for hyper- or hypoadrenocorticism (ACTH-stimulation test)
- ► Use as a screening test for naturally occurring hyperadrenocorticism is becoming less popular than in the past; may also be used to test for iatrogenic hyperadrenocorticism and to monitor therapy when treating with anti-adrenal drugs.
- ► Adverse effects are unlikely unless used chronically.
- ► Commercial formulation contains naturally derived ACTH analogues in a gel for IM administration; do not administer IV.

Uses/Indications
A corticotropin (ACTH) product (*Adrenomone®*) was FDA-approved for use in dogs, cats, and beef or dairy cattle for stimulation of the adrenal cortex (during ACTH-deficient states) and as a therapeutic agent in primary bovine ketosis, but it is no longer commercially available.

In practice, ACTH tends to be used most often in the diagnosis of hypoadrenocorticism (ACTH-stimulation test), iatrogenic hyperadrenocorticism, and to monitor the response to mitotane or trilostane therapy in patients being treated for hyperadrenocorticism. It is less often recommended as a screening test for naturally occurring hyperadrenocorticism in dogs since the test is not as sensitive as the low-dose dexamethasone suppression test.

One reference recommends using the ACTH-stimulation test if the dog has non-adrenal illness, received any form of exogenous glucocorticoids (including topicals) or phenobarbital. When performing the ACTH-stimulation test, cosyntropin is the agent of choice. See ***Cosyntropin***. If the dog has no known non-adrenal illness and moderate to severe clinical signs of hyperadrenocorticism, use the low-dose dexamethasone suppression test.[1]

Pharmacology/Actions
Corticotropin (adrenocorticotropic hormone, ACTH) stimulates the adrenal cortex (principally the zona fasciculata) to produce and release glucocorticoids (primarily cortisol in mammals and corticosterone in birds). ACTH release is controlled by corticotropin-releasing factor (CRF), activated in the hypothalamus via a negative feedback pathway, whereby either endogenous or exogenous glucocorticoids suppress ACTH release.

Pharmacokinetics
Because it is rapidly degraded by proteolytic enzymes in the gut, corticotropin (ACTH) cannot be administered PO. It is not effective if administered topically to the skin or eye.

After IM injection in humans, repository corticotropin injection is absorbed over 8-16 hours. The elimination half-life of circulating ACTH is about 15 minutes but because of the slow absorption after IM injection of the gel, effects may persist up to 24 hours.

Contraindications/Precautions/Warnings
ACTH gel should not be used in patients hypersensitive to porcine proteins.

When used for diagnostic purposes, it is unlikely that increases in serum cortisol levels induced by corticotropin (ACTH) will have significant deleterious effects on conditions where increased cortisol levels are contraindicated (eg, systemic fungal infections, osteoporosis, peptic ulcer disease).

Compounded ACTH preparations may contain ACTH in

amounts that deviate considerably from their labeled potency and may have varying consistency (from watery to solid).[2]

Do not confuse corticotropin with cosyntropin. Corticotropin gel should be administered IM; do not administer by the IV route.

Adverse Effects

Prolonged use may result in fluid and electrolyte disturbances and other adverse effects; potassium supplementation may be required with chronic therapy.[3] Refer to the human literature for an extensive listing of potential adverse reactions if using corticotropin on a chronic basis.

Reproductive/Nursing Safety

Corticotropin (ACTH) may reduce fetal growth and result in preterm birth and may also be embryocidal. Neonates born from mothers receiving ACTH should be observed for signs of adrenocortical insufficiency. It is unknown if ACTH is excreted in milk.[3]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

When used for diagnostic purposes, acute inadvertent overdoses are unlikely to cause any significant adverse effects. Monitor as required and treat based on clinical signs if necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving corticotropin (ACTH) for diagnostic purposes and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinesterases** (eg, **pyridostigmine**): ACTH may antagonize the beneficial effects of anticholinesterase therapy in patients with myasthenia gravis and cause a worsening of signs.
- **Diuretics** (eg, **furosemide**): Long-term administration of ACTH may increase electrolyte loss.

Laboratory Considerations

- Patients should not receive **hydrocortisone** or **cortisone** on test day.
- ACTH may decrease **1^{131} uptake** by the thyroid gland.
- ACTH may suppress **intradermal skin test** reactions**.**
- ACTH may interfere with **urinary estrogen** determinations.
- Obtain specific information from the laboratory on sample handling and laboratory normals for cortisol when doing ACTH stimulation tests.

Dosages

NOTE: When using compounded ACTH products, it is recommended to get several post-ACTH samples (at a minimum, 1 and 2 hours following injection).[2] **Do not confuse these dosages/protocols with those for cosyntropin**.

DOGS:

ACTH stimulation test (extra-label): Draw baseline blood sample for cortisol determination then administer ACTH gel 2.2 units/kg IM. Draw sample 60 and 120 minutes after injection.[1,4]

HORSES:

ACTH stimulation test (extra-label): Draw baseline blood sample for cortisol determination then administer ACTH gel 1 unit/kg IM between 8 AM and 10 AM; draw post-ACTH cortisol levels at 2 and 4 hours postdose. Horses with a functional adrenal gland should have a 2- to 3-fold increase in plasma cortisol when compared with baseline.[5]

BIRDS:

ACTH Stimulation Test (extra-label): Draw baseline blood sample for corticosterone (not cortisol) determination then administer ACTH gel 16 – 25 units IM. Draw post-ACTH corticosterone levels 1 to 2 hours later. Normal baseline corticosterone levels vary with regard to species, but generally range from 1.5 – 7 ng/mL. After ACTH, corticosterone levels generally increase by 5-10 times those of baseline. Specific values are listed in the reference.[6]

Chemistry/Synonyms

A 39 amino acid polypeptide, corticotropin (ACTH) is secreted from the anterior pituitary. The first 24 amino acids (from the N-terminal end of the chain) define its biologic activity. While human, sheep, cattle, and swine corticotropin have different structures, the first 24 amino acids are the same and, therefore, biologic activity is thought to be identical. Commercial products are extracts obtained from porcine pituitaries that contain the full polypeptide ACTH (amino acids 1-39) and related peptide analogues. One USP unit of corticotropin is equivalent to 1 mg of the international standard.

Corticotropin may also be known as ACTH, adrenocorticotrophic hormone, adrenocorticotrophin, corticotrophin, corticotropinum, *Acethropan®, Acortan simplex®, Actharn®, Acthelea®, Acton prolongatum®, H.P. Acthar® Gel* or *Cortrophin-Zinc®*.

Storage/Stability

Repository corticotropin injection should be stored in the refrigerator 2°C to 8°C (36°F-46°F) but warmed to room temperature prior to administration. Do not over-pressurize the vial prior to withdrawing the product.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

Compounded ACTH products may be available from compounding pharmacies.

HUMAN-LABELED PRODUCTS:

Corticotropin Repository Injection: 80 units/mL in 5 mL multi-dose vials; *Acthar® Gel*; (Rx) **NOTE**: This product is only available through a specialty pharmacy distribution system and is not available via regular retail pharmacies or drug wholesalers.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Cortisone

(kor-ti-***zone***)

Corticosteroid

Prescriber Highlights

- ► Oral glucocorticoid with both glucocorticoid and mineralocorticoid effects; an option to manage hypoadrenocorticism by reducing dosage requirements for mineralocorticoid drugs
- ► Not commonly used in veterinary medicine; whether it has any clinically significant benefit in dogs over oral prednis(ol)one is controversial
- ► Similar cautions and adverse effects as with other corticosteroid drugs if used at supra-physiologic replacement doses; otherwise, should be well tolerated

Uses/Indications

Cortisone may be used as an alternative to prednis(ol)one for the oral treatment of hypoadrenocorticism in dogs. In vivo cortisone acetate is rapidly converted to cortisol and therefore could serve as a total replacement therapy for both glucocorticoid and mineralocorticoid deficiencies. Whether cortisone acetate is any more effective than prednis(ol)one for long-term treatment in dogs is controversial, as some clinicians believe that any benefit of the increased mineralocorticoid activity that cortisone has is clinically insignificant.

Pharmacology/Actions

Cortisone is a short-acting corticosteroid with a biologic half-life of 8 to 12 hours. Glucocorticoids have effects on almost every cell type and system in mammals. See ***Glucocorticoid Agents, General Information*** for more details.

Pharmacokinetics

Like other glucocorticoids, cortisone acetate's pharmacokinetics do not correlate with its pharmacodynamic activity. Cortisone acetate is absorbed and converted to cortisol (hydrocortisone) in vivo. Oral bioavailability in humans ranges widely but is ≈50%.

Contraindications/Precautions/Warnings

When used for physiologic replacement in dogs with hypoadrenocorticism, cortisone is contraindicated if the patient is hypersensitive to it. If cortisone is used at supra-physiologic dosages, the typical contraindications and warnings for drugs like prednis(ol)one should be followed. See ***Glucocorticoid Agents, General Information*** for more details.

Adverse Effects

Cortisone is usually well tolerated when it is used for physiologic replacement in dogs with hypoadrenocorticism. Potentially, GI effects (vomiting, inappetence, diarrhea) could occur, and hypersensitivity reactions are possible. If used at supra-physiologic dosages, the typical adverse effect profile for drugs like prednis(ol)one is possible. See ***Glucocorticoid Agents, General Information*** for more details.

Reproductive/Nursing Safety

During normal fetal development glucocorticoids may be required for adequate surfactant production, myelin, retinal, pancreatic, and mammary development; however, excessive dosages early in pregnancy may lead to teratogenic effects. Substantial maternal doses of corticosteroids during pregnancy may result in hypoadrenalism in the offspring.[1] Corticosteroid therapy may induce parturition in large animal species during the later stages of pregnancy.

Caution is advised when cortisone is used in nursing dams; glucocorticoids unbound to plasma proteins can enter the milk. High doses or prolonged administration to nursing dams may potentially inhibit growth, interfere with endogenous corticosteroid production, or cause other unwanted effects in nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute ingestion is rarely a clinical problem and clinical effects are unlikely with an acute overdose. However, neuropsychiatric effects can occur; cardiac arrhythmias and anaphylaxis are possible but rare.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving cortisone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Concomitant administration with glucocorticoid may cause hypokalemia; in humans, there have been cases of CHF and cardiac enlargement reported after using hydrocortisone to treat amphotericin B adverse effects.
- **Anticholinesterase Agents** (eg, **pyridostigmine, neostigmine**): In patients with myasthenia gravis, concomitant glucocorticoid and anticholinesterase agent administration may lead to profound muscle weakness.
- **Aspirin**: Corticosteroids may increase the clearance of salicylates and decrease salicylate serum concentrations; however, there is an increased risk for GI ulceration/bleeding.
- **Diuretics, Potassium-Depleting** (eg, **furosemide, thiazides**): Concomitant administration with glucocorticoids may cause hypokalemia.
- **Estrogens**: The effects of hydrocortisone, and possibly other glucocorticoids, may be potentiated by concomitant administration with estrogens.
- **Fluoroquinolones** (eg, **enrofloxacin, marbofloxacin**): Concurrent use may increase the risk for tendon rupture.
- **Insulin; antidiabetic agents**: Insulin requirements may increase in patients that are receiving glucocorticoids.
- **Mitotane**: Mitotane may alter the metabolism of corticosteroids; higher than usual doses of corticosteroids may be necessary to treat mitotane-induced adrenal insufficiency.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs,** eg, **carprofen, meloxicam**): Administration of ulcerogenic drugs with glucocorticoids may increase the risk for GI ulceration.
- **Phenobarbital/Primidone**: Concurrent use may result in decreased cortisone efficacy.
- **Vaccines, Live Attenuated**: Patients receiving corticosteroids at immunosuppressive dosages should generally not receive live attenuated virus vaccines as virus replication may be augmented; a diminished immune response may occur after vaccine, toxoid, or bacterin administration in patients receiving glucocorticoids.
- **Warfarin**: Hydrocortisone may affect PT; monitor.

Laboratory Considerations

- Cortisone cross-reacts with cortisol in **ACTH response test**. This test must be performed before cortisone is administered. (**NOTE**: Dexamethasone does not cross-react.)
- Glucocorticoids may increase **serum cholesterol.**
- Glucocorticoids may increase **urine glucose** concentrations.
- Glucocorticoids may decrease **serum potassium.**
- Glucocorticoids can suppress the release of **thyroid-stimulating hormone (TSH)** and reduce $\mathbf{T_3}$ and $\mathbf{T_4}$ values. Thyroid gland atrophy has been reported after chronic glucocorticoid administration. Uptake of $\mathbf{I^{131}}$ by the thyroid may be decreased by glucocorticoids.
- Reactions to **skin tests** may be suppressed by glucocorticoids.
- False-negative results of the **nitroblue tetrazolium** test for systemic bacterial infections may be induced by glucocorticoids.
- Glucocorticoids may cause **neutrophilia** within 4 to 8 hours after dosing and return to baseline within 24 to 48 hours after drug discontinuation.
- Glucocorticoids can cause **lymphopenia** that can persist for weeks after drug discontinuation in dogs.

Dosages

DOGS:

Long-term treatment of hypoadrenocorticism (extra-label):

Initially, 0.5 – 1 mg/kg PO once every 12 to 24 hours. Maintenance: 0.5 mg/kg PO once every 12 to 24 hours usually provides adequate additional glucocorticoid supplementation. Begin cortisone once animal recovers from the acute adrenal crisis, starts eating and drinking, and is changed from parenteral to oral medication. Usually used in conjunction with a semi-selective mineralocorticoid (fludrocortisone). Although some sources advocate for cortisone acetate,[2,3] others recommend prednisone as the glucocorticoid supplement of choice in dogs for treatment of hypoadrenocorticism.[4,5]

Monitoring

Monitoring during cortisone therapy is dependent on its reason for use, dosage, adjunctive mineralocorticoid therapy, dosage schedule (daily vs alternate-day therapy), duration of therapy, and the animal's age and condition. The following list may not be appropriate or complete for all animals; use clinical assessment and judgment should adverse effects be noted:

- Weight, appetite, and/or signs of fluid retention
- Serum and/or urine electrolytes
- Total plasma proteins and albumin
- Blood glucose
- Urine culture
- Growth and development in young animals

Client Information

- Give this medicine with food.
- The goal of treatment is to find the lowest dose possible and use it for the shortest period of time. Follow your veterinarian's instructions on how to give this medicine.
- Many side effects are possible, especially when used long-term or when given in higher doses. The most common side effects are increased appetite, thirst, and need to urinate.
- Make sure your animal has access to plenty of fresh, clean water while taking this medicine. Do not restrict water at any time while your animal is taking this medicine.
- In dogs, stomach or intestinal ulcers, perforation, or bleeding can occur while taking this medicine. Contact your veterinarian right away if your animal stops eating or if you notice a high fever, black tarry stools, or bloody vomit (will look like coffee grounds).
- Do not stop therapy abruptly without your veterinarian's guidance, as serious side effects could occur.
- Be sure to tell your veterinarian what other medications (including vitamins, supplements, or herbal therapies) you give your animal.

Chemistry/Synonyms

Cortisone acetate is a synthetic acetate ester of cortisone. It occurs as a white or practically white, odorless, crystalline powder. It is insoluble in water and slightly soluble in alcohol.

Cortisone acetate may also be known as acetato de cortisona, compound E acetate, acétate de cortisone, cortisoni acetas, or 11-dehydro-17-hydroxycorticosterone acetate.

Storage/Stability

Cortisone acetate tablets should be stored in well-closed containers at a temperature less than 40°C (104°F), preferably at 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations

No specific information noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Cortisone Acetate Oral Tablets: 25 mg; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Cosyntropin

Tetracosactide

(koh-***sin***-troh-pin) *Cortrosyn®*

Hormonal Diagnostic Agent

Prescriber Highlights

- ► Used for adrenal function tests. Similar to but not the same as corticotropin (ACTH)
- ► Stimulates cortisol release; agent used primarily to perform an ACTH-stimulation test to evaluate for hyper- or hypoadrenocorticism and to monitor therapy when treating with antiadrenal drugs.
- ► Best results achieved when drug is given IV.
- ► Do not confuse with corticotropin (ACTH) gel.

Uses/Indications

Cosyntropin is used most often to perform an ACTH-stimulation test for the diagnosis of hypoadrenocorticism and iatrogenic hyperadrenocorticism and to monitor the response to mitotane or trilostane in the treatment of hyperadrenocorticism. It is less often recommended as a screening test for naturally occurring hyperadrenocorticism (ie, pituitary-dependent hyperadrenocorticism, adrenal tumors) in dogs because the test is not as sensitive as the low-dose dexamethasone suppression test.[1] One reference[2] recommends using the ACTH stimulation test if the dog has nonadrenal illness or has received any form of exogenous glucocorticoids (including topicals) or phenobarbital. If the dog has no known nonadrenal illness and moderate to severe clinical signs of hyperadrenocorticism, the low-dose dexamethasone suppression test is preferred.

Cosyntropin can also be used to assess adrenal function in horses (both adults and foals).[3-5]

Pharmacology/Actions

Like endogenous corticotropin, cosyntropin stimulates the adrenal cortex (principally the zona fasciculata) to stimulate the production and release of glucocorticoids (primarily cortisol in mammals and corticosterone in birds). Because of its structure, cosyntropin retains biologic activity but is not as immunogenic as endogenous corticotropin. The bulk of immunogenicity appears to reside in the C-terminal portion of corticotropin (amino acids 22-39), and cosyntropin ends after amino acid 24.

Pharmacokinetics

Cosyntropin must be given parenterally because it is inactivated by GI enzymes.

Cosyntropin administration causes a dose-dependent increase in cortisol response in dogs.[6] In both healthy dogs and dogs with hyperadrenocorticism, peak cortisol concentration occurs 90 minutes after administration of cosyntropin at 5 or 10 µg/kg IV but peaks at 30 minutes at 1 µg/kg IV dose.[7] Cosyntropin administered IM or IV results in equivalent peak cortisol concentration.[8] The 2 commercially available parenteral forms in the United States appear to be bioequivalent in dogs when given IV.[9] Under experimental conditions, intentional perivascular administration resulted in similar cortisol response as IV administration.[10]

In cats, cosyntropin given IM resulted in peak cortisol concentration after 45 minutes, as compared with 75 minutes after IV administration. Cortisol returns to baseline by 2 hours and 4 hours after IM and IV administration, respectively.[11]

In neonatal foals, a 10 µg IV total dose produces a peak cortisol response 30 minutes after administration, with a return to baseline

90 minutes after administration. Higher doses (100 or 250 µg IV total dose) have a peak response of greater magnitude, which occurs after 90 minutes, with a duration of 1.5 to 2.5 hours.[4]

It is unknown how cosyntropin is inactivated or eliminated after parenteral administration.

Contraindications/Precautions/Warnings

Cosyntropin is contraindicated in patients with known hypersensitivity to it. Use with caution in patients that have shown hypersensitive reactions to ACTH in the past, as cross-reactivity could occur.

Do not confuse cosyntropin with corticotropin (ACTH).

Adverse Effects

When cosyntropin is used short term, the primary concern is hypersensitivity reactions.

Reproductive/Nursing Safety

Effects on reproductive capacity, risk for fetal harm, or nursing offspring are unknown. Use only when maternal benefits outweigh risk to offspring.

Overdose/Acute Toxicity

Unlikely to be of clinical consequence if used one time.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving corticotropin for diagnostic purposes and may be of significance in veterinary patients receiving cosyntropin:

- **Anticholinesterases** (eg, **pyridostigmine**): ACTH may antagonize the beneficial effects of anticholinesterase therapy in patients with myasthenia gravis and cause a worsening of signs.
- **Diuretics** (eg, **furosemide**): Long-term administration of ACTH may increase electrolyte loss.

Laboratory Considerations

- Patients should not receive **hydrocortisone** or **cortisone**[12] on test day; dexamethasone sodium phosphate does not interfere with cortisol assays.[13]
- If using a fluorometric analysis, falsely high cortisol values may be observed if the patient is taking **estrogens** (eg, DES, estriol) or **spironolactone.**
- Falsely high cortisol values may be observed in patients with high **bilirubin** or if free plasma **hemoglobin** is present.

Dosages

NOTES:

1. The following dosages are for the cosyntropin aqueous (either liquid or lyophilized) products available commercially in the US. There is also depot injectable cosyntropin zinc hydroxide (*Synacthen*® Depot) available in some countries which should only be used IM and **not** given IV. Contact your laboratory for specific dosing protocols if using the depot form.
2. Do not confuse these dosages/protocols with those for ***corticotropin (ACTH).***

DOGS:

Testing (screening) for hyperadrenocorticism using ACTH stimulation test (extra-label): Draw pre-ACTH stim serum cortisol level. Give 5 µg/kg IV (with a maximum dose of 250 µg per dog); draw post-ACTH serum cortisol level 60 minutes after dose during peak cortisol concentrations.[1,14]

Testing (screening) for hypoadrenocorticism using ACTH stimulation test (extra-label): Draw pre-ACTH stim serum cortisol level. Give 1 µg/kg IV; draw post-ACTH serum cortisol level 60 minutes after dose during peak cortisol concentrations.[15,16]

Monitoring dogs diagnosed with hyperadrenocorticism and being treated with mitotane or trilostane using an ACTH stimulation test (extra-label)**:** Draw pre-ACTH stim serum cortisol level. Give 1 µg/kg IV; draw post-ACTH stim serum cortisol level 60 minutes after dose to measure peak cortisol concentrations.[14] Cosyntropin 5 µg/kg IV and 1 µg/kg IV were pharmacologically equivalent in dogs being treated with mitotane or trilostane.

CATS:

Testing (screening) adrenal function using ACTH stimulation test (extra-label): Based on a study[17] in healthy cats, draw pre-ACTH stim serum cortisol level. Give 5 µg/kg IV followed by a post-ACTH stim serum cortisol sample at 60 to 75 minutes. Serum cortisol and aldosterone concentrations were equivalent to those achieved following administration of cosyntropin at 125 µg/cat IV (NOT mg/kg), the historical dose for cats.[18,19]

HORSES:

Testing (screening) adrenal function in adult horses (extra-label): 0.1 µg /kg IV resulted in maximum adrenal stimulation, with peak cortisol concentration 30 minutes after cosyntropin administration.[3]

Testing (screening) adrenal function in neonatal foals (extra-label):

1. 100 µg /foal or 250 µg /foal (total dose, NOT µg /kg) IV.[5] Cortisol response may be reduced in critically ill foals.[20,21]
2. 0.1 to 0.25 µg /kg IV, with peak cortisol concentration 20 to 30 minutes after cosyntropin administration[22,23]
3. Paired low dose/high dose ACTH stimulation test: Cosyntropin 10 µg IV (total dose, NOT µg /kg) after baseline blood draw, and Cosyntropin 100 µg IV (total dose, NOT µg/kg) administered immediately 90 minutes later (after blood draw). Collect blood sample to measure baseline cortisol and ACTH, and repeat blood draw for cortisol 30, 90, 120 and 180 minutes later.[4]

Monitoring

- See specific protocols for test procedures.
- Peak cortisol response is dose dependent and typically observed within 30 to 60 minutes in dogs,[6,7] cats,[24] and horses.[3,5]
- It is recommended to perform ACTH stimulation testing at or about the same time after trilostane administration (4 to 6 hours postdosing is recommended[25]).

Chemistry/Synonyms

Cosyntropin is a synthetic polypeptide that mimics the effects of corticotropin (ACTH). It is commercially available as a lyophilized white to off-white powder containing mannitol. Cosyntropin's structure is identical to the first 24 (of 39) amino acids in natural human, canine, and feline corticotropin.[26] Cosyntropin 0.25 mg is equivalent to 25 units of corticotropin.

Cosyntropin may also be known as tetracosactide, alpha(1–24)-corticotrophin, beta(1–24)-corticotrophin, tetracosactido, tetracosactidum, tetracosactrin, tetracosapeptide, *Cortrosina*®, *Cortrosyn*®, *Cosacthen*®, *Nuvacthen*® *Depot, Synacthen*®, *Synacthen*® *Depot, Synacthène Retard,* or *Synacthène*.

Storage/Stability

The lyophilized powder should be stored at room temperature (20°C-25°C [68°F-77°F]). Reconstitute with sterile normal saline and discard any unused portion.

The commercially available injectable solution is labeled to be

stored at 15°C to 30°C (59°F-86°F); protect from light and freezing. Discard any unused portion.

One study showed that cosyntropin can be reconstituted and stored frozen (-20°C [-4°F]) in plastic syringes for up to 6 months and still show biologic activity in the dog.[27] It is recommended to freeze in small aliquots as it is unknown what effect thawing and refreezing has on potency. At present, it is recommended to store in plastic containers (eg, tuberculin syringes) as it may bind to glass.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Cosyntropin Powder for Injection: 0.25 mg lyophilized (250 µg) in single-dose vials with diluent; *Cortrosyn*®, generic; (Rx)

Cosyntropin Solution for Injection: 0.25 mg/mL (250 µg /mL), preservative-free in 1 mL single-dose vials; generic; (Rx)

NOTE: Corticotropin (compounded ACTH gel for IM or SC use) is not the same as cosyntropin.

For the complete list of references, see **wiley.com/go/budde/plumb**

Crofelemer

(cro-***fell***-a-mer) *Canalevia®-CA1*

Antidiarrheal

Prescriber Highlights

- ► Conditionally approved for the treatment of chemotherapy-induced diarrhea in dogs. Due to conditional approval, this drug must only be used as labeled.
- ► Contraindicated in dogs hypersensitive to it
- ► Rule out infections or other causes of diarrhea prior to use.
- ► Appears well tolerated. Adverse effects may include GI effects (eg, abnormal feces, vomiting, reduced appetite), decreased activity, hypoglycemia, and hypocalcemia.

Uses/Indications

Crofelemer is conditionally approved (pending a full demonstration of effectiveness) by the FDA for the treatment of chemotherapy-induced diarrhea in dogs. In one study, crofelemer administration decreased stool frequency and improved stool consistency in healthy beagles receiving neratinib (a tyrosine kinase inhibitor).[1]

As a conditionally approved drug, it is a violation of United States federal law to use crofelemer other than as directed on the label.

Crofelemer is approved in humans for symptomatic relief of noninfectious diarrhea in adult HIV/AIDS patients on retroviral therapy.[2]

Pharmacology/Actions

The mechanism of action of crofelemer in dogs is not fully characterized. In humans, crofelemer inhibits 2 types of chloride channels: (1) cyclic adenosine monophosphate-stimulated cystic fibrosis transmembrane conductance regulator (CFTR) chloride channels; and (2) calcium-activated chloride channels.[3] By inhibiting both types of channels at the luminal membrane of intestinal epithelial cells, crofelemer blocks chloride ion secretion and the accompanying high volume water loss that occurs with diarrhea, thereby normalizing the flow of chloride ions and water in the GI tract.

Pharmacokinetics

In dogs, crofelemer was not absorbed at dosages used clinically.[4] After oral administration to humans, the drug was undetectable in plasma.[2] Standard pharmacokinetic parameters have not been determined due to the absence of systemically available drug. Humans do not appear to metabolize crofelemer, and presumably the drug is eliminated in the feces. See ***Overdose/Acute Toxicity*** for further information.

Contraindications/Precautions/Warnings

Crofelemer is contraindicated in patients that are hypersensitive to it. Rule out other causes of diarrhea (eg, infection, toxicosis) prior to crofelemer use.

Do not confuse with CROfelemer with SEVelamer.

Adverse Effects

Crofelemer appears to be well tolerated by dogs. Adverse effects observed in preapproval studies occurred at rates similar to the control (placebo) group and included abnormal feces (eg, soft, watery, mucoid, discolored feces), vomiting, reduced appetite, decreased activity, upper respiratory signs (eg, coughing, nasal discharge, sneezing, congestion), and urinary system abnormalities (eg, UTI, cystitis, worsened pyuria). Hypoglycemia and hypocalcemia were noted in 8% and 4% of dogs receiving crofelemer, respectively. Increased neutrophils were also observed.[5]

Adverse effects reported by humans receiving crofelemer include upper respiratory tract infections and bronchitis, cough, flatulence, and increased liver enzymes.

Reproductive/Nursing Safety

Safe use of crofelemer has not been evaluated in dogs that are pregnant, lactating, or used for breeding. However, a reasonable degree of safety during pregnancy can be expected because crofelemer is not absorbed into systemic circulation. Crofelemer was not teratogenic in rats or rabbits, and embryofetal toxicity was not observed in rats; increased fetal resorption was demonstrated in rabbits but this may have been due to maternal toxicity.[2]

It is unknown if crofelemer is excreted into milk.[2] As the lack of systemic absorption should preclude delivery of the drug into milk, and any drug that may be excreted is unlikely to be absorbed by the nursing litters, it is expected that crofelemer may be safely administered to nursing animals.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral LD_{50} in dogs is greater than 1,200 mg/kg.[6] Systemic crofelemer absorption was demonstrated with dosages at or greater than 50 mg/kg PO daily.[4] Dosages up to 600 mg/kg PO daily given for 1 to 9 months to 6- to 7-month-old beagles resulted in decreased food intake, reduced weight gain, vomiting, and black or rust-colored feces, and hematologic changes consistent with microcytic, hypochromic anemia, and thrombocytosis (consistent with GI ulceration and hemorrhage). Pathology changes included red streaks and erosions in the GI tract along with intestinal congestion and inflammation.[7]

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Although in vitro studies suggest that crofelemer has the potential to inhibit CYP3A4 and other transporters in the GI tract, limited studies performed in healthy humans have not demonstrated drug interactions. The following drug interactions have either been reported or are theoretical in humans or animals receiving crofelemer and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential

risks and perform additional monitoring when appropriate.

- **Anticholinergic Agents** (eg, **atropine, glycopyrrolate, hyoscyamine, oxybutynin**): Increased risk for constipation or other GI complications
- **Antidiarrheal Agents** (eg, **diphenoxylate, loperamide**): Increased risk for constipation or other GI complications
- **H_1 Receptor Antihistamines** (eg, **diphenhydramine, hydroxyzine**): Increased risk for constipation or other GI complications
- **Opioids** (eg, **butorphanol**, **fentanyl**, **morphine, tramadol**): Increased risk for constipation or other GI complications
- **Phenothiazines** (eg, **acepromazine**): Increased risk for constipation or other GI complications

Laboratory Considerations

None were noted.

Dosages

DOGS:

Treatment of chemotherapy-induced diarrhea (label dosage; conditionally approved by FDA): 125 mg/dog (NOT mg/kg) PO twice daily for 3 days for dogs weighing 63.6 kg (140 lb) or less, and 250 mg/dog (NOT mg/kg) PO twice daily for 3 days for dogs weighing over 63.6 kg (140 lb)[5]

Monitoring

- Fecal testing (eg, flotation, antigen, and/or PCR testing) prior to treatment to rule out infectious causes of diarrhea
- Efficacy of treatment based on clinical improvement (eg, resolution of diarrhea, improved appetite and food intake)
- Hydration status, body weight, patient reaction to abdominal palpation
- Adverse effects (eg, worsening of GI signs, abdominal discomfort, lethargy)

Client Information

- This medicine may be given either with food or on an empty stomach. If your animal vomits or acts sick after receiving it on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Administer tablets whole; do not split, break, or crush. If the tablet is chewed, one additional dose may be administered.

Chemistry/Synonyms

Crofelemer is a proanthocyanidin mixture derived from the red latex of the South American *Croton lechleri* Müll Arg plant. It is composed primarily of monomer units of (+)–catechin, (–)–epicatechin, (+)–gallocatechin, and (–)–epigallocatechin linked in random sequence, with the average degree of polymerization between 5 and 7.5. In solution, crofelemer is reddish-brown in color.[8]

Crofelemer may also be known as SP-303, *Canalevia*®-CA1, and *Mytesi*®.

Storage/Stability

Store crofelemer tablets at 20°C to 25°C (68°F-77°F); excursions are permitted between 15°C and 30°C (59°F-86°F).

Compatibility/Compounding Considerations

No information was available.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Crofelemer Delayed-Release Tablets: 125 mg enteric coated tablets; *Canalevia*®-CA1; (Rx). Conditional Approval Application Number 141-552. Extra-label use of conditionally approved drugs is not permitted by FDA. See ***Conditional Approval Explained: A Resource for Veterinarians*** for more information on conditionally approved drugs.

HUMAN-LABELED PRODUCTS:

Crofelemer Delayed-Release Tablets: 125 mg enteric coated tablets; *Mytesi*®; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Cromolyn (Inhaled)

(***kroh***-mah-lin) *Intal*®

Mast Cell Stabilizer

For ophthalmic use, see ***Cromolyn Ophthalmic.***

Prescriber Highlights

- ► Inhaled mast cell stabilizer that may be useful adjunctive treatment in preventing respiratory clinical signs and airway obstruction in horses with mild to moderate asthma characterized by an elevated mast cell count or in horses with severe equine asthma
- ► Not for treatment of acute bronchoconstriction; used as a preventive agent
- ► May take several days to weeks for efficacy

Uses/Indications

Cromolyn is a mast cell stabilizer that may be useful in reducing or preventing respiratory clinical signs and airway obstruction in horses with mild to moderate asthma characterized by an elevated mast cell count, or in horses with severe equine asthma (formerly known as recurrent airway obstruction, heaves).[1–4] Use of this agent is somewhat controversial; studies have yielded conflicting efficacy results and it is not widely used clinically. Cromolyn was ineffective in preventing exercise-induced pulmonary hemorrhage (EIPH).[5,6]

Pharmacology/Actions

Cromolyn inhibits the release of histamine and leukotrienes from sensitized mast cells found in lung mucosa, nasal mucosa, and eyes. Its exact mechanism of activity is not understood, but it is thought to block indirect entry of calcium ions into cells. Other effects of cromolyn include inhibition of neuronal reflexes in the lung and bronchospasm secondary to tachykinins, and movement of other inflammatory cells (neutrophils, monocytes, eosinophils). Cromolyn also prevents down-regulation of beta-2 adrenergic receptors on lymphocytes. Cromolyn does not have antihistaminic, anticholinergic, antiserotonin, corticosteroid-like, or anti-inflammatory effects.

Pharmacokinetics

Limited information is available for horses. The amount of cromolyn reaching the distal airways is likely variable and dependent on the type of nebulizer used and amount of concurrent bronchoconstriction present.[7] Absorbed cromolyn is eliminated in the urine and via the bile into the feces.

In humans, less than 2% of cromolyn is absorbed from the GI tract after oral dosing. Approximately 8% is absorbed when inhaled into the lung. Absorbed drug is eliminated via the feces and urine as unchanged drug.

Contraindications/Precautions/Warnings

Do not use cromolyn in patients with documented hypersensitivity to it.

Cromolyn is unlikely to be of benefit in treating horses with mild to moderate asthma free of mastocytic inflammation. Cromolyn has no efficacy in treating acute bronchospasm.[8]

Adverse Effects

Adverse effects associated with inhaled cromolyn use in horses are not well documented. Cough and treatment avoidance (possibly due

to bad taste) have been reported. It has been proposed that pretreatment with albuterol may reduce the incidence of cough.

Humans can occasionally develop a cough, throat irritation, or report unpleasant taste. Very rarely, bronchoconstriction and anaphylaxis have been reported.

Reproductive/Nursing Safety

Laboratory animal studies have shown no effect on fertility. Teratogenicity studies in mice, rats, and rabbits have not demonstrated any teratogenic effects, and it is likely safe for use during pregnancy.[8]

Extremely low (or undetectable) concentrations have been detected in milk; cromolyn is most likely safe for use during nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Because of the drug's low systemic bioavailability after inhalation or oral administration, acute overdoses are unlikely to cause significant morbidity.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

No notable drug interactions have been reported.

Laboratory Considerations

None have been noted.

Dosages

HORSES:

Adjunctive treatment of equine asthma (extra-label):

a) Using a jet nebulizer, 200 mg/horse (NOT mg/kg) every 12 hours[9]

b) Using an ultrasonic nebulizer, 80 mg/horse (NOT mg/kg) every 24 hours[9]

Monitoring

- Clinical efficacy
- For horses with equine asthma, reductions in mast cell counts in bronchoalveolar lavage (BAL) could help confirm efficacy.

Client Information

- This medication does not treat airway constriction but is used to prevent airway constriction by reducing the release of substances from cells that can cause it. It should not be used to treat acute bronchoconstriction (difficulty breathing).
- This medication must be given once to twice daily and it may take several days to weeks before it can be determined if it is working.
- Be sure you understand how to use the device that delivers the medicine to your animal. Contact your veterinarian if you have questions.

Chemistry/Synonyms

Cromolyn sodium occurs as a white, odorless, hygroscopic crystalline powder that is soluble in water and insoluble in alcohol.

Cromolyn sodium may also be known as cromoglicic acid, cromoglycic acid, sodium cromoglicate, disodium cromoglycate, sodium cromoglycate, DSCG, SCG, FPL–670, or DNSG; there are many international trade names.

Storage/Stability

Cromolyn sodium solution for inhalation should be stored below at 20°C to 25°C (68°F-77°F).[8] Protect from freezing and light. Store the product in a foil pouch until ready for use. Do not use solution if it is cloudy or contains a precipitate. Solution remaining in nebulizers after use should be discarded.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Cromolyn solution is reportedly **compatible** with acetylcysteine, albuterol, epinephrine, isoetherine, isoproterenol, metaproterenol, or terbutaline solutions for up to 60 minutes. It is **incompatible** with bitolterol.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES

HUMAN-LABELED PRODUCTS:

Cromolyn Sodium Solution for Inhalation: 20 mg/2 mL (10 mg/mL) vials or amps; generic; (Rx)

Cromolyn Sodium Ophthalmic Solution: 4% solution; generic; (Rx)

There is also an OTC nasal solution (*Nasalcrom®*, generic), and an oral concentrate (*Gastrocrom®*, generic) indicated for mastocystosis available, but these dosage forms are unlikely to be of use in veterinary medicine.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Cyclophosphamide

(sye-kloe-***foss***-fa-mide) *Cytoxan®, Neosar®*

Antineoplastic

Prescriber Highlights

- ► Antineoplastic agent used in dogs and cats
- ► Metronomic (low-dose, continuous) therapy shows promise for some cancers in dogs, with fewer adverse effects than high-dose treatment.
- ► Contraindications include prior anaphylaxis or history of sterile hemorrhagic cystitis. Use with caution in patients with leukopenia, thrombocytopenia, previous radiotherapy, or impaired hepatic or renal function and in patients for which immunosuppression may be dangerous (eg, infection)
- ► Primary adverse effects include myelosuppression, GI effects, alopecia (especially in poodles and old English sheepdogs), and sterile hemorrhagic cystitis
- ► Vigorous diuresis during administration is recommended to reduce the risk for sterile hemorrhagic cystitis.
- ► Potentially teratogenic and fetotoxic; for sexually intact patients, verify pregnancy status prior to administration
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies cyclophosphamide as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

In veterinary medicine, cyclophosphamide is used primarily in dogs and cats in combination with other drugs as an antineoplastic agent for lymphoma[1] and other hematopoietic tumors, carcinomas,[2,3] and sarcomas.[4]

Most clinicians do not consider cyclophosphamide for initial use as an immunosuppressive agent for treating immune-mediated diseases (eg, immune-mediated hemolytic anemia (IMHA),[5] systemic lupus erythematosus [SLE], immune-mediated thrombocytopenia [ITP], pemphigus-related conditions, rheumatoid arthritis, proliferative urethritis) because alternative treatment options with fewer adverse effects (eg, azathioprine, cyclosporine, mycophenolate mofetil, leflunomide) are available. One review article proposed

that cyclophosphamide therapy in dogs be used primarily for cancer treatment, as published efficacy data, although scant, suggest an increased incidence of serious adverse effects (eg, sterile hemorrhagic cystitis, myelosuppression), including death.[6]

Pharmacology/Actions

Cyclophosphamide, an alkylating agent, is a prodrug. One of its primary metabolites, 4-hydroxycyclophosphamide (4-OHCP), is thought to be responsible for the drug's cytotoxic effect. This metabolite enters cells and rapidly decomposes to phosphoramide mustard and acrolein. These alkylating agents interfere with DNA replication and RNA transcription and replication to ultimately disrupt nucleic acid function. The cytotoxic properties of cyclophosphamide are enhanced by its phosphorylating activity.

Cyclophosphamide has marked immunosuppressive activity manifest as decreased WBC and antibody production; the exact mechanisms by which this occurs have not been fully elucidated.

Pharmacokinetics

Peak concentrations of cyclophosphamide and 4-OHCP (active metabolite) were reached in 45 minutes and the elimination half-life of parent and metabolite were between 30 and 60 minutes after oral cyclophosphamide administration in dogs with lymphoma. Area under the curve (AUC) of 4-OHCP was similar after both oral and IV administration. Pharmacokinetics of 4-OHCP in plasma were similar to those of cyclophosphamide after IV or PO dosing, but marked differences were observed in peak concentrations (IV concentration approximately twice as high as PO concentration) and time to reach peak concentrations (IV ≈13 minutes, PO ≈75 minutes). The authors concluded that PO and IV cyclophosphamide can likely be used interchangeably while achieving the same exposure of active metabolite in dogs with lymphoma.[7]

In healthy cats, intraperitoneal (IP) administration resulted in ≈50% lower peak cyclophosphamide concentration and ≈20% lower drug exposure as compared with IV administration, whereas PO administration peak concentration and overall exposure were 80% and ≈50% lower than after IV administration., respectively. The peak concentration and overall exposure of 4-OHCP were similar for all routes of administration. Terminal half-life of cyclophosphamide and 4-OHCP after IV and IP administration were ≈0.6 hours and ≈0.8 hours, respectively, and could not be established after PO administration.[8]

In horses, higher dosages may be necessary to obtain clinically useful concentrations of 4-OHCP.[9]

In humans, cyclophosphamide is well absorbed after PO administration, with peak concentrations of metabolites occurring in 2 to 3 hours. Cyclophosphamide is ≈20% protein bound, and its metabolites are distributed throughout the body, including the CSF (albeit at subtherapeutic concentrations). Cyclophosphamide is metabolized in the liver into several metabolites. Elimination half-life of cyclophosphamide is ≈3 to 12 hours, but drug/metabolites can be detected up to 72 hours after administration. The drug is primarily excreted as metabolites and unchanged drug in the urine.

Contraindications/Precautions/Warnings

Cyclophosphamide should not be used in patients with prior anaphylactic reactions to the drug or in patients with urinary obstruction or a history of sterile hemorrhagic cystitis. Use with caution in patients with impaired hepatic or renal function, patients receiving concurrent radiation, or patients in which immunosuppression may be dangerous (eg, systemic infections). Discontinue cyclophosphamide if sterile hemorrhagic cystitis develops, and further use should be considered contraindicated. Use with caution, if at all, in patients with UTIs or in breeds at risk for developing transitional cell carcinoma (eg, Scottish terriers).

In patients that develop myelosuppression, subsequent doses should be delayed until adequate recovery occurs.

Because of the potential for development of serious adverse effects, cyclophosphamide should be used only in patients that can be adequately and regularly monitored.

Do not confuse cycloPHOSphamide with cycloSPORINE (ciclosporin), or *Cytoxan*® with *Cytotec*®. Consider writing part of the drug's name in uppercase letters on prescriptions/orders to reduce the risk of errors. Additionally, do not write prescriptions for this drug using the abbreviation SID. Many nonveterinary pharmacists are unfamiliar with this abbreviation and could interpret it as another abbreviation (eg, QID).

The National Institute for Occupational Safety and Health (NIOSH) classifies cyclophosphamide as a hazardous drug; personal protective equipment [PPE] should be used accordingly to minimize the risk for exposure.[10]

Adverse Effects

In animals, the primary adverse effects associated with cyclophosphamide are myelosuppression (eg, leukopenia, neutropenia, anemia, thrombocytopenia), gastroenterocolitis (eg, anorexia, especially in cats; nausea; vomiting; diarrhea), renal toxicity (eg, sterile hemorrhagic cystitis, hematuria), and cardiac, hepatic, and pulmonary toxicities. Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant alopecia.

The myelosuppressive effects of cyclophosphamide primarily impact the WBC lines but may also affect RBC and platelet production. The nadir for WBCs generally occurs between 5 and 14 days after dosing and may require up to 4 weeks for recovery. When cyclophosphamide is used with other drugs causing myelosuppression, toxic effects may be exacerbated. A study in dogs using recombinant-canine granulocyte colony-stimulating factor (rcG-CSF) at 2.5 µ/kg 3 times a day for 2 to 5 days after cyclophosphamide treatment showed accelerated recovery and reduced severity of neutropenia.[11] Thrombocytopenia occurs occasionally.

Sterile hemorrhagic cystitis induced by cyclophosphamide is thought to be caused by the metabolite acrolein, with an incidence rate of up to 30% of dogs receiving long-term (greater than2 months) cyclophosphamide at standard doses[12,13] and metronomic doses.[14,15] Furosemide administered with cyclophosphamide may reduce the occurrence of this adverse effect.[16-18]

In cats, cyclophosphamide-induced cystitis (CIC) is rare. Initial signs may present as hematuria and dysuria. Because bacterial cystitis is not uncommon in immunosuppressed patients, it must be ruled out by culturing the urine. A negative urine culture with an inflammatory urine sediment on urinalysis is diagnostic for CIC. Because bladder fibrosis and/or transitional cell carcinoma of the bladder are also associated with cyclophosphamide use, these conditions may need to be ruled out via abdominal ultrasonography or other advanced imaging modalities (eg, computed tomography [CT]). The incidence of CIC may be minimized by increasing urine production and frequent voiding. The drug should be given in the morning, and animals should be encouraged to drink and urinate whenever possible. Recommendation for treatment of CIC includes discontinuing cyclophosphamide and beginning therapy with IV fluids, furosemide, and corticosteroids. Refractory cases have been treated by surgical debridement and 1% formalin or 25% DMSO instillation in the bladder.

In a retrospective study in cats, cyclophosphamide was the most likely chemotherapy agent to cause vomiting, anorexia/inappetence, and neutropenia, although adverse effects were noted to occur only infrequently and the severity was typically graded as mild.[19]

Other adverse effects that may be noted with cyclophosphamide

therapy include pulmonary infiltrates and fibrosis, depression, hyponatremia, and leukemia. Cardiac toxicity (myocarditis, pericardial effusion, CHF, atrial and ventricular arrhythmias) have occurred in humans.

Reproductive/Nursing Safety

Cyclophosphamide is teratogenic and embryotoxic and may cause fetal harm (neural tube defects; cleft palate; limb, digit, and other skeletal malformation) and miscarriage when administered during pregnancy. Cyclophosphamide may impair fertility.

Cyclophosphamide is distributed in milk and nursing is not recommended when dams are receiving the drug.

For sexually intact female patients, verify pregnancy status prior to administration.

Overdose/Acute Toxicity

Only limited information on acute overdoses of this drug is available, but extensions of adverse effects could be expected. The lethal dose in dogs has been reported as 44 mg/kg IV.[20] In case reports describing cyclophosphamide overdose in dogs, rcG-CSF is often used to help stimulate the bone marrow and hasten the recovery of WBCs in peripheral blood. One case report of a dog with complete recovery after administration of cyclophosphamide 1750 mg PO over 21 days (total exposure 2303 mg/m^2) described use of broad-spectrum antibiotics, whole blood transfusions, rcG-CSF, and tranexamic acid.[21] If an oral overdose occurs, gut emptying should proceed if indicated and the animal should be hospitalized for supportive care. Cyclophosphamide is considered moderately dialyzable.

Common clinical signs associated with overdose in dogs may include neutrophilia, anorexia, hematuria, hyperchloremia, hypernatremia, polydipsia, nystagmus, seizures, tremors, and vomiting.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center that specializes in providing information specific to veterinary patients is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to the ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving cyclophosphamide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Allopurinol**: May increase risk for myelosuppression
- **Amiodarone**: Concurrent use may increase risk for pulmonary toxicity.
- **Amphotericin B**: Concurrent use may increase risk for renal toxicity.
- **Azathioprine**: Concurrent use may increase risk for hepatic toxicity.
- **Cardiotoxic Drugs** (eg, **cytarabine, doxorubicin**): May cause potentiation of cardiotoxicity
- **Cyclosporine:** Reduced cyclosporine concentration may result; additive immunosuppressive effect may also occur.
- **Dipyrone:** Increased risk for agranulocytosis and pancytopenia
- **Immunosuppressive Agents** (eg, **leflunomide, tacrolimus**): May increase immunosuppressive effect
- **Myelosuppressive Agents** (eg, **carboplatin, vincristine**): May increase risk for neutropenia or other hematologic effects
- **Thiazide Diuretics** (eg, **hydrochlorothiazide**): May result in increased cyclophosphamide exposure and enhanced myelosuppression
- **Ondansetron**: May decrease cyclophosphamide systemic exposure
- **Phenobarbital** (or other **barbiturates**): When given chronically, may increase the rate of metabolism of cyclophosphamide to active metabolites via microsomal enzyme induction and increase the likelihood of toxicity development
- **Vaccines, Live:** Cyclophosphamide may diminish vaccine efficacy.
- **Warfarin**: May result in increased risk for bleeding

Laboratory Considerations

- **Uric acid** concentrations (blood and urine) may be increased after cyclophosphamide use.
- The immunosuppressant properties of cyclophosphamide may cause false negative **intradermal allergy testing** results for a variety of antigens, including tuberculin, *Candida* spp, and *Trichophyton* spp.

Dosages

NOTES:

1. Because of the potential toxicity of this drug to patients, veterinary personnel, and pet owners, and because chemotherapy indications, treatment protocols, monitoring, and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[22-26] are strongly recommended.
2. Cyclophosphamide dosages are commonly listed as mg/m^2 (NOT mg/kg). Do not confuse with citations that list dosages in mg/kg.
3. When dosing in cats or very small dogs, or if using low-dose therapy, compounding pharmacies may be able to compound oral dosage forms containing less than 25 mg.
4. All dosages are extra-label.

DOGS:

Antineoplastic agent: Often used as part of a multidrug chemotherapy protocol (eg, COP, CHOP). Based on formation of the active 4-OHCP metabolite, IV and PO routes can be used interchangeably.[7] Dosages vary considerably depending on the protocol used, and cyclophosphamide is most often dosed by body surface area (mg/m^2).

a. Standard: 250 mg/m^2 (NOT mg/kg) once every 3 to 4 weeks,[27] or 50 mg/m^2 (NOT mg/kg) once a day for 3 to 4 days each week[28]
b. Metronomic: Dosages can range from 10 – 15 mg/m^2 (NOT mg/kg) PO once daily.[14,29-32] 25 mg/m^2 (NOT mg/kg) PO every other day was associated with a higher incidence of adverse effects, including sterile hemorrhagic cystitis in 32% of dogs.[15]

CATS:

Antineoplastic agent: cyclophosphamide 10 mg/kg IV or 200 – 250 mg/m^2 (NOT mg/kg) IV or PO has been noted as part of a multi-agent protocol.[33,34]

HORSES:

NOTE: Research in horses found that cyclophosphamide administered at doses of 400 mg/m^2 (NOT mg/kg) (IV) and 600 mg/m^2 (NOT mg/kg) (PO) did not achieve therapeutic concentrations of 4-OHCP at levels proven for the treatment of malignancies in other species.[9] Consultation with a veterinary oncologist is encouraged before use.

Antineoplastic agent:

a) Doses historically used in horses have been 200 mg/m^2 (NOT mg/kg) (usually 1 g per horse per dose) IV every 1 to 2 weeks.[35]
b) **CAP protocol for generalized lymphoma**: cytarabine (cytosine arabinoside) at an average dose of 1 – 1.2 g per horse (total dose; NOT mg/kg) SC or IM once every 1 to 2 weeks;

cyclophosphamide 1 g per horse (total dose; NOT mg/kg) IV every 2 weeks (alternating with cytarabine); and prednisolone 1 mg/kg PO every other day. Vincristine 2.5 mg per horse (total dose; NOT mg/kg) IV is added on the weeks when the cytarabine is administered if there is no response.[35] See the ***Vincristine*** monograph for more information.

c) **Squamous cell carcinoma**: cyclophosphamide 0.15 mg/kg PO once daily was administered with meloxicam 0.1 mg/kg PO once daily after debulking surgery.[36]

RABBITS:

Antineoplastic agent (eg, lymphoma): 50 mg/m^2 (NOT mg/kg) PO daily for 3 days each week or 100 – 200 mg/m^2 (NOT mg/kg) IV (cephalic or saphenous veins) every 7 days. Consider using a fully implantable vascular access device for IV administration of multiple chemotherapy agents.[37]

FERRETS

Antineoplastic agent (eg, lymphoma):

a) 10 mg/kg PO or SC every 3 weeks as part of a multi-agent, modified COP protocol[38]

b) An alternative multi-agent, non-IV protocol used 250 mg/m^2 (NOT mg/kg) PO every 4 to 5 weeks throughout the 26-week treatment course.[38]

Monitoring

- Efficacy: assessment of remission
- Baseline and periodic CBCs with differential counts
- Baseline and periodic renal profile
- Baseline and periodic urinalysis and urine culture if indicated
- Hydration status and urinary output

Client Information

- Cyclophosphamide is a chemotherapy (anticancer) drug. This drug can be hazardous to other animals and people that come in contact with it. On the day your animal receives the drug, and then for a few days afterward, only handle all bodily waste (urine, feces, litter), blood, or vomit while wearing disposable gloves. Seal the waste in a plastic bag, then place the bag and gloves in the regular trash.
- Cyclophosphamide can cause vomiting and gastrointestinal upset. Giving with food may minimize these side effects.
- Contact your veterinarian immediately if your animal has any bleeding, bruising, signs of infection, fever, or blood in the urine.
- After dosing in dogs, frequent walks to encourage urination is suggested to attempt to lessen the risk for bladder toxicity. In the interest of public safety, do not take your animal to a park or allow your animal to urinate and defecate in public places until your veterinarian tells you that it is okay to do so.
- Your veterinarian will need to perform follow-up examinations and blood tests on your animal after it receives this medication. Do not miss these important follow-up visits.
- Do not give your animal any vaccinations while receiving this drug without consulting your veterinarian first.
- Your animal should not participate in animal competitions while on this drug. Exposure to other animals may put your animal at serious risk of infections during chemotherapy treatment. Talk with your veterinarian about when it is safe to return to these events.
- Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant hair loss.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

A nitrogen-mustard derivative, cyclophosphamide occurs as a white, crystalline powder that is soluble in water and alcohol. The commercially available injection has a pH of 3 to 7.5.

Cyclophosphamide may also be known as CPM, CTX, CYT, B-518, ciclofosfamida, cyclophosphamidum, cyclophosphanum, NSC-26271, or WR-138719. *Cytoxan*® is a common trade name.

Storage/Stability

Store cyclophosphamide powder for injection at or below 25°C (77°F) and avoid exposure to excessive heat. Cyclophosphamide capsules should be stored between 20°C and 25°C (68°F-77°F); brief excursions between 15°C and 30°C (59°F-86°F) are allowed.

After dilution with sodium chloride 0.9% or 0.45%, use within 24 hours if stored at room temperature or 6 days if refrigerated. When diluting in D_5W or dextrose 5% in sodium chloride 0.9%, the product is stable for 24 hours at room temperature or 36 hours under refrigeration.[21]

Compatibility/Compounding Considerations

Because of the variable potency and stability of compounded cyclophosphamide capsules,[39,40] dosing forms should be obtained from an experienced compounding pharmacist.

Cyclophosphamide power for injection may be dissolved in aromatic elixir to be used as an oral solution. The solution is stable for 14 days if refrigerated in a glass container.[41]

Compatible with multiple IV solutions and drugs, including D_5W, D_5 in sodium chloride 0.9%, lactated Ringer's injection, sodium chloride 0.9% and 0.45%, and total parenteral nutrition containing amino acids 4.25% and dextrose 25%. **Compatible** in syringes or at Y-sites for brief periods with the following drugs: bleomycin sulfate, cefazolin, cisplatin, doxorubicin HCl, droperidol, filgrastim, fluorouracil, furosemide, heparin sodium, hydroxyzine, leucovorin calcium, methotrexate sodium, metoclopramide HCl, mitomycin, ondansetron HCL, vinblastine sulfate, and vincristine sulfate. Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE.

HUMAN-LABELED PRODUCTS:

Cyclophosphamide Capsules: 25 mg and 50 mg; generic; (Rx)

Cyclophosphamide Powder for Injection: 500 mg, 1 g, and 2 g vials; *Cytoxan*®, *Neosar*®, generic; (Rx)

Prescriber Highlights

- ► FDA-approved products are available for dogs to control atopic dermatitis and for cats to control allergic dermatitis.
- ► Often used extra-label for treatment of immune-mediated disorders in dogs and cats, and to prevent rejection of kidney transplants in cats
- ► GI adverse effects (eg, vomiting, soft stools) are common at the start of treatment but typically resolve within a few weeks.
- ► Use of microemulsion or "modified" formulations is highly recommended. If using human-labeled products, *Sandimmune®* is not bioequivalent to, and must not be interchanged with, *Atopica®*, *Cyclavance®*, *Neoral®*, or *Gengraf®*.
- ► Counseling pet owners to ensure knowledge of the dispensing system is important when using solutions FDA-approved for animals.
- ► For indications other than atopic dermatitis, consider therapeutic drug monitoring (pharmacokinetic and pharmacodynamic) to assess efficacy and minimize adverse effect potential.
- ► Many potential drug interactions
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies cyclosporine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Uses/Indications

Cyclosporine is FDA-approved for use in dogs for the control of atopic dermatitis. In cats, it is FDA-approved for the control of feline allergic dermatitis as manifested by excoriations (including facial and neck), miliary dermatitis, eosinophilic plaques, and self-induced alopecia. Therapeutic effect for atopic dermatitis may not be seen in the first few weeks of treatment, and the drug is unsuitable for acute flares of atopic dermatitis.[1] Concurrent treatment with corticosteroids[1,2] or oclacitinib[3] can be considered during this interval to control pruritus.

In dogs, extra-label indications include perianal fistulas (anal furunculosis),[4–7] immune-mediated blood disorders (eg, IMHA),[8] inflammatory bowel disease,[9] idiopathic chronic hepatitis, sebaceous adenitis, sterile nodular panniculitis, sterile granuloma/pyogranuloma complex, neutrophilic dermatosis resembling pyoderma gangrenosum, eosinophilic dermatitis with edema (ie, Wells syndrome), neutrophilic dermatitis (ie, Sweet syndrome), alopecia areata, vasculitis, ulcerative dermatoses of the nasal philtrum, dermatomyositis, contact allergy, chronic pedal furunculosis, metatarsal sinus tracts, refractory cases of juvenile sterile granulomatous dermatitis and lymphadenitis (ie, juvenile cellulitis), reactive histiocytic disorders, proliferative otitis externa, idiopathic keratinization disorders (ie, primary seborrhea in springer spaniels, cairn terriers, and West Highland white terriers and follicular hyperkeratosis in cocker spaniels), autoimmune diseases such as pemphigus foliaceus (controversial results), lupus erythematosus complex, meningoencephalitis of unknown etiology (MUE),[10] erythema multiforme, and uveodermatologic syndrome.[11] Ketoconazole may be concurrently prescribed to reduce cyclosporine dose requirements as a cost-saving measure (see ***Drug Interactions***).

In cats, extra-label indications include feline urticaria pigmentosa, chronic stomatitis,[12] feline acquired alopecia (ie, pseudopelade), pemphigus erythematosus and foliaceus,[13] dirty face syndrome in Persian cats,[11] idiopathic pruritus, allograft transplant rejection,[14] pure red cell aplasia,[15] immune-mediated thrombocytopenia,[16,17] and inflammatory bowel disease.[18]

The microemulsion form, or "modified" version, of oral products (ie, *Atopica®*, *Cyclavance®*, *Neoral®*) is highly recommended, as it is better absorbed and provides more consistent peak and trough drug concentrations.[19]

Pharmacology/Actions

Cyclosporine, a calcineurin inhibitor, is an immunosuppressive agent that focuses on cell-mediated immune responses, with some humoral immunosuppressive action. Cyclosporine binds to T-cell cyclophilin and blocks calcineurin-mediated T-cell activation. T-helper lymphocytes are the primary target, but T-suppressor cells are also affected. Cyclosporine can also inhibit cytokine production and release (including IL-2 and interferon-gamma in dogs[20–22] and IL-3, IL-4, and tissue necrosis factor-alpha in humans), thereby affecting the function of eosinophils, mast cells, granulocytes, and macrophages. It may also inhibit antigen-presenting functions of the dermal immune system.[23] It is not considered myelosuppressive. One study suggests that cyclosporine therapy does not affect circulating lymphocyte CD4/CD8 ratio.[24] Cyclosporine appears to increase thromboxane production in dogs,[25,26] and low-dose aspirin inhibits this effect.[27]

Pharmacokinetics

Cyclosporine is a substrate for the P-glycoprotein (P-gp) efflux transporter, resulting in a wide range of bioavailability between patients. **NOTE:** *Neoral®*, *Gengraf®*, *Atopica®*, and *Cyclavance®* are **NOT** bioequivalent with *Sandimmune®*. In addition, the human microemulsion product (ie, *Neoral®*) has not been proven to be as equally bioavailable as *Atopica®* in dogs; however, a generic veterinary-modified cyclosporine product (ie, *Cyclavance®*) has demonstrated bioequivalence with *Atopica®*.[28]

In dogs, the veterinary-labeled oral product (ie, cyclosporine modified, *Atopica®*) is rapidly absorbed, and bioavailability is 45% in fasted dogs. Food in the GI tract increases variability of bioavailability and reduces it by ≈20%.[29] Protein binding is ≈90%,[23] and volume of distribution is 7.8 L/kg.[30] Cyclosporine is distributed in high concentrations into the liver, fat, and blood cells (granulocytes, 5% to 12%; lymphocytes, 5% to 9%) and significantly accumulates in the skin.[23] It does not appreciably enter the CNS; this may be because it is a P-glycoprotein efflux transporter substrate.[29] The drug is primarily metabolized in the liver via the cytochrome P450 system (likely CYP3A), excreted into the bile, and eliminated in the feces. Less than 1% of a dose is excreted unchanged into the urine. Elimination half-life in dogs has been reported as ≈5 to 12 hours.[31] Clearance has been consistently found to be 3.66 to 7.1 mL/minute/kg.[29] Dogs with diabetes mellitus demonstrate increased clearance and reduced elimination half-life.[32] Pharmacokinetic parameters were not altered when the veterinary-labeled cyclosporine capsules were stored frozen (-20°C [-4°F]) for 28 days.[33]

In cats, oral cyclosporine (modified) bioavailability is ≈25% and is highly variable, but drug absorption is not significantly altered when administered with or without food.[23,34] Additionally, the bioavailability of subcutaneous cyclosporine was reported to be very good in cats.[35] The drug does not appear to be absorbed transdermally.[36] The product label recommends administering on a consistent schedule (ie, with or without food, time of day).[37] Volume of distribution is 3.3 L/kg, time to maximum absorption (T_{max}) is 1 to 2 hours, and maximum concentration (C_{max}) is 480 ng/mL.[23,34] Hepatic and intestinal metabolism (eg, hydroxylation, demethylation) produce inac-

tive metabolites. Elimination half-life in cats is ≈24 hours but varies considerably, with estimates as short as 6.8 hours to more than 40 hours in some healthy cats. Elimination occurs mainly in the feces.

Contraindications/Precautions/Warnings

Cyclosporine is contraindicated in patients that are hypersensitive to it or any component (eg, polyoxyethylated castor oil) in the products. It is contraindicated in animals with malignant disorders or a history of malignant neoplasia and in cats infected with FeLV or FIV. Safe use has not been established in dogs weighing less than 1.8 kg (4 lb); in cats weighing less than 1.4 kg (3 lb); or in dogs or cats less than 6 months of age.[37,38]

This drug should be used with caution in animals with diabetes mellitus or renal insufficiency, as it may cause elevated levels of serum glucose, creatinine, and/or urea nitrogen.[37,38] Cats should test negative for FeLV and FIV before being treated with this drug. Cats on cyclosporine therapy appear to be at risk for developing systemic toxoplasmosis.[39] High cyclosporine blood concentrations (administered doses of 7.5 mg/kg/day orally) may be associated with a higher risk for developing systemic toxoplasmosis.[40] To avoid infection, cats should be kept indoors, not eat raw meat, and not be allowed to hunt during treatment.[41] Ideally, toxoplasma titers should be evaluated prior to starting cyclosporine in cats.[42] Only use cyclosporine in animals with active infection when the benefits outweigh the risks.[23] Use may increase susceptibility to opportunistic bacterial and fungal infections and development of neoplasia.[43,44] Diminished immune response to vaccinations can occur. Killed vaccines are recommended if vaccination is considered in dogs receiving cyclosporine therapy. The drug's impact on the immune response to modified live vaccines is not known.

Cyclosporine is a P-gp substrate. Historically, reports have not shown increased sensitivity to cyclosporine and dose reductions in dogs with the multidrug resistance (*MDR1*) gene mutation (also known as *ABCB1*-1delta) have not been recommended.[45,46] However, there is a case report of one dog receiving a low dose of cyclosporine (3.3 mg/kg PO every 12 hours) who developed a secondary infection. Subsequent pharmacodynamic testing revealed marked immunosuppression and *MDR1* testing showed that the dog was heterozygous for the *MDR1* gene mutation. The *MDR1* mutation was suspected to have contributed to the excessive immunosuppression experienced in this patient.[47] Careful use with clinical and therapeutic drug monitoring is recommended, especially when the patient is not responding to therapy at recommended dosages, or when secondary infections develop at dosages lower than expected to cause significant immunosuppression.

The National Institute for Occupational Safety and Health (NIOSH) classifies cyclosporine as a hazardous drug (nonantineoplastic agent representing an occupational hazard to healthcare workers); personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Do not confuse cycloSPORINE (ciclosporin) with cycloPHOSphamide.[49] In addition, **do not write prescriptions for this drug using the abbreviation SID**. Many human-medicine pharmacists are not aware of this abbreviation and could interpret it as another abbreviation (eg, QID).

NOTE: *Neoral*®, *Gengraf*®, *Atopica*, and *Cyclavance*® are **NOT** bioequivalent with *Sandimmune*®.

Adverse Effects

In dogs, vomiting, anorexia, soft stools, and diarrhea[50] are the most commonly seen adverse effects. Dogs commonly vomit when starting therapy, but this generally abates with time. GI effects rarely require discontinuation of the drug. Giving the drug with a small amount of food or freezing capsules for 30 to 60 minutes before administration have been suggested to alleviate vomiting.[33]

Gingival hyperplasia, altered glucose metabolism/diabetes mellitus,[51] hypertrichosis, excessive shedding, psoriasiform lichenoid-like dermatosis, and papillomatosis have been reported in dogs. Gingival hyperplasia has been treated with oral and toothpaste forms of azithromycin with limited efficacy.[52] Hepatotoxicity or thromboembolic events have been reported but are believed to be rare. One study showed that low-dose aspirin inhibits cyclosporine-induced thromboxane synthesis.[27] One case series of 6 dogs describes the development of *Burkholderia cepacia* complex deep skin infections while receiving oral cyclosporine.[53] Bacteriuria and UTIs may occur.[54]

In one appraisal study, the prevalence of bacterial infections in 828 dogs with atopic dermatitis receiving anti-allergic dosages of oral cyclosporine was 11%, most commonly affecting the cutaneous and urinary systems and not multiple systems.[55] In 95 dogs receiving higher dosages of cyclosporine for other diseases, the prevalence of bacterial infection was 17%, occurring most often in the GI, urinary, and respiratory systems. The prevalence of bacterial infections in atopic dogs treated with cyclosporine appears to be low and occur most often in the skin. However, when given for immunosuppression, the prevalence of bacterial infections appears to be higher and to affect 1 or more body systems.

In cats, GI effects (including vomiting, diarrhea, hypersalivation, decreased appetite, and anorexia) are often reported during the first month of therapy.[56,57] Resulting weight loss may lead to hepatic lipidosis in this species (rare). Lethargy, malaise, behavior changes, increased hair growth, acute bullous keratopathy,[58] gingival hyperplasia, and flares of latent viral infections have also been noted in cats receiving cyclosporine. Hemolytic uremic syndrome has been reported after renal transplant.[59] Cats developing fatal systemic toxoplasmosis while on cyclosporine therapy have been reported.[39,41,60] Anaphylaxis is rare but possible.

Although nephrotoxicity and hepatotoxicity[61] are potential concerns in dogs and cats, extremely high blood cyclosporine concentrations (ie, greater than 3000 ng/mL) must be present before nephrotoxicity is a significant problem.

Because of the drug's immunosuppressive effects, animals may be more susceptible to opportunistic infections (eg, nocardiosis[62], atypical fungal infections[63,64]). Cyclosporine use may predispose dogs and cats to development of neoplastic diseases; however, evidence is lacking. In humans, this risk is increased with long-term use and when administered in combination with other immunosuppressive agents (eg, steroids).[65]

Because the drug has an unpleasant taste, it has been suggested that oral solutions be placed in gelatin capsules or used with water or taste-masking flavoring agents. In one study, *Cyclavance*® oral solution was shown to be significantly more often accepted by dogs, improving dosing compliance, compared with *Atopica*® capsules, when both were mixed with dry food (99.3% vs 27.1%, respectively).[66]

Reproductive/Nursing Safety

Cyclosporine has been shown to be fetotoxic and embryotoxic in rats and rabbits at doses 2 to 5 times the recommended dose.[65] Reduced fetal weight and growth, skeletal retardation, and premature birth have occurred. The manufacturer does not recommend use in pregnant or breeding dogs or cats. Use during pregnancy only when the risks outweigh the benefits.

Cyclosporine is distributed into maternal milk; the manufacturer does not recommend use in lactating queens or bitches.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral LD_{50} in rabbits is greater than 320 mg/kg.[65] Single oral doses of 33 mg/kg in dogs and 40 mg/kg in cats have resulted in no clinical

signs. Acute overdoses may cause adverse GI effects as well as transient renal or hepatotoxicity. Acute kidney injury requiring hemodialysis and increased liver enzymes was reported in a dog that accidentally received a single 33 mg/kg IV dose.[61] Clinical signs in cats given 40 mg/kg for up to 6 months were extensions of adverse effects. Overdoses may be treated with gastric decontamination (induction of emesis is apparently effective in humans if done within 2 hours of ingestion); treat supportively and according to clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving cyclosporine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate. Cyclosporine is a CYP450 and P-glycoprotein substrate and its metabolism can be affected by inhibitors, inducers, and other substrates.

The following drugs may **increase** cyclosporine blood levels and the risk for cyclosporine toxicity:

- **Acetazolamide**
- **Allopurinol**
- **Amiodarone**
- **Amphotericin B Liposome/Lipid complex**
- **Angiotensin Receptor Blockers** (**ARBs**; eg, **telmisartan, valsartan**)
- **Azole Antifungals** (eg, **fluconazole**, **itraconazole**, **ketoconazole**): Ketoconazole significantly increases cyclosporine blood concentration in dogs[67,68]; fluconazole has demonstrated variable effects.[69,70] Itraconazole appears to affect cyclosporine pharmacokinetics in cats[71] but not in dogs. Many clinicians concurrently use ketoconazole in dogs to reduce the dose and resultant cost of cyclosporine treatment, particularly for large dogs. Only use a combination of ketoconazole and cyclosporine with caution and understand that monitoring of cyclosporine levels may be required. Of note, one study found an increase in cyclosporine concentrations up to 75% following a dose of ketoconazole.
- **Bromocriptine**
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**)
- **Carvedilol**
- **Ceftriaxone**
- **Chloramphenicol**
- **Cimetidine:** May delay absorption but was not found to significantly alter maximum concentrations (C_{max})[72]
- **Cisapride**
- **Clonidine**
- **Colchicine:** Colchicine levels may also increase. This combination is contraindicated in human patients with renal impairment.
- **Corticosteroids:** Methylprednisolone does not appear to affect cyclosporine levels in dogs.
- **Danazol**
- **Digoxin**
- **Estrogens**
- **Fatty Acids** (**Essential/Omega**): Fatty acid supplementation may provide a cyclosporine-sparing effect.[73]
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin, marbofloxacin, orbifloxacin, pradofloxacin**)
- **Fluvoxamine**
- **Glipizide, Glyburide**
- **Grapefruit Juice, Grapefruit Juice Powder**[74]
- **Imipenem**
- **Macrolide Antibiotics** (eg, **azithromycin, clarithromycin,**[75,76] **erythromycin**)
- **Medroxyprogesterone**
- **Metoclopramide:** A study in dogs demonstrated that metoclopramide did not significantly alter cyclosporine pharmacokinetics.[74]
- **Metronidazole**
- **Omeprazole**
- **Sertraline**

The following drugs may **decrease** the blood levels of cyclosporine:

- **Azathioprine**
- **Carbamazepine**
- **Clindamycin:** Clindamycin may decrease cyclosporine bioavailability; however, this interaction does not appear to occur in dogs.
- **Cyclophosphamide**
- **Famotidine**
- **Griseofulvin**
- **Mitotane**
- **Octreotide**
- **Phenobarbital**[77]
- **Rifampin**
- **St. John's Wort:** This interaction appears to be of significance in dogs.[78]
- **Sulfadiazine/Sulfamethoxazole**
- **Sulfasalazine**
- **Terbinafine**
- **Trimethoprim**: May also increase the risk for nephrotoxicity
- **Warfarin**: May also reduce efficacy of warfarin

Additional interactions:

- **ACE Inhibitors** (eg, **benazepril, enalapril**): There have been case reports in humans in which renal function declined.
- **Alprazolam:** Concurrent use may decrease alprazolam bioavailability and pharmacodynamics effects.
- **Darbepoetin:** May cause additive increases in blood pressure. Additionally, may alter cyclosporine blood concentrations, as cyclosporine is bound by red blood cells
- **Digoxin**: Cyclosporine may increase digoxin levels with possible toxicity.
- **Doxorubicin:** Cyclosporine can increase doxorubicin and doxorubicinol (active metabolite) levels.
- **Fentanyl:** Concurrent use may increase the risk for fentanyl toxicity.
- **Furosemide:** Concurrent use may increase the risk for gouty arthritis in humans.
- **Hydrochlorothiazide:** Concurrent use may increase the risk for hyperuricemia.
- **Immunosuppressive Agents** (eg, **azathioprine, corticosteroids**): May increase the risk for infection or malignancy
- **Ivermectin:** Cyclosporine may inhibit P-gp (MDR1) transporter and increase ivermectin concentrations.[23,34]
- **Leflunomide:** Increased risk for leflunomide-induced adverse hematologic effects
- **Melphalan:** Increased risk for renal injury
- **Methotrexate (MTX)**: Cyclosporine may increase MTX concentrations.

- **Midazolam**: Concurrent use may decrease midazolam clearance and increase midazolam plasma concentrations.
- **Morphine**: Combination may increase morphine exposure.
- **Mycophenolate**: Concurrent use may reduce levels of mycophenolate.
- **Nephrotoxic Drugs, Other** (eg, **acyclovir, aminoglycosides, amphotericin B, colchicine, NSAIDs, trimethoprim, vancomycin**): Possible additive nephrotoxicity; avoid combination
- **Oclacitinib:** Although concurrent administration of oclacitinib and cyclosporine appears safe when administered for up to 3 weeks,[3] the combination of cyclosporine and oclacitinib is relatively contraindicated for long-term use, especially in cases in which infection is present, because of the theoretical increased risk for immunosuppression.[1]
- **Omeprazole:** Concurrent use may result in altered cyclosporine concentrations.
- **Potassium Supplements:** Increased risk for hyperkalemia
- **Spironolactone** and other **Potassium-Sparing Diuretics** (eg, **triamterene**): Increased risk for hyperkalemia
- **Vaccinations**: Vaccine response may be delayed or reduced in patients receiving cyclosporine[79]; avoid use of modified live vaccines.
- **Vincristine:** Concurrent use may increase vincristine plasma concentrations.

Laboratory considerations

- **Intradermal allergy testing (IDT):** Drug withdrawal may be recommended for at least 4 weeks prior to intradermal testing if cyclosporine has been administered for longer than 30 days.[80]

Dosages

NOTE: Dosages are for cyclosporine (modified), *Atopica®*, *Cyclavance®*, *Neoral®*, or equivalent; these dosages are not interchangeable with *Sandimmune®* (or equivalent) dosages.

DOGS:

Control of atopic dermatitis:

a) **Label dosage; FDA-approved**: 5 mg/kg (3.3 – 6.7 mg/kg) PO once daily for 30 days in dogs weighing at least 1.8 kg (3.9 lb). Following this initial treatment period, dose may be tapered to every other day, then twice per week until a minimum frequency that will maintain the desired therapeutic effect is reached. Give at least 1 hour before, or 2 hours after, meals.[38] It may take 4 to 6 weeks to observe the full benefits. To reduce the incidence of vomiting in dogs when starting therapy, some clinicians will start at a low dose, give with food, and gradually increase oral doses over the first week or so. In one small study[81], 12 of 21 dogs (57%) were able to be maintained on every-other-day or twice-weekly cyclosporine administration.

b) **Concurrent administration with ketoconazole** (extra-label): In larger dogs, cyclosporine 2.5 – 3 mg/kg PO once daily with ketoconazole 2.5 – 5 mg/kg PO once daily is effective and may reduce cost.[68] Ideally, cyclosporine should be given on an empty stomach, but if it causes GI upset, giving with food may help. One study found similar cyclosporine levels in dogs treated with either cyclosporine (alone) 5 mg/kg PO once daily or cyclosporine 2.5 mg/kg PO once daily with ketoconazole 2.5 mg/kg PO once daily.[67] After control of pruritus is achieved, the cyclosporine dose can gradually be reduced to the lowest effective dose (eg, daily, then switch to giving every second or third day). For less than daily administration (eg, every 48 hours), give ketoconazole only on the days cyclosporine is administered.

Perianal fistulas (Anal furunculosis) (extra-label): Many dosages have been found to be effective. When used alone, cyclosporine 4 – 7.5 mg/kg PO twice daily. Alternatively, cyclosporine 1 – 4 mg/kg PO twice daily with ketoconazole 5 mg/kg PO once daily. After condition is controlled, increase the administration interval to the lowest frequency that controls clinical signs.[4–7]

Immune-mediated hemolytic anemia (extra-label): 5 mg/kg PO every 12 hours as adjunctive treatment to corticosteroids[8]

Sebaceous adenitis,[82] sterile nodular panniculitis, neutrophilic dermatoses resembling pyoderma gangrenosum, alopecia areata, chronic pedal furunculosis, metatarsal sinus tracts, cutaneous histiocytosis, dermatomyositis, proliferative chronic otitis, idiopathic keratinization disorders (extra-label): 5 mg/kg PO once daily. After condition is controlled, increase the administration interval to the lowest frequency that controls clinical signs.

Pemphigus foliaceus, refractory cases (extra-label): Variable results have been reported. Higher doses such as cyclosporine 15 mg/kg PO once daily or cyclosporine 5 – 10 mg/kg PO once daily combined with ketoconazole 5 – 10 mg/kg PO once daily may be helpful.[83]

Discoid lupus erythematosus, vesicular cutaneous lupus erythematosus (extra-label): 5 mg/kg PO once daily

Exfoliative cutaneous lupus erythematosus (extra-label): Cyclosporine 2.5 – 10 mg/kg PO once daily with or without ketoconazole 5 – 7 mg/kg PO once daily

Steroid-refractory inflammatory bowel disease (extra-label): Cyclosporine 5 mg/kg PO once daily demonstrated an improvement in clinical signs in 12 out of 14 dogs.[9] Some clinicians advocate for giving cyclosporine as a divided dose given twice daily for treatment of inflammatory bowel disease.

Idiopathic chronic hepatitis (extra-label): Median dose is 8 mg/kg PO daily, with a range of 2.5 – 12.7 mg/kg/day. Median time to biochemical remission (ie, ALT, less than 1.1 times the upper limit of normal) was 2.5 months. Concurrent hepatoprotectant treatment was not associated with increased likelihood of remission.[84]

Juvenile sterile granulomatous dermatitis and lymphadenitis (juvenile cellulitis), refractory cases (extra-label): 10 mg/kg PO once daily

Immunosuppressant for renal transplant (extra-label): Empirical dosages generally range from 3 – 6 mg/kg PO twice daily or 5 – 7.5 mg/kg once daily. Ketoconazole or grapefruit juice powder have been used to lower cyclosporine dose requirements. To reduce transplant rejection, 10 – 15 mg/kg PO twice daily[85,86] is generally used and therapeutic drug monitoring (blood cyclosporine concentrations) or pharmacodynamic monitoring can be used to assess adequacy of therapy.

Meningoencephalitis of unknown etiology/origin (MUE/MUO; extra-label**):** 3 – 15 mg/kg PO every 12 hours.[87] A reasonable starting dosage is 5 mg/kg PO every 12 hours.[10]

Primary immune-mediated polyarthritis (IMPA) (extra label): Cyclosporine 5 mg/kg PO every 12 hours with carprofen 2.2 mg/kg PO every 12 hours for 7 days for analgesia was shown in one study to be an effective alternative to prednisone.[88]

Myasthenia gravis: 4 mg/kg PO every 12 hours demonstrated improved clinical signs of 2 dogs in a case report

CATS:

Allergic dermatitis as manifested by excoriations (including facial and neck), miliary dermatitis, eosinophilic plaques, and self-induced alopecia (label dosage; FDA-approved): Initially, 7 mg/kg PO once daily for a minimum of 4 to 6 weeks or until resolution of clinical signs. Following this initial daily treatment period, the dosage may be tapered by decreasing administration

to every other day or twice weekly to maintain the desired therapeutic effect. The lowest effective dosing frequency should be used. Administer directly on a small amount of food or orally just after feeding. When possible, administer on a consistent schedule with regard to meals and time of day. If a dose is missed, the next dose should be administered (without doubling) as soon as possible, but administration should be no more frequent than once daily.[37] **NOTE:** In studies,[89,90] ≈75% of cats receiving daily cyclosporine were able to undergo dose reduction. Of those cats, ≈60% were able to be maintained on twice-weekly administration and 15% were maintained on every-other-day administration for the 8-week study period.

Allergic dermatitis (extra-label): 2.5 – 5.0 mg/kg SC once daily to every other day seemed to be an effective alternative therapy for cats that cannot be treated orally.[35]

Pemphigus complex (extra-label): 5 mg/kg PO every 24 hours either alone or in combination with a glucocorticoid[13]

Sebaceous adenitis, idiopathic granulomatous folliculitis and furunculosis (extra-label): 5 mg/kg PO once daily[91]

Immunosuppressant (usually as part of an immunosuppressive protocol) (extra-label): 3 – 4 mg/kg PO every 12 hours or 5 – 7 mg/kg PO once daily. To reduce transplant rejection, twice-daily administration with prednisolone 0.125 – 0.25 mg/kg PO every 12 hours is generally used; therapeutic drug monitoring is recommended. See ***Monitoring***.

Alternative to glucocorticoid therapy for feline asthma (extra-label): 4 mg/kg PO every 12 hours was reported in one case as effective for treatment of feline asthma.[92]

Chronic stomatitis (extra-label): 2.5 mg/kg PO twice daily[12]

Pure red cell aplasia (extra-label): 5 – 10 mg/kg/day PO, although a dosage up to 20 mg/kg/day was noted[15]

Thrombocytopenia purpura (extra-label): 5 mg/kg PO every 12 hours with prednisone 2 mg/kg PO every 12 hours, from a case report[17]

Monitoring

- Therapeutic efficacy
- Adverse effects
- Consider therapeutic drug monitoring (pharmacokinetic and pharmacodynamic) to assess effectiveness of therapy, particularly when response is poor or when adverse effects occur. Therapeutic drug monitoring can also be considered when changing brands or manufacturers, especially if response to therapy changes in the individual patient. Cyclosporine blood concentrations are not typically monitored when treating atopic dermatitis[93] or inflammatory bowel disease[9] because the blood concentrations were found to not correlate with clinical efficacy, but this may be warranted in some cases.[50]
  a) Pharmacokinetic monitoring (or measurement of blood concentrations) should ideally occur no sooner than 60 hours after starting therapy and whole blood (not plasma) should be tested, as cyclosporine concentrates in blood cells.[19] When monitoring blood drug concentrations, therapeutic trough whole-blood concentrations (12 hours after last dose) have been suggested to be between 300 and 500 ng/mL for transplantation and life-threatening disease but may not reliably predict clinical response for immunosuppression.[94] Because different methodologies may yield different results and different conditions are managed with a range of cyclosporine blood concentrations, it is recommended to contact a laboratory for current recommendations.
  b) Pharmacodynamic monitoring can also be used in dogs receiving cyclosporine therapy to provide information on dosing for individual animals. This test is offered to clinicians as a PCR-based assay, with samples being submitted after 1 week of starting or changing therapy.[95,96] When using pharmacodynamic monitoring in dogs, a single peak sample (2 hours post-administration) is recommended for dogs receiving twice-daily administration, whereas both peak and trough (just before the next dose) samples are recommended in dogs receiving once daily therapy.
- Baseline CBC; repeat as clinically relevant (eg, signs of infection)
- Baseline serum chemistry profile, then monthly to every 3 to 6 months has been suggested for most conditions. For treatment of IMHA in dogs, recommendations are to evaluate relevant biochemical variables every 2 to 3 months owing to the risk for hepatotoxicity in a small proportion of dogs.[8]
- Urinalysis and urine culture should also be monitored due to potential risks for UTIs.[54]
- Blood glucose in diabetic patients
- Body weight: Persistent, progressive weight loss that resulted in hepatic lipidosis was reported during field studies in 2 out of 205 cats.

Client Information

- For this medication to work, give it exactly as your veterinarian has prescribed. It is a good idea to always check the prescription label to be sure you are giving the medicine correctly.
- Preferably, dogs should receive the medicine on an empty stomach (at least 1 hour before or 2 hours after a meal). If the dog vomits after receiving the drug, try giving the medication frozen or with a small amount of food. Freezing capsules for 30 to 60 minutes before administration can also be tried.
- Cats can be given the medication with or without food; make sure to give it the same way each day. If giving with food, first mix the medication into a small portion of food to ensure the entire dose is consumed, then offer the remaining food.
- For many conditions, if a dose is missed, the next dose should be given as soon as possible and then the usual schedule should be restarted. For serious conditions (eg, kidney transplant), contact your veterinarian if a dose is missed.
- Vomiting, decreased appetite, soft stools, and diarrhea are the most common side effects. These signs usually get better on their own, but if they worsen or continue, contact your veterinarian.
- Capsules should be stored in their original container until administration.
- Capsules should not be broken or opened.
- If using the oral liquid, do not rinse or clean the syringe between doses.
- It is recommended that you wear gloves when giving capsules or oral solutions to your animal. Wash your hands thoroughly after handling.
- Depending on the condition being treated, it may take up to 4 to 6 weeks to see an improvement in your animal's condition.
- Watch for signs of infection (eg, low energy level, poor appetite) and/or persistent, progressive weight loss; if seen, contact your veterinarian immediately.
- If your animal is taking cyclosporine for immunosuppression, your veterinarian may need to perform blood tests to evaluate how well this medicine is working. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

- Cats receiving cyclosporine should be kept indoors and not allowed to hunt or eat raw meat due to the risk for developing an infection called toxoplasmosis.

Chemistry/Synonyms

Cyclosporine (ie, cyclosporin A, ciclosporin, cyclosporin) is a naturally produced immunosuppressant agent. It is a nonpolar, cyclic, polypeptide antibiotic that consists of 11 amino acids and it occurs as a white, fine crystalline powder. It is relatively insoluble in water but generally soluble in organic solvents and oils. Molecular weight is 1202.61.

Because of the difficulties surrounding absorption, many different formulations have been approved over the years. Initial formulations included a vegetable-oil base (ie, *Sandimmune*®), but marked differences in bioavailability led to the approval of a human microemulsion formulation (ie, *Neoral*®) and a veterinary product (ie, *Atopica*®) with better bioavailability as compared with the parent product.[31] Because of the wide differences in formulation, and therefore pharmacokinetics, it is recommended that only the veterinary product (ie, *Atopica*®) be used for veterinary patients.

Cyclosporine is commercially available in several dosage forms, including oral solutions, capsules, and a concentrate for injection. To increase oral absorption, a microemulsion-forming preparation (ie, *Neoral*®) is also available as capsules and an oral liquid. The veterinary products (ie, *Atopica*® and *Cyclavance*®) are microemulsion products equivalent to *Neoral*®. All oral formulations contain ethanol ≈10% to 13% and the injection contains ≈33% ethanol.

Cyclosporine may also be known as ciclosporin, 27-400, ciclosporinum, cyclosporine A, OL-27-400, *Atopica*®, *Cyclavance*®, *Gengraf*®, *Neoral*®, *Sandimmune*®, or *Sigmasporin*®.

Storage/Stability

The veterinary capsules (ie, *Atopica*®) should be stored and dispensed in the original unit-dose container at controlled room temperature (15°C-25°C [59°F-77°F]). One study reported that capsules are stable in the freezer for 28 days.[33] The veterinary oral solutions are labeled to only be dispensed in the original container and stored at controlled room temperature between 15°C to 30°C (59°F-86°F); do not refrigerate. After the container is opened, use contents within 2 months to 12 weeks. Refer to specific product labels for further information.

The human oral liquid and capsules for emulsion (ie, *Neoral*®, *Gengraf*®) should be stored in their original containers at 20°C to 25°C (68°F-77°F). Temperatures below 20°C (68°F) may cause the solution to gel or flocculate. Rewarming to 25°C (77°F) can reverse this process without harm.

The oral liquid and oral capsules (ie, *Sandimmune*®) should be stored in their original containers at temperatures less than 30°C (86°F); protect from freezing and do not refrigerate. After opening the oral liquid, use within 2 months.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Cyclosporine for injection is compatible with lactated Ringer's, sodium chloride 0.9%, and dextrose 5% IV solutions. It is reportedly **Y-site compatible** with amikacin, atropine, buprenorphine, butorphanol, calcium salts, cefazolin, dexamethasone sodium succinate, dexmedetomidine, diphenhydramine, dobutamine, dopamine, doxycycline, epinephrine, erythromycin, famotidine, fentanyl, fluconazole, furosemide, heparin, lidocaine, methadone, methylprednisolone sodium succinate, metoclopramide, metronidazole, morphine, penicillin G, piperacillin/tazobactam, potassium salts, propofol, sodium bicarbonate, vasopressin, and zoledronic acid.

It is **Y-site incompatible** with amphotericin B (lipid-based), ampicillin, cyanocobalamin, diazepam, insulin (regular), ketamine, magnesium sulfate, phenobarbital, sulfamethoxazole/trimethoprim, and voriconazole.

Human preparations of cyclosporine solutions may adhere to plastic and therefore should not be mixed in a plastic cup or with plastic utensils.[65]

Because there are approved oral dosage forms for both dogs and cats, routine compounding for use in these species is discouraged. A study[97] found some compounded cyclosporine solutions deviated by more than 10% from the labeled concentration.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Cyclosporine (Modified) Capsules: 10 mg, 25 mg, 50 mg, and 100 mg; *Atopica*®; (Rx). FDA-approved for use in dogs. NADA #141-218

Cyclosporine (Modified) Oral Solution: 100 mg/mL in 5 mL, 15 mL, 30 mL, and 50 mL vials; *Cyclavance*®; (Rx). FDA-approved for use in dogs. ANADA #200-689

Cyclosporine (Modified) Oral Solution: 100 mg/mL in 5 mL and 17 mL bottles; *Atopica*® for Cats; (Rx). FDA-approved for use in cats. NADA #141-329

HUMAN-LABELED PRODUCTS:

Cyclosporine Modified (Microemulsion) Oral Capsules (Soft-gelatin): 25 and 100 mg; *Neoral*®, *Gengraf*®, generic; (Rx). These products may be bioequivalent with, and *Neoral*® contains the same formulation as, the veterinary-approved product (ie, *Atopica*®).

Cyclosporine Modified Oral Solution (Microemulsion): 100 mg/mL in 50 mL bottles; *Neoral*®, generic; (Rx). This product may be bioequivalent with, and contains the same formulation as, the veterinary-approved product (ie, *Atopica*® *for Cats*).

Cyclosporine Oral Solution: 100 mg/mL in 50 mL bottles with syringe; *Sandimmune*®; (Rx). This product is *not* bioequivalent with the veterinary-approved product (ie, *Atopica*® *for Cats*).

Cyclosporine Oral Capsules (Soft gelatin): 25 and 100 mg; *Sandimmune*®; generic; (Rx). These products are *not* bioequivalent with veterinary-approved products (ie, *Atopica*®).

Cyclosporine Concentrated Solution for Injection: 50 mg/mL in 5 mL single-use amps; *Sandimmune*®, generic; (Rx)

Cyproheptadine

(sip-roe-***hep***-ta-deen) *Periactin*®

First-Generation Antihistamine

Prescriber Highlights

- ► Serotonin antagonist antihistamine that can be useful in the management of serotonin-syndrome in small animals and has been used as an appetite stimulant in cats. Limited or no efficacy as an antipruritic/antihistamine in dogs and cats or for asthma in cats
- ► In horses, used for photic head shaking and treatment of pituitary pars intermedia dysfunction (PPID).
- ► Use with caution in animals with urinary or GI obstruction, severe CHF, or angle-closure glaucoma
- ► Adverse effects include CNS depression (cats may demonstrate paradoxical hyperexcitability) and anticholinergic effects.

Uses/Indications

Cyproheptadine may be useful in cats as an appetite stimulant,[1,2] but it is not recommended in the management of hepatic lipidosis.[3,4] It may be useful for urine spraying in male cats.[5] Cyproheptadine use in cats as monotherapy for eosinophilic airway inflammation[6] and asthma[7] is not effective.

Cyproheptadine is indicated for the treatment of histamine-mediated pruritic and allergic skin conditions, including urticaria and insect-bite hypersensitivity in dogs and cats; however, its efficacy for pruritic and allergic diseases is questionable in dogs. In one double-blind, placebo-controlled study, there was no improvement of pruritus in 16 of 16 allergic dogs that were treated with cyproheptadine 0.1 mg/kg PO every 24 hours.[8] Guidelines for atopic dermatitis treatment in dogs indicate that antihistamines have modest efficacy in controlling pruritus associated with atopic dermatitis; for optimal efficacy, cyproheptadine should be given continuously (ie, daily) as preventive therapy. Cyproheptadine is of limited benefit in the management of acute flares.[9]

Historically the drug has been used as adjunctive therapy for canine hyperadrenocorticism. However, one study demonstrated lack of efficacy of cyproheptadine in dogs treated for pituitary dependent hyperadrenocorticism,[10] and more effective medications (eg, trilostane, mitotane) are now available.

Cyproheptadine may be useful as adjunctive treatment in dogs[11,12] or cats[13] with serotonin syndrome or to reduce dysphoria (vocalization, disorientation) associated with baclofen, carisoprodol, selective serotonin reuptake inhibitors (SSRIs), or tricyclic antidepressants (TCAs).

In horses, cyproheptadine has been used for treating photic head-shaking[14] and as adjunctive therapy for pituitary pars intermedia dysfunction (PPID) when sole therapy with pergolide fails to control signs. [15]

Pharmacology/Actions

Similar to other H_1-receptor antihistamines, cyproheptadine acts by competing with histamine for H_1-receptor sites on effector cells. Antihistamines do not block histamine release but can antagonize its effects. Cyproheptadine also possesses potent antiserotonin activity, in addition to anticholinergic and calcium channel blocking actions.[16]

Pharmacokinetics

Available data are limited. Cyproheptadine is well absorbed after oral administration; however, its distribution characteristics are not well-described. Cyproheptadine may be almost completely metabolized in the liver, and the metabolites are excreted in the urine; in humans, elimination is reduced in chronic kidney disease.[17] Elimination half-life in cats averages about 13 hours,[18] but there is wide interanimal variability.

Contraindications/Precautions/Warnings

Cyproheptadine is contraindicated in patients hypersensitive to it. In humans, the manufacturer states the drug is contraindicated in newborn or premature infants, and should be used with caution in patients with prostatic hypertrophy, hyperthyroidism, bladder neck obstruction, severe cardiac disease, hypertension, epilepsy, angle-closure glaucoma or increased intraocular pressure, or pyloroduodenal obstruction.[17]

Cyproheptadine increased seizure severity, reduced seizure threshold, and decreased anticonvulsant efficacy in animal models of convulsions.[19]

Adverse Effects

The most likely adverse effects seen with cyproheptadine use in veterinary patients are related to its CNS depressant (eg, sedation) and anticholinergic effects (eg, dry mucous membranes, decreased GI motility, hyperthermia, tachycardia, urine retention).

Polyphagia may be an unwanted effect in dogs[8] and cats[20] when this drug is used for indications other than as an appetite stimulant. A paradoxical agitated state can develop in cats, which resolves with dose reduction or drug discontinuation.

Reproductive/Nursing Safety

Cyproheptadine has been tested in pregnant lab animals in doses up to 32 times higher than the labeled dose without evidence of harm to fetuses. Nevertheless, because safety has not been established in other species, its use during pregnancy should be weighed carefully.

It is not known whether cyproheptadine is distributed into milk. In humans, the drug is contraindicated in nursing mothers because of potential for toxicity in newborns and infants.[17] Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The oral LD_{50} in the rat is 295 mg/kg orally.[17] There are no specific antidotes available. Treat significant overdoses using standard GI decontamination protocols when appropriate and supportive therapy when required. The adverse effects seen with overdoses are an extension of the drug's adverse effects, principally CNS depression (although CNS stimulation may be seen), anticholinergic effects (eg, dry mucous membranes, tachycardia, urinary retention, hyperthermia) and possibly hypotension. Physostigmine may be considered for serious CNS anticholinergic effects; benzodiazepines may be used to treat seizures, if necessary.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving cyproheptadine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Agents** (eg, **amantadine, atropine, glycopyrrolate, oxybutynin**): May have additive anticholinergic effects
- **Cholinergic Agonists** (eg, **pilocarpine**): Decreased efficacy of cyproheptadine
- **CNS Depressant Agents** (eg, **acepromazine, anesthetic agents [inhalant, injectable], cannabidiol, diazepam, gabapentin, methocarbamol, phenobarbital**): May increase CNS depression
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, selegiline**): Prolonged and intensified anticholinergic effects. Combination is considered contraindicated in humans.
- **Mirtazapine:** Concurrent cyproheptadine and mirtazapine use should be avoided due to antagonistic mechanisms of action.[2]
- **Opioids** (eg, **buprenorphine, morphine**): May increase anticholinergic and/or CNS depressant effects
- **Selective Serotonin Reuptake Inhibitors** (eg, **fluoxetine, paroxetine, sertraline**): Cyproheptadine may decrease efficacy.
- **Tricyclic Antidepressants** (**TCAs**; eg, **clomipramine, amitriptyline**): Cyproheptadine may decrease TCA efficacy.
- **Tramadol:** Cyproheptadine may decrease tramadol efficacy.

Laboratory Considerations

- It is recommended that antihistamines be discontinued at least 7 days prior to **intradermal allergy testing (IDT).**[21]
- Cyproheptadine may increase amylase and prolactin serum levels

when administered with **thyrotropin-releasing hormone**.
- Cyproheptadine can decrease **TSH** secretion.
- Cyproheptadine may cause a false-positive **tricyclic antidepressant** screen.

Dosages

DOGS:

Appetite stimulant (extra-label): 0.2 mg/kg PO every 12 hours; may be dosed less frequently if inappetence is mild.

Adjunctive treatment of dysphoria associated with serotonin syndrome and toxicoses (eg, SSRIs, TCAs, amphetamines, baclofen; extra-label): 1.1 mg/kg PO; doses may be repeated every 1 to 6 hours as needed until signs have resolved.[11,12] In cases where PO dosing is not possible (eg, severe vomiting), crush tablets, mix with saline, and administer rectally.[22]

Antihistamine (extra-label): 0.5 – 2 mg/kg PO every 12 hours; there is little evidence that higher dosages improve efficacy.

CATS:

Appetite stimulant (extra-label): 1 – 4 mg/cat (NOT mg/kg) PO every 12 to 24 hours; alternatively, 0.2 – 1 mg/kg PO every 12 hours.[1,2] Most cats require twice-daily dosing and it may take 3 days to see effect. Before starting treatment, adequate antiemetic and/or analgesic therapy is necessary. Taper drug when discontinuing to prevent rebound anorexia.

Antihistamine (extra-label): 2 – 4 mg/cat (NOT mg/kg) PO every 12 hours.[20] Efficacy was noted within 3 to 10 days of initiating therapy.

Adjunctive treatment of serotonin syndrome (extra-label): 2 – 4 mg/cat (NOT mg/kg) PO; additional doses may be repeated every 4 to 6 hours as needed until clinical signs related to serotonin syndrome have resolved. In cases where PO dosing is not possible (eg, severe vomiting), crush tablets, mix with saline, and administer rectally.[22]

HORSES:

Photic head shaking (extra-label): 0.3 – 0.6 mg/kg PO every 12 hours[14]

Adjunctive therapy for refractory pituitary pars intermedia dysfunction (PPID) (extra-label): Cyproheptadine 0.25 mg/kg PO once to twice daily given concurrently with pergolide[15,23]; may require 4 to 8 weeks to determine efficacy. See ***Pergolide***.

Monitoring

- Appetite
- Body weight
- Adverse effects (eg, CNS depression, anticholinergic effects [eg, dry mucous membranes, tachycardia, urine retention])

Client Information

- Cyproheptadine is an antihistamine that can also be used as an appetite stimulant or as a treatment for certain toxicities.
- Antihistamines should be used on a regular, ongoing basis in animals that respond to them. They work better if used before exposure to an allergen (eg, pollens).
- May be given with or without food. If your animal vomits or acts sick after receiving the drug on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- May cause drowsiness (sleepiness); this effect may lessen with time.
- Cats can become overly excited when receiving this medication.

Chemistry/Synonyms

An antihistamine that also possesses serotonin antagonist properties, cyproheptadine HCl occurs as a white to slightly yellow crystalline powder. Approximately 3.64 mg are soluble in 1 mL of water and 28.6 mg in 1 mL of methanol.

Cyproheptadine HCl may also be known as cyproheptadini hydrochloridum, *Ciplactin®*, *Cyheptine®*, *Cyprogin®*, *Cyprono®*, *Cyprosian®*, *Klarivitina®*, *Nuran®*, *Periactine®*, *Periactinol®*, *Periatin®*, *Peritol®*, *Polytab®*, *Practin®*, *Preptin®*, *Supersan®*, or *Trimetabol®*.

Storage/Stability

Store cyproheptadine HCl tablets and oral solution at room temperature 20° to 25°C (68°F-77°F). Avoid freezing oral syrup (solution).

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS

Cyproheptadine HCl Oral Tablets: 4 mg; generic; (Rx)

Cyproheptadine HCl Oral Syrup: 2 mg/5 mL (0.4 mg/mL) in 473 mL; generic; (Rx)

Cytarabine

Cytosine Arabinoside

(sye-***tare***-a-bean) *Cytosar-U®*

Antineoplastic

Prescriber Highlights

- ► Parenteral immunosuppressant/antineoplastic used in dogs and cats for lymphoreticular neoplasms and leukemias and meningoencephalomyelitis of unknown origin.
- ► Contraindications include patients with a hypersensitivity to this drug.
- ► Adverse effects primarily include GI effects and myelosuppression; increased ALT may occur.
- ► Adequate monitoring is essential.
- ► Potential embryotoxic and teratogenic effects
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies cytarabine as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Cytarabine is used primarily in small animals as adjunctive treatment for lymphoreticular neoplasms (eg, lymphoma), myeloproliferative disease (ie, leukemias), and CNS lymphoma. Its use as a single agent in canine lymphoma demonstrated poor efficacy.[1] Data for use as a single agent or as part of multiagent protocol in cats for the treatment of lymphoma or leukemia are limited. Other studies have shown that rescue protocols containing cytarabine for the treatment of canine lymphoma are effective.[2-6]

Cytarabine can be used in combination with glucocorticoids for treating meningoencephalomyelitis of unknown origin in dogs[7-10] and cats.[11]

Cytarabine has also been used in horses to treat lymphomas, but data are limited to individual case reports.[12,13]

Pharmacology/Actions

Cytarabine is converted intracellularly into aracytidine triphosphate, which competes with deoxycytidine triphosphate to inhibit DNA polymerase, resulting in inhibition of DNA synthesis. Cytarabine is specific to the S phase of the cell cycle (DNA synthesis) and blocks cell progress from the G_1 phase to the S phase. Incorporation of cytarabine into DNA is responsible for both drug activity and toxicity.

Acquired resistance to cytarabine has been reported and is thought to be due to several mechanisms.

Pharmacokinetics

Cytarabine has very poor systemic availability after oral administration but can be administered IV, SC, and intrathecally. Doses of 600 mg/m^2 IV as a bolus or as an IV CRI over 12 hours cross the blood–brain barrier in healthy beagles.[14] In dogs given cytarabine 50 mg/m^2 SC injections or 25 mg/m^2 per hour IV CRI for 8 hours, the volume of distribution was 0.67 L/kg. Elimination half-lives were similar (1.35 hours SC; 1.15 hours CRI), as were peak concentrations. Rate of absorption after SC was very rapid, with peak levels occurring less than 1 hour after the dose was administered. It is important to note that SC administration did not achieve steady-state concentrations, as cytarabine was rapidly absorbed and eliminated quickly (t½= 1.35 hours). This study also suggests a CRI may produce prolonged exposure of cytarabine at cytotoxic levels in plasma, but it is not known if this correlates with differences in efficacy or toxicity.[15] Similar pharmacokinetic parameters (V_d = 0.9 L/kg, t ½ = 1.1 hours) in dogs given 50 mg/m^2 SC injection were noted in a separate study,[9] and cytarabine concentration remained above 1 µg/mL for 2 hours after administration. Overall drug exposure was similar, but cytarabine concentrations were significantly higher for a longer duration (as compared with 50 mg/m^2 SC every 12 hours for 4 doses) with dosing regimens of 100 mg/m^2 SC every 12 hours for 2 doses or 200 mg/m^2 SC as a single dose.[8]

In humans, cytarabine is widely distributed throughout the body. CSF levels can reach ≈40% of the levels found in plasma. Elimination half-life in the CSF is significantly longer than that of serum. Circulating cytarabine is rapidly metabolized by the enzyme cytidine deaminase principally in the liver to the inactive metabolite ara-U (uracil arabinoside). About 80% of the dose is excreted in the urine within 24 hours as both ara-U (≈90%) and unchanged cytarabine (≈10%).

The drug apparently crosses the placenta, but it is unknown if it enters milk.

Contraindications/Precautions/Warnings

Cytarabine can cause severe toxicity, depending on the dose and rate of administration. It should only be used where adequate monitoring and support can be administered. Cytarabine is contraindicated in patients with previous hypersensitivity reactions and should be used with caution in patients with pre-existing bone marrow depression, hepatic or renal dysfunction, or infection. In humans, acute pancreatitis and sudden respiratory distress syndrome have been reported.

Some commercially available products contain benzyl alcohol.

The National Institute for Occupational Safety and Health (NIOSH) classifies cytarabine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[16]

Adverse Effects

In dogs, the most common adverse effects following IV CRI are GI (65%) and hematologic toxicities, with neutropenia (35%) and thrombocytopenia (12%) being the most common.[1,17] Myelosuppressive effects (eg, anemia, neutropenia, thrombocytopenia) are more pronounced with IV versus SC administration. Lower doses in dogs (eg, for inflammatory brain disease) had minimal adverse effects (ie, mild to moderate anemia in less than 1% of patients).[18] Humans experience biphasic leukocyte nadir, first from days 7 to 9 and again at days 15 to 24, with a brief rise in cell count between the nadirs. Platelet decreases begin around day 5, with nadir occurring at ≈days 12 to 15.

GI disturbances include anorexia, nausea, vomiting, diarrhea, and oral ulceration. Neurotoxicity, hepatotoxicity, lethargy, and fever may also occur with cytarabine therapy. Increased ALT was noted in 15% of dogs in a study.[17]

Alopecia and delayed regrowth of shaven hair have been reported in dogs; breeds with a continuously growing hair coat (eg, poodles, terriers, Afghan hounds, old English sheepdogs) are more likely to experience significant hair loss.

Three cases (n = 138) of calcinosis cutis at cytarabine SC injection sites were reported in dogs receiving concurrent prednisolone for treatment of meningoencephalomyelitis of unknown etiology.[19]

In addition, there was 1 case report of suspected drug-induced infiltrative lung disease following a 24-hour cytarabine infusion.[20]

Reproductive/Nursing Safety

Cytarabine is teratogenic in laboratory animals, particularly when administered during the first trimester. Fetal harm has been described following cytarabine administration to pregnant women.

Although it is unknown if cytarabine enters maternal milk, the potential mutagenicity and carcinogenicity of the drug warrants using extreme caution in allowing the dam to continue nursing while receiving cytarabine.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The toxicity of cytarabine is dependent on dose and rate of administration. The intravenous LD_{50} in dogs is 172 mg/kg and greater than 7000 mg/kg in mice.[21] Treatment is supportive, as there is no known antidote, but the drug is dialyzable.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving cytarabine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Flucytosine (5-FC)**: Cytarabine may antagonize the anti-infective activity of flucytosine.
- **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medication may result in additive myelosuppression, avoid combination when possible.
- **Vaccines** (live and inactivated): May diminish vaccine efficacy and enhance adverse effects of live vaccines

Dosages

NOTE: The following dosages should be used only as a general guide because of the potential toxicity of this drug to patients, veterinary staff, and clients and because chemotherapy indications, treatment protocols, monitoring and safety guidelines often change.

Consultation with a veterinary oncologist and referral to current veterinary oncology references[22-26] are strongly recommended.

DOGS:

Antineoplastic agent (extra-label):

Intravenous:

a) 300 mg/m^2 (NOT mg/kg) as a continuous IV infusion (delivered over 4 to 72 hours) once weekly or as part of the day 1 DMAC multi-agent chemotherapy protocol[17,27,28]
b) 600 mg/m^2 (NOT mg/kg) as a continuous IV infusion (300 mg/m^2 given daily over 48 hours)[1]
c) 300 – 600 mg/m^2 (NOT mg/kg), as a continuous IV infusion (delivered over 5-8 hours) starting on day 1 with an injection of carboplatin chemotherapy, on day 7, and/or day 14 of the treatment cycle[3]
d) 750 mg/m^2 (NOT mg/kg) as a continuous IV infusion (150 mg/m^2 given daily for 5 consecutive days, in addition to GMCSF, EPO, and ondansetron injections) as part of a VCAA-based multi-agent chemotherapy protocol[4]

Subcutaneous: (See ***Pharmacokinetics*** regarding SC administration concerns.)

a) Two doses of 100 mg/m^2 (NOT mg/kg) SC given 2 hours apart (total dose, 200 mg/m^2) as part of the DMAC multi-agent chemotherapy protocol[2]
b) 300 mg/m^2 (NOT mg/kg) SC as a single dose as part of DMAC multi-agent chemotherapy protocol[27,28]
c) 300 – 600 mg/m^2 (NOT mg/kg) SC split into 3 to 4 daily doses over 3 to 4 days, starting on day 1 along with carboplatin chemotherapy[3]
d) 150 mg/m^2 (NOT mg/kg) SC every 12 hours for 48 hours was used in a patient with large granular lymphocyte T-cell lymphoma as part of a multi-agent chemotherapy protocol with L-asparaginase, CCNU, and vincristine.[29]
e) 33 mg/m^2 (NOT mg/kg) SC every 8 hours for 5 days along with bleomycin[6]

Inflammatory brain disease (eg, meningoencephalomyelitis of unknown etiology; extra-label): In combination with glucocorticoid therapy:

Subcutaneous: (see ***Pharmacokinetics*** for SC administration) 50 mg/m^2 (NOT mg/kg) SC every 12 hours for 48 hours, repeat every 3 weeks[7,8,18,30-32]

Intravenous:

a) 100 mg/m^2 (NOT mg/kg) as a continuous IV infusion given over 24 hours[33,34]
b) 200 mg/m^2 (NOT mg/kg) as a continuous IV infusion given over 8 to 24 hours[35] or over 48 hours[36]

CATS:

Antineoplastic agent (extra-label): There are limited data available to support dosing in cats, but cytarabine has been dosed as below:

Subcutaneous: (See ***Pharmacokinetics*** regarding SC administration concerns.)

a) 10 mg/m^2 (NOT mg/kg) SC every 12 hours for 2 to 4 days[37]
b) 50 mg/m^2 (NOT mg/kg) SC every 12 hours for 48 hours as part of multi-agent chemotherapy protocol[38]
c) 300 mg/m^2 (NOT mg/kg) SC has also been used as part of DMAC chemotherapy rescue protocol for feline lymphoma.[5]

Intravenous: 100 mg/m^2 (NOT mg/kg) IV along with other chemotherapeutic agents[39]

Inflammatory brain disease (eg, meningoencephalomyelitis of unknown etiology; extra-label):

Subcutaneous: (See ***Pharmacokinetics*** regarding SC administration concerns.) 50 mg/m^2 (NOT mg/kg) SC every 12 hours for 48 hours[11]

HORSES:

Antineoplastic agent (extra-label): Consultation with a veterinary oncologist is encouraged before use; usual doses in horses are 200 – 300 mg/m^2 (usually 1 – 1.5 g/horse per dose) SC or IM every 1 to 2 weeks.[12,40]

Monitoring

- Adverse effects (eg, inappetence, lethargy, drooling [oral ulcerations], vomiting, diarrhea, fever)
- CBC with platelets (baseline, nadir, prior to subsequent treatments)
- Liver and renal function (baseline and periodic)

Client Information

- Cytarabine is a chemotherapy (ie, cancer) drug. The drug and its byproducts can be hazardous to other animals and people that come in contact with it. On the day your animal gets the drug and then for a few days afterward, all bodily waste (eg, urine, feces, litter), blood, and vomit should only be handled while wearing disposable gloves. Seal the waste in a plastic bag, and then place both the bag and gloves in the regular trash.
- GI toxicity (eg, ulceration, diarrhea, vomiting) can occur. If diarrhea is severe or continues, contact your veterinarian.
- Bone marrow depression can occur. The greatest effects on bone marrow usually occur within a few weeks after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal becomes very tired easily, contact your veterinarian right away.
- It is important to immediately report any signs associated with toxicity (eg, abnormal bleeding, bruising, urination, depression, infection, shortness of breath).
- Hair loss and delayed regrowth of shaven hair have been reported in dogs; breeds with a continuously growing hair coat (eg, poodles, terriers, Afghan hounds, old English sheepdogs) are more likely to experience significant hair loss.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Cytarabine, a synthetic pyrimidine nucleoside antimetabolite, occurs as an odorless, white to off-white crystalline powder with a pK_a of 4.35. It is freely soluble in water and slightly soluble in alcohol.

Cytarabine may also be known as 1-beta-D-arabinofuranosylcytosine, arabinosylcytosine, ara-C, cytarabine liposome, cytarabinum, cytosine arabinoside, liposomal cytarabine, NSC-63878, U-19920, U-19920A, WR-28453, ARA-cell®, *Alexan®*, *Arabine®*, *Aracytin®*, *Aracytine®*, *Citab®*, *Citagenin®*, *Citaloxan®*, *Cylocide*, *Cytarbel®*, *Cytarine®*, *Cytosar-U®*, *DepoCyt®*, *DepoCyte®*, *Erpalfa®*, *Ifarab®*, *Laracit®*, *Medsara®*, *Novutrax®*, *Serotabir®*, *Starasid®*, *Tabine®*, *Tarabine®*, or *Udicil®*.

Storage/Stability

Cytarabine sterile powder for injection should be stored protected from light at 20°C to 25°C (68°F-77°F); store intact vials of solution at 15°C to 30°C (59°F-86°F). After reconstitution with bacteriostatic water for injection, solutions are stable for 48 hours at room temperature, although the manufacturer recommends administration as soon as possible after preparation.

Compatibility/Compounding Considerations

Compatible with 5% dextrose in water, 5% dextrose in sodium chloride (0.2%, 0.9%), 5% dextrose in lactated Ringer's, 10% dextrose in 0.9% sodium chloride, lactated Ringer's, normal saline, Ringer's, and sodium lactate 1/6 M. Cytarabine is **incompatible** with the following for y-site administration: allopurinol, amiodarone, amphotericin B, daptomycin, diazepam, lansoprazole, and phenytoin. **Incompatible** with the following in admixtures and syringes: fluorouracil, heparin, regular insulin, oxacillin, and penicillin G potassium.

Compatibility is dependent on factors such as pH, concentration,

temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Cytarabine Injection: 20 mg/mL in 5 mL, 25 mL, and 50 mL single- and multi-dose vials, and 100 mg/mL in 20 mL single-dose vials; generic; (Rx)

Cytarabine Injection, liposomal: 10 mg/mL preservative free (for intrathecal use only) vials; *DepoCyt®*; (Rx). Marketing status is uncertain.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dacarbazine (DTIC)

(da-***kar***-ba-zeen)

Antineoplastic

Prescriber Highlights

- ► Parenteral antineoplastic used in dogs for relapsed lymphomas, soft tissue sarcomas, and melanoma
- ► Not recommended for use in cats
- ► Contraindications include hypersensitivity to the drug and pregnancy (potentially teratogenic).
- ► GI adverse effects can be severe and dose-limiting; high emetogenic potential necessitates premedication to reduce acute vomiting. Myelosuppression also may occur.
- ► Solution must be diluted before IV administration; extravasation injuries can be serious.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies dacarbazine as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Dacarbazine has been used to treat relapsed canine lymphoma,[1] soft tissue sarcomas, histiocytic sarcoma,[2] and melanoma in dogs. It has also been used in combination with doxorubicin, mitoxantrone, vincristine, or lomustine to treat dogs with relapsed lymphoma[3–6] and hemangiosarcoma.[7,8]

Pharmacology/Actions

Dacarbazine is metabolized by hepatic cytochrome P450 enzymes to methyl-triazeno-imidazole-carboxamide (MTIC), an active metabolite. MTIC spontaneously decomposes to release a methyl diazonium that methylates the O6 and N7 positions of guanine, thereby ceasing DNA replication elongation and causing DNA double-strand breaks. Dacarbazine and MTIC are alkylating agents. Dacarbazine possesses minimal immunosuppressive activity and is probably not a cell cycle-phase specific drug.

Resistance to dacarbazine is mediated by upregulation of O6-methylguanine methyltransferase (MGMT), and potentially through enhancement of several other DNA repair mechanisms.

Pharmacokinetics

No pharmacokinetic data were identified in canines. Dacarbazine is poorly absorbed from the GI tract and must be administered IV. In humans, the drug is only slightly bound to plasma proteins and concentrates in the liver where it is extensively metabolized. It is converted into an active form of the drug (MTIC) in the liver by the cytochrome P450 system. Only limited amounts of the drug cross the blood-brain barrier. It is excreted in the urine via tubular secretion with ≈40% as unchanged drug. Elimination half-life is ≈5 hours.

Contraindications/Precautions/Warnings

Dacarbazine is not recommended for use in cats as it is unknown if cats can adequately metabolize it; however, cats are able to metabolize temozolomide (a similar antineoplastic drug) into the same active metabolite (MTIC).[9]

Dacarbazine is contraindicated in patients with a history of hypersensitivity to it. Dacarbazine can cause life-threatening toxicity and should only be used where adequate monitoring and support can be administered. It should be used with caution in patients with preexisting bone marrow depression, hepatic or renal dysfunction, or infection.

Dacarbazine can cause extensive pain and tissue damage during IV administration. Administer IV following a single, clean venipuncture attempt through an IV catheter (indwelling or butterfly). If clinical signs of extravasation are noted, discontinue infusion immediately at that site and apply moderate, dry heat to the area to help disperse the drug and promote vascular absorption. Dacarbazine should **not** be administered IM or SC due to the risk for extravasation.

The National Institute for Occupational Safety and Health (NIOSH) classifies dacarbazine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

In dogs, GI toxicity (including acute vomiting within 24 hours of administration, anorexia, and diarrhea) is commonly seen after administration and is dose-limiting. Dacarbazine is highly emetogenic and pretreatment with an antiemetic (eg, maropitant, ondansetron) is warranted.

Bone marrow toxicity is usually mild and includes anemia, neutropenia, and thrombocytopenia. One study found thrombocytopenia to be the most common hematological toxicity occurred 1 to 2 weeks after treatment.[1] Occasionally severe hematopoietic toxicity can occur with fatal consequences. Other delayed toxic effects can include alopecia, hepatotoxicity, renal impairment, and photosensitivity reactions, but these are rarely seen.

Dacarbazine is considered a vesicant and can cause extensive pain, venous spasm, phlebitis, and tissue damage during IV administration. Pretreatment with dexamethasone and/or butorphanol has been suggested to reduce associated injection site reactions. Dilution is also recommended to reduce the risk for injection site reactions and extravasation.

If signs of extravasation occur, the following has been recommended[10]:

- Stop the infusion immediately and, if possible, withdraw 3 to 5 mL blood to remove some of the drug.
- Remove the infusion needle.
- Delineate the infiltrated area on the patient's skin with a felt tip marker.
- Elevate for 48 hours above heart level using a sling or stockinette dressing with an observation window cut in the dressing.
- Avoid pressure or friction; do not rub the area.
- Observe for signs of increased erythema, pain, or skin necrosis.
- Ensure that no medication is given distal to the extravasation site.
- After 48 hours, encourage the patient to use the extremity normally to promote full range of motion.

Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or Old English sheepdogs) are more likely to experience significant alopecia, change in hair coat color or texture, or hyperpigmentation.

Reproductive/Nursing Safety

Dacarbazine is teratogenic in rats at higher than clinically used dosages. For intact female patients, verify pregnancy status prior to administration.

Although it is unknown if dacarbazine enters milk, the potential carcinogenicity of the drug warrants using extreme caution in allowing the mother to continue nursing while receiving this drug.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The intravenous LD_{50} in mice is 466 mg/kg.[11] Due to the potential for serious toxicity associated with this agent, dosage calculations should be checked thoroughly to avoid overdosing. Treatment of an overdose is supportive as there is no known antidote.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dacarbazine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **CYP1A2 Inducers** (eg, **phenobarbital**, **rifampin**): May increase the metabolism of dacarbazine
- **CYP1A2 Inhibitors, Strong** (eg, **ciprofloxacin, mexiletine**): May decrease the metabolism of dacarbazine, consider therapy modification
- **Immunosuppressive Agents** (eg, **cyclosporine**, **leflunomide**, **mycophenolate**): Concurrent use with other bone marrow depressant medication may result in additive myelosuppression, avoid combination when possible
- **Myelosuppressive Agents** (eg, **antineoplastics**, **iron chelators**): Concurrent use with other bone marrow depressant medication may result in additive myelosuppression, avoid combination when possible.
- **Vaccines** (live and inactivated): May diminish vaccine efficacy and enhance adverse effects of vaccines.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and because chemotherapy indications, treatment protocols, monitoring and safety guidelines often change, the following dosages should only be used as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[12–16] are strongly recommended.

DOGS:

Antineoplastic (extra-label): Dacarbazine dosage depends on the protocol being used.

a) 600 – 1000 mg/m^2 (NOT mg/kg) IV over 4 to 8 hours every 2 to 3 weeks[6]

b) 200 – 250 mg/m^2 (NOT mg/kg) once daily IV for 5 days with the treatment cycle repeated every 3 to 4 weeks. Administer as a bolus in a freely running IV solution.

Monitoring

- Efficacy
- Toxicity, including CBC with differential and platelets; renal and hepatic function tests

Client Information

- Dacarbazine is a chemotherapy (anticancer) medicine. This medicine can be hazardous to other animals and people that come in contact with it. On the day your animal receives the medicine and then for a few days afterward, all bodily waste (urine, feces, litter), blood, or vomit should only be handled while wearing disposable gloves. Seal the waste in a plastic bag and then place both the bag and gloves in with the regular trash.
- Gastrointestinal toxicity(eg, ulcers, diarrhea) can occur. If diarrhea is severe or continues, contact your veterinarian.
- Bone marrow suppression can occur which may put your animal at risk for infection. The greatest effects on bone marrow usually occur within a few weeks after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal tires easily, contact your veterinarian immediately. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

An antineoplastic agent, dacarbazine occurs as a colorless to ivory colored crystalline solid. It is slightly soluble in water or alcohol. After reconstituting with sterile water, the injection has a pH of 3 to 4.

Dacarbazine may also be known as dacarbazinum, DIC, DTIC, imidazole carboxamide, dimethyl triazeno imadazol carboxamide, NSC-45388, WR-139007, *Asercit®*, *DTI®*, *DTIC-Dome®*, *Dacarb®*, *Dacarbaziba®*, *Dacatic®*, *Deticene®*, *Detilem®*, *Detimedac®*, *Fauldetic®*, *Ifadac®*, or *Oncocarbil®*.

Storage/Stability

The powder for injection should be protected from light and stored at 2°C to 8°C (36°F-46°F). If exposed to heat, the powder may change color from ivory to pink, indicating some decomposition.

As per the manufacturer, after reconstituting with sterile water for injection, the resultant solution is stable for up to 8 hours at room temperature or 72 hours if kept refrigerated. If further diluted (up to 500 mL) with either 5% dextrose or 0.9% sodium chloride, the solution is stable for 24 hours when refrigerated and 8 hours at room temperature.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Dacarbazine is **compatible** with 5% dextrose in water and 0.9% sodium chloride for dilution.

There are many drugs that are reported to be **Y-site compatible** including bleomycin, cyclophosphamide, cytarabine, dactinomycin, doxorubicin, ondansetron, and vinblastine.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dacarbazine Powder for Injection: 100 mg, 200 mg, and 500 mg (may contain mannitol) vials; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dactinomycin

Actinomycin D

(dak-ti-noe-***mye***-sin) *Cosmegen®*

Antineoplastic

Prescriber Highlights

- ► Antibiotic antineoplastic agent used for treatment of a variety of neoplasms in dogs and cats
- ► Contraindications include hypersensitivity to the drug and pregnancy (teratogenic).
- ► Use caution in patients with pre-existing myelosuppression, hepatic dysfunction, or infection
- ► Primary adverse effects include GI toxicity and myelosuppression (may be life-threatening); adequate monitoring essential
- ► Specific administration techniques required; avoid extravasation injuries
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies dactinomycin as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Dactinomycin has been used as treatment of lymphoma, bone and soft tissue sarcomas, and carcinomas in small animals.[1] However, limited efficacy has been shown with carcinomas.[2] Its use as a single chemotherapeutic agent has produced mixed efficacy results in relapsed or resistant lymphomas.[3,4] A study in dogs demonstrated that doxorubicin was superior to dactinomycin when used as part of a 'CHOP' protocol to treat lymphoma.[5] Studies have shown efficacy in rescue protocols containing dactinomycin for canine[6] and feline[7] lymphoma, but significant toxicity has been noted.[8]

Pharmacology/Actions

Dactinomycin is an antibiotic with activity against a variety of gram-negative, gram-positive bacteria, and some fungi, but its cytotoxicity prevents it from being clinically useful as an antimicrobial. Dactinomycin forms a complex with DNA, ultimately binding DNA and inhibiting RNA synthesis. Dactinomycin also possesses immunosuppressive and some hypocalcemic activity.

Pharmacokinetics

Because dactinomycin is poorly absorbed, it must be given IV. It is rapidly distributed and high concentrations may be found in bone marrow and nucleated cells but does not cross the blood-brain barrier. In humans, dactinomycin is only minimally metabolized and ≈30% of the drug is excreted unchanged in the bile and urine. The terminal half-life for radioactivity is 36 hours.

Contraindications/Precautions/Warnings

Dactinomycin can cause life-threatening toxicity. It should only be used where adequate monitoring and support can be administered. Dactinomycin is contraindicated in patients with previous hypersensitivity reactions and should be used with caution in patients with preexisting myelosuppression, hepatic dysfunction, or infection.

The P-glycoprotein pump actively transports dactinomycin, and certain breeds susceptible to *MDR1* mutation (also known as *ABCB1*-1delta; eg, collies, Australian shepherds, Shetland sheepdogs, long-haired whippets) are at higher risk for toxicity. *MDR1* gene mutation testing is suggested for susceptible breeds prior to treating.

Care must be taken to avoid perivascular extravasation. Securely placed indwelling IV catheters and close monitoring of IV patency/integrity during infusion are recommended. Dactinomycin should **not** be administered IM or SC due to the risk for extravasation.

Dactinomycin is a high-alert drug in human medicine.[9] Consider using tall man lettering when writing orders for dactinomycin: DACTINomycin. Dosage calculations should be checked thoroughly to avoid overdosing.

The National Institute for Occupational Safety and Health (NIOSH) classifies dactinomycin as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

In dogs, the two most common adverse effects are GI and hematological toxicities. Bone marrow toxicity is usually mild and includes anemia, neutropenia, and thrombocytopenia. One study found thrombocytopenia to be the most common hematological toxicity.[10] Other adverse effects can include ulcerative stomatitis or other GI ulceration, and hepatotoxicity. Because dactinomycin may increase serum uric acid levels, allopurinol may be required to prevent urate stone formation in susceptible patients.

Dactinomycin is considered a vesicant and can cause extensive pain and tissue damage during IV administration. Administer IV following a single, clean venipuncture attempt through an IV catheter (indwelling or butterfly); administration by IV infusion, or slow IV bolus into a running IV line, is recommended. If clinical signs of extravasation are noted, discontinue infusion and apply ice to the site; in humans it is recommended to apply ice for 15 minutes four times per day for 3 days.[11]

Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, Old English sheepdogs) are more likely to experience significant alopecia, change in hair coat color or texture, or hyperpigmentation.

Reproductive/Nursing Safety

Dactinomycin crosses the placenta and has been demonstrated to be embryotoxic and teratogenic in rats, rabbits, and hamsters at higher than clinically used dosages.[12] For intact female patients, verify pregnancy status prior to administration.

Although it is unknown if dactinomycin enters maternal milk, the potential mutagenicity and carcinogenicity of the drug warrants using extreme caution in allowing the mother to continue nursing while receiving dactinomycin.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The lowest detectable lethal dose in dogs is 0.16 mg/kg IV. The intravenous LD_{50} in mice is 1.025 mg/kg.[13] Due to the potential for serious toxicity associated with this agent, dosage calculations should be checked thoroughly to avoid overdosing. Overdose treatment is supportive as there is no known antidote.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dactinomycin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medication may result in additive myelosuppression, avoid combination when possible.

- **Vaccines** (live and inactivated)**:** May diminish vaccine efficacy and enhance adverse effects of vaccines

Laboratory Considerations

- Dactinomycin may interfere with determination of antibacterial drug levels if using bioassay techniques.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and because chemotherapy indications, treatment protocols, monitoring and safety guidelines often change, the following dosages should only be used as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[13–17] are strongly recommended.

DOGS:

Antineoplastic (extra-label): Depending on the protocol, usual doses for dactinomycin in dogs range from 0.5 – 1 mg/m^2 (NOT mg/kg) IV over 20 minutes; doses may be repeated every 1 to 3 weeks. [1,3,6,10,18]

CATS:

Antineoplastic (extra-label): 0.75 mg/m^2 (NOT mg/kg) IV repeated continuously every 2 weeks as part of a rescue protocol for feline lymphoma.[7]

Monitoring

- CBC with hepatic and renal function tests to monitor for potential toxicities
- Check oral mucous membranes for ulceration.
- Monitor injection site for signs of extravasation.

Client Information

- Dactinomycin is a chemotherapy (anticancer) drug. This medicine can be hazardous to other animals and people that come in contact with it. On the day your animal receives this medicine and then for a few days afterward, all bodily waste (urine, feces, litter), blood, or vomit should only be handled while wearing disposable gloves. Seal the waste in a plastic bag and then place both the bag and gloves in with the regular trash.
- Gastrointestinal toxicity (eg, ulcers, diarrhea) can occur. If diarrhea is severe or continues, contact your veterinarian.
- Bone marrow suppression can occur, which may put your animal at risk for infection. The greatest effects on bone marrow usually occur within a few weeks after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal becomes very tired easily, contact your veterinarian immediately. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

An antibiotic antineoplastic agent, dactinomycin (also known as actinomycin D) occurs as an odorless, bright red, crystalline powder. It is somewhat hygroscopic and soluble in water at 10°C (50°F) and slightly soluble at 37°C (98.6°F). The commercially available preparation is a yellow lyophilized mixture of dactinomycin and mannitol.

Dactinomycin may also be known as ACT, actinomycin C(1), actinomycin D, meractinomycin, NSC-3053, *Ac-De®*, *Bioact-D®*, *Cosmegen®* or *Dacmozen®*.

Storage/Stability

The commercially available powder should be protected from light and stored at 25°C (77°F); excursions permitted to 15°C to 30°C (59°F-86°F). When reconstituting, sterile water for injection without preservatives must be used as preservatives may cause precipitation. After reconstituting, the manufacturer recommends using the solution immediately and discarding any unused portion.[16] IV fluid in-line filters with cellulose ester membranes may partially remove dactinomycin.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

A precipitate may form when dactinomycin is added to sterile water that contains preservatives. **Compatible** with 5% dextrose in water and 0.9% sodium chloride for dilution.

Dactinomycin is reported to be **incompatible** for Y-site administration with the following drugs: diazepam, filgrastim, indomethacin, pantoprazole, and phenytoin. Drugs that are reported to be **compatible with dactinomycin when injected at a Y-site** include: granisetron and ondansetron.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE.

HUMAN-LABELED PRODUCTS:

Dactinomycin Powder for Injection, lyophilized: 0.5 mg with 20 mg mannitol in vials; *Cosmegen®*, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dalteparin

(***dahl***-tep-ah-rin) *Fragmin®*

Anticoagulant

Prescriber Highlights

- ► Low molecular weight (fractionated) heparin that may be useful for treatment or prophylaxis of thromboembolic disease
- ► Preferentially inhibits factor Xa and usually only minimally impacts clotting times
- ► Hemorrhage unlikely, but possible
- ► Must be given SC
- ► Dogs and cats may require very frequent dosing, making outpatient administration unfeasible.
- ► May be cost-prohibitive, particularly in horses and large dogs

Uses/Indications

Dalteparin may be useful for prophylaxis or treatment of thromboembolic disease.[1] Recent pharmacokinetic work in dogs and cats raised questions on whether the drug can be effectively and practically administered in the long term. In humans, it is also indicated for prevention of ischemic complications associated with unstable angina and non-Q-wave myocardial infarction.

Pharmacology/Actions

By binding to and accelerating antithrombin III, low molecular weight heparins (LMWHs) enhance the inhibition of factor Xa and thrombin. The potential advantage to using these products over standard (unfractionated) heparin is that LMWHs preferentially inhibit factor Xa and only minimally impact clotting times (prothrombin time, thrombin time, and activated partial thromboplastin time).

Pharmacokinetics

In dogs, dalteparin is completely absorbed after SC injection. It has a volume of distribution of 50 to 70 mL/kg and a dose-dependent half-life of ≈1.5 to 3 hours.[2]

After SC administration to cats, dalteparin is completely absorbed, and the half-life is ≈2 hours.[3] Cats appear to have a much shorter duration of activity (anti-Xa) associated with low molecular weight heparins (LMWHs) than humans. To maintain a therapeutic target of anti-Xa activity of 0.5 – 1 units/mL, pharmacokinetic modeling in one study predicted that a dalteparin dose of 150 units/kg SC every 4 hours would be required.[4] A later study reported that all cats receiving 75 units/kg SC every 6 hours achieved target peak anti-Xa activity of 0.5 –1 units/mL when measured 2 hours postdose.[5]

In horses, dalteparin's pharmacokinetics are similar to humans, but a pharmacodynamic study where 50 units/kg SC were used showed that twice-daily dosing kept anti-Xa activity above the thromboprophylactic range, but that once-daily administration did not.[6]

In humans, after SC injection, dalteparin is absorbed rapidly with a bioavailability of ≈87%; peak plasma concentration (activity) occurs in ≈4 hours.[7] Anti-Xa activity persists for up to 24 hours and doses are usually given once to twice a day. Dalteparin is excreted in the urine; elimination half-life is ≈3 to 5 hours. Half-life may be prolonged in patients with renal impairment.

Contraindications/Precautions/Warnings

Dalteparin is contraindicated in patients that are hypersensitive to it, heparin, or pork products. It is also contraindicated in patients with major bleeding heparin-induced thrombocytopenia, or thrombocytopenia associated with positive in vitro tests for antiplatelets in the presence of dalteparin. Use dalteparin cautiously in patients with significant renal dysfunction as drug accumulation could result. It should be used with extreme caution in patients receiving epidural anesthesia or with increased risk for hemorrhage.

Do not administer via IM or IV routes; dalteparin must be given via SC injection only. Dalteparin cannot be used interchangeably with other low molecular weight heparins (LMWHs) or heparin sodium, as dosages differ for each.

Do not confuse dalteparin with darbepoetin.

Adverse Effects

A retrospective study observed that bleeding complications occurred in ≈9% of critically ill dogs receiving dalteparin[1]. Bleeding complications in cats were infrequent with client-administered dalteparin.[8] In humans, adverse effects do not routinely occur, but hemorrhage is a possibility. Injection site hematomas or pain, allergic reactions, and neurologic sequelae secondary to epidural or spinal hematomas have been reported.

Reproductive/Nursing Safety

There was no evidence of embryo-fetal toxicity or teratogenicity when dalteparin sodium was administered to pregnant laboratory animals.[7]

Dalteparin is present in human breastmilk in small amounts. As oral absorption of dalteparin is minimal, it is likely safe to use during nursing.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose may lead to hemorrhagic complications. If treatment is necessary, protamine sulfate slow IV may be administered.

Protamine sulfate 1 mg IV can inhibit the effects of 100 units of administered anti-Xa dalteparin. Avoid overdoses of protamine sulfate.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dalteparin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed, and additional monitoring performed when appropriate.

- Anticoagulants, Oral (eg, **rivaroxaban**, **warfarin**): Increased risk for hemorrhage
- Nonsteroidal Anti-Inflammatory Drugs (**NSAIDs;** eg, **carprofen, flunixin, meloxicam, robenacoxib**): Increased risk for hemorrhage
- Platelet-Aggregation Inhibitors (eg, **aspirin, clopidogrel**): Increased risk for hemorrhage
- Selective Serotonin Reuptake Inhibitors (**SSRIs;** eg, **fluoxetine, sertraline**): Concurrent use may increase risk for bleeding.

Laboratory Considerations

- Low molecular weight heparins (LMWHs) may cause subclinical, fully reversible increases in **AST** or **ALT**; **bilirubin** is only rarely increased in these patients, therefore, interpret these tests with caution, as increases do not necessarily indicate hepatic damage or dysfunction.

Dosages

DOGS:

Thromboprophylaxis (extra-label): 150 – 175 units/kg SC every 8 hours[9]

CATS:

Thromboprophylaxis (extra-label): 75 – 150 units/kg SC every 6 hours[5,9]

HORSES:

Thromboprophylaxis (extra-label):

a) Adults: 50 units/kg SC twice daily based on a pharmacodynamic study.[6] There was considerable variability in anti-Xa activity between horses, which may indicate the need for more frequent monitoring.

b) Foals: 100 units/kg SC once daily may be effective[10]

Monitoring

- Baseline and periodic CBC with platelet count during therapy
- Urinalysis (free catch)
- Fecal occult blood test (horses)
- Routine coagulation tests (activated partial thromboplastin time [aPTT], PT) are usually insensitive measures of activity and normally not warranted.[11]
- Anti-Xa activity may be useful to guide dosage adjustments, particularly if bleeding occurs or patient has renal dysfunction. A target peak anti-Xa range of 0.5 – 1 units/mL, extrapolated from human literature, has been suggested for use in dogs and cats.[1,5] The suggested thromboprophylactic range for horses is 0.1 – 0.2 units/mL.[6] **NOTE**: To measure peak anti-Xa activity, sample at 2 hours postdose for cats, 3 hours postdose for dogs, and 3 to 4 hours postdose for horses.[12] If an anti-Xa assay is not available, consider activated clotting time, aPTT, thrombin generation, or viscoelastic tests to monitor anticoagulant treatment.[13]

Client Information

- Dalteparin must be injected subcutaneously (SC, under the skin); be sure you understand how to correctly give the injections. Several injections a day may be required, and treatment may be very expensive. Injections may be painful.
- Bleeding is not likely but can occur. Contact your veterinarian immediately if it happens.

- If your animal is listless (lacking energy or interest in things), appears to be having trouble breathing, trouble walking or loses the use of its rear legs, contact your veterinarian immediately, as it may mean blood clots have formed.

Chemistry/Synonyms

A low molecular weight heparin (LMWH), dalteparin sodium is obtained by nitrous acid depolymerization of heparin derived from pork intestinal mucosa. The average molecular weight is ≈5000 and 90% ranges from 2000 to 9000 daltons (heparin sodium has a molecular weight of ≈12,000). 1 mg of dalteparin is equivalent to not less than 110 units and not more than 210 units of anti-factor Xa.

Dalteparin sodium may also be known by as: Daltaparinum natricum, Kabi-2165, *Boxol®*, *Fragmine®*, *Ligofragmin®*, or *Low Liquemine®*.

Storage/Stability

The manufacturer of the commercially available injection states the product should be stored at controlled room temperature (20°C-25°C [68°F-77°F]). Do not use if particulate matter or discoloration occur. Once the multi-dose vial is punctured, store at room temperature; discard any unused solution after 2 weeks.

A study showed that commercially available dalteparin solution was stable for up to 30 days when drawn into syringes and stored at room temperature or refrigerated.[14]

Compatibility/Compounding Considerations

Do not mix dalteparin with other compounds.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dalteparin Sodium Injection (Anti-factor Xa International Units): Available in a variety of preservative-free single dose syringes that range from 2500 units/0.2 mL to 18,000 units/0.72 mL; these are less likely to be of clinical use in veterinary medicine. A multi-dose vial containing 25,000 units/mL in a 3.8 mL/vial is available; also contains benzyl alcohol; *Fragmin®*; (Rx).

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Danofloxacin

(dan-oh-***floks***-a-sin) *Advocin®*

Fluoroquinolone Antibiotic

Prescriber Highlights

- ► Parenteral third-generation fluoroquinolone antibiotic labeled for use in beef cattle (excluding dairy or veal) to treat and control bovine respiratory disease (BRD) associated with *Mannheimia* (*Pasteurella*) *haemolytica* and *Pasteurella multocida*. May also be of benefit in treating fluoroquinolone-susceptible infections in non-food-producing species (horses, camelids, exotics)
- ► Labeled in cattle for a single SC injection or 2 SC injections 48 hours apart
- ► FDA prohibits extra-label use in food animals.

Uses/Indications

Danofloxacin injection is indicated for the treatment of bovine respiratory disease (BRD) associated with *Mannheimia* (*Pasteurella*) *haemolytica* and *Pasteurella multocida* in beef cattle and for the control of BRD in beef cattle at high risk for developing BRD associated with the same bacteria. Danofloxacin is not indicated for use in dairy or veal cattle. In other countries, danofloxacin may be labeled for use in other cattle (non-dairy) as well as swine and chickens (non-laying), but in the US, it is illegal to use the drug in an extra-label manner in food-producing species.

Danofloxacin may be of benefit in treating susceptible infections in adult horses, camelids, and other non-food-producing species.

Danofloxacin is classified by the World Health Organization as a Critically Important, Highest Priority antimicrobial.[1] The Office International des Epizooties (OIE) has designated danofloxacin as a Veterinary Critically Important Antimicrobial (VCIA) Agent in avian, bovine, caprine, lagomorph, ovine, and swine species.[2]

Pharmacology/Actions

Danofloxacin is a fluoroquinolone bactericidal antibiotic that inhibits bacterial DNA-gyrase, preventing DNA supercoiling and DNA synthesis. Fluoroquinolones have good activity against many gram-negative bacilli and some gram-positive cocci (*Staphylococcus aureus* and *Staphylococcus pseudintermedius*). It has little activity against anaerobes. In general, fluoroquinolones have a dose- or concentration-dependent effect rather than a time-dependent bactericidal effect.

MIC_{90} values for *Mannheimia* (*Pasteurella*) *haemolytica* and *P multocida* average 0.06 µg/mL and 0.015 µg/mL, respectively.[3]

Pharmacokinetics

After SC injection in the neck of cattle, danofloxacin is reportedly rapidly absorbed with high bioavailability (≈90%). Peak serum concentrations occur ≈2 to 3 hours after dosing. Steady-state volume of distribution is ≈2.7 L/kg; lung concentrations exceed those in plasma. Terminal elimination half-life ranges from 3 to 6 hours. In cattle, elimination is primarily unchanged drug into the urine. Other species may metabolize greater percentages of the drug into a desmethyl metabolite (desmethyldanofloxacin). Danofloxacin distributes extensively throughout the body, as evidenced by a steady-state volume of distribution (VDss) in cattle exceeding 1 L/kg. Danofloxacin concentrations in the lung homogenates markedly exceed those observed in plasma, further suggesting extensive distribution to the indicated site of infection. Linear pharmacokinetics has been demonstrated when danofloxacin is administered to cattle by SC injection at doses between 1.25 and 10 mg/kg. One study in calves experimentally infected with *P multocida* showed danofloxacin had a significantly lower clearance rate in 3-week-old calves compared with 6-month-old calves, and a significantly higher AUC in 6-month-old calves than in 3-week-old calves.[4] Plasma protein differences among different ages of calves has not been shown to cause clinically significant changes in danofloxacin pharmacokinetics.[5]

In horses, a research study on the pharmacokinetics of IM, IV, and IG (intragastric) administration of danofloxacin at 1.25 mg/kg to healthy mature horses revealed favorable bioavailability with the IM route at 89% and poor bioavailability of the IG route at 22%.[6] The authors reported good tolerability of the IG route.

In sheep, the drug quickly reaches high tissue concentrations. One hour after IM administration, the concentration peaks in lung tissue and interdigital skin. A study dosing sheep at 1.25 mg/kg IV and IM resulted in similar concentrations for serum, exudates, and transudates.[7]

In goats, a study of danofloxacin administered at 1.25 mg/kg IV or IM revealed similar half-lives of 4.67 and 4.41 hours after IV and IM, respectively.[8] Volume of distribution was high via either route with 100% bioavailability reported after IM administration. The drug's penetration into both exudates and transudates was slightly slower after IM administration[8]. Another study found that goats challenged with *Escherichia coli* endotoxin receiving danofloxacin at 1.25 mg/kg IV or IM had an altered clearance of the drug with significant increases in plasma concentrations and AUC.[9]

In camels, IV administration of the drug at 1.25 mg/kg results in a high volume of distribution, a half-life of 5.37 hours, and rapid clear-

ance.[10] The IM administration of the drug at the same dose resulted in rapid and near complete absorption, with a half-life of 5.71 hours.

In pigs, the drug has been shown to reach a high concentration in lung tissue and GI tissue, including mucosa. In the first 24 hours after an IM dose of 2 mg/kg, 43% of the dose is eliminated in the urine. Elimination half-life in swine is ≈7 hours.

Contraindications/Precautions/Warnings

The FDA prohibits extra-label use of this drug in food animals. The manufacturer cautions use of danofloxacin in animals with known or suspected CNS disorders as quinolones have caused CNS stimulation and seizures (rare). Fluoroquinolones have been shown to produce erosions of cartilage of weight-bearing joints and other signs of arthropathy in immature, rapidly growing animals of various species.[3]

Adverse Effects

Hypersensitivity reactions and lameness have been reported after administration to calves at labeled dosages. Incidence rates are not known, but they are believed to be uncommon. In cattle, SC injections can cause a local tissue reaction that may result in trim loss.

Quinolone-class drugs should be used with caution in animals with known or suspected CNS disorders. In such animals, quinolones have, in rare instances, been associated with CNS stimulation, which may lead to convulsive seizures.

Quinolone-class drugs have been shown to produce erosions of cartilage of weight-bearing joints and other signs of arthropathy in immature, rapidly growing animals of various species.

Reproductive/Nursing Safety

Studies documenting safety during pregnancy in cattle are not available. In studies performed in rats (100 mg/kg/day), mice (50 mg/kg/day), and rabbits (15 mg/kg/day), no teratogenic effects were observed.[3]

Danofloxacin safety during nursing is not known, but it is prohibited from use in lactating dairy cattle where the milk is for human consumption.

Overdose/Acute Toxicity

Limited information is available for cattle. High dosages (18 – 60 mg/kg for 3 to 6 days) administered to feeder calves resulted in arthropathies/lameness (consistent with other fluoroquinolones), CNS stimulation (ataxia, nystagmus, tremors), inappetence, recumbency, depression, and exophthalmos. Some (3/6) 21-day-old calves receiving 18 mg/kg twice 48 hours apart developed nasal pad erythema.

Studies performed in adult dogs given 2.4 mg/kg/day PO for 90 days showed no observable effects.

Drug Interactions

No specific interactions have been reported when danofloxacin is used in cattle. In humans:

- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Concomitant use with fluoroquinolones may increase risk for tendonitis and tendon rupture.
- **Probenecid**: May block renal tubular secretion of danofloxacin and may increase danofloxacin serum level and elimination half-life
- **Theophylline/Aminophylline**: Some injectable fluoroquinolones (eg, ciprofloxacin) can potentially increase serum concentrations; increased monitoring of theophylline concentrations is recommended.

Laboratory Considerations

- None are identified.

Dosages

BEEF CATTLE (EXCLUDING DAIRY CATTLE OR VEAL CALVES):

Label indications (label dosage; FDA-approved): 8 mg/kg SC as a single injection for bovine respiratory disease (BRD) treatment and control in high-risk cattle, or 6 mg/kg SC repeated once ≈48 hours following the first injection as multi-day therapy for BRD treatment.[3] Administered dose volume should not exceed 15 mL per injection site.

REPTILES:

Mycoplasma infections in desert tortoises (extra-label): 6 mg/kg SC (vary injection site) every 48 hours (every other day) for 3 to 6 weeks[11]

Monitoring

- Clinical efficacy

Client Information

- If clients are to administer this product to food animals, they should be advised on correct injection technique and the importance of using the product per the label only.

Chemistry/Synonyms

Danofloxacin mesylate is a synthetic fluoroquinolone that occurs as a white to off-white crystalline powder. Approximately 180 grams are soluble in 1 liter of water. The color of the injectable solution is yellow to amber and does not affect potency.

Danofloxacin may also be known by the following synonyms: CP-76136-27, danofloxacine or danofloxacino. Internationally registered trade names include *Advocin®*, *Advocine®*, *Danocin®*, *Advocid®*, and *Advovet®*.

Storage/Stability

Danofloxacin mesylate for injection should be stored at or below 30°C (86°F) and protected from light and freezing.

Vials of *Advocin®* (danofloxacin) are multiuse vials and should be discarded 28 days after first puncture. Vials should not be punctured more than 7 times (100 mL) or 17 times (250 mL).

Compatibility/Compounding Considerations

Danofloxacin injection for SC use should not be mixed with other medication or diluents. Fluoroquinolone injectable products can be very sensitive to pH changes or chelation with cationic substances (eg, calcium, magnesium, zinc).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Danofloxacin Mesylate: 180 mg/mL (of danofloxacin) in 100 mL and 250 mL multidose vials; *Advocin®;* (Rx). FDA-approved for use in beef cattle only. Not for use in cattle intended for dairy production or calves to be processed for veal. When administered per the label directions, slaughter withdrawal = 4 days from the last treatment.

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dantrolene

(***dan***-troe-leen) *Dantrium®*

Skeletal Muscle Relaxant

Prescriber Highlights

- ► Direct-acting muscle relaxant
- ► Primary indications: horses: post-anesthesia myositis/acute rhabdomyolysis; dogs and cats: functional urethral obstruction, potentially rhabdomyolysis
- ► Use with extreme caution in animals with hepatic dysfunction. Caution in patients with severe cardiac dysfunction or pulmonary disease
- ► Adverse effects: weakness, sedation, increased urinary frequency, GI effects. Hepatotoxicity possible especially with chronic use

Uses/Indications

In humans, oral dantrolene is indicated primarily for the treatment of conditions associated with upper motor neuron disorders (eg, multiple sclerosis, cerebral palsy, spinal cord injuries).[1,2] In veterinary medicine, its proposed indications include prevention and treatment of malignant hyperthermia syndrome in various species, treatment of functional urethral obstruction due to increased external urethral tone in dogs and cats, prevention and treatment of equine post-anesthetic myositis (PAM) and equine exertional rhabdomyolysis. Dantrolene has also been recommended for use in the treatment of bites from black widow spiders in small animals and for the treatment of porcine stress syndrome.

Pharmacology/Actions

Dantrolene exhibits muscle relaxation activity by direct action on muscle. Although the exact mechanism is not well understood, it probably acts on skeletal muscle by interfering with the release of calcium from the sarcoplasmic reticulum. It has no discernible effects on the respiratory or cardiovascular systems, but can cause drowsiness and dizziness; the reasons for these CNS effects are not known.

Pharmacokinetics

After intragastric administration to horses, bioavailability is ≈39%. The drug is slowly absorbed, with peak concentrations occurring within ≈1.5 hours in horses. Oral dantrolene absorption can be affected by food. Although there was considerable interpatient variation in the results, a study concluded that, where possible, feed restriction before nasogastric dantrolene administration should be avoided or should not exceed 4 hours. Oral dantrolene has a half-life of ≈3 to 4 hours in horses.

In the dog, oral administration is well tolerated, and the drug is rapidly absorbed. A 5 mg/kg and 10 mg/kg dose PO had a peak plasma concentration of 0.43 µg/mL and 0.65 µg/mL, respectively and the terminal half-life was 1.26 hours and 1.21 hours, respectively. However, there was large interpatient variability on all parameters.

In humans, bioavailability of dantrolene after oral administration is ≈35%. Peak concentrations occur ≈5 hours after oral administration. The drug is substantially bound to plasma proteins (principally albumin). The elimination half-life in humans is ≈8 hours. Dantrolene is metabolized in the liver and metabolites are excreted in the urine. Only ≈1% of the parent drug is excreted unchanged in the urine and bile.

Contraindications/Precautions/Warnings

Because dantrolene can cause hepatotoxicity, it should be used with extreme caution in patients with preexisting liver disease and with caution in patients with severe cardiac dysfunction or pulmonary disease.

Dantrolene injection has a high pH (9.5 or higher); care must be taken to prevent extravasation at the infusion site.[3]

Adverse Effects

The most significant adverse effect is hepatotoxicity. In humans, this effect is most commonly associated with high-dose chronic therapy but may also be seen after short-term high dose therapy. The incidence of this reaction is unknown in veterinary medicine but monitor for its occurrence.

Hyperkalemia has been reported in dogs and horses receiving dantrolene IV.[4,5]

More common, but less significant, are the CNS associated signs of weakness, sedation, dizziness, headache, and GI effects (diarrhea, nausea, vomiting).[1,2,6] Also seen are increased urinary frequency and, possibly, hypotension.

Reproductive/Nursing Safety

Dantrolene readily crosses the placenta, reaching roughly equivalent fetal and maternal blood concentrations. The drug reduced pup survival in rats and demonstrated embryocidal effects in rabbits.[7]

Dantrolene is distributed into milk; safe use cannot be assured during nursing.[1,2,6]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

There is no specific antidotal therapy to dantrolene overdoses, therefore, remove the drug from the gut if possible and treat supportively.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dantrolene and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Benzodiazepines** (eg, **diazepam, midazolam**): Increased sedation may be seen if tranquilizing agents are used concomitantly with dantrolene.
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**): Rare reports of severe hyperkalemia with cardiovascular collapse in humans; concomitant use with dantrolene during malignant hyperthermia crises not recommended.
- **CNS Depressants** (eg, **acepromazine**, **cannabidiol, dexmedetomidine, methocarbamol, phenobarbital**): Increased sedation may be seen.
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**): Increased risks for hepatotoxicity from dantrolene have been seen in women younger than 35 years of age that are also receiving estrogen therapy; veterinary significance is unknown.
- **Opioids** (eg, **fentanyl, morphine**): Increased sedation may be seen if tranquilizing agents are used concomitantly with dantrolene.
- **Vecuronium**: Dantrolene may potentiate neuromuscular blockade.

Laboratory Considerations

None noted

Dosages

DOGS:

Canine stress syndrome (CSS), malignant hyperthermia (MH); (extra-label):

a) Acute attack: 0.2 – 3 mg/kg IV
b) MH-like syndrome associated with hops (*Humulus lupulus*) ingestion: 2 – 3 mg/kg IV or 3.5 mg/kg PO as soon as possible after ingestion.

Adjunctive treatment of rhabdomyolysis (extra-label): 1.5 mg/kg PO every 8 hours (from a case report; very intensive drug and supportive therapy used).

Functional urethral obstruction due to increased external urethral tone (extra-label): 1 – 5 mg/kg PO every 8 to 12 hours; limited evidence to support this dosage.

CATS:

Functional urethral obstruction due to increased external urethral tone (extra-label):

a) 1 mg/kg IV as a single dose was effective in male cats under experimental conditions.[8,9] May be given with prazosin[8]
b) 0.5 – 2 mg/kg PO every 12 hours; limited evidence to support this dosage.

HORSES:

Rhabdomyolysis prevention (all dosages are extra-label):

a) Thoroughbreds: 4 mg/kg PO or via NG tube. Feed restriction before nasogastric dantrolene administration should be avoided or should not exceed 4 hours.[10]
b) 800 mg/horse (NOT mg/kg); within 30 minutes prior to administration, mix contents of capsules with 9 mL tap water to make a suspension and given PO one hour before exercise.
c) Several dosage regimens have been recommended, but caution should be used, as use and efficacy are uncertain: 2 mg/kg PO once daily for 3 to 5 days and then every third day for a month has been recommended. Drug is diluted in normal saline and given via stomach tube. Another dosage recommendation is 300 mg/horse (NOT mg/kg) PO once daily (may be preferable because the drug is hepatotoxic). Another recommendation is 500 mg/horse (NOT mg/kg) PO for 3 to 5 days and then 300 mg/horse (NOT mg/kg) PO every third day. Monitor hepatic function and status.

Prevention of post-anesthetic myositis (PAM); (extra-label): To prevent muscle damage in horses undergoing hypotensive anesthesia: 4 – 6 mg/kg enterally (in 2 L of water given via NG tube) 60 to 90 minutes prior to general anesthesia.[11] Dantrolene reduces muscle damage in horses undergoing general anesthesia without inhibiting anesthetic recovery, but because it decreases cardiac output and can precipitate hyperkalemia and arrhythmias, this practice is currently discouraged. If horses susceptible to hyperkalemic paralysis need to be treated before the anesthetic is administered, cardiovascular parameters should be closely monitored.

RABBITS:

Functional urethral obstruction due to increased external urethral tone (extra-label): 10 mg/kg intraperitoneally as soon as possible (preferably within 1 hour) after spinal cord injury, along with 30 mg/kg IV methylprednisolone sodium succinate

Monitoring

- Baseline and periodic liver chemistry panel if to be used chronically or using high dosages
- Serum potassium
- Body temperature for patients with malignant hyperthermia
- Urine volume, frequency, continence

Client Information

- Drowsiness, vomiting, diarrhea,[3] and a greater need to urinate are the most likely side effects.
- Liver toxicity can rarely occur. If your animal shows signs of extreme lack of energy, frequent vomiting (small animals), not eating, bleeding, or yellow discoloration of the whites of the eyes, gums, or skin (jaundice), contact your veterinarian immediately.

Chemistry/Synonyms

A hydantoin derivative that is dissimilar structurally and pharmacologically to other skeletal muscle relaxant drugs, dantrolene sodium is a weak acid with a pK_a of 7.5. It occurs as an odorless, tasteless, orange, fine powder that is slightly soluble in water. It rapidly hydrolyzes in aqueous solutions to the free acid form that precipitates out of solution.

Dantrolene Sodium may also be known by the following synonyms and internationally registered trade names: F-440, F-368, *Danlene®*, *Dantamacrin®*, *Dantralen®*, or *Dantrolen®*.

Storage/Stability

Dantrolene products should be stored at room temperature 20°C to 25°C (68°F-77°F). Dantrolene capsules should be stored in well-closed containers. Dantrolene powder for injection should protected from prolonged exposure to light. After reconstitution with sterile water for injection, the powder for injection should be used within 6 hours when stored at room temperature and should be protected from direct light.

Compatibility/Compounding Considerations

To dose small dogs or cats, it has been suggested to re-encapsulate ⅛ to ¼ of the contents of a 25 mg capsule and place into a size 2 or 4 gelatin capsule.

Dantrolene powder for injection is **incompatible** with either 0.9% sodium chloride or 5% dextrose injection.[1,2]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for further information.

HUMAN-LABELED PRODUCTS:

Dantrolene Sodium Oral Capsules: 25 mg, 50 mg, and 100 mg; *Dantrium®*, generic; (Rx)

Dantrolene Sodium Powder for Injection Solution: 20 mg/vial (≈0.32 mg/mL dantrolene after reconstitution; with mannitol 3 g/vial) in 70 mL vials; *Dantrium® Intravenous*, *Revonto®*; (Rx).

Dantrolene Sodium Powder Injectable Suspension: 50 mg/mL in 5 mL vials (250 mg dantrolene sodium per vial); *Ryanodex®*; (Rx).

For the complete list of references, see **wiley.com/go/budde/plumb**

Dapsone

Diaminodiphenyl sulfone (DDS)

(***dap***-sone)

Antimycobacterial Antibiotic

Prescriber Highlights

- ► May be useful for treating protozoal (*Pneumocystis* spp) infections, brown recluse spider bites, and cutaneous vasculitis; however, it is rarely used due to potential for severe adverse effects
- ► Not recommended for use in cats due to severe adverse effects
- ► Adverse effects include hepatotoxicity, methemoglobinemia, anemia, thrombocytopenia, neutropenia, GI effects, neuropathies, and cutaneous drug eruptions; photosensitivity reactions are possible.

Uses/Indications

Because of its leukocyte inhibitory characteristics, dapsone may be useful for adjunctive treatment of brown recluse spider (*Loxosceles reclusa*) bites,[1,2] or when an underlying etiology causing cutaneous vasculitis cannot be determined[3,4]; however, it is rarely used in veterinary medicine and little safety or efficacy information is available.

In a foal, dapsone has been used to treat *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infection.[5]

In humans, dapsone has been used as a second-line treatment for immune-mediated thrombocytopenia.

The World Health Organization (WHO) has designated dapsone as a Highly Important antimicrobial for human medicine.[6]

Pharmacology/Actions

Dapsone's antimicrobial actions are thought to be due to inhibition of the synthesis of dihydrofolic acid via competition with para-aminobenzoate for the active site of dihydropteroate synthetase. Dapsone also decreases neutrophil chemotaxis, complement activation, antibody production, and lysosomal enzyme synthesis. The mechanisms for these actions are not well understood. Dapsone is both bactericidal and bacteriostatic against *Mycobacterium leprae.*

Pharmacokinetics

After oral administration to dogs, dapsone is rapidly and completely absorbed.[7] Elimination half-life ranges from about 6 to 10 hours. In humans, the monoacetyl metabolite is almost completely bound to plasma proteins, but in dogs, it is only about 60% bound. Dapsone is primarily eliminated via the kidneys as conjugates and unidentified metabolites. Half-life in dogs is ≈6 to 10 hours, and in humans is widely variable and ranges from about 10 to 50 hours.[8]

Contraindications/Precautions/Warnings

Because of increased incidences of neurotoxicity and hemolytic anemia, dapsone is generally not recommended for use in cats.[9]

Dapsone is contraindicated in patients that are hypersensitive to it or other sulfone drugs.[8] It should not be used in patients with severe anemias or other preexisting blood dyscrasias. Because of its potential for causing hepatic toxicity, dapsone should be used with caution in animals with preexisting hepatic dysfunction.

Adverse Effects

Adverse effects include hepatotoxicity, dose-dependent methemoglobinemia, hemolytic anemia, thrombocytopenia, neutropenia, GI effects, and neuropathies.[8] A dog developed a fatal bleeding diathesis after 6 days of dapsone treatment for skin disease, and evidence suggested dapsone-induced destruction of the dog's platelets and megakaryocytes.[10] Cutaneous drug eruptions are due to sensitization to dapsone. Photosensitivity is possible. Dapsone is a potential carcinogen.

Reproductive/Nursing Safety

In pregnant animals, dapsone should be used with caution. Animal studies have apparently not been performed with dapsone to determine its effects during pregnancy.[8]

Dapsone is excreted into milk in concentrations equivalent to those found in plasma,[8] and hemolytic reactions have been seen in human neonates. Consider switching to milk replacer if dapsone is required in a nursing dam.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Because of its toxicity potential and species-specific differences in sensitivity and pharmacokinetics, it is recommended to contact an animal poison control center in cases of dapsone overdoses. In humans, dapsone overdoses generally cause nausea, vomiting, and hyperexcitability that can occur within minutes of an overdose. Methemoglobinemia with associated depression, seizures, and cyanosis can occur. Hemolysis may be delayed, occurring from 7 to 14 days after the overdose. Treatment in humans involves removal of the drug from the GI tract including use of activated charcoal, methylene blue for methemoglobinemia, and, sometimes, hemodialysis to enhance removal of the drug and the monoacetyl metabolite.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving dapsone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Clofazimine**: There is weak evidence that suggests dapsone may reduce the anti-inflammatory effects of clofazimine; clinical significance is unclear.
- **Methotrexate**: May increase risk for hematologic reactions occurring with dapsone
- **Probenecid**: May decrease the renal excretion of active metabolites of dapsone
- **Pyrimethamine**: May increase risk for hematologic reactions occurring with dapsone
- **Rifampin**: May decrease plasma dapsone concentrations (7- to 10-fold)
- **Trimethoprim**: May increase plasma concentrations of both drugs and potentially increase each other's toxicity
- **Warfarin**: May increase anticoagulant effects

Laboratory Considerations

- No specific laboratory interactions or considerations are noted.

Dosages

DOGS:

Immunomodulatory agent for cutaneous conditions (eg, **cutaneous vasculitis;** extra-label): 1 – 1.1 mg/kg PO every 8 hours initially.[3,4] May be used in combination with other immunomodulating drugs (eg, prednis(ol)one). Once remission occurs, taper to lowest effective dose frequency (eg, once daily). Evidence is relatively weak to support the use of dapsone in this situation.

Adjunctive treatment of brown recluse spider (*Loxosceles* spp) bite (extra-label): 1 mg/kg PO 3 times daily for 10 to 14 days[1,2]

HORSES:

***Pneumocystis carinii* pneumonia in foals** (extra-label): 3 mg/kg PO every 24 hours. **NOTE**: This dosage is from one case report of a foal treated for 56 days.[5]

Monitoring

- Baseline and periodic CBC with platelets: every 2 to 3 weeks during first 4 months of treatment and then every 3 to 4 months
- Baseline and periodic serum liver chemistry profile during treatment
- Adverse effects (eg, vomiting, diarrhea, cutaneous drug eruptions, neurotoxicity)
- Efficacy based on improvement of clinical condition

Client Information

- Clients should understand that limited experience has occurred with dapsone in animals; serious toxicity is possible.
- Because photosensitivity can occur, exposed skin should be protected from prolonged exposure to sunlight.

Chemistry/Synonyms

A sulfone antimycobacterial/antiprotozoan, dapsone occurs as a white or creamy-white odorless crystalline powder. It is very slightly soluble in water, freely soluble in alcohol, and insoluble in fixed or vegetable oils.

Dapsone may also be known as DADPS, dapsonum, DDS, diaminodiphenylsulfone, NSC-6091, diaphenylsulfone, disulone, sulfonyldianiline, *Avlosulfone®*, *Daps®*, *Dapsoderm-X®*, *Dopsan®*, *Novasulfone®*, *Servidapsone®*, and *Sulfona®*.

Storage/Stability

Dapsone tablets should be stored protected from light at controlled room temperature between 20°C and 25°C (68°F-77°F).

Compatibility/Compounding Considerations

Dapsone tablets may be compounded into a stable liquid dosage form. The simplest method is to use a 1:1 ratio of *Ora-Plus®*:*Ora-Sweet®* and use crushed tablets to make a concentration of 2 mg/mL. This preparation is stable either stored refrigerated or at room temperature for 90 days.[11]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dapsone Oral Tablets: 25 mg and 100 mg (scored); generic; (Rx)

Gel formulations for topical application are also available.

Darbepoetin Alfa

(***dar***-beh-***poe***-eh-tin ***al***-fah) *Aranesp®*

Erythropoiesis-stimulating Agent

Prescriber Highlights

- ► Biosynthetic erythropoietic agent potentially useful for treating anemia associated with chronic kidney disease in dogs and cats
- ► May be less immunogenic in dogs and cats than epoetin alfa (epoetin)
- ► Longer duration of effect as compared with epoetin; initially only dosed once per week
- ► Considerably more expensive than epoetin, and treatment expense may be formidable

Uses/Indications

Darbepoetin is used to treat normocytic, normochromic non-regenerative anemia associated with chronic kidney disease (CKD) in dogs and cats. Chronic anemia has been shown to be a contributing factor in the progression of CKD and has been associated with conditions related to chronic hypoxia (eg, poor appetite, diminished overall health). It is recommended to initiate darbepoetin therapy in dogs and cats with CKD when clinical signs associated with anemia are present or when PCV is less than 20%.[1,2]

A retrospective study in dogs with CKD found that 85% of treated dogs attained packed cell volumes greater than or equal to 30%.[3] One group with experience of treating over 70 cats with epoetin or darbepoetin reported that only about 60% to 65% of treated cats had an adequate response.[4] Another study describing the use of blood products in dogs and cats was unable to demonstrate a reduction in blood transfusion due to erythropoiesis-stimulating agents.[5]

Darbepoetin has largely replaced the use of epoetin alfa (epoetin) due to a 3-fold longer half-life, allowing for less frequent dosing. Additionally, it may be less immunogenic than epoetin.[6,7]

Pharmacology/Actions

Darbepoetin is a hyperglycosylated synthetic human recombinant erythropoietin analogue. It stimulates erythropoiesis using the same mechanism as endogenous erythropoietin by interacting with progenitor stem cells to increase RBC production. Darbepoetin may be less immunogenic in animals than epoetin,[6,7] secondary to its formulation, which utilizes carbohydrates as part of its structure. Theoretically, carbohydrates may shield the sites on the drug of greatest antigenic potential from immune cell detection.

Carbohydrates also increase the solubility and stability of the compound, causing less aggregate formation and, therefore, potentially less immunogenicity. Additionally, despite a four-fold lower EPO receptor binding activity compared to epoetin, PK studies in dogs and mice show that darbepoetin is 13- to 14-fold more potent allowing for lower dosages.[8]

Pharmacokinetics

In dogs, IV darbepoetin has an elimination half-life of 25 hours, which is 3.5 times that of epoetin, and clearance is also correspondingly reduced.[8] No information has been noted for cats.

In humans with chronic kidney disease, bioavailability after subcutaneous injection is about 37%, and the drug is absorbed slowly with a distribution half-life of about 1.4 hours.[9] It is extensively metabolized, and the terminal elimination half-life averages 21 hours after IV administration and 70 hours following SC dosing.[9] Terminal half-life is approximately 3 times greater than that of epoetin, allowing for less frequent dosing.[8]

Contraindications/Precautions/Warnings

Darbepoetin should not be used in dogs or cats with documented anti-epoetin antibodies. Antibody formation diagnosis is based upon high myeloid:erythroid ratio on bone marrow cytology and exclusion of other causes of anemia. In humans, darbepoetin is contraindicated in patients hypersensitive to it or to excipients in the formulation, in those with uncontrolled hypertension, and in patients in whom pure red cell aplasia begins after treatments with erythropoietin or darbepoetin.[9]

Adequate iron stores are necessary for efficacy. Most clinicians prefer using injectable iron dextran rather than oral iron products for this purpose. Iron deficiency may be most relevant after initiation of darbepoetin treatment because of consumption of iron stores in the therapeutically induced regenerative response.[10]

In humans, darbepoetin use is associated with an increased risk of death, serious cardiovascular events (eg, myocardial infarction,

stroke, venous thrombosis), and progression of certain tumors[9]; the relevance of these findings for veterinary patients is uncertain. Using the lowest possible darbepoetin dose to avoid transfusion is recommended. Quality of life and patient well-being have not been demonstrated in humans.

Do not confuse darbepoetin with epoetin alfa or dalteparin.

Adverse Effects

Potential adverse effects include anti-epoetin antibody formation with resultant pure red blood cell aplasia (PRCA), injection site reactions, polycythemia, hypertension, seizures, or iron deficiency. A retrospective study conducted in 33 dogs with chronic kidney disease (CKD) found increased blood pressure (36%), seizures (15%), and vomiting and/or diarrhea (9%). Pure red cell aplasia developed in 2 (6%) treated dogs.[7]

Anecdotally, PRCA is reported to occur less often than with epoetin. One source states that the incidence of PRCA is about 25% to 30% in dogs and cats receiving epoetin and less than 10% with darbepoetin.[6] PRCA can be difficult to treat, but immediate discontinuation of epoetin or darbepoetin is required. Immunosuppressive therapy and blood transfusions can potentially help, but the long-term prognosis is often grave.

Hypertension is reported to occur in up to 50% of dogs and cats treated with darbepoetin. Hypertension may be a result of increased blood viscosity and cardiac output and decreased anemia-mediated vasodilation; it may also be a sequela to CKD in advanced stages. Seizures may occur in response to hypertension.

Reproductive/Nursing Safety

Due to its high molecular weight, darbepoetin is unlikely to cross the placenta or be distributed into milk.

Studies performed in pregnant rats and rabbits demonstrated no overt teratogenicity at daily doses of up to 20 µg/kg IV. However, increased early post-implantation loss was noted with doses of 0.5 mg/kg three times per week. Decreased body weights were noted in some rat pups.

It is unknown if darbepoetin is distributed into milk, but it is unlikely to pose much risk to nursing animals.

Overdose/Acute Toxicity

Little information is available. Humans have received therapeutic dosages of up to 8 µg/kg every week for 12 weeks. Polycythemia and severe hypertension have been reported in humans, and therapeutic phlebotomy may be required; veterinary significance is unclear.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving epoetin (a related compound) and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Androgens** (eg**, danazol, testosterone**): May increase the sensitivity of erythroid progenitors; this interaction has been used for therapeutic effect. **NOTE**: This effect has not been confirmed in well-controlled studies, nor has the safety of this combination been determined.
- **Cyclosporine:** May cause additive increases in blood pressure. Additionally, may alter cyclosporine blood levels, as cyclosporine is bound by red blood cells.
- **Probenecid**: Probenecid has been demonstrated to reduce the renal tubular excretion of EPO; clinical significance remains unclear.

Laboratory Considerations

- No specific lab issues have been identified; see ***Contraindications*** and ***Monitoring*** for more information.

Dosages

DOGS:

Stimulate erythropoiesis in anemia associated with CKD (extra-label): 0.5 – 0.8 µg/kg SC weekly (the higher dosage appears to be more effective).[7] Once the target PCV range is met, the dosing frequency can be extended to the longest interval, which maintains a stable maintenance target for PCV (eg, every 14 or every 21 days). A dosing interval greater than 21 days is unlikely to maintain an effective target PCV long-term.[7] Iron supplementation is recommended.[10] See ***Ferrous Sulfate*** or ***Iron Dextran***.

CATS:

Stimulate erythropoiesis in anemia associated with CKD (extra-label): 1 µg/kg SC once weekly.[11,12] Other recommendations have ranged from 0.25 – 1.5 µg/kg SC per week.[13-15] Once the target PCV range is met, the dosing frequency can be extended to the longest interval, which maintains a stable maintenance target for PCV (eg, every 14 or every 21 days). Iron supplementation is recommended. [6,12,13,16-18] ***See Ferrous Sulfate*** or ***Iron Dextran***.

Monitoring

- **PCV.** Check PCV prior to each dose of darbepoetin or at least until PCV is stable, and then once monthly.
  - A PCV greater than or equal to 30% or a greater than or equal to 10% change in PCV from baseline have been suggested as a positive response for dogs.[12]
  - PCV target goals vary; 25% to 35%[19] and 35% to 40%[14] have been suggested. Ideally, an increase in PCV of no more than 3% per week is suggested as greater increases may increase the risks for hypertension.
- Consider performing reticulocyte counts during the induction phase, but it has been reported that reticulocyte counts in cats receiving darbepoetin may not reflect efficacy.[4]
- Measure baseline and periodic serum ferritin concentrations or supplement with iron. See ***Ferrous Sulfate*** or ***Iron Dextran***.
- Baseline and periodic (every 1-2 months) blood pressure

Client Information

- Injectable (subcutaneous; under the skin) medicine used to treat anemia (too few red blood cells) caused by end-stage kidney failure. This medicine may take several weeks to work. Your veterinarian will need to closely monitor your animal while it is receiving this medicine. Do not miss these important follow-up visits.
- This medicine may cause your animal's immune system to interfere with how well this medicine works. Your veterinarian will monitor for this with blood tests during follow-up visits. At home, watch for skin reactions at the site of the shot.
- Contact your veterinarian immediately if your animal has seizures (convulsions), has loss of vision (bumping into furniture), appears unwell, has a low energy level, is unable to walk, or has a poor appetite.

Chemistry/Synonyms

Darbepoetin alfa is a 165 amino acid protein that is produced using recombinant DNA technology in Chinese hamster ovary cells. Two additional N-linked oligosaccharide chains are added to human erythropoietin, yielding a glycoprotein with a molecular weight of ≈37,000.

Darbepoetin may also be known by the following synonyms: NESP, novel erythropoiesis-stimulating protein, darbepoetina, or darbepoetinum. Internationally registered trade names include *Aranesp*® and *Nespo*®.

Storage/Stability
The commercially available injection solutions (polysorbate-based) should be stored in the refrigerator at 2 to 8°C (36°F-46°F) and protected from light. Do not freeze or shake.

Compatibility/Compounding Considerations
No specific information has been noted. Do not dilute or administer with other compounds.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 1 substance. It is also prohibited on the premises of a racing facility. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Darbepoetin Alfa Solution for Injection (preservative-free; albumin-free); *Aranesp*®; (Rx). The needle cover on prefilled syringes contains natural rubber.

10 µg in single-dose prefilled syringes (0.4 mL)

25 µg in single-dose prefilled syringes (0.42 mL) and single-dose vials (1 mL)

40 µg in single-dose prefilled syringes (0.4 mL) and single-dose vials (1 mL)

60 µg in single-dose prefilled syringes (0.3 mL) and single-dose vials (1 mL)

100 µg in single-dose prefilled syringes (0.5 mL) and single-dose vials (1 mL)

150 µg in single-dose prefilled syringes (0.3 mL)

200 µg in single-dose prefilled syringes (0.4 mL) and single-dose vials (1 mL)

300 µg in single-dose prefilled syringes (0.6 mL) and single-dose vials (1 mL)

500 µg in single-dose prefilled syringes (1 mL)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Decoquinate
(de-koe-***kwin***-ate) *Deccox*®

Antiprotozoal/Coccidiostat

Prescriber Highlights
- ► Not FDA-approved for dairy animals that produce milk for human consumption or laying chickens that produce eggs for human consumption
- ► Not effective against the sexual stage of coccidia development
- ► No effect on clinical coccidiosis; results in treating calves with cryptosporidiosis have been disappointing.

Uses/Indications
Decoquinate is labeled for the prevention of coccidiosis caused by certain pathogenic *Eimeria* spp in cattle (including ruminating and nonruminating calves and veal calves), young goats and sheep, and broiler chickens.

In dogs, decoquinate may be used as adjunctive treatment for hepatozoonosis.[1,2] Decoquinate is being investigated for the treatment of *Sarcocystis neurona* in horses[3] and myositis due to *Sarcocystis* spp in dogs.

Pharmacology/Actions
Decoquinate is a 4-hydroxy quinolone agent that has anticoccidial activity. Decoquinate acts on *Eimeria* spp sporozoites (released from ingested oocysts) and on first-generation meronts to arrest development through disruption of electron transport and respiration in coccidial mitochondria and thus, prevent release of merozoites. The sporozoites can apparently still penetrate the host intestinal cell, but further development is prevented.

Pharmacokinetics
Decoquinate is minimally absorbed from the GI tract of chickens and is primarily eliminated in the feces. The absorbed drug is widely distributed to tissues, in particular skin and adipose tissue. Elimination of absorbed drug is through bile and, to a much lesser extent, urine.

Contraindications/Precautions/Warnings
Decoquinate is not effective for treating clinical coccidiosis and has no efficacy against the sexual stage of coccidia development. Decoquinate is not FDA-approved for use in animals producing milk for human consumption or in laying chickens.

Adverse Effects
No adverse effects listed when given as directed.

Reproductive/Nursing Safety
Decoquinate did not impair fertility in laboratory animals, but embryotoxicity was noted.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity
Decoquinate is considered to have a wide safety margin. Rats receiving single doses up to 5000 mg/kg orally developed no clinical signs of toxicity and had no noted postmortem pathological changes. Pneumonia developed in rats but not beagles receiving 1000 to 2000 mg/kg PO per day in studies lasting up to 2 years, with no other clinical or pathological changes noted.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions
- None noted

Laboratory Considerations
- None noted

Dosages
DOGS:

NOTE: When using decoquinate for dogs, obtain decoquinate 6% (27.2 g/lb) powder. An approximate conversion is ¼ teaspoonful is equivalent to ≈45 mg decoquinate, and 1 teaspoonful (5 mL) is equivalent to ≈180 mg decoquinate.

American canine hepatozoonosis (ACH; *Hepatozoon americanum*) (extra-label): **Initially**, administer a 14-day treatment with **either** ponazuril 10 mg/kg every 12 hours **OR** a triple combination (TCP) of trimethoprim/sulfadiazine 15 mg/kg PO every 12 hours, clindamycin 10 mg/kg PO every 8 hours, and pyrimethamine 0.25 mg/kg PO every 24 hours ***followed by*** 2 years of decoquinate 10 – 20 mg/kg PO twice daily mixed in food.[2] Although this treatment regimen is not curative, it extends life expectancy

and improves the quality of life for many ACH patients. Should clinical relapse occur, repeat TCP or ponazuril treatment again followed by long-term decoquinate.[4]

Canine sarcocystosis myositis (from a case report; 2 dogs) (extra-label)**:** From a case report of 2 dogs, decoquinate 10 – 20 mg/kg PO every 12 hours appeared to be effective in 1 dog. The dog also received clindamycin initially (discontinued after 3 months on decoquinate) and tramadol.[5]

CATTLE:

Prevention of coccidiosis in ruminating and nonruminating calves (including veal calves) and cattle caused by *Eimeria bovis* and *Eimeria zuernii* (label dosage; FDA-approved): 0.5 mg/kg PO once daily in milk or mixed in feed.[6] Administer for at least 28 days during periods of coccidiosis exposure or when experience indicates that coccidiosis is likely to be a hazard. Coccidiostats are not indicated for use in adult animals due to continuous previous exposure.

Treatment of coccidiosis in calves (extra-label): 1 mg/kg in feed PO daily for at least 28 days[7,8]

Cryptosporidium in calves (extra-label): 2 mg/kg PO twice daily for 21 days[9]

SHEEP/GOATS:

Prevention of coccidiosis in young sheep caused by *Eimeria ovinoidalis*, *Eimeria crandallis*, *Eimeria parva*, and *Eimeria bakuensis* (label dosage; FDA-approved): 0.5 mg/kg PO per day mixed in feed.[6] Feed for at least 28 days during periods of coccidiosis exposure or when experience indicates that coccidiosis is likely to be a hazard.

Prevention of coccidiosis in young goats caused by *Eimeria christenseni* and *Eimeria ninakohlyakimovae* (label dosage; FDA-approved): 0.5 mg/kg PO per day mixed in feed.[6] Feed for at least 28 days during periods of coccidiosis exposure or when experience indicates that coccidiosis is likely to be a hazard.

Prevention or treatment of coccidiosis in lambs (extra-label): Treatment: 1 mg/kg in feed PO daily for at least 28 days[7,10,11] ; Prevention: 0.5 mg/kg in feed PO daily for at least 28 days[11]

Aid in the prevention of abortions and perinatal losses caused by toxoplasmosis in ewes (extra-label)**:** 2 mg/kg daily in feed continuously for 14 weeks prior to lambing[7,10]

CAMELIDS:

Prophylaxis of coccidiosis in llamas (extra-label): 0.5 mg/kg daily in feed for at least 28 days[12]

CHICKENS:

Prevention of coccidiosis in broiler chickens caused by *Eimeria tenella, Eimeria necatrix, Eimeria acervulina, Eimeria mivati, Eimeria maxima*, and *Eimeria brunetti* (label dosage; FDA-approved): Thoroughly mix 0.45 kg (1 lb) in each ton of complete ration and feed continuously.[6]

Monitoring

- Efficacy
- Adverse effects

Client Information

- Decoquinate should be administered for at least 4 weeks when it is used for preventing coccidiosis outbreaks.
- When decoquinate is used in dogs for hepatozoonosis, treatment may need to continue for up to 2 years.
- Mix this medicine well into food or milk. When this medicine is mixed into milk, prepare fresh each day, and feed immediately after mixing. Discard unused portions. Not for use in bulk feeding systems.
- Do not feed this medicine to cows, sheep, or goats that produce milk for human consumption, or to laying hens that produce eggs for human consumption.

Chemistry/Synonyms

A coccidiostat, decoquinate occurs as a cream to buff-colored fine amorphous powder with a slight odor. It is insoluble in water and practically insoluble in alcohol.

Decoquinate may also be known as HC-1528, M&B-15497, or *Deccox®*.

Storage/Stability

Follow label storage directions; store in a cool, dry place, preferably in airtight containers.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Decoquinate is reportedly **incompatible** with strong bases or oxidizing material and is **incompatible** with feeds containing bentonite binders. *Deccox®* is labeled as being **compatible** (and cleared for use) with bacitracin zinc (with or without roxarsone), chlortetracycline, and lincomycin.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Decoquinate 6% (27.2 g/lb) Type A Medicated Article (with corn meal, soybean oil, lecithin, and silicon dioxide) in 22.7-kg (50-lb) bags; *Deccox®*; (OTC). FDA-approved for use in cattle, sheep, goats (**DO NOT** feed to cows, goats, or sheep that produce milk for food), and chickens (NOT laying chickens).

Decoquinate 0.5% (2.271 g/lb) Type B Medicated Feed in 22.7-kg (50-lb) bags; *Deccox®-L*; (OTC). FDA-approved for use in ruminating and nonruminating calves and cattle. **DO NOT** feed to cows that produce milk for food.

Decoquinate 0.8% (3.632 g/lb) Medicated Powder for Whole Milk in 2.3-kg (5-lb) and 22.7-kg (50-lb) bags; *Deccox®M*; (OTC). FDA-approved for use in ruminating and nonruminating calves, including veal calves.

Decoquinate (6.8 mg/lb) Medicated Milk Replacer in 22.7-kg (50-lb) bags; *Land O Lakes® Does's Match® Kid Milk Replacer DC Medicated*; (OTC). FDA-approved for use in young goats. **DO NOT** feed to goats that produce milk for food.

Decoquinate (18.15 mg/lb) Type C Medicated Milk Replacer in 11.3-kg (25-lb) and 22.7-kg (50-lb) bags; *Sav-A-Caf® Performance AM DX Calf Milk Replacer Medicated*; (OTC). FDA-approved for use in calves.

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Deferoxamine

(de-fer-***ox***-a-meen) *Desferal®*

Chelating Agent

Prescriber Highlights

- ► Used primarily for parenteral treatment of iron intoxication in dogs and cats
- ► Contraindications include severe chronic kidney disease and anuria, unless used with dialysis.
- ► Use with caution in pregnant and pediatric patients
- ► Adverse effects include allergic reactions, auditory neurotoxicity, pain or swelling at injection sites, and GI distress. Urine may turn reddish-brown.
- ► When used IV, must be given slowly

Uses/Indications

Deferoxamine (DFO) is primarily used for the treatment of acute or chronic iron toxicity.[1] This drug has been evaluated as an iron chelator for adjunctive treatment of acute cardiac ischemia, intracerebral hemorrhage, and as a chelator for aluminum and thallium toxicity.[2–5] Its efficacy in treating reperfusion injuries is disappointing. Additional experimental uses include topical preparations to accelerate wound healing in diabetic rodent models, and local injection to promote angiogenesis and bone formation.[6,7]

Pharmacology/Actions

Deferoxamine (DFO) binds ferric (Fe^{+++}) ions to its 3 hydroxamic groups and forms ferrioxamine, a stable, water-soluble compound that is readily excreted by the kidneys. Approximately 100 mg of DFO will bind 8.5 mg of elemental iron.[8] DFO will not combine with iron already bound to transferrin or hemoglobin but will chelate iron bound to hemosiderin and ferritin.[8] Except aluminum and thallium, DFO does not appear to chelate other trace metals or electrolytes in clinically significant quantities.

Pharmacokinetics

Deferoxamine (DFO) is poorly absorbed from the GI tract and is usually given parenterally. The drug is widely distributed in the body. DFO and ferrioxamine (the chelated compound) are excreted primarily in the urine.

Contraindications/Precautions/Warnings

Deferoxamine (DFO) is contraindicated in patients with severe kidney injury or anuria unless dialysis is used to remove ferrioxamine (the chelated compound). Growth retardation has been associated with use of high doses and the drug should be used with caution in pediatric patients.

Due to increased susceptibility from iron overload, patients infected with *Yersinia enterocolitica* or *Yersinia pseudotuberculosis* should not be treated with DFO. Rare cases in humans have occurred wherein DFO acts as an iron transporter for these organisms, enhancing the susceptibility to infection.[8]

Oral administration of DFO after oral iron ingestions may actually increase the amount of iron absorbed from the gut and use by this route is not recommended.

Fungal infections with mucormycosis have occurred in humans, some fatal; DFO use should be stopped and evaluation of infection should occur if clinical signs are present.[8]

Adverse Effects

Veterinary experience with deferoxamine (DFO) is limited. Potential adverse effects include allergic reactions, auditory neurotoxicity (particularly with long-term, high-dose therapy), changes in visual acuity, renal dysfunction, pain or swelling at injection sites, and GI distress. Respiratory distress syndrome has been reported in humans that have received deferoxamine in very high doses. Rapid IV injection may cause tachycardia, convulsions, hypotension, hives, and wheezing. Ferrioxamine (the chelated compound) will give the urine a reddish-brown color ("vin rosé"), which is innocuous and indicates iron removal.

Reproductive/Nursing Safety

Deferoxamine (DFO) has caused skeletal abnormalities in animals at dosages above those recommended for iron toxicity. It is unknown if deferoxamine enters into milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

See ***Adverse Effects***. Long-term, high-dose use of deferoxamine (DFO) may also lead to hypocalcemia and thrombocytopenia.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving DFO and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Prochlorperazine**: Use with deferoxamine (DFO) may cause temporary impairment of consciousness.
- **Vitamin C**: May be synergistic with DFO in removing iron, and vitamin C deficiency is common in humans with iron overload. However, concurrent use could lead to increased tissue iron toxicity, especially in cardiac muscle; it should be used with caution, particularly in patients with preexisting cardiac disease.

Laboratory Considerations

- Deferoxamine (DFO) may interfere with colorimetric **iron** assays resulting in falsely low values.
- DFO may falsely elevate total iron binding capacity (**TIBC**) measurements.[9]

Dosages

DOGS & CATS:

Animals at risk for or exhibiting signs of severe iron toxicosis (extra-label): Infuse slowly up to 15 mg/kg/hour IV.[10] Initiate therapy as soon as able, within 12 to 24 hours of ingestion, prior to iron distribution to tissues. More rapid infusion may precipitate arrhythmias or aggravate hypotension, although this dosage has been safely exceeded in critical situations. If IV infusion is unfeasible or unable to monitor patient during infusion, give 40 mg/kg IM every 4 to 8 hours, depending on clinical status. Continue therapy until serum iron levels are below 300 µg/dL and the animal is stable. Some clinicians advise continuing chelation until the urine is clear, but there is little evidence for this.[9] Ideally, limit duration of dosing to 24 hours to maximize effectiveness and minimize adverse pulmonary effects.[9] Following recovery, monitor for signs of GI stricture, which may develop 4 to 6 weeks post-ingestion.

Experimentally, as a ferric ion chelator during treatment of cardiac arrest (extra-label):

a) 5 – 15 mg/kg IV, IM, or SC once[11]
b) 10 mg/kg IV or IM every 2 hours for 2 doses, then 3 times daily for 24 hours[12]

HORSES:

To reduce iron overload after packed red blood cell transfusion

in foals (extra-label): 1 g/foal (NOT mg/kg) diluted to 5 mL and administered SC twice daily for 14 days beginning immediately before transfusion. Results suggest that deferoxamine (DFO) increases urinary iron elimination after blood transfusion and may help prevent hepatotoxic iron overload. Additional studies need to evaluate the effects of DFO on iron elimination in foals with neonatal isoerythrolysis that require multiple transfusions.[13]

Monitoring

- Serum ferritin
- Serum iron
- TIBC no longer recommended in cases of iron poisoning[9]
- Kidney function tests (due to renal excretion, measure prior to dosing or serially in animals with renal disease)
- Serum aluminum if used for aluminum chelation
- Treatment is continued until serum iron concentration decreases below 300 µg/dL and the patient is stable.
- If chronic iron overload: eye examinations (iron intoxication and its subsequent removal may adversely affect vision)
- If used in conjunction with vitamin C, monitor cardiac function.

Client Information

- Deferoxamine (DFO) should only be used in an inpatient setting.
- Given the potential toxicity of DFO and the seriousness of most iron intoxications, this drug should be used with close professional supervision only.
- DFO often turns the urine a reddish-brown ("vin rosé") color, which occurs due to urinary iron excretion.

Chemistry/Synonyms

An iron-chelating agent, deferoxamine (DFO) is a white to off-white powder that is freely soluble in alcohol or water.

Deferoxamine may also be known as desferoxamine mesylate, DFO, Ba-33112, Ba-29837, deferoxamini mesilas, desferrioxamine mesylate, desferrioxamine methanesulphonate, NSC-527604, *Desferal*® or *Desferin*®.

Storage/Stability

Reconstituted product further diluted in compatible solution may be stored up to 24 hours at room temperature when protected from light. Do not refrigerate reconstituted product.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Use sterile water for injection to reconstitute product. Deferoxamine should not be mixed with other drugs. Do not use if solution is turbid. Further dilution in normal saline, lactated Ringer's, or dextrose 5% has been recommended when administering as an IV infusion.

After aseptic reconstitution with sterile water for injection use product immediately.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Deferoxamine Mesylate Powder for Injection (lyophilized): 500 mg and 2 g in vials; *Desferal*®, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Deracoxib

(***dare***-a-***cox***-ib) *Deramaxx*®

Nonsteroidal Anti-Inflammatory Drug (NSAID) COX-2 Selective

Prescriber Highlights

- ► FDA-approved for use in dogs for treatment of postoperative pain associated with orthopedic (higher dose, 7 days maximum) and dental surgery (lower dose for 3 days) and treatment for pain and inflammation associated with osteoarthritis (lower dose, ongoing administration).
- ► May be a useful alternative to piroxicam in adjunctive treatment for transitional cell carcinoma of bladder
- ► Appears to cause predominantly COX-2 inhibition at therapeutic doses
- ► Adverse GI and renal effects are possible.
- ► Not for use in cats

Uses/Indications

Deracoxib is indicated in dogs for the treatment of postoperative pain associated with orthopedic (higher dose, 7 days maximum) and dental (lower dose for 3 days) surgery, and treatment for pain and inflammation associated with osteoarthritis (lower dose, ongoing dosing).

Like piroxicam, deracoxib may be used as adjunctive treatment for transitional cell carcinoma of the bladder.[1] The drug has also shown promise in the treatment of canine splenic hemangiosarcoma.[2,3]

Pharmacology/Actions

Deracoxib is a coxib-class NSAID. It is believed to predominantly inhibit cyclooxygenase-2 (COX-2) and spare COX-1 at therapeutic doses in dogs; this selectivity is lost at higher doses. This action would theoretically inhibit production of the prostaglandins that contribute to pain and inflammation (COX-2) and spare those that maintain normal GI and renal function (COX-1).[4,5] However, COX-1 and COX-2 inhibition studies are done in vitro and do not necessarily correlate perfectly with clinical effects seen in vivo.

Deracoxib's effect on platelet function in dogs is not entirely understood. In one study, healthy dogs given 2 mg/kg PO once daily for 7 days had a decrease in platelet aggregation induced by 50 microM ADP, but deracoxib did not affect results of other platelet function tests; the clinical significance of this finding is not known.[6] Another study concluded that all COX-2 selective NSAIDs evaluated (eg, meloxicam, deracoxib, carprofen) caused significantly prolonged Platelet Function Assay (PFA-100) closure times as measured using collagen plus ADP cartridges, suggesting NSAID-induced alterations in platelet function.[7]

Pharmacokinetics

After oral administration in dogs, bioavailability is greater than 90%; the time to peak serum concentration occurs at ≈2 hours. The presence of food in the gut can enhance bioavailability. The drug has an apparent volume of distribution of 1.5 L/kg in dogs and is at least 90% bound to canine plasma proteins. Deracoxib is metabolized in the liver to 4 primary metabolites. These metabolites, along with unchanged drug, are principally eliminated in the feces. Some excretion of metabolites occurs via renal mechanisms. Terminal elimination half-life in dogs is based on dose. At doses up to ≈8 mg/kg, half-life is ≈3 hours (clearance, ≈5 mL/minute/kg). Half-life at a dose of 20 mg/kg is ≈19 hours (clearance, ≈1.7 mL/minute/kg). Serum half-life is not necessarily a good predictor of duration of effect due to the complex relationship between pharmacokinetics and pharmacodynamics with NSAIDs.

In cats, peak concentrations (0.28 µg/mL) occurred ≈3.6 hours after oral administration. Elimination half-life was ≈8 hours.[8]

In horses, deracoxib has a long half-life of ≈13 hours. Based on dosage simulations and plasma concentrations, authors in a study suggested that dosages of 2 mg/kg PO every 12 to 24 hours be further studied for safety and efficacy.[9]

Contraindications/Precautions/Warnings

Deracoxib is contraindicated in patients known to be hypersensitive to it or other NSAIDs; cross-sensitivity with sulfonamides is possible. This drug should be used with caution in patients with concurrent GI ulcerative diseases; with cardiovascular, renal, or hepatic dysfunction; are dehydrated, hypovolemic, or hypotensive; or are on concomitant diuretic therapy.

The product's label states that it cannot be accurately dosed in dogs weighing less than 5.7 kg (12.5 lb); safe use in dogs younger than 4 months of age has not been established.[10]

Deracoxib is not approved or recommended for use in cats.

Adverse Effects

Deracoxib appears to be well tolerated in the majority of dogs treated, particularly when given as labeled and not in conjunction with other NSAIDs or corticosteroids. However, like other NSAIDs, many adverse effects associated with deracoxib have been reported, including GI (eg, vomiting, anorexia, weight loss, diarrhea, melena, hematemesis, hematochezia, GI ulceration, perforation), urinary (eg, azotemia, polydipsia, polyuria, UTI, hematuria, incontinence, chronic kidney disease), hematologic (eg, anemia, thrombocytopenia), hepatic (eg, increased hepatic enzymes, changes in total protein), neurologic (eg, lethargy, weakness, seizures), cardiovascular/respiratory (eg, tachypnea, bradycardia, cough), and dermatologic/immunologic (eg, fever, facial/muzzle edema, urticaria, dermatitis).

Reproductive/Nursing Safety

There is no information on deracoxib's safety during pregnancy or lactation. Until information is available, this drug cannot be recommended in these animals.

Overdose/Acute Toxicity

This medication is an NSAID. As with any NSAID, overdose can lead to GI and renal effects. Decontamination with emetics and/or activated charcoal is appropriate. For doses in which GI effects are expected, the use of GI protectants is warranted.

There is little data available regarding deracoxib's acute toxicity. A 14-day study in dogs demonstrated no clinically observable adverse effects in dogs that received 10 mg/kg PO. Dogs that received 25 mg/kg, 50 mg/kg, or 100 mg/kg PO per day for up to 14 days survived but showed weight loss, vomiting, and melena; gross GI lesions were noted, but no hepatic or renal lesions were demonstrated.[11] A dose of 16.92 mg/kg PO once daily for 7 days resulted in decreased appetite, diarrhea, increased water intake, and vomiting.[12]

In safety studies performed by the manufacturer,[13] oral deracoxib was well tolerated by dogs when administered for up to 6 months at a variety of doses. Some dogs receiving greater than 6 mg/kg/day (1.5 to 5 times the recommended dose) showed signs of focal renal tubular degeneration/regeneration on histopathology that were dose-dependent. Focal tubular necrosis was seen in 1 out of 10 dogs given 8 mg/kg/day and in 3 out of 10 dogs given 10 mg/kg/day. Clinical pathology findings associated with these lesions included elevated BUN and hyposthenuria.

Common clinical signs include vomiting, diarrhea, lethargy, and elevated creatinine.

In otherwise healthy dogs, the ASPCA APCC recommends GI protectants if deracoxib 15 mg/kg or greater has been ingested; IV fluid diuresis should also be given when ingestions are 30 mg/kg or more.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged that a 24-hour poison consultation center that specializes in providing information specific for veterinary patients be consulted. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving coxib-class NSAIDs and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **benazepril, enalapril**): NSAIDs can reduce effects on blood pressure. Because ACE inhibitors can potentially reduce renal blood flow, use with NSAIDs could increase the risk for renal injury.
- **Angiotensin Receptor Blockers** (**ARBs**; eg, **irbesartan, telmisartan**): NSAIDs can reduce effects on blood pressure. Because ARBs can potentially reduce renal blood flow, use with NSAIDs could increase the risk for renal injury.
- **Aspirin**: May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea)
- **Beta-Adrenergic Blockers** (eg, **atenolol, propranolol**): Concurrent use may result in increased blood pressure.
- **Corticosteroids** (eg, **prednis(ol)one**): May increase the risk for GI toxicity (eg, ulceration, GI perforation, bleeding, vomiting, diarrhea). It is not recommended to use corticosteroids in conjunction with an NSAID.
- **Digoxin**: NSAIDs may increase serum levels.
- **Diuretics** (eg, **furosemide**): Increased risk for deracoxib adverse effects[10]
- **Fluconazole**: Administration has increased plasma levels of celecoxib in humans and could also affect deracoxib levels in dogs.
- **Fluoroquinolones** (eg, **enrofloxacin, marbofloxacin**): Concurrent use may result in an increased risk for seizures.
- **Furosemide**: NSAIDs may reduce saluretic and diuretic effects.
- **Methotrexate**: Serious toxicity has occurred when NSAIDs have been used concomitantly with methotrexate; use together with extreme caution.
- **Nephrotoxic Drugs** (eg, **aminoglycosides**, **amphotericin B**): May enhance the risk for nephrotoxicity development
- **NSAIDs, Other** (eg, **carprofen**): May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea). Multiple NSAIDs should not be administered concurrently.
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine**): Concurrent use may increase risk for bleeding.
- **Tramadol:** May increase the risk for GI toxicity (from a case report[14])
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Concurrent use may result in an increased risk for bleeding.

Laboratory Considerations

- No specific laboratory interactions were noted. Deracoxib does not appear to affect thyroid function tests in dogs.

Dosages

DOGS:

NOTE: Manufacturer recommends using the lowest effective dose for the shortest duration possible.

Control of pain and inflammation associated with osteoarthritis (label dosage; FDA-approved): 1 – 2 mg/kg PO once daily as needed[10]

Control of postoperative pain and inflammation associated

with dental surgery (label dosage; FDA-approved): 1 – 2 mg/kg PO once daily for 3 days[10]

Control of postoperative pain and inflammation associated with orthopedic surgery (label dosage; FDA-approved): 3 – 4 mg/kg PO once daily as needed, not to exceed 7 days[10]

Monitoring
- Clinical efficacy
- Adverse effects
- Baseline and periodic physical examination
- Baseline and periodic: CBC, serum chemistry profile (including BUN, creatinine, liver enzymes), urinalysis

Client Information
NOTE: The manufacturer provides a client handout sheet that is recommend to be given each time the drug is dispensed.
- Deracoxib is an NSAID used in dogs for pain and inflammation associated with orthopedic and dental surgery. This medication can be given with or without food, but food may reduce the chances for stomach problems. If your dog vomits or acts sick after receiving this medication on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian. Fresh water should always be available.
- Most dogs tolerate deracoxib well, but some dogs rarely develop stomach ulcers or serious kidney and liver problems. Stop giving this medicine and contact your veterinarian immediately if your animal has decreased appetite (ie, eating less than normal), persistent vomiting, diarrhea, changes in behavior or activity levels (ie, more or less active than normal), changes in drinking and urinating habits (ie, frequency, amount consumed), or yellowing of gums, skin, or whites of the eyes (ie, jaundice).
- Store chewable tablets well out of reach of animals and children.
- Keep water readily accessible during treatment and avoid dehydration.
- Periodic laboratory tests are needed to check for liver and kidney side effects. Do not miss these important follow-up visits.
- Other medicines for pain or inflammation should not be used with this medication without the approval of your veterinarian.
- Do not increase or alter the dose without approval from your veterinarian.

Chemistry/Synonyms
Deracoxib is a diaryl-substituted pyrazole that is chemically related to other coxib-class NSAIDs (eg, celecoxib). Its molecular weight is 397.38.

Storage/Stability
The commercially available chewable tablets for dogs should be stored at room temperature between 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:
Deracoxib Chewable (scored) Tablets: 12 mg, 25 mg, 75 mg, and 100 mg; *Deramaxx*®[10]; generic; (Rx). FDA-approved for use in dogs; NADA # 141-203

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS: NONE

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Desflurane
(dez-***floor***-ane) *Suprane*®
Inhalant Anesthetic

Prescriber Highlights
- ► Inhaled general anesthetic
- ► Primary benefit is when very rapid recoveries are desired
- ► Contraindications include hypersensitivity to desflurane and history of malignant hyperthermia.
- ► Adverse effects include dose-dependent hypotension and respiratory depression.
- ► Requires desflurane-specific vaporizer (electric, heated, pressurized, expensive)

Uses/Indications
Desflurane is a volatile anesthetic that may be of particular use when rapid recoveries are desired.[1] Desflurane has a very high vapor pressure that necessitates the use of an electric, heated, pressurized vaporizer, which can be cumbersome and expensive.

Pharmacology/Actions
Desflurane is a halogenated inhalant anesthetic. It is structurally related to isoflurane, with a fluorine atom substituted for chlorine at the alpha-ethyl carbon. Although the precise mechanism by which inhalant anesthetics exert their general anesthetic effect is not precisely known, inhalant anesthetics may interfere with functioning of nerve cells in the brain by acting at $GABA_A$-R and voltage-gated channels.[2] Desflurane has a very low blood:gas solubility ratio of 0.42 (at 37°C [98.6°F]).

Some of the key pharmacologic effects noted with desflurane include rapid inductions and recoveries[3]; rapid recoveries may be a benefit, but they could also be detrimental, particularly if perioperative analgesics are not used. Desflurane is relatively resistant to biodegradation that may minimize risk for nephrotoxicity.

Pharmacokinetics
Onset of action is very rapid after inhalation; some have described it as "one breath" induction. At body temperature (37°C [98.6°F]), desflurane has a blood/gas coefficient (predicts rate of facemask induction and recovery) of 0.42, an oil/gas coefficient of ≈19, and a brain/blood coefficient of 1.3.

Very little of desflurane is eliminated via hepatic routes, as only 0.02% is recovered as metabolites. In humans, elimination half-life is 2.5 minutes (isoflurane about 9.5 minutes).

Contraindications/Precautions/Warnings
Desflurane is contraindicated in patients that are hypersensitive to it or other halogenated agents, or in those that have a history or predilection towards malignant hyperthermia. It should be used with caution (benefits versus risks) in patients with increased CSF pressure or head injury.

Because of desflurane's rapid action, use caution not to overdose during the induction phase. Because of the rapid recovery associated with desflurane, use caution (and appropriate analgesia and sedation during the recovery phase), particularly with large animals.

Geriatric or critically ill animals may require less inhalation anesthetic.

The National Institute for Occupational Safety and Health (NIOSH) has recommended that no worker should be exposed at ceiling concentrations greater than 2 ppm of any halogenated anesthetic agent over a sampling period not to exceed 1 hour.

Desflurane should only be used in situations in which sufficient

monitoring and patient-support capabilities (eg, intubation, ventilation) are available.

Adverse Effects

Desflurane is usually very well tolerated. Hypotension and respiratory depression may occur and are considered dose dependent. Like all halogenated anesthetics, desflurane can cause malignant hyperthermia in susceptible individuals (usually humans or pigs). Desflurane may have a lower incidence rate of this effect than other halogenated anesthetics.

Like isoflurane and sevoflurane, desflurane does not potentiate catecholamine-induced arrhythmias, and like all the inhalant anesthetics, it decreases arterial blood pressure and depresses ventilation in a dose-dependent manner.

Desflurane is a respiratory irritant, has a pungent odor, and is not well suited for mask inductions. When used for mask inductions, desflurane can cause respiratory irritation and cause salivation in dogs and cats. Rapid changes in desflurane concentrations may result in a sympathetic response and can temporarily increase cardiac work.

Reproductive/Nursing Safety

Desflurane appears to be relatively safe to use during pregnancy, but data are limited. Because of its low blood solubility, desflurane may be one of the safest inhalant anesthetics for use during pregnancy. In rats and rabbits, no overt teratogenic effects were observed when exposed at 1 MAC-hour/day during organogenesis (10 to 13 days exposure).

The minimal alveolar concentration (MAC) of inhalation agents is 25% to 40% lower during pregnancy.[4]

Desflurane is likely compatible with nursing, as levels are low in milk and rapidly washout within 24 hours of use; however, safety during nursing has not been established.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In the event of an overdose, discontinue desflurane; maintain airway and support respiratory and cardiac function as necessary.

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving desflurane and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors or Other Hypotensive Agents**: Concomitant use may increase risks for hypotension. Enalapril caused significant decreases in systolic blood pressure in dogs and cats undergoing isoflurane anesthesia.[5] Similar effects may be expected with desflurane.
- **Acepromazine:** Can decrease minimal alveolar concentration (MAC)
- **Alpha-2 Agonists** (eg, **dexmedetomidine, xylazine**): Can decrease MAC[6]
- **Aminoglycosides:** Use with caution with halogenated anesthetic agents, as additive neuromuscular blockade may occur
- **Anesthetic Agents** (eg, **alfaxalone, ketamine, propofol**): Can decrease MAC
- **Benzodiazepines** (eg, **midazolam**): Can decrease MAC
- **Butorphanol**: Can cause hypotension and decreased ventilation in dogs when given with desflurane[7]
- **Non-Depolarizing Neuromuscular Blocking Agents** (eg, **atracurium**): Additive neuromuscular blockade may occur.
- **Opioids** (eg, **fentanyl**): Can decrease MAC
- **Sympathomimetics** (eg, **dopamine, epinephrine, norepinephrine**): Although desflurane sensitizes the myocardium to the effects of sympathomimetics less so than halothane, arrhythmias may still result. If these drugs are needed, they should be used with caution, and in significantly reduced dosages with intensive monitoring.
- **Succinylcholine**: With inhalation anesthetics, may induce increased incidences of cardiac effects (eg, bradycardia, arrhythmias, sinus arrest, apnea) and, in susceptible patients, malignant hyperthermia

Laboratory Considerations

- Like other halogenated anesthetics, desflurane can cause transient increases in **glucose** and white blood cell count.

Dosages

Approximate minimal alveolar concentration (MAC; %) in oxygen reported for desflurane: dogs = 7 – 10.3; cats = 9.8; horse = 7.23; rabbit = 8.9; alpacas/llamas = 7.8 – 8

General anesthesia (extra-label):

a) Clinically useful concentrations: Induction = 8 – 15%; Maintenance = 5 – 9%[8]
b) Approximate MAC for emergency patients: 6%[9]
c) Following IV induction: The author usually starts with a vaporizer setting of about 8% (around MAC in most animals), increasing the concentration as required.[10]

Monitoring

- Respiratory rate and ventilatory status (eg, $ETCO_2$, SpO_2)
- Heart rate, ECG, blood pressure
- Depth of anesthesia
- Body temperature

Client Information

- Desflurane is only used in an inpatient setting.

Chemistry/Synonyms

Desflurane has the chemical name (±)-2-Difluoromethyl 1,2,2,2-tetrafluoroethyl ether and has a molecular weight of 168. It is a clear, colorless, heavy liquid. It is nonflammable and nonexplosive. At 1 atmosphere, it has a boiling point of 22°C to 23°C (71.6°F-73.4°F), a vapor pressure of 669 mm Hg at 20°C (68°F), and specific gravity of 1.465 at 20°C (68°F). Desflurane is practically insoluble in water, but miscible with anhydrous alcohol.

Halogenated inhalation anesthetics are greenhouse gases. Vaporization of one bottle of desflurane has the same global warming potential as 886 kg of carbon dioxide.[11]

Desflurane may also be known as I-653, desfluraani, desflurano, or desfluranum. A common trade name is *Suprane*®.

Storage/Stability

Desflurane solution should be stored in its original container at 15°C to 30°C (59°F-86°F). Secure cap on bottle tightly after use. Protect this product from light.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Desflurane Solution for Inhalation Anesthesia in 240 mL bottles; *Suprane*®; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Deslorelin

(dess-***lor***-a-lin) *SucroMate®, Suprelorin® F*

Hormonal Agent

Prescriber Highlights

- ► Synthetic GnRH analogue indicated to induce ovulation in cyclic estrous mares. It is especially useful in artificial insemination and estrus synchronization programs.
- ► Deslorelin acetate implants are also prescribed for the management of adrenocortical disease in ferrets.
- ► Deslorelin acetate implants may be used to induce temporary infertility in intact male dogs.

Uses/Indications

Deslorelin is FDA-approved for inducing ovulation in cyclic estrous mares.[1] In the United States, the deslorelin acetate implant is not approved by the FDA, but legally marketed as an FDA-indexed product for use only in ferrets for the management of adrenocortical disease. Extra-label use of FDA-indexed products is prohibited in the United States.

Deslorelin has been used in an extra-label fashion for inducing ovulation in multiple animal species. Various implants are compounded or approved in countries other than the United States, and have been used for long-term, reversible contraception in a variety of animal species. Studies have investigated the use of deslorelin implants for prostatic disease in male dogs, incontinence in ovariectomized female dogs, suppression of egg laying in birds, aggressive behavior in various species, and in various bovine reproductive management protocols.

Pharmacology/Actions

Deslorelin is a potent GnRH analogue that causes the release of FSH and LH. When deslorelin is administered to cyclic estrous mares with a growing, preovulatory follicle at least 30 mm in diameter, the LH increase in the blood induces follicle maturation and ovulation within 48 hours. Deslorelin acetate implants induce an initial release of FSH and LH but the sustained, prolonged action will eventually downregulate GnRH receptors, a phenomenon that desensitizes and internalizes the GnRH receptors; this leads to a decline in ovarian and testicular function.[2]

Pharmacokinetics

In mares and cows, serum LH is elevated 15 minutes after deslorelin IM administration and peaks at ≈2 to 3 hours in cows and ≈8 hours in mares. In horses, after implantation of a 2.1 mg pellet, concentrations of LH and FSH peak ≈12 hours after implant and return to pretreatment levels ≈3 to 4 days after implantation. Oral dosing of 100 µg/kg to beagles showed no increase in LH or FSH.

Contraindications/Precautions/Warnings

The only label contraindication is to not use in animals with known hypersensitivity to deslorelin acetate.[1,3] Do not administer deslorelin suspension for injection by the IV route.

Implants are biocompatible and do not require removal; however, implants may be surgically removed to end treatment.

Pregnant women and women of childbearing age should exercise caution when handling this product; direct contact with skin should be avoided. The National Institute for Occupational Safety and Health (NIOSH) classifies other GnRH analogues as hazardous drugs; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure. Refer to the Occupational Safety and Health Association (OSHA) website for more information."

Adverse Effects

The injectable formulation of deslorelin can cause swelling at the site of injection, which generally subsides within 5 days. With the implants, minor local swelling, sensitivity to touch, and elevated skin temperature at the injection site may occur; these effects should resolve within 5 days of implantation.

Deslorelin use may result in a prolonged interovulatory period. To avoid this potential negative effect when using deslorelin acetate implants, the implant should be removed from mares and bitches as soon as ovulation is documented. Extra-label use of the 4.7 mg implant (not available in the United States) to prevent estrus in female dogs has demonstrated (rarely) adverse effects of follicular cysts, prolonged estrus, and pyometra, especially in older dogs.[4]

Reproductive/Nursing Safety

Deslorelin implants are not for use in ferrets intended for breeding.[3] The decline in ovarian and testicular function associated with deslorelin acetate is reversible in all species tested. A case study was reported of a female cat implanted with a 4.7 mg deslorelin implant (*Suprelorin-6®*, not available in the United States), that later delivered 4 healthy kittens but displayed no maternal care and did not adequately lactate.[5]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In the original tolerance study (8 mares treated with a single IM injection of deslorelin acetate at 10 times the recommended dose of 1.8 mg), one mare exhibited moderate tremors, hives, and elevated heart and respiratory rates 6 hours after injection.[6] If there is inadvertent administration of an additional implant, it can be removed on detection.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

- ■ No specific interactions were noted.

Laboratory Considerations

- ■ None were noted.

Dosages

DOGS:

NOTE: There are several deslorelin products licensed and approved for various species; see specific labels for more information.

Contraceptive in male dogs (extra-label): Using the 4.7 mg implant: Implant SC every 6 months.[7] Using the 9.4 mg implant: Implant SC every 12 months.[8] Place implant in loose skin between lower neck and lumbar area; avoid implanting into fat. Pregnant women should not administer the implant. **NOTE**: Extra-label use of the ferret implant product in dogs is prohibited in the United States.

HORSES:

Induction of ovulation within 48 hours in cyclic estrous mares with an ovarian follicle measuring at least 30 mm in diameter (label dosage; FDA-approved): 1.8 mg/mare (NOT mg/kg) IM; administer in the neck[1]

FERRETS:

Management of adrenal gland cortical disease in the male and female domestic ferret (label dosage; FDA-Indexed product): One 4.7 mg implant/ferret SC every 12 months.[3] Place implant in the back midway between the shoulder blades. See label for specific administration instructions.

Contraceptive in male ferrets (extra-label): One 9.4 mg implant/ferret SC up to every 4 years[8]

Monitoring
- Clinical efficacy is based on indication for use.
- In ferrets treated for adrenal gland disease, monitor for effectiveness by improvement of clinical signs.

Client Information
- This medicine is only given by a veterinarian.
- Swelling or inflammation can occur at injection site. Contact your veterinarian if this gets worse.
- Removal of the implant is not required unless it is necessary to stop treatment.

Chemistry/Synonyms
Deslorelin acetate is a synthetic gonadotropin-releasing hormone (GnRH, gonadorelin) analogue. It is a nonapeptide and has chemical modifications in the amino acid composition at positions 6 and 9/10.

Storage/Stability
Deslorelin implants or injectable suspension should be refrigerated (2°C-8°C [36°F-46°F]). Do not freeze deslorelin implants.

Compatibility/Compounding Considerations
No specific information was noted.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:

Deslorelin Suspension for Injection 1.8 mg/mL in 10 mL multi-dose vials; *SucroMate® Equine*; (Rx). FDA-approved for horses (not intended for food); NADA #141-319

Deslorelin Implants 4.7 mg; *Suprelorin-F®*; not approved by FDA, but legally marketed for use in ferrets only as an FDA Indexed Product under MIF 900-013. Extra-label use is prohibited. This product is not to be used in animals intended for use as food for humans or other animals.

Deslorelin 2.1 mg cylindrical implant with implanter; 5 per box *Ovuplant®*; (Rx). FDA-approved for ovulation induction in mares. Not for use in horses intended for food. This product is FDA-approved in the United States (per FDA Green Book), but it is not currently marketed in the United States.

Other deslorelin products may be licensed for animal use in other countries and compounded preparations may be available.

HUMAN-LABELED PRODUCTS: NONE

Desmopressin

(des-moe-***press***-in) *DDAVP®*

Synthetic Vasopressin (Antidiuretic Hormone) Analogue, Hemostatic Agent

Prescriber Highlights
- ► Used in the diagnosis and treatment of central diabetes insipidus in dogs, cats, and possibly horses, and type 1 von Willebrand disease in dogs
- ► Contraindications include hypersensitivity to desmopressin and those with type IIB, type III, or platelet-type (pseudo) von Willebrand disease.
- ► Use with caution in patients susceptible to thrombosis.
- ► Adverse effects include eye irritation after conjunctival administration; hypersensitivity possible
- ► Overdoses can cause fluid retention and life-threatening hyponatremia.
- ► Monitor serum sodium concentration closely at the onset of treatment.

Uses/Indications
Desmopressin is useful in the diagnosis and/or treatment of central diabetes insipidus in small animals.[1,2] It may be used perioperatively in dogs with type 1 von Willebrand disease.[3-6] Desmopressin may be useful as a surgical adjuvant perioperatively to reduce lymph node involvement and metastatic disease in canine[7] (not feline[8]) mammary carcinoma or other aggressive tumors,[9] although this is controversial.[10]

Desmopressin has demonstrated an antidiuretic response in horses.[11-14]

Pharmacology/Actions
Desmopressin is related structurally to arginine vasopressin, but it has more antidiuretic activity and less vasopressor properties on a per weight basis. Desmopressin causes a dose-dependent increase in water reabsorption by the collecting ducts in the kidneys, thereby increasing urine osmolality and decreasing net urine production. Therapeutic doses do not directly affect either urinary sodium or potassium excretion.

Desmopressin causes a dose-dependent increase in von Willebrand factor by releasing von Willebrand factor from endothelial cells and macrophages; it also increases plasma factor VIII and causes smaller increases in factor VIII-related antigen and ristocetin cofactor activities.[5,15,16]

Pharmacokinetics
Because desmopressin is destroyed in the GI tract, it is usually given parenterally or topically in the eye or nose. Oral tablets have been used in those dogs that cannot tolerate ophthalmic administration, but bioavailability is very low. In humans, intranasal administration is commonly used, although in veterinary medicine topical administration to the conjunctiva is preferred. The onset of antidiuretic action in dogs usually occurs within 1 hour of administration, peaks in 2 to 8 hours, and may persist for up to 24 hours. Distribution characteristics of desmopressin are not well described. The metabolic fate is also not well understood. Terminal half-life in humans after IV administration is 3 hours but increased to 9 hours in a patient with severe renal impairment.[17]

Contraindications/Precautions/Warnings
Desmopressin is contraindicated in patients hypersensitive to it. In humans, it is contraindicated in patients with moderate to severe renal impairment and in patients with hyponatremia or a history of hyponatremia. Desmopressin should be used with caution in patients susceptible to thrombotic events.

Desmopressin is ineffective in the treatment of nephrogenic diabetes insipidus; it is strongly encouraged to consult with a veterinary endocrinologist or endocrinology textbook when using this drug for treatment of diabetes insipidus. Administration of desmopressin may cause sudden drops in serum sodium concentrations due to water retention, and close monitoring of serum sodium concentrations is required. Institute fluid restriction and/or reduce desmopressin dosage if fluid retention or signs of hyponatremia occur.

Desmopressin should not be used for treatment of type IIB von Willebrand disease (vWD) as platelet aggregation and thrombocytopenia may occur, or for type III vWD due to a lack of therapeutic effect. When desmopressin is used with repeated administration to stimulate von Willebrand factor, tachyphylaxis (progressive lack of efficacy) will occur to a variable extent within 24 hours.

Adverse Effects

Adverse effects in small animals are uncommon. Occasionally eye irritation may occur after conjunctival administration. Sodium decreases of more than 0.5 mEq/hour may result in neurologic signs (eg, nausea, vomiting, obtundation, seizures, coma).

Hypersensitivity reactions are possible. Humans using the drug have complained about increased headache frequency. Rarely, increased blood pressure may occur, and thrombotic events have been reported in humans predisposed to thrombus formation[17]; veterinary significance is unknown.

Reproductive/Nursing Safety

Safe use during pregnancy has not been established; however, doses up to 10 µg/kg/day have been given to rats and rabbits without demonstration of fetal harm.[17]

Desmopressin is likely safe to use during nursing; however, because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral dosages of 0.2 mg/kg/day have been administered to dogs for 6 months without any significant drug-related toxicity reported. Dosages that are too high may lead to fluid retention and hyponatremia; dosage reduction and fluid restriction may be employed to treat. Adequate monitoring should be performed.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving desmopressin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Carbamazepine:** May decrease the antidiuretic response. May increase risk for hyponatremia
- **Chlorpromazine:** May increase risk of hyponatremia
- **Corticosteroids** (eg, **dexamethasone, fludrocortisone, predniso(lo)ne**): May increase risk of hyponatremia
- **Heparin**: May decrease the antidiuretic response
- **Loop Diuretics** (eg, **bumetanide, furosemide, torsemide**): May increase risk for hyponatremia
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, flunixin, meloxicam**): May increase risk for hyponatremia
- **Opioids** (eg, **buprenorphine, morphine**): May increase risk for hyponatremia
- **Oxybutynin:** Seizures have occurred with concurrent use in humans
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine**): May increase risk for hyponatremia
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): May increase risk for hyponatremia
- **Vasopressor Agents** (eg, **dobutamine**, **norepinephrine**): Increased risk for hypertension

Laboratory Considerations

- See ***Monitoring***

Dosages

NOTE: Dosages listed below that are administered by SC, IV, or ophthalmic routes use the 0.1 mg/mL (0.01%) nasal solution product.

DOGS:

Treatment of confirmed central diabetes insipidus (extra-label):

a) Using 0.1 mg/mL (0.01%) human intranasal desmopressin product:
   i. Initially, 1 drop/dog (NOT drops/kg or drops/eye) is placed into the conjunctival sac once to twice daily.[18,19] 1 – 2 drops/dog (NOT drops/kg or drops/eye) administered once or twice daily controls clinical signs in most dogs,[20] but up to 4 drops/dog (NOT drops/kg or drops/eye) per dose may be required.[21]
   ii. 0.1 – 0.2 µg/kg SC once or twice daily.[19]

b) Using oral formulations based on body weight: Evaluate response after 7 days. May increase dosing interval to every 8 hours if clinical signs remain uncontrolled.[1]
   i. Less than 5 kg: 0.05 mg/dog (NOT mg/kg) PO every 12 hours
   ii. 5 to 20 kg: 0.1 mg/dog (NOT mg/kg) PO every 12 hours
   iii. More than 20 kg: 0.2 mg/dog (NOT mg/kg) PO every 12 hours

Differentiate central vs nephrogenic diabetes insipidus (extra-label): ½ to 1 tablet (0.1 or 0.2 mg *DDAVP*® tablet)/dog PO every 8 hours OR, using 0.1 mg/mL (0.01%) human intranasal desmopressin product, 1 – 4 drops/dog (NOT drops/kg or drops/eye) into the conjunctival sac every 12 hours for 5 to 7 days. If central DI, there should be a noticeable decrease in PU/PD and an increase in urine specific gravity (USG) by at least 50% from baselines or if the USG is greater than 1.018 by the end of treatment period.[18,22] **NOTE**: Causes of acquired nephrogenic diabetes insipidus (eg, hyperadrenocorticism) must have been ruled out prior to interpreting the findings from this test.

To improve hemostatic function (extra-label):

a) **Presurgical prophylaxis or treatment of type 1 von Willebrand disease or factor VII deficiency**: 1 µg/kg IV or SC 30 minutes to 1 hour before surgery using the 0.01% intranasal solution.[3-6] Duration of activity is ≈2 hours. Have transfusion capability ready.

b) **Aspirin-induced coagulopathy** (extra-label): 0.3 – 1 µg/kg IV over 15 to 30 minutes,[23] or 3 µg/kg SC.[24] Dramatically shortened buccal mucosal bleeding time measured 15 to 120 minutes after administration and reduced the risk for intraoperative hemorrhage during surgery.[23]

c) **Hemorrhage secondary to canine monocytic ehrlichiosis** (extra-label): 1 µg/kg SC once daily for 3 days[25]; dosage based on a case report with 3 dogs

d) **Hemostatic impairment due to chronic liver disease**: 3 µg/kg SC[24]

Adjunctive treatment of mammary gland tumors (extra-label): 1 µg/kg IV in saline 30 minutes before, and 24 hours after sur-

gery appeared to reduce the spread of, survival of, or numbers of residual malignant cells.[7] However, a more recent study did not prevent metastasis in dogs with mammary carcinoma.[10]

CATS:

Differentiate central vs nephrogenic diabetes insipidus (extra-label)**:** 1 drop/cat (NOT drop/kg or drop/eye) into the conjunctival sac twice daily for 2 to 3 days; a dramatic reduction in water intake or a 50% or greater increase in urine concentration gives strong evidence for a deficiency in ADH production. For treatment of central DI: 1 – 2 drops/ cat (NOT drops/kg or drops/eye) into the conjunctival sac once or twice a day; duration of activity is 8 to 24 hours.[26] Intranasal administration (10 µg/cat [NOT µg/kg]) every 24 hours has also been used.[27]

Treatment of confirmed central diabetes insipidus (extra-label):

a) Using 0.1 mg/mL (0.01%) human intranasal desmopressin product:
   i. 1 – 4 drops/cat (NOT drops/kg or drops/eye) of the intranasal solution in the conjunctival sac once to twice daily[28]
   ii. 2 – 5 µg/cat (NOT µg/kg) SC once to twice daily[28]
b) Using oral formulations: 25 – 50 µg/cat (NOT µg/kg) PO every 8 to 12 hours. Dose and response may be variable[2]

HORSES:

Differentiate central vs nephrogenic diabetes insipidus (extra-label): Using 0.1 mg/mL (0.01%) human intranasal desmopressin product:

a) 20 µg/horse (NOT µg/kg) IV[11,14]
b) Dilute the nasal spray formulation (0.1 mg/mL) in sterile water and administer 0.05 µg/kg IV. Urine specific gravity (SG) should be measured every 2 hours. An increase in SG to 1.025 or greater within 2 to 7 hours is consistent with central DI. No change in urine SG is consistent with nephrogenic DI if medullary washout has been accounted for.[29]
c) 1 drop into each eye, and repeated 2 hours later.[13]

Treatment of confirmed central diabetes insipidus (extra-label): Using 0.1% nasal solution, 25 µg/horse (NOT µg/kg) SC every 24 hours administered in the neck and shoulder area. Response was maintained for at least 5 years. A partial response had been achieved using 3 drops (30 µg)/horse (NOT drops/kg or drops/eye) administered into the conjunctival sac of both eyes every 12 hours, but further dose increase was limited by fluid overflow volume from the eye.[12]

BIRDS:

Treatment of documented central diabetes insipidus in an African Grey parrot (extra-label): 24 µg/kg IM every 12 hours was continued for at least 8 months. Initial treatment with oral desmopressin was ineffective.[30]

Monitoring

Central diabetes insipidus:

- Urine volume; improvement of polyuria, polydipsia
- Serum electrolytes (especially sodium) and urine specific gravity
- Fluid intake
- Patient weight

Von Willebrand disease and other coagulopathies:

- Buccal mucosal bleeding time
- Pre-/post procedure packed cell volume

Client Information

- In dogs and cats, the human nasal spray is usually prescribed; however, it is given by putting drops into the eye instead of the nose.
- This medicine is usually tolerated well as an eye drop though sometimes eye irritation occurs.
- Your veterinarian will need to monitor your animal closely with examinations and blood tests during the initial treatment period while an effective dose is being established. Do not miss these important follow-up visits.
- Contact your veterinarian if your animal begins to drink and urinate excessively again.
- Store this medicine in the refrigerator; discard open bottles after 30 days.

Chemistry/Synonyms

A synthetic polypeptide related to arginine vasopressin (antidiuretic hormone), desmopressin acetate occurs as a fluffy white powder with a bitter taste. The commercially available nasal solution has HCl added, and the pH is ≈4. This preparation also contains chlorobutanol 0.5% as a preservative.

Desmopressin acetate may also be known as 1-Deamino-8-D-Arginine Vasopressin, *DFDAVP®*, *Concentraid®*, *D-Void®*, *Defirin®*, *Desmogalen®*, *Desmospray®*, *Desmotabs®*, *Emosint®*, *Minirin®*, *Minirin/DDAVP®*, *Minrin®*, *Minurin®*, *Nocdurna®*, *Nocutil®*, *Octim®*, *Octostim®*, *Presinex®*, or *Stimate®*.

Storage/Stability

Desmopressin nasal solution storage requirements vary by manufacturer, and the manufacturer's label should be consulted. Some nasal solutions are able to be stored at room temperature 20°C to 25°C (68°F-77°F) whereas others require refrigeration at 2°C to 8°C (36°F-46°F), although the latter are able to be stored at room temperature for up to 3 weeks. Consult product label.

The product for injection should be protected from light and refrigerated at 2°C to 8°C (36°F-46°F); do not freeze.

Compatibility/Compounding Considerations

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration. In humans it is recommended that for IV infusion, the appropriate dose of desmopressin acetate be diluted in 10 or 50 mL of 0.9% sodium chloride injection for administration in children weighing 10 kg or less or in adults and children weighing more than 10 kg, respectively; the solution is then infused IV slowly over 15 to 30 minutes. The intranasal solution has been administered SC or diluted and given IV to veterinary patients; however, no specific published safety or stability data were located, and care should be taken to maintain sterility during preparation.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Desmopressin Acetate Intranasal Spray Solution: 0.1 mg/mL (0.01%; 10 µg/spray) in 5 mL bottle or 2.5 mL rhinal tube delivery system; *DDAVP®*; generic; (Rx).

Desmopressin Acetate Injection Solution: 4 µg/mL in 1 mL single-dose vials and amps and 10 mL multiple dose vials; *DDAVP®*; generic; (Rx)

Desmopressin Acetate Oral Tablets: 0.1 mg and 0.2 mg; *DDAVP®*; generic; (Rx)

Desmopressin Acetate Sublingual Tablets: 55.3 µg (0.0553 mg); *Nocdurna®*; generic; (Rx)

NOTE: Desmopressin Acetate Intranasal Spray: 1.5 mg/mL (0.15% [150 µg/spray]; *Stimate®*) is available but is not used in veterinary medicine.

Mineralocorticoid

Prescriber Highlights

- ► Parenteral mineralocorticoid used to treat hypoadrenocorticism (Addison's disease) in dogs; limited experience with its use in cats due to rare nature of this condition in this species.
- ► Adjust dose based on monitoring parameters. Extra-label dosing protocols using either lower desoxycorticosterone pivalate (DOCP) dose or extended dosing interval can be considered.
- ► Does not contain any glucocorticoid activity and thus a glucocorticoid must be used concurrently in the treatment of hypoadrenocorticism.
- ► Contraindications include congestive heart failure, severe renal disease, primary hepatic failure, or edema; use with caution in pregnant animals.
- ► May cause irritation at injection site. Shake vial well prior to withdrawing dose.

Uses/Indications

Desoxycorticosterone pivalate (DOCP) is indicated for the parenteral treatment of primary hypoadrenocorticism (ie, Addison's disease) in dogs. Compared to fludrocortisone, DOCP use resulted in lower prednisolone requirements[1] and more effectively suppressed plasma renin activity.[2] Extra-label lower dosages (ie, lower dose, longer dosing interval, or both) of DOCP can effectively control clinical signs of hypoadrenocorticism and maintain serum electrolytes.[3-5] Oral supplementation with salt (NaCl) is not necessary with animals receiving DOCP.[6]

DOCP has also been used to treat hypoadrenocorticism in cats (extra-label)[7,8]; experience is limited as this condition is rare in this species.

Pharmacology/Actions

Desoxycorticosterone pivalate (DOCP) is a long-acting mineralocorticoid agent that requires a functioning kidney to be effective. The site of action of mineralocorticoids is at the renal distal tubule, where it increases the reabsorption of sodium. Mineralocorticoids also enhance potassium and hydrogen ion excretion in the collecting tubules.

Pharmacokinetics

Little information is available. Desoxycorticosterone pivalate (DOCP) is injected IM or SC as a microcrystalline depot for slow dissolution into the circulation. Duration of action after injection is usually 21 to 30 days.

Contraindications/Precautions/Warnings

Do not use desoxycorticosterone pivalate (DOCP) in patients with documented hypersensitivity reactions to DOCP. Do not administer DOCP IV; acute collapse and shock may result.

DOCP is labeled as contraindicated in dogs suffering from congestive heart failure, severe renal disease, primary hepatic failure, or edema. Animals suffering from an Addisonian crisis (ie, hypovolemia, prerenal azotemia, inadequate tissue perfusion [shock]) must be rehydrated with IV fluid (eg, 0.9% sodium chloride) therapy before starting DOCP therapy.

Animals treated with DOCP for hypoadrenocorticism will also require glucocorticoid supplementation, as DOCP does not have glucocorticoid activity. All animals with hypoadrenocorticism should receive additional glucocorticoids (2-10 times basal) during periods of stress or acute illness. See ***Prednisolone/Prednisone*** monograph.

Ongoing monitoring is required to ensure proper dosing of this drug because individual dosage requirements vary.

Adverse Effects

Occasionally, irritation at the site of injection may occur; injection site abscesses have been reported.

Postapproval reported adverse effects in dogs receiving *Percorten-V®* included (in decreasing frequency) depression and lethargy, vomiting, anorexia, polydipsia, polyuria, diarrhea, facial and muzzle edema, weakness, urticaria, and anaphylaxis. Anemia has been reported following DOCP administration.

Adverse effects in a field safety analysis of *Zycortal®* listed the following (in decreasing frequency): polyuria, polydipsia, depression and lethargy, inappropriate urination, alopecia, decreased appetite/anorexia, panting, vomiting, diarrhea, shaking/trembling, polyphagia, UTI, urinary incontinence, restlessness, urticaria, and facial edema. Postapproval drug experience reporting with *Zycortal®* included reports of anaphylaxis and anemia.

Reproductive/Nursing Safety

The manufacturers state that the drug should not be used in pregnant dogs.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Desoxycorticosterone pivalate (DOCP) overdoses may cause polyuria, polydipsia, hypernatremia, hypertension, edema, and/or hypokalemia. Cardiomegaly is possible with prolonged overdoses; weight gain may be indicative of fluid retention. Glomerulonephropathy has occurred with prolonged exposure to doses 3 to 5 times the labeled initial starting dose.[6,9]

Electrolytes should be aggressively monitored; potassium may need to be supplemented. Discontinue DOCP treatment until clinical signs associated with overdose have resolved, then restart the drug at a lower dose (eg, 20% lower).

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving desoxycorticosterone pivalate (DOCP) and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Patients may develop hypokalemia if mineralocorticoids are administered concomitantly with amphotericin B.
- **Aspirin**: DOCP may reduce salicylate levels.
- **Digoxin**: Because DOCP may cause hypokalemia, it should be used with caution and monitoring should be increased in patients receiving digitalis glycosides.
- **Insulin**: DOCP could potentially increase the insulin requirements of diabetic patients.
- **Potassium-Depleting Diuretics** (eg, **chlorothiazide**, **furosemide**, **hydrochlorothiazide**): Patients may develop hypokalemia if mineralocorticoids are administered concomitantly with potassium-depleting diuretics; because diuretics can cause a loss of sodium, they may counteract the effects of DOCP.

- **Potassium-Sparing Diuretics** (eg, **spironolactone**): Concomitant use of DOCP with potassium-sparing diuretics may counter the effects of DOCP because desoxycorticosterone pivalate and potassium-sparing diuretics exhibit opposing mechanisms of action.

Dosages

DOGS:

Hypoadrenocorticism:

NOTES:

1. Dosage requirements are variable and must be individualized on the basis of the response of the patient to therapy.
2. Many clinicians begin treatment at dosages lower than what is found on the product label (see **Hypoadrenocorticism, lower dosage protocols** for extra-label dosage information).
3. DOCP replaces the mineralocorticoid hormones only. Glucocorticoid replacement (eg, predniso(lo)ne 0.2 – 0.4 mg/kg/day) is necessary. See ***Prednisolone/Prednisone***. Failure to concurrently administer glucocorticoids is the most common reason for treatment failure. Signs of glucocorticoid deficiency include depression, lethargy, vomiting, and diarrhea. Such signs should be treated with high doses of injectable glucocorticoids (prednisolone or dexamethasone), followed by continued oral therapy with predniso(lo)ne 0.2 – 0.4 mg/kg/day. Polyuria and polydipsia (PU/PD) usually indicate excess glucocorticoid but may also indicate DOCP excess. Begin by decreasing the glucocorticoid dose. If PU/PD persists, decrease the DOCP dosage without changing the interval between doses.

Percorten-V® (labeled dose FDA-approved): Begin treatment at a dose of 2.2 mg/kg IM (**NOTE**: *Some administer the drug SC in an extra-label manner—Plumb*) every 25 days. In some patients, the dose may be reduced. Most patients are well controlled with a dosage of 1.65 – 2.2 mg/kg every 21 to 30 days. Serum sodium and potassium levels should be monitored at days 14 and 25 initially and any time there is a dosage change. Well-controlled patients have normal electrolytes at day 14 after administration or may exhibit slight hyponatremia and hyperkalemia. This result needs no additional therapy as long as the patient is active and eating normally. Monitor for depression, lethargy, vomiting, or diarrhea, which indicate a probable glucocorticoid deficiency. Electrolyte results at Day 14 allow assessment of the dose, whereas results at Day 25 allow assessment of dosing interval. At the end of the 25-day dosing interval, the patient should be clinically normal and have normal serum electrolytes; the patient may have slight hyponatremia and slight hyperkalemia. This indicates that the dosage should not be altered. If the dog is not clinically normal or serum electrolytes are abnormal, the dosing interval should be decreased by 2 to 3 days.

Zycortal® (label dose; FDA-approved): Indicated for long-term administration at dosages dependent upon individual response to therapy. Tailor the DOCP dosage and concurrently administered glucocorticoid therapy to the individual dog based on clinical response and normalization of sodium and potassium concentrations. Initial dosage is 2.2 mg/kg SC every 25 days. Re-evaluate the dog and measure the serum sodium/potassium ratio ≈10 days after the first dose, which is the time to maximum concentration of desoxycorticosterone. If the dog's clinical signs have worsened or not resolved, adjust the dose of predniso(lo)ne therapy and/or investigate other causes of the clinical signs.

At ≈25 days after the first dose, re-evaluate the dog and repeat the sodium/potassium ratio:

- If the dog is both clinically normal and has a normal Na+/K+ ratio on Day 25, adjust the dose based on the Day 10 Na+/K+ ratio using the guidelines in the table below.
- If the dog is clinically normal and has a Na+/K+ ratio greater than 32 on Day 25, either adjust the dose based on the Day 10 Na+/K+ ratio according to the table below or delay the dose (see Prolonging the dosing interval below).
- If the dog is either not clinically normal or if the Na+/K+ ratio is abnormal on Day 25, adjust the dose of predniso(lo)ne or *Zycortal*® (see Subsequent doses and long-term management below).

Day 25: Administering the second dose of *Zycortal*® Suspension

If the Day 10 Na+/K+ ratio is:		25 days after the first dose, administer Zycortal® Suspension, as follows:
>34	Do not administer Dose 2 on Day 10.	Decrease dose to 2 mg/kg
>32 to 34	Do not administer Dose 2 on Day 10.	Decrease dose to 2.1 mg/kg
27 to 32	Do not administer Dose 2 on Day 10.	Continue 2.2 mg/kg
24 to <27	Do not administer Dose 2 on Day 10.	Increase dose to 2.3 mg/kg
<24	Do not administer Dose 2 on Day 10.	Increase dose to 2.4 mg/kg

Prolonging the dosing interval: If the dog is clinically normal and the Day 25 Na+/K+ ratio is greater than 32, it is possible to prolong the dosing interval instead of adjusting the dose as described in the above table. Evaluate the electrolytes every 3 to 7 days until the Na+/K+ ratio is less than 32, then administer 2.2 mg/kg of *Zycortal*® Suspension.

Subsequent doses and long-term management: For subsequent doses, use the following guidelines if the dog is not clinically normal and/or has abnormal Na+ or K+ concentrations:

- Clinical signs of polyuria/polydipsia: Decrease the prednisone/prednisolone dose first. If the polyuria/polydipsia persists, decrease the dose of *Zycortal*® Suspension without changing the dosing interval.
- Clinical signs of depression, lethargy, vomiting, diarrhea, or weakness: Increase prednisone/prednisolone dose.
- Hyperkalemia, hyponatremia, or Na+/K+ ratio less than 27: Decrease the *Zycortal*® Suspension dosing interval by 2 to 3 days.
- Hypokalemia or hypernatremia: Decrease the *Zycortal*® Suspension dose.

Hypoadrenocorticism, lower dosage protocols (extra-label): Different options exist; *choose only one* (ie, do not decrease the amount given and increase the dosing interval at the same time).

a) **Lower initial dosage**: In a study evaluating lower initial DOCP dosages for the treatment of canine primary hypoadrenocorticism, dogs were divided into 4 treatment groups (dosage range, median dosage, % of dogs in group): substantially lower than label dosages (0.36 – 0.96 mg/kg, 0.75 mg/kg, 38.8%), moderately lower dosages (1 – 1.47 mg/kg, 1.14 mg/kg, 14.3%), slightly lower dosages (1.76 – 2.19 mg/kg, 2.16 mg/kg, 20.4%), and recommended or higher dosages (2.20 – 3.82 mg/kg, 2.2 mg/kg, 26.5%).[5] All doses were administered IM. Despite the wide range of initial DOCP dosages administered, all dogs had similar responses with no dog developing an Addisonian crisis after diagnosis and beginning therapy. In addition, no dogs, regardless of DOCP dosage, developed persistent or

severe electrolyte derangements warranting a dosage adjustment. This retrospective study suggests that lower initial dosages of DOCP may be sufficient.

b) **Dose reduction**: If using the initial recommended starting dosage of DOCP (2.2 mg/kg IM or SC), follow guidelines to allow normalization of sodium and potassium concentrations. Then consider tapering the dose by 10% each month while monitoring the sodium and potassium concentrations prior to each injection. Using this method, ideally the lowest effective dose can be found for the individual patient. Once electrolyte concentrations begin trending outside of the normal reference range prior to the next injection, return to the previous increased dose that allowed normalization of sodium and potassium concentrations for the entire dosing interval.[10]

c) **Extended dosing interval**: Initial dose 2.1 – 2.6 mg/kg IM or SC. Check plasma sodium and potassium concentration after 30 days and every 7 days thereafter until hyponatremia or hyperkalemia developed at a planned evaluation or the dog exhibited clinical signs (eg, vomiting, diarrhea, anorexia, lethargy, trembling, collapse) with concurrent electrolyte concentration outside the reference interval. The duration of action (dosing interval) of DOCP was recorded as the duration of time from DOCP administration to the time that either hyponatremia or hyperkalemia developed. In dogs newly diagnosed with primary hypoadrenocorticism receiving the first DOCP dose (median dose 2.2 mg/kg), the median dosing interval was 56 days (range 41-85 days). Notably, the median dosing interval was 59 days (range 38-90 days) in dogs previously receiving DOCP, but ≈34% of those dogs received a DOCP dose less than 2 mg/kg. The DOCP dosage (mg/kg) did not predict the duration of action.[4]

CATS:

Hypoadrenocorticism (extra-label):

a) 2.2 mg/kg IM or SC every 25 days plus prednisolone 0.25 – 1 mg/cat (NOT mg/kg) PO twice daily. If daily oral dosing is not feasible, consider methylprednisolone acetate 10 mg IM once a month.[11] From 2 case reports,[7,8] 2.2 mg/kg IM plus prednisolone 0.2 mg/kg/day PO. DOCP dosing interval was every 21 days for one cat,[8] and every 35 to 40 days for the other cat.[7]

b) 10 – 12.5 mg/cat (NOT mg/kg) IM per month. Adjust dose based upon follow-up serum electrolyte concentrations monitored every 1 to 2 weeks during initial maintenance period. Normal electrolyte values 2 weeks following injection suggests adequate dosing but does not provide information regarding duration of action. Prednisolone 1.25 mg/cat (NOT mg/kg) PO once a day or methylprednisolone acetate 10 mg/cat (NOT mg/kg) IM once a month provides long-term glucocorticoid supplementation.[12]

Monitoring

- Serum electrolytes (including calculation of sodium/potassium ratio), BUN, creatinine: initially every 1 to 2 weeks, then once stabilized, every 3 to 4 months. See ***Dosages*** section above for details.
- Body weight and physical exam checking for evidence of edema (eg, peripheral, pulmonary)
- Clinical efficacy

Client Information

- Long-acting injection administered into the muscle (IM) or subcutaneous tissues (SC) every 20 to 30 days. Your veterinarian will adjust the dose and times between doses depending on your animal's response.
- Shake vial vigorously before drawing up into syringe.
- Must not be given IV (into the vein).
- For this medication to work, give it exactly as your veterinarian has prescribed. It's a good idea to always check the prescription label to be sure you are giving the drug correctly. If there is difficulty administering the medicine, contact your veterinarian.
- Watch for signs of the dose being too high (greater thirst and need to urinate, swelling/edema, weight gain, pot belly); be sure to contact your veterinarian if you see any of these signs.
- Watch for signs that the dose is too low (muscle weakness, lethargy [lack of energy], shaking, collapsing/fainting, loss of appetite/weight loss, vomiting, diarrhea, slower heartbeat, or painful abdomen). Contact your veterinarian right away if you see any of these signs.
- Regular laboratory testing is essential for monitoring the effectiveness of the therapy. Do not miss these important follow-up visits.

Chemistry/Synonyms

A mineralocorticoid, desoxycorticosterone pivalate (DOCP) occurs as a white or creamy white powder that is odorless and stable in air. It is practically insoluble in water and slightly soluble in alcohol and vegetable oils. The injectable product is a white aqueous suspension and has a pH between 5 and 8.5.

The commercially available injection (*Percorten-V*®) contains (per mL): 25 mg desoxycorticosterone pivalate, 10.5 mg methylcellulose, 3 mg sodium carboxymethylcellulose, 1 mg polysorbate 80, and 8 mg sodium chloride with 0.002% thimerosal added as preservative in water for injection.

The commercially available injection (*Zycortal*®) contains (per mL): 25 mg desoxycorticosterone pivalate, 10.5 mg methylcellulose, 3 mg sodium carboxymethylcellulose, 1 mg polysorbate 60, 8 mg sodium chloride, and 1 mg chlorocresol in water for injection.

Desoxycorticosterone pivalate may also be known as deoxycorticosterone pivalate, deoxycorticosterone trimethyl-acetate, deoxycortone pivalate, deoxycortone trimethylacetate, desoxycorticosterone trimethyl-acetate, *Cortiron*®,*Zycortal*®, or *Percorten-V*®.

Storage/Stability

Store the injectable suspension at room temperature 25°C (77°F), with excursions between 15°C and 30°C (59°F-86°F) permitted. Protect from light or freezing. The *Zycortal*® label states to use within 120 days of first puncture and puncture a maximum of 4 times.

The *Percorten-V*® label states that once the vial is broached, product should be used within 4 months.

Compatibility/Compounding Considerations

Do not mix desoxycorticosterone pivalate (DOCP) with any other agent.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Desoxycorticosterone Pivalate Injectable Suspension: 25 mg/mL in 4 mL vials; *Percorten-V*®, *Zycortal*® Suspension; (Rx). FDA-approved for use in dogs; NADA #141-029 (*Percorten-V*®) and 141-444 (*Zycortal*®).

Detomidine

(de-***toe***-ma-deen) *Dormosedan®*

Alpha-2-Adrenergic Agonist

Prescriber Highlights

- ► Sedative and analgesic used primarily in horses
- ► Contraindications include pre-existing sinoatrial (SA) or pathologic atrioventricular (AV) block; severe coronary, cerebrovascular, or respiratory disease; and chronic kidney disease
- ► Use with caution in horses with endotoxic or traumatic shock or approaching shock; advanced hepatic or renal disease; stress caused by temperature extremes, fatigue, or high altitude; with intestinal impactions or suspected colic because detomidine may mask abdominal pain or changes in respiratory and cardiac rates when administered prior to establishing diagnosis
- ► Handle animals sedated with detomidine as a single agent with caution as they may respond (eg, kick) to external stimuli even when deeply sedated; the addition of opioids may temper this response.
- ► Adverse effects include decreased GI motility, piloerection, and an initial blood pressure increase with concurrent reflex bradycardia and/or heart block.

Uses/Indications

Detomidine is FDA-approved for use as a sedative analgesic in horses; it is also used clinically (extra-label) in other species (eg, cattle, camelids, sheep, goats). In a comparative study in horses, detomidine delivered as an oral transmucosal (OTM) gel produced sedation (chin to ground) similar to that achieved from IV administration but caused less ataxia.[1] The OTM gel has been used orally in dogs and cats, and in horses, orally and transvaginally.

Pharmacology/Actions

Detomidine, like xylazine, is an alpha-2-adrenergic agonist that reduces norepinephrine-mediated neural impulses, resulting in a dose-dependent sedative and analgesic effect. Detomidine is ≈50 to 100 times more potent than xylazine.

Detomidine effects on the cardiovascular system include an initial increase in peripheral vascular resistance with increased blood pressure followed by a longer period of lowered blood pressures (below baseline). Bradycardia can be seen with some animals developing a second-degree heart block or other arrhythmias. An overall decrease in cardiac output may be seen.

Detomidine effects on respiratory function are usually clinically insignificant, but at high doses it can cause respiratory depression with decreased tidal volumes and respiratory rates, and an overall decreased minute volume. Brachycephalic dogs and horses with upper airway disease may develop dyspnea.

Detomidine causes skeletal muscle relaxation through inhibition of central mediated pathways, and the retractor muscle can be affected. As with other alpha-2-adrenergic agonists, detomidine is emetogenic in species that vomit. Detomidine depresses thermoregulatory mechanisms and either hypo- or hyperthermia is a possibility depending on ambient air temperatures.

Detomidine can increase blood glucose secondary to decreased serum levels of insulin. In nondiabetic animals, there appears to be little clinical significance associated with this effect although an osmotic diuresis may result from transient hyperglycemia.

Pharmacokinetics

In dogs, after receiving an OTM dose of 1 mg/m^2 (NOT mg/kg), median maximum concentration was 7.03 ng/mL, time to maximum concentration was 1 hour, and bioavailability was 34.52%; mean elimination half-life was 0.63 hours.[2]

In horses, onset of sedative effect after IV or IM administration is within 5 minutes, and peaks at ≈5 to 20 minutes; sedative duration is dose-related, lasting 30 to 120 minutes after labeled parenteral doses.[3] Following OTM administration, sedation begins within 40 minutes, peaks at 60 to 80 minutes and is ≈2 hours in duration.

In horses, detomidine is well absorbed after oral administration (ie, swallowed), but because of a high first-pass effect, little drug is available systemically. Bioavailability is 38% with IM administration and 22% after the OTM gel, and the peak concentrations observed after administration of the gel are ≈40% of those observed after IM injection. Following administration, maximum blood concentration is reached ≈2 minutes (IV), 77 minutes (IM), and 1.83 hours (OTM). The drug is 85% protein bound and is rapidly distributed into tissues; the volume of distribution is 0.5 to 1.9 L/kg and is lower at rest (0.47 to 0.59 L/kg) compared to after exercise (1.3 L/kg). Detomidine is extensively metabolized, and elimination half-lives are ≈24 to 66 minutes (IV, at rest), 46 minutes (IV, after exercise), 51 minutes (IM, at rest), and 90 minutes (OTM). Detomidine is a high-extraction drug and clearance (≈12 to 16 mL/minute/kg) can be altered by changes to liver blood flow (eg, with exercise[4]). Metabolites are excreted primarily into the urine.[3,5-10]

When the OTM gel is administered intravaginally in mares, sedation lasts longer than IV detomidine, with a mean maximum plasma concentration of 8.57 ng/mL, time to maximum concentration of 0.37 hour, and bioavailability of 25%.[11]

In cattle, IM administration resulted in peak concentration at ≈16 minutes, bioavailability was 85%, and apparent Vd was 1.9 L/kg. Elimination half-life was 2.6 hours but was 1.3 hours after IV administration.[12]

Contraindications/Precautions/Warnings

Detomidine is contraindicated in horses with preexisting SA block or pathologic AV block, severe coronary insufficiency, cerebrovascular disease, respiratory disease, or chronic renal failure. Use cautiously in animals with endotoxic or traumatic shock or approaching shock, and in patients with advanced hepatic or renal disease. Use with caution in horses that are stressed because of temperature extremes, fatigue, or high altitude; consider using lower dosages. Because this drug may inhibit GI motility, use with caution in patients treated for intestinal impactions. When possible in horses with suspected colic, the use of detomidine analgesia should be used only after confirmation of the diagnosis as it may mask abdominal pain and conceal changes in respiratory and cardiac rates, making diagnosis more difficult.

Although animals may appear to be deeply sedated, some may respond (eg, kick) to external stimuli; use appropriate caution. The addition of opioids (eg, butorphanol) may help temper this effect. To improve the effects of detomidine, allow the horse to stand quietly for 5 minutes prior to injection and for 10 to 15 minutes after injection to improve the effect of the drug.[3] After administering detomidine, protect the animal from temperature extremes.

The OTM gel can be absorbed across human skin; wear impermeable gloves during drug administration or when performing procedures that require contact with the horse's mouth.[10]

In cattle, use of alpha-2-agonists under emergency conditions is discouraged as the risk of profound cardiovascular instability or recumbency exceeds the benefits observed with the use of these drugs.[13]

Adverse Effects

Detomidine can cause an initial and immediate rise in blood pressure followed by reflex bradycardia and AV block. Atropine 0.02 mg/kg IV has been successfully used to prevent or correct the bradycardia that may be seen when detomidine is administered at

labeled dosages. However, routine use of anticholinergics is generally not recommended because of the potential for GI motility reduction and hypertension. In addition, detomidine can cause piloerection, sweating, ataxia, salivation, mild muscle tremors, and penile prolapse. Horses may stagger or appear uncoordinated for 3 to 5 minutes following injection. Decreased tear production has also been noted.[14,15]

When compared to xylazine, detomidine causes more pronounced bradycardia and bradyarrhythmias (eg, AV block). Because the sedative and muscle-relaxing effects of detomidine in horses can persist for up to 90 minutes, it may influence the quality of recovery and contribute to postanesthesia ataxia. One study reported that detomidine caused a mild increase in atrial fibrillation cycle length.[16]

Emesis occurred in 100% of cats receiving OTM gel.[17]

Reproductive/Nursing Safety

Detomidine is not recommend for use in breeding animals as the possible effects of detomidine in breeding horses is limited to uncontrolled clinical reports[3] In small studies, administration during the last trimester or the last 3 weeks of pregnancy in healthy mares resulted in no apparent detrimental effects[18,19]; however, in pregnant ruminants, administration of detomidine at recommended doses is considered less likely than xylazine to induce premature parturition.

Overdose/Acute Toxicity

The manufacturer states that detomidine is tolerated by horses at doses 5 times (0.2 mg/kg) the maximum dose level (0.04 mg/kg). Dosages of 0.4 mg/kg given daily for 3 consecutive days produced microscopic foci of myocardial necrosis in 1 of 8 horses tested. Doses at 10 to 40 times the recommended amount may cause severe respiratory and cardiovascular changes that are irreversible and fatal. Atipamezole or tolazoline can be used to reverse some or all the effects of the drug.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving detomidine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-2 Agonists, Other** (eg, **clonidine, dexmedetomidine, romifidine, xylazine**): Not recommended for routine use with detomidine as effects may be additive
- **Sulfonamides, Potentiated** (eg, **trimethoprim/sulfa**): Concurrent use may precipitate fatal dysrhythmias.[3] Combination is contraindicated.

Although the manufacturer warns to use extreme caution combining detomidine with other sedative or analgesic drugs, the preponderance of research studies and clinical experience indicate balanced anesthetic protocols can safely use detomidine in combination with the following agents although lower dosages of detomidine and/or the following agents may be required.

- **Anesthetic Agents** (eg, **alfaxalone, isoflurane, ketamine, propofol**)
- **Benzodiazepines** (eg, **diazepam, midazolam**)
- **Opioids** (eg, **fentanyl, morphine**)
- **Phenothiazines** (eg, **acepromazine**): Alpha-2 effects may be additive and severe hypotension can result.

Dosages

CAUTION: Do not confuse µg/kg or mg/m^2 with mg/kg doses.

DOGS:

Sedation/anxiolytic (extra-label): Using the equine oromucosal gel, 0.35 – 2 mg/m^2 (NOT mg/kg) administered via the oral transmucosal (OTM) route.[2,20,21] Maximum sedation occurred 45 to 75 minutes after administration; effects were reversed with atipamezole 0.1 mg/kg IM.

CATS:

Sedation (extra-label): Using the equine oromucosal gel, 0.25 mg/kg) OTM, all cats vomited within 2 minutes of administration, yet moderate sedation was noted within 30 minutes after administration and duration was 45 to 60 minutes.[17]

HORSES:

Analgesia (label dosages; FDA-approved): Detomidine 0.02 – 0.04 mg/kg IV; allow animal to rest quietly prior to and after injection. Effects generally occur within 2 to 4 minutes of administration. Lower doses will generally provide 30 to 45 minutes of analgesia. The higher dose will provide 45 to 75 minutes of analgesia.

Sedation (label dosages; FDA-approved):

- *Injection*: Detomidine 0.02 – 0.04 mg/kg IV or IM; allow animal to rest quietly prior to and after injection. Effects generally occur within 2 to 4 minutes of administration. Lower dose will generally provide 30 to 90 minutes of sedation. The higher dose will generally provide 90 to 120 minutes of sedation.
- *OTM Gel*: Detomidine 0.04 mg/kg placed beneath the tongue of the horse; not meant to be swallowed. The dosing syringe delivers the product in 0.25 mL (1.9 mg) increments. See dosing table[3]

Dosing Table for Detomidine Oral Gel

Approximate body weight (kg [lb])	Range of doses (mg/kg)	Dose volume (mL)
150 to 199 (330-439)	0.051 – 0.038	1
200 to 249 (440-549)	0.047 – 0.038	1.25
250 to 299 (550-659)	0.046 – 0.038	1.5
300 to 349 (660-769)	0.044 – 0.038	1.75
350 to 399 (770-879)	0.043 – 0.038	2
400 to 449 (880-989)	0.043 – 0.038	2.25
450 to 499 (990-1099)	0.042 – 0.038	2.5
500 to 549 (1100-1209)	0.042 – 0.038	2.75
550 to 600 (1210-1320)	0.041 – 0.038	3

Sedation, chemical restraint, analgesia (extra-label):

As a single agent:

a) Detomidine 0.005 – 0.03 mg/kg IV[22]
b) Detomidine 0.022 mg/kg/hr IV CRI
c) **Oral gel formulation**: Detomidine 0.04 mg/kg intravaginally; sedation lasts over 3 hours.[11]
d) **Caudal epidural**: Detomidine 0.06 mg/kg diluted to 10 mL with sterile water and administered as a caudal epidural block[23]; onset of action: ≈5 minutes, duration of analgesia: ≈3 hours.

As a combination:

a) Detomidine 0.01 mg/kg IV in combination with methadone 0.2 mg/kg and administered IV was more antinociceptive than methadone 0.2 mg/kg in combination with acepromazine 0.05 mg/kg IV.[24]
b) Detomidine 0.01 mg/kg slow IV followed by buprenorphine 0.005 mg/kg IV will produce sedation for standing procedures; if sedation is inadequate, doses can be repeated. Horses developed marked ataxia, bradycardia (some with 2nd AV block), and decreased respiratory rates. Sedation lasted 60 minutes.[25]
c) **CRI for standing procedures**:
   i. Begin with acepromazine 0.02 mg/kg IV followed 30

minutes later by detomidine 0.01 mg/kg IV then 5 minutes later by *either* buprenorphine 0.01 mg/kg IV or morphine 0.1 mg/kg IV. Then add detomidine 0.006 mg/kg/minute IV CRI. Both protocols (eg, using buprenorphine or morphine) provided sedation and analgesia; however, more adverse effects were observed with buprenorphine (eg, CNS excitation [box-walking, head bobbing]).[26]

ii. Detomidine 0.005 mg/kg in combination with methadone 0.2 mg/kg IV followed by detomidine 0.0125 mg/kg/hour and methadone 0.05 mg/kg/hour (starting rate) IV CRI produced adequate sedation for standing surgery when combined with locoregional anesthesia.[27]

d) **Caudal epidural**: Detomidine 0.03 mg/kg in combination with morphine 0.2 mg mg/kg and administered as a caudal epidural block[28]; duration of analgesia is greater than 6 hours.

CRI for partial intravenous anesthesia (PIVA; extra-label): Detomidine 0.013 – 0.038 mg/kg/hour IV resulted in a significant MAC reduction.[29]

CRI for total intravenous anesthesia (TIVA; extra-label): Detomidine 10 mg (total amount; NOT mg/kg) and ketamine 500 – 1000 mg (total amount; NOT mg/kg) added to 500 mL of guaifenesin 5%. This drug combination will yield a solution of guaifenesin 50 mg/mL, ketamine 1 – 2 mg/mL, and detomidine 0.02 mg/mL to be infused at a rate of 1.2 – 1.6 mL/kg/hour IV CRI. **NOTE**: If 500 mL of guaifenesin 10% is used as the base, the total amounts of detomidine and ketamine to be added should be doubled, which will result in final concentrations that are also doubled, and thus, the infusion rate for this solution will need to be halved to deliver the same CRI rate.[30]

Donkeys, sedation (extra-label):

a) Detomidine 0.0135, 0.017, and 0.02 mg/kg IV increased sedation scores above control in 1 study.[31]

b) Detomidine 0.06 mg/kg in combination with butorphanol 0.05 mg/kg IM sedated miniature donkeys for 38 minutes.[32]

c) Detomidine gel 0.04 mg/kg OTM may be useful for standing sedation prior to painful minor procedures.[33]

CATTLE:

Standing sedation (extra-label): Information regarding the use of detomidine in ruminants is limited. The dosage ranges provided are estimates and should be adjusted based on experience. Administering the IV dose IM further reduces the possibility of recumbency.[34]

a) Tractable cattle: Detomidine 0.002 – 0.005 mg/kg IV or 0.006 – 0.01 mg/kg IM

b) Anxious cattle: Detomidine 0.005 – 0.0075 mg/kg IV or 0.01 – 0.015 mg/kg IM

c) Extremely anxious or unruly cattle: Detomidine 0.01 – 0.015 mg/kg IV or 0.015 – 0.02 mg/kg IM

Analgesia (extra-label): 0.01 mg/kg IV[35]; short (½ hour) duration of action.

Sedation/analgesia for horn disbudding in calves (extra-label): Detomidine 0.03 mg/kg IV or detomidine gel 0.08 mg/kg OTM produced sedation in 11 and 38 minutes, respectively. All recoveries were without complications.[36]

Restraint in free-ranging cattle (extra-label): Detomidine 0.04 mg/kg in combination with tiletamine-zolazepam 0.53 mg/kg and ketamine 0.53 mg/kg IM. Rapid onset and suitable immobilization were achieved for minor procedures. Atipamezole was administered at the end of the procedure to decrease recovery time.[37]

SHEEP, GOATS:

Analgesia (extra-label): Detomidine 0.005 – 0.05 mg/kg IV, IM every 3 to 6 hours[38]

Sedation in sheep (extra-label): Loading dose of detomidine 0.02 mg/kg IV followed by detomidine 0.06 mg/kg/hour IV CRI produces satisfactory sedation for minimally invasive procedures with minimal cardiorespiratory adverse effects.[39]

Anesthesia (extra-label): Detomidine 0.01 mg/kg IM, followed by propofol at 3 – 5 mg/kg IV

Lumbosacral epidural in goats (extra-label): Detomidine 0.02 – 0.04 mg/kg produced analgesia within 1 to 5 minutes of administration, which lasted 70 to 120 minutes.[40,41]

CAMELIDS:

Analgesia (extra-label): Detomidine 0.005 – 0.05 mg/kg IV or IM every 3 to 6 hours (once)[42]

Epidural in calves (extra-label): Detomidine 0.05 mg/kg in combination with lidocaine 0.22 mg/kg administered into the sacro-coccygeal epidural space had reliable sedation and analgesia for 60 to 90 minutes.[43]

BIRDS:

Sedation/analgesia (extra-label): 12 – 15 mg/kg intranasally in parakeets and canaries.[44-46]

Monitoring

- Level of sedation and analgesia; body temperature
- Heart rate and rhythm, blood pressure, respiratory rate, and pulse oximetry

Client Information

- When used parenterally (by injection), detomidine should be used in a professionally supervised setting by individuals familiar with its properties.
- Withhold feed and water until the sedative effects of detomidine have subsided.
- When administering the oromucosal gel, ensure the following:
  a) The lock ring is securely in place at the desired volume mark before administering.
  b) The horse's mouth contains no feed.
  c) The dose is deposited under the horse's tongue.
- When handling the oromucosal gel, wear disposable gloves; avoid contact with human skin.
- If dispensing gel for clients to administer to their animals, give clients the ***Client Information Sheet for Owner/Handler Use and Safety*.**

Chemistry/Synonyms

An imidazoline derivative alpha-2-adrenergic agonist, detomidine HCl occurs as a white, crystalline substance that is soluble in water.

Detomidine HCl may also be known as demotidini hydrochloridum, MPV-253-AII, or *Dormosedan*®.

Storage/Stability

Detomidine HCl for injection should be stored at room temperature, 15°C to 30°C (59°F-85°F) and protected from light.

Detomidine gel for sublingual administration should be stored at controlled room temperature, 20°C to 25°C (68°F-77°F); excursions are permitted from 15°C to 30°C (59°F-85°F).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Detomidine HCl for Injection: 10 mg/mL in 5 mL and 20 mL vials; *Dormosedan*®; (Rx). FDA-approved for use in mature horses

and yearlings. In cattle, goats, and sheep, the FARAD-suggested withdrawal time[47] for single or multiple doses of detomidine (up to 0.08 mg/kg IM or IV) are 3 days for meat and 72 hours for milk.

Detomidine HCL Oromucosal Gel for Sublingual Administration: 7.6 mg/mL in 3 mL graduated dosing syringes; *Dormosedan Gel®*; (Rx). FDA-approved for use in horses not intended for human consumption. NADA #141-306. Based on times when detomidine was indetectable in blood and urine, 1 study recommended a 72-hour withdrawal time (prior to racing) after a single 40 µg/kg SL dose for horses.[48]

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS: NONE

Dexamethasone

Dexamethasone Sodium Phosphate

(dex-a-***meth***-a-zone) *Azium®, Dexasone®*

Glucocorticoid

For more information, see ***Glucocorticoid Agents, General Information****.*

Prescriber Highlights

- ► Injectable, oral, and ophthalmic glucocorticoid
- ► Long-acting; 30 times more potent than hydrocortisone; no mineralocorticoid activity. For practical dosing in dogs and cats, determine the dosage of prednis(ol)one needed and divide by 7 to determine the dexamethasone dosage.
- ► Dexamethasone sodium phosphate has an effective dexamethasone concentration of 3 mg/mL.
- ► Contraindications (relative) include systemic fungal infections. Concurrent use with NSAIDS increases the risk for GI ulceration.
- ► Caution is advised for use in animals with active bacterial infections, corneal ulcers, hyperadrenocorticism, diabetes mellitus, osteoporosis, chronic psychotic reactions, predisposition to thrombophlebitis, hypertension, and renal insufficiency.
- ► Goal of therapy should be to use the lowest dose possible for the least amount of time to treat and control patient's condition.
- ► Primary adverse effects with sustained use are Cushingoid in nature, but acute effects (primarily GI related, colon perforation in dogs receiving high doses) can be seen.
- ► Many potential drug and laboratory interactions

Uses/Indications

Although glucocorticoids have been used to treat many conditions in humans and animals, dexamethasone has 5 primary uses with accompanying dosage ranges: 1) as a diagnostic agent to test for hyperadrenocorticism, 2) as a replacement or supplementation (eg, relative adrenal insufficiency associated with septic shock) for glucocorticoid deficiency secondary to hypoadrenocorticism, 3) as an anti-inflammatory agent, 4) for immunosuppression, and 5) as an antineoplastic agent.[1,2]

Glucocorticoids are used in the treatment of endocrine conditions (eg, adrenal insufficiency), autoimmune and immune-mediated diseases (eg, rheumatoid arthritis, systemic lupus, masticatory myositis[3]), severe allergic conditions, anaphylaxis, envenomation, respiratory diseases (eg, asthma), dermatologic diseases (eg, pemphigus, allergic dermatoses), hematologic disorders (eg, thrombocytopenia, autoimmune hemolytic anemia), neoplasias, nervous system disorders (eg, increased CSF pressure), GI diseases (eg, ulcerative colitis exacerbations, inflammatory bowel disease), renal diseases (eg, nephrotic syndrome), and induction of fetal maturation. Some glucocorticoids are used topically on the eye and skin or are injected intra-articularly or intralesionally. This list is not exhaustive. High-dose glucocorticoid use in the treatment of hemorrhagic or hypovolemic shock, head trauma, spinal cord trauma, and/or sepsis is not supported.[4]

In general, when administering glucocorticoids, the following principles should be followed:

- A specific diagnosis is needed before glucocorticoids are administered, as they can mask disease.
- A course of treatment should be determined prior to treatment.
- A therapeutic endpoint should be determined prior to treatment.
- The least potent glucocorticoid should be used at the lowest dose for the shortest amount of time.
- It is important to understand when glucocorticoid use is inappropriate (eg, acute infection, diabetes).[5]

See ***Glucocorticoid Agents, General Information.***

Pharmacology/Actions

Dexamethasone is a long-acting glucocorticoid with a rapid onset. Glucocorticoids have effect on virtually every cell type and system:

- **Cardiovascular system**: Glucocorticoids can reduce capillary permeability and enhance vasoconstriction. Increased blood pressure and a clinically insignificant positive inotropic effect can occur after glucocorticoid administration.
- **Cells**: Glucocorticoids can inhibit fibroblast proliferation, macrophage response to migration inhibiting factor, sensitization of lymphocytes, and cellular response to inflammation mediators; they can also stabilize lysosomal membranes.
- **CNS/autonomic nervous system**: Glucocorticoids can lower seizure threshold, alter mood and behavior, diminish response to pyrogens, stimulate appetite, and maintain α rhythm. Glucocorticoids are necessary for normal adrenergic receptor sensitivity.
- **Endocrine system**: When an animal is not stressed, glucocorticoids suppress the release of corticotropin (adrenocorticotropic hormone [ACTH]) from the anterior pituitary, which reduces or prevents the release of endogenous corticosteroids. Stress factors (eg, renal disease, liver disease, diabetes) may occasionally nullify the suppressing aspects of exogenously administered steroids. The release of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), prolactin, and luteinizing hormone may be reduced when glucocorticoids are administered at pharmacologic doses. Conversion of thyroxine (T_4) to triiodothyronine (T_3) may be reduced by glucocorticoids, and plasma levels of parathyroid hormone may be increased. Glucocorticoids may inhibit osteoblast function. Vasopressin (antidiuretic hormone [ADH]) activity is reduced at the renal tubules, and diuresis may occur. Glucocorticoids inhibit insulin binding to insulin receptors and the postreceptor effects of insulin.
- **Fluid and electrolyte balance**: Glucocorticoids can increase renal potassium and calcium excretion, sodium and chloride reabsorption, and extracellular fluid volume. Hypokalemia and/or hypocalcemia rarely occur. Diuresis may develop following glucocorticoid administration.
- **GI tract and hepatic system**: Glucocorticoids increase the secretion of gastric acid, pepsin, and trypsin. Glucocorticoids alter the structure of mucin and decrease mucosal cell prolifer-

ation. Iron salts and calcium absorption are decreased, whereas fat absorption is increased. Hepatic changes can include increased fat and glycogen deposits in hepatocytes and increased serum concentrations of alanine aminotransferase (ALT) and gamma-glutamyl transpeptidase (GGT). Significant increases can be seen in serum alkaline phosphatase (ALP) concentrations. Glucocorticoids can cause minor increases in bromosulfophthalein (BSP) retention time.

- **Hematopoietic system**: Glucocorticoids can increase the number of circulating platelets, neutrophils, and red blood cells (RBCs), but platelet aggregation is inhibited. Decreased amounts of lymphocytes (peripheral), monocytes, and eosinophils can be seen, as glucocorticoids sequester these cells in the lungs and spleen and can decrease the release from bone marrow; removal of old RBCs becomes diminished. Glucocorticoids can cause involution of lymphoid tissue.
- **Immune system** (also see ***Cells*** and ***Hematopoietic system***): Glucocorticoids can decrease circulating levels of T lymphocytes; inhibit lymphokines; inhibit neutrophil, macrophage, and monocyte migration; reduce production of interferon; and inhibit phagocytosis, chemotaxis, antigen processing, and intracellular killing. Specific acquired immunity is affected less than nonspecific immune responses. Glucocorticoids can also antagonize the complement cascade and mask clinical signs of infection. Mast cells are decreased in number, and histamine synthesis is suppressed. Many of these effects only occur at high doses, and different species have different responses.
- **Metabolic effects**: Glucocorticoids stimulate gluconeogenesis. Lipogenesis is enhanced in certain areas of the body (eg, abdomen), and adipose tissue can be redistributed away from the extremities to the trunk. Fatty acids are mobilized from tissue, and their oxidation is increased. Plasma levels of triglycerides, cholesterol, and glycerol are increased. Protein is mobilized from most areas of the body (except the liver).
- **Musculoskeletal**: Glucocorticoids can cause muscular weakness, atrophy, and osteoporosis. Bone growth can be inhibited via growth hormone and somatomedin inhibition, increased calcium excretion, and inhibition of vitamin D activation. Resorption of bone can be enhanced. Fibrocartilage growth is also inhibited.
- **Ophthalmic**: Prolonged glucocorticoid use (both systemic or topically to the eye) can cause increased intraocular pressure, glaucoma, cataracts, and exophthalmos.
- **Skin**: Thinning of dermal tissue and skin atrophy can be seen with glucocorticoid therapy. Hair follicles can become distended, and alopecia can occur.

Pharmacokinetics

The pharmacokinetics of dexamethasone do not translate into pharmacologic effects. The half-life of dexamethasone in dogs is ≈2 to 5 hours, but biologic activity can persist for 48 hours or more after administration. In a study, transdermal absorption was *not* demonstrated after dexamethasone 0.25 mg/0.05 mL in PLO was applied to the inner pinna of healthy cats.[6] The half-life in cattle is ≈4.5 to 5 hours.[7,8] In a study of horses, after doses of 0.05 mg/kg PO, IV, IM, or IA, half-life was ≈3.5 hours, and endogenous cortisol concentrations did not return to baseline until 96 to 120 hours (IV, IM, and IA) and 72 hours (PO) after administration.[9] In another study, bioavailability of dexamethasone sodium phosphate injection delivered via nebulization to healthy horses was 4.3%.[10] Application of dexamethasone ophthalmic ointment to equines has been shown to produce anti-inflammatory concentrations only in the anterior parts of the eye, but dexamethasone has been detected in the serum of horses receiving 7 applications per day.[11] Dermal dexamethasone application to horses has been shown to suppress plasma cortisol more than 75% below baseline and blunt cortisol response to ACTH stimulation.[12]

Contraindications/Precautions/Warnings

Because dexamethasone has negligible mineralocorticoid effects, it should generally not be used alone in the treatment of adrenal insufficiency.

The injectable propylene glycol base product should not be administered rapidly IV, as hypotension, collapse, and hemolytic anemia can occur. Many clinicians only use dexamethasone sodium phosphate when administering the drug IV.

Systemic use of glucocorticoids is generally contraindicated in patients with systemic fungal infections (unless used for replacement therapy for Addison's disease), when administered IM in patients with idiopathic thrombocytopenia, and in patients hypersensitive to glucocorticoids. Concurrent use of sustained-release injectable glucocorticoids is contraindicated with chronic corticosteroid therapy in the treatment of systemic diseases. Corticosteroid use may be contraindicated in horses predisposed to laminitis or exhibiting endocrinopathies.

Patients that have received systemic glucocorticoids for more than 2 weeks should be slowly tapered off the drug to allow return of normal endogenous ACTH and corticosteroid function. If the animal undergoes a stressful event (eg, surgery, trauma, illness) during the tapering process and/or before normal adrenal and pituitary functions resume, additional glucocorticoids should be administered.

Animals, particularly cats, at risk for diabetes mellitus (eg, obese patients, patients with hyperadrenocorticism) should receive glucocorticoids with caution due to the potent hyperglycemic effect.

In dogs, dexamethasone can cause more GI complications and bleeding as compared with prednisone, so careful attention to the minimum dose necessary is required. There is a high incidence of GI bleeding and colonic perforation in canine neurosurgical patients treated with dexamethasone (also seen with methylprednisolone sodium succinate); as a result, the dose and duration of therapy should be limited to as short a time as possible, and prednisone or prednisolone should be used instead of dexamethasone when possible.[13] Animals with significantly diminished renal function may be more susceptible to adverse GI effects.

Use dexamethasone with caution in rabbits as serious adverse effects may occur, even after single doses.

Dexamethasone sodium phosphate delivered via nebulization is not an effective treatment for severe equine asthma.[10,14,15] Dexamethasone should be withdrawn at least 14 days prior to intradermal skin testing in horses.[16] Intra-articular dexamethasone administration to horses results in systemic endocrine effects.[9,17]

Adverse Effects

Adverse effects are generally associated with long-term administration of these drugs, especially if the drugs are administered at high doses or not on an alternate-day regimen. Effects typically manifest as clinical signs of hyperadrenocorticism. Glucocorticoids can delay growth when administered to young, growing animals. A list of potential effects is provided in ***Glucocorticoid Agents, General Information***.

In dogs, polyuria (PU), polydipsia (PD), and polyphagia (PP) may occur during short-term burst therapy and on days when the drug is administered during alternate-day maintenance therapy. Adverse effects in dogs can include dull/dry coat, weight gain, panting, vomiting, diarrhea, elevated liver enzymes, GI ulceration/perforation (especially with high parenteral or oral doses), hypercoagulability, hyperlipidemia, activation or worsening of diabetes mellitus, muscle wasting, and behavior changes (eg, depression, lethargy, aggression).[18] Glucocorticoids have been known to delay growth in young animals. Discontinuation of the drug may be necessary; changing to

an alternate steroid may also alleviate adverse effects. Adverse effects associated with anti-inflammatory therapy are relatively uncommon, with the exception of PU, PD, and PP. Adverse effects (eg, secondary infections) associated with immunosuppressive doses are more common and potentially more severe.

High dexamethasone doses in dogs with spinal cord injuries have caused fatal colonic perforations.

In a study, topical otic and dermal dexamethasone administration to healthy beagles reduced cortisol and thyroid T_4 and T_3 concentrations.[19]

Cats generally require higher doses than dogs for clinical effects but typically develop fewer adverse effects. Glucocorticoids appear to have a greater hyperglycemic effect in cats than in other species. Occasionally, PU, PD, and PP with weight gain, diarrhea, and/or depression will be present. Long-term, high-dose therapy can lead to Cushingoid effects. Increases in intraocular pressure have been reported after prolonged administration of dexamethasone eye drops.[20]

Administration of dexamethasone or triamcinolone may play a role in the development of laminitis in horses, but this is thought to only occur rarely. In a study of healthy adult horses, hyperglycemia and hyperinsulinemia returned to baseline values within 2 to 3 days of discontinuing dexamethasone, but recovery of insulin secretion was delayed by ≈2 weeks.[21]

In pigeons, dexamethasone at high doses (0.5 mg/kg IV) suppressed the hypothalamic–pituitary–adrenal (HPA) axis for ≈52 hours, and suppression may persist longer as compared with dogs and cats.[22] Birds appear particularly susceptible to immunosuppressive effects.[23]

Reproductive/Nursing Safety

A positive effect of dexamethasone supplementation on preimplantation of in vitro bovine embryos has been reported.[24,25] Pregnancy rate has reportedly been enhanced by dexamethasone injection administered during early lactation[26] or with intrauterine dexamethasone administration at the time of artificial insemination.[25] Corticosteroid therapy may induce parturition in large animal species during the later stages of pregnancy. Dexamethasone administered to pregnant mares has altered foal pancreatic cell function.[27] Use of corticosteroids in pregnant laboratory animals has resulted in cleft palate.[28]

Corticosteroids are present in human breast milk.[29] In humans, single doses of dexamethasone are considered compatible with breastfeeding. Exposure of the nursing offspring to dexamethasone over a longer time period may suppress growth or interfere with endogenous corticosteroid production.[30]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

When administered in the short term, glucocorticoids are unlikely to cause significant harmful effects, but dogs may be susceptible to GI ulceration/perforation. Should clinical signs occur, supportive treatment should be implemented if necessary.

Chronic glucocorticoid administration can lead to serious adverse effects. Refer to the ***Adverse Effects*** section for more information.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dexamethasone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Amphotericin B**: May cause hypokalemia when administered concomitantly with glucocorticoids
- **Anticholinesterase Agents** (eg, **pyridostigmine, neostigmine**): In patients with myasthenia gravis, concomitant glucocorticoid and anticholinesterase agent administration may lead to profound muscle weakness. If possible, anticholinesterase medication should be discontinued at least 24 hours prior to glucocorticoid administration.
- **Aspirin**: Concurrent use with glucocorticoids may reduce salicylate blood concentrations.
- **Azole Antifungals**: May decrease the metabolism of glucocorticoids and increase dexamethasone blood concentrations; ketoconazole may induce adrenal insufficiency when glucocorticoids are withdrawn by inhibiting adrenal corticosteroid synthesis.
- **Cyclophosphamide**: Glucocorticoids may inhibit the hepatic metabolism of cyclophosphamide; cyclophosphamide dosage adjustments may be required.
- **Cyclosporine**: Concomitant administration of glucocorticoids and cyclosporine may increase blood concentrations of each by mutually inhibiting the hepatic metabolism of each other; the clinical significance of this interaction is not clear.
- **Diazepam**: Concurrent use with dexamethasone may decrease diazepam concentrations.
- **Diuretics, Potassium-Depleting** (eg, **furosemide, thiazides**): May cause hypokalemia when administered concomitantly with glucocorticoids
- **Doxorubicin**: Concurrent use with dexamethasone may result in decreased doxorubicin exposure.
- **Ephedrine**: May reduce dexamethasone blood levels and interfere with dexamethasone suppression tests
- **Fentanyl**: Concurrent use with dexamethasone may result in decreased plasma concentrations of fentanyl.
- **Fluoroquinolone Antibiotics** (eg, **enrofloxacin**, **marbofloxacin**): Concurrent use with glucocorticoids may result in an increased risk for tendon rupture.
- **Insulin**: Insulin requirements may increase in patients receiving glucocorticoids.
- **Ivermectin**: Dexamethasone may alter ivermectin pharmacokinetics by modulating P-glycoprotein.[31] In a study in cattle, concurrent dexamethasone injection impaired ivermectin anthelmintic activity against *Cooperia oncophora* but not *Osteragia ostertagia*.[32]
- **Macrolide Antibiotics** (eg, **erythromycin, clarithromycin**): May decrease the metabolism of glucocorticoids and increase dexamethasone blood concentrations
- **Mitotane**: May alter the metabolism of steroids; higher than usual doses of steroids may be necessary to treat mitotane-induced adrenal insufficiency
- **Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)**: Administration of ulcerogenic drugs with glucocorticoids may increase the risk for GI ulceration.
- **Phenobarbital**: Concurrent use with glucocorticoids may result in decreased dexamethasone efficacy.
- **Praziquantel**: Concurrent use with dexamethasone may significantly decrease praziquantel plasma concentrations.
- **Quinidine**: In a study of dogs, dexamethasone increased quinidine volume of distribution (49% to 78%) and elimination half-life (1.5 to 2.3 times greater than that associated with quinidine use alone).[33]

- **Rifampin**: May increase the metabolism of glucocorticoids and decrease dexamethasone blood concentrations
- **Vaccines, Modified Live**: Patients receiving immunosuppressive doses of glucocorticoids should generally not receive live attenuated-virus vaccines, as virus replication may be augmented; a diminished immune response may occur after vaccine, toxoid, or bacterin administration in patients receiving glucocorticoids.
- **Vincristine**: Concurrent use with dexamethasone may result in decreased vincristine plasma concentrations.

Laboratory Considerations

- Although dexamethasone does not interfere with the cortisol assay, it will start to suppress the hypothalamic–pituitary–adrenal (HPA) axis over a few days and thus suppress endogenous release of cortisol. If dexamethasone is being used to treat patients with suspected hypoadrenocorticism, **ACTH stimulation tests** should be performed as soon as possible. When interpreting the results of the ACTH stimulation test, the effects of dexamethasone on the HPA axis should be considered.
- Glucocorticoids may increase **serum cholesterol**.
- Glucocorticoids may induce **ALP** activity in dogs but not cats.
- Glucocorticoids may increase **urine glucose** concentrations.
- Glucocorticoids may decrease **serum potassium.**
- Glucocorticoids can suppress the release of **thyroid stimulating hormone (TSH)** and reduce $\mathbf{T_3}$ and $\mathbf{T_4}$ values. Thyroid gland atrophy has been reported after chronic glucocorticoid administration. Uptake of I^{-131} by the thyroid may be decreased by glucocorticoids.
- Reactions to **skin tests** may be suppressed by glucocorticoids.
- False negative results of the **nitroblue tetrazolium** test for systemic bacterial infections may be induced by glucocorticoids.
- Glucocorticoids may cause **neutrophilia** within 4 to 8 hours of administration, which can return to baseline within 24 to 48 hours after drug discontinuation.
- Glucocorticoids can cause **lymphopenia** in dogs; this effect can persist for weeks after drug discontinuation.

Dosages

NOTE: All dosages should be titrated to effect to maximize therapeutic benefit but minimize adverse effects. Strong scientific evidence for dose regimens is lacking, and the following serve as guidelines.

DOGS:

NOTE: In general, most clinicians use prednisone or prednisolone when administering a glucocorticoid orally as an anti-inflammatory or immunosuppressive agent in dogs. Despite a short circulating half-life, dexamethasone has a long biologic duration of effect (thought to be greater than 48 hours, whereas the biologic duration of effect of prednisone is 12 to 36 hours). Thus, it is difficult to spare normal adrenal function, even when dexamethasone is administered every other day.[13] The dose of dexamethasone can be extrapolated from standard prednis(ol)one dosages by dividing by 7 (ie, prednis(ol)one 1 mg/kg/day is equivalent to 0.14 mg/kg/day dexamethasone).

Anti-inflammatory; glucocorticoid agent (label dosage; FDA-approved): **NOTE**: The label dosage for dogs is much higher than what is generally used by most clinicians today. Injection: 0.25 – 1 mg/dog (NOT mg/kg) IV or IM[34]; may be repeated for 3 to 5 days. Tablets: 0.25 – 1.25 mg/dog (NOT mg/kg) PO daily in single or 2 divided doses[35]

Anti-inflammatory; glucocorticoid agent (extra-label): 0.1 mg/kg IM or 0.05 – 2 mg/kg PO daily

Initial anti-inflammatory indications (extra-label): 0.07 – 0.14 mg/kg/day[36,37]

Postvaccination reactions (extra-label): 0.1 mg/kg IV once. Dogs that have a mild postvaccination reaction that requires treatment should receive a single, anti-inflammatory dose.[38]

Replacement of glucocorticoid activity in patients with adrenal insufficiency (**NOTE**: Dexamethasone has no mineralocorticoid activity):

a) **Addisonian crisis**: Dexamethasone sodium phosphate 0.1 – 0.2 mg/kg IV as the initial dose. Dexamethasone is not measured on the cortisol assay, so the ACTH stimulation test will be valid after dexamethasone is administered. If the dog is vomiting or inappetent, dexamethasone may be continued at 0.05 – 0.1 mg/kg IV every 12 hours until able to switch to oral predniso(lo)ne as the glucocorticoid replacement (see ***Prednisolone/Prednisone*** for more information).[13]

b) **Addisonian crisis**: Dexamethasone sodium phosphate 0.2 – 0.5 mg/kg IV once; followed by maintenance therapy with prednisone. Dexamethasone, unlike prednisone, will not interfere with cortisol assays.[39]

Immunosuppressive agent (eg, immune-mediated hemolytic anemia; extra-label): 0.2 – 0.4 mg/kg/day IV on a temporary basis if the patient cannot tolerate oral medication.[40] One publication describes injectable and oral dexamethasone for the treatment of masticatory muscle myositis in dogs, with an initial injectable dosage of 0.2 mg/kg followed by an initial oral dosage of ≈0.1 mg/kg that was then tapered over time.[3]

As a chemotherapeutic agent (extra-label):

a) **Parenteral glucocorticoid therapy when oral predniso(lo)ne is not an option**: Anecdotally, calculate prednis(ol)one equivalent dosage (predniso(ol)ne dosage divided by 7) and administer IV until oral prednis(ol)one may be instituted.

b) **Lymphoma rescue protocol (DMAC)**: Dexamethasone 1 mg/kg PO or SC with actinomycin D 0.75 mg/m^2 IV and cytarabine 300 mg/m^2 SC or IV as a 4-hour CRI on day 1; followed by dexamethasone 1 mg/kg PO or SC and melphalan 20 mg/m^2 PO on day 8 of a 14-day cycle. This treatment cycle is repeated every 2 weeks while the dog is in remission (complete or partial) or demonstrates static disease or until signs of relapse or progressive disease occur.[1] It is recommended to consult with a board-certified oncologist or an oncology textbook for further details surrounding chemotherapy protocols.

As a diagnostic agent:

a) **Low-dose dexamethasone suppression (LDDS) test** (extra-label): Plasma samples for cortisol should be obtained before and 4 and 8 hours after administration of dexamethasone 0.01 mg/kg IV. The 8-hour plasma cortisol level is used as a screening test for hyperadrenocorticism; cortisol concentrations above the laboratory cutoff (often greater than 1.4 µg/dL) are consistent with hyperadrenocorticism. The LDDS test is a *screening* test with a sensitivity of 85% to 100% and specificity of 44% to 73%.[41] Approximately 90% of dogs with hyperadrenocorticism have an 8-hour postdexamethasone plasma cortisol concentration greater than 1.4 µg/dL, and another 6% to 8% have values of 0.9 to 1.3 µg/dL. The results of a LDDS test may also aid in discriminating pituitary-dependent hyperadrenocorticism (PDH) from adrenocortical tumor (ACT) using 3 criteria. If a dog has hyperadrenocorticism and it meets any of these 3 criteria, it most likely has PDH: 1) an 8-hour plasma cortisol greater than 1.4 µg/dL but less than 50% of the basal value, 2) a 4-hour plasma cortisol concentration less than 1 µg/dL, and 3) a 4-hour plasma cortisol concentration less than 50% of the basal value. Approximately 65% of dogs with naturally occurring PDH demonstrate suppression as defined by these 3 criteria. A dog with hyperadrenocorticism that fails to meet any of these 3 cri-

teria could have either PDH or ACT. Additional testing with abdominal ultrasonography or high-dose dexamethasone suppression (see below) may be helpful in distinguishing between the 2 conditions; if 2 relatively equal-sized adrenal glands are present on abdominal ultrasonography, the patient most likely has PDH.[42]

b) **High-dose dexamethasone suppression (HDDS) test** (extra-label): Plasma samples for cortisol should be obtained before and 4 and 8 hours after administration of dexamethasone 0.1 mg/kg IV. The HDDS test is a *differentiating* test to discriminate PDH from an ACT; it should only be performed in dogs when a screening test (LDDS or ACTH stimulation test) is diagnostic for hyperadrenocorticism. Dogs with HDDS results that meet any of the following criteria likely have PDH: 1) a 4- or 8-hour plasma cortisol less than 50% of the basal value or 2) a 4- or 8-hour plasma cortisol less than the laboratory cutoff (often ≈1 – 1.5 µg/dL). Approximately 75% of dogs with PDH demonstrate suppression with the HDDS test. Because ≈65% of PDH dogs demonstrate suppression with the LDDS test (consistent with PDH), the HDDS test may only identify an additional 10% of afflicted dogs.[41]

CATS:

NOTE: Generally, most clinicians use prednisolone when a glucocorticoid is administered orally to cats. Approximately 0.75 mg of dexamethasone is equivalent to 5 mg of prednisolone. Doses can be approximated by dividing the prednisolone dose by 7 to obtain the dexamethasone dose.

Anti-inflammatory; glucocorticoid agent (label dosage): Injection: 0.125 – 0.5 mg/cat (NOT mg/kg) IV or IM[34]; may be repeated for 3 to 5 days; Tablets: 0.125 – 0.5 mg/cat (NOT mg/kg) PO daily in a single dose or 2 divided doses[35]

Anti-inflammatory; glucocorticoid agent (extra-label): Injection: 0.1 mg/kg IM. Tablets: 0.05 – 2 mg/kg/day orally

Initial anti-inflammatory indications (extra-label): 0.14 – 0.28 mg/kg/day[36,37]

Hypersensitivity dermatitis (extra-label): Using dexamethasone sodium phosphate (4 mg/mL) *injection*, 0.2 mg/kg/day PO rapidly relieved pruritus and clinical lesions.[43]

Replacement of glucocorticoid activity in patients with adrenal insufficiency (**NOTE**: Dexamethasone has no mineralocorticoid activity): Dexamethasone sodium phosphate 0.1 – 0.2 mg/kg IV or IM as the initial dose.[44] Dexamethasone is not measured on the cortisol assay, so the ACTH stimulation test will be valid after dexamethasone is administered. If the cat is vomiting or inappetent, dexamethasone may be continued every 12 hours until able to switch to oral prednisolone as the glucocorticoid replacement. See ***Prednisolone/Prednisone***.

As a diagnostic agent:

a) **Low-dose dexamethasone suppression (LDDS) test** (extra-label): Test of choice for the initial diagnosis of feline hyperadrenocorticism. **NOTE**: Cats require a higher dexamethasone dosage for this test than dogs. Plasma samples for cortisol should be obtained before and 4 and 8 hours after administration of dexamethasone 0.1 mg/kg IV. A cortisol concentration greater than or equal to 1.4 µg/dL is consistent with a diagnosis of hyperadrenocorticism if the patient is also displaying appropriate clinical signs.[45,46]

b) **High-dose dexamethasone suppression (HDDS) test** (extra-label): Hyperadrenocorticism should be confirmed before performing this test to differentiate PDH from ACT. **NOTE**: Cats require a higher dexamethasone dosage for this test than dogs. Plasma samples for cortisol should be obtained before and 4 and 8 hours after administration of dexamethasone 1 mg/kg IV. Cats with HDDS results that meet any of the following criteria likely have PDH: 1) a 4- or 8-hour plasma cortisol less than 50% of the basal value or 2) a 4- or 8-hour plasma cortisol less than the laboratory cutoff (often ≈1 – 1.5 µg/dL).

c) **HDDS test combined with urine cortisol creatinine ratio (UCCR;** extra-label): For cats with elevated UCCR values *and* clinical signs consistent with hyperadrenocorticism: At home, dexamethasone 0.1 mg/kg PO every 8 hours, with urine samples collected the following morning to perform UCCR.[46] If the postdexamethasone UCCR is less than 50% of the pretest samples, the results are consistent with PDH; results greater than 50% do not discriminate between PDH and ACT.

HORSES:

Anti-inflammatory; glucocorticoid agent (label dosage; FDA-approved): dexamethasone 2.5 – 5 mg/horse (NOT mg/kg) IV or IM[34]; dexamethasone sodium phosphate: 2.5 – 5 mg/horse (NOT mg/kg) IV[47]

Anti-inflammatory; glucocorticoid agent (extra-label): Injection: 0.06 mg/kg IM or IV[48]

Adjunctive treatment of severe equine asthma (extra-label):

a) For a 500 kg (1102.3 lb) horse, dexamethasone 40 mg/horse (NOT mg/kg) IM once every other day for 3 treatments, followed by 35 mg/horse (NOT mg/kg) IM once every other day for 3 treatments, followed by 30 mg/horse (NOT mg/kg) IM once every other day for 3 treatments; continue tapering until horse is weaned off this therapy.[49]

b) For short-term treatment with environmental control: In a study, dexamethasone sodium phosphate was dosed at 0.1 mg/kg IM once daily for 4 days, 0.075 mg/kg IM once daily for 4 days, and 0.05 mg/kg IM once daily for 4 days. Except for bronchoalveolar lavage cytology results, PO prednisolone (1 mg/kg PO for 4 days, 0.75 mg/kg PO for 4 days, 0.5 mg/kg PO for 4 days) was shown to be as effective as IM dexamethasone.[50]

c) In a study, dexamethasone 0.05 mg/kg IM every 24 hours was as effective as inhaled fluticasone in reducing clinical signs, airway inflammatory cells, and bronchoprovocative histamine response.[51]

d) In a study, horses under continuous antigen exposure were given dexamethasone at 0.05 mg/kg PO once daily for 7 days or prednisolone at 2 mg/kg PO once daily for 7 days. Both were effective but dexamethasone more so.[52]

e) In a study, horses received 0.1 mg/kg PO once daily for 3 weeks. The study states: *The VAS (visual analog scale) score (owner scored) improved significantly in dexamethasone but not placebo treated horses. In contrast, the clinician failed to differentiate between dexamethasone and placebo treated animals based on clinical observations, BALF cytology or endoscopic mucus score. Respiratory rate and arterial oxygen pressure (PaO_2) improved with dexamethasone but not placebo. The authors concluded, in the design of clinical trials of airway disease treatments, more emphasis should be placed on owner-assessed VAS than on clinical, cytological and endoscopic observations made during brief examinations by a veterinarian*.[53]

Dexamethasone suppression test to diagnose pituitary pars intermedia dysfunction (extra-label):

a) 20 mg/horse (NOT mg/kg) IM. Normal values: Cortisol levels should decrease by 50% in 2 hours, 70% in 4 hours, and 80% in 6 hours. At 24 hours, cortisol levels should remain depressed by ≈30% of presuppression value.[54] Seasonal variability may

affect results.[55]

b) After baseline cortisol (serum or plasma) is collected, dexamethasone 0.04 mg/kg IM can be administered, and a second cortisol sample collected 18 to 20 hours later.[56] Cortisol values greater than 10 µg/mL are diagnostic. Testing performed in autumn is more likely to yield false positive results.[57]

Treatment of arthritis, bursitis, or tenosynovitis (extra-label): 2 – 10 mg/horse (NOT mg/kg) as an intra-articular injection[48]

CATTLE:

Primary bovine ketosis | anti-inflammatory agent (label dosage; FDA-approved): 5 – 20 mg/cow (NOT mg/kg) IV or IM[34]

Anti-inflammatory; glucocorticoid agent (label dosage; FDA-approved): 5 – 10 mg/animal (NOT mg/kg) PO on the first day, then 5 mg/animal (NOT mg/kg) PO daily as required.[58] Administer as a drench or sprinkled on a small amount of feed.

Primary bovine ketosis (extra-label): 0.02 – 0.04 mg/kg IM. Larger doses will be required if the signs have been present for some time or if relapsed animals are being treated[48]

Anti-inflammatory; glucocorticoid agent (extra-label): 0.06 mg/kg IM[48]

Induction of parturition (extra-label): A single injection of 0.04 mg/kg IM after day 260 of pregnancy.[48] Parturition will normally occur within 48 to 72 hours.

SWINE:

Anti-inflammatory; glucocorticoid agent (extra-label): 0.06 mg/kg IM[48]

RABBITS/RODENTS/SMALL MAMMALS:

Mice, rats, gerbils, hamsters, guinea pigs, chinchillas (extra-label): 0.6 mg/kg IM (as an anti-inflammatory)[59]

Monitoring

Monitoring of glucocorticoid therapy is dependent on the reason for use, dosage, agent used (amount of mineralocorticoid activity), dose schedule (daily versus alternate-day therapy), duration of therapy, and the animal's age and condition. The following list may not be appropriate or complete for all animals; clinical assessment and judgment should be used if adverse effects are noted:

- Weight, appetite, and/or signs of fluid retention
- Serum and/or urine electrolytes
- Total plasma protein and albumin
- Blood glucose
- Periodic urine culture especially with chronic use
- GI adverse effects (eg, vomiting, diarrhea, melena)
- Growth and development in young animals

Client Information

- Long-acting glucocorticoid that is best given with food but may be given without. If your animal vomits or acts sick after receiving the drug on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- There are many side effects, especially when the drug is used long term. The most common side effects in dogs are excessive thirst, urinations, and appetite.
- In dogs, stomach or intestinal ulcers, perforation, or bleeding can occur. The risk for this occurring is increased if used with drugs like aspirin, NSAIDs (eg, carprofen) or other cortisone-like drugs (eg, prednisone). If your animal stops eating, or develops a low energy level, black tarry stools, or bloody vomit, contact your veterinarian immediately.
- Do not stop this drug suddenly if your animal has been on the drug for more than a couple of weeks as serious side effects could occur.

Chemistry/Synonyms

Dexamethasone, a synthetic glucocorticoid, occurs as an odorless white to practically white crystalline powder that melts with some decomposition at ≈250°C (482°F). It is practically insoluble in water and sparingly soluble in alcohol. Dexamethasone sodium phosphate occurs as a white to slightly yellow hygroscopic powder and is odorless or has a slight odor. One gram is soluble in ≈2 mL of water; it is slightly soluble in alcohol.

1.3 mg of dexamethasone sodium phosphate is equivalent to 1 mg of dexamethasone. 4 mg/mL of dexamethasone sodium phosphate injection is equivalent to ≈3 mg/mL of dexamethasone.

Dexamethasone may also be known as desamethasone, dexametasone, dexamethasonum, 9-alpha-fluoro-16-alpha-methylprednisolone; hexadecadrol; many trade names are available.

Storage/Stability

Dexamethasone is heat labile and should be stored at room temperature (15°C-30°C [59°F-86°F]) unless otherwise directed by the manufacturer. Dexamethasone sodium phosphate injection should be protected from light. Dexamethasone tablets should be stored in well-closed containers.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dexamethasone sodium phosphate for injection is reportedly **compatible** with the following drugs: amikacin sulfate, aminophylline, bleomycin sulfate, cimetidine HCl, glycopyrrolate, lidocaine HCl, prochlorperazine edisylate, and verapamil.

Dexamethasone sodium phosphate is reportedly **incompatible** with daunorubicin HCl, doxorubicin HCl, metaraminol bitartrate, and vancomycin.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Dexamethasone Injection: 2 mg/mL; *Azium® Solution*, generic; (Rx). FDA-approved for use in dogs, cats, horses (those not intended for food), and cattle. There are no withdrawal times required for use in cattle. A withdrawal period has not been established for this product in preruminal calves; should not be used in veal calves

Dexamethasone Sodium Phosphate Injection: 4 mg/mL (equivalent to 3 mg/mL dexamethasone), generic; (Rx). FDA-approved for use in horses

Dexamethasone Oral Powder: 10 mg crystalline in 10 mg packets; *Azium® Powder*; (Rx). FDA-approved for use in cattle and horses (not horses intended for food)

Dexamethasone 5 mg and trichlormethiazide 200 mg oral bolus: In boxes of 30 and 100 boluses; *Naquasone® Bolus*; (Rx). FDA-approved for use in cattle. Milk withdrawal = 72 hours

The Association of Racing Commissioners International (ARCI) has designated dexamethasone as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Dexamethasone Oral Tablets: 0.5 mg, 0.75 mg, 1 mg, 1.5 mg, 2 mg, 4 mg, and 6 mg; *Decadron®*, generic; (Rx)

Dexamethasone Oral Elixir/Solution: 0.5 mg/5 mL in 100 mL, 237 mL, and 500 mL and UD 5 mL and UD 20 mL; 1 mg/mL (concentrate) in 30 mL with dropper; *Dexamethasone Intensol®*, generic; (Rx)

Dexamethasone Sodium Phosphate Injection: 4 mg/mL (as sodium phosphate solution) in 1 mL, 5 mL, 10 mL, and 30 mL vials, 1 mL syringe and 1 mL fill in 2 mL vials; generic; (Rx); 10 mg/mL (as sodium phosphate solution) in 1 mL and 10 mL vials and 1 mL syringes; generic; (Rx); 20 mg/mL (as sodium phosphate solution) in 5 mL vials (IV); *Hexadrol® Phosphate*; (Rx)

Dexamethasone is also available in topical ophthalmic and inhaled aerosol dose forms.

Dexmedetomidine

(deks-mee-deh-***toe***-mih-deen) *Dexdomitor®, Sileo®*

Alpha-2-*Adrenergic Agonist*

Prescriber Highlights

- ► Reversible sedative analgesic used primarily in dogs, cats, small mammals, and exotic species; can also be used as an emetic in cats.
- ► Contraindications include most forms of cardiac disease, respiratory disorders, shock, severe debilitation, or animals stressed due to heat, cold, or fatigue. It is also contraindicated in liver or kidney disease, although some anesthesiologists consider those contraindications to be relative because dexmedetomidine effects can be reversed.
- ► Use with caution in geriatric and pediatric animals.
- ► Adverse effects include bradycardia, occasional AV block, decreased respiratory rate, hypothermia, urination, vomiting, and hyperglycemia. Rarely, prolonged sedation, hypersensitivity, apnea, and death from circulatory failure may occur.
- ► Systemic and central effects may be reversed with atipamezole; however, analgesia will also be reversed, and additional analgesic agents may be required for adequate pain control.
- ► Do **NOT** confuse dexmedetomidine with detomidine or medetomidine.
- ► Gloves should be worn when handling products, particularly the oral transmucosal gel, as the drug is absorbed through the skin, eyes, and mouth.

Uses/Indications

Dexmedetomidine is FDA-approved for dogs and cats for use as a sedative and analgesic to facilitate clinical examinations, clinical procedures, minor surgical procedures, and minor dental procedures and as a preanesthetic to general anesthesia. In cats, the injectable formulation has been used in an extra-label manner as an emetic,[1,2] but hydromorphone may be a better emetic.[3] Dexmedetomidine rapidly controlled clinical signs of sympathetic nervous system stimulation in a 5-month-old kitten that ingested lisdexamphetamine.[4]

The oromucosal gel product (*Sileo®*) is approved for the treatment of noise aversion in dogs and is used extra-label to reduce fear and anxiety during veterinary examinations.[5]

Pharmacology/Actions

Dexmedetomidine is the dextrorotatory enantiomer of the alpha-2-adrenergic agonist medetomidine. The other enantiomer, levomedetomidine, is thought to be pharmacologically inactive[6]; dexmedetomidine is therefore ≈2 times more potent than medetomidine.[7] Dexmedetomidine is more specific than xylazine for alpha-2 receptors versus alpha-1 receptors. The alpha-2 to alpha-1 selectivity of dexmedetomidine and xylazine is 1620:1 and 160:1, respectively.[8]

The pharmacologic effects of dexmedetomidine include depression of CNS (eg, sedation, anxiolysis), GI (eg, decreased secretions, reduced intestinal smooth muscle tone), and endocrine functions (eg, inhibition of insulin release leading to hyperglycemia); peripheral and coronary vasoconstriction; bradycardia; respiratory depression; diuresis; hypothermia; analgesia; muscle relaxation; and blanched or cyanotic mucous membranes. Effects on blood pressure are biphasic, with initial hypertension followed by hypotension; dexmedetomidine can cause hypertension for a longer period than can xylazine. Vomiting is mediated by central alpha-2-adrenergic agonist stimulation.[1,2,9]

Pharmacokinetics

After IM administration to dogs, dexmedetomidine is absorbed (bioavailability 60%) and reaches peak plasma concentrations in ≈35 minutes. Volume of distribution is 0.9 L/kg, and elimination half-life is ≈40 to 50 minutes. The drug is primarily metabolized in the liver via hydroxylation[10,11]; metabolism depends on hepatic blood flow. No metabolites are active, and they are eliminated primarily in the urine and, to lesser extent, in the feces.

The mean bioavailability of the oral transmucosal gel (*Sileo®*) in dogs is 28%. Protein binding is 93%. Peak concentrations occur at ≈0.6 hours, similar to IM administration. Half-life is 0.5 to 3 hours after oromucosal administration.[12,13]

After IM administration in cats, dexmedetomidine is absorbed and reaches peak plasma concentrations of ≈17 ng/mL in ≈15 minutes. Oral transmucosal (OTM [buccal]) administration of dexmedetomidine 0.5 mg/mL injection solution (40 µg/kg) appears to give similar concentrations (extrapolated from clinical effects) as IM administration in cats.[14] Two studies compared OTM versus IM dexmedetomidine 20 µg/kg combined with buprenorphine 20 µg/kg. IM administration resulted in a higher peak dexmedetomidine concentration more quickly than the OTM group,[15] and sedation was more satisfactory with IM administration.[16,17] After administration as a 5-minute IV infusion in isoflurane-anesthetized cats, clearance was 6.3 mL/minute/kg and elimination half-life was 198 minutes.[18] Volume of distribution is 2.2 L/kg and elimination half-life is ≈1 hour. Metabolism occurs via hydroxylation in the liver and is dependent on hepatic blood flow.[19] Metabolites are eliminated primarily in the urine and, to lesser extent, in the feces.

In adult horses given 5 µg/kg IV bolus, elimination half-life was 8.3 minutes; pharmacologic effects (eg, head height, analgesia, bradycardia, reduced ambulation) lasted less than 1 hour.[20] When administered as an IV CRI at 8 µg/kg/hour, volume of distribution at steady-state was 13.7 L/kg, clearance was 0.3 L/minute/kg, and elimination half-life was ≈21 minutes.[21]

In humans, after IV administration, dexmedetomidine is rapidly distributed (volume of distribution ≈1.6 L/kg) and is 94% bound to plasma proteins.[22] It undergoes almost complete biotransformation via both glucuronidation and CYP450 enzyme systems and has a terminal elimination half-life of ≈2 hours. Metabolites are eliminated in the urine and feces. Clearance is reduced in patients with hepatic impairment. CYP450 isoenzymes have, at best, a minor role in dexmedetomidine metabolism.

Contraindications/Precautions/Warnings

Do not use dexmedetomidine in dogs or cats that are hypersensitive to dexmedetomidine or in patients with cardiovascular disease, respiratory disorders, or liver or kidney disease, or in conditions of shock, severe debilitation, stress caused by extreme heat or cold, or fatigue.[23] Because of the pronounced cardiovascular effects of dexmedetomidine, only clinically healthy dogs and cats should be treated; do not use dexmedetomidine in animals with preexisting hypotension, bradycardia, and hypoxia. Although not contraindicated in pediatric or geriatric dogs or cats, the drug's United States label states that the drug has not been evaluated in dogs younger than 16 weeks, in cats younger than 12 weeks, or in geriatric dogs and cats. Geriatric

patients should be dosed based on health, not age. Use with caution in pediatric patients, as cardiac output in this population is heart rate dependent.

Dexmedetomidine should only be used in situations in which sufficient monitoring and patient support capabilities (eg, intubation, ventilation) are available.

Because the systemic and CNS effects of dexmedetomidine are reversible, some anesthesiologists consider dexmedetomidine contraindications to be relative, particularly in patients with hepatic or renal disease. Dexmedetomidine may be used in patients with a seizure history; however, it should not be used in patients with severe CNS clinical signs (eg, obtundation). Not all forms of cardiac disease create a contraindication. For instance, medetomidine administered to cats with left ventricular outflow obstruction improved cardiac function secondary to slowed heart rate with subsequent increased ventricular filling.[24]

Although dexmedetomidine can be used as an emetic in cats, sedation may increase the incidence of aspiration of vomitus. More effective emetics (eg, apomorphine, ropinirole) are available for dogs.

The United Kingdom label states not to use dexmedetomidine in puppies younger than 6 months or kittens younger than 5 months or in animals with cardiovascular disorders, with severe systemic disease, that are moribund, or that are known to be hypersensitive to the active substance or any of the excipients.

Although the manufacturer recommends that patients be fasted for 12 hours before use,[23] general recommendations for fast duration are 4 to 6 hours prior to sedation/anesthesia in most patients due to adverse effects of long-duration fasting (eg, decreased gastric pH, decreased intestinal motility).[25] If vomiting could be detrimental to the patient, an antiemetic should be administered at least 1 hour prior to dexmedetomidine administration.

Transient alpha-2-mediated hyperglycemia is a common sequelae with dexmedetomidine administration.[23]

Dexmedetomidine reduces tear flow in dogs and cats.[26–28] Ophthalmic ointment should be used to protect eyes when using this drug.

The oromucosal product for dogs (*Sileo*®) has not been evaluated in dogs younger than 16 weeks of age or in dogs with dental or gingival disease.[13] Avoid feeding or giving treats within 15 minutes after a dose, as this may decrease absorption from the mucous membranes. Drinking water within that time frame may have the same effect. It should not be swallowed, as it may not be effective. If swallowed, the dose should not be repeated for at least 2 hours to eliminate the risk for overdose in the event that some of the drug was absorbed across the mucous membranes.

Dexmedetomidine effects (eg, sedation, physiologic effects, and analgesia) can be reversed with atipamezole; however, the use of additional analgesics may be required for adequate pain control.

In humans, dose reduction may be necessary in patients with hepatic disease.[22]

Do not confuse dexmedetomidine with dexamethasone, detomidine, or medetomidine. Do not interchange dexmedetomidine with medetomidine dosages. On a **mg**/kg basis, dexmedetomidine doses are ≈½ of the medetomidine dose because dexmedetomidine is more potent; however, dexmedetomidine is ½ the concentration of medetomidine so the doses are the same on a **mL**/kg basis.

Adverse Effects

The adverse effects reported with dexmedetomidine are essentially extensions of its pharmacologic effects, including bradycardia, vasoconstriction, muscle contractions or tremors, transient hypertension, reduced tear production, occasional arrhythmias (second-degree AV block, supraventricular tachycardia [SVT], ventricular escape beats, premature ventricular complexes [PVCs]), hypoventilation, dyspnea, hypothermia, urination, vomiting, hyperglycemia, and decreased or absent pupil response. Hypothermia may persist longer than sedation and analgesia[29]; body temperature may need to be externally maintained. In field studies of dexmedetomidine injection, vomiting occurred in 12% to 25% of dogs and 57% to 68% of cats.[23] Ondansetron[9] and maropitant[30] may ameliorate dexmedetomidine-induced emesis, as may combination with butorphanol.[31]

Rare effects include prolonged sedation, paradoxical excitation, defensive reaction from handling or sudden stimuli, hypersensitivity, pulmonary edema, apnea, and death from circulatory failure.[13,23] Adverse effects that require treatment can generally be alleviated with atipamezole; however, it is important to note that analgesic effects will also be reversed.

In dogs, medetomidine causes a significant decrease in tear production whereas dexmedetomidine caused an initial decrease followed by an increase.[32] Intraocular pressure was decreased. In 2 other studies, dexmedetomidine caused a decrease in tear production lasting for ≈8 hours[33] and occurring within 15 minutes of administration when combined with butorphanol.[28] In the latter study, tear production was improved but still below baseline when atipamezole was administered. The cumulative conclusion from these studies was that dexmedetomidine was safe for patients undergoing ocular procedures but that eye lubrication should be used.

In humans, withdrawal-like symptoms (eg, nausea, vomiting, agitation) occurred in 3% to 5% of patients receiving dexmedetomidine infusion for up to 7 days for ICU sedation.[22] The veterinary significance of this finding is uncertain.

Reproductive/Nursing Safety

Although the product label recommends against use in pregnant dogs or those used for breeding purposes due to lack of safety information, **medetomidine and dexmedetomidine combinations with propofol have demonstrated safety in dogs undergoing cesarean section**.[34,35] The parent drug of dexmedetomidine, medetomidine (7 µg/kg IV), combined with propofol (1 – 2 mg/kg IV) was also determined safe for cesarean sections in dogs.[34]

Placental transfer of dexmedetomidine occurred in pregnant rats. No teratogenic effects were observed when rats were given up to 200 µg/kg SC from days 5 to 16 of gestation or when rabbits were given up to 96 µg/kg IV from days 6 to 18 of gestation.

Dexmedetomidine is distributed into the milk of lactating rats[22]; safe use during nursing has not been established.[22,23]

Overdose/Acute Toxicity

Single doses up to 5 times the label-recommended IV dose and 10 times the label-recommended IM dose were tolerated in healthy young dogs, but adverse effects can occur (see ***Adverse Effects***) in a dose-related manner. Doses of 200 µg/kg IM in cats (5 times the label dose) produced prolonged sedation (longer than 8 hours), reduced respiratory rate, hypothermia, bradycardia, and junctional escape arrhythmias. Vomiting occurred in 5 of 6 cats given 400 µg/kg IM. Because of the potential for additional adverse effects (eg, AV block, PVCs, tachycardia), treatment of dexmedetomidine-induced bradycardia with anticholinergic agents (eg, atropine, glycopyrrolate) is usually not recommended if the blood pressure is normal or high but anticholinergics can be used if both the heart rate and the blood pressure are low. Reversal with atipamezole is recommended to treat any dexmedetomidine-induced adverse effects.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dexmedetomidine or mede-

tomidine (the parent compound of dexmedetomidine) and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate. **NOTE**: Before attempting combination therapy with dexmedetomidine, it is strongly advised to consult veterinary anesthesia references or veterinary anesthesiologists familiar with the use of this drug.

- **Angiotensin-Converting Enzyme Inhibitors** (**ACEIs**; eg, **enalapril**): Additive hypotensive effects may occur.
- **Acepromazine**: Effects may be additive; dose reduction of one or both agents may be required. General anesthetic requirements may be reduced by 30% to 60%.
- **Amlodipine**: Additive hypotensive effects may occur.
- **Anesthetics** (eg, **alfaxalone, isoflurane, ketamine, propofol**): Effects may be additive; dose reduction of one or both agents may be required. General anesthetic requirements may be reduced by 30% to 60%. Dexmedetomidine lowered the seizure threshold in cats undergoing anesthesia with enflurane.[36]
- **Atropine, Glycopyrrolate**: The use of atropine (or glycopyrrolate) with dexmedetomidine can significantly increase arterial blood pressure, heart rate, cardiac work, and may increase the risk for arrhythmias; use together is not recommended in dogs (and probably other species).[37]
- **Benzodiazepines** (eg, **diazepam, midazolam**): Effects may be additive; dose reduction of one or both agents may be required. General anesthetic requirements may be reduced by 30% to 60%.
- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, esmolol, metoprolol**): AV-blocking and bradycardic effects may be enhanced.
- **Epinephrine**: Because epinephrine possesses alpha-agonist effects and could cause or exacerbate hypertension and arrhythmias, it should not be used to treat cardiac effects caused by dexmedetomidine.
- **Opioids** (eg, **butorphanol, morphine**, **tramadol**): Effects may be additive; dose reduction of one or both agents may be required. General anesthetic requirements may be reduced by 30% to 60%. Sedation with buprenorphine and dexmedetomidine is less predictable and of slower onset but longer duration than that achieved with butorphanol and dexmedetomidine.[38,39]
- **Sildenafil**: Additive hypotensive effects may occur.
- **Telmisartan**: Additive hypotensive effects may occur.
- **Yohimbine**: Effects may be partially reversed, but atipamezole is preferred for full reversal of dexmedetomidine's effects.

Laboratory Considerations

Dexmedetomidine can inhibit ADP-induced **platelet aggregation** in cats, but this does not appear to be clinically significant.[40]

Dosages

NOTES:

1. Dexmedetomidine dosages depend on the combination of drugs used and the dosage(s) of the other drug(s). Premedication with dexmedetomidine will significantly reduce the dose of the induction agent required and will reduce volatile anesthetic requirements for maintenance anesthesia. All anesthetic agents used for induction or maintenance of anesthesia should be administered to effect.
2. Dose adjustments will also need to be made to account for the degree of desired sedation; type, duration, and pain level of the procedure; and patient temperament and body weight/size.
3. Dosing based on body surface area (BSA; or allometric scaling) is not common in clinical practice but decreases the variability in drug response between giant/large and small/toy breed dogs. See ***Conversion Tables: Body Weight (kg) to Body Surface Area (m^2)***.
4. For all dosages, the low end of the dose range is generally appropriate for IV administration, whereas the mid-upper range is most appropriate for IM or SC administration. Higher dosages will provide more profound sedation and analgesia.
5. When SC administration is used, the speed of sedation is slower, and the level of sedation is lighter and inconsistent. For more predictable sedation, IM or IV administration is recommended.
6. The effects of dexmedetomidine can be reversed with atipamezole. It is most often dosed by volume at ½ or the same volume of dexmedetomidine that was administered and given IM. See ***Atipamezole***.

DOGS:

Label dosages (FDA-approved):

a) **Sedation and analgesia**: 375 µg/m^2 BSA IV; 500 µg/m^2 BSA IM. The µg/kg dosage decreases as body weight increases. It is recommended that patients be fasted for 12 hours before use.

b) **Preanesthetic agent**: Depending on duration and severity of the procedure and anesthetic regimen: 125 – 375 µg/m^2 BSA IM. The µg/kg dosage decreases as body weight increases. Accurate dosing is not possible with dogs weighing less than 2 kg (4.4 lb). An extensive dosing table using patient weights is available in the package insert. After injection, allow the animal to rest quietly for 15 minutes; sedation/analgesia occurs within 5 to 15 minutes, with peak effects occurring 30 minutes postdose. When used as a preanesthetic, dexmedetomidine can reduce induction agent dose requirements by 30% to 60% and inhalational anesthetic requirements by 40% to 60%. The anesthetic dose should always be titrated against the response of the patient.[23]

c) **Noise aversion using the oromucosal gel (*Sileo*®)**: 125 µg/m^2 BSA administered onto the oral mucosa between the dog's cheek and gum.[13] The first dose should be administered ≈30 to 60 minutes before the fear and/or anxiety-eliciting noise stimulus, immediately after the dog shows the first signs of anxiety or fear related to noise, or when the owner detects a typical noise stimulus (eg, sound of fireworks) eliciting anxiety or fear in the dog. Dosing should only be performed by an adult wearing disposable, impermeable gloves. The gel must be administered using the accompanying syringe (*Sileo*® dot syringe). The following table can be used to convert a dog's body weight into the appropriate number of dots (•).

Body weight (lb)	Number of dots	Body weight (kg)
4.4 – 12.1	1 •	2 – 5.5
12.2 – 26.5	2 ••	5.6 – 12
26.6 – 44	3 •••	12.1 – 20
44.1 – 63.9	4 ••••	20.1 – 29
64 – 86	5 •••••	29.1 – 39
86.1 – 110.2	6 ••••••	39.1 – 50
110.3 – 137.8	7 •••••••	50.1 – 62.6
137.9 – 166.4	8 ••••••••	62.7 – 75.6
166.5 – 196.2	9 •••••••••	75.7 – 89.2
196.3 – 220.5	10 ••••••••••	89.3 – 100.2

If the dose is more than 6 dots, divide the dose between both sides of the mouth. Avoid feeding or giving treats within 15 minutes after a dose, as this may decrease absorption from the

mucous membranes. Drinking water within that time frame may have the same effect. If noise lasts longer than 2 to 3 hours and the dog's signs of fear and/or anxiety reappear, another dose may need to be given. To avoid overdosing, there should always be a pause of at least 2 hours between doses. No more than 5 doses can be given during one noise event. Partially used syringes can be used again within 2 weeks of initial opening, provided there is enough gel to administer a complete dose. To minimize risk for incorrect dosing, a partially used syringe without enough gel for a complete dose should not be used. Make sure to give owner a copy of the client information sheet found on the reverse side of the package insert.[13]

Extra-label dosages:

In combination with an opioid and ketamine (ie, "doggie magic") to provide anesthesia and pain management (extra-label): **NOTE**: Dosing tables for conversion of patient weight to various μg/m^2 doses of dexmedetomidine (based on depth of sedation needed) have been presented.[41] Opioid concentrations used in the reference are butorphanol 10 mg/mL, hydromorphone 2 mg/mL, morphine 15 mg/mL, and buprenorphine 0.3 mg/mL. Ketamine concentration is 100 mg/mL. As these drugs may be available in other concentrations, only use those products with the above concentrations if using this protocol. For lighter sedation/anesthesia, the ketamine can be omitted from these protocols.

a) **Geriatric dogs and dogs with renal or liver dysfunction as a premedication before propofol induction, followed by maintenance on isoflurane or sevoflurane**: Dexmedetomidine 62.5 μg/m^2 IM or IV. Combine this dose with equal volumes of one of the opioids noted above and ± an equal dose of ketamine.

b) **For slightly heavier sedation in ASA class II or III dogs requiring sedation for radiographic procedures**: Dexmedetomidine 125 μg/m^2 IM or IV. Combine this dose with equal volumes of one of the opioids noted above and an equal volume of ketamine.

c) **Dogs undergoing minor surgery, Penn hip, or OFA types of radiographic procedures that require significant muscle relaxation**: Dexmedetomidine 250 μg/m^2 IM or IV. Combine this dose with equal volumes of one of the opioids noted above and an equal volume of ketamine.

d) **Induction of general anesthesia for OHE, castration, or other abdominal surgery**: Dexmedetomidine at 375 μg/m^2 IM or IV. Combine with equal volumes of one of the opioids noted above and an equal volume of ketamine. Provides rapid immobilization; lateral recumbency in 5 to 8 minutes. This protocol provides deep enough sedation to allow intubation before maintenance of general anesthesia. Dogs can be intubated and maintained on oxygen. Supplemental low doses of isoflurane (0.5%) or sevoflurane (1%) can be used.

e) **Immobilizing extremely fractious dogs and wolf-hybrid dogs**: Dexmedetomidine 500 μg/m^2 IM. Combine this dose with equal volumes of one of the opioids noted above and an equal volume of ketamine. **NOTE**: This high dose is rarely required.

In combination with alfaxalone (extra-label): Dexmedetomidine 3 μg/kg in combination with methadone 0.3 mg/kg and alfaxalone 0.5 – 1 mg/kg and administered IM[42]

Postoperative pain management IV CRI in critically ill dogs (extra-label):

a) After surgery, dexmedetomidine 25 μg/m^2 IV as a loading dose followed by dexmedetomidine 25 μg/m^2/hour IV CRI for 24 hours was as effective as morphine 2.5 mg/m^2 IV loading dose, followed by morphine 2.5 mg/m^2/hour CRI.[43]

b) Dexmedetomidine 1 – 2 μg/kg IV as a loading dose followed by 0.72 – 1 μg/kg/hour IV CRI has been used with satisfactory results.[44–47]

Dexmedetomidine/morphine/lidocaine/ketamine (DMLK) (extra-label): Dexmedetomidine 0.5 μg/kg/hour with lidocaine 3 mg/kg/hour, morphine 0.2 mg/kg/hour, and ketamine 0.6 mg/kg/hour admixed in IV fluids and administered as CRI[48]

Dexmedetomidine gel to decrease fear/anxiety prior to veterinary visits (extra-label): 78% of dogs receiving dexmedetomidine 125 μg/m^2 or 250 μg/m^2 were easier to handle and had relaxed body posture compared to only 4.3% of the placebo dogs.[5]

CATS:

Sedation, analgesia, and preanesthesia (label dosage; FDA-approved): 40 μg/kg IM. A dosing table is available in the package insert. After injection, allow the animal to rest quietly for 15 minutes; sedation/analgesia occurs within 5 to 15 minutes, with peak effects occurring 30 minutes postdose. When used as a preanesthetic, dexmedetomidine can markedly reduce anesthetic requirements. The anesthetic dose should always be titrated against the response of the patient.[23]

Extra-label dosages:

Sedation/analgesia when dexmedetomidine is used as a sole agent (extra-label): Dosage ranges commonly used to achieve general sedation levels include:

a) **Light sedation (often used for preanesthesia)**: 5 – 15 μg/kg IV, IM, or SC

b) **Moderate sedation (may be used for preanesthesia if deeper sedation is desired or the patient has a high energy or anxiety level)**: 20 – 30 μg/kg IV, IM, or SC

c) **Deep sedation**: 40 μg/kg IV, IM, or SC

CRI (extra-label): For ovariohysterectomy, hydromorphone 0.1 mg/kg IM premedication was followed by anesthesia induction with propofol 4.3 – 7.8 mg/kg IV; during isoflurane anesthesia cats were given dexmedetomidine 0.5 μg/kg IV loading dose followed by dexmedetomidine 0.5 μg/kg/hour IV CRI. Isoflurane maintenance requirements were reduced.[49]

In combination with an opioid and ketamine (ie, "kitty magic", DKT, or Triple Combination) to provide sedation and analgesia (extra-label): Dexmedetomidine concentration is 0.5 mg/mL (500 μg/mL). Opioid concentrations referenced here are butorphanol 10 mg/mL, hydromorphone 2 mg/mL, and buprenorphine 0.3 mg/mL. Ketamine concentration is 100 mg/mL. These drugs may be available in other concentrations, but only the products with these concentrations should be used for this protocol. See the table below for volumes used to attain the desired degree of patient sedation.[50]

Drug Volume of *Each* Drug (Ketamine/Dexmedetomidine*/Opioid) to Be Given IM

Cat body weight	Mild†	Moderate‡	Profound§
2-3 kg (4-7 lb)	0.025 mL	0.05 mL	0.1 – 0.15 mL
3-4 kg (7-9 lb)	0.05 mL	0.1 mL	0.2 – 0.25 mL
4-6 kg (9-13 lb)	0.1 mL	0.2 mL	0.3 – 0.35 mL
6-7 kg (14-15 lb)	0.2 mL	0.3 mL	0.4 – 0.45 mL
7-8 kg (15-18 lb)	0.3 mL	0.4 mL	0.5 – 0.55 mL

*Dexmedetomidine can be reversed immediately with an equal volume (of dexmedetomidine used) of atipamezole.

†For sedation or as a premedication prior to anesthetic induction

‡For castration or minor surgical procedures

§Invasive surgical procedures, including OHE and declawing

In combination with alfaxalone OR ketamine (extra-label): Dexmedetomidine 10 µg/kg and butorphanol 0.2 mg/kg combined with *either* alfaxalone 3 mg/kg OR ketamine 5 mg/kg and administered IM provided adequate analgesia with minor physiologic and anesthetic duration differences when administered to cats undergoing castration.[51]

In combination with buprenorphine: Dexmedetomidine 40 µg/kg in combination with buprenorphine 20 µg/kg administered by either the OTM (buccal cavity) or IM (quadriceps muscle) routes provided equal sedation and antinociceptive scores.[17] Vomiting occurred in both groups; however, dexmedetomidine 20 µg/kg with buprenorphine 20 µg/kg IM provided more reliable sedation than the OTM route.[16]

Induction of emesis: 6 – 18 µg/kg IM[1–3] or 3.5 µg/kg IV[1]

HORSES:

Total IV anesthesia in foals (extra-label): Dexmedetomidine 3 – 7 µg/kg IV to place arterial catheter; alfaxalone 2 mg/kg IV for anesthesia induction; anesthesia maintained with a combination of dexmedetomidine 1 µg/kg/hour, alfaxalone 6 mg/kg/hour, and remifentanil 3 µg/kg/hour IV CRI. Regimen was suitable for laparotomy, although prolonged recovery may occur (time to standing was 46 to 106 minutes after stopping infusion).[52]

Constant rate infusion in adult horses/ponies (extra-label):

a) Dexmedetomidine used for MAC reduction and analgesia example: 3.5 µg/kg dexmedetomidine IV followed by dexmedetomidine 1.75 µg/kg/hour IV CRI reduced sevoflurane MAC by an average of 52% in anesthetized ponies.[53]

b) Dexmedetomidine 3.5 – 5.5 µg/kg combined with butorphanol 30 µg/kg and given IV followed by dexmedetomidine 1.75 – 5.3 µg/kg/hour IV CRI successfully allowed transvenous electrical cardioversion in 5 adult horses with atrial fibrillation.[54]

SMALL MAMMALS:

Rabbits (extra-label): Numerous protocols are published for sedation/anesthesia in rabbits using medetomidine. Dexmedetomidine can be substituted for medetomidine at ½ the dose in mg/kg or same dose in mL/kg.

a) Dexmedetomidine 100 µg/kg, ketamine 15 mg/kg and buprenorphine 30 µg/kg combined in the same syringe and administered SC.[55] Anecdotally, this dosage can also be used IV or IM. If longer duration anesthesia is necessary, inhalants can be administered.

b) Dexmedetomidine 250 µg/kg in combination with ketamine 35 mg/kg ± buprenorphine 30 µg/kg and administered IM[56]

Dwarf rabbits (extra-label):

a) Dexmedetomidine 25 µg/kg in combination with midazolam 0.2 mg/kg and administered IM allowed complete abdominal ultrasonography to be performed, but 3 (33%) required additional doses of the drug combination.[57]

b) Dexmedetomidine 100 µg/kg in combination with butorphanol 0.4 mg/kg and midazolam 2 mg/kg and administered intranasally produced deep sedation and analgesia suitable for minor surgical procedures.[58]

Guinea pigs (extra-label): Dexmedetomidine 250 µg/kg in combination with buprenorphine 0.05 mg/kg and alfaxalone 15 – 20 mg/kg SC yielded sedation within ≈7 to 8 minutes and recumbency for 74 minutes but did not induce anesthesia.[59]

Monitoring

- Level of sedation and analgesia
- Heart rate and rhythm, blood pressure, pulse oximetry
- Respiratory depth and rate, $ETCO_2$
- Body temperature

Client Information

- When given by injection (in the veterinary clinic), dexmedetomidine should be used in a professionally supervised setting by individuals familiar with its properties.
- Withhold feed and water until the sedative effects of dexmedetomidine have subsided.

When using the dexmedetomidine *oromucosal gel*:

- Avoid handling this medicine if pregnant.
- Because this medicine can be absorbed through the skin, mucous membranes (mouth/gums), and eyes, impermeable (eg, latex) disposable gloves should be worn when handling the syringe. If the medicine makes contact with skin, thoroughly wash affected area with soap and water. In case of accidental eye exposure, flush eye(s) with water for 15 minutes. In the case of accidental ingestion, seek medical attention immediately; alert physician about exposure to an alpha-2-adrenergic agonist.
- When dialing the "ring-stop" to the appropriate dose (ie, number of dots), the ring-stop must be locked in place prior to administration. An accidental overdose may occur if the ring-stop is not fully locked.
- Administer the medicine between your dog's cheek and gums. The medicine is intended to be absorbed from the inside of the mouth and may be less effective if swallowed.
- If your veterinarian instructed you to give the medicine more than once, you may give another dose at least 2 hours after the previous dose. Give another dose only if your dog is showing signs of fear or anxiety. Do not give the medicine if your dog is still sleepy from the previous dose. Up to 5 doses (total) may be given to your dog during any one noise event.
- The potential side effects associated with use, particularly in dogs at risk (ie, those that are older or have preexisting conditions) include low-energy level, weakness, sedation, sleepiness, slow heart rate, loss of consciousness, shallow or slow breathing, trouble breathing, impaired balance or incoordination, low blood pressure, and muscle tremors.

Chemistry/Synonyms

Dexmedetomidine is the dextrorotatory enantiomer of medetomidine. It occurs as a white or almost white crystalline substance that is water-soluble.

Dexmedetomidine HCl may also be known as (*S*)-medetomidine, (+)-medetomidine, MPV 1440, MPV 295, or MPV 785. Trade names include *Cepedex®*, *Dexdomitor®*, *Dexvetidine®*, *Precedex®*, *Sedadex®*, and *Sileo®*.

Storage/Stability

Store the injection at room temperature (ie, 15°C-30°C [59°F-86°F]); do not freeze. Discard unused product 90 days after first piercing the vial.

Store the oromucosal gel syringes (unopened or opened) at controlled room temperature of 20°C to 25°C (68°F-77°F), with excursions permitted to 15°C to 30°C (59°F-86°F). Use syringe contents within 4 weeks after opening the syringe.

Compatibility/Compounding Considerations

Information from the manufacturer states that dexmedetomidine 0.5 mg/mL solution for injection can be mixed with butorphanol 2 mg/mL, ketamine 50 mg/mL solution, or with butorphanol 2 mg/mL solution and ketamine 50 mg/mL solution, in the same syringe for up to 2 hours. Anecdotal comments have been noted that buprenorphine, hydromorphone, or morphine can also be mixed with dexmedetomidine.

In humans, dexmedetomidine injection is administered as a 0.004 mg/mL (4 µg/mL) IV infusion. The drug is **compatible** in the following solutions: 0.9% sodium chloride, 5% dextrose, lactat-

ed Ringer's, and 20% mannitol. Dexmedetomidine is **incompatible** with amphotericin B, diazepam, pantoprazole and blood or plasma products.

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Dexmedetomidine HCl 0.5 mg/mL (500 µg/mL) in 10 mL multidose vials; *Dexdomitor*®; (Rx). FDA-approved for use in dogs and cats. NADA #141-267

Dexmedetomidine HCl 0.1 mg/mL (100 µg/mL) in 10 mL multidose vials; *Dexdomitor*® 0.1; (Rx). FDA-approved for use in dogs and cats. NADA #141-267

Dexmedetomidine Oromucosal Gel 0.09 mg/mL (equivalent to 0.1 mg/mL dexmedetomidine HCl) in 3 mL dosing syringes; *Sileo*® (Rx). FDA-approved for use in dogs. NADA #141-456

HUMAN-LABELED PRODUCTS:

Dexmedetomidine HCl Concentrated Solution for Injection: 100 µg/mL (equivalent to dexmedetomidine hydrochloride 118 µg), in 2 mL single-dose vials and 4 mL multi-dose vials; *Precedex*®, generic; (Rx). Must be diluted prior to administration.

Dexmedetomidine HCl in 0.9% NaCl Solution for Infusion: 4 µg/mL in 20 mL and 50 mL; *Precedex*®, generic; (Rx)

Dexrazoxane

(dex-ra-***zox***-ane) *Zinecard*®

Antidote

Prescriber Highlights

- ► May attenuate the cardiotoxic effects of doxorubicin in dogs showing signs of anthracycline cardiotoxicity, that have cardiac disease prior to doxorubicin therapy, or that are at maximum cumulative doses of doxorubicin; also used to treat extravasation injuries associated with doxorubicin
- ► Contraindications include use in patients receiving non-anthracycline chemotherapy.
- ► Adverse effects include myelosuppression; this effect is additive with anthracycline-related myelosuppression.
- ► Administer within 6 hours of extravasation injury to attenuate local tissue damage and necrosis
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies dexrazoxane as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Dexrazoxane may be useful to attenuate the cardiotoxic effects of doxorubicin in patients that are showing signs of anthracycline cardiotoxicity, that develop cardiac disease while taking doxorubicin, or that are at maximum cumulative life-time dosage of doxorubicin. Dexrazoxane can also be used to treat extravasation injuries associated with doxorubicin. In a case series involving 4 dogs, it was recommended that because of the importance of timely administration (within 6 hours), veterinarians that administer doxorubicin should have dexrazoxane readily available.[1,2]

Pharmacology/Actions

Dexrazoxane is hydrolyzed to an active metabolite that chelates intracellular iron, which is believed to prevent the formation of an anthracycline-iron complex free radical that is thought to be the primary cause of anthracycline-induced cardiomyopathy and extravasation injury.

Pharmacokinetics

In dogs, dexrazoxane's pharmacokinetics fit a 2-compartment open model.[3] Steady-state volume of distribution is 0.67 L/kg; terminal half-life is about 1.2 hours; and clearance is about 11 mL/kg/minute. Clearance was dose-independent, and the drug showed low tissue and protein binding. Dexrazoxane is primarily excreted in the urine as unchanged drug and metabolites.

Contraindications/Precautions/Warnings

Dexrazoxane should not be used unless an anthracycline antineoplastic agent is being used.

Efficacy and safety of dexrazoxane for use in cats is not known.

The National Institute for Occupational Safety and Health (NIOSH) classifies dexrazoxane as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure. Refer to the Occupational Safety and Health Association (OSHA) website for more information.

Adverse Effects

Dexrazoxane may cause additive myelosuppression when used with other myelosuppressive agents.

Wear gloves when handling this product and use normal procedures for handling and disposing of anticancer medications. If non-reconstituted powder contacts skin or mucous membranes, thoroughly wash the exposed area with soap and water.

Reproductive/Nursing Safety

Dexrazoxane has been shown to cause testicular atrophy in dogs when it is administered at usual doses for 13 weeks.[4] In rats and rabbits, dexrazoxane was teratogenic at doses lower than those administered to humans.

It is unknown if dexrazoxane enters maternal milk; human mothers are advised to discontinue nursing if they are given the drug.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Because of the method of administration and drug expense, overdoses of dexrazoxane are unlikely in veterinary medicine. As there is no known antidote, treatment would be supportive. Potentially, the drug could be removed via hemodialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Dexrazoxane does not influence the pharmacokinetics of doxorubicin.

The following drug interactions either have been reported or are theoretical in humans or animals receiving dexrazoxane and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Myelosuppressive Agents, Other**: Additive myelosuppression may occur when dexrazoxane is used with other myelosuppressive agents.

Laboratory Considerations

- ■ No specific laboratory interactions or considerations were noted.

Dosages

DOGS:

Treatment of anthracycline (eg, **doxorubicin, epirubicin) extravasation** (extra-label): **NOTE**: In a retrospective study of 4 dogs, the authors concluded that the most effective dosage and timing of administration are unknown; however, there is evidence to suggest that administration within 6 hours after the event is warranted; further studies are needed.[1]

a) IV administration of dexrazoxane at 10 times the doxorubicin dose within 3 hours (when possible) and again at 24 and 48 hours after extravasation significantly reduces local tissue injury.[1,2,5]

b) Terminate doxorubicin infusion immediately and infuse IV 1000 mg/m^2 of dexrazoxane at a separate (new) infusion site within 6 hours of extravasation and again on day 2. Infuse 500 mg/m^2 IV on day 3. Acute surgical evaluation is performed. **NOTE**: Dosage recommendations are for human patients but may apply to veterinary patients.[6]

Prevention of doxorubicin-induced cardiomyopathy (extra-label): In dogs that met at least one of the following criteria: pre-existing diagnosed clinical heart disease; onset of impaired systolic function during the course of doxorubicin therapy; cumulative dose of doxorubicin of 180 mg/m^2; or cardiac disease as determined by echocardiographic evaluation: 10 minutes prior to doxorubicin infusion, dexrazoxane at a dose of 10 times the administered milligram dose of doxorubicin administered IV over 5 to 10 minutes. Although no information regarding efficacy of cardioprotection could be gleaned, it appears that 1 to 2 doses of dexrazoxane administered with doxorubicin are safe and well tolerated.[7]

Monitoring

- Baseline and periodic CBC
- If used for cardioprotection: serial echocardiogram and ECG

Client Information

- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

A derivative of EDTA, dexrazoxane occurs as a white crystalline powder that is soluble in water, slightly soluble in ethanol, and practically insoluble in nonpolar organic solvents. It has a pK_a of 2.1 and degrades rapidly at a pH above 7.

Dexrazoxane may also be known as 2,6-Piperazinedione, ADR-529, ICRF-187, NSC-169780, *Zinecard®*, *Cardioxane®* or *Eucardion®*.

Storage/Stability

Unreconstituted dexrazoxane vials should be stored at 25°C (77°F); excursions are permitted to 15°C to 30°C (59°F-86°F). Once reconstituted with the supplied diluent, the product is stable for 6 hours at room temperature or refrigerated.[4] Unused solutions after that time should be discarded. After reconstitution, the resulting solution may be diluted with either 0.9% sodium chloride injection or 5% dextrose in concentrations of 1.3 – 5 mg/mL. Inspect visually for particulate matter and discoloration prior to administering.

Compatibility/Compounding Considerations

Dexrazoxane should not be mixed with any other drug.[4]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dexrazoxane Lyophilized Powder for Injection Solution: 250 mg in single-use vials with 25 mL vial of sodium lactate injection; and 500 mg regular and preservative free in single-use vials with 50 mL vial of sodium lactate injection; *Zinecard®*, generic; (Rx)

Dextran 70

(***dex***-tran)

Synthetic Colloid, Plasma Volume Expander

NOTE: Dextran is also available as Dextran 40. As Dextran 70 has been the most commonly used version in veterinary medicine, the following monograph is limited to Dextran 70.

Prescriber Highlights

- ► Branched polysaccharide plasma volume expander
- ► Limited availability. Other colloids (eg, hydroxyethyl starch) have largely supplanted use.
- ► Contraindicated in patients with preexisting coagulopathies
- ► Use with caution in patients susceptible to circulatory overload (severe heart or chronic kidney disease), or with thrombocytopenia.
- ► Adverse effects are quite rare in dogs and include increased bleeding times, acute kidney injury, and anaphylaxis (very rare).
- ► Must monitor for fluid overload

Uses/Indications

Dextran 70 is a relatively low-cost colloid for the adjunctive treatment of hypovolemic shock. Hydroxyethyl starches are the more commonly employed synthetic colloids in use today.

Pharmacology/Actions

Dextran 70 has osmotic effects similar to albumin. Dextran's colloidal osmotic effect draws fluid into the vascular system from the interstitial spaces, resulting in increased circulating blood volume.

Pharmacokinetics

After IV infusion, circulating blood volume is increased maximally within 1 hour and effects can persist for 24 hours or more.

Approximately 20% to 30% of a given dose remains in the intravascular compartment at 24 hours and it may be detected in the blood 4 to 6 weeks after dosing. Dextran 70 is slowly degraded to glucose by dextranase in the spleen and then metabolized to carbon dioxide and water. A small amount may be excreted directly into the gut and eliminated in the feces.

Contraindications/Precautions/Warnings

Patients overly susceptible to circulatory overload (severe heart or chronic kidney disease) should only receive dextran 70 with great caution. Dextran 70 is contraindicated in patients with severe coagulopathies and should be used with caution in patients with thrombocytopenia, as it can interfere with platelet function. Do not give dextran IM. Patients on strict sodium restriction should receive dextran cautiously as a 500 mL bag contains 77 mEq of sodium.

Adverse Effects

Dextran 70 may increase bleeding time and decrease von Willebrand factor antigen, platelet function, buccal mucosal bleeding time, and factor VIII activity; however, this effect does not usually cause clinical bleeding in dogs.[1,2]

Anaphylactoid reactions to dextran 70 occur rarely in dogs, but at a higher rate than with hetastarch. Unlike dextran 40, dextran 70 has rarely been associated with acute kidney injury. In humans, GI effects (abdominal pain, nausea, vomiting) have been reported with use of dextran 70.

Reproductive/Nursing Safety

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The drug should be dosed and monitored carefully as volume overload may result.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dextran 70 and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- Anticoagulants (eg, **heparins, rivaroxaban, warfarin**): Increased risk for bleeding
- Anti-Platelet Agents (eg, **aspirin, clopidogrel**): Increased risk for bleeding

Laboratory Considerations

- Dextran 70 may interfere with **blood cross-matching,** as it can cross-link with red blood cells and appear as rouleaux formation. Isotonic saline may be used to negate this effect.
- **Blood glucose** levels may be increased as dextran is degraded.
- Falsely elevated **bilirubin** levels may be noted; reason unknown

Dosages

DOGS:

Volume resuscitation (extra-label):

a) Small-volume resuscitation techniques are recommended in any dog with closed cavity hemorrhage, head injury, pulmonary contusions or edema, cardiogenic shock, or oliguric acute kidney injury. An initial dose of balanced isotonic crystalloids (10 – 15 mL/kg) is given. Either a hydroxyethyl starch or dextran 70 is then administered (5 mL/kg in dogs) over 1 to 5 minutes. The perfusion parameters are reassessed, and the initial mL/kg bolus is repeated as needed until the end point of resuscitation is reached.[3]

b) 20 mL/kg/day; when acute resuscitation is required, may be given as a slow bolus over 30 to 60 minutes. May also be given as a constant rate infusion (CRI) over a longer period to augment colloid oncotic pressure or decrease the volume of crystalloids infused, thereby reducing hemodilution.[4]

CATS:

Volume resuscitation (extra-label):

a) Small-volume resuscitation techniques are recommended in the hypovolemic cat with closed cavity hemorrhage, head injury, pulmonary contusions or edema, cardiogenic shock, or oliguric acute kidney injury. An initial dose of balanced isotonic crystalloids (5 – 10 mL/kg) is given. Either hetastarch or dextran 70 is then administered (2 – 5 mL/kg) over 1 to 5 minutes. The perfusion parameters are reassessed, and the initial mL/kg bolus repeated as needed until the end point of resuscitation is reached.[3]

b) 10 mL/kg/day; when acute resuscitation is required. May be given as a slow bolus over 30 to 60 minutes. May also be given as a CRI over a longer period to augment colloid oncotic pressure or decrease the volume of crystalloids infused, thereby reducing hemodilution[4]

CATTLE:

Volume resuscitation in calves with dehydration due to diarrhea (extra-label): Administered as 6% dextran 70 in 7.2% sodium chloride. To prepare this solution, add 31.6 g sodium chloride crystals into the barrel of a 60 mL syringe. Draw 60 mL of 6% dextran 70 in 0.9% sodium chloride from the bag/bottle and use to dissolve the sodium chloride crystals. Using a 0.22 µm filter, reinject the dissolved solution into the 6% dextran 70 in 0.9% sodium chloride bag/bottle to produce a 6% dextran 70 in 7.2% sodium chloride solution. Resultant solution may be refrigerated for up to 3 months. Inject 4 – 5 mL/kg IV of the prepared solution over 4 to 5 minutes, followed immediately by oral administration of isotonic electrolyte solution. Give dextran 70 solution only once or hypernatremia may result; following up with isotonic fluids (oral or IV) is critical. [5]

Monitoring

- Hydration status and signs of fluid overload (eg, increased respiratory rate and effort, pulmonary edema)
- Clinical signs of anaphylactic-like reactions, including worsening signs of shock and pruritus
- Renal chemistry panel and urine output
- Serum electrolytes, acid-base balance
- Colloid oncotic pressure
- Blood pressure, central venous pressure
- Coagulation parameters, particularly in high-risk patients or when using high doses of dextran 70

Chemistry/Synonyms

A branched polysaccharide, dextran 70 occurs as a white to light yellow amorphous powder. It is freely soluble in water and insoluble in alcohol. Dextran 70 contains (on average) molecules of 70,000 daltons. Each 500 mL of the commercially available 6% dextran 70 in normal saline provides 77 mEq of sodium. Dextran 70 in normal saline has a viscosity of 3.68 centipoise (blood is 3 centipoise) and a colloid osmotic pressure of 62 mm Hg (canine plasma is ≈20 mm Hg).

Dextran 70 may also be known as dextranum 70, polyglucin, *Dextran 70®*, *Fisiodex 70®*, *Gentran 70®*, *Hyskon®*, *Lomodex 70®*, *Longasteril 70®*, *Macrodex®*, *Macrohorm 70®*, *Neodextril 70®*, *Plander®*, *RescueFlow®*, or *Solplex 70®*.

Storage/Stability

Dextran 70 injection should be stored at room temperature, preferably in an area with little temperature variability. Although only clear solutions should be used, dextran flakes can form but may be resolubilized by heating the solution in a boiling water bath until clear or autoclaving at 110°C (230°F) for 15 minutes.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dextran 70 is **compatible** with many other solutions and drugs; refer to specialized references or a hospital pharmacist for more information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dextran 70: 6% in 5% dextrose in 500 mL; generic; (Rx). Not available in all countries

For the complete list of references, see **wiley.com/go/budde/plumb**

Dextromethorphan

(***dex***-troe-meth-***or***-fan) *Delsym®*

N-Methyl-D-Aspartate (NMDA) Receptor Antagonist

Prescriber Highlights

- ► May reduce self-directed behaviors in dogs with atopic dermatitis and cribbing in horses
- ► Oral use in dogs is limited by poor absorption and short half-life.
- ► PK studies in horses suggest significant interpatient variability with drug metabolism.
- ► GI effects (eg, vomiting, diarrhea) and ataxia are possible.

Uses/Indications

Dextromethorphan may be useful in reducing compulsive[1] or self-injurious behavior in dogs[2] and cribbing in horses.[3]

In humans, dextromethorphan is used primarily as an antitussive for the short-term control of coughing. In dogs, however, it is not a first-line medication for management of coughing. When other therapies have failed, dextromethorphan may be useful for some animals. The dosage for this indication is unknown.

Pharmacology/Actions

Dextromethorphan and its active metabolite dextrorphan are noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonists. Sustained or repetitive NMDA activation by the excitatory amino acids glutamate and aspartate appears to sensitize neurons, stimulate C-fibers, and cause neurotoxicity. The resulting effects include reduced opioid efficacy, allodynia, wind-up pain, and secondary pain. By blocking the NMDA receptor, dextromethorphan and dextrorphan may potentiate the effects of other analgesics.[4]

In the medullary cough center, dextromethorphan stimulates σ-1 receptors, which inhibit glutamate transmission, and interferes with the cough impulse and reduces cough receptor sensitivity. Although dextromethorphan is structurally similar to codeine (see ***Chemistry/Synonyms***), its affinity for the mu, delta, and kappa opioid receptors is weak, even at excessive doses following abuse or overdose. Naloxone does not block the drug's antitussive effect, but it can reverse some effects associated with toxicity.

Dextromethorphan weakly inhibits serotonin reuptake, leading to the potential for drug interactions with other serotonergic agents.

Pharmacokinetics

In a randomized crossover study of 6 dogs, oral bioavailability was 11%. Volume of distribution and elimination half-life after IV dextromethorphan administration were 5.1 L/kg and 2 hours, respectively. Dextrorphan (the active metabolite) was not detected. Ex vivo treatment of plasma samples indicated the drug was conjugated.[4]

In horses given dextromethorphan 2 mg/kg PO once,[5,6] peak concentration was reached 30 minutes to 1 hour after administration, and elimination half-life was between 12 and 18 hours. Significant interpatient variability in pharmacokinetic parameters was attributed to differences in CYP2D50 metabolic activity, with horses classified as ultrarapid metabolizers ($n = 3$), extensive metabolizers ($n = 19$), and poor metabolizers ($n = 1$).[5] The highest dextrorphan exposure (AUC) was observed in the ultrarapid metabolizers, and the lowest exposure occurred in the poor metabolizer.[5] Free and glucuronidated dextrorphan were identified in plasma.[6] Dextrorphan was identified in urine as the primary form of excretion.[6]

In humans, peak concentration is reached 2 to 3 hours after administration, and antitussive effects typically last less than 6 hours. Metabolism depends on CYP2D6 enzyme expression; humans can be poor metabolizers or extensive metabolizers. The drug is hepatically metabolized to the active form, dextrorphan. Demethylation by CYP2D6 occurs in the liver; CYP3A subfamilies also have a minor role. Elimination half-life averages 11 hours but can range from 2 to 4 hours (in extensive CYP2D6 metabolizers) to 24 hours (in poor CYP2D6 metabolizers).

Contraindications/Precautions/Warnings

Dextromethorphan should not be used in patients hypersensitive to it. Dextromethorphan should be used with caution in patients with hepatic impairment. Use of the drug has been associated with histamine release in humans, and it should be used with caution in atopic patients, as it is unknown if this effect occurs in animals.

In humans, dextromethorphan should be used with caution in patients with a chronic cough or a cough due to excessive secretions.

Dextromethorphan should not be confused with dextromethorphan/quinidine, which is approved for use in humans with pseudobulbar affect. Caution should be used when referring clients to purchase OTC dextromethorphan products, because many of these products contain other drugs or ingredients (eg, xylitol) that are not appropriate for use in veterinary medicine.

Adverse Effects

Adverse effects in dogs receiving oral dextromethorphan appear uncommon, likely due to the drug's poor and erratic absorption in this species. In a blinded study of 14 dogs, lethargy was noted in 1 dog receiving oral dextromethorphan 2 mg/kg twice daily.[2] Sedation, diarrhea, vomiting, excitement, loss of balance, disorientation, lethargy, and decreased rate of breathing have been observed.[7] In a randomized crossover study of 6 dogs, dextromethorphan caused muscle rigidity, ataxia, sedation, and ptyalism after IV administration.[4]

Adverse effects from oral dextromethorphan were not observed in single-dose pharmacokinetic study in horses.[6]

In humans, adverse effects (eg, GI distress [eg, nausea, anorexia, constipation[8]], dizziness, drowsiness) may limit therapy. Case studies have shown fixed drug eruption after therapeutic doses of dextromethorphan. Respiratory distress may occur rarely. Doses greater than 100 mg may cause euphoria, hallucinations, dissociation, and coma.[9]

Reproductive/Nursing Safety

In humans, dextromethorphan is considered safe for use during pregnancy at standard doses.[10,11]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The LD_{50} of IV dextromethorphan in dogs is 22 mg/kg. The LD_{50} of oral dextromethorphan in mice and rats is 210 mg/kg and 116 mg/kg, respectively, and the LD_{50} of IV dextromethorphan in rats is 16.3 mg/kg.[12] Nausea, vomiting, CNS effects (eg, ataxia, hyperexcitability, dystonia, nystagmus, stupor), respiratory depression, hypertension, tachycardia, and seizures are possible.

For overdoses in veterinary patients, treatment is based on clinical signs and is supportive. Gut decontamination can be considered. Naloxone may reverse some manifestations of toxicity.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Dextromethorphan is a CYP2D6 substrate in humans. Canine polymorphism of CYP2D15 is recognized,[13] but relation to dextromethorphan metabolism in this species is unknown. Polymorphism of equine CYP2D50, as well as variability of dextromethorphan metabolism (ie, poor, extensive, and ultrarapid metabolizers), has been

demonstrated.[5] The following drug interactions have been reported or are theoretical in humans or animals receiving dextromethorphan and may be of significance in veterinary patients; unless otherwise noted, use together may not be contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate:

- **CYP2D6 Inhibitors** (eg, **amiodarone**, **fluoxetine**, **paroxetine**, **terbinafine**): Concurrent use may increase detromethorphan exposure via inhibition of cyp2d6.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz**, **methylene blue, selegiline**): Concurrent use should be avoided. The MAOI should be discontinued 2 weeks prior to dextromethorphan use.
- **Naloxone**: Naloxone does not block antitussive effect of dextromethorphan in humans.
- **Opioids** (eg, butorphanol, hydrocodone, hydromorphone, morphine): Concurrent use may increase risk for serotonin syndrome.
- **Quinidine**: Concurrent use may result in 20-fold increases in dextromethorphan levels and exposure. Concurrent use should be avoided.
- **Serotonergic Agents** (eg, **clomipramine**, **metoclopramide**, **mirtazapine**, **ondansetron, SSRIs** [eg, **fluoxetine, paroxetine**], **tramadol, trazodone**): Concurrent use may increase risk for serotonin syndrome.

Laboratory Considerations

- In humans, dextromethorphan can cause false-positive results for **phencyclidine (PCP)** on **urine drug screening tests**; it may also cause false-positive results for **opioids**.[14]

Dosages

DOGS:

Reduction of self-directed scratching, biting, or chewing in dogs with allergic dermatitis (extra-label): 2 mg/kg PO twice daily reduced pruritus score and modestly reduced time engaged in self-injurious behavior in a blinded study of 14 dogs.[2]

CATS:

Adjunctive pain management (extra-label): Anecdotally, 0.5 – 2 mg/kg PO every 6 to 8 hours provides mild to moderate analgesia.[15]

HORSES:

Reduction of cribbing (extra-label): 1 mg/kg IV reduced cribbing rate (bites/minute) in 4 of 9 horses. Effect lasted ≈35 to 60 minutes. Cribbing rate increased in 1 horse.[3]

Monitoring

- Clinical efficacy
- Adverse effects

Client Information

- GI effects (eg, vomiting, loose stools, diarrhea) or lethargy may occur. Contact your veterinarian if these become serious or persist.
- Contact your veterinarian if your animal's condition worsens.

Chemistry/Synonyms

Dextromethorphan is the methyl ether of d-levorphanol. Commercial formulations contain dextromethorphan hydrobromide, which occurs as a white or crystalline powder. It is sparingly soluble in water and freely soluble in alcohol.

Dextromethorphan may also be known as dextromethorphan hydrobromide, dextromethorphan polistirex, d-Methorphan, DM, *Cough-Tabs*®, or *Delsym*®. Many other trade names exist.

Storage/Stability

Store dextromethorphan at controlled room temperature (20°C-25°C [68°F-77°F]).

Compatibility/Compounding Considerations

- Dextromethorphan is **incompatible** with penicillins, tetracyclines, salicylates, phenobarbital sodium, and high concentrations of sodium or potassium iodide.[16]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Dextromethorphan and Guaifenesin Tablets: Dextromethorphan 10 mg and Guaifenesin 100 mg tablets; *Cough Tabs for Dogs and Cats*®, generic; (OTC). Note: This drug has not been found by FDA to be safe and effective, and this labeling has not been approved by FDA.

The Association of Racing Commissioners International (ARCI) has designated dextromethorphan as a class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

NOTE: Some products may contain xylitol; label should be checked to avoid toxicity in dogs.

Dextromethorphan Hydrobromide GelCaps: 15 mg; generic; (OTC)

Dextromethorphan Hydrobromide Syrup: 1 mg/mL, 1.33 mg/mL, 2 mg/mL in 118 mL, 120 mL, 236 mL, and 354 mL bottles; generic; (OTC)

Dextromethorphan Polistirex Extended Release Suspension: 6 mg/mL in 89 mL and 148 mL bottles; *Delsym*®, *Robitussin 12 Hour Cough Relief*®, generic; (OTC). Contains dextromethorphan polistirex equivalent to dextromethorphan hydrobromide 6 mg/mL

Dextromethorphan is also available as a spray, lozenge, chewable tablet, orally disintegrating film or strip, and oral granules or powder, in a variety of strengths and sizes. Many products that combine dextromethorphan with guaifenesin, analgesics, antihistamines, and/or decongestants are available, but these are generally inappropriate for use in animal patients because of the potential for unpredictable adverse effects.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dextrose 50% Injection

D-glucose

*(**deks**-trose)*

Glucose Elevating Agent

Prescriber Highlights

► Used primarily to treat acute hypoglycemia
► Used concomitantly with IV insulin for treatment of severe hyperkalemia
► Diluting dextrose to 10% or less for administration to dogs and cats decreases the risk for phlebitis.
► Glucose levels should be monitored during therapy.

Uses/Indications

IV dextrose is indicated in emergency treatment of hypoglycemia caused by various conditions (eg, neonatal/juvenile hypoglycemia, hepatic insufficiency or failure, hypoadrenocorticism, insulin overdose, sepsis, insulinoma, glycogen storage disease, pregnancy, xylitol toxicity). Buccal administration increased blood glucose concentration in healthy dogs; however, the effect was not observed until 15 minutes after administration and may be too slow for more severely

hypoglycemic patients.[1]

In veterinary patients, IV dextrose is given IV concomitantly with regular insulin to treat hyperkalemia.[2] In dogs and cats, ECG changes seen in critical patients with hyperkalemia may be affected by concurrent metabolic derangements (eg, metabolic acidosis, hypermagnesemia, hypocalcemia) and thus may not typify the expected ECG changes (eg, bradyarrhythmias, loss of P wave, wide QRS complexes, peaked T waves) previously described for hyperkalemia.[3] In humans, treatment for hyperkalemia is recommended when serum potassium is greater than 5.5 mEq/L if there are ECG changes or when serum potassium is greater than 6 mEq/L, regardless of ECG findings.[4]

Dextrose may also be used as adjunctive therapy for nutritional support and as part of fluid therapy for some patients with diabetic ketoacidosis (see ***Insulin, General Information***).

Pharmacology/Actions

Dextrose solution provides a source of water and glucose. The solution restores blood glucose levels; it is thought to aid in minimizing liver glycogen depletion and to exert a protein-sparing effect.

Pharmacokinetics

No pharmacokinetic data in animals were located. In humans, serum glucose levels cannot be quantitatively predicted after a single IV bolus. Dextrose is metabolized to carbon dioxide and water with the release of energy (ie, ATP).

Contraindications/Precautions/Warnings

IV dextrose supplementation is contraindicated in patients with severe hyperglycemia or with CNS hemorrhage. Avoid IV dextrose boluses in patients with suspected insulinoma (or other insulin-like analogue secreting tumors) as additional insulin can be secreted, leading to rebound hypoglycemia. Use with caution in patients with head trauma or intracranial edema as hyperglycemia can worsen neurologic injury.[5]

Dextrose 50% is a hypertonic solution and can cause severe phlebitis when administered IV; diluting with a sterile isotonic (eg, lactated Ringer's solution, 0.9% sodium chloride) or hypotonic solution (eg, 0.45% sodium chloride) reduces this risk. Dextrose concentrations 10% or greater are best administered via a central line; if a peripheral line is used, administer slowly.

Dextrose-only IV fluids (eg, dextrose 5%) should not be used as sole fluid therapy for prolonged periods as hyponatremia and water intoxication may occur.

Adverse Effects

The primary adverse effect caused by IV administration of dextrose is hyperglycemia. Hyperosmolar syndrome can occur if dextrose is administered too rapidly; clinical signs can include neurologic changes (eg, decreased mentation, weakness, ataxia, abnormal pupillary light reflexes, seizure activity). Administration site reactions (eg, phlebitis, infection) are possible especially when administered through a peripheral vein; avoid extravasation.

Fluid overload is a risk if large volumes are administered. Fluid overload may occur in patients with cardiac or chronic kidney disease, even at recommended dosages.

In humans, IV dextrose 50% may increase histamine release and has rarely caused a febrile response or anaphylaxis.

Reproductive/Nursing Safety

When used in humans during breastfeeding, risk to the infant cannot be ruled out. Available evidence and/or expert consensus is inconclusive or is inadequate for determining infant risk.

Potential benefits versus risk should be weighed when considering use of dextrose in pregnant or lactating animals.

Overdose/Acute Toxicity

There are no data available on overdose in veterinary patients. However, an overdose will likely result in hyperglycemia, phlebitis, neurologic changes, or fluid overload. Discontinue or reduce dextrose dose if hyperglycemia occurs. Monitor clinical signs and blood glucose concentrations. Treat supportively; rapid-/short-acting insulin (eg, regular insulin) may be considered.

Drug Interactions

No drug interactions were noted.

Laboratory Considerations

None

Dosages

DOGS/CATS:

Emergency treatment of hypoglycemia (extra-label):

1. Dextrose 50% 0.5 – 1 mL/kg (0.25 – 0.5 g/kg) is diluted 1:2 – 1:4 in a sterile fluid and administered slowly as bolus (usually over 5 minutes).[6] Follow with dextrose 2.5% to 5% (or more) IV CRI as needed in isotonic fluids.[6-8] Administration via a central IV line is strongly encouraged. Solution should be administered very slowly (eg, 3 mL/minute) in the rare instance when dextrose 50% cannot be diluted or if clinical situation requires administration via a peripheral line (see ***Adverse Effects***).[9]
2. 0.5 – 1 g/kg slow bolus IV followed by IV CRI of dextrose ranging from 1.25% to 10% in crystalloid fluid[10]
3. **Buccal administration**: 1 g/kg administered in the buccal vestibule followed by gentle lip massage. Increase in blood glucose may not be observed until 15 minutes after administration.[1]

Adjunctive treatment of hyperkalemia with corresponding ECG changes (extra-label): Redistribution of serum potassium can be achieved with dextrose and regular insulin. Dextrose 50% 1 mL/kg (0.5 g/kg) can be given as an IV bolus slowly (eg, 3 mL/minute). Regular insulin can be given at the same time at 0.25 – 0.5 units/kg slow IV. When using insulin and dextrose, it is imperative that dextrose be supplemented in the fluids at 2.5% to 5% to prevent secondary hypoglycemia.[11]

HORSES:

Hypoglycemia (label dosage; not FDA-approved): 100 – 500 mL IV.[12] Warm solution to body temperature and administer slowly.

Short-term caloric source for foals with diarrhea: 0.25 – 0.5 g/kg added to resuscitation fluids for 24 to 48 hours[13]

CATTLE:

Uncomplicated primary ketosis or hypoglycemia (label dosages; not FDA-approved):

1. 100 – 500 mL IV, depending on size and condition of animal. Solution should be warmed to body temperature and administered slowly.[14]
2. 1.1 mL/kg IV (50 mL per 45 kg [100 lb] body weight[15]), every 8 to 10 hours. Warm solution to body temperature and administer slowly.

SHEEP & SWINE:

Hypoglycemia (label dosage; not FDA-approved): 30 – 100 mL IV.[12] Warm solution to body temperature and administer slowly.

Monitoring

- Blood glucose concentrations should be assessed immediately after initiating dextrose and periodically thereafter to maintain euglycemia.
- Hydration status
- Electrolytes

Client Information

- If clients are to administer this product to food animals, they should be advised on correct injection technique and the importance of using the product per the label only.
- Unused vial or bottle portions should be discarded and not be saved for reuse.

Chemistry/Synonyms

Each 1 mL contains 0.5 g dextrose (hydrous), which delivers 3.4 kcal/g. The injection may contain hydrochloric acid or sodium hydroxide for pH adjustment. Dextrose 50% has an osmolarity of 2.5 mOsmol/mL and a pH of 3.2 to 6.5. Dextrose is also known as D-glucose.

Storage/Stability

Avoid excessive heat. Protect from freezing. Storage requirements vary by manufacturer; products intended for use in cattle typically are stored at 15°C to 30°C (59°F-86°F). The solution does not contain a preservative and is intended for single use only. Do not use cloudy solutions. Discard any unused portion.

Compatibility/Compounding Considerations

Dextrose 50% is compatible with isotonic fluids such as 0.9% sodium chloride (saline), lactated Ringer's solution, *PlasmaLyte®*, and *Normosol®*.

Examples of how to add dextrose to crystalloid solutions:

- 2.5% dextrose in a crystalloid solution: remove 50 mL of crystalloid fluid from a 1000 mL bag then add 50 mL of 50% dextrose to the bag
- 5% dextrose solution in a crystalloid solution: remove 100 mL of crystalloid fluid from a 1000 mL bag then add 100 mL of 50% dextrose to the bag

Dextrose should not be simultaneously administered with blood through the same infusion set because there is a possibility of pseudoagglutination of red blood cells.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Dextrose 50% Solution: 500 mL bottle; generic, (OTC and Rx). Not an FDA approved product

HUMAN-LABELED PRODUCTS:

Dextrose 50% Solution: 50 mL syringes, 10 mL, 20 mL, and 50 mL vials, and 500 mL and 1000 mL bottles/bags; generic; (Rx). Some products may not be approved by the FDA.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Diazepam

(dye-**az**-e-pam) *Valium®, Diastat®*

Benzodiazepine

Prescriber Highlights

- ► Benzodiazepine used for a variety of indications (eg, anxiolytic, muscle relaxant, hypnotic, appetite stimulant, anticonvulsant, anesthetic adjunct, behavioral modifier) in several species
- ► In dogs, long-term use results in tolerance to anticonvulsant effects, making the drug less useful when treating status epilepticus.
- ► Contraindications include hypersensitivity to benzodiazepines, significant liver disease (especially in cats), and in cats exposed to chlorpyrifos. Oral use in cats should be avoided.
- ► Caution is advised with hepatic or renal disease; aggressive behavior; debilitated or geriatric patients; and patients in coma, in shock, or with significant respiratory depression. May be teratogenic. Withdraw slowly after long-term dosing
- ► Adverse effects of sedation and ataxia are most prevalent. Dogs: CNS excitement, increased appetite. Cats: Hepatic failure (with oral administration) or behavior changes. Horses: Muscle fasciculations, ataxia
- ► IV injections should be administered slowly to prevent hypotension. IM injections cause pain and result in unpredictable absorption.
- ► DEA schedule IV (C-IV) controlled substance
- ► Effects are reversible with flumazenil.

Uses/Indications

Diazepam is used clinically for its anxiolytic, muscle relaxant, hypnotic, appetite stimulant, and anticonvulsant effects. It is also used in preanesthetic and/or anesthetic induction protocols for neuroleptanesthesia and to decrease the amount of induction agents required to induce general anesthesia. Diazepam has been shown to significantly decrease the amount of anesthetic (ie, alfaxalone, propofol) required for endotracheal intubation.[1–3] Diazepam is commonly used with ketamine to prevent ketaminemediated excitement and muscle rigidity.

Benzodiazepines are drugs of choice for treating status epilepticus and cluster seizures in dogs. Although diazepam can be used, it is relatively short-acting, and midazolam may be preferred. In a study, intranasal midazolam appeared to control status epilepticus better than did rectal diazepam.[4] Long-term administration of benzodiazepines usually results in the animal developing a tolerance to the drug's anticonvulsant effects.[5] In addition, long-term use of this class of drugs in dogs may prevent effective use for emergency treatment of seizures. In cats, diazepam has a longer elimination half-life, and tolerance is not a major concern.

Pharmacology/Actions

Diazepam and other benzodiazepines depress CNS subcortical levels (primarily limbic, thalamic, and hypothalamic), thereby producing anxiolytic, sedative, skeletal muscle relaxation, and anticonvulsant effects. Diazepam binds to gamma-aminobutyric acid type A ($GABA_A$) receptors and increases the affinity of the receptor for GABA, a major CNS inhibitory neurotransmitter, which results in increased chloride conductance and hyperpolarization of the postsynaptic cell membrane. Other postulated mechanisms include antagonism of serotonin, increased release of GABA, and diminished release or turnover of acetylcholine in the CNS. Benzodiazepine-specific receptors have been located in the mammalian brain, kidney, liver, lung, and heart; receptors are lacking in the white matter of all species studied.

Pharmacokinetics

Diazepam is rapidly absorbed following oral administration. Peak plasma concentrations occur within 30 minutes to 2 hours after oral

dosing. As compared with PO administration, diazepam is slowly and incompletely absorbed following IM administration. The rectal bioavailability of diazepam (parent drug) in dogs is less than 10%,[6] but bioavailability increases to 50% to 80% when considering diazepam plus its metabolites (eg, desmethyldiazepam, oxazepam).[6,7] Bioavailability is ≈80% when diazepam is administered intranasally to dogs.[8]

Diazepam is highly lipid-soluble and is widely distributed throughout the body. It readily crosses the blood–brain barrier and is highly bound to plasma proteins. In horses, 87% of the drug is bound to plasma proteins when the diazepam serum concentration was 75 ng/mL.[9] In humans, this value has been reported to be 98% to 99%.

Diazepam is metabolized in the liver to several metabolites, including desmethyldiazepam (nordiazepam), temazepam, and oxazepam, which are pharmacologically active. Diazepam metabolites are conjugated with glucuronide and eliminated primarily in urine in most species.[10] In horses, CYP3A is largely responsible for temazepam formation.[11] In 4-day-old foals, the diazepam half-life, clearance, and volume of distribution were significantly lower as compared with 21-day-old foals.[12] Because of the active metabolites, serum values of diazepam are not useful in predicting efficacy.

Serum Half-Lives (Approximated) for Diazepam and Metabolites in Dogs, Cats, and Horses

Metabolite	Dogs[10,13,14] (hours)	Cats[10] (hours)	Horses[15] (hours)	Humans (hours)
Diazepam	1-3.2	3.5-5.5	7-13	20-50
Nordiazepam	2-10	21.3	12	30-200
Temazepam	3	4.5	No data found	10-20
Oxazepam	3-6	No data found	18-28	3-21

Contraindications/Precautions/Warnings

Diazepam should not be used in patients that are hypersensitive to it or that have severe hepatic disease.[16] Fulminant hepatic failure has occurred in cats receiving oral diazepam,[17] and PO administration is best avoided in cats. Diazepam should be used cautiously, if at all, in aggressive patients and, if used, it should always be paired with another sedative drug (eg, alpha-2 agonist). Some clinicians believe that benzodiazepines are contraindicated in aggressive dogs, as anxiety may restrain the animal from aggressive tendencies; however, this remains controversial.[18] Diazepam may impair the performance of working animals.

Caution is advised when using in animals that have hepatic or renal disease, that are comatose or in shock, that have respiratory depression, or that are debilitated, obese, or geriatric. Although uncommon, cardiovascular or respiratory support may be necessary if diazepam is being administered IV.

Rapid injection of diazepam IV in small-sized animals or neonates may cause hypotension or cardiotoxicity secondary to propylene glycol in the formulation. Slow IV injection is recommended, particularly when using a small vein for access or in small-sized animals, because diazepam may cause significant phlebitis. Intracarotid artery injections must be avoided.

Other than in debilitated patients, diazepam used as a premedicant is unlikely to provide sedation and may cause paradoxical excitement, especially in young healthy patients. Thus, if used as a premedicant, diazepam should always be combined with an opioid or a true sedative. Diazepam is more commonly used during induction.

Long-term use of diazepam may induce physical dependence, and if the drug is to be discontinued, the dose must be gradually decreased (tapered) over several weeks.[19]

As compared with dosages for humans, diazepam dosages for dogs are very high; human pharmacists may be unaware that these are appropriate.

Using diazepam to control adverse effects related to toxicities should be approached with caution to avoid exacerbating clinical signs. It is recommended not to use diazepam for seizure control in cats exposed to chlorpyrifos because organophosphate toxicity may be potentiated.[16] Animals with toxicity from ingesting amphetamines or human sleep aids, such as zolpidem (*Ambien®*) or eszopiclone (*Lunesta®*), should not receive diazepam or other benzodiazepines to treat paradoxical CNS stimulation, as these drugs also increase GABA activity; IV phenothiazines (eg, acepromazine, chlorpromazine) or phenobarbital are recommended instead.

Do not confuse diazePAM with dilTIAZem or diaZOXide.

Adverse Effects

Rapid IV administration of diazepam can potentially cause hypotension; IV administration should be done slowly (5 mg/minute), and the IV catheter should be flushed with fluids after administration to help prevent phlebitis. IM injection may cause pain at the injection site.

Adverse effects reported in dogs include sedation, increased appetite, agitation, ataxia, and aggression. In addition, dogs may exhibit a contradictory response (eg, in ≈30% of dogs, CNS excitement was described as increased activity or agitation) following administration of diazepam; doses greater than or equal to 0.8 mg/kg are more likely to cause this effect.[20] Because sedation and tranquilization in dogs can be variable, diazepam may not be an ideal sedating agent, particularly when used alone. Diazepam used alone or in combination with ketamine increases intraocular pressure in dogs.[21,22]

Cats may exhibit changes in behavior (eg, irritability, depression, aberrant demeanor) after receiving diazepam. Anesthetic recovery from diazepam/ketamine was more active and unsettled as compared with alfaxalone as a sole agent.[23] There have been sporadic reports of cats developing idiosyncratic hepatic failure after receiving oral (but not injectable) diazepam (not dose-dependent) for several days.[17] Clinical signs (eg, anorexia, lethargy, increased ALT/AST, hyperbilirubinemia) occurred 5 to 11 days after beginning oral therapy, and 10 out of 11 patients died or were euthanized within 15 days. Slow biotransformation and inhibition of the efflux of bile, resulting in accumulation of bile acids in the hepatocytes, might contribute to the liver injury observed in cats that received repeated doses of oral diazepam.[10]

In horses, diazepam may cause muscle fasciculations, weakness, and ataxia at doses sufficient to cause sedation. Doses greater than 0.2 mg/kg may induce recumbency as a result of muscle relaxant properties and general CNS depressant effects. Diazepam is not recommended as a sole agent for sedation in this species.

Adverse effects can be reversed with flumazenil. See ***Flumazenil.***

Reproductive/Nursing Safety

In humans, diazepam has been implicated in causing congenital abnormalities when it is administered during the first trimester of pregnancy. Infants born to mothers who were given large doses of benzodiazepines shortly before delivery have been reported to suffer from apnea, impaired metabolic response to cold stress, difficulty in feeding, hyperbilirubinemia, and hypotonia. Withdrawal symptoms have occurred in infants whose mothers took benzodiazepines long-term during pregnancy. The veterinary significance of these effects is unclear, but these agents should only be used during the first trimester of pregnancy when the benefits clearly outweigh the risks associated with their use.

Benzodiazepines and their metabolites are distributed into milk

and may cause CNS effects in nursing neonates. In humans, diazepam use is not recommended while breastfeeding.[24]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

When diazepam is administered alone, overdose effects are generally limited to significant CNS depression (eg, confusion, coma, decreased reflexes). In rare circumstances, hypotension, respiratory depression, and cardiac arrest have been reported in human patients.

Treatment of acute toxicity consists of standard protocols for removing and/or binding the drug in the gut if diazepam is administered orally; provide supportive systemic therapies as needed. Use of analeptic agents (ie, CNS stimulants such as caffeine) is generally not recommended. Flumazenil may be considered for adjunctive treatment of benzodiazepine overdose.

Successful treatment of a cat with hepatic necrosis included the use of lactulose, metronidazole, vitamin K, N-acetylcysteine, and Sadenosylmethionine, along with supportive care.[25]

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving diazepam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: Concurrent use may increase the bioavailability and pharmacologic effects of benzodiazepines; monitoring and adjustment of benzodiazepine dose are needed.
- **Antacids, Aluminum-, Calcium- And Magnesium-Containing**: May slow the rate, but not the extent, of oral absorption; administration 2 hours apart may avoid this potential interaction.
- **Antidepressants** (eg, **amitriptyline**, **clomipramine**, **mirtazapine**): Concurrent use increases the risk for CNS and/or respiratory depression.
- **Antihypertensive Agents** (eg, **amlodipine**, **atenolol**, **enalapril**): Concurrent use may increase the risk for hypotension and orthostasis. Blood pressure monitoring is necessary.
- **Azole Antifungals** (eg, **itraconazole, ketoconazole**[11]): Metabolism of diazepam may be decreased, and excessive sedation may occur.
- **Carbonic Anhydrase Inhibitors** (eg, **acetazolamide**, **methazolamide**): Benzodiazepines may interfere with the beneficial effects of carbonic anhydrase inhibitors by inhibiting respiratory responses to hypoxia; this combination should be avoided.
- **CNS Depressant Agents** (eg, **barbiturates, opioids, anesthetics**): Combination may increase the risk for CNS and/or respiratory depression; monitoring and adjustment of dosages are needed.
- **Digoxin**: Serum levels may be increased; monitoring of serum digoxin levels and clinical signs of toxicity is needed.
- **Fluoxetine, Fluvoxamine**: Increased benzodiazepine levels are possible.
- **Hepatic Enzyme Inducers** (eg, **glucocorticoids**, **mitotane**, **rifampin, phenobarbital**[26]): Concurrent use may decrease benzodiazepine levels; monitoring of clinical response and adjustment of doses are necessary.
- **Hepatic Enzyme Inhibitors** (eg, **cimetidine, isoniazid**): Metabolism of diazepam may be decreased, and excessive sedation may occur.
- **Ifosfamide**: Concurrent use may increase the risk for ifosfamide-induced neurotoxic effects. Careful monitoring is needed, and discontinuation of both drugs may be necessary if signs of encephalopathy occur.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): Metabolism of diazepam may be decreased, and excessive sedation may occur.
- **Macrocyclic Lactones** (eg, **ivermectin, milbemycin oxime**): Benzodiazepine effects may be potentiated by concurrent macrocyclic lactone use.
- **Melatonin**: Increased risk for CNS depression and prolonged diazepam effects
- **Non-Depolarizing Neuromuscular Blockers** (eg, **atracurium**, **pancuronium**): Concurrent use may potentiate, attenuate, or have no effect; monitoring of respiratory status is necessary.
- **Propranolol**: May slow diazepam metabolism
- **Theophylline, Aminophylline**: Concurrent use may decrease the concentrations and effectiveness of benzodiazepines. Withdrawing theophylline from a stable patient may increase the risk for benzodiazepine toxicity; monitoring for adverse effects is needed, and dosages must be adjusted accordingly.
- **Yohimbine**: Limited data indicate that yohimbine may decrease the therapeutic effects of anxiolytic drugs.

Laboratory Considerations

- Patients receiving diazepam may show false-negative **urine glucose** results if *Diastix*® or *Clinistix*® tests are used.
- Secondary to propylene glycol in IV diazepam, patients may show a false-positive **ethylene glycol** test.
- Benzodiazepines may decrease the thyroidal uptake of I^{123} or I^{131}.

Dosages

DOGS:

Cluster seizures or status epilepticus (extra-label):

Rectal: Using diazepam parenteral solution, diazepam 0.5 – 2 mg/kg rectally[27,28]; if the patient is receiving phenobarbital, diazepam 2 mg/kg rectally can be used.[26] Administer at the onset of a seizure and up to 3 times in a 24-hour period.[28] If the client is administering, they should stay with the dog for 1 hour after administration. Because diazepam is inactivated by light and adheres to plastic, it is best to dispense the drug in the original glass vial and instruct the client to draw the required amount into a syringe when needed. A rubber catheter or teat cannula is then placed on the syringe for rectal administration. A study found that compounded 2 mg rectal suppositories did not achieve plasma levels of diazepam/nordiazepam sufficient for emergency treatment of seizures in dogs.[14] **NOTE:** Intranasal midazolam appears superior to rectal diazepam for controlling status epilepticus.[4]

Intranasal: Based on a pharmacokinetic study, diazepam may also be given intranasally (at home or in the clinic) at 0.5 mg/kg. Dogs on chronic phenobarbital therapy may require higher doses (1 – 2 mg/kg).[29]

IV (bolus): Diazepam 0.5 – 1 mg/kg IV; may be repeated every 10 minutes up to 3 times[16]

IV (CRI) : Diazepam 0.1 – 2 mg/kg/hour IV CRI. Caution is advised, as diazepam can crystallize in solution and adsorb to PVC tubing. (See ***Compatibility/Compounding Considerations*** and ***Storage/Stability***)

Functional urethral obstruction/urethral sphincter hypertonus (extra-label): Diazepam 2 – 10 mg/dog (NOT mg/kg) PO every 8 hours[30]

Short-term management of skeletal muscle spasms (extra-label): Diazepam 0.5 – 2 mg/kg IV[31]

Psychotherapeutic agent (extra-label):

a) **Situational anxiety**: Diazepam 0.5 – 2 mg/kg PO PRN; preferably 30 minutes to 1 hour in advance of the anticipated event.[32] **NOTE**: As compared with humans, diazepam dosages for dogs are very high; human pharmacists may be unaware that these are appropriate.

b) **In combination with fluoxetine and behavior modification therapy for anxiety-related disorders**: Diazepam 0.3 mg/kg PO once daily for 4 weeks; it should be initiated at the same time as fluoxetine 1 mg/kg PO once daily.[33]

Adjunctive treatment of metronidazole toxicity (extra-label): 0.43 mg/kg IV as an initial bolus, followed by 0.43 mg/kg PO every 8 hours for 3 days[34]

Strychnine poisoning (extra-label): Diazepam 1 mg/kg IV slowly, followed by 1 mg/kg IM[35]

Anesthetic premedication in combination with other sedatives (extra-label): Diazepam 0.1 – 0.5 mg/kg IV. Combination with opioids or alpha-2 agonists is highly recommended to decrease drug dosages, minimize paradoxical excitation, and achieve a more profound, predictable level of sedation and muscle relaxation.[36] A slightly higher dose of diazepam 0.2 – 0.6 mg/kg IV is approved for products available in other countries.[31,37] Diazepam is more commonly used as part of induction rather than as a premedicant.

In combination with an induction agent for anesthesia (extra-label): Diazepam 0.1 – 0.3 mg/kg IV. Can be combined with ketamine to counteract the muscle rigidity caused by ketamine and reduce the dose of ketamine. Diazepam is also used with propofol or alfaxalone to reduce the amount of these induction agents, which decreases dose-dependent cardiovascular and respiratory depression caused by many induction drugs.[38–42]

CATS:

NOTE: Because of concerns associated with oral diazepam and rare idiosyncratic hepatic failure in cats, oral use in cats is not recommended; safer alternatives are available.

Anesthetic premedication in combination with other sedatives (extra-label): Diazepam 0.1 – 0.3 mg/kg IV. Combination with opioids or alpha-2 agonists is highly recommended to decrease drug dosages, minimize paradoxical excitation, and achieve a more profound, predictable level of sedation and muscle relaxation. A slightly higher dose of diazepam (0.2 – 0.6 mg/kg IV) is approved in a UK product.[16,31] Diazepam 0.5 mg/cat (NOT mg/kg) in combination with ketamine 10 mg/cat (NOT mg/kg) given IV was deemed effective and safe to assist physical restraint for blood sampling.[43] Diazepam is more commonly used as part of induction rather than as a premedicant.

In combination with an induction agent for anesthesia (extra-label): Diazepam 0.1 – 0.3 mg/kg IV. Can be combined with ketamine to counteract the muscle rigidity caused by ketamine and reduce the dose of ketamine. Diazepam is also used with propofol or alfaxalone to reduce the amount of these induction agents, which decreases dose-dependent cardiovascular and respiratory depression caused by many induction drugs.[38–42]

EQUINE:

Anticonvulsant in foals (extra-label): 0.1 – 0.4 mg/kg slow IV and repeated as necessary[17]

Field anesthesia (extra-label):

a) The following protocol was used for field castration in ponies with good results: After premedication with detomidine 20 µg/kg IV and phenylbutazone 4.4 mg/kg IV, anesthesia was induced with diazepam 0.06 mg/kg combined with ketamine 2.2 mg/kg IV. Midazolam can be substituted for diazepam at the same dosage.[44]

b) Preanesthetic: Diazepam 0.13 mg/kg IM 20 minutes prior to xylazine and ketamine[37]

c) Total IV anesthesia in mules: Following sedation with xylazine 1.3 mg/kg IV, induce anesthesia with diazepam 0.03 mg/kg and ketamine 2.2 mg/kg IV, lateral recumbency and normal gait occurred at 1.8 and 32.8 minutes, respectively; duration of anesthesia was 15.3 minutes.[45]

d) Tranquilization in donkeys: Diazepam 0.1 mg/kg with acepromazine 0.1 mg/kg IV decreased the latency period and enhanced tranquilization compared with acepromazine alone.[46]

SHEEP/GOATS:

Sedation/tranquilization (extra-label): Diazepam 0.2 – 0.5 mg/kg IV or 0.5 – 1 mg/kg IM.[47] Lower doses (ie, 0.1 – 0.2 mg/kg IV) of diazepam have also been recommended.[48,49]

Anesthesia (extra-label):

a) Diazepam 0.15 – 0.5 mg/kg IV in combination with ketamine 5 – 10 mg/kg IV is one of the most common anesthetic protocols.[47,50–54]

b) Diazepam 0.4 mg/kg IM in combination with ketamine 22 mg/kg IM[55]; however, this combination provided longer time to onset and inadequate anesthetic depth during the most painful portion of the surgery when compared to IM ketamine combined with xylazine.

NEW WORLD CAMELIDS:

Field anesthesia in alpacas (extra-label): Diazepam 0.2 mg/kg with ketamine 4 mg/kg IV[56]

BIRDS:

Adjunctive therapy of pain control (with analgesics); (extra-label): Diazepam 0.5 – 2 mg/kg IV or IM[57]

Sedation/induction (extra-label):

a) Diazepam 0.5 – 2 mg/kg IV or IM. Dosage applies to small pet birds and medium-sized parrots. Adjustments need to be made for large-sized parrots or wild species, such as raptors.[58]

b) Diazepam 0.5 mg/kg IM with ketamine 10 mg/kg IM as premedication reduced induction time and sevoflurane requirements in parrots.[59]

c) Intranasal sedation with diazepam 13.6 mg/kg produced adequate sedation in budgerigars; midazolam had a faster onset (1.3 vs 2.8 minutes, respectively) but shorter duration (71 vs 165 minutes).[60]

FERRETS:

Premedication/sedation (extra-label):

Diazepam 0.5 mg/kg IM or IV (IV preferred)

Diazepam 0.2 mg/kg (IV assumed) if using in combination with ketamine 2 – 5 mg/kg[58]

RABBITS/RODENTS/SMALL MAMMALS (extra-label):

Rabbits: *Sedation*: Diazepam 0.5 – 2 mg/kg IV, IM, or intranasally[61,62] (IV preferred; intranasal may cause tissue irritation – midazolam is preferred for this route). *Anesthesia:* Diazepam 0.5 – 1 mg/kg in combination with ketamine 20 – 35 mg/kg IM or IV[58]

Hedgehogs: *Long anesthesia:* Diazepam 0.5 – 2 mg/kg in combination with ketamine 5 – 20 mg/kg IM[58]

Hamsters, gerbils, mice, rats: Diazepam 3 – 5 mg/kg IM

Guinea pigs: Diazepam 0.5 – 3 mg/kg IM[63]

Monitoring

- CNS: signs of sedation or paradoxical excitement
- Cardiovascular system: blood pressure—can cause hypotension if administered rapidly IV

- Respiratory system: respiratory rate, $ETCO_2$, and SpO_2—mild respiratory depression can occur, with a more moderate impact if other respiratory depressants (eg, opioids) are administered.
- Horses should be observed carefully for ataxia.
- Clinical response to treatment

Client Information

- This medicine may cause sedation and/or disorientation, which may impair the performance of working animals.
- When using this medicine for thunderstorm phobias or other triggers (eg, separation anxiety), give the medicine to your animal about an hour before the event or trigger.
- This medicine may be given with or without food. If your animal vomits or acts sick after receiving the medication on an empty stomach, give the medicine with food or small treats. Contact your veterinarian if vomiting continues.
- Contact your veterinarian immediately if your animal develops yellowing of the skin, gums, or whites of the eyes (*jaundice*).
- Sleepiness is the most common side effect. This medicine can change your animal's behavior (eg, hyperactivity, anxiety) in unexpected ways.
- This medicine may increase your animal's appetite, especially in cats.
- Contact your veterinarian immediately if your animal stops eating or seems depressed.

Chemistry/Synonyms

Diazepam, a benzodiazepine, is a white-to-yellow, practically odorless, crystalline powder with a melting point between 131°C (267.8°F) and 135°C (275°F) and pK_a of 3.4. Diazepam is tasteless initially but develops a bitter aftertaste. One gram of diazepam is soluble in 333 mL of water or 25 mL of alcohol and is sparingly soluble in propylene glycol. The pH of the commercially prepared injectable solution is 6.2 to 6.9. It consists of a 5 mg/mL solution with 40% propylene glycol, 10% ethanol, 5% sodium benzoate/benzoic acid buffer, and 1.5% benzyl alcohol as a preservative.

Diazepam may also be known as diazepamum, LA-III, NSC-77518, or Ro-5-2807; many trade names are available.

Storage/Stability

Store all diazepam products at room temperature (15°C to 30°C [59°F-86°F]). Keep the injection from freezing temperatures and protect from light. Store the oral forms (eg, tablets, capsules) in tightly closed containers and protect them from light.

Because diazepam may adsorb to plastic, it should not be stored in plastic syringes but can be drawn up in syringes if intended to be administered within 4 hours. The drug may also significantly adsorb to IV solution plastic (eg, PVC) bags and infusion tubing. This adsorption appears to be dependent on several factors (eg, temperature, drug concentration, flow rates, line length).

Consider the following to minimize the adsorption of diazepam. Use glass or polyolefin containers; if you use PVC bags, select the lowest possible surface:volume ratio and minimize the storage time. The use of non-PVC administration sets will reduce loss. If you use PVC tubing, it should be the shortest possible length with a small diameter, and the set should not contain a burette chamber. More rapid flow rates (consistent with safe clinical use) will also reduce the loss of diazepam.[64]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The manufacturers of injectable diazepam do not recommend the drug be mixed with any other medication or IV diluent, and diluting for infusion cannot be recommended. Although some studies have shown that dilution in some IV solutions at low concentrations may not exhibit visible precipitates, microcrystal formation could not be ruled out. Because there is continued interest in IV infusions of diazepam, some studies indicate that diazepam injection may be **compatible** with various drugs and IV fluids (eg, diluted to a concentration of 5 mg/50 mL to 5 mg/100 mL with 0.9% sodium chloride, 5% dextrose, Ringer's, or lactated Ringer's injection).

Mixing ketamine with diazepam in the same syringe or IV bag has been suggested but is not recommended, as precipitation may occur. Although there are many anecdotal reports of mixing ketamine with diazepam in the same syringe just prior to injection, there does not appear to be any published information documenting the stability of the drugs after mixing. Use should be avoided if a visible precipitate forms.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

The International Federation for Equestrian Sports (FEI) lists this drug as a *prohibited substance–controlled substance*.

HUMAN-LABELED PRODUCTS:

Diazepam Injection: 5 mg/mL in 2 mL *Carpuject*® cartridges; generic; (Rx, C-IV)

Diazepam Oral Tablets: 2 mg, 5 mg, and 10 mg; *Valium*®, generic; (Rx, C-IV)

Diazepam Oral Solution: 1 mg/mL in 500 mL, and 5 mg and 10 mg patient cups; generic; (Rx, C-IV); Concentrated oral solution: 5 mg/mL in 30 mL with dropper; *Diazepam Intensol*®; (Rx, C-IV)

Diazepam Rectal Gel: 2.5 mg, 10 mg, and 20 mg; *Diastat*®, generic; (Rx, C-IV)

Diazoxide

(di-az-***ok***-side) *Proglycem*®

Direct Vasodilator/Hyperglycemic

Prescriber Highlights

- ► Orally administered drug used in the management of insulinomas in small animal species
- ► Contraindications include functional hypoglycemia or hypoglycemia secondary to insulin overdose (diabetics) and hypersensitivity to thiazide diuretics.
- ► Use with caution in patients with congestive heart failure or renal insufficiency
- ► Most common adverse effects include anorexia, vomiting, and/or diarrhea (may be reduced by giving with food).
- ► Availability and expense may be problematic. May need to be compounded
- ► Bitter taste may make administration difficult.

Uses/Indications

Oral diazoxide has been used for the treatment of hypoglycemia secondary to hyperinsulin secretion (eg, insulinoma) in patients refractory to glucocorticoid and dietary therapy.

Pharmacology/Actions

Although related structurally to the thiazide diuretics, diazoxide does not possess any appreciable diuretic activity. By directly causing a vasodilatory effect on the smooth muscle in peripheral arterioles, diazoxide reduces peripheral resistance and blood pressure.

Diazoxide exhibits hyperglycemic activity by directly inhibiting pancreatic insulin secretion, stimulating hepatic gluconeogenesis and glycogenolysis, and stimulating the beta-adrenergic system to cause epinephrine release and inhibit tissue use of glucose. Diazoxide's inhibition of insulin release may be a result of the drug's ability to decrease the intracellular release of ionized calcium, thus preventing release of insulin from beta cell insulin granules. Diazoxide does not apparently affect the synthesis of insulin, nor does it possess any antineoplastic activity.

Pharmacokinetics

The serum half-life of diazoxide has been reported to be ≈5 hours in dogs; other pharmacokinetic parameters in dogs appear to be unavailable. In humans, serum diazoxide levels (dosed at 10 mg/kg PO) peaked at ≈12 hours after dosing with capsules. It is unknown what blood levels are required to obtain hyperglycemic effects. Highest concentrations of diazoxide are found in the kidneys with high levels also found in the liver and adrenal glands. Approximately 90% of the drug is bound to plasma proteins and it crosses the placenta and into the CNS. It is not known if diazoxide is distributed into milk. Diazoxide is partially metabolized in the liver and is excreted as both metabolites and unchanged drug by the kidneys. Serum half-life of the drug is prolonged in patients with renal impairment.

Contraindications/Precautions/Warnings

Diazoxide should not be used in patients with functional hypoglycemia or for treating hypoglycemia secondary to insulin overdose in diabetic patients. Unless the potential advantages outweigh the risks, do not use in patients hypersensitive to thiazide diuretics.

Because diazoxide can cause sodium and water retention, use cautiously, and consider dose reductions in patients with congestive heart failure or renal insufficiency.

Do not confuse diaZOXide with DIAZepam or diltiazem.

Adverse Effects

When used to treat insulinomas in dogs, the most common adverse effects include hypersalivation, anorexia, vomiting, and/or diarrhea. Other effects that may be seen include tachycardia, hematologic abnormalities (eg, agranulocytosis, aplastic anemia, thrombocytopenia), pancreatitis, diabetes mellitus, cataracts, and sodium and water retention.

Administering the drug with meals or temporarily reducing the dosage may alleviate the GI side effects. Because diazoxide is metabolized in the liver, adverse effects may be more readily noted in dogs with concurrent hepatic disease.

Adverse effects reported in ferrets include inappetence, vomiting, diarrhea, malaise, and myelosuppression.

Reproductive/Nursing Safety

Diazoxide crosses the placenta.[1] Fetal islet cell degeneration has been demonstrated in animals. In addition, fetal resorption has been observed in rats, and fetal skeletal and cardiac malformations or teratogenicity have been observed in rabbits. Diazoxide may cause cessation of uterine contractions when administered during labor.

It is unknown if diazoxide enters milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral doses of up to 500 mg/kg have been tolerated in dogs.[1] The oral LD_{50} is over 5000 mg/kg in rats and 219 mg/kg in guinea pigs. An acute overdose may result in severe hyperglycemia and ketoacidosis. Treatment should include insulin (see specific ***Insulin*** monographs), fluids, and electrolytes. Intensive and prolonged monitoring is recommended.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving diazoxide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-Adrenergic Agents** (eg, **phenoxybenzamine**): May decrease the effectiveness of diazoxide by increasing glucose levels
- **Glucocorticoids** (eg, **dexamethasone, prednis(ol)one**): If used in combination with diazoxide, may enhance hyperglycemic effects
- **Hypotensive Agents, Other** (eg, **amlodipine**, **hydralazine**, **prazosin, telmisartan**): Diazoxide may enhance the hypotensive actions of other hypotensive agents.
- **Phenothiazines** (eg, **acepromazine**, **chlorpromazine**): May enhance the hyperglycemic effects of diazoxide
- **Thiazide diuretics**: May potentiate the hyperglycemic effects of oral diazoxide.[1] Some clinicians have recommended using hydrochlorothiazide in combination with diazoxide, if diazoxide alone is ineffective to increase blood glucose levels. Caution: hypotension may occur.

Laboratory Considerations

- Diazoxide will cause a false negative insulin response to the **glucagon-stimulation** test.
- Diazoxide may displace **bilirubin** from plasma proteins.

Dosages

DOGS:

Adjunctive treatment of hypoglycemia secondary to insulin-secreting islet cell or non-islet cell tumors (extra-label): Initially 5 mg/kg PO twice daily.[2] May gradually increase to effect up to a maximum dosage of 30 mg/kg PO twice daily. If diazoxide alone is ineffective, may consider using hydrochlorothiazide (1 – 2 mg/kg PO every 12 hours) in combination with diazoxide.

FERRETS:

Hypoglycemia secondary to insulin-secreting islet cell tumors (extra-label): After surgical resection of pancreatic nodules or partial pancreatectomy: Prednisone 0.5 – 2 mg/kg PO every 12 hours will usually control mild to moderate clinical signs. Begin at lowest dose and gradually increase as needed. Add diazoxide when clinical signs cannot be controlled with prednisone alone. Begin diazoxide 5 – 10 mg/kg PO every 12 hours. Prednisone dosage may need to be lowered at the same time. If the initial dosage does not control clinical signs, the dosage can be gradually increased to a maximum of 30 mg/kg PO every 12 hours.

SMALL MAMMALS:

Guinea pigs; Hypoglycemia secondary to insulin-secreting islet cell tumors (extra-label): Based on a single case report: Initially, 5 mg/kg PO every 12 hours. Based on the blood glucose curve, dosage was gradually increased to 25 mg/kg PO every 12 hours.

Monitoring

- Blood (serum) glucose. The goal of therapy is to identify a dosage

that reduces or eliminates hypoglycemia and its associated clinical signs. The ideal dosage would also avoid hyperglycemia (glucose greater than 180 mg/dL). The dosage should be adjusted, starting with lower dosages and titrating upwards, until the lowest dosage is found to produce the desired clinical and laboratory results.
- Baseline and periodic (at least every 3 to 4 months) CBC
- Physical examination (monitor for adverse effects)

Client Information
- This medicine is used to increase blood sugar levels.
- Give this medicine with food to decrease the gastrointestinal side effects (drooling, vomiting, diarrhea, loss of appetite).
- If you have difficulty getting your animal to take the medicine, contact your veterinarian or pharmacist for tips to help with dosing and reducing the stress of medication time. Diazoxide has a bitter taste and taste-masking agents (preferably sugar-free) may be useful in increasing acceptance of this medication.
- Shake suspensions well.
- Watch for signs of high blood sugar (*hyperglycemia*) such as drinking more than normal, needing to urinate more, increased appetite, lack of energy, muscle weakness, depression, or severe vomiting. These signs may indicate the dose of the medicine may need to be adjusted.
- Contact your veterinarian if you notice your animal has signs of low blood sugar (*hypoglycemia*) such as seizures, muscle weakness, collapse, muscle twitching, low energy level/depression, or unsteadiness. These signs may indicate the dose of the medicine may need to be adjusted.

Chemistry/Synonyms
Related structurally to the thiazide diuretics, diazoxide occurs as an odorless white to creamy-white crystalline powder with a melting point of ≈165°C (330°F). It is practically insoluble to sparingly soluble in water and slightly soluble in alcohol.

Diazoxide may also be known as diazoxidum, NSC-64198, Sch-6783, SRG-95213, *Eudemine®*, *Glicemin®*, *Hypertonalum®*, *Hyperstat IV®*, *Proglycem®*, *Proglicem®*, *Sefulken®*, or *Tensuril®*.

Storage/Stability
Diazoxide capsules and oral suspensions should be stored protected from light at 25°C (77°F), with excursions permitted from 15°C to 30°C (59°F-86°F).[1] Protect solutions and suspensions from freezing. Do not use darkened solutions/suspensions, as they may be subpotent.

Compatibility/Compounding Considerations
Diazoxide has a very bitter taste and taste-masking agents (preferably sugar-free) may be useful in increasing patient acceptance of this medication.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Diazoxide Oral Suspension: 50 mg/mL with sorbitol in 30 mL calibrated dropper; *Proglycem®*; (Rx). Available in chocolate-mint flavor.

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Dichlorphenamide
(dye-klor-***fen***-a-mide) *Keveyis®*

Carbonic Anhydrase Inhibitor

Prescriber Highlights
- ► Oral agent used primarily for open-angle glaucoma when topical carbonic anhydrase inhibitors cannot be used
- ► Contraindicated in patients with significant hepatic, renal, pulmonary, or adrenocortical insufficiency; hyponatremia; hypokalemia; hyperchloremic acidosis; or electrolyte imbalance
- ► Adverse effects include panting, GI disturbances, alteration of CNS state, and rashes.
- ► Give oral doses with food if GI upset occurs.
- ► Monitor for glaucoma with tonometry; check electrolytes
- ► Limited product availability; may need to be obtained from a compounding pharmacy

Uses/Indications
Dichlorphenamide is used for the medical treatment of glaucoma. Because of availability issues and toxic effects associated with systemic therapy, topical carbonic anhydrase inhibitors (eg, dorzolamide, brinzolamide) are preferred over those administered orally.

Pharmacology/Actions
The carbonic anhydrase inhibitors act by a noncompetitive, reversible inhibition of the enzyme carbonic anhydrase. This reduces the formation of hydrogen and bicarbonate ions from carbon dioxide and reduces the availability of these ions for active transport into body secretions.

Pharmacologic effects of the carbonic anhydrase inhibitors include decreased formation of aqueous humor and thus reduced intraocular pressure; increased renal tubular secretion of sodium and potassium and, to a greater extent, bicarbonate, leading to increased urine alkalinity and volume; and anticonvulsant activity, which is independent of its diuretic effects (mechanism not fully understood, but may be due to carbonic anhydrase or a metabolic acidosis effect).

Pharmacokinetics
The pharmacokinetics of this agent have apparently not been studied in domestic animals. In small animal species, onset of action is 30 minutes, maximal effect occurs in 2 to 4 hours, and duration of action is 8 to 12 hours.

Contraindications/Precautions/Warnings
Carbonic anhydrase inhibitors are contraindicated in patients with significant hepatic disease (may precipitate hepatic coma), renal or adrenocortical insufficiency, hyponatremia, hypokalemia, hyperchloremic acidosis, or electrolyte imbalance. They should not be used in patients with severe pulmonary obstruction that are unable to increase alveolar ventilation or those that are hypersensitive to them.

Adverse Effects
Adverse effects that may be encountered include panting, GI disturbances (eg, inappetence, vomiting, diarrhea), CNS effects (eg, sedation, depression, excitement), hematologic effects (eg, myelosuppression), renal effects (eg, crystalluria, dysuria, renal colic, polyuria), metabolic acidosis, hypokalemia, hyperglycemia, hyponatremia, hyperuricemia, hepatic insufficiency, dermatologic effects (rash), and hypersensitivity reactions.

Reproductive/Nursing Safety
Teratogenicity has been demonstrated in rats given dichlorphenamide at 17 times the maximum recommended human dose.[1] It is unknown if dichlorphenamide enters into milk. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Information regarding overdose of this drug is not readily available. It is suggested to monitor serum electrolytes, blood gases, volume status, and CNS status during an acute overdose. Treat clinical signs supportively.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dichlorphenamide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amantadine**: Increased amantadine concentrations may occur.
- **Antidepressants, Tricyclic**: Alkaline urine caused by dichlorphenamide may decrease excretion.
- **Aspirin** (or other **salicylates**): Increased risk for dichlorphenamide accumulation and toxicity; increased risk for metabolic acidosis; dichlorphenamide may result in elevated salicylate levels. This combination is contraindicated in human patients.
- **Digoxin**: Increased risk for toxicity, as dichlorphenamide may cause hypokalemia
- **Famotidine**: Increased famotidine exposure may occur.
- **Insulin**: Rarely, carbonic anhydrase inhibitors interfere with the hypoglycemic effects of insulin.
- **Methenamine Compounds**: Dichlorphenamide may negate antiseptic effects in the urine.
- **Methotrexate**: May increase methotrexate exposure and risk for methotrexate toxicity. Avoid combination if possible.
- **Mexiletine**: Dichlorphenamide may reduce mexiletine excretion and increase risk for mexiletine toxicity.
- **Potassium, Drugs Affecting** (eg, **amphotericin B, corticosteroids, corticotropin,** or other **diuretics**): Concomitant use may exacerbate potassium depletion.
- **Phenobarbital**: Dichlorphenamide increases urinary excretion of phenobarbital and may reduce phenobarbital levels.
- **Primidone**: Decreased primidone concentrations
- **Quinidine**: Alkaline urine caused by dichlorphenamide may decrease excretion.

Laboratory Considerations

- By alkalinizing the urine, carbonic anhydrase inhibitors may cause false positive results in determining **urine protein** using bromophenol blue reagent (*Albustix®, Albutest®, Labstix®*), sulfosalicylic acid (*Bumintest®*, Exton's Test Reagent), nitric acid ring test, or heat and acetic acid test methods.
- Carbonic anhydrase inhibitors may decrease **iodine uptake** by the thyroid gland in hyperthyroid or euthyroid patients.

Dosages

DOGS:

Adjunctive glaucoma treatment (extra-label): 2 – 5 mg/kg PO every 8 to 12 hours[2–4]

CATS:

Adjunctive glaucoma treatment (extra-label): 0.5 – 2 mg/kg PO every 8 to 12 hours[3,5]

Monitoring

- Intraocular pressure measurement (ie, tonometry)
- Baseline and periodic serum electrolytes and acid-base status
- Baseline and periodic CBC with differential when used long term
- Adverse effects (eg, GI signs, rash, panting, altered CNS status)

Client Information

- Give this medicine as directed by your veterinarian. If your animal vomits or acts sick after receiving the medicine on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Notify your veterinarian if you notice abnormal bleeding or bruising, vomiting, diarrhea, abnormal behavior, tremors, or a rash.

Chemistry/Synonyms

A carbonic anhydrase inhibitor, dichlorphenamide occurs as a white or nearly white crystalline powder with a melting range of 235-240°C, and pK_as of 7.4 and 8.6. It is very slightly soluble in water and soluble in alcohol.

Dichlorphenamide may also be known as diclofenamidum, *Antidrasi®, Daranide®, Fenamide®, Glaucol®, Glauconide®, Glaumid®, Keveyis®, Oralcon®, Oratrol®,* or *Tensodilen®*.

Storage/Stability

Store tablets in well-closed containers and at room temperature (20°C-25°C [68°F-77° F]).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Oral Tablet: 50 mg; *Keveyis®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Diclazuril

(dye-***klaz***-yoor-il) *Protazil®, Clinacox®*

Antiprotozoal

Prescriber Highlights

- ► FDA-approved for equine protozoal myeloencephalitis (EPM) in horses and as a coccidiostat in broiler chickens and growing turkeys
- ► Appears to be well tolerated

Uses/Indications

In the United States, diclazuril is FDA-approved for the treatment of equine protozoal myeloencephalitis (EPM) caused by *Sarcocystis neurona*[1] and as a coccidiostat in broiler chickens and growing turkeys.[2] Diclazuril prevents *S neurona* infection in foals that live in high exposure areas.[3]

In the United Kingdom, oral diclazuril suspension is approved for the treatment and prevention of coccidial infections in lambs, caused in particular by the more pathogenic *Eimeria* spp, *Eimeria crandallis,* and *Eimeria ovinoidalis,* and in calves as an aid in the control of coccidiosis caused by *Eimeria bovis* and *Eimeria zuernii*. Studies comparing diclazuril and toltrazuril have shown that both are effective in reducing oocyte shedding in calves, whereas toltrazuril appears to be more effective than diclazuril in lambs.[4–7]

Diclazuril could potentially be useful in treating coccidiosis, *Neospora caninum,* and *Toxoplasma* spp infections in dogs or cats.

Pharmacology/Actions

The triazine class of antiprotozoals is believed to target the plastid body, an organelle found in the members of the Apicomplexa phy-

lum, including *Sarcocystis neurona*. The actual mechanism of action is not well described. In vitro levels required to inhibit (95%) *S neurona* are about 1 ng/mL.[1]

Pharmacokinetics

In horses, oral bioavailability is about 5%. CSF concentrations are ≈5% of those found in plasma. Elimination half-life is prolonged (43 to 65 hours).[1] Doses of 1 mg/kg/day should give mean steady-state plasma concentrations of about 2 – 2.5 mg/mL, with corresponding CSF concentrations of 20 – 70 ng/mL, which is in excess of the in vitro IC_{95} (1 ng/mL).[8] A dosage of 0.5 mg/kg/day given to adult horses resulted in CSF concentrations of 26 ng/mL, compared with 25 ng/mL in horses that received 1 mg/kg/day.[9]

Contraindications/Precautions/Warnings

Diclazuril is contraindicated in patients that are known to be hypersensitive to it.

Do not feed diclazuril to breeding turkeys or to birds that produce eggs for human consumption.[2]

Adverse Effects

Diclazuril appears to be well tolerated in horses. In field trials, no adverse effects could be ascribed to the drug.[1,8]

On rare occasions, highly susceptible lambs may develop severe diarrhea (scour) after dosing; fluid therapy is required, and antibiotics may be necessary.

Reproductive/Nursing Safety

The manufacturer states that the safe use of diclazuril in horses used for breeding purposes, during pregnancy, or in lactation has not been evaluated.[1] Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to the offspring.

Overdose/Acute Toxicity

Limited information is available, but diclazuril appears to have a large safety margin in animals. Normal horses dosed up to 50 mg/kg/day (50 times the label dosage) for 42 days developed only marginal adverse effects (decreased grain intake, decreased weight gain, increases in creatinine and BUN).[1] Single doses of up to 60 times the label dosage in lambs and calves did not cause any demonstrable adverse effects.[10]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

- None were noted. The safety of diclazuril with concomitant therapies in horses has not been evaluated.[1]

Laboratory Considerations

- None were noted.

Dosages

DOGS/CATS

***Cystoisospora* spp (Coccidiosis) infection** (extra-label):

a) 25 mg/kg PO once[11,12]
b) Kittens: 1 mL (2.5 mg) of the sheep solution per 4 kg (8.8 lb) PO[13]
c) 2.5 – 5 mg/kg PO once, using product labeled for mammals[14]

HORSES:

Treatment of equine protozoal myeloencephalitis | *Sarcocystis neurona* (label dosage; FDA-approved): Using the oral pellets and provided cup: Top-dress at the rate of 1 mg/kg/day for 28 days.[1] If horse's bodyweight is in between 2 graduations on the dosing cup, fill the cup to the higher of the 2 marks. **NOTE**: Although the label lists the duration of treatment as 28 days, most horses will require longer periods of therapy (ie, 6 to 8 weeks or longer); endpoint of therapy is determined by sustained improvement of neurologic signs.[15]

Prevention of equine protozoal myeloencephalitis (*S neurona*) in foals (extra-label): Using the oral pellets, top-dress at daily ration of 0.5 mg/kg. Begin at 4 weeks of age; study duration was 12 months.[3]

Prevention of equine protozoal myeloencephalitis (*S neurona*) in adult horses (extra-label): 0.5 mg/kg twice weekly (every 3 or 4 days). Horses maintained serum diclazuril concentration above 1 ng/mL throughout the study period.[16]

CATTLE (CALVES):

Aid to control coccidiosis (extra-label): 1 mg/kg PO as a single dose, 14 days after moving into a potentially high-risk environment.[10] It is good practice to ensure the cleanliness of calf housing. Recommended to treat all calves in pen.

SHEEP (LAMBS):

Coccidiosis (extra-label):

a) Treatment: 1 mg/kg PO once[10]
b) Prevention: 1 mg/kg PO once at about 4 to 6 weeks of age at the time that coccidiosis can normally be expected on the farm.[10] May repeat one time ≈3 weeks after the first dosing if conditions of high infection pressure exist. Recommended to treat all lambs in flock.

BROILER CHICKENS:

Prevention of coccidiosis caused by *Eimeria tenella, Eimeria necatrix, Eimeria acervulina, Eimeria brunetti, Eimeria mitis (mivati),* and *Eimeria maxima* (label dosage; FDA-approved). The Type A medicated feed article must be mixed per manufacturer's directions to result in a Type B (and ultimately a Type C) medicated feed to be fed directly to broilers.[2]

GROWING TURKEYS:

For the prevention of coccidiosis caused by *Eimeria adenoeides, Eimeria gallopavonis,* and *Eimeria meleagrimitis* (label dosage; FDA-approved). The Type A medicated feed article must be mixed per manufacturer's directions to result in a Type B (and ultimately a Type C) medicated feed to be fed directly to turkeys.[2]

RABBITS:

Coccidiosis (extra-label): Add to drinking water at 10 ppm (0.01 mg/mL) for 48 hours[17]

Monitoring

- Clinical efficacy
- In horses with equine protozoal myeloencephalitis (EPM): neurologic examinations

Client Information

- Diclazuril is an antiprotozoal medication that is used for treating equine protozoal myeloencephalitis (EPM) in horses. It is also used to treat coccidiosis in dogs, cats, chickens, and other species.
- In dogs and cats, this medicine may be given with or without food. If your animal vomits or acts sick after receiving the drug on an empty stomach, give the medicine with food or a small treat to see if that helps. If vomiting continues, contact your veterinarian.
- For horses, this medicine is used as a "top-dress" over feed. This medicine must be given daily. It is important that your horse eats the entire dose.
- It is recommended to treat all animals in a pen or flock. Be sure to keep housing and pens clean.
- This medicine appears to be tolerated well, but you should report any side effects to your veterinarian.

Chemistry/Synonyms

Diclazuril occurs as a white to light-yellow powder. It is practically insoluble in water and alcohol.

Diclazuril may also be known as diclazurilo; diclazurilum; R 64433; and by the trade names, *Clinacox®*, *Protazil®*, and *Vecoxan®*.

Compatibility/Compounding Considerations

No specific information was noted.

Storage/Stability

Diclazuril pellets should be stored at room temperature (15-30°C [59°-86°F]). Store diclazuril granules at or below 25°C (77°F), excursions permitted to 40°C (104°F).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Diclazuril Oral Pellets 1.56% in 1.1 kg (2.4 lb) and 4.5 kg (10 lb) containers: *Protazil®*; (Rx). FDA-approved for use in horses not intended for food. One 1.1 kg (2.4 lb) bucket will treat a 577.9 kg (1274 lb) horse for 28 days; a 4.5 kg (10 lb) bucket treats five 500 kg (1100 lb) horses for 28 days.

Diclazuril 0.2% Type A Medicated Feed Article in 11.3 kg (25 lb) containers; *Clinacox®*; (OTC). FDA-approved for use in broiler chickens and growing turkeys; do not feed to breeding turkeys or birds producing eggs for human consumption. When used as labeled, no withdrawal time is required in the United States.

In the United Kingdom and other countries, diclazuril may be available as an oral suspension containing 2.5 mg/mL diclazuril.

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Diclofenac, Topical

(dye-***kloe***-fen-ak) *Surpass®*

Nonsteroidal Anti-Inflammatory Agent (NSAID)

Prescriber Highlights

- ► Topical NSAID FDA-approved for control of joint pain and inflammation in horses
- ► Use with caution in horses that are dehydrated or have pre-existing GI, cardiac, or renal disease.
- ► Adverse effects (uncommon) may include local inflammation at the site of application, GI ulceration, diarrhea, weight loss, and renal toxicity.
- ► Avoid concurrent use with other NSAIDs and with glucocorticoids; use cautiously with diuretics.
- ► Wear gloves when handling this product.

Uses/Indications

Diclofenac topical cream is labeled for control of pain and inflammation associated with osteoarthritis in tarsal (hock), carpal (knee), metacarpophalangeal (forelimb fetlock), metatarsophalangeal (hindlimb fetlock), and proximal interphalangeal (pastern) joints in horses for up to 10 days. Topical administration has been shown to reduce lameness regardless of the severity or chronicity of the clinical condition.[1] Application of topical diclofenac reduced inflammation at the injection site of an amikacin IV regional limb perfusion.[2]

In a case report, topically applied diclofenac 3% gel resulted in clinical resolution of actinic keratosis in a rabbit.[10]

Pharmacology/Actions

Diclofenac is a nonspecific inhibitor of cyclooxygenase (COX1 and COX2) and may also have some inhibitory effects on lipoxygenase. By inhibiting COX2 enzymes, diclofenac reduces the production of prostaglandins associated with pain, hyperpyrexia, and inflammation.

Pharmacokinetics

Diclofenac 1% liposomal cream administered topically to horses is absorbed locally, but specific bioavailability data was not located. Peak concentrations in transudate obtained from tissue cages were ≈80 ng/mL; drug concentrations stay increased from 6 to at least 18 hours after administration. At the dosages recommended for the topical cream, most of the drug remains in the tissues local to the administration point, but detectable drug concentrations in systemic circulation may occur.[3] In humans, diclofenac is more than 99% bound to plasma proteins. It is metabolized in the liver, and the metabolites are excreted primarily in the urine.

Contraindications/Precautions/Warnings

Topical diclofenac should not be used in horses hypersensitive to it or any component of the cream. According to the manufacturer's label, diclofenac topical has not been evaluated in horses younger than 1 year of age; however, repeated applications (every 12 hours for 7 days) on the tarsometatarsal region were well tolerated in neonatal foals.[4]

Exceeding the recommended dosage (ie, applying a strip longer than 5 inches or treating multiple joints) may increase plasma concentrations of diclofenac and the risk of adverse effects.

The risk for developing renal toxicity is increased in patients that are dehydrated or with renal, cardiovascular, or hepatic dysfunction.

Diclofenac has been implicated in causing death in vultures,[5,6] and toxicity has been observed in other avian species.[7,8]

Caretakers should wear disposable, impermeable (eg, rubber) gloves during application of this medicine to prevent dermal exposure.[9]

Adverse Effects

In horses, the topical cream appears to be well-tolerated. Adverse effects may include weight loss, gastric ulcers, diarrhea, colic, icterus, renal toxicity, uterine discharge, and local dermatologic reactions (eg, erythema, swelling, alopecia). During the field study for FDA approval, 1 horse developed colic on day 4 of therapy and responded to supportive care.[9]

Reproductive/Nursing Safety

Reproductive safety has not been investigated in breeding, pregnant, or lactating horses.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs associated with topical overdose of diclofenac in horses reflect the adverse effect profile and include renal toxicity, weight loss, glandular gastric ulcers, colic, diarrhea, and uterine discharge; treatment is supportive based on clinical presentation.

Enteral overdose of diclofenac cream may cause GI ulceration and renal toxicity. For horses with recent ingestion, consider placing a nasogastric tube for gastric lavage followed by administration of mineral oil. For species that can vomit (eg, dogs, cats), GI decontamination with emesis induction and activated charcoal is appropriate in situations of recent ingestion. For doses in which GI adverse effects are expected, use of GI protectants (eg, proton pump inhibitors, sucralfate) is warranted. If renal adverse effects are also expected, IV fluid diuresis is warranted in all species.

Diclofenac ingestion has caused death in vultures that ingested carcasses of animals that received diclofenac.[5,6]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

When used topically at recommended dosages, there are no reported drug interactions in horses. The following drug interactions have either been reported or are theoretical in humans or animals receiving diclofenac and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Use with corticosteroids may increase the risk for adverse GI effects (eg, gastric ulceration); concurrent use is not recommended.
- **Diuretics** (eg, **furosemide**): Concurrent diuretic therapy may increase the risk for renal toxicity.
- **nonsteroidal anti-inflammatory drugs (NSAIDs, Other;** eg, **firocoxib, flunixin, phenylbutazone**): Use with other NSAIDs may increase the risk for adverse GI effects (eg, gastric ulceration); concurrent use is not recommended.

Laboratory Considerations

- No specific laboratory interactions or considerations were noted.

Dosages

HORSES:

Control of pain and inflammation associated with osteoarthritis in tarsal (hock), carpal (knee), metacarpophalangeal (forelimb fetlock), metatarsophalangeal (hindlimb fetlock), and proximal interphalangeal (pastern) joints (label dosage; FDA-approved): Apply a 12.7-cm (5-in) ribbon twice daily over the affected joint for up to 10 days.[9] Wear impermeable rubber gloves and rub cream thoroughly into the hair covering the joint until cream disappears.

Monitoring

- Efficacy
- Adverse effects, including weight loss, gastric ulcers, diarrhea, icterus, uterine discharge, and dermatologic inflammation at application site
- Baseline and periodic serum chemistry profile as needed during therapy

Client Information

- The manufacturer-provided Client Information Sheet should be included with the medication at the time of dispension.
- This medicine is a topical nonsteroidal anti-inflammatory drug (NSAID) cream used to treat horses for joint pain and inflammation for up to 10 days. It may take several applications before your horse's condition improves.
- For this medication to work, give it exactly as your veterinarian has prescribed. Always check the prescription label to ensure you are giving the drug correctly. Do not use more cream than your veterinarian recommends.
- Horses usually tolerate this medicine well; loss of hair or mild swelling at the application site is possible.
- Discontinue and immediately contact your veterinarian if you see signs of loss of appetite, weight loss, colic, diarrhea, yellowing of the skin, eyes, gums (ie, jaundice).
- Manufacturer warns against using this medicine on more than 1 joint or using more than a 12.7-cm (5-in) ribbon, as this may cause side effects.
- Wear rubber or other disposable impermeable gloves and rub cream thoroughly into the hair covering the joint until cream disappears. Wash hands immediately with soap and water in case of direct skin contact.

Chemistry/Synonyms

Diclofenac sodium, a phenylacetic acid derivative NSAID, occurs as a white to off-white hygroscopic crystalline powder. It is sparingly soluble in water, soluble in alcohol, and practically insoluble in chloroform and ether. The commercial (equine) cream is formulated in a liposomal base.

Diclofenac may also be known as GP-45840, diclofenacum, or diclophenac; many trade names are available for diclofenac products outside the United States.

Storage/Stability

The commercially available 1% cream should be stored at temperatures up to 25°C (77°F); protect from freezing.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

Diclofenac sodium (liposomal) 1% (1 g contains 10 mg diclofenac sodium) topical cream in 124 g tubes; *Surpass*®; (Rx). FDA-approved for use in horses. NADA #141-186

Injectable forms of this medication are available in some countries.

HUMAN-LABELED PRODUCTS:

Diclofenac Topical Patch, Extended Release: 1.3%; *Flector*®; (Rx)

Diclofenac Sodium Gel: 1% (1 g contains 10 mg diclofenac sodium) and 3% (1 g contains 30 mg diclofenac sodium) with benzyl alcohol in 25 g and 50 g; *Voltaren Gel*®, *Solaraze*®, *Diclo Gel*®, *Diclozor*®, generic; (Rx)

Diclofenac Sodium Topical Solution: 1.5%; *Klofensaid* II®, *Pennsaid*®, *Xrylix*®, generic; (Rx)

Diclofenac Sodium Topical Spray: 3%; generic; (Rx)

Diclofenac sodium is also FDA-approved as a topical ophthalmic agent (see ***Diclofenac Ophthalmic***).

Diclofenac is also available in a variety of oral dosage forms (eg, tablets, capsule, oral powder), including in combination with misoprostol.

References

Dicloxacillin

(di-klox-a-***sill***-in) *Dicloxin®, Dynapen®*

Anti-Staphylococcal Penicillin

Prescriber Highlights

- ► Oral anti-staphylococcal penicillin
- ► Contraindicated in patients hypersensitive to it; do not use oral medications in critically ill patients.
- ► Use with caution in patients with known hypersensitivity to other beta-lactam antibiotics.
- ► Adverse effects may include GI disturbances, CNS disturbances, elevated liver values, and cardiorespiratory disturbances (tachypnea, tachycardia).
- ► Rarely used in veterinary medicine as it has no apparent advantages over approved veterinary products, and administering doses every 6 to 8 hours may be challenging for owners.

Uses/Indications

The veterinary use of dicloxacillin has been primarily in the PO treatment of bone, skin, and other soft tissue infections in small animals when penicillinase-producing *Staphylococcus* spp have been isolated. Because of its low oral bioavailability and short half-life, other drugs with good staphylococcal coverage are usually employed.

The World Health Organization has designated dicloxacillin as a Highly Important antimicrobial for human medicine.[1] The Office International des Epizooties (OIE) has designated dicloxacillin as a Veterinary Critically Important Antimicrobial (VCIA) Agent in avian, bovine, caprine, ovine, and swine species.[2]

Pharmacology/Actions

Penicillins are beta-lactam antimicrobials that disrupt bacterial cell wall synthesis by binding penicillin-binding proteins (PBPs) within the bacterial cell wall, which inhibits peptidoglycan synthesis. This results in a defective barrier and an osmotically unstable spheroplast. The number and type of PBPs vary between different bacteria, as do the different affinities for various beta-lactams. This helps explain the differences in spectrums of activity the drugs have, which are not explained by the influence of beta-lactamases. Penicillins are timedependent antimicrobials, usually bactericidal, and like other beta-lactam antibiotics, they are generally considered more effective against actively growing bacteria.

Cloxacillin, dicloxacillin, and oxacillin have nearly identical spectrums of activity and can be considered therapeutically equivalent when comparing *in vitro* activity. These penicillinase-resistant penicillins have a narrower spectrum of activity than the natural penicillins. Their antimicrobial efficacy is aimed directly against penicillinase-producing strains of gram-positive cocci, particularly *Staphylococcus* spp. They are sometimes called anti-staphylococcal penicillins. They are ineffective against methicillin-resistant staphylococci. While this class of penicillins has activity against some other gram-positive and gram-negative aerobes and anaerobes, other antibiotics (penicillins and others) are usually better choices. The penicillinase-resistant penicillins are inactive against *Rickettsia* spp, mycobacteria, fungi, *Mycoplasma* spp, and viruses.

Pharmacokinetics

Dicloxacillin is only available in oral dosage forms. Dicloxacillin sodium is resistant to acid inactivation in the gut but is only partially absorbed. The bioavailability after oral administration in dogs is only about 23%,[3] and in humans has been reported to range from 35% to 76%. If given with food, both the rate and extent of absorption are decreased.

The drug is distributed to the liver, kidneys, bone, bile, pleural, and synovial fluids. Five or more doses are required before clinically therapeutic concentrations of the drug are achieved in ascitic fluid.[4] As with the other penicillins, only minimal amounts are distributed into the CSF. In dogs, dicloxacillin is 90% protein-bound,[4] whereas in humans, ≈95 *to* 99% of the drug is bound to plasma proteins.

Dicloxacillin is partially metabolized to both active and inactive metabolites. These metabolites and the parent compound are rapidly excreted in the urine via both glomerular filtration and tubular secretion mechanisms. A small amount of the drug is also excreted in the feces via biliary elimination. The serum half-life in humans with normal renal function ranges from about 24 to 48 minutes. In dogs, the elimination half-life is 0.8 to 2.6 hours,[3,4] and in cats the half-life is ≈0.9 hours.[5]

Contraindications/Precautions/Warnings

Penicillins are contraindicated in patients with a history of hypersensitivity to them. Because there may be cross-reactivity, use penicillins cautiously in patients that have documented hypersensitivity to other beta-lactam antibiotics (eg, cephalosporins, cephamycins, carbapenems).

Do not administer systemic antibiotics orally in patients with septicemia, shock, or other grave illnesses as absorption of the medication from the GI tract may be significantly delayed or diminished. Parenteral (preferably IV) routes should be used for these cases.

Do not confuse dicloxacillin with doxycycline.

Adverse Effects

Adverse effects with the penicillins are usually not serious and have a relatively low frequency of occurrence.

Hypersensitivity reactions, unrelated to dose, can occur with these agents and can manifest as rashes, fever, eosinophilia, neutropenia, agranulocytosis, thrombocytopenia, leukopenia, anemias, lymphadenopathy, or anaphylaxis. In humans, it is estimated that 1% to 15% of patients hypersensitive to cephalosporins will also be hypersensitive to penicillins. The incidence of cross-reactivity in veterinary patients is unknown.

When given orally, penicillins may cause GI effects (eg, anorexia, vomiting, diarrhea). Because the penicillins may also alter gut flora, antibiotic-associated diarrhea can occur and allow the proliferation of resistant bacteria in the colon (superinfections).

Neurotoxicity (eg, ataxia in dogs) has been associated with high doses or prolonged use. Although the penicillins are not considered hepatotoxic, elevated liver enzymes have been reported. Other effects reported in dogs include tachypnea, dyspnea, edema, and tachycardia.

Reproductive/Nursing Safety

Penicillins cross the placenta, but there have not been any documented teratogenic problems associated with these drugs.

Dicloxacillin is distributed into milk in very small amounts. Although it may alter neonatal gut flora or cause hypersensitivity, it is unlikely to pose much risk to nursing offspring. Penicillins are considered compatible with breastfeeding.[6]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute oral penicillin overdoses are unlikely to cause significant problems other than GI distress, but other effects are possible (see ***Adverse Effects***). In humans, very high dosages of parenteral penicillins, especially in patients with renal disease, have induced CNS effects.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and

toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving dicloxacillin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aminoglycosides**: In vitro evidence of synergism with dicloxacillin against *S aureus* strains
- **Cyclosporine**: Dicloxacillin may reduce levels.
- **Methotrexate**: May increase methotrexate concentration and risk of toxic effects
- **Mycophenolate**: May reduce formation of the active mycophenolate metabolite, possibly decreasing mycophenolate efficacy
- **Probenecid**: Competitively blocks the tubular secretion of dicloxacillin, thereby increasing serum levels and serum half-lives
- **Tetracyclines**: Theoretical antagonism; use together usually not recommended
- **Warfarin**: Dicloxacillin may cause decreased warfarin efficacy.

Laboratory Considerations

- As penicillins and other beta-lactams can inactivate aminoglycosides in vitro (and in vivo in patients with renal insufficiency), serum concentrations of aminoglycosides may be falsely decreased if the patient is also receiving beta-lactam antibiotics and the serum is stored prior to analysis. It is recommended that if the assay is delayed, samples be frozen and, if possible, drawn at times when the beta-lactam antibiotic is at a trough.

Dosages

DOGS/CATS:

Pyoderma due to sensitive penicillinase-producing staphylococci in dogs (label dosage; FDA-approved): 11 – 22 mg/kg PO three times daily; in severe cases, up to 55 mg/kg PO three times daily may be used.[7] **NOTE**: The lower end of the label dosage range is considered to be less than what is currently recommended.

Susceptible infections (extra-label): 20 – 40 mg/kg PO every 8 hours[8]

Monitoring

- Efficacy (ie, resolution of clinical signs)
- Culture and susceptibility as indicated for clinical condition being treated
- Adverse effects including hypersensitivity reactions and GI disturbances (ie, vomiting, diarrhea, inappetence)
- Serum levels and therapeutic drug monitoring are not routinely done with this drug.

Client Information

- Give dicloxacillin to animals on an empty stomach. If GI side effects (not eating, vomiting, diarrhea) occur, give with a small meal or treat.
- The most common side effects are diarrhea, vomiting, and loss of appetite.
- It is important to give this medication exactly as prescribed and to complete the full course of treatment, even if your animal seems better. Missing doses or stopping treatment early may result in treatment failure.

Chemistry/Synonyms

An isoxazolyl-penicillin, dicloxacillin sodium is a semisynthetic, penicillinase-resistant penicillin. It is available commercially as the monohydrate sodium salt that occurs as a white to off-white crystalline powder that is freely soluble in water and has a pK_a of 2.7 to 2.8.

One mg of dicloxacillin sodium contains not less than 850 micrograms of dicloxacillin.

Dicloxacillin sodium may also be known as sodium dicloxacillin, dichlorphenylmethyl isoxazolyl penicillin sodium, methyldichlorophenyl isoxazolyl penicillin sodium, dicloxacilina sodica, dicloxacillinum natricum, or P-1011; many trade names are available.

Storage/Stability

Dicloxacillin sodium capsules should be stored at temperatures at 20°C to 25°C (68°F-77°F).

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

No products currently marketed in the United States; however, the FDA's Green Book still lists *Dicloxin*® capsules as approved for use in dogs.

HUMAN-LABELED PRODUCTS:

Dicloxacillin Sodium Capsules: 250 mg and 500 mg; generic; (Rx)

Diethylstilbestrol (DES)

(dye-ethel-stil-***bes***-tral)

Hormonal Agent

Prescriber Highlights

- ► Synthetic estrogen used in dogs primarily for estrogen-responsive urinary incontinence and other estrogen indications (eg, prostatic hypertrophy, estrus induction). FDA approval of estriol for dogs has made diethylstilbestrol (DES) use controversial, particularly in dogs starting estrogen therapy for urinary incontinence.
- ► Prohibited for use in food animals (potential carcinogen)
- ► Many potential adverse effects: blood dyscrasias, GI effects, cystic endometrial hyperplasia and pyometra (nonspayed females), feminization (males), neoplasia
- ► Teratogenic and carcinogenic
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies DES as a hazardous drug; use appropriate precautions when handling.
- ► Availability issues; must be obtained from a compounding pharmacy

Uses/Indications

Diethylstilbestrol (DES) has been used in estrogen-responsive urinary incontinence in spayed female dogs and for medical treatment of benign prostatic hypertrophy in male dogs. DES is no longer the first drug of choice for benign prostatic hypertrophy because of risk of squamous metaplasia, the availability of finasteride,[1] and poor efficacy.[2] It has also been used for the prevention of pregnancy after mismating in female dogs and cats but is typically no longer recommended because of serious adverse effects.

Pharmacology/Actions

Estrogens are necessary for the normal growth and development of the female sex organs and in some species contribute to the development and maintenance of secondary female sex characteristics. Estrogens cause increased cell height and secretions of the cervical mucosa, thickening of the vaginal mucosa, endometrial proliferation, and increased uterine tone.

Estrogens affect the skeletal system by increasing calcium deposi-

tion, accelerating epiphyseal closure, and increasing bone formation. Estrogens have a mild anabolic effect and can increase sodium and water retention.

Estrogens affect the release of gonadotropins from the pituitary gland, which can inhibit lactation, ovulation, and androgen secretion.

Excessive estrogen will delay the transport of the ovum and prevent it from reaching the uterus at the appropriate time for implantation. DES also possesses antineoplastic activity against some types of neoplasias (perianal gland adenoma and prostatic hyperplasia). It affects mRNA and protein synthesis in the cell nucleus and is cell cycle nonspecific.

The mechanism of action of DES in patients with estrogen-responsive urinary incontinence is thought to be caused by increased sphincter sensitivity to norepinephrine.

Pharmacokinetics

Diethylstilbestrol (DES) is well absorbed from the GI tract of monogastric animals. It is slowly metabolized by the liver, primarily to a glucuronide form, and then excreted in the urine and feces.

Contraindications/Precautions/Warnings

Diethylstilbestrol (DES) is prohibited by the FDA for use in food animals.

DES is contraindicated in patients hypersensitive to it, and in females with estrogen-sensitive neoplasms. Because of its potential effects on bone marrow, DES should be used with extreme caution in patients with preexisting anemias or leukopenias (refer to the ***Adverse Effects*** section for more information). Use with caution in patients with hepatic impairment.

The National Institute for Occupational Safety and Health (NIOSH) classifies DES as a hazardous drug; personal protective equipment [PPE] should be used accordingly to minimize the risk of exposure. Because of the potential for danger to the public health, DES must not be used in animals intended for human consumption.

Adverse Effects

Although adverse effects with estrogen therapy can be serious (see below) in small animals, when used for estrogen-responsive incontinence at the lowest effective dose, it is usually well tolerated.

In cats and dogs, estrogens are considered toxic to the bone marrow and can cause blood dyscrasias. Blood dyscrasias are more prevalent in older animals and when higher dosages are used. Initially, a thrombocytosis and/or leukocytosis may be noted, but thrombocytopenia and/or leukopenias will gradually develop. Changes in a peripheral blood smear may be apparent within 2 weeks after estrogen administration. Chronic estrogen toxicity may be characterized by a normocytic, normochromic anemia; thrombocytopenia; and neutropenia. Bone marrow depression may be transient and begin to resolve within 30 to 40 days or may persist or progress to a fatal aplastic anemia. Dosages of 2.2 mg/kg per day have caused death in cats secondary to bone marrow toxicity.

In females, signs of estrus may occur and persist for 7 to 10 days. Estrogens may cause cystic endometrial hyperplasia and pyometra in intact females; an open-cervix pyometra may be noted 1 to 6 weeks after initiation of therapy.

When used chronically long-term in male animals, feminization and squamous metaplasia may occur.

Estrogens have been documented to be carcinogenic at low concentrations in some laboratory animals. Estrogens may induce mammary neoplasias. Experimental administration of DES to female dogs as young as 8 months of age have induced malignant ovarian adenocarcinomas. Doses ranging from 60 – 495 mg/dog (NOT mg/kg) given over 1 month to 4 years were implicated in causing these tumors.

In cats, daily administration of DES has resulted in pancreatic, hepatic, and cardiac lesions.

In humans (females), estrogen use may cause GI distress, increased liver enzymes, glucose intolerance, increased risk of thromboembolic events, and menstrual irregularities.

Reproductive/Nursing Safety

Diethylstilbestrol (DES) is contraindicated during pregnancy, as it can cause fetal malformations of the genitourinary system. Chronic use in males may lead to feminization.

Estrogens are found in breast milk; therefore, consider use of milk replacer for nursing offspring.

Overdose/Acute Toxicity

Acute estrogen overdose in humans has resulted in nausea, vomiting, and withdrawal bleeding in women. No information was located regarding acute overdose in veterinary patients; however, the reader is referred to the warnings and adverse effects listed above.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving DES and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): May increase estrogen concentrations
- **Cimetidine**: May decrease metabolism of estrogens
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Enhanced glucocorticoid effects may result if estrogens are used concomitantly with corticosteroid agents. It has been postulated that estrogens may either alter the protein binding of corticosteroids and/or decrease their metabolism. Corticosteroid dosage adjustment may be necessary when estrogen therapy is either started or discontinued.
- **Erythromycin, Clarithromycin**: May decrease the metabolism of estrogens
- **Estrogens, Other** (eg, **diethylstilbestrol [DES]**): Possible additive effects. Do not use with other estrogens; concomitant use with other estrogens has not been evaluated.
- **Levothyroxine**: Estrogens may diminish the therapeutic effect of levothyroxine, and an increase in levothyroxine dose may be needed. Monitor thyroid status when using these drugs in combination and adjust levothyroxine dose accordingly. See ***Monitoring*** in ***Levothyroxine***.
- **Phenobarbital**: May decrease estrogen concentrations
- **Rifampin**: May induce hepatic microsomal enzymes and decrease estrogen concentrations
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline**, **clomipramine**): Concurrent use may attenuate TCA efficacy and toxicity.
- **Warfarin**: Oral anticoagulant activity may be decreased if estrogens are administered concurrently; increases in anticoagulant dosage may be necessary if adding estrogens.

Laboratory Considerations

- Estrogens in combination with progestins (eg, oral contraceptives) have been demonstrated in humans to increase **thyroxine-binding globulin (TBG)** with resultant increases in total circulating **thyroid hormone**. Decreased $\mathbf{T_3}$ resin uptake also occurs, but **free** $\mathbf{T_4}$ concentrations are unaltered.

Dosages

DOGS:

Primary urethral sphincter mechanism incompetence (idiopathic urinary incontinence, hormone-responsive urinary incontinence); (extra-label): 0.1 – 1 mg/dog (total dose; NOT mg/kg) (0.02 mg/kg; maximum total dose of 1 mg/dog [total dose; NOT mg/kg]) for 3 to 5 days as an induction dose and then periodically decreased to the lowest dose that will maintain continence (typically 1 to 3 doses per week). In difficult cases, may be used with phenylpropanolamine[3,4]

Monitoring

When therapy is either at high dosages or chronic:

- Baseline and (at least) monthly CBC with platelet count
- Serum chemistry profile at baseline and 1 month after therapy begins; repeat in 2 months after cessation of therapy if results are abnormal.

Client Information

- **Pregnant women should avoid handling diethylstilbestrol (DES)**; wear gloves and wash hands after handling.
- May be given with or without food. If your animal vomits or acts sick after receiving the drug on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Although DES can cause serious side effects, when used to treat urinary incontinence at the lowest effective dose, itis usually well-tolerated in dogs.
- Your veterinarian will need to do blood tests to watch for serious side effects. Do not miss these important follow-up visits.
- Contact your veterinarian if your animal has weakness, diarrhea, vomiting, bruising, abnormal discharge from the vulva, abnormal growth or swelling near the teats (nipples), excessive water consumption and urination, or abnormal bleeding.

Chemistry/Synonym

A synthetic nonsteroidal estrogen agent, diethylstilbestrol (DES) occurs as an odorless white crystalline powder with a melting range of 169°C to 175°C (336°F-347°F). It is practically insoluble in water and soluble in alcohol or fatty oils.

Diethylstilbestrol may also be known as DES, diethylstilbestrolum, diethylstilboestrol, NSC-3070, stilbestrol, stilboestrol, *Apstil®*, *Boestrol®*, *Destilbenol®*, or *Distilbene®*.

Storage/Stability

Diethylstilbestrol should be stored at room temperature between 15°C and 30°C (59°F-86°F) in well-closed containers unless otherwise specified by the compounding pharmacy.

Compatibility/Compounding Considerations

No specific information noted. It is recommended that when compounding diethylstilbestrol (DES), it be treated as a cytotoxic agent with appropriate safety precautions to prevent exposure to humans.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS: NONE

No commercially available regular oral diethylstilbestrol (DES) products are available in the United States. Compounded preparations may be available from compounding pharmacies. Use of DES in food producing animals is prohibited by the FDA.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Digoxin

(di-***jox***-in) *Lanoxin®*

Cardiac Glycoside

Prescriber Highlights

- ► Oral and parenteral cardiac glycoside used primarily for supraventricular tachycardia (SVT)
- ► Contraindications include ventricular fibrillation, digitalis intoxication. Many veterinary cardiologists feel that digoxin is relatively contraindicated in cats with hypertrophic cardiomyopathy.
- ► Use extreme caution in patients with renal disease and heart failure, with frequent and/or complex ventricular arrhythmias, or with subaortic stenosis (SAS).
- ► Adverse effects usually associated with high or toxic blood digoxin concentrations. Cardiac adverse effects may include almost every type of cardiac arrhythmia described with a resultant worsening of clinical signs associated with heart failure. Extracardiac adverse effects include mild GI upset, anorexia, weight loss, vomiting, or diarrhea.
- ► Vesicant, avoid extravasation
- ► Many drug interactions possible
- ► Monitoring of digoxin blood concentrations highly recommended

Uses/Indications

Digoxin is used in the treatment of congestive heart failure (CHF), atrial fibrillation or flutter, and supraventricular tachycardia. Presently, digoxin use (often combined with diltiazem) is generally limited to dogs for the management of rapid atrial fibrillation with concurrent CHF caused by either dilated cardiomyopathy or myxomatous mitral valve disease (MMVD) without evidence of renal insufficiency. Digoxin therapy is more controversial for treating heart failure in dogs or cats without accompanying supraventricular arrhythmias and its use for this indication has diminished. Today, most cardiologists no longer use digoxin as a first line therapy for heart failure in dogs and cats and its use as a positive inotropic agent has been supplanted by pimobendan. In a review of the pharmacologic management of MMVD in dogs,[1] the authors state: *Digoxin has little role in veterinary cardiology other than for heart rate control in atrial fibrillation or as an inotrope in patients whose owners have financial constraints.*

In horses, digoxin is still used in the management of CHF, particularly when complicated by atrial arrhythmias, as other oral inotropic drugs are not feasible. It has also been used as adjunctive therapy for CHF in ferrets, and for supraventricular tachycardia in cattle.

Pharmacology/Actions

Digoxin causes the following effects in patients with a failing heart: increased myocardial contractility (inotropism) with increased cardiac output; increased diuresis with reduction of edema secondary to a decrease in sympathetic tone; reduction in heart size, heart rate, blood volume, and pulmonary and venous pressures; and (usually) no net change in myocardial oxygen demand.

Digoxin has several electrocardiac effects, including decreased conduction velocity through the atrioventricular (AV) node and a prolonged effective refractory period (ERP), ECG changes include prolonged PR interval, shortened QT interval, and ST segment depression.

The exact mechanism of action of these agents has not been fully described, but they are thought to increase the availability of Ca^{++} to myocardial fibers and inhibit Na^{+}-K^{+}-ATPase with resultant increased intracellular Na^{+} and reduced K^{+}.

Pharmacokinetics

Absorption following oral administration occurs in the small intestine and is variable dependent upon the oral dosage form used (see ***Dosage Forms/Regulatory Status***). The bioavailability of digoxin in veterinary species has only been studied in a limited manner, with oral bioavailability for tablets ≈58% and oral elixir ≈71 % in dogs,[2] but in horses only ≈20% of an intragastric dose of crushed oral tablets was bioavailable.[3] The bioavailability of digoxin formulations in humans: IV 100%, IM ≈80%, oral tablets ≈60%, and oral elixir ≈75%. Food may delay, but not alter, the extent of absorption in most species studied; however, food reportedly decreases the amount absorbed by 50% in cats after tablet administration. Peak serum concentration generally occurs within 45 to 60 minutes after oral elixir and ≈90 minutes after oral tablet administration. In patients receiving an initial oral dose of digoxin, peak effects may occur 6 to 8 hours after the dose.

The drug is distributed widely throughout the body with highest concentrations found in kidneys, heart, intestine, stomach, liver, and skeletal muscle. Lowest concentrations are found in the brain and plasma. Digoxin does not significantly enter ascitic fluid, so dosage adjustments may be required in animals with ascites. At therapeutic levels, ≈20% to 30% of the drug is bound to plasma proteins. Because only small amounts are found in fat, dosing calculations should be based on lean body weight.

Digoxin is metabolized slightly, but the primary method of elimination is renal excretion both by glomerular filtration and tubular secretion. As a result, dosage adjustments must be made in patients with significant renal disease. Values reported for the elimination half-life of digoxin in dogs and cats have been highly variable, with values reported from 30 to 42 hours for dogs[2,4] and 33 hours for cats.[5] Approximate elimination half-lives reported in other species include sheep, 7 hours[6]; horses, 17 to 29 hours[3,7-9]; and cattle, 8 hours.[10]

Contraindications/Precautions/Warnings

Digoxin is contraindicated in patients hypersensitive to it, in those with ventricular fibrillation, or in digitalis intoxication. Digoxin is contraindicated in patients with third-degree AV block without implantation of a permanent pacemaker. In cattle, it is also contraindicated in monensin toxicosis.[11] Digoxin should be used with extreme caution in patients with renal dysfunction, frequent or complex ventricular tachycardia, heart failure, or with subaortic stenosis (SAS). Digoxin should be used with caution in patients with severe pulmonary disease, hypoxia, acute myocarditis, myxedema, or acute myocardial infarction, frequent ventricular premature contractions, chronic constrictive pericarditis, preexisting sinus node disease, or second-degree AV block.

When used to treat atrial fibrillation or flutter prior to administration with an antiarrhythmic agent that has anticholinergic activity (eg, quinidine, procainamide, disopyramide), digoxin will reduce but not eliminate the increased ventricular rates that may be produced by those agents. Because digoxin may cause increased vagal tone, they should be used with caution in patients with increased carotid sinus sensitivity.

Elective cardioversion of patients with atrial fibrillation should not be attempted in patients with signs of digoxin toxicity.

The p-glycoprotein pump actively transports digoxin. Washington State University clinical pharmacology laboratory does not recommend any dose reductions in dogs with *MDR1* genetic mutations; however, they recommend therapeutic drug monitoring.[12] One case of digoxin toxicity in a collie with the *MDR1* mutation has been described.[13]

Digoxin is relatively contraindicated in cats with hypertrophic cardiomyopathy as it may worsen dynamic outflow tract obstruction and increase ventricular arrhythmogenesis.

Principally eliminated by the kidneys, digoxin should be used with caution in patients with renal disease. In these patients, therapy should be initiated at ¼ to ½ the normal dose, and serum digoxin concentrations should be monitored. Animals that are hypernatremic, hypokalemic, hypercalcemic, hypomagnesemic, hyperthyroid, or hypothyroid may require lower doses; monitor carefully. Hypokalemia and hypomagnesemia, in particular, should be corrected prior to digoxin therapy. Digoxin competes for the same ATPase binding site as potassium, whereas magnesium is a cofactor of the sodium-potassium ATPase pump; depletion of either electrolyte makes digoxin toxicity more likely, even with normal blood concentrations of the drug.

As digoxin does not distribute well into ascitic fluid or fat, dosing is generally based on lean body weight. Underweight patients may be at increased risk for digoxin toxicity.

As digoxin is a vesicant, IV doses should be injected slowly to reduce extravasation risk.

Do not confuse digoxin with doxepin.

Adverse Effects

Adverse effects of digoxin are usually associated with high or toxic serum concentrations and are categorized into cardiac and extracardiac adverse effects. There are also species differences with regard to the sensitivity to digoxin's toxic effects; cats are relatively sensitive to digoxin, whereas dogs tend to be more tolerant of high serum digoxin concentrations.

Cardiac effects may include almost every type of cardiac arrhythmia described with a resultant worsening of heart failure clinical signs. More common arrhythmias or ECG changes observed include complete or incomplete AV block, ventricular bigeminy, ST segment changes, paroxysmal ventricular or atrial tachycardias with concurrent AV block, and multifocal premature ventricular complexes. Because these effects can also be caused by worsening heart disease, it may be difficult to determine if they are a result of the disease process or digitalis intoxication. If in doubt, monitor serum digoxin concentrations or stop digoxin therapy temporarily.

Extracardiac clinical signs most commonly seen in veterinary medicine include mild GI upset or colic, anorexia, weight loss, and diarrhea. Vomiting has been associated with IV injections. Ocular and neurologic effects are routinely seen in humans but are not prevalent in animals or are not detected.

Reproductive/Nursing Safety

Digoxin crosses the placenta, but studies in animals have not been conducted. Studies have shown that digoxin concentrations in a mother's serum and milk are similar; however, it is unlikely to have any pharmacological effect on nursing offspring.[14]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs of chronic toxicity are discussed above. In dogs, the acute toxic dose after IV administration has been reported to be 0.2 mg/kg IV and 0.3 mg/kg PO.[15] Cats given 0.11 mg/kg IV (≈10-fold overdose) experienced salivation, vomiting, anorexia, and depression prior to ECG changes (increased PR interval, elevated ST segment, bradycardia), and plasma digoxin concentration was 4.5 – 12 ng/mL,[16] although toxicity also has been observed with concentrations at or above 2.4 ng/mL.[5]

Treatment of chronic digoxin toxicity is dictated by the severity of the clinical signs. Many patients do well after temporarily stopping the drug and reevaluating the dosage regimen.

If an acute ingestion has recently occurred and no cardiotoxic or neurologic signs (eg, coma, seizures) have manifested, emptying the stomach may be indicated, followed with activated charcoal admin-

istration. Because digoxin can be slowly absorbed and there is some enterohepatic recirculation of the drug, repeated charcoal administration may be beneficial even if the ingestion occurred well before treatment. Anion-exchange resins such as colestipol or cholestyramine have been suggested to reduce the absorption and enterohepatic circulation of digoxin.

Dependent on the type of cardiotoxicity, supportive therapy based on clinical signs should be implemented. Serum electrolyte concentrations, serum digoxin concentrations (if available on a stat basis), and continuous ECG monitoring should be instituted. Careful attention is required to correct fluid and electrolyte imbalances (particularly hypokalemia and hypomagnesemia), acid-base disturbances, and hypoxia. The use of potassium in normokalemic patients is controversial and should only be attempted with constant monitoring and clinical expertise.

The use of specific antiarrhythmic agents in treating life-threatening digitalis-induced arrhythmias may be necessary. Lidocaine is most commonly employed for ventricular arrhythmias, and phenytoin also may be used. Atropine may be used to treat sinus bradycardia, sinoatrial arrest, or second- and third-degree AV block.

Digoxin immune Fab (a digoxin-specific IgG antibody that binds to and directly inactivates the drug) is a potential treatment for life-threatening digoxin toxicity. Although veterinary experience with digoxin immune Fab is extremely limited, it has been successfully used for the treatment of oleander (glycoside-containing plant) toxicosis in a dog.[17] Digoxin is not removed by dialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

There are many potential drug interactions associated with digoxin and the following list is not necessarily all-inclusive. Because of the narrow therapeutic index associated with the drug, consider enhanced monitoring when these drugs (or those in the same class) are added to patients stabilized on digoxin.

The following drug interactions have either been reported or are theoretical in humans or animals receiving digoxin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Blockers** (eg, **atenolol, carvedilol, propranolol**): Can have additive negative effects on AV conduction, complete heart block possible
- **Calcium**: Concurrent use may result in a serious risk for arrhythmia and cardiovascular collapse. Oral calcium administration may reduce oral digoxin absorption.
- **Calcium-Channel Blockers** (eg, **diltiazem, verapamil,** but not **amlodipine**): Can have additive negative effects on AV conduction. Data are conflicting. Safe and effective diltiazem use has been demonstrated in dogs.[18]
- **Colchicine**: Concurrent use with digoxin may enhance the adverse effects of colchicine in humans.
- **Penicillamine**: May decrease serum levels of digoxin independent of route of digoxin dosing
- **Potassium/Electrolyte Balance, Drugs Affecting** (eg, **amphotericin B, dextrose/insulin infusions, diuretics, furosemide, glucagon, glucocorticoids, high dose IV dextrose, laxatives, sodium polystyrene sulfonate, thiazides**): May predispose the patient to digitalis toxicity
- **Spironolactone**: May enhance or decrease the toxic effects of digoxin
- **Thyroid Supplements**: Patients on digoxin that receive thyroid replacement therapy may need their digoxin dosage adjusted.

The following drugs or plants/herbs may **reduce digoxin serum concentration**:

- **Aminosalicylic acid**
- **Albuterol, Systemic**
- **Aluminum Hydroxide**
- **Aluminum or Magnesium Containing Oral products**
- **Chloramphenicol** (dogs)[19]
- **Cholestyramine**
- **Metoclopramide**
- **Neomycin, Oral**
- **Phenobarbital**[4]
- **Phenytoin**
- **St John's Wort**
- **Sucralfate** (oral digoxin only)
- **Sulfasalazine**

The following drugs or herbs may **increase serum concentration, decrease the elimination rate, or enhance the toxic effects of digoxin**:

- **Amiodarone**
- **Angiotensin-Converting Enzyme Inhibitors (ACEIs;** eg, **benazepril, enalapril)**
- **Anticholinergics** (eg, **atropine, glycopyrrolate, oxybutynin**)
- **Benzodiazepines** (specifically **alprazolam, diazepam**)
- **Clonidine**
- **Coleus**
- **Cyclosporine**
- **Furosemide**: Not significantly altered in cats receiving furosemide and aspirin[20]
- **Gentamicin**
- **Hawthorn**
- **Ketoconazole; Itraconazole**
- **Macrolide antibiotics** (eg, **azithromycin, clarithromycin, erythromycin**)
- **NSAIDs** (eg, **carprofen**, **meloxicam**)
- **Octreotide**
- **PPIs** (eg, **omeprazole, pantoprazole**)
- **Quinidine**: If used together, the rule of thumb is to decrease digoxin dose by 50%.
- **Reserpine**
- **Spironolactone**
- **Succinylcholine**
- **Telmisartan**
- **Tetracyclines** (eg, **minocycline, oxytetracycline**)
- **Thiazide Diuretics** (eg, **hydrochlorothiazide**)
- **Trazodone**
- **Trimethoprim**

Laboratory Considerations

- No specific laboratory test concerns

Dosages

NOTE: Do not confuse µg/kg, mg/kg, and µg/m^2 doses. **Always double-check calculations**.

DOGS:

Atrial fibrillation and CHF with normal renal function (extra-label): Initially, 0.0025 – 0.005 mg/kg PO every 12 hours[21] (alternatively in dogs weighing more than 20 kg [44 lb], use di-

goxin/body surface area at 0.22 mg/m^2). Median dosage in one study was 0.004 mg/kg PO every 12 hours.[22] Can increase up to 0.011 mg/kg if warranted. Do not exceed 0.25 mg/dog (NOT mg/kg) (regardless of size) twice daily. Monitor for signs of toxicity and efficacy and measure serum digoxin concentrations to adjust dose (see ***Monitoring***). One study[18] demonstrated that digoxin 0.005 mg/kg PO every 12 hours and diltiazem used together had a more effective ventricular rate reduction in dogs with secondary atrial fibrillation than when either was given alone, but it still remains unknown if this translates into decreased morbidity or mortality.

Dilated cardiomyopathy (extra-label): 0.003 mg/kg PO every 12 hours with an ACE-inhibitor (eg, enalapril) and furosemide.[23] Doses of 0.008 – 0.011 mg/kg per day PO also have been used.[24,25]

CATS:

Dilated cardiomyopathy or atrial fibrillation (**NOTE**: digoxin is generally contraindicated for feline hypertrophic cardiomyopathy); (extra-label): The starting dose for healthy cats weighing less than 3 kg (6.6 lb), ¼ of a 0.125 mg tablet PO every other day; for cats weighing 3 to 6 kg (6.6 – 13.2 lb), ¼ of a 0.125 mg tablet PO once daily; for cats weighing more than 6 kg (13.2 lb), ¼ of a 0.125 mg tablet PO once daily to every 12 hours. Tablets are better tolerated than the alcohol-based elixir.[26]

HORSES:

Supraventricular tachycardia (extra-label):

1. 0.0022 mg/kg IV every 12 hours or 0.011 mg/kg PO every 12 hours.[27,28] If unsuccessful, propranolol 0.03 mg/kg IV may be tried.[29]
2. Loading dosage: 0.0022 mg/kg IV given slowly every 12 hours for 2 doses. Use loading dose with caution due to risk for digoxin toxicity. Maintenance dosage: 0.0022 mg/kg slow IV every 24 hours or 0.011 mg/kg PO every 12 hours.[30] Maintain trough serum digoxin concentrations between 0.8 – 1.2 ng/mL.[31]

Adjunct to quinidine cardioversion of atrial fibrillation (extra-label): If cardioversion has not occurred after 24 hours of quinidine therapy, digoxin 0.0055 - 0.011 mg/kg PO every 12 hours may be added for 24 to 48 hours.[11,30] If digoxin is continued beyond 24 hours, use the lower end of the dosing range and monitor digoxin serum digoxin concentration. See ***Drug Interactions***.

CATTLE:

Supraventricular tachycardia (extra-label): Loading dosage: 0.022 mg/kg slow IV; followed by maintenance dosage (choose one): 0.011 mg/kg slow IV 3 times daily,[27] 0.00086 mg/kg/hour (0.86 µg/kg/hour) IV CRI,[10] *or* 0.0034 mg/kg slow IV every 4 hours[10]

FERRETS:

Adjunctive therapy for heart failure associated with dilated cardiomyopathy (extra-label): 0.005 – 0.01 mg/kg PO once daily initially (use oral liquid). May increase to twice daily if necessary. Furosemide and an ACE-inhibitor are also commonly employed.

Monitoring

- Serum digoxin concentrations: Because of significant interpatient pharmacokinetic variation and narrow therapeutic index seen with this drug, it is strongly recommended to monitor serum digoxin concentrations to help guide therapy. Unless the patient received an initial loading dose, at least 3 to 6 days should pass after beginning therapy to monitor serum concentrations to allow levels to approach steady-state.[7,32] Usually a trough measurement (just before next dose or at least 8 to 10 hours after the last dose[32]) is recommended. Historically, suggested therapeutic serum concentrations in the dog have ranged widely, but most now believe that concentrations above 1.2 ng/mL are potentially toxic. Serum trough digoxin concentration of 0.5 – 1.2 ng/mL have been suggested for dogs.[21,33] Therapeutic concentrations in cats are reported to be between 0.9 – 2 ng/mL.[34] Therapeutic concentrations in the horse are reported as 0.8 – 1.2 ng/mL.[30] Concentrations at the higher end of the suggested range may be necessary to treat some atrial arrhythmias but may also result in greater incidence of adverse effects.
- Appetite and body weight
- Baseline and periodic heart rate and rhythm (ECG), chest radiographs, echocardiography, pulse oximetry as indicated
- Baseline and periodic BUN, creatinine, and electrolytes
- Resting respiratory rate
- Improved clinical signs related to underlying heart disease (eg, cough, energy level)

Client Information

- Digoxin can be given with or without food. If your animal vomits or acts sick after receiving this medication on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Digoxin side effects usually occur when the dose is too high. Signs that may be observed include gastrointestinal effects (eg, lack of appetite, vomiting, diarrhea), lack of energy, behavior changes, and collapse. Digoxin toxicity can be very serious. Contact your veterinarian immediately if your animal develops any of these signs.
- Regular monitoring of blood digoxin levels and electrolytes helps detect problems. Do not miss these important follow-up visits with your veterinarian.

Chemistry/Synonyms

The cardiac glycosides (or digitalis glycosides), including digoxin, are derived from the foxglove plant *Digitalis purpura*. Digoxin occurs as bitter tasting, clear to white crystals or as a white crystalline powder. It is practically insoluble in water, slightly soluble in diluted alcohol, and very slightly soluble in 40% propylene glycol solution. Above 235°C (455°F), it melts with decomposition. The commercial injection consists of a 40% propylene glycol, 10% alcohol solution, and has a pH of 6.6 to 7.4.

Digoxin may also be known as digoxinum or digoxosidum. Cardiac glycosides maybe be referred to as digitalis glycosides; digoxin occasionally may be described as digitalis.

Storage/Stability

Digoxin tablets, elixir, and injection should be stored at room temperature 20°C to 25°C (68°F-77°F) and protected from light.

At pH of 5 to 8, digoxin is stable, but in solutions with a pH of less than 3, it is hydrolyzed.

Compatibility/Compounding Considerations

The injectable product is **compatible** with most commercially available IV solutions, including lactated Ringer's, D5W, and normal saline. To prevent the possibility of precipitation occurring, one manufacturer recommends that the injection be diluted by a volume at least 4 times with either sterile water, D5W, or normal saline. Digoxin injection has been demonstrated to be **compatible** with bretylium tosylate, cimetidine HCl, lidocaine HCl, and verapamil HCl.

Digoxin is **incompatible** with dobutamine HCl, acids, and alkalies. The manufacturer does not recommend mixing digoxin injection with other medications. Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Dosage Forms/Regulatory Status

There are bioavailability differences between dosage forms and in tablets produced by different manufacturers. It is recommended that tablets be used from a manufacturer that the clinician has confidence in and that brands not be routinely interchanged. Should a change in dosage form be desired, bioavailability differences (see ***Pharmacokinetics***) can be used as guidelines in altering the dose for monogastric animals.

VETERINARY-LABELED PRODUCTS:

The veterinary-labeled products are no longer commercially available in the US.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Digoxin Solution for Injection: 250 µg/mL (0.25 mg/mL), Pediatric solution for Injection: 100 µg/mL (0.1 mg/mL) in 1 mL amps; *Lanoxin®*, generic, (Rx)

Digoxin Oral Tablets: 125 µg (0.125 mg), and 250 µg (0.25 mg); *Lanoxin®*, generic; (Rx)

Digoxin Oral Solution: 50 µg/mL (0.05 mg/mL) and 100 µg/mL (0.1 mg/mL); generic; (Rx)

Diltiazem

(dil-***tye***-a-zem) *Cardizem®, Dilacor XR®*

Calcium Channel Blocker

Prescriber Highlights

- ► Calcium channel blocker used in dogs, cats, and ferrets for supraventricular tachycardias (SVT) and as adjunctive therapy for systemic or pulmonary hypertension; also used historically in cats and ferrets for hypertrophic cardiomyopathy. May prove useful in horses with atrial fibrillation during quinidine therapy to control ventricular response rate
- ► Contraindications include severe hypotension, sinus node dysfunction, high grade atrioventricular (AV) block, concurrent radiographically documented pulmonary congestion or edema, acute myocardial infarction, hypersensitivity.
- ► Use with caution in geriatric patients or in those with controlled heart failure (particularly if also receiving beta-blockers), hepatic or renal impairment.
- ► Several extended-/sustained-release products available; ensure prescriptions are sufficiently clear and clients understand how to administer.
- ► Many drug interactions are possible.

Uses/Indications

Diltiazem may be useful in dogs with tachyarrhythmias originating above the atrioventricular (AV) node (broadly termed supraventricular tachycardias [SVTs]) such as focal atrial tachycardia, focal junctional tachycardia, atrial flutter, atrial fibrillation, or AV-reciprocating tachycardia. For the tachyarrhythmias listed here, the primary effect of diltiazem is slowing of AV nodal conduction and improved control of the ventricular response rate. One study demonstrated that when digoxin and diltiazem were used together, they resulted in more effective ventricular rate reduction in dogs with secondary atrial fibrillation than when either was given alone.[1] Although not proving a causal benefit of rate control in dogs with atrial fibrillation, another study demonstrated that a lower 24-hour mean heart rate in a dog with atrial fibrillation was associated with longer survival.[2] In cats, diltiazem has historically been used for the treatment of feline hypertrophic cardiomyopathy and some clinicians continue this practice, but enthusiasm for its use for this indication has waned, and a recent expert consensus panel did not advise use of diltiazem in feline cardiomyopathy.[3] Diltiazem potentially could be used as third-line therapy for systemic arterial hypertension or pulmonary arterial hypertension, although other medications are more targeted (amlodipine for systemic arterial hypertension, sildenafil for pulmonary arterial hypertension) and are often used first.

The injectable formulation can be used in animals for acute therapy of hemodynamically unstable SVT.

Pharmacology/Actions

Diltiazem is a calcium channel blocker and a class IV antiarrhythmic. There are 3 subclasses of calcium channel blockers: benzothiazepines (eg, diltiazem), dihydropyridines (eg, amlodipine), and phenylalkylamines (eg, verapamil). Although all calcium channel blockers inhibit the transmembrane influx of extracellular calcium ions into cardiac and vascular smooth muscle cells, they show different affinities, and the relative actions of each class differ. The dihydropyridines act primarily on vascular smooth muscle with a primary effect of smooth muscle vasodilation and reduced total peripheral resistance. The nondihydropyridines (eg, diltiazem) act predominately on nodal cells to prolong the refractory period and slow conduction. All calcium channel blockers can have effects on cardiac contractility, although diltiazem is typically associated with weak negative inotropic effects compared with other calcium channel blockers.

Diltiazem affects cardiac conduction; it slows atrioventricular (AV) node conduction, prolongs PQ interval, and prolongs refractory times. Diltiazem rarely affects sinoatrial node activity, but in patients with sinus node dysfunction (sick sinus syndrome), diltiazem is contraindicated as resting heart rates may be reduced.

Diltiazem does not appear to affect plasma renin, aldosterone, glucose, or insulin concentrations.

Pharmacokinetics

In dogs, bioavailability of tablet forms may only be ≈25%.[4] Volume of distribution is ≈8 L/kg and ≈97% of the drug is bound to serum proteins. Elimination half-life is ≈2 to 4 hours, but up to 8 hours has been reported. Time to peak plasma concentration in dogs is ≈3 hours after oral administration of immediate-release tablets.[4, 5]

Bioavailability of immediate-release tablets in cats is reported to range from 50% to 80% with peak concentrations occurring ≈45 minutes after oral dosing.[6] Protein binding is ≈50%. Half-life is ≈1-2 hours.

Pharmacokinetics of a long-acting product (*Cardizem® CD*) given at 10 mg/kg PO once daily to healthy cats were noted as follows: bioavailability was 22% to 59%; peak concentrations were achieved in 4 to 8 hours; protein binding was ≈40%; and half-life was ≈7 hours.[6]

In horses, elimination half-life is ≈90 minutes. The distribution half-life was 12 minutes after IV administration, total plasma clearance was 14.4 mL/kg/minute, and the volume of distribution at steady-state was 1.84 L/kg.[7]

Diltiazem is rapidly and almost completely metabolized by the liver into several metabolites, including some that are active.[5]

In humans after an oral dose, ≈80% of the dose is absorbed rapidly from the gut, but because of a high first-pass effect, only about half of the absorbed drug reaches the systemic circulation; elimination half-life ranges from 3 to 9 hours.[5]

Contraindications/Precautions/Warnings

Diltiazem is contraindicated in patients hypersensitive to it or those with severe hypotension (less than 90 mm Hg systolic), sinus node dysfunction (eg, sick sinus syndrome), high-grade atrioventricular

(AV) block (unless a functioning artificial pacemaker is in place), or radiographically documented pulmonary congestion.

Diltiazem should be used with caution in geriatric patients or in those with heart failure (particularly if also receiving beta-blockers) or with hepatic or renal impairment.

When diltiazem is administered IV, it should be given slowly over at least 2 minutes.[8]

Adverse Effects

Diltiazem appears to be well tolerated at recommended doses. One feline study found that the 60 mg sustained-release pellet (9.3 to 14.8 mg/kg) was associated with lethargy, GI disturbances, and weight loss in 36% of treated cats.[9] GI disturbances were recognized within one week, and weight loss was detected after 2 to 6 months of treatment.[9] Lethargy, GI distress (anorexia), hypotension, atrioventricular (AV) block and other rhythm disturbances, CNS effects, rashes, and elevations in liver function tests could potentially occur in any species.

Reproductive/Nursing Safety

High doses in rodents have resulted in increased embryolethality, fetal deaths, and skeletal abnormalities.[10, 11] Use during pregnancy only when the benefits outweigh the potential risks.

Diltiazem is excreted in milk and concentrations may approximate those found in the plasma; therefore, it should be used with caution when nursing.

Overdose/Acute Toxicity

The oral LD_{50} in dogs has been reported as greater than 50 mg/kg.[11] Clinical signs noted after an overdose may include GI signs (eg, inappetence, vomiting, diarrhea), atrioventricular (AV) block, bradycardia, hypotension, and heart failure.[12] A dog that ingested ≈100 mg/kg PO of a sustained-release product developed bradycardia, hypotension, CNS depression, second-degree AV block with ventricular escape, and GI effects. Ultimately the dog required a temporary transvenous pacemaker for 19 hours, but recovered.[13]

Treatment for calcium channel blocker intoxication can be complicated and treatment modalities are evolving. GI decontamination (including emesis or activated charcoal) should be considered in subclinical cases (particularly with recent exposure of less than 2 hours), along with supportive care based on clinical signs, including IV fluids and calcium supplementation IV.[12] Atropine may be used to treat bradycardias and second- or third-degree AV blocks. Patients that are not responsive to atropine can be administered glucagon or may require temporary artificial pacemaker implantation. Inotropic agents (eg, glucagon, dobutamine, dopamine) and vasopressors (eg, dopamine, norepinephrine) may be required to treat heart failure and hypotension. IV lipid emulsion (ILE) and high-dose insulin have been suggested as potential therapies for severe diltiazem toxicity; a successful case report using this treatment in a 4-year-old Pomeranian has been published.[14]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving diltiazem and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: Concurrent use may result in bradycardia, atrioventricular (AV) block, or sinus arrest.
- **Anesthetics, General** (eg, **isoflurane, propofol**): May increase cardiac depressant effects of diltiazem
- **Azole Antifungals** (eg, **fluconazole**, **ketoconazole, itraconazole**): Concurrent use may increase diltiazem exposure and risk for toxicity.
- **Benzodiazepines** (eg, **diazepam, midazolam**): Diltiazem may increase benzodiazepine concentrations.
- **Beta-Adrenergic Antagonists** (eg, **atenolol, esmolol, propranolol**): Diltiazem may increase the likelihood of bradycardia, AV block, or congestive heart failure developing in patients also receiving beta-blockers (including **ophthalmic beta-blockers (eg, timolol)**); additionally, diltiazem may substantially increase the bioavailability of propranolol.
- **Buspirone**: Diltiazem may increase buspirone concentrations.
- **Cannabidiol**: Diltiazem may increase cannabidiol concentration.
- **Clonidine**: Increased risk for bradycardia
- **Clopidogrel**: Concurrent use may result in decreased antiplatelet effects and increased risk for thrombotic events.
- **Cimetidine/Ranitidine**: Cimetidine may increase plasma diltiazem concentrations; increased monitoring of diltiazem's effects is warranted. Ranitidine may also affect diltiazem concentrations but to a lesser extent.
- **Cyclosporine**: Diltiazem may increase serum cyclosporine concentrations; increased monitoring and dosage adjustments may be required.
- **Dexamethasone**: Concurrent use may result in increased plasma dexamethasone concentrations and enhanced adrenal-suppressant effects.
- **Digoxin**: Although data conflict regarding whether diltiazem affects digoxin pharmacokinetics, diligent monitoring of serum digoxin concentrations should be performed.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): Concurrent use may result in an increased risk for cardiotoxicity.
- **Methylprednisolone**: Concurrent use may result in increased plasma methylprednisolone concentrations and enhanced adrenal-suppressant effects.
- **Opioids** (eg, **buprenorphine, fentanyl, hydrocodone, morphine, methadone**): Concurrent use may increase opioid exposure and risk for increased or prolonged effects.
- **Quinidine**: Diltiazem may increase serum quinidine concentrations; increased monitoring and dosage adjustments may be required.
- **Rifampin**: May decrease diltiazem concentrations
- **Tacrolimus**: Concurrent use may increase tacrolimus trough concentrations and risk for tacrolimus toxicity.
- **Theophylline**: Concurrent use may result in increased serum theophylline concentrations and risk for theophylline toxicity.
- **Vincristine**: Concurrent use may increase plasma vincristine concentrations.

Dosages

NOTE: See *Dosage Forms/Regulatory Status* for important information related to different formulations of diltiazem as they are not interchangeable**.**

DOGS:

Supraventricular tachyarrhythmias (extra-label): **NOTE**: Dosage recommendations can vary significantly and evidence supporting any dosage recommendation is not strong. The following information is adapted from multiple sources[15-18]:

Acute treatment of supraventricular tachycardia:

a) 0.05 – 0.1 mg/kg IV administered over 2 minutes; this dose may be repeated up to 2 times with 5 minutes between doses.
b) 0.25 mg/kg IV administered over 2 to 5 minutes; if required, dosage may be carefully increased up to a total dose of 0.5 mg/kg IV.
c) 2 – 6 µg/kg/minute IV CRI has been described when the arrhythmia recurs before oral dosing is feasible.
d) 0.5 mg/kg PO followed by 0.25 mg/kg PO every hour until conversion or a total oral dose of 1.5 – 2 mg/kg has been given.[15-17]

Chronic treatment of supraventricular tachycardia: Initially, 1 mg/kg PO every 8 hours and titrated upward to a maximum of 3 mg/kg PO every 8 hours. Doses exceeding 2.5 mg/kg every 8 hours should probably not be given to dogs that have severe myocardial failure or with significant cardiac compromise.

Decreasing ventricular rate associated with atrial fibrillation (extra-label):
a) Using immediate-release tablets, initially 0.5 – 2 mg/kg PO 3 times daily. Titrate upward if necessary. Total daily dose of 7 – 9 mg/kg is often necessary for adequate ventricular rate control.
b) Using a sustained-release product, initially 2 – 4 mg/kg PO twice daily. Dosage may carefully be titrated upward if required. Total daily dose required is similar to the regular tablets but divided twice, rather than 3 times, daily.
c) Diltiazem administered either as extended-release 3 mg/kg PO every 12 hours *OR* immediate-release tablet 1 mg/kg PO every 8 hours in combination with digoxin (0.003 – 0.006 mg/kg PO every 12 hours) had a more effective ventricular rate reduction than either agent given alone.[1, 19]

CATS:

Acute treatment of supraventricular tachyarrhythmias (extra-label): 0.125 – 0.25 mg/kg IV over 2 minutes with subsequent boluses at 15-minute intervals until conversion to a normal sinus rhythm or to a cumulative dose of 0.75 mg/kg IV.[16]

Adjunctive treatment of hypertrophic cardiomyopathy; supraventricular tachyarrhythmias (extra-label): Dosage recommendations can vary significantly and evidence supporting any dosage is not strong. If using the immediate-release tablets, dose at 7.5 – 15 mg/cat (NOT mg/kg) PO 2 to 3 times daily. If using a sustained-release product, 30 – 45 mg/cat (NOT mg/kg) PO once daily.

HORSES:

Ventricular rate control in atrial fibrillation and interruption of nodal-dependent supraventricular tachyarrhythmias (extra-label): 0.125 mg/kg IV over 2 minutes, repeated every 10 minutes to effect, up to 1.25 mg/kg cumulative dose.[20]

FERRETS:

Hypertrophic cardiomyopathy (extra-label): 1.5 – 7.5 mg/kg PO every 12 hours[21]

SMALL MAMMALS (RABBITS, RODENTS):

Supraventricular tachyarrhythmias (extra-label): 0.5 – 1 mg/kg PO every 12 to 24 hours[22]

Monitoring

- Baseline and periodic heart rate, ECG, and blood pressure
- Adverse effects

Client Information

- Diltiazem is used in animals to treat heart rhythm problems and, in cats and ferrets, heart muscle disease.
- Be sure your animal receives all doses. It is important to not skip any treatments.
- This medicine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Common side effects include vomiting (cats), poor appetite, diarrhea, and a slowed heart rate.
- Your veterinarian will need to monitor your animal while they are receiving this medicine. Do not miss these important follow-up visits.
- Extended-release capsules may need to be opened and only a partial amount of the capsule contents administered per dose. Follow your veterinarian's instructions closely.

Chemistry/Synonyms

A benzothiazepine calcium channel blocker, diltiazem HCl occurs as a white to off-white crystalline powder with a bitter taste. It is soluble in water and alcohol. Potencies may be expressed in terms of base (active moiety) and the salt. Dosages are generally expressed in terms of the salt.

Diltiazem may also be known as CRD-401, diltiazemi hydrochloridum, latiazem hydrochloride, and MK-793; many trade names are available.

Storage/Stability

Diltiazem oral products should be stored at room temperature in tight, light-resistant containers.

The powder for injection should be stored between 15°C to 30°C (59°F-86°F). Discard 24 hours after reconstituting. Diltiazem solution for injection should be refrigerated at 2°C to 8°C (36°F-46°F). It may be stored at room temperature for up to one month but must be discarded after 30 days if stored in this manner; do not freeze.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Diltiazem is **compatible** with D5W and sodium chloride 0.9%, digoxin, bumetanide, dobutamine, dopamine, epinephrine, lidocaine, morphine, nitroglycerin, potassium chloride, sodium nitroprusside, and vasopressin. It is **incompatible** with diazepam, furosemide, phenytoin, and thiopental.

Dosage Forms/Regulatory Status

NOTE: Oral diltiazem is available in several human dosage forms, including different types of sustained-release products. There is only limited information available on the pharmacokinetics of these sustained-release products in dogs or cats.[6, 9, 23] There are multiple trade names and strengths, and 4 basic groups: immediate-release tablets, sustained-release capsules containing coated beads, sustained-release compressed tablets containing coated beads, and sustained-release capsules containing multiples of 60 mg pellets. Sustained-release products for use in small animals are most commonly reformulated (compounded) capsules using the coated beads or pellets – in some formulations (eg, *Dilacor XR*), clients should be advised to remove the pellets from the sustained-release capsule to provide the prescribed dosage if obtained from a human pharmacy (eg, the 240 mg capsules contain four 60 mg pellets; the dosage should be clearly defined, such as "*open capsule and administer one 60 mg pellet twice daily*" and not a 240 mg capsule). For cats, when using sustained-release capsules, compound capsules made from the coated beads, or ½ of a 60-mg pellet is preferred over the use of the sustained-release diltiazem tablets.

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain

animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Diltiazem Oral Tablets: 30 mg, 60 mg, 90 mg, and 120 mg; *Cardizem®*, generic; (Rx)

Diltiazem Tablets and Capsules Extended/Sustained Release: 60 mg, 90 mg, 120 mg, 180 mg, 240 mg, 300 mg, 360 mg, and 420 mg; *Cardizem CD®* and *LA®*, *Cartia XT®*, *Dilacor XR®*, *Dilt-XR®*, *Taztia XT®*, *Tiazac®*, generic; (Rx)

Diltiazem Injection: 5 mg/mL in 5 mL, 10 mL, and 25 mL vials; Powder for Injection: 25 mg in single-use containers (carton of 6 Lyo-Ject® syringes with diluent); *Cardizem®*, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dimenhydrinate

(dye-men-***hye***-dri-nate) *Dramamine®, Gravol®*

Antihistamine; Antiemetic

Prescriber Highlights

- ► Antihistamine used primarily for prevention of motion sickness in dogs and as an antiemetic in dogs (less so in cats)
- ► Contraindications include hypersensitivity to it or others in its class. Caution: Angle closure glaucoma, GI or urinary obstruction, COPD, hyperthyroidism, seizure disorders, cardiovascular disease or hypertension; may mask clinical signs of ototoxicity
- ► Adverse effects include CNS depression and anticholinergic effects. GI effects (eg, diarrhea, vomiting, anorexia) are less common.

Uses/Indications

In veterinary medicine, dimenhydrinate is used primarily for its antiemetic effects and in the prophylactic treatment of motion sickness (eg, vestibular disease) in dogs. Because histamine is thought to not be an important mediator of vomiting in cats, other agents such as NK-1 antagonists (eg, maropitant) or M_1-cholinergic antagonists (eg, prochlorperazine, chlorpromazine, meclizine) may be better choices for treating motion sickness or vomiting in cats.[1]

Pharmacology/Actions

Dimenhydrinate has antihistaminic (H_1), antiemetic, anticholinergic, CNS depressant, and local anesthetic effects; it is a combination of diphenhydramine and 8-chlorotheophylline. These principal pharmacologic actions are thought to be a result of only the diphenhydramine moiety. Used most commonly for its antiemetic/motion sickness effects, dimenhydrinate's exact mechanism of action for this indication is unknown, but the drug does inhibit vestibular stimulation. The anticholinergic actions of dimenhydrinate may play a role in blocking acetylcholine stimulation of the vestibular and reticular systems. Tolerance to the CNS depressant effects can ensue after a few days of therapy and antiemetic effectiveness may also diminish with prolonged use.

In humans, the 8-chlorotheophylline component is intended to offset the sedating effect of diphenhydramine.

Pharmacokinetics

In beagles, oral bioavailability was 22% and peak diphenhydramine concentration (124 ng/mL) was reached 1 hour after administration.[1] C_{max} and bioavailability were ≈3 times higher with dimenhydrinate compared to an equivalent oral diphenhydramine dose. Diphenhydramine apparent volume of distribution was ≈180 L/kg and elimination half-life was 11.5 hours. An inactive metabolite (N-desmethyl diphenhydramine) is formed. 8-Chlorotheophyline peak concentration occurred 1.5 hours after administration, and elimination half-life was 21 hours.

In humans, the drug is well absorbed after oral administration, with antiemetic effects occurring within 30 minutes of administration. Antiemetic effects occur almost immediately after IV injection. The duration of effect is usually 3 to 6 hours. Diphenhydramine is metabolized in the liver, and the majority of the drug is excreted as metabolites into the urine. The terminal elimination half-life in adult humans ranges from 2.4 to 9.3 hours.

Contraindications/Precautions/Warnings

Dimenhydrinate is contraindicated in patients that are hypersensitive to it or to other antihistamines in its class. Because of their anticholinergic activity, antihistamines should be used with caution in patients with angle closure glaucoma, prostatic hypertrophy, pyloroduodenal or bladder neck obstruction, and COPD and asthma if mucosal secretions are a problem. Additionally, they should be used with caution in patients with hyperthyroidism, seizure disorders, cardiovascular disease, or hypertension. It may mask the clinical signs of ototoxicity[2] (eg, head tilt, hearing loss, ataxia) and should therefore be used with this knowledge when concomitantly administering ototoxic drugs.

The sedative effects of antihistamines may adversely affect the performance of working dogs.

In humans, pediatric patients are more susceptible to the adverse CNS effects of antihistamines, and it is recommended to avoid use in neonates.

Do not confuse dimenhyDRINATE with diphenhydrAMINE.

Adverse Effects

Most common adverse effects seen are CNS depression (eg, lethargy, somnolence) and anticholinergic effects (eg, dry mouth, urinary retention). GI effects (eg, diarrhea, vomiting, anorexia) are less common, but have been noted. Anecdotally, the sedative effects of antihistamines may diminish with time.

Because dimenhydrinate contains diphenhydramine, paradoxical excitement or agitation may occur in some animals (particularly cats).

Reproductive/Nursing Safety

Dimenhydrinate is the 8-chlorotheophylline salt of diphenhydramine. Diphenhydramine crosses the placenta. No evidence of impaired fertility, reproductive performance, or fetal harm have been noted in rats or rabbits.[2] Theophylline crosses the placenta and has been shown to reduce uterine contractions; relevance for 8-chlorotheophylline is uncertain.

Small amounts of dimenhydrinate are excreted in milk. Use is contraindicated in breastfeeding women, particularly those feeding neonates and/or premature infants. Theophylline is distributed into milk; relevance for 8-chlorotheophylline is uncertain.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose may cause CNS stimulation (excitement to seizures) or depression (lethargy to coma), anticholinergic effects, respiratory depression, and death. Treatment consists of GI decontamination, including induction of emesis if the patient is alert and CNS status is stable. Administration of a saline cathartic and/or activated charcoal may be given after emesis or gastric lavage. Treatment of other clinical signs should be performed using symptomatic and supportive therapies.

For patients that have experienced or are suspected to have expe-

rienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dimenhydrinate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Drugs** (eg, **atropine, glycopyrrolate**): Dimenhydrinate may potentiate the anticholinergic effects of other anticholinergic drugs.
- **CNS Depressant Drugs**: Increased sedation can occur if dimenhydrinate is combined with other CNS depressant drugs.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, selegiline**): MAOIs may potentiate anticholinergic effects.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): TCAs may potentiate anticholinergic effects.

Laboratory Considerations

- **Intradermal allergy testing (IDT)**: Whereas antihistamines may suppress IDT results,[3] dimenhydrinate did not demonstrate an effect on wheal formation despite reaching plasma diphenhydramine concentration believed to be therapeutic.[1]
- Dimenhydrinate may falsely elevate theophylline concentrations (see ***Chemistry/Synonyms***).

Dosages

DOGS/CATS:

Antiemetic/Antihistamine (particularly for prevention and treatment of motion sickness in dogs) (extra-label): 4 – 8 mg/kg PO, IM, IV every 8 hours.[4] When given IV, each 50 mg dimenhydrinate must be diluted with 10 mL 0.9% saline solution and administered over 2 minutes.[2]

Vomiting and nausea due to vestibular disease (extra-label): 25 – 50 mg/dog (NOT mg/kg) PO 3 times daily[2]

Monitoring

- Clinical efficacy
- Adverse effects (eg, sedation, anticholinergic signs)

Client Information

- Use only products that contain dimenhydrinate as a single active ingredient. Any other ingredients (eg, pain relievers, decongestants) found in human-label combination products can be toxic to animals.
- Antihistamine (related to diphenhydramine [*Benadryl®*]) that is used for prevention of motion sickness.
- When used for motion sickness, it is best to administer at least 30 to 60 minutes prior to travel.
- May cause drowsiness/sleepiness, which can be a beneficial effect when used to treat motion sickness.
- This medicine can be given on an empty stomach or with a small amount of food.

Chemistry/Synonyms

An ethanolamine derivative antihistamine, dimenhydrinate contains ≈54% diphenhydramine and ≈46% 8-chlorotheophylline. Hence, it is sometimes called "½ strength diphenhydramine." It occurs as an odorless, bitter-tasting and numbing, white crystalline powder with a melting range of 102°C to 107°C (215°F-225°F). Dimenhydrinate is slightly soluble in water and is freely soluble in propylene glycol or alcohol. The pH of the commercially available injection ranges from 6.4 to 7.2.

Dimenhydrinate may also be known as chloranautine, dimenhydrinatum, diphenhydramine teoclate, and diphenhydramine theoclate; many trade names are available, a common name is *Dramamine®*.

Storage/Stability

Dimenhydrinate products should be stored at room temperature 20°C to 25°C (68°F-77°F); avoid freezing of oral and injectable solutions. Store tablets in air-tight containers.

Compatibility/Compounding Considerations

Dimenhydrinate injection is reportedly physically **compatible** with all commonly used IV replenishment solutions and the following drugs: amikacin sulfate, atropine sulfate, calcium gluconate, chloramphenicol sodium succinate, corticotropin, diphenhydramine HCl, fentanyl citrate, ketamine, metoclopramide, morphine sulfate, norepinephrine bitartrate, oxytetracycline HCl, penicillin G potassium, phenobarbital sodium, scopolamine HBr, vancomycin HCl, and vitamin B complex with vitamin C.

The following drugs are either physically **incompatible** or **compatible only in certain concentrations** with dimenhydrinate: aminophylline, ammonium chloride, midazolam, oxytocin, pantoprazole sodium, pentobarbital sodium, prochlorperazine edisylate, potassium chloride, promazine HCl, promethazine HCl, and tetracycline HCl.

Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult a hospital pharmacist or specialized references for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dimenhydrinate Oral Tablets: 50 mg (regular and chewable); *Dramamine®*, *Driminate®*, *Travtabs®*, *Triptone®*, generic; (OTC)

Dimenhydrinate Injection: 50 mg/mL in 1 mL and 10 mL vials; generic; (Rx). Some preparations may contain benzyl alcohol and propylene glycol.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dimercaprol (BAL)

(dye-mer-***kap***-role) *BAL in Oil®*

Heavy Metal Chelator

Prescriber Highlights

- ► Chelating agent for arsenicals; less frequently used for lead, mercury, and gold compounds
- ► Contraindications include patients with impaired hepatic function (unless secondary to acute arsenic toxicosis), and iron, cadmium, or selenium toxicosis.
- ► Use caution in patients with impaired renal function.
- ► Adverse effects are usually transient and may include vomiting, seizures with higher dosages, increased blood pressure, and tachycardia. Injection site pain may occur; injecting deeply IM may decrease this.
- ► Alkalinize urine to ensure optimal clearance of chelated compound.

Uses/Indications

The principal use of dimercaprol in veterinary medicine is to treat intoxications caused by arsenical compounds. Due to the risk for nephrotoxicity, succimer is preferred in small animals and sodium

thiosulfate in large animals.[1] Dimercaprol has historically been used for the treatment of lead (with edetate calcium disodium [CaEDTA]), mercury, and gold intoxication although use has waned with development of safer chelators.

Pharmacology/Actions

Sulfhydryl groups found on dimercaprol form heterocyclic ring complexes with heavy metals, principally arsenic, lead, mercury, and gold. This binding prevents or reduces heavy metal binding to sulfhydryl-dependent enzymes. Different metals have differing affinities for both dimercaprol and sulfhydryl-dependent enzymes and the drug is relatively ineffective in chelating some metals (eg, selenium). Chelation to dimercaprol is reversible as metals can dissociate from the complex when dimercaprol concentrations decrease, as in an acidic environment or with oxidation. The dimercaprol-metal complex is excreted via renal and fecal routes.

Pharmacokinetics

After IM injection, peak serum/plasma concentrations occur in 30 to 60 minutes. Dimercaprol is slowly absorbed through the skin after topical administration.

Dimercaprol is distributed throughout the body, including the brain. The highest tissue concentrations are found in the liver and kidneys.

Non-metal bound drug is rapidly metabolized to inactive compounds and excreted in the urine, bile, and feces. The duration of action in humans is ≈4 hours with complete drug elimination within 6 to 24 hours.

Contraindications/Precautions/Warnings

Dimercaprol is contraindicated in patients with impaired hepatic function, unless secondary to acute arsenic toxicosis. The drug is also contraindicated in iron, cadmium, and selenium toxicosis, as the chelated complex can be more toxic than the metal alone, nor is it recommended for methylmercury intoxication due to redistribution of mercury to the brain.[2]

Because dimercaprol is potentially nephrotoxic, it should be used cautiously with impaired renal function. To protect the kidneys, the urine should be alkalinized to prevent chelated drug from dissociating in urine. Animals with diminished renal function, or that develop renal dysfunction during therapy, should have the dosage adjusted or discontinue therapy dependent on the clinical situation.

Some dosage forms may contain benzyl alcohol as a preservative. In human newborns, drug formulations containing benzyl alcohol and derivatives should be used with caution as they can potentially displace bilirubin from protein binding sites.

Adverse Effects

Injection site pain may occur, particularly if not administered deeply IM[3]; other injection sites reactions (eg, hematoma) are possible. Most systemic adverse effects are transient in nature as the drug is eliminated rapidly. Transient increases in blood pressure with concomitant tachycardia have been reported.[4] Vomiting and seizures can occur with higher dosages. In humans, the frequency of adverse effects is related to the dose and frequency of administration.

Dimercaprol is potentially nephrotoxic.

Reproductive/Nursing Safety

Safe use of dimercaprol during pregnancy has not been determined. It is unknown if dimercaprol is excreted in milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs of dimercaprol overdose in animals include vomiting, seizures, tremors, coma, and death. No specific doses were located to correspond with these clinical signs in veterinary species.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dimercaprol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Iron** or **Selenium**: Because dimercaprol forms a toxic complex with certain metals (**cadmium, selenium, uranium**, **iron**), do not administer with iron or selenium salts. Wait 24 hours after the last dimercaprol dose before starting iron or selenium therapy.

Laboratory Considerations

- **Iodine^{131} thyroidal uptake** values may be decreased during or immediately following dimercaprol therapy as dimercaprol interferes with normal iodine accumulation by the thyroid.[5]

Dosages

DOGS & CATS:

Note: It is highly recommended to contact an animal poison center before treating heavy metal poisonings.

Arsenic toxicosis (extra-label)[6]: 2.5 – 5 mg/kg IM every 4 hours for the first 2 days of treatment and then every 12 hours until recovery. 5 mg/kg doses are typically only given on the first day of treatment and only to acutely affected patients. Provide aggressive supportive therapy if indicated.

RUMINANTS:

Arsenic, lead, or mercury toxicosis (extra-label): 2.5 – 5 mg/kg IM every 4 hours for 2 days. Withdrawal information is not available in food animals. Efficacy is questionable unless dimercaprol is given before signs appear or very early in the clinical course. FDA has not exempted this drug for compounding from bulk supplies.[5]

HORSES:

Arsenic toxicosis (extra-label): 5 mg/kg IM initially, followed by 3 mg/kg IM every 6 hours for the remainder of the first day, then 1 mg/kg IM every 6 hours for 2 or more additional days, as needed. Dimercaprol therapy in horses is challenging because of the large amounts of dimercaprol that are required, the necessity to inject the drug IM, and the requirement to administer it as soon as possible after exposure because any substantial delays in treatment significantly decrease its effectiveness.[7]

Monitoring

- Liver enzymes
- BUN, Creatinine
- CBC
- Hydration and cardiovascular status
- Electrolytes and acid/base status
- Urine pH

Client Information

- Dimercaprol should only be used with close professional supervision due to the potential toxicity of this agent and the seriousness of most heavy metal intoxications.
- Dimercaprol can cause bad breath.

Chemistry/Synonyms

A dithiol chelating agent, dimercaprol occurs as a colorless or nearly colorless, viscous liquid that is soluble in alcohol, vegetable oils, and water, but unstable in aqueous solutions. It has a disagreeable mercaptan-like odor. The commercially available injection is a peanut oil and benzyl benzoate solution. The solution may be turbid or contain small amounts of flocculent material or sediment, this does not mean that the solution is deteriorating.

Dimercaprol may also be known as BAL, British Anti-Lewisite, dimercaptopropanol, dithioglycerol dimercaprolum, *BAL in Oil®*, or *Sulfactin Homburg®*.

Storage/Stability

Dimercaprol injection should be stored below 40°C (104°F); preferably at room temperature (15°C-30°C [59°F-86°F]).

Compatibility/Compounding Considerations

Dimercaprol is not on the FDA's GFI #256 list of drugs allowed to be compounded from bulk supplies.[8]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dimercaprol Injection: 100 mg/mL (10%); (for IM use only) in 3 mL amps; *BAL in Oil®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dimethyl Sulfoxide

(dye-***meth***-el sul-***fox***-ide) *Domoso®*

Free Radical Scavenger

Prescriber Highlights

- ► Free radical scavenger that has anti-inflammatory, cryopreservative, anti-ischemic, and radioprotective effects
- ► Use with caution in patients with mast cell tumors, dehydration, and shock; may mask existing pathology
- ► May cause localized burning when administered topically
- ► Administer IV to horses slowly and at concentrations of ≈10%; may occasionally cause diarrhea, tremors, and colic.
- ► Handle cautiously; will be absorbed through skin and can carry toxic compounds across skin. Use of impervious gloves is recommended.
- ► Strong, offensive odor may be an issue.

Uses/Indications

The purported uses for dimethyl sulfoxide (DMSO) are rampant, but the only FDA-approved veterinary indication for DMSO is as a topical application to reduce acute swelling due to trauma.[1] Other possible indications for DMSO include adjunctive treatment in transient ischemic conditions; CNS trauma and cerebral edema; calcinosis cutis; endometritis; skin ulcers; wounds; burns; adjunctive therapy in intestinal surgeries; analgesia for postoperative or intractable pain; amyloidosis in dogs; reduction of mammary engorgement in the nursing bitch; enhancement of antibiotic penetration in mastitis in cattle; treatment of cyclophosphamide-induced hemorrhagic cystitis in dogs[2]; and limitation of tissue damage following extravasation injuries secondary to chemotherapeutic agents.[3] DMSO plus calcium chloride intratesticular injections have been used for chemical castration in dogs and cats.[4,5]

Although the potential indications for DMSO are many, the lack of well-controlled studies leaves many more questions than answers regarding this drug.

Pharmacology/Actions

The pharmacologic effects of dimethyl sulfoxide (DMSO) are diverse. DMSO traps free radical hydroxide, and its metabolite (dimethyl sulfide [DMS]) traps free radical oxygen. It appears that these actions help to explain some of the anti-inflammatory, cryopreservative, anti-ischemic, and radioprotective qualities of DMSO.

DMSO easily penetrates the skin. It serves as a carrier agent in promoting the percutaneous absorption of other compounds (including drugs and toxins) that normally would not penetrate. Drugs such as insulin, heparin, phenylbutazone, and sulfonamides may all be absorbed systemically when they are mixed with DMSO and applied to the skin. DMSO has been shown to increase the rate of oral absorption of the triazine antiprotozoal drugs, diclazuril, and toltrazuril in horses.[6]

DMSO has weak antibacterial activity and possibly has some clinical efficacy as an antifungal when it is used topically. The mechanism for these antimicrobial effects has not been elucidated.

The anti-inflammatory/analgesic properties of DMSO have been thoroughly investigated. DMSO appears to be more effective as an anti-inflammatory agent when it is used for acute inflammation versus chronic inflammatory conditions. The analgesic effects of DMSO have been compared with those produced by narcotic analgesics. It can be efficacious for both acute and chronic musculoskeletal pain.

DMSO decreases platelet aggregation, but reports regarding its effects on coagulability and the myocardium have been conflicting. DMSO has diuretic activity independent of the method of administration. It provokes histamine release from mast cells, which likely contributes to the local vasodilatory effects seen after topical administration.

DMSO also apparently has some anticholinesterase activity and enhances prostaglandin E, but blocks the synthesis of prostaglandins E_2, F_2-alpha, H_2, and G_2. DMSO inhibits the enzyme alcohol dehydrogenase, which is responsible for not only the metabolism of alcohol, but also the metabolism of ethylene glycol into toxic metabolites.

Pharmacokinetics

Dimethyl sulfoxide (DMSO) is well absorbed after topical administration, especially at concentrations between 80% and 100%. It is extensively and rapidly distributed to virtually every area of the body. After IV administration to horses, the serum half-life is ≈9 hours. In dogs, the elimination half-life is ≈1.5 days. DMSO is metabolized to dimethyl sulfide (DMS) and primarily excreted by the kidneys, although biliary and respiratory excretion also takes place.

In cattle, the drug is eliminated quite rapidly and after 20 days, no detectable drug or metabolites are found in milk, urine, blood, or tissues.

Contraindications/Precautions/Warnings

Wear impervious gloves when applying dimethyl sulfoxide (DMSO) topically and apply this product with clean or sterile cotton to minimize the chances for contamination with potentially harmful substances. Only apply this product to clean, dry areas, to avoid carrying other chemicals into the systemic circulation. Do not apply DMSO topically mixed with compounds (eg, heavy metals) that could be toxic if absorbed systemically.[7] The topical DMSO application site should be dry before other topical medications or treatments are applied to that area.

DMSO may mask existing pathology with its anti-inflammatory and analgesic activity.

Because DMSO may degranulate mast cells, animals with mast cell tumors should only receive DMSO with extreme caution. DMSO should be used cautiously in animals that are suffering from dehydration or shock, as its diuretic and peripheral vasodilatory effects may exacerbate these conditions.

Because DMSO is absorbed transdermally and may carry with it potentially toxic chemicals into the systemic circulation, it is recommended that staff and caregivers wear impervious gloves while han-

dling DMSO products.

Adverse Effects

When dimethyl sulfoxide (DMSO) is used as labeled, it appears to be an extremely safe drug. Local effects (burning, erythema, vesiculation, dry skin, local allergic reactions) and garlic or oyster-like breath odor are the most likely adverse effects. These effects are transient and quickly resolve when therapy is discontinued. Lenticular changes, which may result in myopia, have been noted, primarily in dogs and rabbits, when DMSO is used chronically at high doses. These effects are slowly reversible after the drug is discontinued.

When DMSO is administered IV to horses, it may cause hemolysis and hemoglobinuria. Although older dosage references often recommended concentrations of 20% or less for IV use in horses, 10% solutions, which are likely safer, are more commonly recommended today.[8] Slow IV administration may reduce adverse effects. Other adverse effects can include diarrhea, muscle tremors, and colic.

Hepatotoxicity and renal toxicity have been reported for various species and dosages. These conditions occur fairly rarely, and some clinicians actually believe DMSO has a protective effect on is chemically insulted renal tissue.

Reproductive/Nursing Safety

At high doses, dimethyl sulfoxide (DMSO) has been shown to be teratogenic in hamsters, mice, rats, and rabbits[9]; weigh the risks versus benefits when using in pregnant animals.

It is not known whether this drug is excreted in milk; use in nursing dams with caution.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The reported LD_{50} following IV dosage is ≈200 mg/kg in cats and ≈2.5 g/kg in dogs.[10] Signs of toxicity include sedation and hematuria at non-lethal doses; coma, seizures, opisthotonus, dyspnea, and pulmonary edema at higher dosages. Should an acute overdose be encountered, treat the patient supportively.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving DMSO and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alcohol**: Effects may be potentiated by dimethyl sulfoxide (DMSO).
- **Atropine**: Effects may be potentiated by DMSO.
- **Corticosteroids**: Effects may be potentiated by DMSO.
- **Insulin**: Effects may be potentiated by DMSO.
- **Organophosphates** (or other cholinesterase inhibitors): Avoid use with DMSO.

Dosages

DOGS:

Reduce acute swelling due to trauma (label dosage; FDA-approved): Apply topically to the skin over the affected area 3 to 4 times daily.[11] Total daily dosage should not exceed 20 g (or mL of liquid) and therapy should not exceed 14 days.

Calcinosis cutis (extra-label): Clinical recommendations generally are to treat each lesion with topical dimethyl sulfoxide (DMSO; gel is preferred if available) once daily. If there are many sites, or a large area is involved, treat ⅓ of the lesions (or ⅓ of the affected areas) each day. There are differing recommendations to 1) either rotate these sites each day, or 2) add new treatment areas as the treated sites improve. Dogs reportedly appear ill if large areas are treated initially, but usually do not become hypercalcemic. Wear impervious gloves when applying. Treatment may require several weeks and not all cases resolve. Most clinicians recommend periodic monitoring of serum calcium.

Bladder instillation to treat persistent cases of hemorrhagic cystitis (secondary to cyclophosphamide treatment): 10 mL of DMSO medical-grade 50% solution is diluted with 10 mL of water and instilled into bladder and removed after 20 minutes.[2]

Doxorubicin extravasation: See the ***Doxorubicin*** monograph for more information.

HORSES:

Reduce acute swelling due to trauma; topical application (label dosage; FDA-approved): Liberal application should be administered topically to the skin over the affected area 2 to 3 times daily.[11] Total daily dosage should not exceed 100 g (or mL of liquid) and therapy should not exceed 30 days.

Anti-inflammatory/hydroxyl radical scavenger (IV administration) (extra-label): 0.5 – 2 g/kg via slow IV infusion as a 10% solution (diluted in a polyionic solution) every 12 to 24 hours.[8] **NOTE**: Although DMSO has been used IV for many years in horses for a variety of purposes, actual evidence demonstrating its efficacy is slim.

Chronic endometritis; abnormal mucous (extra-label): 30% solution as an intrauterine infusion daily; up to 5 days during estrus. To prepare a 30% solution using 90% DMSO, 33 mL of a 90% DMSO solution is added to 64 mL of sterile saline.[12]

Monitoring

- Efficacy
- Check for hemoglobinuria with urinalysis
- Hematocrit, if indicated
- Ophthalmic examinations with high dosages or chronic use in dogs

Client Information

- Use only medical-grade dimethyl sulfoxide (DMSO), as other products may contain harmful impurities.
- Wear rubber gloves when applying this medicine topically. Use medicine in well-ventilated area; avoid inhalation and contact with eyes.
- Apply with clean or sterile cotton to reduce chances for contaminating DMSO with other substances. Apply only to clean, dry skin.
- Do not mix DMSO with other drugs or chemicals without your veterinarian's approval. Keep the lid tightly closed on the container when the medicine is not in use.
- DMSO can cause garlic or oyster-like breath odor or local skin reactions.

Chemistry/Synonyms

Dimethyl sulfoxide (DMSO) is a clear, colorless to straw-yellow liquid. It is dipolar, aprotic (acts as a Lewis base) and extremely hygroscopic. It has a melting/freezing point of 18.5°C (65.3°F), boiling point of 189°C (372.2°F), and a molecular weight of 78.1. It is miscible with water (heat is produced), alcohol, acetone, chloroform, ether, and many organic solvents. A 2.15% solution in water is isotonic with serum.

Dimethyl sulfoxide may also be known as dimethyl sulphoxide, dimethylis sulfoxidum, DMSO, methyl sulphoxide, NSC-763, SQ-9453, sulfonylbismethane, *Domoso®*, *Kemsol®*, *Rheumabene®*, *Rimso®*, or *Synotic®*.

Storage/Stability

This product must be stored in airtight containers away from light. As dimethyl sulfoxide (DMSO) may react with some plastics, it should be stored in glass or in the container provided by the manufacturer. If DMSO is allowed to contact room air it will self-dilute to a concentration of 66% to 67%.

Compatibility/Compounding Considerations

Dimethyl sulfoxide (DMSO) is compatible with many compounds, but because of the chances for accidental percutaneous absorption of potentially toxic compounds, the admixing of DMSO with other compounds is not to be done casually.

Dosage Forms/Regulatory Status

VETERINARY APPROVED PRODUCTS:

Dimethyl Sulfoxide Veterinary Gel 90%: *Domoso® Gel* 90% (medical grade) in 60 g and 120 g tubes, and 425 g containers. FDA-approved (NADA #47-925) for use in dogs and horses. Do not administer to horses that are to be used for food.

Dimethyl Sulfoxide Veterinary Solution 90%: *Domoso® Solution* 90% (medical grade) in 1 pint and 1 gallon bottles. FDA-approved (NADA #32-168) for use in canines and equines. Do not administer to horses that are to be used for food. Marketing status is uncertain.

Dimethyl Sulfoxide Veterinary Solution: 99% in 1 pint and 1 gallon bottles; generic. Not FDA-approved

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 5 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

NOTE: Topical otic products, *Synotic®* that contains DMSO 60% and fluocinolone acetonide 0.01% and *Synsac®*, which is DMSO 20% and fluocinolone 0.01%, are also available for veterinary use. Supplied in 8 mL and 60 mL dropper bottles.

HUMAN APPROVED PRODUCTS:

Dimethyl Sulfoxide Solution: 50% aqueous solution in 50 mL; *Rimso-50®*; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Diminazene

(dye-***min***-ah-zeen) *Berenil® RTU*

Antiprotozoal

Prescriber Highlights

- ► Antiprotozoal agent used in several species for trypanosomiasis, babesiosis, or cytauxzoonosis
- ► Usually administered once; repeat doses may increase risk for toxicity
- ► Available in several countries, but not in United States

Uses/Indications

Diminazene is used to treat trypanosomiasis in dogs and livestock (eg, sheep, goats, cattle), *Babesia* spp infections in dogs and horses, cytauxzoonosis and babesiosis in cats, and leishmaniasis in humans. A prospective, unmasked study in dogs with *Babesia gibsoni* infection comparing atovaquone/azithromycin (AA) with a protocol using clindamycin, diminazene, and imidocarb (CDI) found that CDI had higher recovery and lower relapse rates, albeit longer therapy duration and slower reduction in parasite numbers, than AA. The authors concluded that CDI was effective for initial therapy and when the *M121I* gene in *B gibsoni* had mutated.[1] A study in naturally infected cats with chronic *Cytauxzoon felis* parasitemia found no difference in parasite burden between diminazene (3 mg/kg IM; 2 doses 7 days apart) and placebo-treated cats.[2] A dose-intensified treatment (diminazene 4 mg/kg IM once daily for 5 consecutive days) failed to reduce parasite burden and was accompanied by frequent side effects.[3]

Diminazene is not commercially available in the United States but is available and used in many countries.

Pharmacology/Actions

Diminazene's exact mechanism of action is not well understood. With *Babesia* spp, it is thought to interfere with aerobic glycolysis and DNA synthesis.

Diminazene may not completely eradicate the organism, but, because it is slowly metabolized, suppression of recurring clinical signs or prophylaxis can be attained for several weeks after a single dose.

Pharmacokinetics

Diminazene's pharmacokinetics have been investigated in several species. The drug is rapidly absorbed and distributed after IM administration in target species studied. High concentrations can be found in the liver and kidney. The drug appears to enter the CSF but at concentrations significantly lower than that found in plasma in healthy animals. CSF concentrations are higher in dogs infected with African trypanosomiasis, probably due to meningeal inflammation. Diminazene apparently is metabolized somewhat in the liver, but identification of these metabolites and whether they possess antiprotozoal activity is not known.

Reported elimination half-lives are widely variable. Values range from 5 to 30 hours in dogs, goats, and sheep to over 200 hours in one study for cattle. Elimination half-life in cats is short, with an average of ≈1.7 hours.[4] Differences in assay methodology and study design may account for some of this variation, but even within one individual study in dogs using a modern assay (HPLC), wide interpatient variability was noted.

Contraindications/Precautions/Warnings

Camels appear highly susceptible to the toxic effects of diminazene, and product labels[5] may state the drug is contraindicated in camelids.

CNS toxic effects in dogs may be associated with cumulative dosages of diminazene, and repeated dosing must be carefully considered. One reference states, *the dose cannot be repeated with this or another diaminidine-derivative within a 6-week period.*[6,7]

Adverse Effects

At usual dosages in domestic livestock, diminazene is reportedly relatively free of adverse effects. Adverse effects associated with therapeutic dosages of diminazene in dogs may include vomiting and diarrhea, pain and swelling at the injection site, and transient decreases in blood pressure. Very rarely (less than 0.1%), ataxia, seizures, or death have been reported.

Reproductive/Nursing Safety

Little information is available. Rats given diminazene up to 1 g/kg PO on days 8 to 15 demonstrated no teratogenic effects, but decreased body weights and increased resorptions were noted at the highest dose.

Diminazene is distributed into milk; safety for nursing offspring has not been established.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the poten-

tial risks to offspring.

Overdose/Acute Toxicity

Little information is available. Diminazene appears most toxic in dogs and camels. Dosages greater than 7 mg/kg can be very toxic to camels; dosages above 10 mg/kg IM in dogs can cause severe GI, respiratory, nervous system, or musculoskeletal effects.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

- No significant drug interactions were identified.

Laboratory Considerations

- No issues were noted.

Dosages

NOTE: There is a multitude of protozoal diseases worldwide that may respond to diminazene. Depending on the infective agent and species of the patient treated, there may be local specific recommendations for treatment and prevention. The following should be used as general guidelines only.

DOGS:

***Babesia* spp infections** (extra-label):

a) Large or small *Babesia* spp (extra-label): 3.5 mg/kg IM once. Variable efficacy and unpredictable toxicity (CNS signs may be severe)[8]

b) Babesiosis when the *M121I* gene in *Babesia gibsoni* has mutated (based on a prospective, unmasked study): Clindamycin 30 mg/kg PO every 12 hours with diminazene aceturate 3.5 mg/kg IM once on the day of presentation and imidocarb dipropionate 6 mg/kg SC once on the day after the diminazene was administered[1]

African trypanosomiasis (extra-label): 3.6 – 7 mg/kg IM every 2 weeks as needed to control relapse or reinfection[9,10]

HORSES, CATTLE, SHEEP, GOATS:

Susceptible protozoal (trypanosomes, *Babesia* spp) infections (extra-label): 3.5 mg/kg IM once. In some jurisdictions the label states that, depending on susceptibility, the dose can be increased to 8 mg/kg. See ***Overdose/Acute Toxicity***. Regardless of the dosage used, do not exceed 4 grams total dose per animal.[5,11]

RABBITS:

***Trypanosoma evansi* infections** (extra-label): 3.5 mg/kg IM[12]

Monitoring

- For *Babesia* spp infections in dogs, monitoring should include surveillance for potential adverse effects of diminazene and signs of clinical efficacy, including baseline and periodic CBCs. Severe cases may have elevated BUN or liver enzymes and hypokalemia.
- Current recommendation for determining clearing of the organism (*Babesia gibsoni*) is to perform a PCR test at 60 and 90 days posttherapy.

Client Information

- Clients should understand that depending on the species treated, parasites may not be completely eradicated and that retreatment may be required.

Chemistry/Synonyms

Diminazene aceturate is an aromatic diamidine derivative chemically related to pentamidine. One gram of diminazene is soluble in ≈14 mL of water and it is slightly soluble in alcohol.

Diminazene aceturate may also be known as diminazene diaceturate or diminazeno; many international trade names are available.

Storage/Stability

Read and follow label directions for storage and preparation of each product used; diminazene powder, granules, or packets for reconstitution for injection should generally be stored in a dry, cool place out of direct sunlight. Once reconstituted, the solution's stability is temperature dependent: up to 14 days when refrigerated, up to 5 days at 20°C (68°F) and only for 24 hours at temperatures above 50°C (122°F).

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE IN THE UNITED STATES

Diminazene aceturate is available in many countries either alone or in combination products (eg, with antipyrine), with the following trade names: *Azidin®*, *Berenil®* RTU, *Dimesol®*, *Demin®*, *Diminicin RTU®*, *Veriben®*, or *Veriben® B12 LA*.

Withdrawal times may vary depending on the product, dosage, and the country where it is used; check local regulations.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Dinoprost

Prostaglandin F2-alpha

(***dye***-noe-prost) *Lutalyse®*

Prostaglandin

Prescriber Highlights

- ► Naturally occurring prostaglandin F2alpha used as a luteolytic agent for estrus induction and synchronization, pyometra treatment, and parturition induction; also used as an abortifacient
- ► Contraindicated during pregnancy (when abortion or induced parturition are not wanted). Dinoprost has been associated with serious toxicity and death in camelids.
- ► Do not administer IV; use with extreme caution in elderly or debilitated animals.
- ► Adverse effects in dogs and cats include abdominal pain, emesis, defecation, urination, pupillary dilation followed by constriction, tachycardia, restlessness, anxiety, fever, hypersalivation, dyspnea, and panting; death is possible (especially in dogs).
- ► Adverse effects in cattle include infection at injection site, salivation, and hyperthermia.
- ► Adverse effects in swine include erythema, pruritus, urination, defecation, mild ataxia, hyperpnea, dyspnea, nesting behavior, abdominal muscle spasms, tail movements, increased vocalization, and salivation.
- ► Adverse effects in horses include body temperature changes and/or sweating. Less frequent effects include increased respiratory and heart rates, ataxia, abdominal pain, and lying down; more adverse effects are observed with prostaglandin F2alpha than with cloprostenol.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies dinoprost as a hazardous drug; use appropriate precautions when handling.
- ► Pregnant women should not handle dinoprost; humans with asthma and women of childbearing age should handle with caution.

Uses/Indications

Dinoprost (ie, prostaglandin F2alpha; PGF2alpha) is a luteolytic agent labeled for use in cattle for treatment of estrus synchronization, unobserved (ie, silent) estrus in lactating dairy cattle, pyometra, and abortion in feedlot and nonlactating dairy cattle. This drug is labeled in swine to act as a parturient-inducing agent. Dinoprost is labeled for use in cycling mares as a luteolytic agent to control the time of estrus and to assist in inducing estrus in mares that are difficult to breed.

In small animals, dinoprost is used extra-label as an abortifacient agent and as adjunctive medical therapy treatment for pyometra. Combination therapies (eg, dinoprost with cabergoline) allow lower doses of dinoprost to be used, reducing or eliminating GI adverse effects that may occur when dinoprost is used alone.

Although dinoprost is not FDA-approved, it is also used in sheep and goat reproductive medicine.

A review of the evidence for the therapeutic efficiency of antibiotics and dinoprost in postpartum dairy cows with clinical endometritis concluded that no scientific evidence supports the effectiveness of dinoprost as a treatment for clinical endometritis in postpartum dairy cows.[1]

Pharmacology/Actions

Dinoprost has several pharmacologic effects on the female reproductive system, including stimulation of myometrial activity, relaxation of the cervix, and inhibition of steroidogenesis by corpora lutea. Dinoprost can potentially lyse corpora lutea.

Pharmacokinetics

In studies done in rodents, dinoprost was demonstrated to distribute very rapidly into tissues after injection. In cattle, the serum half-life of dinoprost has been stated to be only minutes long.[2]

Contraindications/Precautions/Warnings

Unless dinoprost is being used as an abortifacient or to induce parturition, it should not be used in any species during pregnancy. Dinoprost is contraindicated in animals with bronchoconstrictive respiratory disease (eg, asthma, recurrent airway obstruction [RAO] in horses). This drug should not be administered IV.

According to the manufacturer, dinoprost is contraindicated in mares with acute or subacute disorders of the vascular system, GI tract, respiratory system, or reproductive tract.

Dinoprost should be used with extreme caution, if at all, in dogs or cats older than 8 years of age or with pre-existing cardiopulmonary or other serious disease (eg, liver, kidney, sepsis, peritonitis). Some clinicians regard closed-cervix pyometra as a relative contraindication to the use of dinoprost.

Dinoprost has been associated with acute toxicity and death in camelids.

The National Institute for Occupational Safety and Health (NIOSH) classifies the human-labeled drug dinoprostone as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk of exposure.[3] Dinoprost should be handled in the same manner as dinoprostone. It has been recommended that dinoprost should not be dispensed for client administration due to the risk of adverse effects in the patient as well as the risk associated with potential human exposure.[4]

Adverse Effects

Bacterial infections at the injection site and limited salivation have been reported. If administered IV, increased heart rates have been noted.

In mares, transient decreased body (rectal) temperature and sweating are most often reported. Less frequently, increased respiratory and heart rates, ataxia, abdominal pain, and lying down have also been noted. These effects are generally seen within 15 minutes of administration and resolve within 1 hour.

In swine, dinoprost has caused erythema and pruritus, urination, defecation, slight ataxia, hyperpnea, dyspnea, nesting behavior, abdominal muscle spasms, tail movements, increased vocalization, and salivation. Although these effects may last up to 3 hours, they are not detrimental to the animal.

In dogs and cats, dinoprost can cause abdominal pain, emesis, defecation, urination, pupillary dilation followed by constriction, tachycardia, restlessness, anxiety, fever, hypersalivation, dyspnea, and panting. Cats may also exhibit increased vocalization and intense grooming behavior. Severity of effects is generally dose dependent. Defecation can be seen with very low doses. Signs generally appear 5 to 120 minutes after administration and may persist for 20 to 30 minutes. Death has occurred (especially in dogs) after receiving this drug. Dogs and cats should be monitored for cardiorespiratory effects, especially after receiving higher doses.

When used as an abortifacient in humans, dinoprost causes nausea, vomiting, and diarrhea in ≈50% of patients.

Reproductive/Nursing Safety

Pregnancy status should be determined prior to use. Unless being used as an abortifacient or parturition inducer, dinoprost should not be used in any species during pregnancy. In swine, dinoprost should not be administered prior to 3 days of normal predicted farrowing, as increased neonatal mortality may result.

Because safety has not been established in nursing animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Dogs are apparently more sensitive to the toxic effects of dinoprost than are other species. The LD_{50} in the bitch has been reported as 5.13 mg/kg after SC injection,[5] which may be only 5 times greater than the recommended dosage given by some clinicians.

Increased body temperature has been reported when dinoprost is administered to cattle in overdose quantities (5-10 times recommended doses). Vomiting may be seen in swine given 10 times the recommended dosage. In any species, if clinical signs are severe and require treatment, supportive therapy is recommended.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dinoprost and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Other Oxytocic Agents**: Activity may be enhanced by dinoprost. Reduced effect of dinoprost would be expected with concomitant administration of a progestin.

Dosages

DOGS:

Abortifacient (extra-label):

a) After day 25 or 30, dinoprost SC injections must be given at least twice daily using a maximum dose of 80 – 100 µg/kg, starting with half the dose the first day (or first 2 administrations). Treatment must initially be administered under the supervision of a clinician and adverse effects carefully (monitored) after the first injection, after which the bitch can be sent home (with subsequent dose administered by owner). Treat-

ment must continue (for 6 days or longer) until verification with ultrasound or palpation.[6]

b) Combination therapies may allow for a lower dinoprost dose to be used and minimize adverse effects as compared with dinoprost used alone.
   i. Starting on day 25, give dinoprost 0.025 mg/kg SC every other day with cabergoline 5 µg/kg PO once daily until termination of pregnancy.[7]
   ii. After day 27, give dinoprost 0.03 mg/kg IM once daily with cabergoline 5 µg/kg PO once daily until termination of pregnancy (6-9 days).[8]
   iii. Once pregnancy is confirmed with ultrasound, treatment should be started no sooner than 30 days after breeding. Give dinoprost 0.1 mg/kg SC 3 times daily for 3 days, then 0.2 mg/kg SC 3 times daily to effect in conjunction with misoprostol 1 – 3 µg/kg intravaginally once daily.[9]

Pyometra (extra-label): Use is restricted to bitches 6 years of age or younger that have an open cervix, are not critically ill, do not have significant concurrent illness, and have an owner adamant about saving the animal's reproductive potential.

a) Day 1, dinoprost 0.1 mg/kg SC once daily; day 2, 0.2 mg/kg SC once daily; days 3 to 7, 0.25 mg/kg SC once daily. Use antibiotics (effective against *E coli*) concurrent with dinoprost treatment and for 14 days beyond completion of the 7-day dinoprost regimen. Reevaluate the patient at 7 and 14 days after being treating with dinoprost. Re-treat at 14 days if purulent discharge persists or fever, increased WBC, and fluid-filled uterus persist.[10]
b) Dinoprost 0.1 mg/kg SC once daily for 7 days along with supportive therapy showed resolution of pyometra in all 7 dogs, with recurrence occurring in 3 dogs and successful subsequent pregnancies in 4 dogs.[10]
c) Dinoprost 250 µg/kg SC every 12 hours until the uterus reduces to near normal size (typically, 3-5 days).[4]
d) Dinoprost 150 µg/kg intravaginal infusion once or twice daily for 3-12 days along with antibiotics (amoxicillin or gentamicin administered IM). No adverse effects from dinoprost were observed.[11]
e) Combination therapy: Dinoprost 0.025 – 0.03 mg/kg SC or IM with cabergoline 5 µg/kg PO once daily; combination may allow for a lower dinoprost dose to be used and minimize adverse effects as compared with dinoprost used alone.

CATS:

Abortifacient (extra-label): 2 mg (total dose) per cat (NOT mg/kg) IM once daily beginning at day 33. Adverse effects include prostration, vomiting, and diarrhea.[6]

Pyometra (extra-label): Initially, 0.1 mg/kg SC on the first day, then 0.25 mg/kg SC once daily for 5 days.[12] Give bactericidal antibiotics concurrently. Not recommended in animals older than 8 years of age or in severely ill animals. Closed-cervix pyometra is a relative contraindication. Re-evaluate in 2 weeks; re-treat for 5 more days if necessary.[13,14]

HORSES:

Labeled indications; as a luteolytic agent to control the timing of estrus in estrous cycling and clinically anestrous difficult-to-breed mares that have a corpus luteum (FDA approved): Evaluate the reproductive status of the mare. Administer a single injection of dinoprost 1 mg/45 kg (1 mg/100 lb) IM. Observe for signs of estrus by means of daily teasing with a stallion, and evaluate follicular changes on the ovary by palpation of the ovary per rectum. Some clinically anestrus mares will not express estrus but will develop a follicle that will ovulate. These mares may become pregnant if inseminated at the appropriate time relative to rupture of the follicle. Breed mares in estrus in a manner consistent with normal management.[2]

Estrus synchronization in normally cycling mares (extra-label): Choose one.

1) **Two-injection method**: On days 1 and 16, give dinoprost 5 mg IM. Most mares (60%) will begin estrus 4 days after the second injection and ≈90% will show estrus behavior by the sixth day after the second injection. Breed using artificial insemination every second day during estrus or inseminate at predetermined times without estrus detection. Alternatively, add an injection of hCG (2500 – 3300 IU) IM on the first or second day (usually day 21) of estrus to hasten ovulation. Breed using artificial insemination on days 20, 22, 24, and 26. This protocol may be of more benefit when used early in the breeding season.
2) **Progestogen/prostaglandin method**: Give altrenogest 0.44 mg/kg PO for 8 to 12 days. On the last day of altrenogest therapy (usually day 10) give dinoprost IM (dose is not noted, but it is suggested to use the same dose as the two-injection method listed above). The majority of mares will show estrus 2 to 5 days after their last treatment. Inseminate every 2 days after detection of estrus. Synchronization may be improved by giving hCG 2500 IU IM on the first or second day of estrus or 5 to 7 days after altrenogest is withdrawn.
3) On day 1, inject progesterone 150 mg and 17-beta-estradiol 10 mg daily for 10 days. On the last day, also give dinoprost IM (dose is not noted, but it is suggested to use the same dose as the two-injection method listed above). Perform artificial insemination on alternate days after estrus detection or on days 19, 21, and 23.[15]

Abortifacient (extra-label):

a) Prior to the twelfth day of pregnancy: dinoprost 5 mg IM. After the fourth month of pregnancy, give 1 mg/45 kg (1 mg/100 lb) body weight daily until abortion takes place.[16]
b) From day 80 to 300: dinoprost 2.5 mg IM every 12 hours; ≈4 injections are required on average to induce abortion.[17]

CATTLE:

Labeled indications as a luteolytic agent (FDA approved): Dinoprost is effective only in cattle with a corpus luteum (ie, those that ovulated at least 5 days prior to treatment). Future reproductive performance of animals that are not cycling will be unaffected by injection of dinoprost.

Management considerations: Many factors contribute to success and failure of reproduction management; these factors are also important when the time of breeding is to be regulated with dinoprost sterile solution. Some of these factors are: (a) cattle must be ready to breed—they must have a corpus luteum and be healthy; (b) nutritional status must be adequate, as this has a direct effect on conception and the initiation of estrus in heifers or return of estrous cycles in cows following calving; (c) physical facilities must be adequate to allow cattle handling without being detrimental to the animal; (d) estrus must be detected accurately if timed artificial insemination is not employed; and (e) highly fertile semen must be used and inseminated properly. A successful breeding program can employ dinoprost effectively, but a poorly managed breeding program will continue to be poor when dinoprost is employed unless other management deficiencies are remedied first. Cattle expressing estrus following dinoprost are receptive to breeding by a bull. Using bulls to breed large numbers of cattle in heat following dinoprost will require proper management of bulls and cattle.

a) **Estrus synchronization in beef cattle and nonlactating dairy heifers**: Dinoprost is used to control the timing of estrus and

ovulation in estrous cycling cattle that have a corpus luteum. Inject dinoprost 25 mg IM once, dose may be repeated 10 to 12 days later. Dose may be administered SC if using high-concentration dinoprost product. With the single injection, cattle should be bred at the usual time relative to estrus. If receiving 2 injections of dinoprost, cattle can be bred after the second injection either at the usual time relative to detected estrus or at ≈80 hours after the second injection. Estrus is expected to occur 1 to 5 days after injection if a corpus luteum was present. Cattle that do not become pregnant to breeding at estrus on days 1 to 5 after injection will be expected to return to estrus in ≈18 to 24 days.

b) **Estrus synchronization in suckled beef cows, replacement beef and dairy heifers**: Using high-concentration dinoprost product: 25 mg IM or SC. Used in combination with progesterone vaginal insert[18]; see dinoprost product label for administration schedule.[2,19]

c) **Estrus synchronization in lactating dairy cows**: Dinoprost 25 mg IM. Used in combination with progesterone vaginal insert[18]; see dinoprost product label for administration schedule.[2,19] Dose may be administered SC if using high-concentration dinoprost product.

d) **Estrus synchronization in lactating dairy cows to allow fixed-time artificial insemination**: Dinoprost 25 mg IM. Used in combination with gonadorelin injection; see dinoprost product label for administration schedule.[2,19] Dose may be administered SC if using high-concentration dinoprost product.

e) **Unobserved (silent) estrus in lactating dairy cows with a corpus luteum**: Dinoprost 25 mg IM. If the cow returns to estrus, breed at the usual time relative to estrus. If estrus has not been observed by 80 hours after injection, breed at 80 hours. Dose may be administered SC if using high-concentration dinoprost product.

f) **Pyometra (chronic endometritis)**: Dinoprost 25 mg IM. Dose may be administered SC if using high-concentration dinoprost product.

g) **Abortifacient for feedlot and other nonlactating cattle during the first 100 days of gestation**: Dinoprost 25 mg IM. Cattle that abort will do so within 35 days of injection.[2] Dose may be administered SC if using high-concentration dinoprost product.

Induce parturition (extra-label): 25 – 30 mg IM; delivery will occur in ≈72 hours.[20]

Increase fertility during artificial insemination (extra-label): 10 mg IM given concurrently with timed artificial insemination significantly increased the conception rate in lactating dairy cows in a study.[21]

Cystic ovarian disease in dairy cows (extra-label): 25 mg IM. The response to dinoprost was greater in cows with luteal cysts than in those with follicular cysts.[22]

SWINE:

Parturition induction in swine when injected within 3 days of normal predicted farrowing (label dose; FDA approved): 10 mg (2 mL) IM[2]

Management considerations: The product must be administered at a relatively specific time (there is an increased chance of piglet mortality if treatment is given earlier than 3 days prior to normal predicted farrowing). It is important that adequate records be maintained on (1) the average length of gestation period for the animals on a specific location and (2) the breeding and projected farrowing dates for each animal.

Parturition induction in swine (extra-label): 5 mg IM injected into the vulva-cutaneous junction, with a second dose administered 6 hours after the first dose, will result in most sows farrowing during the next working day.[23]

Estrus synchronization (grouping) (extra-label): At gestation day 15 to 55, give dinoprost 15 mg IM followed by dinoprost 10 mg IM 12 hours later. Animals will abort and return to estrus in 4 to 5 days. Close observation of estrus over several days is needed.[24]

SHEEP/GOATS:

Estrus synchronization in cycling ewes and does (extra-label):

a) **Ewes**: Dinoprost 8 mg IM on day 5 of the estrous cycle, and repeat in 11 days. Estrus will begin ≈2 days after the last injection.

b) **Does**: Dinoprost 8 mg IM on day 4 of the estrous cycle, and repeat in 11 days. Estrus will begin ≈2 days after the last injection.[24]

Pseudopregnancy (hydrometra, mucometra) in goats (extra-label): dinoprost 5 mg IM once[25]

Abortifacient (extra-label):

a) **Does**: Dinoprost 5 – 10 mg IM once; effective throughout the entire pregnancy; abortion takes place in 4 to 5 days.

b) **Ewes**: Dinoprost 10 – 15 mg IM once; effective during the first 2 months of pregnancy; abortion takes place within 72 hours.[20]

Induce parturition in does (extra-label): Dinoprost 2.5 – 20 mg on days 144 to 149. Higher dose (20 mg) yields a more predictable interval from injection to delivery (ie, ≈32 hours).[26]

Monitoring

- Adverse effects
- Abdominal ultrasound to confirm pregnancy and/or termination of pregnancy

Client Information

- Dinoprost should be used only by individuals familiar with its use and precautions.
- Pregnant women, people with asthma, or other persons with bronchial diseases should handle this product with extreme caution. Dinoprost may be absorbed through the skin; in the event of accidental exposure, wash the affected area immediately and contact a physician.

Chemistry/Synonyms

Dinoprost tromethamine, the tromethamine (THAM) salt of naturally occurring prostaglandin F2alpha, occurs as a white to off-white, very hygroscopic, crystalline powder with a melting point of ≈100°C (212°F). One gram is soluble in ≈5 mL of water. Dinoprost tromethamine 1.3 µg is equivalent to dinoprost 1 µg.

Dinoprost and dinoprost tromethamine may also be known as PGF(2alpha), prostaglandin F(2alpha), idinoprostum trometamoli, PGF(2-alpha) THAM, prostaglandin F(2-alpha) trometamol, U-14583E, U-14583, *Amtech Prostamate®*, *Dinolytic®*, *Enzaprost®*, *Glandin®*, *In-Synch®*, *Lutalyse®*, *Minprostin F(2)alpha®*, *Noroprost®*, *Oriprost®*, *Prostamate®*, *Prostarmon F®*, *Prostin®*, *Prostin F2®*, *Prostin F2 Alpha®*, or *Prostine F(2) Alpha®*.

Storage/Stability

Dinoprost for injection should be stored at room temperature (20°C-25°C [68°F-77°F]). Protect from freezing. Dinoprost is relatively insensitive to heat, light, and alkalis. Vials may be punctured no more than 20 times, and unused portions should be discarded 12 weeks after the first vial puncture.

Compatibility/Compounding Considerations

No specific information is noted. This drug should not be compounded by pregnant humans.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Dinoprost for Injection, equivalent to 5 mg/mL of dinoprost in 30 mL and 100 mL vials; *Lutalyse*®; (Rx). FDA-approved for use in beef and nonlactating dairy cattle, horses, and swine. No preslaughter withdrawal or milk withdrawal is required when used as labeled; no specific tolerance for dinoprost residues has been published. Dinoprost is not for use in horses intended for food. NADA #108-901

Dinoprost for Injection, equivalent to 12.5 mg/mL of dinoprost in 20 mL, 100 mL, and 250 mL vials; *Lutalyse® HighCon*; (Rx). For use in cattle only; no preslaughter withdrawal or milk withdrawal is required when used as labeled. NADA #141-442

HUMAN-LABELED PRODUCTS: NONE

Diphenhydramine

(dye-fen-***hye***-dra-meen) *Benadryl*®

First-Generation Antihistamine

Prescriber Highlights

- ► Antihistamine that is used primarily for its antihistaminic effects, but it also has additional indications (eg, motion sickness prevention, sedative, antiemetic)
- ► Should be used with caution in patients with angle-closure glaucoma, GI or urinary obstruction, chronic obstructive pulmonary disease, hyperthyroidism, seizure disorders, cardiovascular disease, and/or hypertension. In humans, diphenhydramine may mask ototoxicity signs.
- ► Adverse effects can include CNS depression and anticholinergic effects. GI effects (eg, diarrhea, vomiting, anorexia) are less common.
- ► Its use in neonates should be avoided.

Uses/Indications

Diphenhydramine is used primarily for its antihistaminic effects. In dogs and cats, diphenhydramine may be used to manage allergic and pruritic conditions, including urticaria, angioedema, and insect bite hypersensitivity. There is no conclusive evidence regarding the efficacy of oral, first-generation antihistamines in the treatment of chronic and acute flares of canine atopic dermatitis, with only highly variable therapeutic efficacy reported anecdotally.[1,2] Additionally, a randomized, double-blind crossover study found that diphenhydramine did not have an inhibitory effect on cutaneous allergic reactions in dogs.[3]

Diphenhydramine may be more effective in mildly pruritic animals and in preventing flares rather than treating them after clinical signs have occurred.[2] It has also been used as a steroid-sparing agent and with essential fatty acids to improve potential efficacy; however, no difference in measured outcomes was observed between dogs treated with diphenhydramine alone versus those treated with glucocorticoid and diphenhydramine in a population of dogs with uncomplicated allergic reactions.[4]

Diphenhydramine may also be used as adjunctive therapy for mast cell tumors to help prevent the local effects of histamine release from mast cells during surgical excision of mast cell tumors. However, diphenhydramine had no clear clinical cardiorespiratory benefits as compared with a placebo in isoflurane-anesthetized dogs undergoing mast cell tumor excision.[5]

This drug has also been used in the treatment and prevention of motion sickness and as an antiemetic in small animals.[6] Diphenhydramine was not effective in preventing motion-induced emesis in cats,[6] and NK_1 antagonists (eg, maropitant) or M_1-cholinergic antagonists (eg, prochlorperazine, chlorpromazine) may be better choices in the treatment of motion sickness or vomiting in this species. Diphenhydramine did not offer significantly different sedative effects as compared with a saline placebo when used as a sole sedative at single IM doses in healthy dogs,[7] although sedation may be observed in dogs when diphenhydramine is administered orally.

Pharmacology/Actions

Diphenhydramine has antihistaminergic (H1), antiemetic, anticholinergic, CNS depressant, and local anesthetic effects. Diphenhydramine did not suppress wheal response after intradermal histamine administration.[3,8] In one study, diphenhydramine was shown to have more potent growth-inhibitory effects in primary neoplastic mast cell tumors when compared to other H1-receptor antagonists.[9]

Pharmacokinetics

In a study of dogs, diphenhydramine had low oral bioavailability (2.8% to 7.8%),[8,10] whereas bioavailability after IM administration was 88%.[11] IV and IM administration in dogs rapidly resulted in plasma concentrations that exceeded therapeutic concentrations in humans. In dogs, the volume of distribution after a single IV dose was 7.6 L/kg, and the terminal half-life was 4.2 hours.[11] Terminal half-lives after oral and IM administration were 5 hours[8] and 6.8 hours,[11] respectively. In another study, oral absorption of diphenhydramine in healthy dogs was ≈3 times greater, with a longer half-life, when administered as the combination product, dimenhydrinate (*Dramamine*®, a combination of diphenhydramine with 8-chlorotheophylline). Mean oral bioavailability of diphenhydramine and dimenhydrinate was 7.8% and 22%, respectively, whereas mean peak plasma concentrations were 36 (±20) ng/mL and 124 (±46) ng/mL, respectively. Terminal elimination half-lives of diphenhydramine and dimenhydrinate were 5 (±7.1) hours and 11.6 (±17.7) hours, respectively.[8] One dog in this study was considered an outlier, with oral diphenhydramine bioavailability 9 times higher than other dogs, peak plasma concentration 5.5 times higher than other dogs, and an elimination half-life of 288 hours.[8]

In horses that received diphenhydramine 0.625 mg/kg IV, the volume of distribution (steady-state) was 6 L/kg, and the elimination half-life was 6.1 hours.[12]

In humans, diphenhydramine is well absorbed after oral administration, but due to a relatively high first-pass effect, only ≈40% to 60% reaches systemic circulation. The volume of distribution is 14 to 22 L/kg. Diphenhydramine is ≈80% bound to plasma proteins. Diphenhydramine is metabolized in the liver, and most of the drug is excreted as metabolites in urine. Terminal elimination half-life in adult humans ranges from 2.4 to 9.3 hours.

Contraindications/Precautions/Warnings

Diphenhydramine is contraindicated in patients that are hypersensitive to it or other antihistamines in its class. Because of their anticholinergic activity, antihistamines should be used with caution in patients with angle-closure glaucoma, prostatic hypertrophy, pyloroduodenal or bladder neck obstruction, and asthma or chronic obstructive pulmonary disease if mucosal secretions are a problem. In addition, antihistamines should be used with caution in patients with hyperthyroidism, cardiovascular disease, seizure disorders, or hypertension. In humans, it has been shown that diphenhydramine may also mask the clinical signs of ototoxicity (eg, head tilt, hearing loss, ataxia) and should therefore be used with caution when concomitantly administering ototoxic drugs.

The sedative effects of antihistamines may adversely affect the performance of working dogs.

In humans, pediatric patients are more susceptible to the adverse CNS effects of antihistamines, including paradoxical CNS excitation (eg, hallucinations, seizures); antihistamines are contraindicated in neonates.

DiphenhydrAMINE should not be confused with dimenhyDRINATE.

Adverse Effects

The most common adverse effects are CNS depression (eg, lethargy, sedation) and anticholinergic effects (eg, constipation, dry mouth, urinary retention). The sedative effects of antihistamines may be dose-dependent and diminish with chronic administration. GI effects (eg, diarrhea, vomiting, anorexia) are also possible. Oral diphenhydramine had no effect on tear production or intraocular pressure in healthy dogs.[13,14]

Diphenhydramine may cause paradoxical excitement or agitation, particularly in cats.

Liquid formulations are unpalatable, may contain alcohol, and may not be easily administered. SC injections may cause local necrosis.

Reproductive/Nursing Safety

Diphenhydramine crosses the placenta. No evidence of impaired fertility, reproductive performance, or fetal harm has been noted in rats or rabbits.

Diphenhydramine is excreted in milk. Use is contraindicated in breastfeeding women, particularly those feeding neonates and/or premature infants.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Reported LD_{50} in rats following IV, SC, and PO dosing was 35 mg/kg,[15] 201 mg/kg,[16] and 500 mg/kg,[17] respectively.

Overdose with diphenhydramine can cause CNS stimulation (eg, excitement, seizures) or depression (eg, lethargy, coma), anticholinergic effects, cardiovascular abnormalities, respiratory depression, and death. Treatment consists of GI decontamination, including induction of emesis if the patient is alert and CNS status is stable. Administration of saline cathartic and/or activated charcoal may be given after emesis or gastric lavage. Other clinical signs should be treated using supportive therapies.

Of 621 dogs with diphenhydramine toxicosis reported between 2008 and 2013, 146 developed clinical signs (eg, lethargy, hyperactivity, agitation, hyperthermia, ataxia, tremors, fasciculations, tachycardia), and 3 dogs died.[18] Supportive treatment based on clinical signs has been suggested.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving diphenhydramine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetylcholinesterase Inhibitors** (eg, **neostigmine, pyridostigmine**): Diphenhydramine may reduce the efficacy of acetylcholinesterase inhibitors.
- **Anticholinergic Drugs** (eg, **atropine, glycopyrrolate**): Diphenhydramine may potentiate anticholinergic effects.
- **CNS Depressant Agents** (eg, **anesthetics [inhalant and injectable], barbiturates, benzodiazepines, opioids**): Increased CNS depression can occur. Consider lower initial doses of CNS depressants.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): MAOIs may potentiate anticholinergic effects.
- **Potassium Supplements**: Diphenhydramine's anticholinergic effects may reduce GI motility, increasing the risk for focal upper GI injury from solid oral potassium formulations (ie, tablets, capsules).
- **Prokinetic Agents** (eg, **cisapride, metoclopramide**): Diphenhydramine may diminish the therapeutic effect of prokinetic agents.
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): TCAs may potentiate anticholinergic effects.

Laboratory Considerations

- **Intradermal allergy testing (IDT)**: Although antihistamines may suppress IDT results,[19] diphenhydramine did not demonstrate an effect on wheal formation in dogs despite reaching a plasma diphenhydramine concentration believed to be therapeutic in humans.[3] A 7-day withdrawal prior to IDT is considered optimal; a 2-day withdrawal should be considered the minimum.[19]
- Diphenhydramine may cause false-positive screening results for **TCAs** (serum) and **methadone** (urine).

Dosages

DOGS/CATS:

Antihistamine (eg, adjunctive treatment of allergic pruritus or reactions, including angioedema, urticaria, insect bite hypersensitivity, and atopic dermatitis, in addition to anaphylaxis, mast cell tumors, vaccine or transfusion reactions; extra-label):

a) 2 – 4 mg/kg PO every 8 to 12 hours
b) 0.5 – 2 mg/kg IM, SC, or IV. **NOTE**: In humans, it is recommended to avoid the SC route due to risk for tissue necrosis, and IV administration should occur at a rate not exceeding 25 mg/minute with undiluted diphenhydramine or as an infusion over 10 to 15 minutes. Relevance in veterinary patients is not known.

Prevention of motion sickness/antiemetic (extra-label): 2 – 4 mg/kg PO or IM every 8 hours. Usually not very effective in cats

HORSES:

Antihistamine (extra-label):

a) 1 – 2 mg/kg PO every 8 to 12 hours
b) 0.5 – 1 mg/kg IV or IM every 6 to 8 hours[20]

CATTLE:

a) **Adjunctive therapy for anaphylaxis** (extra-label): 0.5 – 1 mg/kg IM or IV[20]; used in combination with epinephrine and glucocorticoids[21]
b) **Adjunctive therapy for aseptic laminitis during the acute phase** (extra-label): 0.55 – 1.1 mg/kg IV or IM every 6 to 8 hours[20] in combination with corticosteroids[22]

BIRDS:

Adjunctive treatment of pruritus causing feather picking in psittacines (extra-label): 2 mg/kg PO every 12 hours[23]

FERRETS:

Prevaccination (extra-label): 2 mg/kg PO, IM, or IV 10 minutes before vaccination[24]

Pretreatment before doxorubicin (extra-label): 5 mg/ferret (NOT mg/kg) IM

RABBITS/RODENTS/SMALL MAMMALS:

Guinea pigs (extra-label): 7.5 mg/kg PO[25]

Rabbits (extra-label): 1 – 2 mg/kg PO every 12 hours as an antihistamine.[26,27] 2 mg/kg IV before blood transfusion[28]

Monitoring

- Clinical efficacy (trial periods to determine an individual antihistamine's efficacy are usually 1 to 2 weeks long)
- Adverse effects (eg, lethargy, sedation, constipation, urinary retention, vomiting, diarrhea, anorexia)

Client Information

- Use antihistamines on a regular, ongoing basis in animals that respond to them. They work better if used before exposure to an allergen or an allergy flare-up.
- When used for motion sickness, it is best to give this medicine at least 30 to 60 minutes prior to travel.
- May cause drowsiness/sleepiness. This effect may lessen with long-term use.
- Rarely, cats may become excited when given this medication.
- Discontinue medication in animals that develop severe drowsiness or agitation.
- Discuss with your veterinarian if your animal becomes constipated, has difficulty urinating, or develops redness or discharge from the eyes.
- Use caution with over-the-counter formulations of this medicine, as other potentially toxic ingredients may be combined in the products (eg, decongestants, such as pseudoephedrine or acetaminophen). Be sure the product used only contains diphenhydramine as the active ingredient. Alcohol-free formulations may be more palatable.
- This medicine can be given either with or without food, but if an animal vomits or drools after receiving the medication on an empty stomach, try giving it with food. If vomiting continues, contact your veterinarian.

Chemistry/Synonyms

Diphenhydramine HCl, an ethanolamine-derivative antihistamine, occurs as an odorless white crystalline powder that slowly darkens when exposed to light. It has a melting range between 167°C and 172°C (332.6°F and 341.6°F). One gram is soluble in ≈1 mL of water or 2 mL of alcohol. Diphenhydramine HCl has a pK_a of ≈9; the pH of the commercially available injection is adjusted to 5 to 6.

Diphenhydramine HCl may also be known as chloranautine, dimenhydrinatum, diphenhydramine teoclate, and diphenhydramine theoclate; many trade names exist.

Storage/Stability

Store the preparations containing diphenhydramine away from light at room temperature 20°C to 25°C (68°F to 77°F); protect solutions from freezing. Keep tablets, oral solutions, capsules, and elixir in airtight containers.

Compatibility/Compounding Considerations

Compatibility is dependent on factors, such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Diphenhydramine for injection is reportedly physically **compatible** with all commonly used IV solutions and the following drugs: amikacin sulfate, ascorbic acid injection, atropine sulfate, buprenorphine HCl, butorphanol tartrate, calcium gluconate, ciprofloxacin, clindamycin phosphate, cyclosporine, dobutamine HCl, erythromycin lactobionate, famotidine, fentanyl citrate, glycopyrrolate, hydromorphone HCl, hydroxyzine HCl, iothalamate meglumine/sodium, ketamine HCl, lidocaine HCl, meperidine HCl, metoclopramide, midazolam HCl, morphine sulfate, ondansetron HCl, penicillin G potassium/sodium, piperacillin/tazobactam, potassium chloride, propofol, ranitidine, tetracycline HCl, and vitamin B complex with vitamin C.

Diphenhydramine is reportedly physically **incompatible** with the following drugs: amphotericin B, ampicillin sodium, most cephalosporins, dexamethasone sodium phosphate, diazepam, furosemide, hydrocortisone sodium succinate, insulin (regular), nitroprusside sodium, pantoprazole, phenobarbital sodium, and pentobarbital sodium.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: Diphenhydramine tablets labeled for veterinary use have not been found by FDA to be safe or effective.

Diphenhydramine HCl Chewable Tablets (liver-flavored): 10 mg and 30 mg; *Vetadryl*®; (OTC).

Diphenhydramine HCl Tablets: 25 mg; generic; (OTC).

Diphenhydramine HCl Capsules: 25 mg; *Calmatrol*®; (OTC).

Various topical formulations containing diphenhydramine are available. See ***Diphenhydramine, Topical*** for more information.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

The International Federation for Equestrian Sports (FEI) lists this drug as a *prohibited substance – controlled medication*.[29]

For guidance in determining the use and associated withdrawal times, contact FARAD (see ***Important Contact Information*** in ***Appendix***).

HUMAN-LABELED PRODUCTS:

NOTE: ONLY products containing diphenhydramine as a single agent should be used in veterinary species.

Diphenhydramine Capsules and Tablets: 12.5 mg (as hydrochloride, chewable), 25 mg (as either hydrochloride or tannate, chewable), and 50 mg (as hydrochloride). There are many trade name products that contain diphenhydramine. *Benadryl*®, *Banophen*®, and *Diphenhist*® are commonly seen; generic; (OTC, Rx).

Diphenhydramine Orally Disintegrating Tablets: 12.5 mg and 25 mg; *Benadryl*®, *Unisom Sleep*®, generic; (OTC)

Diphenhydramine Orally Disintegrating Strips: 12.5 mg (as hydrochloride); *Triaminic*® *Children's Allergy*; (OTC)

Diphenhydramine Oral Liquid, Solution, Suspension, Elixir, or Syrup: 12.5 mg/5 mL (as hydrochloride) in 30 mL, 118 mL, 120 mL, 236 mL, 237 mL, 473 mL, and 3.8 L; 31.25 mg/5 mL (as HCl); 25 mg/5 mL (as tannate) in 118 mL. There are many trade name products, including *Benadryl*®, *Diphenhist*®, *Banophen*®, *Hydramine Cough* (various), generic; (OTC, Rx). Some products may contain alcohol; consult the label before prescribing.

Diphenhydramine Injection: 50 mg/mL (as hydrochloride); generic; (Rx)

Topical creams, gels, solutions, and sprays are also available.

Diphenoxylate/Atropine

(dye-fen-***ox***-i-late/***at***-roe-peen) *Lomotil®*

Opioid Agonist/Anticholinergic

Prescriber Highlights

- ► Opioid GI motility modifier with antitussive properties that is used primarily in dogs
- ► Contraindications include known hypersensitivity to opioids, partial or complete biliary obstruction, diarrhea caused by an infectious agent or toxic ingestion, and intestinal obstruction.
- ► Use with caution in patients with respiratory disease, CNS depression, uncontrolled hypothyroidism (myxedema), renal insufficiency, Addisonian crisis, and acute GI conditions; use in patients with acute abdominal conditions (eg, hemoabdomen, splenic torsion) may obscure the diagnosis or worsen the clinical course.
- ► Adverse effects include constipation, bloating, and sedation; cats may exhibit excitable behaviors. Potential for paralytic ileus, toxic megacolon, pancreatitis, and CNS depression
- ► Drug interactions possible with other CNS depressants. Avoid concurrent use with monoamine oxidase inhibitors.
- ► DEA Schedule V (C-V) controlled substance

Uses/Indications

Diphenoxylate is an opioid that is commercially available in a fixed-dose combination with atropine. It is used primarily in dogs for its antidiarrheal and antitussive properties. Diphenoxylate/atropine may also be used for medical management in dogs with tracheal collapse.[1,2]

Many clinicians do not recommend using this drug in cats.[3]

Pharmacology/Actions

Among other effects, opioids inhibit GI motility and propulsion. They decrease intestinal secretions induced by cholera toxin and prostaglandin E_2 and alleviate diarrhea caused by factors in which calcium is the second messenger (noncyclic AMP/GMP mediated). Opioids may also enhance intestinal mucosal absorption.

In dogs, diphenoxylate directly affects the smooth muscle in the GI tract by enhancing segmentation contractions and results in prolongation of GI transit time.[4]

Atropine is present in drug formulations in subtherapeutic amounts to deter human abuse of diphenoxylate for its narcotic effects. Atropine is not expected to have a clinical effect at therapeutic diphenoxylate doses.

Pharmacokinetics

In dogs, ≈72% of an oral dose is eliminated in the feces within 5 days of administration.[5] No other pharmacokinetic information in veterinary species was located.

In humans, diphenoxylate is rapidly absorbed after administration of either the tablets or oral solution; bioavailability of the tablets is ≈90% of the solution's bioavailability. Generally, onset of action occurs within 45 to 60 minutes after administration and is sustained for 3 to 4 hours. Diphenoxylate is metabolized into diphenoxylic acid, an active metabolite. The serum half-lives of diphenoxylate and diphenoxylic acid are ≈2.5 hours and 4 to 14 hours, respectively.[4,6]

Contraindications/Precautions/Warnings

Opioid antidiarrheals are contraindicated in patients who are hypersensitive to narcotic analgesics, with partial or complete biliary obstruction, intestinal obstruction, and with diarrhea caused by an infectious agent or toxic ingestion.

Opioid antidiarrheals should be used with extreme caution in patients with respiratory disease or acute respiratory dysfunction (eg, pulmonary edema secondary to smoke inhalation) and in patients with conditions that cause CNS depression (eg, traumatic head injuries, hepatic encephalopathy, increased intracranial pressure) as this may exacerbate CNS depression to the point of coma or death. All opioids should be used with caution in patients with renal insufficiency, uncontrolled hypothyroidism (myxedema), Addisonian crisis, and in debilitated patients.

Use of opioid antidiarrheals in patients with acute abdominal conditions (eg, hemoabdomen, splenic torsion) may obscure the diagnosis or worsen the clinical course of these conditions.

Many clinicians recommend not using diphenoxylate or loperamide in dogs weighing less than 10 kg (22 lb), but this is likely a result of the potency of the tablet or capsule forms and the resultant difficulty in accurately dosing the medication. Dosage titration using the liquid forms may allow safer, more accurate dosing in small dogs when indicated.

Adverse Effects

In dogs, constipation, bloat, and sedation are the most likely adverse effects encountered when recommended dosages are used; paralytic ileus, toxic megacolon, vomiting, pancreatitis, and CNS depression (ie, sedation) may also be seen. Constipation can be managed with dietary changes, stool softeners, or laxatives.[2] Reduced GI motility may delay or prolong nutrient absorption.

Because opioids prolong GI transit time, use in animals with acute infectious diarrhea may contribute to bacterial overgrowth and delay expulsion of the pathogen and/or enterotoxins from the GI tract, thus increasing the risk for sepsis and/or prolonged recovery.

Use of antidiarrheal opioids in cats is controversial; this species may react with excitatory behavior.

Reproductive/Nursing Safety

Safety of diphenoxylate/atropine has not been clearly established in pregnant animals. Reduced maternal weight gain and fertility in rats were noted at 20 mg/kg/day.[4] Teratogenic effects were not noted in laboratory animals given oral doses of 0.4 – 20 mg/kg/day.

Diphenoxylic acid may be, and atropine is, excreted in maternal milk. Exercise caution when administering diphenoxylate/atropine to nursing animals.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute overdose of opioid antidiarrheals could result in CNS, cardiovascular, GI, or respiratory toxicity. GI decontamination and supportive therapy should be employed with recent ingestions. Naloxone may reverse the opioid effects.

Massive overdoses of diphenoxylate/atropine sulfate may induce atropine toxicity. Refer to ***Atropine*** for more information.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving opioid antidiarrheals and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Anticholinergic Agents** (eg, **glycopyrrolate, oxybutynin**): Additive anticholinergic effects (eg, dry mucous membranes, tachycardia, constipation, urinary retention) may occur.
- ■ **Antihistamine H1 Receptor Antagonists, First Generation** (eg, **chlorpheniramine, diphenhydramine**): Concurrent use may increase risk of CNS depression and have additive anticholinergic effects.

- **CNS Depressant Drugs** (eg, **anesthetic agents, barbiturates, cannabidiol**): Concurrent use may cause increased CNS or respiratory depression when used with opioid antidiarrheal agents.
- **Digoxin**: Concurrent use may result in increased serum digoxin concentrations.
- **Laxatives** (eg, **oral magnesium salts, polyethylene glycol 3350**): Concurrent use may decrease efficacy of diphenoxylate.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, methylene blue**, **selegiline**): Opioid antidiarrheal agents are contraindicated in human patients receiving systemic MAOIs for at least 14 days after receiving MAOIs because of an increased risk of a hypertensive crisis.
- **Opioids** (eg, **buprenorphine, morphine, tramadol**): Therapeutic duplication. Concurrent use may increase risk of CNS or respiratory depression and have additive anticholinergic effects.
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**): Concurrent use may increase risk of CNS depression and have additive anticholinergic effects.
- **Potassium Salts, Oral**: Reduced GI motility may increase the risk for GI irritation and ulceration caused by potassium salts. The use of solid oral forms of potassium concurrently with drugs that decrease GI motility is contraindicated in humans; consider use of liquid/gel potassium formulations.
- **Prokinetic Agents** (eg, **cisapride, erythromycin, metoclopramide**): Concurrent use may result in decreased efficacy of both agents.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): Concurrent use may increase risk of CNS depression and have additive anticholinergic effects.

Laboratory Considerations

- Opioids may increase biliary tract pressure, resulting in increased plasma **amylase** and **lipase** values up to 24 hours following their administration.

Dosages

DOGS:

Antidiarrheal agent (extra-label): Dosage is based on the diphenoxylate component:

a) 0.05 – 0.1 mg/kg PO 3 to 4 times daily [7–9]

b) 0.1 – 0.2 mg/kg PO every 12 hours

Antitussive agent (extra-label): 0.2 – 0.5 mg/kg PO every 8 to 12 hours[2]

CATS:

Antidiarrheal agent (extra-label): 0.08 – 0.1 mg/kg PO every 12 hours[10]; **NOTE**: Not usually recommended for cats.

Monitoring

- Clinical efficacy: as antidiarrheal, decrease in volume and frequency of diarrhea; for tracheal collapse, improved cough suppression
- Monitor hydration and serum electrolytes in patients with severe diarrhea
- Adverse effects: respiratory and CNS depression, constipation, vomiting

Client Information

- This medicine may be used to treat diarrhea or as a cough suppressant.
- May be given with or without food. If your animal vomits or acts sick after receiving the drug on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Constipation and sleepiness are the most common side effects in dogs.
- Must use cautiously in cats as they can get overly excited
- This medicine is a controlled drug in the United States. It is against federal law to use, give away, or sell this medication to others than for whom it was prescribed.
- Contact your veterinarian if diarrhea does not improve or if your animal appears listless.

Chemistry/Synonyms

Structurally related to meperidine, diphenoxylate HCl is a synthetic phenylpiperidine-derivative opioid agonist. It occurs as an odorless, white, crystalline powder that is slightly soluble in water and sparingly soluble in alcohol. Commercially available preparations also contain a small amount of atropine sulfate as a bittering agent to discourage abuse of diphenoxylate for its narcotic effects; at therapeutic doses, the atropine component has no clinical effect in humans.

This combination may be known as co-phenotrope in the United Kingdom and elsewhere. Other synonyms include R 1132, NIH 7562, or difenoxilato. A commonly used trade name is *Lomotil*®.

Compatibility/Compounding Considerations

No specific information is noted.

Storage/Stability

Diphenoxylate/atropine tablets should be stored at room temperature of 20°C to 25°C (68°F-77°F). Diphenoxylate/atropine oral solution should be stored at room temperature of 20°C to 25°C (68°F-77°F); avoid freezing.

Follow applicable local, state, and federal rules regarding controlled drug storage, waste, and disposal.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Diphenoxylate HCl and Atropine Sulfate Tablets: Diphenoxylate 2.5 mg and Atropine 0.025 mg; *Lomotil*®, generic; (Rx, C-V)

Diphenoxylate HCl and Atropine Sulfate Liquid: Diphenoxylate 2.5 mg and Atropine Sulfate 0.025 mg per 5 mL; *Lomotil*®, generic; (Rx, C-V)

Report prescribing and/or dispensing to state monitoring programs where required.

Dipyrone
Metamizole

(***dye***-purr-own) *Zimeta*®

Nonsteroidal Anti-Inflammatory Drug (NSAID)

Prescriber Highlights

- ► Approved for short-term (up to 3 days) control of pyrexia in horses
- ► Not approved for use in food-producing animals in the United States
- ► May also be useful for analgesia in dogs and cats
- ► Use with caution in horses at risk for hemorrhage or those receiving nephrotoxic drugs (eg, aminoglycosides).
- ► Do not administer concurrently with other NSAIDs or with corticosteroids.
- ► Adverse effects include increased serum sorbitol dehydrogenase, hypoalbuminemia, and gastric ulcers. Prolongation of coagulation parameters (eg, PT, aPTT) may occur.

Uses/Indications

Dipyrone injection is indicated for the control of pyrexia in horses.

The drug was deemed effective (decrease of rectal temperature by more than 1.1°C [2°F] or return to normothermia by 6 hours after drug administration) in ≈75% of treated horses.[1]

Historically, dipyrone was FDA-approved for use in humans but was withdrawn from the market in 1977 due to reports of agranulocytosis. Dipyrone had been used in a variety of veterinary species as an analgesic, antipyretic, and muscle relaxant. An unapproved dipyrone product continued to be sold for equine use until 1996 when the FDA removed the product due to concerns of use in food-producing animals. Veterinary use of compounded dipyrone formulations increased after its withdrawal. A commercially prepared formulation for use in horses is now available and is strongly recommended over use of a compounded product.

In countries outside the United States, dipyrone may be approved for use in other species as an analgesic and/or antipyretic. Dipyrone has demonstrated analgesic properties in dogs.[2–5] In cats, dipyrone may be useful for postoperative analgesia[6] but efficacy is unclear.[7]

Pharmacology/Actions

Dipyrone is an NSAID. It is a prodrug that is rapidly hydrolyzed to the active compound 4-methylaminoantipyrine (4-MAA).[8]

Dipyrone is thought to inhibit peripheral cyclooxygenase COX-1 and COX-2 mediated production of prostaglandins. Dipyrone also inhibits cyclooxygenase (COX-3) within the CNS[9] and may have agonist activity on cannabinoid and opioid systems. In addition to its antipyretic effects, the drug has analgesic and weak anti-inflammatory properties. It may also have antispasmodic activity on bradykinin-induced spasms on the intestinal tract without appreciably altering spontaneous intestinal motility.[10–12]

Dipyrone inhibits platelet aggregation in dogs.[13] In horses, it prolongs coagulation parameters (eg, PT, aPTT) at higher doses.[8]

Pharmacokinetics

Dipyrone circulates only briefly before rapid hydrolysis into the active primary metabolite 4-methylaminoantipyrine (4-MAA). In humans, 4-MAA is hepatically metabolized to 4-aminoantypyrine (4-AA) and other inactive end metabolites that are renally excreted.[8] 4-MAA and 4-AA are both considered active metabolites in humans and therefore pharmacokinetic studies focus primarily on 4-MAA and 4-AA. In veterinary species, it is unknown if 4-AA contributes to analgesic activity as plasma concentrations are very low compared with 4-MAA.[14,15]

In healthy dogs, peak 4-MAA concentration occurs ≈2 hours after oral dosing and ≈0.6 hours after IM injection. Volume of distribution is ≈5 to 7.5 L/kg, clearance is 552 to 921 mL/kg/hour, and elimination half-life is ≈6 hours. Plasma 4-MAA concentrations remain at or above human inhibitory concentrations (IC50) for COX-1 and COX-2 enzymes for ≈12 and 8 hours, respectively.[15,16] Rectal administration produces low levels of 4-MAA and is likely the least effective route in dogs.[15]

In healthy cats, oral absorption is high with maximum concentrations achieved ≈6 hours after dosing. Volume of distribution is ≈1 to 1.4 L/kg, clearance is ≈92 to 131 mL/kg/hour, and half-life is ≈6 to 7 hours. Low absorption was seen after IM administration compared to both IV and PO routes.[17]

In healthy horses receiving dipyrone, 4-MAA elimination half-life is reported as 3 to 5 hours and clearance is 230 to 285 mL/kg/hour.[14,18] 4-MAA has a large volume of distribution (1 to 1.9 L/kg), moderate protein binding (low compared with other NSAIDs), and readily penetrates into the CNS.[10] When dipyrone was given IM, time to peak concentration was ≈1.2 hours and the maximum concentration was lower than when given IV, but otherwise the pharmacokinetic profiles were similar between routes.[14] When dipyrone was given to horses at the labeled dose every 12 hours, minimal accumulation was seen after 9 days. However, higher doses and more frequent dosing did result in drug accumulation and increases in trough concentrations and AUC that were not proportional to increases in dose alone, which suggests the possibility of nonlinear pharmacokinetics at higher doses.[19]

In healthy donkeys, 4-MAA volume of distribution is 0.5 to 0.8 L/kg, clearance is 160 to 300 mL/kg/hour, and elimination half-life is ≈1.9 hours.[20]

Contraindications/Precautions/Warnings

Dipyrone is contraindicated in patients that are hypersensitive to it. Safe use in horses younger than 3 years has not been evaluated.[8] Due to the potential for prolongation of PT, dipyrone should not be given more frequently than every 12 hours.[8]

The drug should be used with caution in horses at risk for hemorrhage and those that are dehydrated, receiving diuretics, or with preexisting renal, cardiac, or hepatic dysfunction. Use with caution in animals with a history of or current hematologic or bone marrow abnormalities.

In humans, a significant decrease in clearance was seen in patients with liver cirrhosis. In humans with renal impairment, elimination of end metabolites was impaired, but 4-MAA clearance was not significantly altered.[21] It is unclear how this translates to veterinary species, but dipyrone should be used with caution in animals with renal or hepatic dysfunction.

Do not use dipyrone in horses intended for human consumption or in any food-producing animal.[8]

Due to risk for agranulocytosis in humans, those preparing or administering the drug should avoid direct contact with skin or accidental injection.[8]

Do not confuse meTAMizole with meTHIMazole. Do not confuse ZImeta (dipyrone) with ZOmeta (zoledronic acid).

Adverse Effects

Adverse effects associated with administration of dipyrone to horses during an FDA field study were elevated serum sorbitol dehydrogenase (SDH; an acute marker of hepatocellular injury) (5%), hypoalbuminemia (3%), and gastric ulcers (2%).[8] In addition, one of each of the following occurred in different horses: hyperemic mucosa right dorsal colon, prolonged aPTT, elevated creatinine, injection site reaction, and anorexia. Bloody nasal discharge and death occurred in one horse during a safety study. Clinical signs associated with NSAID intolerance may include colic, diarrhea, and decreased appetite.[8]

Reported adverse effects in dogs and cats include vomiting and salivation.[15,17] In dogs, dipyrone has been shown to inhibit platelet aggregation.[22]

Experience in EU countries suggests the drug is well tolerated in horses at approved dosages.[23] Historically, the occurrence of agranulocytosis and leukopenia was associated with high doses and prolonged treatment.

In humans, dipyrone seems to have a lower risk for GI bleeding as compared with other NSAIDs such as piroxicam and aspirin.[24]

Reproductive/Nursing Safety

Safe use in horses used for breeding, or in pregnant or lactating horses has not been evaluated. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Decreased pup survival was observed in rats treated with 250 – 625 mg/kg/day prior to and throughout pregnancy.[23]

Overdose/Acute Toxicity

Dipyrone 30 mg/kg given every 8 hours did not demonstrate an adequate margin of safety due to prolongation of PT and aPTT, clinical signs of coagulopathy, and hepatotoxicity (increased bilirubin and liver weight). In healthy horses receiving 60 mg/kg or 90 mg/kg IV 3

times daily, the following adverse effects were noted: cough, depression, tachypnea or dyspnea, epistaxis, nasal discharge, inappetence, loose manure, colic, and fever. PT was prolonged in both treatment groups and minimal or mild renal tubular dilation was noted; however, there were no clinical signs of renal dysfunction. Two horses receiving 90 mg/kg IV developed epistaxis and pneumonia, and one died.

Treatment of an overdose consists of supportive therapy based on clinical signs. Monitor for coagulopathy.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dipyrone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetaminophen**: Combined use may increase risk for hepatocellular injury.
- **Anticoagulants** (eg, **clopidogrel, heparins, rivaroxaban, warfarin**): Risk for bleeding may be increased.
- **Chloramphenicol**: Combined use may increase risk for myelosuppression.
- **Chlorpromazine**: Concurrent use may cause profound hypothermia.[25] Effect of other phenothiazines (eg, **acepromazine**) is uncertain.
- **Corticosteroids**: Concomitant use of dipyrone with corticosteroids should be avoided.[8]
- **Diuretics** (eg, **furosemide**): Concurrent use increases risk for adverse renal effects.
- **Naloxone**: May block antinociceptive effect of dipyrone
- **Nephrotoxic Drugs** (eg, **amphotericin B, aminoglycosides, cyclosporine, trimethoprim**): Concurrent use with nephrotoxic drugs should be avoided.[8]
- **NSAIDs** (eg, **flunixin, phenylbutazone**): Concomitant use of dipyrone with NSAIDs should be avoided.[8] Consider appropriate washout time when switching between NSAIDs. Concomitant administration of dipyrone and meloxicam resulted in more prolonged inhibition of platelet function than dipyrone alone[13]; however, this combination has been used clinically in dogs.[5]
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs**; eg, **fluoxetine**): Risk for bleeding may be increased.
- **Tricyclic Antidepressants** (**TCAs**, eg, **amitriptyline, clomipramine**): Risk for bleeding may be increased.

Laboratory Considerations

- None noted

Dosages

DOGS:

Analgesic (extra-label): 25 mg/kg IV prior to[2] or immediately following[4] surgery. The results of one study suggest that dipyrone should not be used as the sole analgesic in the perioperative period.[26]

CATS:

Analgesic (extra-label): 25 mg/kg IV every 24 hours and 12.5 mg/kg IV every 12 hours have been reported for postoperative analgesia.[6]

HORSES:

Control of pyrexia (label dosage; FDA-approved): 30 mg/kg IV once or twice daily (at 12-hour intervals) for up to 3 days. Under field conditions, pyrexia was controlled in most horses with once-daily treatment.[8]

Monitoring

- Body temperature
- Level of pain control
- Hydration status
- Baseline and periodic CBC and serum chemistry profile
- Adverse effects
- Signs of coagulopathy

Client Information

- The manufacturer's client information sheet should be provided to the person(s) treating the animal or providing care.
- Dipyrone can cause bone marrow suppression in humans. Avoid contact with skin. Immediately wash skin with soap and water in case of accidental contact. Seek medical care urgently in cases of self-injection.
  - Side effects include colic, decreased appetite, depression, and diarrhea. If serious side effects occur, discontinue treatment, and contact your veterinarian.
  - Check with your veterinarian before administering any other medications.
  - Overdoses can be very serious; measure liquid doses very carefully and keep out of reach of children or animals.

Chemistry/Synonyms

A pyrazolone derivative, dipyrone occurs as an odorless, bitter, white or yellowish-white crystalline powder. One gram of dipyrone is very soluble in water and soluble in alcohol. The commercial solution for injection is preserved with benzyl alcohol.

Dipyrone may also be known as metamizole sodium, dipyronium, methamizole, and methampyrone. Many trade names exist, including *Analate®*, *Analgin®*, *Myovin®*, *Novin®*, *Novalgin®*, *Vetalgin®*, and *Zimeta®*.

Storage/Stability

Store dipyrone injection protected from light, at controlled room temperature of 20°C to 25°C (68°F-77°F) with excursions permitted between 15°C to 30°C (59°F-86°F). Use multi-dose vial within 30 days of first puncture.

Compatibility/Compounding Considerations

Compounding of dipyrone is no longer necessary given the availability of an FDA-approved dipyrone formulation (as well as the availability of therapeutically equivalent drugs such as flunixin).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Dipyrone Injection: 500 mg/mL in 100 mL multi-dose vial; *Zimeta®*, (Rx). NADA #141-513. Not for use in horses intended for human consumption or in food-producing animals

The Association of Racing Commissioners International (ARCI) has designated dipyrone as a drug class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

In some countries, dipyrone may be found in combination with butylscopolamine (*Buscopan® Compositum* solution for injection).

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Dobutamine

(***doe***-byoo-ta-meen) *Dobutrex®*

Beta-Adrenergic Inotrope

Prescriber Highlights

- ► Parenteral, rapid-acting inotropic agent used in a variety of species to improve cardiac output
- ► Contraindications in humans (may not be applicable to animals) include patients with known hypersensitivity to the drug or to the preservative (sodium bisulfite); patients with idiopathic hypertrophic subaortic stenosis (IHSS).
- ► Use with caution in patients with pre-existing arrhythmias.
- ► Animals with atrial fibrillation should receive a digoxin preparation prior to dobutamine administration.
- ► Most common adverse effects include facial twitching (dogs), tachycardia; CNS effects (eg, tremors, seizures) may be seen in cats receiving higher doses.
- ► Dobutamine should be used in critical care settings with continuous monitoring of heart rate/rhythm and blood pressure.

Uses/Indications

Dobutamine is an injectable, rapid-onset positive inotropic agent for short-term adjunctive treatment (usually less than 72 hours) of congestive heart failure. It is also useful in shock patients when fluid therapy alone does not restore acceptable arterial blood pressure, cardiac output, or tissue perfusion. Dobutamine is also used to treat hypotension caused by decreased cardiac contractility in patients undergoing general anesthesia.

Dobutamine is administered as an IV CRI and should be used only in critical care settings where adequate monitoring (eg, continuous BP, ECG, cardiac output, pulmonary capillary wedge pressure) can be provided.

Pharmacology/Actions

Dobutamine is considered a direct beta-1-adrenergic agonist. At therapeutic doses, it also has mild beta-2- and alpha-1-adrenergic effects, which balance each other and cause little direct effect on the systemic vasculature. In contrast to dopamine, dobutamine does not cause the release of norepinephrine. Dobutamine has relatively mild chronotropic, arrhythmogenic, and vasodilative effects, but higher doses can cause tachycardia.

Increased myocardial contractility and stroke volumes result in increased cardiac output. However, increased myocardial contractility may increase myocardial oxygen demand and coronary blood flow. Blood pressure and heart rate generally are mildly increased because of increased cardiac output.

Pharmacokinetics

Because dobutamine is rapidly metabolized in the GI tract and is not systemically absorbed after oral administration, dobutamine is only administered intravenously as a constant rate infusion (CRI). After IV administration, the onset of action generally occurs within 2 minutes and peaks within 10 minutes.

Dobutamine is metabolized rapidly in the liver and other tissues and has a plasma half-life of ≈2 minutes in humans. The drug's effects diminish rapidly after cessation of therapy.

Pharmacokinetic data for domestic animals is unavailable.

Contraindications/Precautions/Warnings

Dobutamine is contraindicated in patients with known hypersensitivity to the drug or its preservative, sodium bisulfite, which has been documented to cause allergic-type reactions in humans. Dobutamine is also contraindicated in humans with idiopathic hypertrophic subaortic stenosis (IHSS).

Adequate vascular volume is required for dobutamine use; hypovolemic states must be corrected before use.

Use with extreme caution in patients with ventricular tachyarrhythmias or atrial fibrillation because dobutamine can enhance atrioventricular conduction. In animals with atrial fibrillation, digoxin (ie, digitalization) is recommended before dobutamine administration to slow AV nodal conduction. In horses that will receive electrocardioversion for atrial fibrillation, dobutamine should be stopped for at least 5 minutes before shock delivery.[1]

Do not confuse DOBUTamine with DOPamine. Writing part of the drug's name in upper case on prescriptions/orders may reduce the risk of errors.

Adverse Effects

Adverse effects reported in dogs include tachycardia, facial twitching, and seizures. Infusions greater than 20 µg/kg/minute IV may cause tachycardia. One published study has reported dobutamine-induced bradycardia.[2] Tachyphylaxis (a rapid decrease in drug response; increased dosages may be required to achieve the desired effect) may occur, and in dogs, can become apparent within 48 to 72 hours of starting dobutamine therapy.

In cats, doses greater than 5 µg/kg/minute may cause CNS effects such as tremors or seizures. In this species, dobutamine can be administered under general anesthesia but should be discontinued before recovery.

Dobutamine is a weaker proarrhythmic drug than most other catecholamines, and arrhythmias observed at 3 – 5 µg/kg/minute in horses are usually limited to bradyarrhythmias, second-degree atrioventricular blocks, premature atrial complexes, and isorhythmic atrioventricular dissociation. Use parasympatholytics (eg, atropine) with caution, as the risk for tachyarrhythmias[3] and ileus is increased.

In humans, the most commonly reported adverse effects are increased heart rate (5 to 15 bpm) and increased blood pressure (10 to 20 mm Hg). Ectopic beats, chest pain, and palpitations may also occur. At usual doses, these effects are generally mild and will not necessitate halting therapy; modify dose as clinically indicated. Other, less common, adverse effects reported include nausea, headache, hypotension, vomiting, hypokalemia, leg cramps, paresthesia, and dyspnea. Phlebitis and infusion-site reactions may occur.

Reproductive/Nursing Safety

Fetal toxicity was not demonstrated in rats or rabbits at doses used clinically. It is unknown if dobutamine crosses the placenta or enters maternal milk. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs reported with excessive doses include tachycardia, hypertension, nervousness, vomiting, fatigue, tremor, and seizures. Because of the drug's short duration of action, temporarily halting therapy usually reverses these effects. Tachyarrhythmias may be treated with propranolol or lidocaine.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to the ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dobutamine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Anticholinergics** (eg, **atropine; butylscopolamine, glycopy-**

rrolate): May increase the risk for tachyarrhythmias in horses; use with caution.

- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, metoprolol, propranolol**): May antagonize the cardiac effects of dobutamine and result in a preponderance of alpha-adrenergic effects and increased total peripheral resistance
- **Nitroprusside**: Synergistic effects (increased cardiac output and reduced wedge pressure) can result if dobutamine is used with nitroprusside.

Laboratory Considerations

- None

Dosages

NOTE: Dobutamine is administered as an IV CRI and should be used only in critical care settings where adequate monitoring (eg, continuous BP, ECG, cardiac output, pulmonary capillary wedge pressure) can be provided.

DOGS:

Short-term treatment of low cardiac output and acute congestive heart failure (**CHF**; extra-label): Dosages are usually started on the low end and titrated upward. Most recommendations fall in the 2 – 15 µg/kg/minute IV CRI range,[4-7] but suggested lower end dosages ranging from 1 – 5 µg/kg/minute and upper end dosages of up to 40 µg/kg/minute can be found.

CHF associated with myxomatous mitral valve disease (MMVD; extra-label):

Acute management of patients in stage C heart failure (either current or past clinical signs of heart failure): Start with dobutamine 2.5 µg/kg/minute IV CRI and increase as needed up to 10 µg/kg/minute.[8] Dobutamine should be used in addition to other treatments to improve the left ventricular function in patients that fail to respond adequately to diuretics, pimobendan, sedation, oxygen, and comfort care measures.

Acute management of patients in stage D heart failure (end-stage, in which clinical signs of heart failure are refractory to standard treatment): Start with dobutamine 1 µg/kg/minute IV CRI and up-titrate every 15 to 30 minutes to a maximum of ≈10 – 15 µg/kg/minute.[8] May be administered concomitantly with nitroprusside to provide afterload reduction. Use for 12 to 48 hours to improve hemodynamics and refractory cardiogenic pulmonary edema.

Hypotension during general anesthesia (extra-label):

a) 5 µg/kg/minute IV CRI during propofol anesthesia[9]
b) 2 – 12 µg/kg/minute during isoflurane anesthesia[10]

CATS:

Short-term treatment of low cardiac output and acute congestive heart failure (extra-label): 1 – 5 µg/kg/minute IV CRI.[7] Dosage suggestions tend to be lower for cats (than dogs). Dosages are usually started on the low end and titrated upward. Titrate dose to effect, but doses above 5 µg/kg/minute have anecdotally been associated with seizures.

Hypotension during general anesthesia (extra-label): 2 – 20 µg/kg/minute IV CRI[11]

HORSES:

Cardiovascular support in anesthetized horses (extra-label):

a) 1 – 1.5 µg/kg/minute IV CRI, arterial blood pressure increases, but cardiac output is marginally affected. At higher rates, both cardiac output and arterial blood pressure are increased, but the risk for arrhythmias is increased.[3]
b) **Hypotension during inhalant anesthesia** (extra-label): Doses between 0.5 – 3 µg/kg/minute IV CRI have been used to treat hypotension caused by inhalational agents (ie, isoflurane and sevoflurane). At these doses, an increase in blood pressure, right atrial pressure, stroke volume, jejunum and colon blood flow, cardiac output, oxygen content, and oxygen delivery is noted.[12-15]

Foals (after volume repletion) (extra-label): 2 – 20 µg/kg/minute IV CRI[16]

BIRDS:

Isoflurane-induced severe hypotension in Hispaniolan Amazon parrots (extra-label): In the study, dobutamine CRI at 15 µg/kg/minute caused the greatest increases in arterial blood pressure of the 3 tested dobutamine infusions (5, 10, or 15 µg/kg/minute).[17]

Monitoring

- Blood pressure, heart rate and rhythm, including continuous ECG
- Mucous membrane color, capillary refill time, hydration status
- Serum potassium
- Baseline and periodic renal parameters (eg, BUN, creatinine) as needed for underlying problem being treated
- Urine output
- Ideally, measurement of central venous or pulmonary capillary wedge pressures and cardiac output

Client Information

- Dobutamine should only be administered by professionals familiar with its use and in a setting in which adequate patient monitoring can be performed.

Chemistry/Synonyms

Dobutamine HCl is a synthetic inotropic agent related structurally to dopamine. It occurs as a white, to off-white, crystalline powder with a pK_a of 9.4. Dobutamine is sparingly soluble in water and alcohol.

Dobutamine HCl may also be known as 46236, compound 81929, dobutamini hydrochloridum, and LY-174008; many trade names are available.

Storage/Stability

Dobutamine injection should be stored at room temperature, 20°C to 25°C (68°F-77°F); diluted solutions should be used within 24 hours.

Compatibility/Compounding Considerations

To prepare solution: The solution for injection must be further diluted to a concentration no greater than 5 mg/mL (total of at least 50 mL of diluent/20 mL of dobutamine) before administering.

Generally, dobutamine is added to D_5W, normal saline (if animal not severely sodium restricted), or other compatible IV solutions. The following approximate concentrations will result if 1 vial (250 mg) is added to 250 mL, 500 mL, or 1000 mL IV solutions: 250 mL: ≈1000 µg/mL; 500 mL: ≈500 µg/mL; 1000 mL: ≈250 µg/mL.

A mechanical fluid administration control device (eg, fluid pump) should be used to administer dobutamine. To calculate a dobutamine CRI[18]: 6 times body weight (in kg) = the number of mg (NOT mL) of dobutamine added to a sufficient quantity of 0.9% NaCl to obtain a total volume of 100 mL. When this solution is delivered at 1 mL/hour IV, 1 µg/kg/min is administered.

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dobutamine is physically **compatible** with the following IV solutions: D_5W, sodium chloride 0.45% and 0.9%, dextrose-saline combinations, and lactated Ringer's. Dobutamine is physically **compatible** with the following drugs: amiodarone, atropine sulfate, dopamine, epinephrine, hydralazine, isoproterenol, lidocaine, meperidine, morphine sulfate, nitroglycerin, norepinephrine, phentolamine, phenylephrine, procainamide, propranolol, and verapamil.

Dobutamine may be physically **incompatible** with the following

agents: aminophylline, bumetanide, calcium chloride, calcium gluconate, diazepam, digoxin, furosemide, heparin (inconsistent results), regular insulin, magnesium sulfate, phenytoin sodium, potassium chloride (at high concentrations [160 mEq/L] only), potassium phosphate, and sodium bicarbonate.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated dobutamine as a class 2 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Dobutamine HCl Injection Concentrated Solution: 12.5 mg/mL in 20 mL and 40 mL single-use vials; generic; (Rx)

Dobutamine HCL Solution for Injection: 250 mg/250 mL (1 mg/mL) preservative free in 250 mL single-use containers; 500 mg/250 mL (2 mg/mL) preservative free in 250 mL single-use containers and 1000 mg/250 mL (4 mg/mL) preservative free in 250 mL single-use containers Dobutamine Hydrochloride in 5% Dextrose Injection; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Docusate

Dioctyl Sodium Sulfosuccinate (DSS)

(***dok***-yoo-sate) *Colace®*

Surfactant Stool Softener

Prescriber Highlights

- ► Used to soften and ease passage of hard stools in a variety of species
- ► Use with caution in patients with fluid/electrolyte abnormalities. Overdoses can be fatal in horses.
- ► Adverse effects include cramping, diarrhea, and GI mucosal damage.

Uses/Indications

Docusate is used in small animal species when feces are hard or dry, or with anorectal conditions when passing firm feces would be painful or detrimental. Docusate can be used alone or in combination with mineral oil in treating fecal impactions in horses, although one study found docusate to be as effective as water[1] and that psyllium is the preferred treatment (over docusate) in cases of sand accumulation.[2] Docusate can be used for partial defaunation in sheep to increase voluntary food intake and increase digestion and absorption of nutrients.[3,4]

Pharmacology/Actions

Docusate salts reduce surface tension and allow water and fat to penetrate the ingesta and formed feces thereby softening the stool. Recent in vivo studies have demonstrated that docusate also increases cAMP concentrations in colonic mucosal cells that may increase both ion secretion and fluid permeability from these cells into the colon lumen.

Pharmacokinetics

It is unknown how much docusate is absorbed after oral administration, but it is believed that some is absorbed from the small intestine and then excreted into the bile.

Contraindications/Precautions/Warnings

Docusate is contraindicated in patients hypersensitive to it. Use with caution in patients with preexisting fluid or electrolyte abnormalities and in those at risk for aspiration.

Adverse Effects

At usual doses, clinically significant adverse effects should be rare. Cramping, diarrhea, and intestinal mucosal damage are possible. The liquid preparations may cause throat irritation if administered by mouth. Docusate sodium is bitter tasting.

Severe gastric and esophageal changes have been reported in snakes.[5]

Reproductive/Nursing Safety

It is not known whether docusate crosses the placenta or is excreted in milk, but it is unlikely to be of concern.

Overdose/Acute Toxicity

Overdoses in horses may be serious.[6] In healthy horses, single doses of 0.65 – 1 g/kg have caused dehydration, intestinal mucosal damage, and death.[6] Maximum therapeutic dosages up to 0.2 g/kg have been reported. Signs of overdoses in horses can begin within 1 to 2 hours of dosing with initial signs including restlessness and increased intestinal sounds; increases in respiratory and cardiac rates can follow. Abdominal pain, watery diarrhea, and dehydration can occur with horses deteriorating over hours to several days to lateral recumbency and death. Because high dose docusate can cause secretory effects, hydration and electrolyte status should be monitored and treated if necessary. Treatment is supportive; GI protectants, correct fluid and electrolyte imbalances, analgesics, and antiendotoxemic agents (eg, corticosteroids or NSAIDs) have been suggested.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving docusate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

Mineral Oil: Theoretically, mineral oil should not be given with docusate (DSS) as enhanced mineral oil absorption could occur; however, this interaction does not appear to be of significant clinical concern with large animal species. It is less clear whether this could be of significance with small animals; therefore the concurrent use of these agents in dogs or cats cannot be recommended. If it is deemed necessary to use both docusate and mineral oil in small animal species, separate doses by at least 2 hours.

Dosages

DOGS:

Stool softener (extra-label): 25 – 100 mg/dog (depending on dog size; NOT mg/kg) PO once to twice daily. May give up to 240 mg or 250 mg once daily to very large dogs

CATS:

Stool softener (extra-label): 50 mg/cat (NOT mg/kg) PO once daily

HORSES:

Large colon impaction (extra-label): 6 – 12 g/500 kg (1102 lb) diluted in 2 to 4 liters of water by nasogastric tube every 12 to 24 hours[7]

Cecal impaction (extra-label): 10 – 20 mg/kg in 8 L water and administered via NG tube[8]

SHEEP:

Partial defaunation (extra-label): 0.8 – 1.2 g/kg of diet (NOT per kg body weight)[3,4]

Monitoring

- Clinical efficacy
- Hydration and serum electrolyte status, if indicated

Client Information

- Used to treat constipation caused by hard or dry stools
- Generally well tolerated with few side effects
- Should be given on an empty stomach; 1 hour before or 2 hours after a meal
- Docusate is available OTC (over the counter; without a prescription), but do **NOT** give it (or any other laxatives or medications) to your animal without first consulting your veterinarian.

Chemistry/Synonyms

Docusate is available in sodium and calcium salts. They are anionic, surface-active agents and possess wetting and emulsifying properties.

Docusate sodium (also known as dioctyl sodium succinate, DSS, or DOSS) occurs as a white, wax-like plastic solid with a characteristic odor. One gram is soluble in ≈70 mL of water and it is freely soluble in alcohol and glycerin. Solutions are clear and have a bitter taste.

Docusate calcium (also known as dioctyl calcium succinate) occurs as a white, amorphous solid with a characteristic odor (octyl alcohol). It is very slightly soluble in water, but freely soluble in alcohol.

Docusate sodium may also be known as dioctyl sodium sulphosuccinate, dioctyl sodium sulfosuccinate, docusatum natricum, DSS, and sodium dioctyl sulphosuccinate; many trade names are available; *Colace*® is the most commonly known sodium salt product and *Surfak*® is the most commonly known calcium salt product.

Storage/Stability

Capsules of salts of docusate should be stored in tight containers at room temperature. Temperatures above 30°C (86°F) can soften or melt soft gelatin capsules. Docusate sodium solutions should be stored in tight containers and the syrup should be stored in tight, light-resistant containers.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY APPROVED PRODUCTS:

There are several docusate products marketed for veterinary use; their FDA-approval status is unknown, and no entries were found in the FDA Green Book, searchable at AnimalDrugs@FDA. Commercially available products may include:

Docusate Sodium Bloat Preparation: 240 mg/30 mL in 360 mL containers; (OTC). Labeled milk withdrawal = 96 hours; slaughter withdrawal = 3 days.

Docusate Sodium Enema: 5% water miscible solution in 1-gallon containers; *Dioctynate*®; (OTC)

Docusate Sodium Enema: 250 mg in 12 mL syringes; *Pet-Enema*®, *Enema SA*®, *Docu-Soft*® *Enema*; (OTC or RX)

Docusate Sodium Oral Liquid 5% in gallons; various; generic. May also be called Veterinary Surfactant (OTC)

HUMAN-LABELED PRODUCTS:

There are many trade name products for docusate. The two most commonly known are *Colace*® (sodium salt) and *Surfak*® (calcium salt).

Docusate Sodium Oral Tablets: 100 mg; (OTC)

Docusate Sodium Oral Capsules and Soft-gel Capsules: 50 mg, 100 mg, and 250 mg; generic; (OTC)

Docusate Sodium Oral Syrup/Liquid: 50 mg/5 mL (10 mg/mL); (OTC)

Docusate Calcium Capsules: 240 mg (regular and soft gel); (OTC)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Dolasetron

(dole-***a***-se-tron) *Anzemet*®

Antiemetic Agent; 5-HT_3 Receptor Antagonist

Prescriber Highlights

- ► 5-hydroxytryptamine$_3$ (5-HT_3) receptor antagonist antiemetic particularly useful for chemotherapy-related nausea and vomiting in small animals
- ► Once-daily administration
- ► Usually well tolerated; may cause dose-related ECG changes
- ► Oral human tablets not easily dosed in small animals due to strength sizes; must be reformulated for PO use in cats
- ► Expense and availability may be issues.

Uses/Indications

Dolasetron may be effective in treating severe nausea and vomiting in dogs and cats, particularly if it is caused by chemotherapy drugs. Because dolasetron is given once daily, it is often preferred over ondansetron (a similarly effective antiemetic). However, for oral use in small animals, dolasetron tablets are too large (50 and 100 mg) to be practically administered. In a study, dolasetron did not prevent xylazine-induced emesis in cats.[1]

Pharmacology/Actions

Dolasetron exerts its antinausea and antiemetic actions by selectively antagonizing 5-hydroxytryptamine$_3$ (5-HT_3) receptors. These receptors are found primarily in the CNS chemoreceptor trigger zone, on vagal nerve terminals, and on enteric neurons in the GI tract. Chemotherapy-induced vomiting is believed to be caused principally by serotonin release from the mucosal enterochromaffin cells in the small intestine. Dolasetron does not have prokinetic activity.

Pharmacokinetics

After dolasetron is administered IV to dogs, its half-life is only minutes long, as it is rapidly reduced via carbonyl reductase to hydrodolasetron (also called reduced dolasetron or red-dolasetron), and it is presumed that, as in humans, hydrodolasetron is primarily responsible for the drug's pharmacologic effect. Oral dolasetron is rapidly absorbed and converted to hydrodolasetron, although oral bioavailability of dolasetron is only 7%. Hydrodolasetron's apparent volume of distribution in dogs is 8.5 L/kg; total body clearance is 25 mL/minute/kg and half-life is about 4 hours.[2]

In humans, dolasetron is rapidly absorbed and converted to hydrodolasetron, which is ≈100 times more potent as a serotonin antagonist than its precursor. Oral bioavailability is ≈75%. Hydrodolasetron's half-life in humans is ≈7 to 8 hours. The drug is partially metabolized in the liver, but 50% *to* 60% is excreted unchanged into the urine. Clearance may be reduced in patients with severe renal or hepatic impairment.[3]

Contraindications/Precautions/Warnings

Dolasetron is contraindicated in patients that are hypersensitive to it, with second- and third-degree atrioventricular block, or with markedly prolonged QT interval. It should be given with caution to patients with (or who are susceptible to developing) prolongation of cardiac conduction intervals. Use this drug with caution in patients with congenital QT syndrome, hypokalemia, hypomagnesemia; patients receiving anti-arrhythmic drugs or diuretics that affect electro-

lyte levels; or patients with high cumulative doses of anthracycline (eg, doxorubicin) chemotherapy.

Adverse Effects
Dolasetron appears to be well tolerated in the limited numbers of small animal patients that have received it. In humans, it has been associated with dose-related ECG interval (PR, QT) prolongation and QRS widening. Other adverse effects that have been reported in humans using dolasetron during chemotherapy include headache, dizziness, and increased appetite.[3]

Reproductive/Nursing Safety
Teratogenicity studies in laboratory animals failed to demonstrate any teratogenic effects.

It is unknown if the drug enters milk; the manufacturer urges caution.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity
There are limited data available. One human patient who received 13 mg/kg of dolasetron developed severe hypotension and dizziness and was treated with vasopressors and IV fluids. The patient's blood pressure returned to baseline 3 hours after the dose was administered. It is suggested to manage overdoses with supportive therapy. The lethal IV doses in mice and rats were 160 mg/kg and 140 mg/kg, respectively.[4] This is equivalent to 6 to 12 times the human recommended dose when comparing equivalent body surface areas.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions
The following drug interactions either have been reported or are theoretical in humans or animals receiving dolasetron and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: Concurrent use may increase risk for QT interval prolongation.
- **Apomorphine**: Emetics and antiemetics counteract the effects of each other. 5-hydroxytryptamine$_3$ (5-HT$_3$) antagonists may enhance the hypotensive effect of apomorphine. In humans, it is recommended to avoid this combination.
- **Atenolol**: May reduce the clearance and increase blood levels of hydrodolasetron
- **Azole antifungals** (eg, **ketoconazole, itraconazole**): May reduce the clearance and increase blood levels of hydrodolasetron
- **Buprenorphine**: Concurrent use may increase risk for serotonin syndrome.
- **Cisapride**: Concurrent use may increase risk for QT interval prolongation.
- **Fluoroquinolone Antibiotics** (eg, **ciprofloxacin, moxifloxacin**): Concurrent use may increase risk for QT interval prolongation.
- **Macrolide Antibiotics** (eg, **erythromycin, clarithromycin**): Concurrent use may increase risk for cardiotoxicity.
- **Metronidazole**: Concurrent use may increase risk for QT interval prolongation.
- **Phenobarbital**: Can reduce hydrodolasetron blood levels
- **Phenothiazines** (eg, **acepromazine**): Concurrent use may increase risk for cardiotoxicity.
- **Quinidine**: Concurrent use may increase risk for QT interval prolongation.
- **Sotalol**: Concurrent use may increase risk for QT interval prolongation.

Laboratory Considerations
- None are noted.

Dosages
DOGS/CATS:

Antiemetic (extra-label): 0.6 mg/kg PO once daily (every 24 hours). Some clinicians recommend giving higher dosages up to 1 mg/kg to treat active vomiting disorders.

Monitoring
- Efficacy
- ECG in at-risk patients

Client Information
- This medicine is often used to prevent or treat chemotherapy-induced nausea and vomiting.
- Side effects are uncommon.

Chemistry/Synonyms
A 5-hydroxytryptamine$_3$ (5-HT$_3$) receptor antagonist antiemetic, dolasetron mesylate occurs as a white to off-white powder. It is freely soluble in water or propylene glycol, and slightly soluble in 0.9% sodium chloride solution or alcohol.

Dolasetron may also be known as *Anzemet®*, *Anemet®* or *Zamanon®*.

Storage/Stability
The commercially available tablets should be stored at room temperature 20°C to 25°C (68°F -77°F) and protected from light.

Compatibility/Compounding Considerations
Dolasetron 10 mg/mL oral suspension prepared with a 1:1 mixture of *Ora-Plus®* and *Ora-Sweet®* was stable for at least 90 days when stored at room temperature or refrigerated.[5]

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Dolasetron Tablets: 50 mg; *Anzemet®*; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Domperidone
(dohm-***pare***-i-dohne) *Equidone®, Motilium®*

Dopamine-2 Antagonist

Prescriber Highlights

► D_2 dopamine antagonist used in horses for prevention of fescue toxicosis, treatment of agalactia/hypogalactia in periparturient mares, and as a diagnostic agent for pituitary pars intermedia dysfunction (PPID). Potential treatment for leishmaniasis in dogs

► Galactorrhea and gynecomastia are the most likely adverse effects.

Uses/Indications
Domperidone is FDA-approved in the United States for prevention of fescue toxicosis in periparturient mares. Domperidone has been shown to increase plasma ACTH in horses with equine pituitary pars intermedia dysfunction (PPID, equine hyperadrenocorticism), and has been considered for use in the diagnosis of this condition.[1] However, the thyrotropin-releasing hormone (TRH) stimulation test appears to be more accurate for the diagnosis of PPID.[2]

Domperidone appears ineffective as a GI prokinetic and antiemetic agent in small animals. A study and follow-up report in dogs showed that domperidone may have some efficacy in both preventing and treating mild to moderate canine leishmaniasis.[3–5]

Pharmacology/Actions

Domperidone's apparent efficacy for the treatment of fescue toxicosis in pregnant mares is related to the fact that tall fescue toxicosis causes decreased prolactin levels. Dopamine is involved in the reduction of prolactin secretion, and it is postulated that the alkaloids found in tall fescue act as dopaminergic agonists. Domperidone ostensibly blocks this effect.

Domperidone is a dopamine antagonist (D_2 receptors) with similar actions as metoclopramide. It does not readily cross into the CNS, but CNS adverse effects in overdose situations are common, and extrapyramidal adverse effects have been reported in some human patients. In dogs and cats, metoclopramide appears to have more prokinetic effects on gastric emptying than domperidone. Domperidone does not appreciably affect small intestinal transit time but may increase lower esophageal sphincter tone. Horses that received 5 mg/kg PO (4.5 times the normal dose) demonstrated increased rate of gastric emptying, without changes in GI contractility or overall transit time.[6]

Domperidone antagonizes dopamine in the GI tract and chemoreceptor trigger zone, which is thought to be the primary cause of its prokinetic and antiemetic effects. It also is an antagonist for alpha-2 and beta-2-adrenergic receptors in the stomach, which may contribute to the drug's pharmacological actions.

Domperidone may have effects on cell-mediated immunity possibly due to its stimulation of prolactin. Prolactin has been classified as a pro-inflammatory lymphocyte-derived cytokine, and a study done in healthy dogs found that domperidone induced a statistically significant increase in the percentages of activated phagocytes in the treated group during and for up to one month after treatment.[7]

Pharmacokinetics

Domperidone is absorbed from the GI tract, but its bioavailability in dogs is only about 20%, presumably due to a high first pass effect. Peak serum concentrations occur about 2 hours after oral dosing and the drug is highly bound (93%) to serum proteins. Domperidone is primarily metabolized and is a substrate of the cytochrome P450 3A4 family. Metabolites are excreted in the feces and urine.

Domperidone is poorly absorbed in horses. It is widely distributed throughout the body but does not readily cross the blood-brain barrier or placenta. The average terminal half-life in horses is 6 hours.

Contraindications/Precautions/Warnings

Domperidone should not be used in animals with known hypersensitivity to it, or when GI hemorrhages, perforations, or obstructions are present or suspected. Do not use domperidone in pregnant mares more than 15 days prior to their expected foaling date (see ***Reproductive/Nursing Safety***). In horses, failure of passive transfer of immunoglobulins (IgG) may occur even in the absence of leakage of colostrum or milk. All foals born to mares treated with domperidone should be tested for serum IgG concentrations.

Because domperidone is potentially a neurotoxic substrate of P-glycoprotein, it should be used with caution in those herding breeds (eg, Collies) that may have the multidrug sensitivity gene (*MDR-1)* gene mutation (also known as *ABCB1*-1delta) that causes a nonfunctional protein. Also see ***Drug Interactions***.

Domperidone is contraindicated in human patients with hepatic failure. Prolongation of the QT interval prompted removal of the human product in the US; use cautiously in patients receiving other drugs that prolong the QT interval or inhibit domperidone metabolism. Also see ***Drug Interactions***.

Adverse Effects

Because plasma prolactin levels may be increased, galactorrhea or gynecomastia may result. In horses, the most commonly reported adverse effects are premature lactation (dripping of milk prior foaling) and failure of transfer of passive immunity. Foals of mares treated with domperidone may experience loose stools or diarrhea. Injectable products (no longer available) have been associated with arrhythmias in human patients with heart disease or hypokalemia. Rarely, somnolence or dystonic reactions have occurred in humans.

Reproductive/Nursing Safety

Accurate breeding date(s) and an expected foaling date are needed for the safe use of domperidone.[8] When administered more than 15 days prior to the expected foaling date, domperidone may lead to premature birth, low birth weight foals, or foal morbidity. The safety of domperidone has not been evaluated in stallions or in breeding, pregnant, and lactating mares other than in the last 45 days of pregnancy and the first 15 days of lactation. The long-term effects on foals born to mares treated with domperidone have not been evaluated.

Domperidone has been shown to have teratogenic effects when it is used at high doses in mice, rats, and rabbits. The drug's effect of causing prolactin release may impact fertility in both female and male patients.

Domperidone has been used to increase milk supply in humans. In rats, it enters milk in small amounts with ≈1/500th of the adult dose reaching the pups.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

There is no specific antidote for domperidone overdose. Methemoglobinemia has been reported in humans. Use standard decontamination procedures and treat supportively.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving domperidone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): May increase domperidone concentrations
- **Antacids, Aluminum- Calcium- or Magnesium-Containing**: May decrease domperidone bioavailability
- **Anticholinergic Drugs** (eg, **atropine, diphenhydramine, hyoscyamine**): May reduce the efficacy of domperidone
- **Bromocriptine/Cabergoline**: Domperidone may antagonize effects on prolactin.
- **Cimetidine**: May decrease domperidone bioavailability and decrease domperidone metabolism
- **Drugs that prolong QT interval** (eg, **ciprofloxacin, chlorpromazine, cisapride, methadone, ondansetron, quinidine**): May increase risk for QT prolongation
- **H_2-Receptor Antagonists** (eg, **ranitidine**): May decrease domperidone bioavailability
- **Macrolide Antibiotics** (eg, **erythromycin, clarithromycin**): May increase domperidone concentrations and may increase risk of QT prolongation.

- **Opioids** (eg, **morphine**): May reduce the efficacy of domperidone
- **Pergolide**: May reduce the efficacy of domperidone
- **Proton Pump Inhibitors** (**PPIs**; eg, **omeprazole, pantoprazole**): May decrease domperidone bioavailability
- **Sustained-Release** or **Enteric-Coated Oral Medications**: Domperidone may alter the absorptive characteristics of these drugs by decreasing GI transit times.

Laboratory Considerations

- Domperidone may increase **serum prolactin** concentrations.
- Domperidone may increase **ALT** and **AST.**
- Domperidone may cause a false positive result on the **milk calcium** test used to predict foaling.

Dosages

DOGS:

Alternative treatment for leishmaniasis in dogs with mild to moderate clinical signs (extra-label): In the initial study, dogs received 1 mg/kg PO twice daily for 30 days. In the short-term follow-up report, dosages reported were 0.5 mg/kg PO once daily (every 24 hours) for 30 days.[3,4] In one study, domperidone 0.5 mg/kg PO was administered once daily for 4 weeks was followed by 3 months without treatment and which time domperidone 0.5 mg/kg PO was administered once daily for another 4-week treatment.[9]

Prevention of leishmaniasis (extra-label): 0.5 mg/kg PO once daily for 30 days, every 4 months[5] for dogs living in endemic areas

HORSES:

Fescue toxicity (label dosage; FDA-approved): 1.1 mg/kg PO once daily starting 10 to 15 days prior to expected foaling date (EFD).[8] Treatment may be continued for up to 5 days after foaling if mares are not producing adequate milk after foaling.

Assisting in the diagnosis of pituitary par intermedia dysfunction (PPID) | domperidone response test (extra-label): Collect EDTA plasma for endogenous ACTH level at 8 AM. Administer domperidone, 3.3 mg/kg PO. Collect additional EDTA plasma for endogenous ACTH levels at 2 hours and 4 hours after domperidone administration. A 2-fold increase in plasma ACTH concentration suggests PPID. Higher doses (5 mg/kg PO) may improve response. The 2-hour sample is more diagnostic in the summer and autumn, and the 4-hour sample is best in the winter and spring.[1,10]

Monitoring

- Clinical efficacy

Client Information

- Equine gel: Be sure you understand the proper use of the multi-dose dosing syringe, including how to set the dial ring for accurate dosing after the first dose.
- This medicine should not be given to mares more than 15 days before their expected foaling date, as premature birth can occur.
- In mares, premature lactation (dripping of milk prior to foaling) and failure of the mare's milk to pass on immunoglobulins to the foal are the most common side effects.
- In dogs, this medicine may be given with or without food. Do not give this medicine to your animal at the same time as antacids while it is receiving this medication. If your animal vomits or acts sick after receiving this medicine on an empty stomach, try giving the medicine with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Pregnant or nursing women should use caution when handling this medication.

Chemistry/Synonyms

Domperidone maleate occurs as a white or almost white powder that exhibits polymorphism. It is very slightly soluble in water or alcohol.

Domperidone may also be known as domperidonum and R-33812. Common trade names include *Motilium*® or *Equidone*®, but many trade names are available internationally.

Storage/Stability

Domperidone gel should be stored at controlled room temperature 25°C (77°F) with excursions between 15°C to 30°C (59°F-86°F) permitted. Recap the container after each use. Domperidone tablets should be stored at room temperature and protected from light and moisture.

Compatibility/Compounding Considerations

No specific information is noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Domperidone Oral Gel 11% (110 mg/mL) in 25 mL multi-dose oral syringes; *Equidone*® *Gel*; (Rx). FDA-approved for use in horses. Do not use in horses intended for human consumption. NADA #141-314.

An FDA Indexed Product (MIF 900-001) also containing salmon gonadotropin releasing hormone is available for use in ornamental finfish.

HUMAN-LABELED PRODUCTS: NONE IN THE UNITED STATES

In Canada (10 mg tablet only) and in Europe, human oral tablets of 10 mg; suppositories and oral suspension may be available.

Dopamine

(***doe***-pa-meen) *Intropin*®

Adrenergic/Dopaminergic Inotrope

Prescriber Highlights

- ► Parenteral, rapid-acting inotrope used primarily in dogs and cats
- ► Catecholamine that increases systemic peripheral resistance to raise blood pressure and can be considered for treatment of hypotension associated with poor cardiac contractility and/or vasodilation.
- ► There is no evidence that dopamine increases GFR or improves outcome in the treatment of oliguric or anuric renal failure; therefore, dopamine is not recommended as a treatment modality to increase GFR and urine output.
- ► Contraindications include pheochromocytoma, ventricular fibrillation, and uncorrected tachyarrhythmia.
- ► Administered dose should be substantially reduced in patients receiving monoamine oxidase inhibitors (MAOIs).
- ► Adverse effects include nausea/vomiting, ectopic beats, tachycardia, hypotension, hypertension, dyspnea, and vasoconstriction.
- ► Dopamine should be used in critical care settings with continuous monitoring of heart rate/rhythm and blood pressure.

Uses/Indications

Dopamine is an injectable rapid-onset positive inotrope used to correct hypotension associated with low cardiac output in patients with shock after adequate fluid volume replacement and as adjunctive therapy for acute congestive heart failure. Dopamine is also used to treat hypotension in patients under general anesthesia. In rabbits, however, this treatment is not recommended because hypotension in New Zealand white rabbits anesthetized with isoflurane did not improve when given 5, 10, 15, 20, or 30 µg/kg/minute IV.[1]

Dopamine is administered as an IV CRI and should be used only

in critical care settings where adequate monitoring (eg, continuous blood pressure, ECG, cardiac output, pulmonary capillary wedge pressure) can be provided.

In humans with oliguric acute kidney injury, low-dose dopamine does not effectively improve GFR[2]; this use is unproven and somewhat controversial in dogs. In cats, low-dose dopamine reportedly does not cause renal vasodilation. Generally, for dogs and cats with acute kidney injury, a dopamine CRI is not recommended as part of therapy to increase GFR and urine output.

Pharmacology/Actions

Dopamine is a precursor to norepinephrine and acts directly and indirectly (by releasing norepinephrine) on alpha and beta receptors. Dopamine also has peripheral dopaminergic effects. In dogs and cats, dopamine 5 – 10 µg/kg/minute IV CRI will have predominantly beta-1 effects, exerting positive cardiac inotropic activity (eg, increased contractility, cardiac output, heart rate); a CRI of 10 to 15 µg/kg/minute IV will have both alpha-1 and beta-1 effects,[3–6] although alpha-1 effects (eg, increased systemic and pulmonary vascular resistance, increased venous return) predominate in a dose-dependent fashion.

Pharmacokinetics

Because dopamine is rapidly metabolized in the GI tract and is not systemically absorbed after oral administration, dopamine is only administered as an IV CRI. After IV administration, onset of action is usually within 5 minutes and persists for less than 10 minutes after infusion has stopped.

Dopamine is widely distributed in the body but does not cross the blood-brain barrier in appreciable quantities.

Plasma half-life is ≈2 minutes. The drug is metabolized in the kidney, liver, and plasma by monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) to inactive compounds. Up to 25% of a dose of dopamine is metabolized to norepinephrine in the adrenergic nerve terminals. In humans receiving MAO inhibitors, dopamine's duration of activity can be as long as 1 hour. Inactive metabolites are eliminated renally.

Contraindications/Precautions/Warnings

Dopamine is contraindicated in patients with pheochromocytoma, ventricular fibrillation, and uncorrected tachyarrhythmias and is not a substitute for adequate fluid, electrolyte, or blood product replacement therapy. Dopamine should be used with caution in patients with ischemic heart disease or occlusive vascular disease. Decrease dose or discontinue the drug if clinical signs occur that implicate dopamine as the cause of reduced circulation to the extremities or the heart and if arrhythmias (eg, PVCs) occur.

Cats with oliguric acute kidney injury are unlikely to benefit from low-dose dopamine therapy, and treatment may be detrimental.

Do not confuse DOPamine with DOBUTamine or *Dopram*® (doxapram). Writing part of the drug›s name in upper case on prescriptions/orders may reduce the risk for errors.

Adverse Effects

The most frequent adverse effects include nausea and vomiting, ectopic beats, tachycardia, hypotension, hypertension, dyspnea, and vasoconstriction. Ventricular arrhythmias were noted in 2 cats receiving dopamine.[7] A stepwise dose reduction leading to discontinuation can reduce risk for hypotension.

Two dogs with hypotension that were given dopamine 7 µg/kg/minute IV CRI while under isoflurane general anesthesia had a profound decrease in heart rate (ie, 40 to 45 beats per minute) and blood pressure.[8] Dopamine was discontinued, and atropine was given to one of the dogs. Heart rate and blood pressure returned to normal values in both patients. This demonstrates how dopamine can cause an increase in cardiac contractility and initiate the Bezold-Jarisch reflex, which is an inhibitory reflex that causes hypopnea, bradycardia, and hypotension.

Extravasation injuries, including necrosis and sloughing of surrounding tissue, have occurred rarely with dopamine use in humans. Administration through large veins is recommended, and the infusion site should be closely monitored.

Reproductive/Nursing Safety

It is not known whether dopamine crosses the placenta or is excreted into milk. Decreased pup survival resulted from dopamine administration to pregnant rats.[9] Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Accidental overdose is manifested by excessive blood pressure elevation (see ***Adverse Effects***). Treatment consists of temporarily discontinuing therapy because dopamine's short duration of action. If the patient fails to stabilize, phentolamine can be used.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving dopamines and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-Adrenergic Receptor Antagonists** (eg, **prazosin**): May antagonize the vasoconstrictive properties of dopamine (high-dose)
- **Anesthetics, Inhalant** (eg, **halothane, isoflurane**): Use of halothane with dopamine may result in increased incidences of ventricular arrhythmias.
- **Bromocriptine**: Concurrent use may result in severe hypertension and tachycardia
- **Beta-Blockers** (eg, **metoprolol**, **propranolol**): May antagonize the cardiac effects of dopamine
- **Digoxin**: Concurrent use may increase risk for arrhythmias.
- **Haloperidol**: May inhibit dopaminergic renal and mesenteric vasodilation
- **Hypotensive Agents, Other** (eg, **amlodipine, enalapril, telmisartan**): May antagonize the vasoconstrictive properties of dopamine
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): MAOIs can significantly prolong and enhance the effects of dopamine. Reduce dopamine dose by up to 90%.
- **Oxytocin**: May cause severe hypertension when used with dopamine
- **Phenothiazines** (eg, **acepromazine, prochlorperazine**): May inhibit dopaminergic renal and mesenteric vasodilation
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): May potentiate the arrhythmogenic and hypertensive effect of dopamine
- **Vasopressors/Vasoconstrictors**: Use with dopamine may cause severe hypertension

Laboratory Considerations

Dopamine may:

- Suppress **serum prolactin** secretion from the pituitary

- Suppress **thyrotropin** secretion from the pituitary
- Suppress **growth hormone** secretion from the pituitary

Dosages

NOTE: Dopamine is administered as an IV CRI only in a critical care setting. Use an IV pump or other flow-controlling device to increase precision in dosing. A stepwise dose reduction prior to discontinuation can reduce the risk for hypotension.

DOGS/CATS:

Severe hypotension/shock caused by poor cardiac contractility and/or peripheral vasodilation (extra-label): 5 – 20 µg/kg/minute IV.[10] Initially, 2.5 – 5 µg/kg/minute is recommended and then should be titrated upward to effect. Adequate volume replacement is required before use. A study in cats noted an initial CRI of 10 µg/kg/minute IV, with increases in increments of 2.5 – 5 µg/kg/minute IV.[7]

Isoflurane-induced hypotension: 7 – 10 µg/kg/minute IV[11,12]

Monitoring

- Blood pressure, heart rate and rhythm, including continuous ECG
- Mucous membrane color, capillary refill time, hydration status
- Ideally, measurement of central venous or pulmonary capillary wedge pressures and cardiac output
- Baseline and periodic renal parameters (eg, BUN, creatinine) as needed for underlying problem being treated
- Urine output
- IV infusion site for signs of inflammation related to extravasation

Client Information

- Dopamine should be used only in an intensive care setting or settings in which adequate monitoring is possible.

Chemistry/Synonyms

Dopamine (as the HCl salt), an endogenous catecholamine that is the immediate precursor to norepinephrine, occurs as a white to off-white crystalline powder. It is freely soluble in water and soluble in alcohol. The injectable concentrated solution has a pH of 2.5 to 5.5 and may contain an antioxidant (sodium bisulfate). The pH of the ready-to-use injectable products in dextrose range from 3 to 5.

Dopamine HCl may also be known as ASL-279, dopamini hydrochloridum, and 3-hydroxytyramine hydrochloride; many trade names are available.

Storage/Stability

Dopamine injectable products should be protected from light. Solutions that are pink, yellow, brown, or purple indicate decomposition of the drug. Solutions that are darker than a light yellow should be discarded. Dopamine solutions should be stored at room temperature of 20°C to 25°C (68°F-77°F).

After dilution in a common IV solution (NOT 5% bicarbonate), dopamine is stable for at least 24 hours at room temperature, but it is recommended to dilute the drug just prior to use. Dopamine is stable in solutions with a pH of less than 6.4 and most stable at a pH less than 5. It is oxidized at alkaline pH.

Compatibility/Compounding Considerations

To prepare solution: Add contents of the dopamine vial to 250 mL, 500 mL, or 1000 mL of normal saline, D_5W, lactated Ringer's injection, or other compatible IV fluid. If adding a 200 mg vial (5 mL; 40 mg/mL) to a 1 L bag, the resultant solution concentration will be ≈200 µg/mL.

A mechanical fluid administration control device (fluid pump) should be used to administer dopamine. If using a mini-drip IV set (60 drops/mL), each drop will contain ≈3.3 µg. To calculate a dopamine CRI[6]: 6 times body weight (in kg) = the number of mg (NOT mL) of dopamine added to a sufficient quantity of 0.9% NaCl to obtain a total volume of 100 mL. When this solution is delivered at 1 mL/hour IV, 1 µg/kg/minute is administered.

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dopamine is physically **compatible** with the following IV solutions: D_5 in LRS, D_5 in half-normal saline, D_5 in normal saline, D_5W, mannitol 20% in water, lactated Ringer's solution, normal saline, and $^1/_6$ molar sodium lactate. Dopamine is reported to be physically **compatible** with the following drugs: aminophylline, calcium chloride, chloramphenicol sodium succinate, dobutamine HCl, gentamicin sulfate (gentamicin potency retained for only 6 hours), heparin sodium, hydrocortisone sodium succinate, lidocaine HCl, methylprednisolone sodium succinate, potassium chloride, tetracycline HCl, and verapamil HCl.

Dopamine is reported to be physically **incompatible** with amphotericin B, ampicillin sodium, iron salts, metronidazole with sodium bicarbonate, penicillin G potassium, and sodium bicarbonate.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated dopamine as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Dopamine HCl for Concentrated Solution for Injection: 40 mg/mL, 80 mg/mL, and 160 mg/mL in 5 mL and 10 mL vials; generic; (Rx). Dilute prior to administration.

Dopamine HCl in Dextrose 5% Injection Solution: 200 mg/250 mL (0.8 mg/mL); 400 mg/500 mL (0.8 mg/mL); 400 mg/250 mL (1.6 mg/mL); 800 mg/500 mL (1.6 mg/mL); and 800 mg/250 mL (3.2 mg/mL) in premixed single-use containers; generic; (Rx)

Doramectin

(dor-a-***mek***-tin) *Dectomax®*

Avermectin Antiparasitic

Prescriber Highlights

- ► Injectable (cattle, swine) and topical (cattle only) avermectin ecto- and endoparasiticide
- ► Manufacturer warns about extra-label use in other species.
- ► IM injections may cause muscle blemishes.
- ► Not labeled for female dairy cattle 20 months or older
- ► Relatively long slaughter withdrawal times

Uses/Indications

Doramectin injection is indicated for the treatment and control of the following endo- and ectoparasites in cattle: GI roundworms (adults and some fourth-stage larvae)—*Ostertagia ostertagi* (including inhibited larvae), *Ostertagia lyrata, Haemonchus placei, Trichostrongylus axei, Trichostrongylus colubriformis, Trichostrongylus longispicularis, Cooperia oncophora, Cooperia pectinata, Cooperia punctata, Cooperia surnabada* (syn. *Cooperia mcmasteri*), *Bunostomum phlebotomum, Strongyloides papillosus, Oesophagostomum radiatum, Trichuris* spp; lungworms (adults and fourth-stage larvae)—*Dictyocaulus viviparus*; eyeworms (adults)—*Thelazia* spp; grubs (parasitic stages)—*Hypoderma bovis*, *Hypoderma lineatum*; sucking

lice—*Haematopinus eurysternus*, *Linognathus vituli*, *Solenopotes capillatus*; and mange mites—*Psoroptes bovis*, *Sarcoptes scabiei*.[1] The manufacturer states doramectin protects cattle against infection or reinfection with *Cooperia oncophora* and *Haemonchus placei* for 14 days, *Ostertagia ostertagi* for up to 21 days, and *Cooperia punctata*, *Oesophagostomum radiatum*, and *Dictyocaulus viviparus* for 28 days after treatment. Doramectin topical (pour-on) is FDA-approved for the treatment and control in cattle of a similar spectrum of endo- and ectoparasites, but also includes horn flies (*Haematobia irritans*) and biting lice (*Bovicola* [*Damalinia*] *bovis)*.[2]

In swine, the injection is labeled for the treatment and control of GI roundworms (adults and some fourth-stage larvae)—*Ascaris suum*, *Oesophagostomum dentatum*, *Oesophagostomum quadrispinolatum*, *Strongyloides ransomi*, and *Hydrostrongylus rubidus*; lungworms (adults)—*Metastrongylus* spp; kidney worms (adults)—*Stephanurus dentatus*; mange mites (adults and immature stages)—*Sarcoptes scabiei* var. *suis*); and sucking lice (adults and immature stages)—*Haematopinus suis*.[1]

Injectable doramectin has been used in an extra-label manner orally or as an SC injection for treating a variety of nematode and arthropod parasites in companion animals, including generalized demodicosis in dogs and cats.[3–5] However, isoxazolines (eg, fluralaner, sarolaner) have supplanted avermectins for the treatment of demodicosis.[6–9] Based on an open, clinical study in 38 dogs, 72% with generalized demodicosis and 89% with localized demodicosis showed remission after a mean of 11.4 weeks (generalized) and 7.8 weeks (localized). In a retrospective review of 232 dogs with generalized demodicosis, remission was achieved in 94.8% of patients that completed treatment with weekly doramectin injections; the average treatment duration was 7.1 weeks.[3]

Pharmacology/Actions

The primary mode of action of avermectins like doramectin is to affect chloride ion channel activity in the nervous system of nematodes and arthropods. Doramectin binds to receptors that increase membrane permeability to chloride ions. This inhibits the electrical activity of nerve cells in nematodes and muscle cells in arthropods and causes paralysis and the death of the parasites. Avermectins also enhance the release of gamma-aminobutyric acid (GABA) at presynaptic neurons. GABA acts as an inhibitory neurotransmitter and blocks the post-synaptic stimulation of the adjacent neuron in nematodes or the muscle fiber in arthropods.

Avermectins are generally not toxic to mammals as they do not have glutamate-gated chloride channels, and these compounds do not readily cross the blood–brain barrier where mammalian GABA receptors occur.

Pharmacokinetics

After subcutaneous injection, the time to peak plasma concentration in cattle is about 5 days. Bioavailability is, for practical purposes, equal with SC and IM injections in cattle.

In llamas and alpacas given doramectin 0.5 mg/kg topically, peak plasma concentration of ≈4 ng/mL was reached ≈5.5 hours after administration, and half-life was 9 days.[10] When doramectin 0.2 mg/kg SC was given to alpacas, peak concentration of 6 ng/mL was reached ≈ 4 hours after administration and half-life was 6 days.[11]

Contraindications/Precautions/Warnings

Doramectin should not be used in other animal species as severe adverse reactions, including fatalities in dogs, may result.[1,2]

Although extra-label use is not advised in small animal species, if it is used, it is recommended to test all dogs for the *MDR1* mutation (also known as *ABCB1*-1delta) before treatment; use only in dogs tested negative for heartworm microfilariae or heartworm infection. If this testing is not possible: 1) Use alternative treatments in untested dogs of breeds susceptible to *MDR1* mutation (collies, Australian shepherds, shelties, long-haired whippet) as they are at higher risk for toxicity; 2) Obtain informed consent from the owner.

Adverse Effects

Doramectin appears to be well-tolerated in cattle and swine when administered at label dosages. IM injections may have a higher incidence of injection site blemishes at slaughter than do SC injections. Short-term fiber discoloration was noted in llamas and alpacas after application of the pour-on formulation.[10]

When doramectin is used to treat demodicosis in dogs (not recommended), adverse effects are uncommon but may include pupil dilation, lethargy, blindness, or coma.

Reproductive/Nursing Safety

In studies performed in breeding animals (bulls and boars, as well as sows and cows in early and late pregnancy), 3 times the recommended dose had no effect on breeding performance.[1,2] Doramectin administration (0.3 mg/kg, route not stated) to inexperienced male rats resulted in a diminution of the appetitive and consummatory phases of sexual behavior.[12] Safety in neonatal calves and piglets treated with up to 3 times the recommended dose has also been demonstrated.

Overdose/Acute Toxicity

In field trials, no toxic signs were seen in cattle given up to 25 times the recommended dose of the injectable product.[1,2]

Doramectin toxicity may be alleviated with the use of IV lipid emulsion therapy.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

- None noted

Dosages

DOGS:

NOTE: Caution is warranted when administering doramectin to dogs with the *MDR1* mutation (also known as *ABCB1*-1delta). See ***Contraindications/Precautions/Warnings*** before using doramectin in dogs.

Ectoparasiticide: **NOTE**: isoxazolines (eg, fluralaner, sarolaner) have supplanted avermectins for ectoparasite management.

Adjunctive treatment of generalized demodicosis (extra-label): Based on retrospective reviews and open clinical studies, 600 µg/kg (0.6 mg/kg) PO or SC once weekly; continue treatment until remission of clinical signs and no evidence of mites on 2 successive skin scrapings 2 weeks apart.[4,13,14] Giving an initial dose of 300 µg/kg (0.3 mg/kg) has been suggested to minimize adverse effects.[4] Twice weekly doses of 300 µg/kg (0.3 mg/kg) SC may be better tolerated than 600 µg/kg (0.6 mg/kg) once weekly.[15]

Sarcoptic mange (extra-label): 400 µg/kg (0.4 mg/kg) SC once weekly[16]

***Spirocerca lupi* infections** (extra-label): 400 µg/kg (0.4 mg/kg) SC every 14 days. Treatment duration has ranged from 3[17] to 6[18] treatments followed by 400 µg/kg (0.4 mg/kg) SC once monthly until clinical resolution.

CATS:

Follicular demodicosis (extra-label): 400 – 600 µg/kg (0.4 – 0.6 mg/kg) SC once weekly for 4 weeks past 2 consecutive negative skin scrapings 4 to 6 weeks apart[15]

Notoedric mange (extra-label): 200 – 300 µg/kg (0.2 – 0.3 mg/kg) SC as a single dose or once weekly for 2 to 3 treatments[15]

CATTLE:

Label indications for injectable product (label dosage; FDA-approved): 200 µg/kg (1 mL/50 kg [110 lb] body weight) SC or IM.[1] Injections should be given using 16- to 18-gauge needles. Subcutaneous injections should be administered under the loose skin in front of or behind the shoulder. Intramuscular injections should be administered into the muscular region of the neck. Beef Quality Assurance guidelines recommend subcutaneous administration as the preferred route.

Label indications for pour-on product (label dosage; FDA-approved): 500 µg/kg (1 mL/10 kg [22 lb] body weight) applied topically along the mid-line of the back in a narrow strip between the withers and tailhead[2]

SWINE:

Label indications (label dosage; FDA-approved): 300 µg/kg (1 mL/ 34 kg [75 lb] body weight) IM.[1] Injections should be made using 16 g x 1.5 inch needles for sows and boars and 18 g x 1 inch needles for young animals. Use a tuberculin syringe and a 20 g x 1 inch needle for piglets. IM injections should be administered into the muscular region of the neck. See the label for a recommended treatment program for sows, gilts, boars, feeder pigs, weaners, growers, and finishers.

EQUINE:

Control of strongylid (large and small strongyles) infections (extra-label): 200 µg/kg (0.2 mg/kg) SC had 99.6% efficacy against large strongyles at 14 days after injection, 82.4% at 28 days, and 47.8% at 58 days; small strongyle infections were eradicated from 83.3% horses at 14 days.[19]

NEW WORLD CAMELIDS

Control of susceptible parasites in alpacas (extra-label):

a) 200 – 300 µg/kg (0.2-0.3 mg/kg) IM, SC once[20]

b) 500 µg/kg (0.5 mg/kg) applied topically once[21]

RABBITS:

***Psoroptes cuniculi* infestations** (extra-label): 200 µg/kg (0.2 mg/kg) IM once[22]

Monitoring

- Efficacy
- Adverse effects

Client Information

- Use this medicine only as directed by your veterinarian.
- As an antiparasite medication in cattle and swine: Carefully read and follow all instructions and drug residue withdrawal times listed on the product label. Do not apply pour-on product to the backline if covered with mud or manure.
- The pour-on product is flammable. Store away from sources of ignition. Do not smoke while handling this product.

Chemistry/Synonyms

Doramectin, an avermectin antiparasitic compound, is isolated from fermentations from the soil organism *Streptomyces avermitilis*.

Doramectin may also be known as Doramectina, Doramectine, Doramectinum, Doramektiini, Doramektin, UK-67994, or *Dectomax*®.

Storage/Stability

The commercially available injectable solution is colorless to pale yellow, sterile solution. Store the injectable solution below 30°C (86°F). Discard vial 90 days after first puncture, and puncture vial no more than 25 times.[1]

The topical pour-on solution is flammable; store it below 30°C (86°F) and protect it from light.[2] Wear protective clothing when administering the topical pour-on solution.[2]

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Doramectin Injectable Solution: 10 mg/mL in 100 mL, 200 mL, and 500 mL multi-dose vials; *Dectomax*®; (OTC). FDA-approved for use in cattle and swine. When used at labeled doses: Slaughter withdrawal: cattle = 35 days, swine = 24 days. Do not use it in female dairy cattle 20 months of age or older or in calves to be used for veal. A withdrawal period has not been established in pre-ruminating calves.

Doramectin Pour-On Solution: 5 mg/mL in 250 mL, 1 L, 2.5 L, and 5 L multi-dose containers; *Dectomax*® *Pour-On,* generic; (OTC). FDA-approved for use in cattle. Slaughter withdrawal = 45 days. Not for use in female dairy cattle 20 months of age or older. A withdrawal period has not been established in pre-ruminating calves. Do not use it in calves to be used for veal.

HUMAN-LABELED PRODUCTS: NONE

Doxapram

(***docks***-a-pram) *Dopram-V*®

CNS/Respiratory Stimulant

Prescriber Highlights

- ► CNS stimulant usually used to initiate respirations in newborns or after anesthesia. Also used for assessment of laryngeal function in small animals. Use in small animal neonates is controversial.
- ► Not a substitute for aggressive artificial (mechanical) ventilatory support
- ► Possible contraindications include patients with hypersensitivity to doxapram, seizure disorders, head trauma, cerebrovascular accident (CVA), significant cardiovascular impairment (eg, decompensated heart failure, severe hypertension), mechanical disorders of ventilation (eg, neuromuscular disorders or blockade, airway obstruction, pulmonary embolism or fibrosis, pneumothorax, acute asthma, dyspnea, or whenever hypoxia is not associated with hypercapnia) and those receiving mechanical ventilation.
- ► Use with caution in patients with a history of asthma, arrhythmias, or tachycardias. Use extreme caution in patients with cerebral edema or increased CSF pressure, pheochromocytoma, or hyperthyroidism.
- ► Avoid IV extravasation or using a single injection site for a prolonged period.
- ► Adverse effects include hypertension, arrhythmias, seizures, and hyperventilation (leading to respiratory alkalosis).

Uses/Indications

Doxapram is FDA-approved for use in horses, cats, and dogs to stimulate the respiratory center during and after anesthesia to speed awakening and the return of reflexes.[1] It is also approved for use in neonatal dogs and cats to initiate respiration following dystocia or caesarean section. Use of doxapram to initiate ventilation by stimulation of the respiratory center in newborns is controversial, as the drug has been shown in experimental animals to increase myocardial oxygen demand and reduce cerebral blood flow. Many no longer recommend its use for this purpose, and some state that the drug is contraindicated in situations of respiratory arrest. In humans, rou-

tine use of doxapram in neonatal infants is no longer recommended.[2]

Doxapram has been used for treatment of CNS depression in many species and has been suggested as a treatment for respiratory depression in small animal species caused by reactions to radiopaque contrast media[3] or adverse effects from CNS-depressing drugs (eg, acepromazine). See ***Contraindications/Precautions/Warnings***

Doxapram has been shown to be useful to offset suppression of general anesthetic agents when laryngeal function is being assessed.[4-7]

Pharmacology/Actions

Doxapram appears to directly stimulate peripheral chemoreceptors within the carotid bodies leading to subsequent release of catecholamines and other neurotransmitters. As doses increase, the central respiratory center is also stimulated, as are other parts of the brain and spinal cord, leading to general CNS stimulation.[8] Respiratory stimulation leads to an increase in tidal volume with a slight increase in rate of respirations with resultant increased oxygen consumption and carbon dioxide production. Doxapram has been associated with an increased release of catecholamines.

Doxapram can antagonize opioid-induced respiratory depression without affecting analgesia in humans.[8] However, the mu-receptor antagonist naloxone is more commonly used in humans to reverse opioid-induced respiratory depression due to high receptor affinity as well as ease of use. Doxapram does not reverse respiratory depression caused by barbiturates such as pentobarbital.[9]

Pharmacokinetics

There are little published pharmacokinetic data available for dogs and cats. The onset of effect in humans and animals after IV injection usually occurs within 2 minutes. Doxapram is well-distributed into tissues. In dogs, doxapram is rapidly metabolized and most is excreted as metabolites in the urine and feces within 24 to 48 hours after administration. Small quantities of metabolites may be excreted up to 120 hours after dosing.[10]

Doxapram administered IV to horses, protein binding was 76% to 85%, median volume of distribution at steady-state was 1.2 L/kg, median biologic half-life was ≈2-3 hours, and median plasma clearance was 10.6 to 10.9 mL/minute/kg.[11] Following administration of 2.5 mg/kg IV doxapram in newborn lambs (2 to 6 days old), the terminal half-life was 5.2 hours, clearance was 9 mL/kg/minute, C_{max} was 3.1 mg/L, and apparent Vd was 1.2 L/kg.[12]

Contraindications/Precautions/Warnings

Doxapram is contraindicated for patients with a history of hypersensitivity to it or that are receiving mechanical ventilation.; doxapram should not be used as a substitute for aggressive artificial (mechanical) ventilatory support in instances of severe respiratory depression. Use to stimulate respiration in newborns is controversial, and some state it is contraindicated in apnea.

Doxapram has been reported as contraindicated in premature calves or other patients with clinical signs indicative of lung immaturity, as effects are only minimal. In addition, its use could lead to increased pulmonary blood pressure with fetal circulation persisting resulting from a right-to-left shunt via the patent ductus and foramen ovale.[13]

Doxapram should be used with caution in patients with a history of asthma, arrhythmias, or tachycardias. It should be used with extreme caution in patients with cerebral edema or increased CSF pressure, pheochromocytoma, or hyperthyroidism. Impaired hepatic or renal function may alter response to doxapram. Vomiting may occur, and airway protection may be required.

Avoid using a single IV injection site for a prolonged period to minimize risk for thrombophlebitis.[8] Ensure IV catheter patency before administering to avoid extravasation. Rapid IV infusion of doxapram can result in hemolysis.

Repeated IV doses in neonates should be done with caution, as the product contains benzyl alcohol.[8]

Contraindications from the human literature include seizure disorders, head trauma, cardiovascular impairment (eg, decompensated heart failure, severe hypertension), respiratory failure secondary to neuromuscular disorders, airway obstruction, pulmonary embolism, pulmonary fibrosis, and pneumothorax.

Do not confuse doxapram with doxazosin or doxepin or confuse *Dopram®* with dopamine.

Adverse Effects

Doxapram has a narrow margin of safety when used in humans. Hypertension, arrhythmias, seizures, and hyperventilation (leading to respiratory alkalosis) have been reported. These effects appear most probable with repeated or high doses. Depth of anesthesia may be reduced when doxapram is used intraoperatively.

Doxapram has been shown in experimental animals to increase myocardial oxygen demand and reduce cerebral blood flow.

Reproductive/Nursing Safety

Although adverse effects have not been observed in animal reproduction studies, the safety of doxapram has not been established in pregnant animals. No evidence of fetal harm was noted in rats given doses up to 1.6 times the human label dose.[8] It is not known whether doxapram is excreted in milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Reported LD_{50} for IV administration in dogs and cats is 40 – 100 mg/kg.[8,10] Clinical signs of an overdose include respiratory alkalosis, hypertension, skeletal muscle hyperactivity, tachycardia, vomiting, diarrhea, and generalized CNS excitation including seizures. Treatment is supportive (eg, oxygen, anticonvulsants) based on clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving doxapram and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anesthetics, Inhalant** (eg, **halothane**, but not **isoflurane**): Doxapram may increase epinephrine release; therefore, use should be delayed for ≈10 minutes after discontinuation of anesthetic agents that have been demonstrated to sensitize the myocardium to catecholamines (eg, **halothane**).
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): Additive pressor effects may occur.
- **Muscle Relaxants** (eg, **guaifenesin, methocarbamol**): Doxapram may mask the effects of muscle relaxant drugs.
- **Neuromuscular Blockers** (eg, **pancuronium, vercuronium**): Doxapram may temporarily mask residual effects of neuromuscular blockers.
- **Sympathomimetic Agents** (eg, **dopamine, epinephrine, phenylpropanolamine**): Additive pressor effects may occur.
- **Theophylline, Aminophylline**: Additive skeletal muscle activity, agitation, and hyperactivity may occur.

Dosages

DOGS/CATS:

To stimulate respirations during and after general anesthesia; to speed awakening and return of reflexes after anesthesia (label dosage; FDA-approved): 1.1 mg/kg (when used with gas anesthesia) or 5.5 – 11 mg/kg (when used with barbiturate anesthesia) IV; adjust dose based on depth of anesthesia, tidal volume and respiratory rate.[1] Dosage may be repeated in 15 to 20 minutes if necessary.

To initiate or stimulate respirations in neonates after cesarean section or dystocia (label dosage; FDA-approved): *Kittens*: 1 – 2 mg/kitten (NOT mg/kg) SC or sublingually (SL); *Puppies*: 1 – 5 mg/puppy NOT mg/kg) SC, SL, or via the umbilical vein.[1] Dosage may be repeated in 15 to 20 minutes if necessary. **NOTE**: In humans, routine use of doxapram in neonatal infants is no longer recommended.[2]

Stimulate respiratory function in neonates (extra-label): 0.1 mL (2 mg)/neonate (NOT mL/kg) IV, IM, SL; most likely to be beneficial to increase efforts in neonates with a low-frequency, gasping, and erratic pattern of breathing after receiving oxygen therapy.[14] **NOTE**: In humans, routine use of doxapram in neonatal infants is no longer recommended.[2]

Assess laryngeal function (extra-label): 0.25 – 2.5 mg/kg IV to stimulate respiration and increase intrinsic laryngeal motion.[6,7,15-18] Premedicating dogs permits lower doses of anesthetic induction drugs to be used, which improves the diagnostic utility of the procedure.[18]

To reduce sedative effects of acepromazine (extra-label): doxapram 1.25 mg/kg IV given 30 minutes after acepromazine 0.05 mg/kg IM significantly reduced sedation in a study with 10 dogs.[19]

HORSES:

Stimulate respiration during and after general anesthesia and speed awakening and return of reflexes after anesthesia (label dosage; FDA-approved): 0.44 mg/kg (for inhalant anesthesia) or 0.55 mg/kg (for barbiturate anesthesia) IV; adjust dosage for depth of anesthesia, respiratory volume, and rate.[1] Dose may be repeated in 15 to 20 minutes if necessary.

Adjunctive treatment to stimulate respirations in foals with sepsis or hypoxic-ischemic encephalopathy/neonatal maladjustment syndrome (extra-label): 0.02 – 0.05 mg/kg/hour IV CRI[20,21]; foals with significant hypercapnia and hypoxia, despite O_2 treatment, require positive pressure ventilation.

CATTLE & SWINE:

Primary apnea in asphyxic calves when intubation and mechanical ventilation are not feasible (extra-label): 2 mg/kg IV[13,22]

BIRDS:

Emergency treatment of respiratory depression (extra-label):
a) 5 – 10 mg/kg IM or IV
b) 5 – 20 mg/kg IM, IV, IO, or IT[23]

FERRETS/RABBITS/RODENTS/SMALL MAMMALS:

Emergency treatment of respiratory depression (extra-label): Suggested anecdotal dosages range from 1 – 10 mg/kg.[24,25] Suggested routes of administration include IV, SL, IO, IP, SC, and intratracheally.

REPTILES:

Stimulate respiration after general anesthesia (extra-label): 5 mg/kg IV, IO[26-28]

Monitoring

- Respiratory rate and depth
- Cardiac rate and rhythm, blood pressure, pulse oximetry
- Arterial blood gas if available and indicated
- CNS level of excitation; deep tendon reflexes

Client Information

- This drug should only be used in an inpatient setting (ie, in a veterinary clinic) or with direct professional supervision.

Chemistry/Synonyms

Doxapram HCl is a white to off-white, odorless, crystalline powder that is stable in light and air. It is soluble in water, sparingly soluble in alcohol, and practically insoluble in ether. Injectable products have a pH from 3.5 to 5. Benzyl alcohol or chlorobutanol is added as a preservative agent in the commercially available injections.

Doxapram HCl may also be known as AHR-619, doxaprami hydrochloridum, *Docatone®*, *Dopram®*, *Doxapril®*, or *Respiram®*.

Storage/Stability

Store at room temperature 20˚C to 25˚C (68˚F-77˚F) and avoid freezing.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Doxapram is physically **compatible** with D_5W or normal saline.[1]

Do not mix with alkaline solutions (eg, thiopental, aminophylline, sodium bicarbonate). Doxapram is also **incompatible** with ascorbic acid, cefoperazone, cefotaxime, cefotetan, cefuroxime, folic acid, dexamethasone disodium phosphate, diazepam, hydrocortisone sodium phosphate, methylprednisolone sodium, minocycline, and hydrocortisone sodium succinate.[1]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Doxapram HCl for Injection: 20 mg/mL; 20 mL multi-dose vial; *Dopram-V®*, *Respiram®*; (Rx). FDA-approved for use in dogs, cats, and horses. Although this drug is still listed in the FDA's Green Book of approved animal drugs, it may not be commercially available.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Doxapram HCl for Injection: 20 mg/mL in 20 mL multi-dose vials; *Dopram®*, (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Doxepin

(***dox***-e-pin) *Sinequan® Sinequan®*

Tricyclic Antidepressant, Antihistamine

Prescriber Highlights

- ► Used primarily in small animal species for adjunctive therapy of pruritus associated with atopic dermatitis and psychogenic dermatoses, particularly those that have an anxiety component; also has anticholinergic, alpha-1-adrenergic, and antihistaminic (H1, H2) properties
- ► Contraindications include prior sensitivity to tricyclic antidepressants (TCAs) and concomitant use with monoamine oxidase inhibitors (MAOIs).
- ► Use with extreme caution in patients with urinary retention or glaucoma.
- ► Common adverse effects include hyperexcitability, GI distress, or lethargy.

Uses/Indications

The primary use for doxepin in veterinary medicine is for the adjunctive therapy of pruritus associated with atopic dermatitis and psychogenic dermatoses, particularly those that include an anxiety component (eg, tail biting, flank sucking, anal licking, acral lick dermatitis, excessive grooming, psychogenic alopecia, feather plucking). Its efficacy as an antihistamine for atopic dermatitis is in question[1,2]; however, it may be beneficial in dogs to prevent acute flares of mild pruritus associated with atopic dermatitis[3] and concurrent behavior abnormalities. Anecdotally, doxepin has also been used to improve clinical signs in animals with canine laryngeal paralysis, but in one study its use did not improve quality of life.[3]

Pharmacology/Actions

Doxepin is a tricyclic antidepressant. In the CNS, doxepin inhibits the reuptake of norepinephrine and serotonin (5-HT) by the presynaptic neuronal membrane, thereby increasing their synaptic concentrations. Doxepin is considered a moderate inhibitor of norepinephrine and weak inhibitor of serotonin. Doxepin also has anticholinergic, alpha-1-adrenergic, and potent antihistamine effects.

Pharmacokinetics

Pharmacokinetic information in veterinary species is lacking. In humans, doxepin appears to be well-absorbed after oral administration and is extensively metabolized in the liver.

Contraindications/Precautions/Warnings

Doxepin is contraindicated if prior sensitivity to any other tricyclic antidepressant (TCA) has been noted. Monoamine oxidase inhibitors should be discontinued at least 14 days prior to starting doxepin. Doxepin should be used with extreme caution in patients with urinary retention or glaucoma. Use with caution or avoid use in patients with cardiovascular disease. Use with caution in patients with a history of seizures, as it may lower seizure threshold.

In humans who have taken doxepin chronically, it is recommended to withdraw the drug slowly; this caution likely applies to veterinary patients.

Do not confuse DOXepin with DIGoxin, doxaPRAM or doxycycline.

Adverse Effects

In dogs, doxepin may cause hyperexcitability, GI distress, constipation, urine retention, or lethargy. Although doxepin has less potential for cardiac adverse effects than many other TCAs, it can cause ventricular arrhythmias, particularly after overdose. In humans, common adverse effects include CNS depression, tremor, weakness, blurred vision, dry eyes, hypotension, tachycardia, constipation, urinary retention, and blood dyscrasias.

Reproductive/Nursing Safety

Reproduction studies in rats, rabbits, monkeys, and dogs indicate no evidence of fetal harm.

Doxepin and its N-demethylated active metabolite are distributed into milk in concentrations that are roughly equivalent to that of plasma. Exercise caution when using in a nursing patient.

Overdose/Acute Toxicity

Overdoses with TCAs can quickly become life-threatening. Manifestations may include arrhythmias, profound hypotension, cardiorespiratory collapse, seizures, and coma. Airway support, antiarrhythmics, and anticonvulsants often are required; inducing emesis is contraindicated. Doxepin toxicity may be amenable to activated charcoal and IV lipid emulsion (ILE) treatments.[4]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving doxepin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Agents** (eg, **atropine, oxybutynin**): Because of additive effects, use with doxepin cautiously.
- **Antihistamines** (eg, **diphenhydramine, hydroxyzine, meclizine**): Potential for increased sedation
- **Antiplatelet Agents** (eg, **aspirin, clopidogrel**): Increased risk for bleeding
- **Cannabidiol**: Additive CNS depression is possible.
- **Cimetidine**: May inhibit tricyclic antidepressant metabolism and increase the risk for toxicity
- **Hypotensive Agents** (eg, **amlodipine, enalapril, prazosin, telmisartan**): Additive blood pressure reduction is possible
- **Dextromethorphan**: Increased risk for serotonin syndrome.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid,** possibly **selegiline**): Concomitant use (within 14 days) of tricyclics with monoamine oxidase inhibitors is generally contraindicated due to risk for serotonin syndrome.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam, robenacoxib**): Increased risk for bleeding
- **Opioids** (eg **buprenorphine, morphine**): Additive CNS depression and anticholinergic effects may occur. The risk for serotonin syndrome may be increased when doxepin is used concurrently with opioids with greater serotonergic activity (eg, **meperidine, tramadol).**
- **Phenobarbital**: May reduce doxepin concentration
- **Prokinetic Agents** (eg, **bethanechol, cisapride, metoclopramide**): Doxepin may decrease prokinetic effects.
- **QT Prolongation Agents** (eg, **amiodarone, chlorpromazine, cisapride, fluconazole, fluoxetine, ketoconazole, methadone, ondansetron, quinidine, sotalol**): May increase risk for QT prolongation
- **Serotonergic Agents** (eg, **buspirone**, **fluoxetine**, **mirtazapine, trazodone**): Increased risk for serotonin syndrome
- **Sympathomimetic Agents** (eg, **albuterol, phenylpropanolamine**): Use in combination with tricyclic agents may increase the risk for cardiac effects (eg, arrhythmias, hypertension, hyperpyrexia).
- **Tramadol**: Increased risk for serotonin syndrome

Laboratory Considerations

- Tricyclics can widen QRS complexes, prolong PR intervals, and invert or flatten T-waves on **ECG**.
- Tricyclics may alter (increase or decrease) **blood glucose** levels.
- **Intradermal allergy testing (IDT)**: Antihistamines may suppress IDT results. It is recommended to discontinue antihistamine 1 week prior to testing; a 2-day withdrawal should be considered the minimum.[5,6]

Dosages

DOGS:

Pruritus associated with atopic dermatitis | Antihistamine (extra-label):

a) 0.5 – 1 mg/kg PO every 12 hours, then titrate upward to maximum as for psychogenic dermatoses (above). There is little evidence to support any dosage recommendation.[7]

b) Apply doxepin 5% cream to affected areas up to 4 times daily.[8-10]

Psychogenic dermatoses (extra-label): 3 – 5 mg/kg (maximum dose 50 mg/dog [NOT mg/kg]) PO every 12 hours. Generally, start at the low end of the dosing range and increase in increments of 1 mg/kg every 12 hours every two weeks to the maximum (5 mg/kg or 50 mg/dog [NOT mg/kg]). If no effect is seen after 4 weeks, wean to the starting dose in increments of 1 mg/kg every 12 hours every two weeks before discontinuing. There is little evidence to support any dosage recommendation.[6,11]

CATS:

Psychogenic dermatoses and allergies (extra-label): 0.5 – 1 mg/kg PO every 12 to 24 hours. May titrate slowly upward if cat tolerates, but many cats become profoundly sedated and ataxic at higher dosages. There is little evidence to support any dosage recommendation.[4,5]

HORSES:

Antihistamine (extra-label): 0.5 – 0.75 mg/kg PO every 12 hours[12]

BIRDS:

Anxiety, pruritus-caused feather plucking in psittacines (extra-label): 0.5 – 2 mg/kg PO every 12 hours[13]

Monitoring

- Efficacy
- Adverse effects

Client Information

- When used as an antihistamine, doxepin should be used on a regular, ongoing basis in animals that respond to it. This medicine works better if used before exposure to an allergen (eg, pollens).
- When doxepin is used for behavior modification, it may take several days to several weeks to determine if the drug is effective.
- This medicine may be given with or without food. If your animal vomits or acts sick after receiving this medicine on an empty stomach, try giving the next dose with food or small treat. If vomiting continues, contact your veterinarian.
- Most common side effects are sleepiness, dry mouth, and constipation. Be sure your animal has access to plenty of fresh, clean water.
- Rare side effects that can be serious (contact veterinarian immediately) include abnormal bleeding, fever, seizures, collapse, or profound sleepiness.
- Overdoses (in animals and in humans) can be very serious; keep out of the reach of animals and children.
- Certain flea and tick collars should not be used on your animal while it is receiving this medicine. Let your veterinarian know if your animal has worn a flea and tick collar in the past 2 weeks.

Chemistry/Synonyms

A dibenzoxazepine derivative tricyclic antidepressant, doxepin HCl occurs as a white powder that is freely soluble in water and alcohol.

Doxepin may also be known as doxepini hydrochloridum, NSC-108160, P-3693A, *Adapin®*, *Anten®*, *Aponal®*, *Deptran®*, *Desidoxepin®*, *Doneurin®*, *Doxal®*, *Doxepia®*, *Gilex®*, *Mareen®*, *Quitaxon®*, *Sinequan®*, *Triadapin®*, *Xepin®*, and *Zonalon®*.

Compatibility/Compounding Considerations

No specific information noted

Storage/Stability

Store doxepin products protected from direct sunlight in tight, light-resistant containers at room temperature (20°C-25°C [68°F-77°F]).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Doxepin Capsules: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg and 150 mg; generic; (Rx)

Doxepin Tablets: 3 mg and 6 mg; *Silenor®*; (Rx)

Doxepin Oral Solution Concentrate: 10 mg/mL in 120 mL; generic; (Rx)

Doxepin Hydrochloride 5% Cream: 45 gram; generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Doxorubicin

(dox-oh-***roo***-bi-sin) *Adriamycin®*

Antineoplastic

Prescriber Highlights

- ► Injectable antibiotic antineoplastic used alone or in combination chemotherapy protocols in small animal species
- ► Relatively contraindicated in patients with myelosuppression, with impaired cardiac function, or that have reached the total cumulative dose of doxorubicin
- ► Caution is recommended in patients with hyperuricemia, hyperuricuria, or impaired hepatic function; dosage adjustments may be necessary.
- ► Monitor cardiac status carefully or avoid use in breeds predisposed to developing cardiomyopathy (eg, Doberman pinschers, Great Danes, rottweilers, boxers).
- ► Adverse effects include myelosuppression, cardiac toxicity (dogs), nephrotoxicity (cats), alopecia, gastroenteritis (eg, vomiting, diarrhea), and stomatitis.
- ► Immediate hypersensitivity has been reported (primarily in dogs).
- ► Avoid extravasation; vesicant injuries can be severe.
- ► Teratogenic and embryotoxic. Handle and administer drug carefully.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies doxorubicin as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Doxorubicin is perhaps the most widely used antineoplastic agent in small animal medicine. In dogs and cats, it may be useful in the treatment of a variety of lymphomas, leukemias, carcinomas, and sarcomas, either as a single agent or in combination protocols.

Pharmacology/Actions

Although doxorubicin possesses antimicrobial properties, its cytotoxic effects preclude its use as an anti-infective agent. The drug causes inhibition of DNA synthesis, DNA-dependent RNA synthesis, and protein synthesis by inhibiting DNA and RNA polymerases and impairing topoisomerase II, as well as through generation of free radicals. Doxorubicin alters transcription and replication by intercalating with DNA base pairs.[1] The drug acts throughout the cell cycle and also possesses some immunosuppressant activity. Rapidly proliferating normal cells (eg, bone marrow, hair follicles in anagen, GI mucosa) are affected by the drug.

Pharmacokinetics

Doxorubicin must be administered IV, as it is not absorbed from the GI tract, and is extremely irritating to tissues if administered SC or IM. After IV injection, the drug is rapidly and widely distributed, but it does not appreciably enter the CSF. Doxorubicin is highly bound to tissue and plasma proteins, probably crosses the placenta, and is distributed into milk.

Doxorubicin is extensively metabolized in the liver and other tissues by aldo-keto reductase, primarily to form doxorubicinol (active) and other inactive metabolites. Doxorubicin and its metabolites are excreted mostly in bile and feces. Only ≈5% of the drug is excreted in the urine within 5 days of dosing. Doxorubicin is eliminated in a triphasic manner. During the first phase (half-life, ≈0.6 hours), doxorubicin is rapidly metabolized via the first pass effect; a second phase (half-life, ≈3.3 hours) follows. The third phase has a slower elimination half-life (doxorubicin, ≈17 hours; metabolites, ≈32 hours), presumably due to the slow release of the drug from tissue proteins.

Contraindications/Precautions/Warnings

Only clinicians who have the experience and resources to monitor the toxicity of this agent should administer this drug. Doxorubicin is contraindicated in patients hypersensitive to it or other anthracyclines, with pre-existing myelosuppression or impaired cardiac function, or that have reached the total cumulative dose concentration of doxorubicin or other anthracyclines.[2]

Doxorubicin is contraindicated in cats with pre-existing renal insufficiency.

Doxorubicin should be used with caution in patients with hyperuricemia, hyperuricuria, or impaired hepatic function. Dosage reductions are necessary in patients with severe hepatic impairment.

Extreme care must be taken to avoid perivascular extravasation. Securely placed indwelling IV catheters and close monitoring of IV patency/integrity during infusion are recommended. Automated fluid pumps should not be used. Doxorubicin should be administered IV slowly over at least 10 to 15 minutes in a free-flowing line.

Breeds predisposed to developing dilated cardiomyopathy (eg, Doberman pinschers, Great Danes, rottweilers, boxers) should be monitored carefully (see ***Monitoring***) while receiving doxorubicin therapy.

Doxorubicin is actively transported by the p-glycoprotein pump. Certain breeds that are susceptible to mutation in the *MDR1* gene (also known as *ABCB1*; including but not limited to collies, Australian shepherds, Shetland sheepdogs, and long-haired Whippets) may be at higher risk for toxicity. In dogs with the *MDR1* mutation, myelosuppression (particularly neutropenia) and GI toxicity (eg, anorexia, vomiting, diarrhea) are more likely to occur at normal dosages. If a mutant/normal dog must receive doxorubicin, a reduced dose should be given to decrease the likelihood of severe toxicity.[3] Doxorubicin should be avoided in mutant/mutant dogs.[4]

After treatment, doxorubicin drug residues may be found in a treated dog's urine for up to 21 days and in feces for several days.[5]

The National Institute for Occupational Safety and Health (NIOSH) classifies doxorubicin as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Do not confuse conventional doxorubicin formulations with liposomal doxorubicin. Do not confuse DOXOrubicin with doxapram.

Adverse Effects

Doxorubicin may cause myelosuppression, cardiac toxicity, alopecia, gastroenteritis (eg, vomiting, diarrhea), and stomatitis. After administration, nausea and vomiting most commonly occur within the first 72 hours, diarrhea can occur in ≈4 to 5 days, and neutrophil and platelet nadirs are generally observed after 7 to 10 days. Systemic doxorubicin exposure, as measured by AUC, demonstrates a relationship to neutrophil nadir and the degree of neutropenia; however, the clinical application of this finding is unclear.[7]

In dogs, administration of maropitant 2 mg/kg PO daily for 5 days immediately followed by doxorubicin has been shown to reduce the frequency and severity of vomiting and diarrhea the first week after treatment.[8]

An immediate histamine-mediated hypersensitivity reaction characterized by urticaria, facial swelling, vomiting, arrhythmias, and/or hypotension may be seen (particularly in dogs). The rate of infusion can have a direct impact on this effect; generally, IV infusions should be administered no faster than over 10 minutes. Pretreatment with a histamine$_1$ antagonist (eg, diphenhydramine 1 – 2 mg/kg IM) or a glucocorticoid (eg, dexamethasone 0.1 – 0.2 mg/kg IV or IM) have been used to reduce or prevent histamine-mediated effects.

Cardiac toxicity of doxorubicin falls into 2 categories: acute and cumulative. Acute cardiac toxicity may occur during IV administration or several hours after the drug is given. This toxicity is manifested by ECG changes (eg, T-wave flattening, S-T depression, voltage reduction, arrhythmias), and in humans, may include cardiac arrest. Acute cardiac toxicity does not preclude further use of the drug, but additional treatment should be delayed. Administration of diphenhydramine and/or glucocorticoids before doxorubicin may prevent these effects.

Doxorubicin-iron complex free radicals are thought to be the primary cause of cardiomyopathy and extravasation injury. Cumulative cardiotoxicity can be extremely serious and necessitates halting any further therapy. Diffuse cardiomyopathy, with severe congestive heart failure refractory to traditional therapies, is generally noted. It is believed that the risk for cardiac toxicity is greatly increased in dogs when the cumulative doxorubicin dose exceeds 180 – 240 mg/m^2 (NOT mg/kg); however, cardiac toxicity may be seen at cumulative doses as low as 90 mg/m^2 (NOT mg/kg), particularly in dog breeds predisposed to dilated cardiomyopathy. In dogs, the safety of concurrent administration of the cardioprotective agent dexrazoxane has been documented,[9,10] but the benefit of such therapy in preventing cardiotoxicity in this species has not yet been prospectively evaluated.

Doxorubicin-associated alopecia in dogs may be generalized or local and may include loss of whiskers[11]; cats may lose whiskers and guard hairs.

In cats, doxorubicin is a potential nephrotoxin; renal chemistry values (eg, BUN, creatinine) should be monitored both before and during therapy.[12,13] The incidence of cardiotoxicity or the dosage ceiling for doxorubicin in cats is unknown.

Extravasation injuries secondary to perivascular administration of doxorubicin can be serious, with severe tissue ulceration and necrosis and subsequent tissue sloughing possible. If extravasation occurs, dexrazoxane can be administered (through a new IV catheter placed in a different vein) at 10 times the doxorubicin dosage immediately (within 3-6 hours of extravasation), with doses repeated at 24 hours and at 48 hours in most cases (see ***Dexrazoxane***).[10,14,15] In addition, ice compresses should be applied to the affected area for 15 minutes every 6 hours for 48 hours.

Reproductive/Nursing Safety

For sexually intact patients, verify pregnancy status prior to administration.

Doxorubicin is abortifacient, teratogenic, and embryotoxic in laboratory animals given doses lower than the clinical dose. Other effects include decreased fertility in females, as well as testicular atrophy and oligospermia in males.

Doxorubicin is excreted in milk in concentrations that may exceed those found in plasma. Because of risks to nursing offspring, consider using milk replacer if the dam is receiving doxorubicin.

Overdose/Acute Toxicity

Acute overdose may manifest as exacerbations of the adverse effects. In dogs, a lethal dose has been reported to be 72 mg/m^2 (NOT mg/kg).[16] Supportive therapy in response to clinical signs (eg, antiemetics, antidiarrheals, GI protectants, broad-spectrum antibacterial coverage, filgrastim) are suggested in cases of overdose.[10]

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving doxorubicin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Calcium Channel Blockers** (eg, **diltiazem, verapamil**): Potential increased risk for cardiotoxicity associated with doxorubicin
- **Cisplatin**: Increased risk for toxicity (eg, myelosuppression); carefully weigh the risks versus the benefits.
- **Cyclophosphamide**: May increase doxorubicin blood concentrations (AUC) and prolong hematologic toxicity; coma and seizures have been reported in humans. A study in dogs, in which 1 of the treatment protocols combined doxorubicin and cyclophosphamide, did not find a significant difference in the prevalence of toxicity.[17]
- **Cyclosporine**: Cyclosporine can increase doxorubicin and doxorubicinol (active metabolite) concentrations. Avoid use together.
- **Glucosamine**: May reduce doxorubicin effectiveness; use together not recommended in humans
- **Ketoconazole**: Can increase doxorubicin and doxorubicinol (active metabolite) concentrations and lead to toxicity. Avoid use together.
- **Leflunomide**: May have additive adverse hematologic toxicity
- **Morphine**: Concurrent use may increase morphine exposure.
- **Phenobarbital**: May increase elimination and reduce blood concentrations of doxorubicin
- **Quinidine**: Concurrent use may result in increased doxorubicin exposure.
- **Spinosad**: Can increase doxorubicin and doxorubicinol (active metabolite) concentrations and lead to toxicity. Avoid use together.
- **Streptozocin**: May inhibit doxorubicin metabolism
- **Vaccines**. Live or live-attenuated vaccines may result in active infections in immunocompromised patients.
- **Warfarin**: Increased risk for bleeding
- **Zidovudine**: Increased risk for neutropenia

Laboratory Considerations

- Doxorubicin may significantly increase both blood and urine concentrations of **uric acid.**

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary staff, and pet owners and because chemotherapy indications, treatment protocols, monitoring, and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[18-22] are strongly recommended. All dosages are extra-label. **When administering doxorubicin, do NOT flush IV catheters with heparin or heparinized saline; use sterile saline** (See ***Compatibility/Compounding Considerations***).

DOGS:

Chemotherapeutic agent (extra-label): 30 mg/m^2 (NOT mg/kg) IV every 2 to 3 weeks, depending on the protocol used. Smaller patients (eg, less than 10-15 kg [22-33 lb]) may be dosed at 1 mg/kg IV. The maximum cumulative dose is 180 – 240 mg/m^2 (NOT mg/kg) depending on breed and risk factors.

CATS:

Chemotherapeutic agent (extra-label):

a) 20 – 25 mg/m^2 (NOT mg/kg) IV every 3 weeks
b) 1 mg/kg IV every 3 weeks

FERRETS:

Chemotherapeutic agent (extra-label):

a) 20 mg/m^2 (NOT mg/kg) IV[23,24]; premedicate with diphenhydramine 1 – 2 mg/kg IM 30 minutes before doxorubicin administration
b) 2 mg/kg IV[24]; premedicate with diphenhydramine 1 – 2 mg/kg IM 30 minutes before doxorubicin administration

Rescue therapy (extra-label): 1 – 2 mg/kg IV[23]; premedicate with diphenhydramine 1 – 2 mg/kg IM 30 minutes before doxorubicin administration

HORSES:

Chemotherapeutic agent (extra-label): 70 mg/m^2 (NOT mg/kg) IV every 3 weeks. Adjunctive treatment with antihistamines and NSAIDs should be used to control hypersensitivity.[25,26]

Monitoring

- Baseline CBC, serum chemistry profile, urinalysis
- Prior to each chemotherapy, check CBC, BUN, creatinine, and USG
- Dogs with pre-existing heart disease should be monitored with echocardiography;[27] baseline and every 60 – 90 mg/m^2 (NOT mg/kg) cumulative dose increments could be considered. Cardiac troponin I can be a sensitive tool for detecting doxorubicin cardiotoxicity.[28]
- Efficacy/response to therapy

Client Information

- Doxorubicin is a chemotherapy (anticancer) drug. The drug and its byproducts can be hazardous to other animals and humans. On the day your animal receives the drug and for ≈72 hours after,

all bodily waste (eg, urine, feces, litter), blood, or vomit should be handled only while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in the regular trash. Pregnant women SHOULD NOT handle any waste or items used to clean the waste while your animal is on this drug.

- Doxorubicin has a maximum total amount that can be given to a patient over its lifetime. Exceeding this limit greatly increases the chance that your animal will develop heart damage from the drug. Your veterinarian will be keeping track of how much doxorubicin your animal has received.
- Your veterinarian will need to perform examinations and lab work on your animal after it receives this medication. Do not miss these important follow-up visits.
- Your animal should not receive vaccines containing live (or modified live) viruses while receiving this medication.
- In the interest of safety to other animals and humans, don't take your dog to a dog park or allow your animal to urinate and defecate in public places until your veterinarian tells you that it is okay to do so.
- Your animal should not participate in animal competitions while on this drug. Exposure to other animals may put your animal at serious risk of infections during chemotherapy treatment. Talk with your veterinarian about when itis safe to return to these events.
- Immediately report any signs associated with toxicity (eg, abnormal bleeding, bruising, infection, fever, gastrointestinal upset, injection site irritation).
- It is normal for urine to appear red for 1 to 2 days after administration.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Doxorubicin HCl, an anthracycline glycoside antibiotic antineoplastic, occurs as a lyophilized, red–orange powder that is freely soluble in water, slightly soluble in normal saline, and very slightly soluble in alcohol. The commercially available powder for injection also contains lactose and methylparaben to aid dissolution. After reconstituting, the solution has a pH of 3.8 to 6.5. The commercially available solution for injection has a pH of ≈3.

Doxorubicin HCl may also be known as cloridrato de doxorrubicina, doxorubicini hydrochloridum, NSC-123127, *Adriamycin RDF®*, *Adriblastin®*, *Adriblastina®*, *Adriblastine®*, *Adrim®*, *Adrimedac®*, *Biorrub®*, *DOXO-cell®*, *Doxolem®*, *Doxorbin®*, *Doxorubin®*, *Doxotec®*, *Doxtie®*, *Farmiblastina®*, *Fauldoxo®*, *Flavicina®*, *Ifadox®*, *Neoxan®*, *Ribodoxo-L®*, and *Rubex®*.

Storage/Stability

Lyophilized powder for injection should be stored away from direct sunlight and in a dry place. After reconstituting with sodium chloride 0.9%, the single-use lyophilized powder product is reportedly stable for 24 hours at room temperature and 48 hours when refrigerated. The manufacturer recommends protecting from sunlight, not freezing the product, and discarding any unused portion. However, one study found that powder reconstituted with sterile water to a concentration of 2 mg/mL lost only ≈1.5% of its potency per month over 6 months when stored in the refrigerator. When frozen at -20°C (-68°F), no potency loss after 30 days was detected, and sterility was maintained by filtering the drug through a 0.22-micron filter before injection.

The manufacturer states that after reconstitution, the multidose vials may be stored for up to 7 days at room temperature in normal room light and up to 15 days in the refrigerator.

The commercially available solution for injection is stable for 18 months when stored in the refrigerator at 2°C to 8°C (36°F-46°F) and protected from light.

Compatibility/Compounding Considerations

Do not flush IV catheters with heparin or heparinized saline; use sterile saline.

Doxorubicin HCl is reportedly physically **compatible** with the following IV solutions and drugs: dextrose 3.3% in sodium chloride 3%, D_5W, *Normosol® R* (pH 7.4), lactated Ringer's injection, and sodium chloride 0.9% and in syringes with bleomycin sulfate, cisplatin, cyclophosphamide, droperidol, fluorouracil, leucovorin calcium, methotrexate sodium, metoclopramide HCl, mitomycin, and vincristine sulfate. The drug is physically **compatible during Y-site injection** with bleomycin sulfate, cisplatin, cyclophosphamide, droperidol, fluorouracil, leucovorin calcium, methotrexate sodium, metoclopramide HCl, mitomycin, and vincristine sulfate.

Doxorubicin HCl **compatibility information conflicts** or is dependent on diluent or concentration factors with the following drugs or solutions: vinblastine sulfate (in syringes and as an IV additive). Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Doxorubicin HCl is reportedly physically **incompatible** with the following solutions or drugs: aminophylline, dexamethasone sodium phosphate, diazepam, fluorouracil (as an IV additive only), furosemide, heparin sodium, and hydrocortisone sodium succinate.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Doxorubicin HCl (Conventional) Lyophilized Powder for Injection, (conventional): 10 mg and 150 mg vials; *Adriamycin RDF®*, generic; (Rx). Reconstitute with appropriate amount of 0.9% sodium chloride for final concentration of 2 mg/mL.

Doxorubicin HCl (Conventional) Injection (aqueous): 2 mg/mL in 5 mL, 10 mL, 25 mL, and 100 mL; *Adriamycin PFS®*, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Doxycycline

(dox-i-***sye***-kleen) *Vibramycin®, Doxy 100®*

Tetracycline Antibiotic

Prescriber Highlights

- ► Oral and parenteral tetracycline antibiotic
- ► Bone and teeth abnormalities are possible but much less likely to occur than with other tetracyclines; ensure benefits outweigh potential risks in pregnant and pediatric animals.
- ► May be used in patients with renal insufficiency
- ► Not for IV injection in horses. Should not be given IM or SC to any species due to injection site adverse effects
- ► Most common adverse effects are GI, but increased liver enzymes can occur.
- ► Esophagitis and strictures are possible, particularly in cats. Oral doses must be followed with sufficient fluid to minimize the risk for medication becoming lodged in the esophagus.
- ► Drug interactions with mineral-containing antacids, iron products, and other antibiotics are well documented.

Uses/Indications

Although there are no FDA-approved systemic veterinary doxycycline products available, the drug's efficacy, favorable pharmacokinetic parameters (ie, longer half-life, wide volume of distribution, higher CNS penetration), and safety profile, as compared with tetracycline or oxytetracycline, make it the preferred choice in small animal species when a tetracycline is indicated, particularly in azotemic patients.

Doxycycline is commonly used in small animals to treat a variety of infections caused by several different microorganisms, including *Borrelia* spp, *Leptospira* spp, *Rickettsia* spp, *Anaplasma* spp, *Ehrlichia* spp, *Chlamydia* spp, *Mycoplasma* spp, *Bartonella* spp, and *Bordetella* spp. In a study, use of doxycycline to treat *A phagocytophilum* infection resulted in clinical resolution in all infected dogs (n = 16)[1], all of which became blood PCR-negative 30 and 60 days after treatment onset. Hematologic abnormalities (ie, leukopenia, eosinophilia, lymphopenia) persisted in 4 dogs. A small study suggested that a combination of doxycycline, clindamycin, and metronidazole may be an effective alternative treatment for canine babesiosis caused by *Babesia gibsoni* in dogs that fail first-line therapy (atovaquone and azithromycin).[2]

Doxycycline therapy is part of the American Heartworm Society's recommended canine heartworm treatment protocol.[3,4] *Dirofilaria immitis* harbors *Wolbachia* spp organisms as endosymbiotic bacteria. The presence of *Wolbachia* spp—even in very low numbers—appears necessary for filarial embryogenesis. In addition, *Wolbachia* spp organisms contribute to pulmonary and renal inflammation of filarial disease.[3] Doxycycline greatly reduces *Wolbachia* spp organisms in filarial nematodes, which can result in amicrofilaremia for up to 12 months.[3,4] Antibiotic resistance has been noted in heartworm-treated dogs receiving adjunctive doxycycline therapy,[5] but this data should not prevent doxycycline use in dogs requiring adulticidal therapy.

In a study, 6 dogs were given subantimicrobial doses of systemic doxycycline to treat experimentally induced periodontitis,[6] which was effectively treated, and antimicrobial resistance did not appear to be induced[7]; however, systemic use of antimicrobial drugs for nonantimicrobial uses is discouraged.[7]

In foals with mild to moderate bronchopneumonia, the combination of doxycycline and azithromycin appears effective in treating *Rhodococcus equi*.[8] In horses, doxycycline use for synovial infection may be a suitable first-line treatment of synovial sepsis while culture and susceptibility results are pending,[9] but a negative effect on return to function following doxycycline use has also been demonstrated.[10] The usefulness of doxycycline will likely depend on regional susceptibility of expected pathogens.

In avian species, doxycycline may be a suitable first-line choice for oral treatment of chlamydiosis.[11,12]

The World Health Organization (WHO) has designated doxycycline as a Highly Important antimicrobial in human medicine.[13] The Office International des Epizooties (OIE) has designated doxycycline as a Veterinary Critically Important Antimicrobial (VCIA) Agent in avian, bovine, camelid, caprine, equine, lagomorph, ovine, piscine, and swine species.[14]

Pharmacology/Actions

Tetracyclines are time-dependent bacteriostatic antibiotics that inhibit protein synthesis by reversibly binding to 30S ribosomal subunits of susceptible organisms, thereby preventing aminoacyl transfer-RNA binding to those ribosomes. Tetracyclines also alter cytoplasmic membrane permeability in susceptible organisms. In high concentrations, tetracyclines can also inhibit protein synthesis by mammalian cells.

Doxycycline generally has similar activity as other tetracyclines against susceptible organisms, but some strains of bacteria, including methicillin resistant *Staphylococcus pseudintermedius* (MRSP), may be more susceptible to doxycycline or minocycline; additional in vitro testing may be required.

Tetracyclines have activity against most *Mycoplasma* spp, spirochetes (including *Borrelia burgdorferi*, the causative agent for Lyme disease), *Chlamydia* spp, and *Rickettsia* spp. For gram-positive bacteria, tetracyclines have activity against some strains of staphylococci and streptococci, but resistance by these organisms is increasing.[15]

Staphylococcal resistance to tetracyclines occurs via the *tet*(K) and *tet*(M) genes. *tet*(K) confers resistance to tetracycline but not doxycycline or minocycline, whereas *tet*(M) confers resistance to tetracycline, doxycycline, and minocycline. Tetracycline susceptibility indicates doxycycline susceptibility; however, the reverse is not true. Tetracycline-resistant bacteria can be susceptible to doxycycline, necessitating doxycycline susceptibility testing.

Other gram-positive bacteria that are usually susceptible to tetracyclines include *Actinomyces* spp, *Bacillus anthracis, Clostridium perfringens*, *C tetani*, *Listeria monocytogenes*, and *Nocardia* spp. Tetracyclines usually have in vitro and in vivo activity against some gram-negative bacteria, including *Bordetella* spp, *Brucella* spp, *Bartonella* spp, *Haemophilus* spp, *Pasteurella multocida*, *Shigella* spp, and *Yersinia pestis*. Many or most strains of *Escherichia coli, Klebsiella* spp, *Bacteroides* spp, *Enterobacter* spp, *Proteus* spp, and *Pseudomonas aeruginosa* are resistant to tetracyclines.[16]

Minocycline and doxycycline have significant inhibitory properties against the activity of matrix metalloproteinases (eg, collagenase, gelatinase) and can act as a disease-modifying agent for osteoarthritis. In a pharmacokinetic study, doxycycline at 5 mg/kg PO every 48 hours significantly decreased synoviocyte matrix metalloproteinase (MMP)-13 concentration and gene expression in healthy horses.[17] The clinical relevance of this is unclear.

Doxycycline did not impair olfactory function in explosives detection dogs.[18]

Pharmacokinetics

In most species, doxycycline is well absorbed after oral administration. Bioavailability after PO administration is 90% to 100% in humans, and the drug is thought to be readily absorbed in most monogastric animals. Unlike tetracycline or oxytetracycline, doxycycline absorption in humans may only be reduced by 20% by either a high-fat meal or dairy products in the gut. However, in horses, oral administration of doxycycline in the fed state may reduce bioavailability, possibly because of the high fiber content in most equine diets.[19]

Tetracyclines are generally widely distributed to the heart, kidneys, lungs, muscle, pleural fluid, bronchial secretions, sputum, bile, synovial fluid, and ascitic fluid in most species. Doxycycline is more lipid soluble and penetrates body tissues and fluids better than tetracycline or oxytetracycline, including into the CSF, prostate, and eye. Although CSF concentrations are generally insufficient to treat most bacterial infections, doxycycline has been shown to be efficacious in the treatment of CNS effects associated with *Borrelia burgdorferi* infection in humans. Doxycycline (10 mg/kg PO every 12 hours) given to horses did not yield appreciable concentrations in the aqueous or vitreous humor,[20] but 20 mg/kg every 24 hours resulted in an aqueous humor concentration that was 10% to 75% that of plasma.[21] Drug concentration in tear film did not appear to be dose-related[22]; the tear:serum ratio in cats and dogs was 12% and 16%, respectively.[23] In horses, doxycycline has been shown to penetrate into the synovial fluid with an AUC synovial fluid-to-plasma factor of 4.6 and is eliminated from synovial fluid more slowly than plasma.[24]

The volume of distribution at steady state in dogs is ≈1.5 L/kg. Doxycycline is bound to plasma proteins in varying amounts depending on the species. The drug is ≈25% to 93% bound to plasma

proteins in humans, 75% to 86% in dogs, 82% in horses, and ≈93% in cattle and pigs. Cats have higher binding to plasma proteins as compared with dogs. Doxycycline accumulates intracellularly and concentrates in equine polymorphonuclear neutrophils (PMNs).[21]

Doxycycline's elimination from the body is relatively unique. The drug is primarily excreted into the feces via nonbiliary routes in an inactive form. The drug is thought to be partially inactivated in the intestine by chelate formation and excreted into the intestinal lumen; in dogs, ≈75% of a dose is processed in this manner. Renal excretion of doxycycline can only account for ≈25% of a dose in dogs, and biliary excretion can only account for less than 5%.[25] The serum half-life of doxycycline in dogs is ≈10 to 12 hours, and clearance is ≈1.7 mL/kg/minute[25]; similar pharmacokinetic values are found in calves. In horses, elimination half-life is 9 to 12 hours,[21,26] and estimated clearance is ≈0.7 mL/kg/minute.[27] Doxycycline does not accumulate in patients with renal dysfunction.

Contraindications/Precautions/Warnings

Doxycycline is contraindicated in patients that are hypersensitive to it. Because tetracyclines can retard fetal skeletal development, discolor deciduous teeth, and lead to enamel hypoplasia; tetracyclines should only be used in the last half of pregnancy when the benefits outweigh the fetal risks; however, doxycycline is much less likely to cause these abnormalities than other more water-soluble tetracyclines (eg, tetracycline, oxytetracycline). Unlike oxytetracycline or tetracycline, doxycycline can be used in patients with renal insufficiency. Because increases in hepatic enzymes have been documented in some dogs after doxycycline treatment, this drug should be used with caution in dogs that have significant liver dysfunction. Tetracycline therapy (especially long-term) may result in overgrowth (ie, superinfections) of nonsusceptible bacteria or fungi. In humans, tetracyclines can cause photosensitivity; limit sun exposure for patients with thin or light-colored coats.

Doxycycline use has been associated with the development of esophageal stricture, particularly in cats.[28–32] If using oral tablets in cats, pilling should be followed by at least 5 mL of water or food.[32] Dry pilling should be avoided. Oral doxycycline monohydrate may have a lower risk for causing esophagitis than the hyclate salt, as it is much less acidic and slower to dissolve in neutral solutions[32]; however, it is recommended that all oral formulations administered to cats should be followed by a water or food swallow, regardless of the salt used.[32,33]

In horses, IV injection of even relatively low doses of doxycycline has been associated with cardiac arrhythmias, collapse, and death.[34] Until further studies are performed to document the safety of IV doxycycline in horses, the parenteral route of administration should be considered contraindicated in horses.

Doxycycline is a P-glycoprotein substrate; however, the Washington State University Clinical Pharmacology Laboratory has reported no increased sensitivity to doxycycline in dogs with the multidrug sensitivity (*MDR1*; ie, *ABCB1*) gene mutation and does not recommend any dose alterations in these dogs.[35]

Adverse Effects

The most commonly reported adverse effects of oral doxycycline therapy in dogs and cats are vomiting, diarrhea, and anorexia. Giving the drug with food may help alleviate these GI effects without significantly reducing drug absorption. Doxycycline monohydrate may be less likely to cause GI adverse effects and esophagitis/strictures than doxycycline hyclate,[33] but comparative data in animals are lacking. Increased ALT and ALP have been reported in up to 40% of dogs and 19% of cats.[36] This increase does not appear to be clinically significant in dogs.[37]

Oral doxycycline has been implicated in causing esophagitis and esophageal strictures, particularly in cats. See ***Contraindications/Precautions/Warnings*** for more information.

In goats, IM injection has led to severe edema and pain at the injection site.[38]

In humans, doxycycline and other tetracyclines have also been associated with photosensitivity reactions and, rarely, hepatotoxicity or blood dyscrasias. In humans, IV administration should occur over a minimum of 1 hour, and the SC or IM routes should not be used.[39]

Reproductive/Nursing Safety

Tetracyclines cross the placenta; they are embryotoxic when used early in pregnancy and can retard fetal skeletal growth and permanently discolor teeth. A litter of puppies with midline and congenital cardiac defects was born to a dam treated with doxycycline, prednisone, and tramadol at 21 days gestation.[40]

Tetracyclines are excreted in milk. Milk:plasma ratios vary between 0.25 and 1.5. Dams that require doxycycline should not nurse their young.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

With the exception of IV administration in horses (see ***Adverse Effects***), doxycycline is apparently safe in most mild overdose cases. Oral overdoses most commonly cause GI disturbances (eg, vomiting, anorexia, diarrhea). Increased serum cardiac troponin 1 was found in 3 calves receiving doxycycline 32.5 mg/kg/day PO.[41]

Although doxycycline is less vulnerable to chelation with cations than other tetracyclines, oral administration of divalent or trivalent cation antacids may bind some of the drug and reduce GI distress. If a patient develops severe emesis or diarrhea, fluids and electrolytes should be monitored and replaced if necessary.

Rapid IV injection of doxycycline has induced transient collapse in horses[34] and cats[34,42] and cardiac arrhythmias in horses, presumably due to chelation with intravascular calcium ions. These effects may be more pronounced if overdose quantities are inadvertently administered.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving doxycycline and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Aluminum, Calcium,** and **Magnesium-Containing Oral Products**: When orally administered, tetracyclines can chelate divalent or trivalent cations that can then decrease the absorption of the tetracycline or the other drug if it contains these cations. Oral products that contain aluminum, calcium, or magnesium cations are most commonly associated with this interaction. Although doxycycline has a relatively low affinity for calcium ions, it is recommended that all oral tetracyclines be given at least 1 to 2 hours before or after any cation-containing product.
- **Ascorbic Acid** (ie, **Vitamin C**): May result in decreased doxycycline efficacy
- **Avermectins** (eg, **doramectin, ivermectin**): Doxycycline inhibited P-glycoprotein in an experimental model of the blood–brain barrier in alpacas. This interaction may have clinical rele-

vance in treating meningeal worms.[43]

- **Bismuth Subsalicylate**: May reduce absorption of tetracyclines; it is recommended that all oral tetracyclines be given at least 1 to 2 hours before or after bismuth subsalicylate.
- **Enrofloxacin**: Concurrent doxycycline use reduced and delayed enrofloxacin in vitro activity against *Escherichia coli*. Bactericidal effects were better with concomitant administration than when separated by 12 hours.[44]
- **Iron, Oral**: Oral iron products are associated with decreased tetracycline absorption, and administration of iron salts should preferably be 3 hours before or 2 hours after the tetracycline dose.
- **Kaolin/Pectin**: May reduce absorption of tetracyclines; it is recommended that all oral tetracyclines be given at least 1 to 2 hours before or after kaolin/pectin.
- **Penicillins**: Bacteriostatic drugs (eg, tetracyclines) may interfere with bactericidal activity of penicillins, cephalosporins, and aminoglycosides. The actual clinical significance, if any, of this interaction has likely been overstated.[45]
- **Phenobarbital**: May decrease doxycycline half-life and reduce concentrations
- **Proton Pump Inhibitors (PPIs)** (eg, **omeprazole, pantoprazole**): May reduce oral bioavailability of doxycycline
- **Sucralfate**: Concomitant sucralfate significantly reduces peak doxycycline concentration and overall exposure in dogs. No interaction occurred when sucralfate was administered 2 hours after doxycycline.[46]
- **Warfarin**: Tetracyclines may depress plasma prothrombin activity, and patients receiving anticoagulant (eg, warfarin) therapy may need a dosage adjustment.
- **Zinc**: When orally administered, tetracyclines can chelate divalent or trivalent cations that can then decrease the absorption of tetracycline or the other drug if it contains zinc; it is recommended that all oral tetracyclines be given at least 1 to 2 hours before or after the zinc-containing product.

Laboratory Considerations

- Tetracyclines (not minocycline) may cause falsely elevated values of **urine catecholamines** when fluorometric methods of determination are used.
- Tetracyclines can reportedly cause false positive **urine glucose** results if the cupric sulfate method of determination (Benedict's reagent, *Clinitest®*) is used; however, this may be the result of ascorbic acid that is found in some parenteral formulations of tetracyclines. Tetracyclines have also reportedly caused false-negative **urine glucose** results when the glucose oxidase method (*Clinistix®*, *Tes-Tape®*) is used.

Dosages

DOGS:

Susceptible bacterial infections (extra-label): 5 – 10 mg/kg PO every 12 to 24 hours. Treatment durations vary, but 7 to 14 days is commonly recommended.

a) **Acute respiratory infections** (extra-label): 5 mg/kg PO every 12 hours or 10 mg/kg PO every 24 hours; treat for 7 to 10 days[47]

b) **Adjunctive treatment for canine heartworm disease** (extra-label): In combination with an approved heartworm preventive, doxycycline 10 mg/kg PO every 12 hours for 4 weeks (days 1 through 28 of the American Heartworm Society protocol)[48]

c) **Leptospirosis** (extra-label): 5 mg/kg PO or IV every 12 hours for 2 weeks is recommended. For dogs that experience significant GI signs (eg, vomiting, anorexia, diarrhea) while receiving doxycycline PO, an alternative antibiotic (eg, ampicillin, penicillin G) should be considered. Once GI signs resolve, dogs should then receive doxycycline at the recommended dosage to eliminate organisms from the renal tubules. Duration of antibiotic therapy appears uncertain; most recommend a 2-week regimen of doxycycline.[49] If given IV, doxycycline should be administered as a slow IV infusion. In humans, 100 mg diluted to 0.5 mg/mL is given over at least 1 hour. Doxycycline IV is not recommended unless GI adverse effects prevent PO administration and other antimicrobials cannot be used.

d) **Granulocytic anaplasmosis (*Anaplasma phagocytophilum*)** (extra-label): 5 mg/kg PO every 12 hours for 14 days; most dogs show clinical improvement in 24 to 48 hours.[50]

e) **Borreliosis (ie, *Borrelia burgdorferi* [Lyme disease])** (extra-label): 10 mg/kg PO every 12 to 24 hours for 30 days[51]

f) **Ehrlichiosis** (extra-label): 10 mg/kg PO every 24 hours for 28 days[52,53]

g) **Rickettsial diseases (eg, *Rickettsia rickettsii* [Rocky Mountain spotted fever])** (extra-label): 5 mg/kg PO every 12 hours[54]

h) **Alternative treatment for *Babesia gibsonii* after atovaquone and azithromycin failed to eliminate infection on PCR test**: doxycycline 5 mg/kg PO once daily in combination with clindamycin 25 mg/kg PO twice daily and metronidazole 15 mg/kg PO twice daily and for 30 to 90 days[2]

Periodontitis (subantimicrobial regimen) (extra-label): 2 mg/kg PO once daily appeared to be an appropriate dose and may be suitable for treatment of gelatinolytic inflammatory diseases (eg, periodontitis).[6,55] **NOTE**: Systemic use of antimicrobial drugs at subantimicrobial doses for nonantimicrobial uses is discouraged.

CATS:

WARNING: Cats should not be dry pilled with doxycycline PO; administration should be followed with at least 5 mL of water. Alternatively, a compounded slurry (eg, "triple fish" or similar) can be used to administer the dose (see ***Compatibility/Compounding Considerations***).

Susceptible infections (extra-label): 5 mg/kg PO twice daily or 10 mg/kg PO once daily is generally recommended.

a) **Acute respiratory infections** (extra-label): 5 mg/kg PO every 12 hours or 10 mg/kg PO every 24 hours; treat for 7 to 10 days[47]

b) ***Mycoplasma felis* upper respiratory tract infections** (extra-label): Shelter cats were given 10 mg/kg PO (as oral liquid) once daily for either 7 or 14 days.[56] Authors concluded that the 14-day course produced superior microbiologic, but not clinical, results.

c) ***Mycoplasma haemofelis* (ie, hemotropic mycoplasmosis, hemoplasmosis, or feline infectious anemia)** (extra-label): 10 mg/kg PO once daily or 5 mg/kg PO every 12 hours for 2 to 4 weeks.[57–59] An alternate antimicrobial (eg, marbofloxacin) should be considered if bacteremia persists.[57]

d) **Ehrlichiosis or anaplasmosis** (extra-label): 5 – 10 mg/kg PO every 12 hours for 21 days[60,61]

e) **Bartonellosis** (extra-label): 10 mg/kg PO every 12 to 24 hours[62]

f) **Clinical *Toxoplasma gondii*** (extra-label): 5 – 10 mg/kg PO every 12 hours for 4 weeks[63]

g) **Susceptible mycobacterial, L-forms, or mycoplasma infections** (extra-label): 5 – 10 mg/kg PO every 12 hours[64]

h) ***Nocardia* spp (eg, *N nova*) infections** (extra-label): doxycycline 5 mg/kg or higher PO twice daily in combination

with amoxicillin 20 mg/kg PO twice daily; clarithromycin 62.5 – 125 mg/cat (NOT mg/kg) PO twice daily can also be added [65]

i) **Feline chlamydial infections (eg, *Chlamydia felis*)** (extra-label): 10 mg/kg PO every 24 hours for a minimum of 3 to 4 weeks; additional topical ocular treatment may reduce ocular discomfort[66–68]

HORSES:

WARNING: Doxycycline IV in horses has been associated with fatalities. Until this drug's safety has been further demonstrated, it cannot be recommended for parenteral use in this species. Commercially available PO doxycycline hyclate or monohydrate has low bioavailability in horses and treating Lyme disease or anaplasmosis may be problematic. Food appears to significantly reduce absorption in horses, and administration on an empty stomach is recommended.

Borreliosis (ie, *Borrelia burgdorferi* [Lyme disease]) (extra-label): 10 mg/kg PO every 12 hours. Treatment for 2 weeks may be adequate for early-stage infections, whereas treatment for 1 to 2 months may be required for patients with neuroborreliosis or ocular involvement.[26,69]

Equine granulocytic ehrlichiosis (EGE; anaplasmosis) as an alternative to oxytetracycline (extra-label): 10 mg/kg PO every 12 hours for 10 to 14 days[70]

***Rhodococcus equi* bronchopneumonia in foals** (extra-label): Doxycycline 10 mg/kg in combination with azithromycin 5 mg/kg PO twice daily for a minimum of 41 days; continue treatment until resolution of clinical signs and no evidence of pulmonary consolidation is seen on thoracic ultrasound. The efficacy of this combination was similar rifampin/azithromycin.[8]

RABBITS/RODENTS/SMALL MAMMALS:

***Mycoplasma* spp pneumonia (mice, rats)** (extra-label): Doxycycline 5 mg/kg PO twice daily with enrofloxacin 10 mg/kg PO twice daily[71]

Chinchillas, gerbils, guinea pigs, hamsters, mice, rats (extra-label): 2.5 – 5 mg/kg PO every 12 hours. Doxycycline should not be used in young or pregnant animals

BIRDS:

Psittacosis (*Chlamydia psittaci*) (extra-label):

a) 25 – 50 mg/kg PO once a day is the recommended starting dosage for unstudied avian species[72–74]; split and give twice daily if regurgitation occurs. May be administered orally via liquid/suspension, or by medicated feed (doxycycline hyclate 1 g per kg feed [corn, beans, rice, oatmeal]).

b) **Cockatiels, Senegal parrots, blue-fronted Amazon parrots, and orange-winged Amazon parrots**: 40 – 50 mg/kg PO once daily.[72,73] In a study of experimentally infected cockatiels, doxycycline 35 mg/kg PO was given once daily for 21 days, which was as effective as a 45-day treatment. The drug was administered via a metallic feeding tube into the crop using the commercially available human oral suspension (*Vibramycin*®).[12]

c) **African grey parrots, Goffin's cockatoos, blue and gold macaws, and green-winged macaws**: 25 mg/kg PO once daily[72]

d) Using the injectable product (*Vibaravenos*®—may not be available commercially in the United States): 25 – 50 mg/kg IM every 5 to 7 days for 45 days[74]; **NOTE**: May cause muscle necrosis

REPTILES:

Susceptible infections (extra-label):

Chelonians: 10 mg/kg PO once daily for 4 weeks. Useful for bacterial respiratory infections in tortoises with suspected *Mycoplasma* spp infections

In most species: 10 mg/kg PO once daily for 10 to 45 days[75]

Monitoring

- Clinical efficacy
- Adverse effects (eg, vomiting, diarrhea, anorexia)
- Renal and hepatic function during long-term use

Client Information

- This medicine *must* be given with a moist treat or a small amount of liquid to ensure it reaches the stomach; this is especially important for cats. Doxycycline can cause ulcers in the throat and esophagus if it gets stuck before reaching the stomach. If your animal has trouble swallowing or eating while taking this medicine, contact your veterinarian immediately.
- This medicine may cause stomach upset. Give with a small amount of food that does not contain iron or dairy products.
- Do not give multivitamins, calcium supplements, antacids, or laxatives 2 hours before or after giving doxycycline as these products can reduce effectiveness of the medicine.
- This medicine may make your animal's skin more sensitive to sunlight and increase the risk for sunburn on hairless areas such as the nose and around the eyelids and ears. Tell your veterinarian if you notice any reddening of the skin (sunburn) while your animal is on this medication.
- Complete the entire course of this medication (even if your animal seems back to normal) unless directed otherwise by your veterinarian.

Chemistry/Synonyms

Doxycycline is a semisynthetic tetracycline that is derived from oxytetracycline. It is available as hyclate, calcium, and monohydrate salts. The hyclate salt is used in the injectable dosage form, oral tablets, and oral capsules. It occurs as a yellow crystalline powder that is soluble in water and slightly soluble in alcohol. After reconstitution with sterile water, the hyclate injection has a pH between 1.8 and 3.3. Doxycycline hyclate may also be known as doxycycline hydrochloride.

The monohydrate salt is found in the oral powder for reconstitution. It occurs as a yellow crystalline powder that is very slightly soluble in water and sparingly soluble in alcohol. The calcium salt is formed in situ during manufacturing. It is found in the commercially available oral syrup and other oral dosage forms.

Doxycycline may also be known as doxycycline monohydrate, doxycyclinum, and GS-3065; many trade name products are available.

Storage/Stability

Doxycycline hyclate tablets and capsules should be stored in tight, light-resistant containers below 30°C (86°F), preferably at controlled room temperature (15°C to 30°C [59°F-86°F]). After being reconstituted with water, the monohydrate oral suspension is stable for 14 days when stored at room temperature.

When reconstituted with a suitable diluent (eg, 5% dextrose, Ringer's injection, 0.9% sodium chloride, *Plasma-Lyte*® *56* in 5% dextrose) to a concentration of 0.1 to 1 mg/mL, the hyclate injection may be stored for 72 hours if refrigerated. Infusions should be completed within 12 hours of removal from the refrigerator. Frozen reconstituted solutions (10 mg/mL in sterile water) are stable for at least 8 weeks if kept at -20°C (-4°F) but should not be refrozen once thawed. For diluted solutions stored at room temperature, different manufacturers give different recommendations regarding stability, ranging from 12 to 48 hours. Refer to product label for specific information.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Doxycycline hyclate for injection is reportedly physically **compatible** with the following IV infusion solutions and drugs: 5% dextrose, Ringer's injection, lactated Ringer's injection, 0.9% sodium chloride, *Plasma-Lyte® 56* in 5% dextrose, *Plasma-Lyte® 148* in 5% dextrose, *Normosol-M* in 5% dextrose, *Normosol-R* in 5% dextrose, invert sugar 10%, acyclovir sodium, amikacin sulfate, aminophylline, amiodarone HCl, atracurium, atropine sulfate, azithromycin, buprenorphine HCl, butorphanol tartrate, calcium chloride, calcium gluconate, cefotaxime, ceftriaxone, clindamycin, cyanocobalamin, cyclosporine, dexmedetomidine HCl, digoxin, diltiazem HCl, diphenhydramine HCl, dopamine HCl, ephedrine sulfate, famotidine, fentanyl citrate, fluconazole, gentamicin sulfate, hydromorphone HCl, insulin regular, lorazepam, magnesium sulfate, meperidine HCl, methadone HCl, metoclopramide HCl, metronidazole, midazolam HCl, morphine sulfate, multiple vitamins injection, mycophenolate mofetil HCl, naloxone HCl, norepinephrine bitartrate, ondansetron HCl, oxytocin, pantoprazole sodium, phenylephrine HCl, polymyxin B sulfate, potassium chloride, propofol, propranolol HCl, ranitidine HCl, voriconazole, and zoledronic acid.

It is **incompatible** with aminocaproic acid, amphotericin B (conventional and liposomal), ampicillin, cefazolin, ceftazidime, chloramphenicol, dexamethasone sodium phosphate, diazepam, erythromycin lactobionate, furosemide, heparin sodium, hydrocortisone sodium succinate, ketorolac tromethamine, methylprednisolone sodium succinate, penicillin G sodium/potassium, phenobarbital sodium, piperacillin sodium, and sodium bicarbonate.

One study examining doxycycline blood concentrations in birds following injection of a commercially available (not in United States) IM formulation (*Vibravenos®*; Pfizer CH) and 2 concentrations of a pharmacist-compounded product showed variable blood concentrations and a high incidence of localized tissue reactions, including necrosis, with the compounded products.[11]

Doxycycline 250 – 300 ppm administered to budgerigars in a hulled seed diet has been shown to maintain concentrations sufficient for treatment of chlamydiosis.[76]

An oral extended-release formulation that combined doxycycline with acrylic acid and polymethacrylate produced a longer release time and a favorable pharmacokinetic–pharmacodynamic relationship in healthy dogs.[77]

The commercially available syrup (*Vibramycin®*) and powder for oral suspension should be used when possible. Compounded doxycycline oral suspensions should be refrigerated, protected from light, and used within 7 days. Although some compounding pharmacies claim stability of 6 months for compounded doxycycline suspensions, others have demonstrated that compounded aqueous doxycycline suspensions degrade rapidly after 7 to 14 days, even when refrigerated.[78] A study evaluating compounded aqueous oral suspensions made from 100 mg doxycycline tablets at concentrations of 33.3 and 166.7 mg/mL concluded that stability cannot be assured beyond 7 days.[79] Another study demonstrated that doxycycline tablets mixed with water or foods (eg, milk, pudding, yogurt, applesauce, jellies) lose more than 10% potency after 24 hours.[80] Compounded doxycycline formulations (ie, chews, aqueous- and oil-based suspensions) had variable doxycycline content, and no formulation met US Pharmacopeia standards after 21 days of storage under recommended conditions.[81]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None for systemic use

Doxycycline gel (*Doxirobe®*) is FDA-approved for subgingival application for the prevention and treatment of periodontal disease in dogs.

HUMAN-LABELED PRODUCTS:

Doxycycline (as hyclate) Tablets and Capsules: 20 mg, 50 mg, and 100 mg; *Periostat®*, *Alodox® Convenience Kit*, *Vibramycin®*, *Vibra-Tabs®*, *Oraxyl®*, generic; (Rx)

Doxycycline (as hyclate) Delayed-Release Tablets and Capsules: 75 mg, 100 mg, and 150 mg; 40 mg (30 mg immediate release and 10 mg delayed release); *Doryx®*, *Oracea®*; (Rx)

Doxycycline (as monohydrate) Tablets and Capsules: 50 mg, 75 mg, 100 mg, and 150 mg; *Monodox®*, *Adoxa®*, generic; (Rx)

Doxycycline Capsules (coated pellets; as hyclate): 75 mg and 100 mg; *Doryx®*, generic; (Rx)

Doxycycline (as monohydrate) Powder for Oral Suspension: 5 mg/mL after reconstitution in 60 mL; *Vibramycin®*, generic; (Rx)

Doxycycline (as calcium salt) Oral Syrup: 10 mg/mL in 473 mL; *Vibramycin®*; (Rx)

Doxycycline Injection: 42.5 mg (as hyclate, 10%) in vials; *Atridox®*; (Rx)

Doxycycline (as hyclate) Lyophilized Powder for Injection: 100 mg and 200 mg with 300 mg and 600 mg mannitol, respectively, in vials; *Doxy®-100* and *-200*, generic; (Rx)

Edetate Calcium Disodium (CaEDTA)

(***ed***-a-tayt ***kal***-see-um dye-***so***-dee-um)

Calcium Disodium Versenate

Antidote

Prescriber Highlights

- ► Heavy metal chelator used primarily for lead and zinc toxicities
- ► Contraindications include patients with anuria, renal disease, or lead still in the GI tract; use extreme caution in patients with decreased renal function.
- ► Recommend using the SC route when treating small animals; do not administer orally.
- ► Adverse effects include pain on injection and renal toxicity (renal tubular necrosis). May cause depression and GI signs in dogs
- ► Do not confuse calcium disodium edetate with sodium edetate (edetate disodium).

Uses/Indications

Edetate calcium disodium (CaEDTA) is a chelating agent used in the treatment of lead and zinc toxicities. Oral succimer is more commonly recommended today for treating lead poisoning in dogs and cats, but CaEDTA can be considered when oral therapy is not practical.

CaEDTA may be used in combination with dimercaprol treatment.

Pharmacology/Actions

The calcium in edetate calcium disodium (CaEDTA) can be displaced by divalent or trivalent metals to form a stable, water-soluble complex that is excreted in the urine. One gram of CaEDTA can theoretically bind 620 mg of lead, but in reality, only about 5 mg of lead per gram of CaEDTA is actually excreted into the urine of patients

that are treated for lead toxicity. In addition to chelating lead, CaEDTA readily chelates and eliminates zinc from the body. CaEDTA also binds cadmium, copper, iron, and manganese, but does not facilitate removal of those metals from the body.[1] CaEDTA is relatively ineffective for use in treating mercury, gold, or arsenic toxicities.

There is some evidence that thiamine supplementation may increase the clinical efficacy of CaEDTA in treating acute lead poisoning in cattle.

Pharmacokinetics

Edetate calcium disodium (CaEDTA) is poorly absorbed from the GI tract but is well absorbed after either IM or SC administration. It is distributed primarily in the extracellular fluid. Unlike dimercaprol, CaEDTA does not penetrate erythrocytes or enter the CNS in appreciable amounts. The drug is rapidly excreted renally, either as an unchanged drug or chelated with metals. Changes in urine pH or urine flow do not significantly alter the rate of excretion. In humans with normal renal function, the average elimination half-life of CaEDTA is 20 to 60 minutes after IV administration.[1] Decreased renal function can cause accumulation of CaEDTA and can increase its nephrotoxic potential.

Contraindications/Precautions/Warnings

Edetate calcium disodium (CaEDTA) is contraindicated in patients with anuria. It should be used with extreme caution in patients with diminished renal function; reduced doses are necessary in these patients.

Most small animal clinicians recommend using the SC route when treating small animals. Rapid IV administration of CaEDTA has been associated with abrupt increases in intracranial pressure and death in patients with lead encephalopathy and cerebral edema.

Termination of lead or zinc exposure is essential in the management of toxicities. Ideally, lead or zinc material should be removed from the GI tract before using CaEDTA. Do not administer CaEDTA orally as it may increase the amount of lead absorbed from the GI tract.

Do not confuse edetate CALCIUM disodium with sodium edetate (edetate disodium), which should **not** be used for lead poisoning as it may cause fatal hypocalcemia.[2]

Adverse Effects

The most serious adverse effect associated with this compound is dose-dependent renal toxicity (renal tubular necrosis resulting in nephrosis). Glycosuria, proteinuria, and microscopic hematuria may occur. This effect may be reduced by ensuring adequate diuresis prior to initiating therapy. In dogs, edetate calcium disodium (CaEDTA) can cause depression, vomiting, and diarrhea. GI clinical signs may be alleviated by zinc supplementation. Injection site pain and thrombophlebitis may occur after IV infusion. Fever, transient hypotension, mild increases in hepatic enzymes, tremor, and rash have been reported in humans. Prolonged administration of CaEDTA at high doses may produce transient bone marrow depression and skin and mucous membrane lesions, but these adverse effects usually resolve on discontinuation of the drug.

No evidence of muscle damage, nephrotoxicity, or hepatotoxicity was seen when administered IM to falcons.

Long-term therapy may lead to zinc deficiency; zinc supplementation should be considered in these animals.

Reproductive/Nursing Safety

Safe use of edetate calcium disodium (CaEDTA) during pregnancy has not been established. It is not known whether this drug is excreted in milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The oral LD_{50} in dogs is 12 g/kg; refer to ***Adverse Effects*** for more information.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving edetate calcium disodium (CaEDTA) and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Glucocorticoids** (eg, **dexamethasone, prednis(ol)one**): Concurrent administration of CaEDTA with glucocorticoids may increase the risk for renal toxicity.
- **Insulin** (eg, **NPH, PZI**): Concurrent administration of CaEDTA with zinc insulin preparations (NPH, PZI) will decrease the sustained action of the insulin preparation.
- **Nephrotoxic Drugs** (eg, **aminoglycosides, amphotericin B**): Use with caution with other nephrotoxic compounds
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam, robenacoxib**): Concurrent administration of CaEDTA with NSAIDs may increase the risk for renal toxicity.

Laboratory Considerations

- May increase **urine glucose** values
- Inverted T waves on **ECG** are possible.

Dosages

NOTES:

1. It is imperative that the source of lead/zinc is removed from the animal (eg, GI decontamination).
2. The manufacturer of the injectable (human) product recommends diluting the total daily dose with 250 to 500 mL of either 0.9% sodium chloride or 5% dextrose when used IV.
3. Maintain adequate hydration throughout edetate calcium disodium (CaEDTA) treatment.
4. Consider zinc supplementation when treating for lead poisoning.

DOGS/CATS:

Lead and zinc toxicities (extra-label):

a) Dogs: 25 mg/kg (diluted in 5% dextrose to a concentration of 10 mg/mL) SC 4 times a day for 5 days.[3] Some sources say not to exceed 2 g per animal per day.[4] Repeat course of treatment if required.

b) Cats: 27.5 mg/kg diluted in 15 mL of 5% dextrose and administered SC every 6 hours for 5 days.[3,4] Repeat course of treatment if required.

Lead poisoning (extra-label): 75 mg/kg IV slowly as a 5% (50 mg/mL) solution in 0.9% sodium chloride or 5% dextrose. Total daily CaEDTA dose for dogs not to exceed 2000 mg. Administer calculated dose in 4 equally divided doses per day (ie, every 6 hours) for 2 to 5 days. Repeat the treatment course after 2 to 3 days, as necessary, if signs of lead poisoning are still present.[5]

HORSES:

Lead poisoning (extra-label): If severely affected, administer CaEDTA 75 mg/kg IV slowly in 5% dextrose or 0.9% sodium chloride daily for 4 to 5 days (may divide daily dose into 2 to 3 administrations per day). Stop therapy for 2 days, then repeat for another 4 to 5 days.[6]

FOOD ANIMALS:

Lead poisoning (extra-label):

a) 110 mg/kg per day; administer calculated dose in 3 to 4 divided doses; dilute CaEDTA solution to 1 g/mL in 5% dextrose. Administer the first dose IV, then subsequent doses are given SC[7]

b) Cattle: 67 mg/kg slow IV twice daily for 2 days; withhold dose for 2 days and then give again for 2 days. Cattle may require 10 to 14 days to recover and may require several series of treatments.[8]

c) Cattle (extra-label): 75 mg/kg as 5% (50 mg/mL) solution in saline or glucose; give IV slowly. Administer in 4 equally divided doses per day (ie, every 6 hours) for 2 to 5 days. Repeat the treatment course after 2 to 3 days, as necessary, if signs of lead poisoning are still present.[5]

CAMELIDS:

Lead poisoning (extra-label): 110 mg/kg (route not specified) for 5 days[9]

BIRDS:

Lead and zinc toxicities (extra-label):

a) 30 – 35 mg/kg IM every 12 hours for 3 to 5 days, off 3 to 5 days, may repeat same treatment and/or use another chelator. Can be used IV short term (48 hours) at 20 – 35 mg/kg diluted in 0.9% sodium chloride. Many published regimens[10]

b) Raptors (falcons): In this study, 25% CaEDTA was given undiluted IM at a dose of 100 mg/kg every 12 hours for 5 to 25 consecutive days.[11] Falcons were treated for 5-day courses if blood lead level was greater than 65 µg/dL until blood lead level was less than 20 µg/dL. No evidence of muscle damage, nephrotoxicity, or hepatotoxicity was seen.

c) Raptors: 35 – 50 mg/kg IM (diluted with saline and given as a 6.6% solution) SC every 8 or 12 hours for 5 days. Repeat after 2 to 3 days if indicated by blood lead levels. Higher dosages, up to 100 mg/kg, have been used.[12]

RABBITS:

Lead poisoning (extra-label): 27 – 30 mg/kg SC every 12 hours for 5 to 7 days[13,14]

Monitoring

- Serial blood lead or zinc levels; monitor during treatment and for 1 to 2 weeks after treatment
- Urinalysis (including urine sediment), hydration status, and urine output daily or every other day during treatment
- Baseline and periodic serum chemistry panel that includes renal values and phosphorus and calcium
- Blood levels of zinc, iron, and copper when treating for lead intoxication, as levels may be affected during treatment
- Heart rate and rhythm (ECG) when using IV route for edetate calcium disodium (CaEDTA) treatment

Client Information

- Because of the potential toxicity of this agent and the seriousness of most heavy metal intoxications, this drug should only be used with close professional supervision.

Chemistry/Synonyms

Edetate calcium disodium (CaEDTA), a heavy metal chelating agent, occurs as an odorless, white, crystalline powder or granules and is a mixture of dihydrate and trihydrate forms. It has a slightly saline taste and is slightly hygroscopic. CaEDTA is freely soluble in water and very slightly soluble in alcohol. The commercially available injection (human) has a pH of 6.5 to 8 and has ≈5.3 mEq of sodium per gram of CaEDTA.

Edetate calcium disodium may also be known as sodium calcium edetate, calcium disodium edathamil, calcium disodium edetate, calcium disodium ethylenediaminetetra-acetate, calcium disodium versenate, calcium EDTA, disodium calcium tetracemate, E385, natrii calcii edetas, sodium calciumedetate, *Calcium Vitis®*, *Calciumedetat-Heyl®*, *Chelante®*, *Chelintox®*, or *Ledclair®*.

Storage/Stability

Store edetate calcium disodium CaEDTA at 25°C (77°F); excursions to 15°C to 30°C (59°F-86°F) are permitted. Dilute the injection with either normal saline or 5% dextrose.

Compatibility/Compounding Considerations

Commercially available CaEDTA injection is usually diluted to a 1% solution with 5% dextrose for SC administration in small animals. CaEDTA is **incompatible** with Ringer's solution, lactated Ringer's solution, amphotericin B, and 10% dextrose.

To minimize pain from the IM injection, CaEDTA can be mixed in equal quantities with lidocaine hydrochloride 1% (eg, 1 mL of lidocaine 1% for each 1 mL of CaEDTA).

Dosage Forms/Regulatory Status

NOTES:

1) Edetate calcium disodium (CaEDTA) should not be confused with SODIUM edetate (edetate disodium), which should **not** be used for lead poisoning, as it may cause fatal hypocalcemia.[2]
2) FARAD recommends 2-day meat and milk withdrawal time after use in food animals.[15]

VETERINARY-LABELED PRODUCTS:

None; may be available from compounding pharmacies

HUMAN-LABELED PRODUCTS:

Edetate Calcium Disodium Injection Solution: 200 mg/mL in 5 mL ampules (1 g/amp); *Calcium Disodium Versenate*; (Rx)

Edrophonium

(ed-roe-***foe***-nee-um) *Tensilon®, Enlon®*

Anticholinesterase (Cholinergic) Agent

Prescriber Highlights

- ► Short-acting parenteral cholinergic used primarily to test for myasthenia gravis (MG).
- ► Secondary indications are to reverse nondepolarizing neuromuscular blocking agents (NMBAs) and to treat some supraventricular tachycardias (SVTs).
- ► Relatively contraindicated for use in patients that have asthma or mechanical urinary or intestinal tract obstruction
- ► Use with caution in patients that have bradycardia or atrioventricular blocks.
- ► Overdoses can cause cholinergic crisis; atropine for IV injection and ventilatory support should be readily available.
- ► Commercial availability may limit use.

Uses/Indications

The primary use for edrophonium is in the diagnostic workup for myasthenia gravis (MG). The edrophonium response test for MG is not specific or sensitive and has limitations, but a dramatic positive response is suggestive of MG. Both false-positive and false-negative results can occur; therefore, it is best to use while awaiting results from a more specific, sensitive test (eg, acetylcholine receptor antibody test).

In patients that do not have good control of clinical signs, edrophonium can be used to assess the efficacy of longer-acting anticho-

linesterase inhibitors by providing immediate amelioration of weakness if the dose of the long-acting agent is too low.

Edrophonium can also be used for the reversal of nondepolarizing neuromuscular blocking agents (NMBAs; eg, pancuronium, metocurine, atracurium, cisatracurium, rocuronium, or tubocurarine). Because of its short duration of action, the clinical usefulness of edrophonium for this indication is questionable since longer-acting drugs such as neostigmine or pyridostigmine may be more useful.

Edrophonium, in a controlled intensive care-type setting, may also be useful in the diagnosis and treatment of some supraventricular tachycardias (SVTs), particularly when other more traditional treatments are ineffective.

Pharmacology/Actions

Edrophonium is a relatively short-acting anticholinesterase agent. It inhibits acetylcholinesterase by reversible electrostatic attachment to the enzyme, thereby blocking its hydrolytic activity on acetylcholine. By blocking acetylcholinesterase, acetylcholine accumulates in the synaptic cleft to prolong cholinergic stimulation. Cholinergic effects result in miosis, increased skeletal muscle tone, intestinal hyperperistalsis, bronchoconstriction, ureter constriction, salivation, sweating (in animals with sweat glands), and bradycardia, and possibly sinus arrest (overdose). For these reasons, it is recommended to administer an anticholinergic (eg, atropine or glycopyrrolate) immediately before administering edrophonium. Compared to other drugs used to reverse nondepolarizing (NMBAs; eg, neostigmine and pyridostigmine), the effects of edrophonium on muscarinic receptors are mild. Edrophonium is a better choice in species where anticholinergics should be avoided (eg, horses).

Pharmacokinetics

Edrophonium is only effective when given parenterally. After IV administration, it begins to have effects on skeletal muscle within one minute, persisting up to 10 minutes. Myasthenic patients may have effects persisting longer after the first dose. In humans, ≈30% of edrophonium is metabolized in the liver to an inactive metabolite, edrophonium glucuronide, and renal excretion is responsible for the elimination of the remainder of the drug.

Contraindications/Precautions/Warnings

Edrophonium is contraindicated in patients that are hypersensitive to it or other acetylcholinesterase inhibitors. Edrophonium is considered relatively contraindicated in patients with bronchial asthma or mechanical urinary or intestinal tract obstruction. This drug should be used with caution (with adequate monitoring and treatment available) in patients with bradycardia or atrioventricular blocks.

It is recommended to have atropine injection (0.02 – 0.04 mg/kg IV) and ventilatory support readily available before administering edrophonium.

Adverse Effects

Adverse effects associated with edrophonium are generally dose-related and cholinergic in nature (eg, urination, lacrimation, vomiting, defecation, bradycardia, sinus arrest, and bronchospasm). Although the effects are usually mild and easily treated with time, pretreatment or treatment with an anticholinergic drug (eg, atropine, glycopyrrolate) can help prevent or alleviate these effects. Severe adverse effects are possible with large overdoses (see ***Overdose/Acute Toxicity***).

Reproductive/Nursing Safety

Edrophonium is a quaternary ammonium chloride that is ionized at physiologic pH and therefore would not be expected to cross the placenta in significant amounts. However, the drug's safety profile during pregnancy has not been established.

It is unknown whether edrophonium enters maternal milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose of edrophonium may induce a cholinergic crisis. Clinical signs of cholinergic toxicity include GI effects (nausea, vomiting, diarrhea), salivation, sweating (in animals able to do so), respiratory effects (increased bronchial secretions, bronchospasm, pulmonary edema, respiratory paralysis), ophthalmic effects (miosis, blurred vision, lacrimation), cardiovascular effects (bradycardia or tachycardia, hypotension, cardiac arrest), muscle cramps, and weakness.

Treatment of edrophonium overdose consists of both ventilatory and cardiac supportive therapy and atropine injection (0.02 to 0.04 mg/kg IV) if necessary. Refer to ***Atropine*** for more information on its use for cholinergic toxicity.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving edrophonium and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Atropine**: Atropine will antagonize the muscarinic effects of edrophonium. Although some clinicians routinely use the 2 medications together, caution is advised, as atropine can mask the early clinical signs of cholinergic crisis.
- **Dexpanthenol**: Theoretically, dexpanthenol may have additive effects when it is used with edrophonium.
- **Digoxin**: Edrophonium's cardiac effects may be increased in patients receiving digoxin; excessive slowing of heart rate may occur.
- **Muscle Relaxants**: Edrophonium may prolong the Phase I block of depolarizing muscle relaxants (eg, **succinylcholine, decamethonium**), and edrophonium antagonizes the actions of nondepolarizing neuromuscular blocking agents (eg, **pancuronium, tubocurarine, gallamine, vecuronium, atracurium**).

Dosages

DOGS:

Presumptive diagnosis of myasthenia gravis (MG)| Edrophonium response test (extra-label): Place indwelling IV catheter and flush with sterile saline. The patient is gently exercised, or if nonambulatory, they are encouraged to rise until fatigued. Administer edrophonium 0.1 – 0.2 mg/kg IV[1] In patients with focal MG, such as facial muscle weakness, the palpebral reflex may be assessed after edrophonium is given.[2,3] **NOTE**: Be sure to have atropine (0.02 – 0.04 mg/kg IV) readily available in the event cholinergic signs (eg, salivation, lacrimation, urination, defecation, GI distress, emesis ["SLUDGE"]) develop.

Reversal of nondepolarizing neuromuscular blocking agents (NMBAs; extra-label): 0.25 – 0.5 mg/kg IV.[4] Start with a low dose first; repeat if necessary. **NOTE**: Administration of atropine 0.02 – 0.04 mg/kg IV immediately prior to edrophonium is recommended.[5]

CATS:

Presumptive diagnosis of MG | Edrophonium response test (extra-label): Place indwelling IV catheter and flush with sterile saline. The patient is gently exercised, or if nonambulatory, they are encouraged to rise until fatigued. Administer edrophonium

0.2 – 0.5 mg/cat (NOT mg/kg) IV.[1,6] In patients with focal MG, such as facial muscle weakness, the palpebral reflex may be assessed after edrophonium is given.[2,3] **NOTE**: Be sure to have atropine (0.02 – 0.04 mg/kg IV) readily available in the event cholinergic signs (eg, salivation, lacrimation, urination, defecation, GI distress, emesis ["SLUDGE"]) develop.

Reversal of NMBAs (extra-label): 0.25 – 0.5 mg/kg IV.[7] Start with a low dose first and repeat if necessary. **NOTE**: Administration of atropine 0.02 – 0.04 mg/kg IV immediately prior to edrophonium is recommended.

HORSES:

Reversal of NMBAs (extra-label): 0.1 – 0.5 mg/kg IV have been commonly used.[7,8] Because edrophonium can increase acetylcholine concentrations, parasympathetic tone may increase, causing bradycardia, bronchospasm, and increased salivation. Slow IV administration using low doses helps to minimize this effect.

Monitoring

- Cholinergic adverse effects: salivation, lacrimation, urination, defecation, GI distress, emesis ("SLUDGE")
- Improvement (for ≈1 to 15 minutes) of paresis is consistent with but not definitive for the diagnosis of myasthenia gravis (MG).

Client Information

- Edrophonium is a medicine that is only given to your animal in the veterinary clinic.

Chemistry/Synonyms

Edrophonium chloride, a synthetic quaternary ammonium cholinergic (parasympathomimetic) agent, occurs as a white crystalline powder having a bitter taste. Approximately 2 g are soluble in 1 mL of water. The injection has a pH of ≈5.4.

Edrophonium chloride may also be known as edrophonii chloridum, *Anticude®*, *Camsilon®*, *Enlon®*, *Reversol®*, or *Tensilon®*.

Storage/Stability

Store edrophonium chloride injection at room temperature.

Compatibility/Compounding Considerations

Compatibility is dependent on factors, such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Edrophonium is reportedly physically **compatible** at Y-site injections with heparin sodium, hydrocortisone sodium succinate, potassium chloride, and vitamin B complex with C.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Edrophonium Chloride Solution for Injection: 10 mg/mL in 10 mL and 15 mL vials; *Enlon®*; (Rx)

Edrophonium Chloride/Atropine Sulfate for Injection: 10 mg/mL with 0.14 mg/mL atropine sulfate in 5 mL single-dose amps and 15 mL multi-dose vials; *Enlon-Plus®*; (Rx)

NOTE: Edrophonium appears to no longer be manufactured, and no commercially available dosage forms could be located.

Emodepside/Praziquantel

(ee-moe-***dep***-side with pra-zi-***kwon***-tel) *Profender®*

Topical Antiparasitic (Nematocide; Cestocide)

Prescriber Highlights

- ► Topical formulation is FDA-approved for use in cats weighing more than 1 kg (2.2 lb) and that are at least 8 weeks of age for the treatment of roundworms, hookworms, and tapeworms; it may also be used extra-label for the treatment of lungworms.
- ► Emodepside may be considered for oral use in dogs with confirmed multidrug-resistant hookworm infections; however, efficacy is still being established for this indication, and safety is a major concern in this species.
- ► Use with caution in cats with a history of an adverse reaction to MDR1 substrates (eg, ivermectin). Dogs with the *MDR1* gene mutation (also known as *ABCB1*-1delta) are more susceptible to emodepside toxicity.
- ► Emodepside has a microfilaricidal effect; use with caution in heartworm-positive dogs and cats.

Uses/Indications

Emodepside/praziquantel topical solution is FDA-approved for use in cats to treat and control roundworm (*Toxocara cati*), hookworm (*Ancylostoma tubaeforme*), and tapeworm (*Dipylidium caninum, Taenia taeniaeformis*) infections.[1]

Emodepside/praziquantel has also demonstrated effectiveness against *Toxascaris leonina*, *Echinococcus multilocularis*, and *Echinococcus granulosus*, as well as lungworm infections caused by *Troglostrongylus brevior*, *Aelurostrongylus abstrusus*, and *Capillaria aerophila* (*Eucoleus aerophagia*).[2-8] Emodepside/praziquantel can be administered to queens in late pregnancy to prevent lactogenic *T cati* transmission to kittens.[5,9]

In dogs, emodepside/praziquantel combinations are not FDA-approved; however, tablet formulations are available in other countries to treat dogs with roundworms, hookworms, whipworms, and tapeworms.[8] In the US, the feline *topical* product has been used *orally* in an extra-label manner in dogs for cases in which there is multidrug resistance from all 3 major anthelmintic classes (nicotinic agonists [eg, pyrantel], benzimidazoles [eg, fenbendazole], and avermectin/milbemycin endectocides [eg, moxidectin]), as confirmed by fecal egg count reduction testing.[10,11]

The topical emodepside/praziquantel formulation may also be of use for treating other species (eg, reptiles, rodents) in which oral dosing may be challenging.[12,13]

Pharmacology/Actions

Emodepside has a unique mode of action as compared with other antiparasitic compounds. In the parasite, the drug attaches presynaptically at the neuromuscular junction to a latrophilin-like receptor, resulting in increased intracellular calcium and diacylglycerol concentrations. At the end of the signal transduction cascade, vesicles containing inhibitory neuropeptide fuse with presynaptic membranes. Inhibitory neuropeptides (eg, PF-1, PF-2-like receptors) are then released into the synaptic cleft. When these peptides bind to postsynaptic receptors, there is an inhibition of pharyngeal pumping and locomotion of the nematode. The end result is flaccid paralysis and death of the parasite.

Emodepside also has activity against microfilaria, including in vitro activity against dirofilarial fourth-stage larvae and microfilaria.[1,14,15]

Praziquantel's exact mechanism of action against cestodes has not been determined. It may be the result of interacting with phospholipids in the integument of the parasite, causing ion fluxes of sodium, potassium, and calcium. At low concentrations in vitro, the drug

appears to impair the function of mouth parts and stimulates the worm's motility. At higher concentrations in vitro, praziquantel increases the contraction (irreversibly at very high concentrations) of the worm's strobila (ie, chain of proglottids). In addition, praziquantel causes irreversible focal vacuolization and subsequent cestodal disintegration at specific sites within the cestodal integument.

A synergistic effect against nematodes has been suggested when emodepside is used with diethylcarbamazine.[16,17]

Pharmacokinetics

Following dermal application of the emodepside/praziquantel product to cats, both drugs are absorbed through the skin and into the systemic circulation. Absorption of both active ingredients through the skin is relatively rapid, with serum concentrations detectable within 2 hours for emodepside and 1 hour for praziquantel. Peak concentrations occur within 6 hours for praziquantel and 2 days for emodepside. After a single application, both emodepside and praziquantel were detectable for up to 28 days following treatment.

In dogs, peak concentrations of emodepside and praziquantel were reached 2 hours after administration, and half-life was ≈1.5 hours for both agents.[8]

A study looking at topical absorption in a variety of reptiles found variability in blood concentrations associated with skin thickness.[18]

Contraindications/Precautions/Warnings

Do not use emodepside/praziquantel in animals that are hypersensitive to emodepside or praziquantel.[1] Safe use has not been evaluated in cats younger than 8 weeks of age, weighing less than 1 kg (2.2 lb), used for breeding, or during pregnancy or in lactating queens. Use with caution in sick, debilitated, or heartworm-positive cats.

Dogs with the *MDR1* gene mutation (also known as *ABCB1*-1delta) may be susceptible to emodepside toxicity; vomiting, mydriasis, ataxia, muscle tremors, and seizures have been reported.[19-22] It is advisable to test susceptible breeds of dogs before using emodepside-containing products. Cats with *MDR1* gene mutations may also experience neurotoxicity,[23] and emodepside/praziquantel should be used with caution in cats with a history of adverse reaction to MDR1 substrates (eg, ivermectin).

Oral administration of emodepside or emodepside/praziquantel to dogs should be only to fasted dogs as administration with food increases the incidence and severity of adverse reactions; no food should be given until 4 hours after treatment.[8]

Emodepside is microfilaricidal at label dosages and should be used with caution in heartworm-positive animals.[1,15] See ***Adverse Effects***.

Adverse Effects

In pre-approval efficacy studies for emodepside/praziquantel topical solution, the most common adverse effects observed in cats were dermal and GI related. In a field study, adverse reactions reported by cat owners included licking and excessive grooming (3%), scratching treatment site (2.5%), salivation (1.7%), lethargy (1.7%), alopecia (1.3%), agitation and nervousness (1.2%), vomiting (1%), diarrhea (0.5%), eye irritation (0.5%), respiratory irritation (0.2%), and shaking/tremors (0.2%)[1]; all adverse reactions were self-limiting. The following additional adverse events were reported voluntarily during post-approval use of the product in markets outside the US: pyoderma, edema, erythema, dehydration, ataxia, loss of appetite, facial swelling, rear leg paralysis, seizures, hyperesthesia, twitching, and death. A case report of one cat developing a morphea-like (ie, scleroderma) lesion after application has been reported.[24]

In a study of cats artificially infected with heartworms then treated with topical emodepside/praziquantel, adverse effects consistent with a microfilaricidal effect included salivation, labored breathing, and lethargy.[1,14]

In dogs, adverse effects documented to have occurred following oral administration of emodepside/praziquantel tablets include hypersalivation, vomiting, tremors, and incoordination.[8] These effects are described as rare, transient, and mild but may be more common and more severe in dogs with the MDR1 mutation (also known as *ABCB1*-1delta). Heartworm-positive dogs treated with emodepside exhibited adverse effects consistent with dead or dying circulating microfilariae (eg, lethargy, tremors, ataxia, hypersalivation) within 2 hours of dosing.[15] Oral administration without fasting may increase the risk for adverse effects. Adverse effects associated with extra-label oral administration of the topical formulation in dogs are unknown.

Reproductive/Nursing Safety

Emodepside/praziquantel topical solution can be safely used in late pregnancy in queens to prevent lactogenic *Toxocara c*ati transmission.[5,9,25] Studies performed in laboratory animals (eg, rats, rabbits) suggest that emodepside may interfere with fetal development in those species.[1]

Overdose/Acute Toxicity

Emodepside 200 mg/kg PO was tolerated in rats without mortalities. The oral LD_{50} in rats is greater than 500 mg/kg and in mice is greater than 2500 mg/kg. The acute dermal toxicity dose of emodepside in rats is high; a dose of 2000 mg/kg was tolerated without mortality.[26,27]

Praziquantel has a wide margin of safety. In rats and mice, the oral LD_{50} is at least 2000 mg/kg. An oral LD_{50} could not be determined in dogs because vomiting was induced at doses greater than 200 mg/kg. Parenteral doses of 50 to 100 mg/kg in cats caused transient ataxia and depression; parenteral doses of 200 mg/kg were lethal.

Kittens ≈8 weeks of age were treated topically with the combination product up to emodepside 15 mg/kg and praziquantel 60 mg/kg (5 times the labeled dose) at 2-week intervals for 6 treatments.[1] Clinical signs of transient salivation and/or tremors were observed in the group receiving 5 times the labeled dose. All clinical signs in this group were self-limiting. Cats 7 to 8 months of age treated with the topical solution at emodepside 30 mg/kg and praziquantel 120 mg/kg (10 times the labeled dose) developed transient salivation, tremors, and lethargy.

The combination product administered orally to cats caused salivation, vomiting, anorexia, tremors, abnormal respiration, and ataxia.[1] Adverse effects resolved without treatment.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving emodepside/praziquantel and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **P-Glycoprotein Substrates Or Inhibitors** (eg, **ivermectin**, **erythromycin**, **prednisolone**, **cyclosporine**): Emodepside is a substrate for P-glycoprotein.[20,22,28] Concurrent use with other drugs that are P-glycoprotein substrates or inhibitors could cause pharmacokinetic drug interactions.[5]
- **CYP3A4 Inducers** (eg, **dexamethasone**, **phenobarbital**, **rifampin**): Concurrent use may decrease praziquantel concentrations and efficacy, and concurrent use is contraindicated in humans. A 4-week washout period is recommended in humans following rifampin treatment.
- **CYP3A4 Inhibitors** (eg, **itraconazole**, **ketoconazole**): May increase praziquantel concentrations. Monitor for praziquantel toxicity.

Laboratory Considerations

None

Dosages

DOGS:

NOTE: Dogs should be fasted overnight prior to oral administration and for 4 hours after treatment.

Treatment of susceptible ascarids, hookworms (including MDR hookworms[10]), whipworms[8,29], and tapeworms[5,8] (extra-label): Minimum dose of emodepside 1 mg/kg and praziquantel 5 mg/kg PO once rounding up to the nearest tablet size (tablet formulation not available in the US).[30]

Treatment of multidrug-resistant hookworms (extra-label): Emodepside 1 mg/kg and praziquantel 4 mg/kg PO once using topical formulation administered orally. As the safety and efficacy of this protocol have not been evaluated, its use should be reserved for cases in which resistance to drugs from all 3 other major anthelmintic classes (ie, nicotinic agonists [eg, pyrantel], benzimidazoles [eg, fenbendazole], and avermectin/milbemycin endectocide [eg, moxidectin]) as confirmed by the fecal egg count reduction test.

CATS:

Treatment and control of susceptible roundworms, hookworms, and tapeworms (label dosage; FDA-approved): Minimum dose is emodepside 3 mg/kg and praziquantel 12 mg/kg applied to the skin on the back of the neck as a single topical dose (see ***Table*** for dose information).[1] A second treatment should not be necessary; however, if re-infection occurs, the product can be re-applied after 30 days.

Cat weight kg (lb)	Topical solution size	Volume (mL)	Emodepside (mg)	Praziquantel (mg)
1-2.5 (2.2-5.5)	Small	0.35	7.5	30
2.5-5 (5.5-11)	Medium	0.7	15	60.1
5-8 (11-17.6)	Large	1.12	24	96.1
More than 8 (17.6)	Use appropriate number of tube sizes			

Susceptible lungworms (*Troglostrongylus brevior, Aelurostrongylus abstrusus, Capillaria aerophilia* [aka *Eucoleus aerophilius*]; extra-label): Emodepside 3 mg/kg and praziquantel 12 mg/kg topically, repeat dose 14 days after initial treatment[2,4,6,7]

REPTILES:

Ascarids, oxyurids, and rhabditids in various reptile species (extra-label): Topical absorption varies between species, but 4 drops/100 g body weight appears to be effective. Aquatic species must be kept in a dry place for 48 hours after treatment. Caution is advised until further studies verify safety and efficacy, particularly in sick animals.[18]

Oxyurids in tortoises (extra-label): Emodepside 21.5 mg/kg and praziquantel 85.5 mg/kg (1 mL/kg) applied to the prefemoral fossa may be considered as an alternative to oral treatment.[12]

Monitoring

- Clinical efficacy: fecal flotation, fecal antigen testing, fecal egg count reduction test
- Adverse effects: GI effects (salivation, vomiting, diarrhea), topical reactions (pruritis, alopecia), neurologic effects (tremors, incoordination), particularly when using the topical solution orally in dogs.
- Prior to treatment: consider heartworm antigen testing with microfilaria check (dogs and cats) and MDR1 testing (dogs)

Client Information

- Topical (spot-on) medication is for treatment of roundworms, hookworms, and tapeworms in cats. Re-application usually is not necessary but can be administered after 30 days if reinfection occurs. More than one treatment may be needed when treating for lungworm infections.
- To apply the product, part the hair on the back of the cat's neck at the base of the head, place the tip of the tube on the skin, and squeeze the entire contents directly onto the skin.
- This medication is typically well-tolerated.
- Do not apply to broken skin or if hair coat is wet.
- Do not get topical product in the cat's mouth or eyes and do not allow the animal to lick the application site for 1 hour. Oral exposure to cats can cause salivation and vomiting; treatment at the base of the head minimizes the opportunity for ingestion.
- In households with multiple pets, keep them separated to prevent licking of the application site.
- Avoid direct human contact with the application site while it is wet. Avoid prolonged contact (eg, sleeping) with treated cats for 24 hours after application. In case of accidental spillage onto human skin, immediately wash off using soap and water.
- Your veterinarian may recommend *oral* administration of the *feline topical* product for dogs with resistant hookworm infections. Side effects may include salivation, vomiting, loss of appetite, tremors, abnormal breathing, and abnormal gait. Because this treatment is a new way to use this product, it is important to monitor your dog for any unusual signs not mentioned here and report them to your veterinarian if you have concerns.

Chemistry/Synonyms

Emodepside is an N-methylated 24-membered cyclooctadepsipeptide that consists of 4 alternating residues of N-methyl-L-leucine, 2 residues of D-lactate, and 2 residues of D-phenylacetate.

Praziquantel occurs as a white to practically white, hygroscopic, bitter tasting, crystalline powder that is either odorless or has a faint odor. It is very slightly soluble in water and freely soluble in alcohol. Available formulation is a clear yellow ready-to-use solution.

Emodepside may also be known as BAY44-4400 or PF1022-221. Praziquantel may also be known as EMBAY-8440 or praziquantelum.

Storage/Stability

Store product at or below 25°C (77°F); do not allow product to freeze.

Compatibility/Compounding Considerations

No specific information noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Emodepside (1.98% w/w; 21.4 mg/mL)/Praziquantel (7.94% w/w; 85.8 mg/mL) Topical Solution in 0.35 mL (cats, 1 to 2.5 kg [2.2 to 5.5 lb]), 0.7 mL (cats, 2.5 to 5 kg [5.5 to 11 lb]), and 1.12 mL (cats, 5 to 8 kg [11 to 17.6 lb]) tubes; *Profender*®; (Rx). NADA #141-275

An oral product for dogs (ie, *Profender*® for Dogs) is available in many countries but is not FDA-approved in the US. A combination oral suspension for dogs and cats that contains emodepside and toltrazuril (ie, *Procox*®) is also available in some markets.

HUMAN-LABELED PRODUCTS: NONE

Enalapril
Enalaprilat

(e-***nal***-a-pril) *Enacard®, Vasotec®*
Angiotensin-Converting Enzyme (ACE) Inhibitor

Prescriber Highlights

- ► Used to treat congestive heart failure (CHF), hypertension, chronic kidney disease (CKD), and proteinuria in dogs and cats
- ► Not recommended for acute kidney injury
- ► Should be used with caution in animals with dehydration, increased creatinine, hyperkalemia, hyponatremia, systemic lupus erythematosus (SLE), and hematologic disorders
- ► Adverse effects are uncommon. GI disturbances are the most likely adverse effects, but hypotension, renal dysfunction, and hyperkalemia are also possible.
- ► Use during pregnancy should be avoided.

Uses/Indications

Enalapril may be useful in the adjunctive treatment of congestive heart failure (CHF) in dogs and cats. Enalapril has been approved for use in dogs, and published studies have found therapeutic benefits in dogs with CHF[1,2]; however, concerns about those studies, coupled with a lack of prospective, controlled studies in cats, have raised questions regarding enalapril's value in small animals with CHF. Despite these concerns and the ongoing debate, ACE inhibitors continue to be used by many veterinary cardiologists to treat CHF in cats and dogs.[3] According to the 2019 ACVIM consensus guidelines for the treatment of degenerative mitral valve disease in dogs, use of an ACE inhibitor is recommended in the chronic management of dogs with stage C and stage D heart failure.[1] In the 2020 ACVIM consensus guidelines for the treatment of CHF in cats with cardiomyopathy, the use of an ACE inhibitor was not encouraged.[4]

Recommendations for ACE inhibitor use in dogs with the early stages of degenerative mitral valve disease (eg, prior to the onset of clinical signs) are mixed, with only half of the ACVIM panelists recommending its use in this stage.[1] Prior prospective, placebo-controlled clinical trials in dogs with subclinical degenerative mitral valve disease receiving enalapril failed to show a significant delay in the onset of CHF compared to placebo.[5,6] In another study, dogs with mitral regurgitation receiving enalapril 0.5 mg/kg/day for 14 days had increased cardiac parasympathetic tone and decreased sympathetic tone, which may theoretically lead to a reduction in cardiac preload and afterload.[7] The benefit, or lack of benefit, for ACE inhibitors in dogs with heart disease may relate to dose, with a retrospective study suggesting a twice-daily dosing of ACE inhibitors was predictive of improved 2 year survival compared to a once daily dosing.[8]

In a study of 26 Doberman pinschers with occult dilated cardiomyopathy, enalapril at a dosage of 10 mg/dog (NOT mg/kg) PO every 12 hours for 1 week, followed by 20 mg/dog (NOT mg/kg) PO every 12 hours showed a *statistically* significant increase in serum magnesium, serum potassium, and BUN from baseline when used in combination with spironolactone, carvedilol, and mexiletine. However, these changes were small and not *clinically* significant, suggesting this medication combination appears to be safe at the studied dosages.[9]

Because ACE inhibitors can decrease efferent glomerular resistance, can reduce proteinuria, and have renoprotective effects,[10] they are used for adjunctive treatment of idiopathic glomerulonephritis, CKD, and protein-losing nephropathies (PLNs) in small animals. There is stronger evidence for ACE inhibitor efficacy in dogs with PLN as compared with animals that have CKD without severe PLN. Enalapril at 0.5 mg/kg PO every 12 hours, in combination with a renal diet, further ameliorates proteinuria.[11] However, one study found that the angiotensin receptor blocker telmisartan was superior to enalapril in reducing proteinuria.[12]

Although ACE inhibitors are a mainstay in the treatment of hypertension in humans, they have not been particularly useful when used alone in the treatment of hypertension in cats.[13] In experimental models of renal insufficiency in dogs, enalapril at 0.5 mg/kg PO every 12 hours lowered mean arterial blood pressure.[14] ACE inhibitors are considered first-line treatment for hypertension in dogs due to the high prevalence of CKD in this population.[15] Combining ACE inhibitors with amlodipine ± an angiotensin receptor blocker (eg, telmisartan) can be considered for blood pressure management in dogs with CKD.[16]

Pharmacology/Actions

Enalapril is converted in the liver to the active compound enalaprilat. Enalaprilat prevents the formation of angiotensin-II, a potent vasoconstrictor, by competing with angiotensin-I for the ACE. ACE appears to have a much higher affinity for enalaprilat than for angiotensin-I. Because angiotensin-II concentrations are decreased, aldosterone secretion is reduced, and plasma renin activity is increased (due to the negative feedback mechanism). However, aldosterone breakthrough (elevated secretion of aldosterone) has been consistently documented in dogs receiving enalapril, which may be due to angiotensin-II reactivation, alternative renin-angiotensin-aldosterone pathways, or overriding effects in patients with activated ACE.[17]

The cardiovascular effects of enalaprilat in patients with CHF include decreased total peripheral and pulmonary vascular resistance, mean arterial and right atrial pressures, and pulmonary capillary wedge pressure; unchanged or decreased heart rate; and increased cardiac index and output, stroke volume, and exercise tolerance.

ACE inhibitors increase renal blood flow and decrease glomerular efferent arteriole resistance. In animals with glomerular disease, ACE inhibitors may decrease proteinuria and may help to preserve renal function. In healthy dogs, enalapril partially blocks activation of the renin-angiotensin-aldosterone system (RAAS) caused by amlodipine[18] and furosemide[17,19] Aldosterone breakthrough from ACE inhibition is independent of dose.[19]

Pharmacokinetics

Enalapril and enalaprilat have different pharmacokinetic properties as compared with captopril (ACE inhibitor) in dogs. Enalapril has a slower onset of action (4 to 6 hours) but a longer duration of action (12 to 14 hours) than captopril. In dogs, enalapril is readily absorbed and subsequently hydrolyzed to the active metabolite enalaprilat. Approximately 95% of enalaprilat is cleared via renal routes; reduced renal function can impact elimination rates.

In a study of horses, after administration of enalapril 0.5 mg/kg IV or PO, elimination half-lives of enalapril and enalaprilat were 0.59 and 1.25 hours, respectively.[20] After PO administration, enalapril and enalaprilat were not detectable in the serum. ACE activity had a tendency to decrease 40 to 120 minutes after enalapril PO administration, but ACE suppression was never greater than 16%. Serum concentrations of potassium, magnesium, serum creatinine, BUN, venous blood gases, and lactate did not change.[20]

In a different study, horses were given enalapril 0.5 mg/kg IV and 0.5 mg/kg, 1 mg/kg, and 2 mg/kg PO.[21] After IV administration, elimination half-lives of enalapril and enalaprilat were 0.67 and 2.76 hours, respectively. After PO administration, enalapril was below the limits of detection. Maximum mean ACE inhibition from baseline was 88.38% following IV administration and 21.69%, 26.11%, and 30.19% following the respective PO doses. Blood pressure and concentrations of BUN, serum creatinine, and electrolytes remained unchanged.[21]

In humans, enalapril is well absorbed after oral administration, but enalaprilat is not. Approximately 60% of an oral dose of enalapril is bioavailable, and food does not alter bioavailability. Both enalapril and enalaprilat are distributed poorly in the CNS. Enalaprilat is ≈50% bound to plasma proteins. In humans, the half-life of enalapril is ≈2 hours and the half-life of enalaprilat is ≈11 hours. Half-lives are increased in patients with CKD or severe CHF. The drug is renally eliminated.

Contraindications/Precautions/Warnings

Enalapril and enalaprilat administration is contraindicated in patients that have demonstrated hypersensitivity to ACE inhibitors. It is also contraindicated in humans with hereditary or idiopathic angioedema; veterinary clinical significance is unknown.

Enalapril should be used with caution and under close supervision in patients with renal insufficiency; doses may need to be reduced. One recommendation for an empiric dose reduction in cats with CKD is to start the daily administration at 50% of the usual total daily dose of 0.5 mg/kg every 12 hours when serum creatinine is greater than 2.3 mg/dL (roughly equivalent to creatinine clearance greater than 0.4 mL/kg/minute).[22] Although there are no specific dose adjustment recommendations for dogs, the same empiric approach would likely apply. Use of ACE inhibitors in critically ill patients with acute kidney injury (AKI) is generally not recommended because of their potential negative effects on glomerular filtration rate (GFR). Before receiving this class of drugs, patients should be stable after recovering from AKI.

Enalapril and enalaprilat should also be used with caution in patients with hyponatremia or sodium depletion, dehydration, pre-existing hematologic abnormalities, and/or collagen vascular disease (eg, SLE).

Dogs given enalapril at 0.5 mg/kg PO every 12 hours under isoflurane general anesthesia experienced significant hypotension and required more interventions as compared with dogs that did not receive the drug.[23] As such, withholding enalapril on the day of general anesthesia is advisable.

Liver disease does not appear to alter drug effects or dosing. Hepatic failure due to administration of enalapril has rarely been reported in humans.

Adverse Effects

Enalapril's primary adverse effect in dogs is GI distress (eg, anorexia, vomiting, diarrhea). Weakness and hypotension can also occur. In a study of Doberman pinschers with cardiomyopathy treated with enalapril, carvedilol, and spironolactone, elevated concentrations of magnesium, potassium, and BUN were noted but deemed clinically insignificant.[9] Polydipsia and polyuria have also been observed.

Adverse effects associated with enalapril in cats include lethargy and inappetence.

Because enalapril lacks a sulfhydryl group (unlike captopril), there is less likelihood that immune-mediated reactions will occur, but rashes, neutropenia, and agranulocytosis have been reported in humans. In humans, ACE inhibitors can commonly cause coughing, but this reaction is rare in dogs and cats.

Reproductive/Nursing Safety

Enalapril and enalaprilat cross the placenta, and the human label has a black box warning to discontinue enalapril as soon as possible when pregnancy is detected.[24] Veterinary-labeled enalapril is contraindicated in pregnant dogs in the United Kingdom.[25] High doses in rodents have caused decreased fetal weights and increases in fetal and maternal death rates; teratogenic effects have not been reported.

Enalapril and enalaprilat are excreted in milk, and use is not recommended in nursing animals.

Overdose/Acute Toxicity

In a study of dogs, administration of 200 mg/kg (400 times recommended dose) was reported to be lethal, but 100 mg/kg (200 times recommended dose) was not.[26] No adverse effects were noted in dogs given 15 mg/kg/day for up to one year.[26] In overdose situations, the primary concern is hypotension; supportive treatment with volume expansion using normal saline is recommended to correct blood pressure. Because of the drug's long duration of action, prolonged monitoring and treatment may be required. Acute overdoses should be managed by using gut-emptying protocols when warranted. The drug is removed by dialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving enalapril or enalaprilat and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Anesthetic Agents, Inhalant and Injectable** (eg, **alfaxalone, etomidate, isoflurane, propofol**): Concurrent use may increase risk for hypotension. Dogs given enalapril 0.5 mg/kg PO every 12 hours under isoflurane general anesthesia experienced significant hypotension and required more interventions as compared with dogs that did not receive enalapril.[23]
- **Angiotensin Receptor Blockers (ARBs;** eg, **telmisartan**): Concurrent use of an ACE inhibitor with an angiotensin II receptor antagonist may cause additive effects on the renin-angiotensin system causing hyperkalemia, hypotension, syncope, and acute kidney injury.
- **Antacids, Aluminum-, Calcium-, or Magnesium-Containing**: Reduced oral absorption of enalapril may occur if administered concomitantly with antacids; administration should be separated by at least 2 hours.
- **Antihypertensive Agents and Vasodilators** (eg, **amlodipine, hydralazine, nitrates, prazosin**): Concurrent use may increase the risk for hypotension and other adverse effects; doses should be titrated carefully.
- **Buspirone**: Concurrent use may increase the risk for hypotension.
- **Cabergoline**: Concurrent use may lead to additive hypotension.
- **Cimetidine**: Concurrent use with ACE inhibitors has caused neurologic dysfunction in 2 human patients.
- **Corticosteroids** (eg, **dexamethasone, fludrocortisone, prednis(ol)one**): May decrease the antihypertensive effects of ACE inhibitors
- **Dalteparin, Enoxaparin**: Concurrent use may increase the risk for hyperkalemia.
- **Darbepoetin Alfa; Epoetin Alfa**: ACE inhibitors may interfere with erythropoietin.
- **Digoxin**: Digoxin concentration may increase by 15% to 30% when an ACE inhibitor is added; automatic dose reduction is not recommended but monitoring of serum digoxin concentration should be performed.
- **Diphenhydramine**: Concurrent use may increase the risk for hypotension.
- **Disopyramide**: Hypoglycemic effects may be enhanced.

- **Diuretics** (eg, **furosemide**): Concomitant diuretics may cause hypotension if used with enalapril; doses should be titrated carefully.
- **Doxepin**: Concurrent use may increase the risk for hypotension.
- **Glycerin, Oral**: Concurrent use may increase the risk for hypotension.
- **Heparin**: Concurrent use may increase the risk for hyperkalemia.
- **Lanthanum**: Reduced oral absorption of enalapril may occur if administered concomitantly; administration should be separated by at least 2 hours.
- **Lithium**: May increase risk for lithium toxicity
- **Nonsteroidal Anti-Inflammatory Drugs (NSAIDs**; eg, **carprofen, meloxicam, robenacoxib**): Potentially could increase the risk for nephrotoxicity and/or reduce efficacy of the ACE inhibitor in animals with cardiac or renal disease[27,28]; monitoring is advised.
- **Opioids** (eg, **butorphanol, hydrocodone, morphine**): Concurrent use may increase the risk for hypotension.
- **Potassium** Or **Potassium-Sparing Diuretics** (eg, **spironolactone**): Hyperkalemia may develop. The UK label states that combination with veterinary-labeled enalapril is contraindicated.
- **Probenecid**: Can decrease renal excretion of enalapril and possibly enhance the clinical and toxic effects of probenecid
- **Sildenafil**: Concurrent use may increase risk for hypotension.

Laboratory Considerations

- When iodohippurate sodium I-123/I-134 or technetium-99m pentetate is used for **renal imaging** in patients with renal artery stenosis, ACE inhibitors may cause a reversible decrease in localization and excretion of these agents in the affected kidney, which may lead to confusion in test interpretation.

Dosages

DOGS:

NOTE: Dehydration should be corrected prior to initiating therapy.

Adjunctive treatment of heart failure (label dosage; FDA-approved): 0.5 mg/kg PO once daily initially with or without food; if after 2 weeks the response is inadequate, dose can be increased to a maximum of 0.5 mg/kg every 12 hours. Diuretics should be administered at least 1 day prior to starting enalapril.[26] **NOTE**: Many consider the labeled starting dose to be too low; an initial dose of 0.5 mg/kg PO every 12 hours has been recommended.[3]

Adjunctive treatment of proteinuria (extra-label):

NOTE: Therapeutic goal is to reduce the urine protein:creatinine ratio by at least half—ideally, into the normal range (ie, UP:C less than 0.5).[29]

a) Nonazotemic patients: 0.25 – 1 mg/kg PO every 12 hours. Most initially treat at ≈0.5 mg/kg PO every 12 hours.[29,30]

b) Azotemic patients: 0.25 mg/kg PO every 12 hours. If azotemia does not worsen after 7 days of therapy, enalapril can be increased to 0.5 mg/kg PO every 12 hours with continued monitoring. See ***Monitoring***. **NOTE**: No conclusive data support a specific dose adjustment based on degree of azotemia. Higher dosages (eg, 2 mg/kg twice daily) may reduce progression of CKD in dogs.[31,32]

Systemic hypertension in dogs with CKD (extra-label): Initially 0.5 mg/kg PO every 12 hours. Dose can be increased (as tolerated) up to 2 mg/kg PO every 12 hours until target blood pressure is reached.[15] If this treatment regimen does not adequately control blood pressure, adding a second antihypertensive agent (eg, amlodipine, telmisartan) could be considered to achieve blood pressure management goals.[16]

CATS:

NOTE: Dehydration should be corrected prior to initiating therapy.

Chronic adjunct treatment for congestive heart failure (extra-label): 0.25 – 0.5 mg/kg PO every 24 hours. Practically given as 1.25 – 2.5 mg/cat (NOT mg/kg) PO every 24 hours[33]

Adjunctive treatment of proteinuria (extra-label):

NOTE: The therapeutic goal is to reduce the urine protein:creatinine ratio by at least half or, ideally, into the normal range (ie, UP:C less than 0.4).

a) Nonazotemic patients: 0.25 – 0.5 mg/kg PO every 12 to 24 hours. Most initially treat at ≈0.25 mg/kg PO every 12 hours.

b) Azotemic patients: 0.25 mg/kg PO every 12 to 24 hours. See ***Monitoring***. **NOTE**: No conclusive data support a specific dose adjustment based on degree of azotemia.[16,31,34,35]

Systemic hypertension (extra-label): Most recommend using amlodipine as the first-line agent in cats; however, for patients with hypertension that cannot be controlled with amlodipine alone or those with concurrent proteinuria, enalapril can be added at 0.5 mg/kg PO every 24 hours.[15]

FERRETS:

Adjunctive therapy for heart failure (extra-label):

a) 0.25 – 0.5 mg/kg PO every 48 hours; can be increased to every 24 hours as tolerated by the patient[36]

b) Dilated cardiomyopathy: 0.5 mg/kg PO every 24 to 48 hours[37]

BIRDS:

Adjunctive therapy for heart failure (extra-label):

a) 1.25 mg/kg PO every 8 to 12 hours[38]

b) 0.25 – 0.5 mg/kg PO every 24 to 48 hours in combination with furosemide[39]

Monitoring

- Clinical signs of CHF (eg, exercise intolerance, cough, increased resting respiratory rate and effort)
- Renal function (serum creatinine, BUN, urine protein:creatinine ratio) and electrolytes (in particular, potassium): These parameters should be measured prior to starting enalapril therapy and within 1 to 2 weeks of starting therapy or changing dose. These parameters should be rechecked every 3 months if the patient is stable. Large or progressive increases in serum creatinine should prompt reassessment of therapy. If serum creatinine increases by more than 0.2 mg/dL, a dose decrease is recommended.[34] ACE inhibitor doses should be cautiously increased to maximize impact on degree of proteinuria yet minimize the impact on renal function. Hyperkalemia or anorexia may also limit dose increases.
- Periodic CBCs are performed on humans receiving enalapril; this test may not be necessary in veterinary patients unless the patient's underlying condition warrants it.
- Blood pressure: baseline and periodic (eg, 7 to 10 days after initiating treatment [sooner if patient develops clinical signs associated with hypotension or if target organ damage is present in hypertensive animals]) or after dosage changes

Client Information

- Enalapril is used to treat heart failure, high blood pressure, and some forms of kidney disease in dogs and cats.
- This medicine is usually well tolerated but vomiting and diarrhea can occur. It may be given with or without food. If your animal vomits, stops eating, or acts sick after getting enalapril on an empty stomach, give with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.

- If a rash or signs of infection (eg, fever) occur, contact your veterinarian immediately.
- Very important to give this medicine as prescribed by your veterinarian. Do not stop or change the amount of medicine you give your animal without talking to your veterinarian first.
- Your animal will need to be monitored with blood tests and blood pressure checks while on this medication. Do not miss these important follow-up visits.

Chemistry/Synonyms

As ACE inhibitors, enalapril maleate and enalaprilat are derivatives of an alanine-proline dipeptide. Enalapril is a prodrug and is converted in vivo by the liver to enalaprilat. Enalapril maleate occurs as a white to off-white crystalline powder; 25 mg is soluble in 1 mL of water. Enalaprilat occurs as a white to off-white crystalline powder and is slightly soluble in water.

Enalapril maleate may also be known as enalaprili maleas and MK-421; many trade names are available. Enalaprilat may also be known as enalaprilic acid, MK-422, *Enacard®*, *Enalfor®*, *Epaned®*, *Glioten®*, *Lotrial®*, *Pres®*, *Renitec®*, *Reniten®*, *Vasotec®*, and *Xanef®*.

Storage/Stability

Enalapril tablets should be stored at temperatures less than 30°C (86°F) in tight containers. Enalapril solution should be stored under refrigeration at 2°C to 8°C (36°F-46°F) in tightly closed containers; avoid freezing or excessive heat. Enalapril solution may be stored at room temperature (20°C-25°C [68°F-77°F]) but must be discarded after 60 days.

Enalaprilat injection should be stored at 25°C (77°F), with excursions permitted between 15°C and 30°C (59°F-86°F). After dilution with D5W, normal saline, normal saline in D5W, or D5W in lactated Ringer's solution, the injectable formulation is stable for up to 24 hours at room temperature.

Compatibility/Compounding Considerations

Enalaprilat has been documented to be physically **incompatible** with amphotericin B, diazepam, and phenytoin sodium. Enalaprilat has **uncertain compatibility** with ampicillin, ampicillin/sulbactam, hydralazine, pantoprazole, and sulfamethoxazole/trimethoprim. Many other medications have been noted to be **compatible** with enalaprilat at various concentrations.

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Compounded preparation stability: Enalapril oral suspension compounded from commercially available tablets has been published.[40] Triturating 6 enalapril 20 mg tablets with 60 mL of *Ora-Plus®* and qs ad to 120 mL with *Ora-Sweet®* (or *Ora-Sweet® SF*), yields a 1 mg/mL oral suspension that retains greater than 90% potency for 60 days stored at both 5°C (41°F) and 25°C (77°F). Degradation of enalapril is pH dependent, with maximum stability at a pH of 3 and increased decomposition above a pH of 5. Compounded preparations of enalapril should be protected from light.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Enalapril Maleate Tablets: 1 mg, 2.5 mg, 5 mg, 10 mg, and 20 mg; *Enacard®*; (Rx). FDA approved for use in dogs. Although this product is still listed as approved at AnimalDrugs@FDA, it is no longer marketed in the United States. It is licensed for use in dogs in Canada, the United Kingdom, Australia, and other countries.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Enalapril Maleate Tablets: 2.5 mg, 5 mg, 10 mg, and 20 mg; *Vasotec®*, generic; (Rx)

Enalapril Oral Solution: 1 mg/mL; *Epaned®*; (Rx)

Enalaprilat Injection: (for IV use) equivalent to 1.25 mg/mL in 1 mL and 2 mL vials; generic; (Rx)

Enalapril also is available in combination with hydrochlorothiazide.

Enoxaparin

(en-***ocks***-a-par-in) *Lovenox®*

Anticoagulant

Prescriber Highlights

- ► Low molecular weight (fractionated) heparin that may be useful for treatment or prophylaxis of thromboembolic disease
- ► Preferentially inhibits factor Xa and only minimally impacts clotting times
- ► Hemorrhage unlikely, but possible
- ► Must be given SC; uncertainty about effective dosing requirements for dogs or cats

Uses/Indications

Enoxaparin may be useful for prophylaxis or treatment of thromboembolic disease, including use in dogs with primary immune-mediated hemolytic anemia[1,2]; however, for dogs and cats, there is little published data to support its use in clinical patients, and it is still not known if it is safe and effective as well as economically viable for veterinary patients. Enoxaparin has also been used in horses to prevent laminitis following colic surgery.[3] In humans, enoxaparin is also indicated for prevention of ischemic complications associated with unstable angina and non-Q-wave myocardial infarction.[4]

Pharmacology/Actions

By binding to and accelerating antithrombin, low molecular weight heparins (LMWHs) enhance the inhibition of factor Xa and thrombin. The potential advantage to using these products over standard (unfractionated) heparin is that LMWHs preferentially inhibit factor Xa and only minimally impact clotting times (prothrombin time, thrombin time, and activated partial thromboplastin time). Recent studies in cats suggest that inhibition of factor Xa activity may not be an accurate indicator for predicting antithrombotic activity, as there may not be an association between the pharmacokinetics and pharmacodynamics in vivo.[5]

Pharmacokinetics

It is unclear if enoxaparin's pharmacokinetics directly relate to its antithrombotic actions in animals. In dogs after SC administration, enoxaparin has a shorter duration of inhibitory activity on factor Xa than in humans and therefore likely requires more frequent dosing in dogs. A study examining enoxaparin dose response (based on inhibition of factor Xa) in healthy greyhounds showed that enoxaparin 0.8 mg/kg SC every 6 hours was required to effectively and consistently inhibit factor Xa activity.[6] A subsequent study evaluating enoxaparin 0.8 mg/kg SC every 6 hours in healthy beagles demonstrated transient inhibition of factor Xa activity in only 3 of 8 dogs, and suggested that assumptions regarding pharmacodynamic effects of enoxaparin cannot be generalized across breeds.[7]

Cats appear to have a much shorter duration of factor Xa inhibitory activity associated with low molecular weight heparins (LMWHs) than do humans. To maintain a therapeutic target of factor Xa inhibitory activity of 0.5 – 1 IU/mL, 1.5 mg/kg enoxaparin SC every 6 hours is required.[8] However, a recently published study suggests that factor Xa inhibitory activity may not be an accurate determiner for antithrombotic activity of enoxaparin in cats. In their venous stasis model, antithrombotic activity persisted well beyond the expected therapeutic time for factor Xa inhibition.[5] A different study found that following a single enoxaparin SC injection, C_{max} was 0.83 anti-Xa IU/mL with a T_{max} of 110 minutes. The total clearance for enoxaparin was 23.4 mL/kg/hour, and the terminal half-life was 2.27 hours.[9]

A study investigating the pharmacokinetic variables of enoxaparin in horses demonstrated that the drug has similar activity (effect, duration) as in humans and the once daily SC injections may be useful for anticoagulant therapy.[10]

After SC injection in humans, enoxaparin is absorbed rapidly, with a bioavailability of ≈92%; peak plasma concentrations occur in 3 to 5 hours. Activity against factor Xa persists for up to 24 hours; doses are usually given once to twice a day. Enoxaparin is metabolized in the liver and excreted in the urine as both unchanged drug and metabolites; elimination half-life is ≈4 to 5 hours.

Contraindications/Precautions/Warnings

Enoxaparin is contraindicated in patients that are hypersensitive to it, other low molecular weight heparins (LMWHs), heparin, or porcine products. Its use is contraindicated in patients with active major bleeding and heparin-induced thrombocytopenia.[4] It should be used with extreme caution in patients receiving epidural anesthesia or with increased risk for hemorrhage, such as with a congenital or acquired bleeding disorder. In humans, it is recommended to use enoxaparin with caution in patients with bleeding diathesis, uncontrolled arterial hypertension, or history of recent GI ulceration, or diabetic retinopathy. Use enoxaparin cautiously in patients with hepatic impairment or significant renal dysfunction as drug accumulation could result.

Do **not** administer via IM or IV routes; enoxaparin must be given via SC injection only. Enoxaparin cannot be used interchangeably with other LMWHs or heparin sodium products as the dosages differ for each.

Adverse Effects

Minor hemorrhage was reported in ≈10% of dogs with immune-mediated hemolytic anemia receiving enoxaparin.[11]

In humans, adverse effects do not routinely occur with enoxaparin. Hemorrhage is a possibility and has been reported in 13% of patients in one study.[4] Injection site pain, ecchymosis, erythema, and hematoma are possible. Anemia, thrombocytopenia, nausea, and fever have also been reported.

Reproductive/Nursing Safety

No evidence of teratogenicity or fetotoxicity was observed when enoxaparin was given to pregnant laboratory animals.[4]

It is unclear whether enoxaparin enters milk.[4] As the drug is not absorbed orally, effects on nursing offspring would be unlikely.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose may lead to hemorrhagic complications. If treatment is necessary, protamine sulfate may be administered at 1 mg IV slowly for each 1 mg of enoxaparin given within the past 8 hours.[4] If enoxaparin administration occurred greater than 8 hours previously, or if a second protamine dose is needed (eg, if activated partial thromboplastin time (aPTT) remains prolonged 2 to 4 hours after first protamine dose), an infusion of protamine 0.5 mg IV slowly may be administered for every 1 mg enoxaparin given. Avoid overdoses of protamine sulfate.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving enoxaparin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticoagulants, Oral** (eg, **warfarin**): Increased risk for hemorrhage
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, flunixin, meloxicam, robenacoxib**): Increased risk for hemorrhage
- **Platelet-Aggregation Inhibitors** (eg, **aspirin**, **clopidogrel**): Increased risk for hemorrhage
- **Selective Serotonin Reuptake Inhibitors** (**SSRIs;** eg, **fluoxetine, sertraline**): Increased risk for hemorrhage
- **Thrombolytic Agents**: Increased risk for hemorrhage

Laboratory Considerations

Low molecular weight heparins (LMWHs) may cause subclinical, fully reversible increases in **AST** or **ALT**[4]; bilirubin is only rarely increased in these patients. Therefore, interpret these tests with caution; increased values do not necessarily indicate hepatic damage or dysfunction.

Dosages

DOGS:

Thromboprophylaxis (extra-label): At present, there is no substantial evidence to support any dosage, but based on pharmacokinetics and inhibition of Xa activity in dogs, suggested dosages are:

a) 0.8 – 1 mg/kg SC every 6 to 8 hours[1,2]

b) 0.8 mg/kg SC every 6 hours[12]; dosage was found to be safe and well tolerated in dogs but may not achieve anti-Xa concentrations considered therapeutic in all breeds.

CATS:

Thromboprophylaxis (extra-label): 0.75 – 1 mg/kg SC every 6 to 12 hours[12]; every-6-hour administration provided the most consistent anti-Xa activity.[9]

HORSES:

Thromboprophylaxis (extra-label): 0.35 mg/kg SC every 24 hours was used in horses to prevent laminitis after colic surgery.[13]
NOTE: The drug's expense may be problematic for use in this species.

Monitoring

- Baseline and periodic CBC with platelet count during treatment
- Urinalysis (free catch)
- Routine coagulation tests (activated partial thromboplastin time [aPTT], ACT, PT) are insensitive measures of enoxaparin's effect and usually not warranted.[14]
- Anti-Xa activity (available at Cornell University, Animal Health Diagnostic Center) may be useful to guide dosage adjustments, particularly if bleeding occurs or patient has renal dysfunction. A

target anti-Xa peak range of 0.5 to 1 IU/mL, extrapolated from human literature, has been suggested for use in dogs and cats. The suggested thromboprophylactic range for horses is 0.1 – 0.2 IU/mL.[15]

NOTE: To measure peak anti-Xa activity, sample at 2 hours postdose for cats, 3 hours postdose for dogs, and 3 to 4 hours postdose for horses.[16] If an anti-Xa assay is not available, consider activated clotting time, aPTT, thrombin generation, or viscoelastic tests to monitor anticoagulant treatment.[1,17]

Client Information

- This medicine must be injected subcutaneously (under the skin). Be sure you understand how to correctly give the injections. Several injections a day may be required, and treatment can be very expensive. Administration of the injections may be painful for your animal.
- Bleeding is not likely, but if it does occur, contact your veterinarian immediately.
- If your animal is very listless (lacking energy), appears to be having trouble breathing, trouble walking, or loses the use of its rear legs, contact your veterinarian immediately, as it may mean blood clots have formed.

Chemistry/Synonyms

A low molecular weight heparin (LMWH), enoxaparin sodium is obtained by alkaline depolymerization of heparin derived from pork intestinal mucosa. The average molecular weight is ≈4500 and ranges from 3500 to 5500 (heparin sodium has a molecular weight of ≈12,000); 1 mg of enoxaparin is equivalent to 100 units of anti-factor Xa.

Enoxaparin sodium may also be known as Enoxaparinum natricum, PK-10169, RP-54563, *Clexane®, Decipar®, Klexane®, Lovenox®, Plaucina®*, and *Trombenox®*.

Storage/Stability

The commercially available injection should be stored at room temperature (25°C [77°F]); excursions permitted to 15°C to 30°C (59°F-86°F).

One study showed that diluting the 100 mg/mL commercially available solution with sterile water to 20 mg/mL resulted in a product that was stable for 4 weeks when stored in a glass vial or in plastic syringes at room temperature or refrigerated.[18]

Compatibility/Compounding Considerations

Do not mix or coadminister enoxaparin with other medications.[4]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Enoxaparin Sodium for Injection: 30 mg/0.3 mL, 40 mg/0.4 mL, 60 mg/0.6 mL, 80 mg/0.8 mL, 100 mg/1 mL, 120 mg/0.8 mL, and 150 mg/1 mL preservative-free in single-dose prefilled syringes; 300 mg/3 mL containing 15 mg/mL benzyl alcohol in 3 mL multidose vials; *Lovenox®*, generic; (Rx)

Enrofloxacin

(en-roe-***flox***-a-sin) *Baytril®, Zobuxa®*

Fluoroquinolone Antibiotic

Prescriber Highlights

- ► Effective against a variety of pathogens except for anaerobes
- ► In dogs, oral bioavailability is greater and more predictable than with ciprofloxacin.
- ► When possible, use should be avoided in young, growing animals because of the potential negative impact on cartilage development.
- ► Caution is advised in patients with hepatic or renal insufficiency or dehydration.
- ► Higher doses (greater than 5 mg/kg/day) not recommended in cats; may cause blindness
- ► Adverse effects include GI distress, CNS stimulation, crystalluria, or hypersensitivity.
- ► Oral administration to dogs and cats ideally should be on an empty stomach (unless vomiting occurs).
- ► Many potential drug interactions
- ► FDA prohibits extra-label use in food animals.

Uses/Indications

Enrofloxacin is FDA-approved for use in dogs (by oral[1] and IM[2] routes) and cats (oral[2] only) for the management of bacterial infections susceptible to enrofloxacin. Because of the feline dose restriction (5 mg/kg/day) and because better options are usually available for cats, enrofloxacin is generally used in this species to treat only the most susceptible bacterial infections or if an injectable fluoroquinolone is needed and where enrofloxacin is the only injectable option.

Enrofloxacin is FDA-approved for use in beef and nonlactating dairy cattle for the treatment and control of bovine respiratory disease (BRD).[3] It is conditionally approved for the treatment of clinical anaplasmosis associated with *Anaplasma marginale* in replacement dairy heifers under 20 months of age, in all classes of beef cattle except beef calves less than 2 months of age, and in beef bulls of any age that are intended for breeding.[4] Enrofloxacin is also FDA-approved for use in pigs for the treatment and control of swine respiratory disease (SRD) and as second-line therapy for the control of colibacillosis in groups or pens of weaned pigs.[3]

The World Health Organization (WHO) has designated fluoroquinolones as Critically Important, Highest Priority antimicrobials for human medicine.[5] The Office International des Epizooties (OIE) has designated enrofloxacin as a Veterinary Critically Important Antimicrobial (VCIA) Agent in veterinary species.[6]

Pharmacology/Actions

Enrofloxacin has broad-spectrum coverage. Enrofloxacin has good activity against many gram-negative bacilli and cocci, including most species and strains of *Pseudomonas aeruginosa, Klebsiella* spp, *Escherichia coli, Enterobacter* spp, *Campylobacter* spp, *Shigella* spp, *Salmonella* spp, *Aeromonas* spp, *Haemophilus* spp, *Proteus* spp, *Yersinia* spp, *Serratia* spp, and *Vibrio* spp. Other organisms that are generally susceptible include *Brucella* spp, *Chlamydia trachomatis,* staphylococci (including penicillinase-producing and methicillin-resistant strains), *Mycoplasma* spp, and some *Mycobacterium* spp (but not the etiologic agent for Johne's disease).

Fluoroquinolones have variable activity against most streptococci and are not usually recommended for use in these infections. Enrofloxacin is contraindicated with *Streptococcus canis* infections (or when it has not been ruled out) because of the potential for drug-induced necrotizing fasciitis.[7] This adverse effect does not appear to be a problem with other fluoroquinolones. Enrofloxacin has weak activity against enterococci and is not recommended in the treat-

ment of enterococcal infections. Enrofloxacin is generally ineffective in treating anaerobic infections.

Development of bacterial resistance is an ongoing concern with many different bacteria, particularly staphylococci, Enterobacterales (eg, *E coli*), and *Pseudomonas* spp. Resistance occurs by mutation, particularly with *P aeruginosa, Klebsiella pneumoniae, Acinetobacter* spp, and enterococci, but plasmid-mediated resistance is not thought to commonly occur. *E coli* resistance was demonstrated in enrofloxacin-treated weaner pigs as well as untreated pigs housed with treated animals.[8]

The bactericidal activity of enrofloxacin is concentration-dependent (antibacterial activity improves with high peak concentrations), and susceptible bacteria cell death occurs within 20 to 30 minutes of exposure. Enrofloxacin's mechanism of action is believed to be inhibition of bacterial DNA gyrase (a type II topoisomerase), thereby preventing DNA supercoiling and DNA synthesis.

Enrofloxacin has demonstrated a significant postantibiotic effect for both gram-negative and gram-positive bacteria and is active in stationary and growth phases of bacterial replication. In vitro kill assays for enrofloxacin and its active metabolite, ciprofloxacin, have demonstrated an additive response (effect equal to the combined action of each of the drugs used separately) in dog and cat isolates of *E coli, Staphylococcus pseudintermedius,* and *P aeruginosa*.[9] Methicillin-resistant *S pseudintermedius* present within biofilm have higher MICs, indicating reduced susceptibility to enrofloxacin.[10]

In vitro synergic antibacterial effects were not observed when enrofloxacin was combined with amikacin.[11]

Pharmacokinetics

Enrofloxacin is well absorbed after oral administration in most species. In dogs, enrofloxacin's bioavailability (≈80%) is approximately twice that of ciprofloxacin after oral administration. Oral bioavailability in horses is between 60% and 80%.[12,13] Fifty percent of peak plasma concentration (C_{max}) is reportedly attained within 15 minutes of administration and C_{max} occurs within 1 hour of administration. In sheep, oral enrofloxacin bioavailability is ≈90% or higher[14] and 83% after IM administration.[15] Presence of food in the stomach generally delays the rate but not the extent of absorption; however, foods with increased divalent or trivalent cation concentrations (eg, milk) can reduce bioavailability. Enrofloxacin is rapidly absorbed after IM administration in dogs (peak concentrations in ≈30 minutes).[2]

Enrofloxacin is widely distributed throughout the body. Volume of distribution in dogs is ≈3 to 4 L/kg. Only ≈27% is bound to canine plasma proteins. Highest concentrations are found in the bile, kidney, liver, lungs, and reproductive system (including prostatic fluid and tissue). Enrofloxacin reportedly concentrates in macrophages. Therapeutic concentrations are also attained in bone, synovial fluid, skin, muscle, aqueous humor, and pleural fluid. Low concentrations are found in the CSF; concentrations may only reach 6% to 10% of those found in serum. In hospitalized horses, volume of distribution was ≈1.25 L/kg. After mechanical disruption of the blood–aqueous humor barrier in horses, enrofloxacin (7.5 mg/kg IV) produced concentrations in the aqueous humor sufficient to treat *Leptospira pomona*.[16] Enrofloxacin concentration in bronchoalveolar fluid of calves was higher than plasma 1 hour and 2 hours after SC injection.[17] After SC administration to steers, enrofloxacin penetrated GI tissue better than ciprofloxacin.[18] The volume of distribution was 1.5 to 2.3 L/kg in sheep[15] and ≈1.5 L/kg in cattle.

Enrofloxacin is eliminated via renal and hepatic mechanisms. Approximately 15% to 50% of the drug is eliminated unchanged into the urine by tubular secretion and glomerular filtration. Enrofloxacin is metabolized to various metabolites, most of which are less active than the parent compounds. Approximately 10% to 40% of circulating enrofloxacin is metabolized to ciprofloxacin in most species, including, dogs, cats, adult horses, cattle, turtles, snakes, and humans. Foals, pigs, and some lizards convert little, if any, enrofloxacin to ciprofloxacin. Enrofloxacin metabolites are eliminated in the urine and feces. Because of the dual elimination routes (renal and hepatic), dogs with moderately impaired renal function may have slightly prolonged half-lives and higher serum concentrations but may not require any dosage adjustment. Approximate elimination half-lives in various species are in dogs, 2 to 5 hours[19,20]; cats, 6 hours; calves, 9 hours[18]; sheep and goats, 1.5 to 4.5 hours[15,21]; horses, 5 to 10 hours[12,22]; turtles, 18 hours; and alligators, 55 hours. After SC administration to calves, fecal enrofloxacin and ciprofloxacin concentrations were ≈ 115 and ≈50 times higher than their respective plasma concentrations.

Contraindications/Precautions/Warnings

Enrofloxacin is labeled as contraindicated in patients that are hypersensitive to it as well as in small- and medium-breed dogs aged 2 to 8 months. Bubble-like changes in articular cartilage have been noted when the drug was given at 2 to 5 times the recommended dosage for 30 days, although clinical signs have only been seen at 5 times the recommended dosage. To avoid cartilage damage, treatment for large- and giant-breed dogs may need to wait until 12 and 18 months of age, respectively. Enrofloxacin at concentrations greater than 1 mg/mL was toxic to equine chondrocytes.[23] Enrofloxacin is not recommended in cats with impaired renal function or at doses above 5 mg/kg/day due to increased risk for retinal degeneration.[24]

Because ciprofloxacin has occasionally been reported to cause crystalluria in humans, animals should not be allowed to become dehydrated during fluoroquinolone therapy. Enrofloxacin may cause CNS stimulation and should be used with caution in patients with seizure disorders. Patients with severe renal or hepatic impairment may require dosage interval adjustments to prevent drug accumulation.

Use of the canine injectable products in cats or dogs via non-FDA–approved parenteral routes (eg, IV, SC) is controversial and may result in significant adverse effects. Because of the high pH (≈11) of the solution, SC administration in any species may cause pain and tissue damage. Rapid or undiluted IV administration to dogs increases risk for cardiac arrhythmias, hypotension, vomiting, and mast cell degranulation (ie, release of histamine and other inflammatory mediators). See ***Compatibility/Compounding Considerations***.

Dilution and extra-label use of the large animal product (100 mg/mL; 10%) in small animal species via any route is strongly discouraged.

Enrofloxacin should not be used in foals, as they appear to be highly susceptible to the fluoroquinolone's arthropathic effects. Although there has been much discussion regarding the potential for cartilage abnormalities or other arthropathies in horses, objective data are lacking. In horses, IV administration should be slow as ataxia and other neurologic effects may occur when given rapidly. Intrauterine infusion and IM injections are not recommended in horses, as localized tissue reactions (eg, endometrial ulceration, necrosis, fibrosis, inflammation, hemorrhage) can occur.[25]

Extra-label use of fluoroquinolones is prohibited in food animals.

Enrofloxacin and ciprofloxacin cannot be considered equivalent due to pharmacokinetic differences (see ***Pharmacokinetics***).

Enrofloxacin should not be used in humans; it may cause hallucinations, vivid dreams, and/or headaches.

Adverse Effects

When enrofloxacin is used as labeled, its adverse effect profile is usually limited to GI distress (eg, vomiting, diarrhea, anorexia). In dogs, rare incidences of elevated hepatic enzymes, ataxia, seizures, depression, lethargy, and nervousness have also been reported[1,2]; dogs may vomit after IV administration. Hypersensitivity reactions or crystal-

luria could occur.

In cats, ocular toxicity has been reported, characterized by mydriasis, retinal degeneration, and blindness.[24,26] These effects were generally seen at higher dosage ranges and have necessitated a maximum dosage of 5 mg/kg/day in cats. Mydriasis may be an indication of impending or existing retinal changes. Retinal toxicity in cats appears to be caused by amino acid changes in the ABCG2 transporter in the blood–retina barrier, which allows photoreactive fluoroquinolones to accumulate in the feline retina.[27] Other rare adverse effects seen in cats can include vomiting, anorexia, elevated hepatic enzymes, diarrhea, ataxia, seizures, depression/lethargy, vocalization, and aggression.

Articular cartilage abnormalities have been noted in young, rapidly growing animals given fluoroquinolones (see ***Contraindications/Precautions/Warnings***).[1,2,4]

Fluoroquinolones may cause photosensitization and prolonged exposure of bare skin (eg, nose) to direct sunlight should be avoided.

Enrofloxacin 100 mg/mL injection can be irritating to the mouth when given orally to horses. This effect may be alleviated by coating the liquid with molasses or preparing a gel (see ***Compatibility/Compounding Considerations***) and rinsing the horse's mouth with water after administration. The prevalence of antibiotic-associated diarrhea due to enrofloxacin use in horses is ≈5%.[28]

In humans, fluoroquinolones may alter cardiac conduction and cause prolongation of the QT interval, especially in those with a history of QT interval prolongation, electrolyte disorders, cardiac disease, or are taking other QT interval prolonging medications.

Reproductive/Nursing Safety

The safety of enrofloxacin use in pregnant dogs has been investigated; breeding, pregnant, and lactating dogs receiving up to 15 mg/kg/day have demonstrated no treatment-related adverse effects.[1,2] However, because of the risk for cartilage abnormalities in young animals, fluoroquinolones are not generally recommended for use during pregnancy unless the benefits of therapy clearly outweigh the risks. Limited studies in male dogs at various dosages have indicated no effects on male breeding performance.

Safety in breeding, pregnant, or lactating cats has not been established.[1]

Enrofloxacin administration to mares during pregnancy resulted in detectable concentrations of enrofloxacin and ciprofloxacin in fetal fluids and cartilage.[29] Fetal abnormalities were not detected after enrofloxacin administration to pregnant mares for 2 weeks during early pregnancy (gestation days 46 to 60).[30] Enrofloxacin administration during late pregnancy did not result in clinical lameness or cartilage lesions in the foals[31]; however, the small sample sizes (6 or 7 horses per treatment arm) of these studies cannot be taken as an indication of no risk to the fetus.

The effects of enrofloxacin on cattle and swine reproductive performance, pregnancy, and lactation have not been adequately determined. Enrofloxacin and its metabolite ciprofloxacin are actively secreted into bovine milk.[32]

No teratogenic effects were observed in rabbits given a dose of 25 mg/kg or rats given a dose of 50 mg/kg.[3]

Overdose/Acute Toxicity

The oral LD_{50} for enrofloxacin in laboratory rats was greater than 5000 mg/kg. Dogs receiving 50 mg/kg/day for at least 14 days developed only vomiting and anorexia, but signs associated with an overdosage of 125 mg/kg/day for 11 days (in decreasing frequency) included vomiting, anorexia, depression, difficult locomotion, and death.[1,2]

In cats, an overdose can be serious (eg, blindness, seizures); a dose of 20 mg/kg or more can cause retinopathy and blindness,[1] which can be irreversible. Enrofloxacin 20 or 50 mg/kg/day for 3 weeks resulted in salivation, vomiting, and depression.[1]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

In pigs, enrofloxacin induced expression and activity of CYP1A2 and inhibited CYP2E1 and CYP3A4.[33] In hepatic microsomes from healthy beagles, enrofloxacin and ciprofloxacin inhibited CYP1A activity, but clinically relevant drug interactions were more likely with ciprofloxacin than with enrofloxacin.[34] The following drug interactions have either been reported or are theoretical in humans or animals receiving ciprofloxacin or enrofloxacin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed, and additional monitoring performed when appropriate.

- **Aluminum-, Calcium-, and Magnesium-Containing Oral Products**: May bind to enrofloxacin and prevent its oral absorption; doses of these products should be separated from enrofloxacin by at least 2 hours.
- **Antibiotics, other** (eg, **aminoglycosides, third-generation cephalosporins** [eg, **cefpodoxime, ceftiofur**], **doxycycline, extended-spectrum penicillins**): Synergism may occur against some bacteria (particularly *Pseudomonas aeruginosa*), but this is unpredictable.[35] Although enrofloxacin and ciprofloxacin have minimal activity against anaerobes, in vitro synergy has been reported when these drugs are used with clindamycin against strains of *Peptostreptococcus* spp, *Lactobacillus* spp, and *Bacteroides fragilis*.
- **Blood Glucose Lowering Agents** (eg, **insulins**, **sulfonylureas** [eg, **glipizide**, **glyburide**]): Fluoroquinolones may enhance the hypoglycemic effect of blood glucose lowering agents.
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Concomitant use with fluoroquinolones may increase risk for tendonitis and tendon rupture.
- **Cyclosporine, Systemic**: Fluoroquinolones may exacerbate nephrotoxicity and reduce the metabolism of cyclosporine.
- **Doxorubicin**: Enrofloxacin may increase doxorubicin exposure.
- **Flunixin**: In dogs, flunixin has been shown to increase the area under the curve (AUC) and elimination half-life of enrofloxacin, and enrofloxacin increases the AUC and elimination half-life of flunixin; it is unknown whether other NSAIDs interact with enrofloxacin in dogs.
- **Iron, Zinc** (**oral**): Concomitant administration may decrease fluoroquinolone absorption; doses should be separated by at least 2 hours.
- **Levothyroxine**: Ciprofloxacin may decrease levothyroxine efficacy.
- **Mycophenolate Mofetil**: Ciprofloxacin may decrease mycophenolic acid exposure.
- **Methotrexate (MTX)**: Concomitant administration may increase MTX concentrations and increase risk for toxicity.
- **Nitrofurantoin**: May antagonize the antimicrobial activity of fluoroquinolones; concomitant use of these drugs is not recommended.
- **Probenecid**: May block renal tubular secretion of ciprofloxacin and may increase ciprofloxacin serum concentration and elimination half-life; monitor for increased enrofloxacin adverse effects (nausea, diarrhea)

- **QT Interval Prolongation Drugs** (eg, **azithromycin, chlorpromazine, cisapride, fluconazole, fluoxetine, ketoconazole, methadone, ondansetron, quinidine, sotalol**): Combination with ciprofloxacin may increase risk for QT prolongation; concurrent use of cisapride and ciprofloxacin is contraindicated in humans. These interactions may also apply to enrofloxacin.
- **Sildenafil**: Concomitant use with ciprofloxacin may increase sildenafil serum concentrations and adverse effects.
- **Sucralfate**: In dogs, sucralfate can affect absorption of ciprofloxacin but does not appear to affect enrofloxacin absorption.[36]
- **Theophylline, Aminophylline**: Enrofloxacin may increase theophylline blood concentrations; in dogs, theophylline concentrations may be increased by ≈30% to 50%.[37]
- **Tilmicosin**: May decrease enrofloxacin metabolism[38]
- **Warfarin**: Concomitant use may increase anticoagulant effects of warfarin.

Laboratory Considerations

- Enrofloxacin may cause false positive **urine glucose** determinations when cupric sulfate solution (Benedict's solution, *Clinitest®*) is used. Tests using glucose oxidase (*Tes-Tape®*, *Clinistix®*) are not affected by enrofloxacin.
- In some humans, fluoroquinolones caused increases in **liver enzymes**, **BUN**, and **serum creatinine** and decreases in **hematocrit**. The clinical relevance of these changes in veterinary patients is unknown.

Dosages

DOGS:

Susceptible infections (label dosage; FDA-approved):

Oral tablets: 5 – 20 mg/kg PO once daily for at least 2 to 3 days beyond resolution of clinical signs.[1] Selection of a dose from this range is based on clinical experience, severity of infection, susceptibility of the pathogen. If no improvement is seen within 5 days, diagnosis should be reevaluated. Maximum duration of therapy is 30 days.

Injectable solution 2.27% (22.7 mg/mL): 2.5 mg/kg IM once, followed by oral enrofloxacin therapy[2]

Susceptible infections (extra-label): Using the 2.27% (22.7 mg/mL) injection, 10 – 20 mg/kg every 24 hours IM, SC (must be diluted), or slow IV based on the susceptibility, site, and severity of the infection. See ***Compatibility/Compounding Considerations***.

Lower UTIs (extra-label):

a) 10 – 20 mg/kg PO every 24 hours. Use of this drug should be reserved for cystitis cases caused by bacteria resistant to other antibiotics (eg, amoxicillin). Enrofloxacin has limited efficacy against *Enterococcus* spp.[39]

b) Sporadic bacterial cystitis: 18 – 20 mg/kg PO every 24 hours for 3 days was shown to be as effective as a 14-day treatment with amoxicillin plus clavulanate.[40]

Pyelonephritis (extra-label): 20 mg/kg PO every 24 hours; good first-line choice for treatment of pyelonephritis[39]

Enteric infections (extra-label):

a) **Enrofloxacin-sensitive *E coli* in dogs with granulomatous colitis** (extra-label): 10 mg/kg PO every 24 hours for 8 weeks[41]

b) **Campylobacteriosis**: 10 mg/kg PO every 24 hours. Resistance can develop during treatment.[42]

Bacterial skin infections (extra-label): 5 – 20 mg/kg PO every 24 hours.[43] Administration of this drug at the high end of the dose range may be required for treatment of *Pseudomonas* spp infections. Most clinicians consider enrofloxacin to be a second-line drug for the treatment of deep pyoderma in dogs; use is only recommended if culture and susceptibility results indicate first-line drugs will not be effective.

CATS:

Susceptible infections (label dosage; FDA-approved): 5 mg/kg PO every 24 hours or divided and given every 12 hours; continue for at least 2 or 3 days beyond cessation of clinical signs to a maximum of 30 days.[1] **NOTE**: Because enrofloxacin is a concentration-dependent antibiotic, once-daily administration is recommended. For serious infections that require a higher dose, consider using a different fluoroquinolone (eg, pradofloxacin).

Susceptible infections (extra-label): 5 mg/kg (or less) every 24 hours IM or IV using the canine injectable product (2.27%, 22.7 mg/mL). For IV administration, see ***Compatibility/Compounding Considerations.***

HORSES:

Susceptible infections (extra-label):

a) 5 – 7.5 mg/kg PO or IV every 24 hours.[44] Respiratory infections should be treated with the high end of the dose range.[45]

b) 7.5 mg/kg PO as a compounded gel every 24 hours. See ***Compatibility/Compounding Considerations.*** Horses should have feed withheld for 11 to 14 hours before and 1 to 2 hours after administration. The horse's mouth should be rinsed with water after administration to reduce the risk for oral ulceration.[46]

CATTLE:

Single day treatment of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica, Pasteurella multocida, Histophilus somni,* and *Mycoplasma bovis* in beef and nonlactating dairy cattle (label dosage; FDA-approved): 7.5 – 12.5 mg/kg SC once.[3]

Multiple day treatment of BRD associated with *M haemolytica, P multocida, H somni,* and *M bovis* in beef and nonlactating dairy cattle (label dosage; FDA-approved): 2.5 – 5 mg/kg SC every 24 hours for 3 days; additional daily treatments may be given to animals that have shown improvement but not complete recovery.[3]

Control of BRD in beef and nonlactating dairy cattle at high risk for developing BRD associated with *M haemolytica, P multocida, H somni, and M bovis* (label dosage; FDA-approved): 7.5 – 12.5 mg/kg SC once[3]

Clinical anaplasmosis associated with *Anaplasma marginale* in replacement dairy heifers under 20 months of age, all classes of beef cattle except beef calves less than 2 months of age, and beef bulls (of any age) intended for breeding (label dosage; conditionally approved by FDA): 12.5 mg/kg SC once; do not administer more than 20 mL per injection site.[4]

NEW WORLD CAMELIDS:

Susceptible infections in alpacas (extra-label): 5 mg/kg SC or 10 mg/kg PO every 24 hours[47]

SWINE:

Treatment and control of swine respiratory disease (SRD) associated with *Actinobacillus pleuropneumoniae, P multocida, Haemophilus parasuis, Streptococcus suis, Bordetella bronchiseptica,* and *Mycoplasma hyopneumoniae* and control of colibacillosis in groups or pens of weaned pigs where colibacillosis associated with *E coli* has been diagnosed (label-dosage; FDA-approved): 7.5 mg/kg IM or SC (behind the ear) once; do not administer more than 5 mL per injection site.[3]

BIRDS:

NOTE: Compounding the liver-flavored tablets with grape syrup

(*Syrpalta*®) may improve acceptance when enrofloxacin is administered PO.[48]

Susceptible gram-negative infections in Psittacines (extra-label):

a) Stable, immune-competent birds: 20 mg/kg PO every 24 hours
b) Debilitated, immune-competent birds: 15 – 20 mg/kg SC in fluid pocket every 24 hours
c) Debilitated, immunocompromised birds: 15 – 20 mg/kg SC in fluid pocket every 12 hours

FERRETS:

Susceptible infections (extra-label): 10 – 20 mg/kg PO, IM, or SC every 24 hours.[49] **NOTE**: If parenteral administration is required, it is recommended to dilute the solution to avoid injection site tissue necrosis.

RABBITS, RODENTS, & SMALL MAMMALS:

NOTE: All dosages are extra-label.

Rabbits:

a) For *Pasteurella* spp upper respiratory infection: 15 – 20 mg/kg PO every 12 hours for a minimum of 14 days in mild cases and up to several months for chronic infections; first dose may be given SC. Subsequent doses should NOT be given SC, as severe tissue reactions can occur.[50]
b) 5 mg/kg PO, SC, IM, or IV every 12 hours for 14 days. Enrofloxacin is the drug of choice for treatment of *Pasteurella* spp infections. Dilution is suggested if administering SC, as skin may slough. Injectable product should not be given PO because it is unpalatable.[51] See ***Compatibility/Compounding Considerations***.

Hedgehogs: 5 – 10 mg/kg PO or SC every 12 hours[52]

Chinchillas: 5 – 10 mg/kg PO or IM every 12 hours[53]

Chinchillas, gerbils, guinea pigs, hamsters, mice, rats: 5 – 10 mg/kg PO or IM every 12 hours or 5 – 20 mg/kg PO or SC every 24 hours. 50 – 200 mg/L for 14 days in drinking water. Not for use in young animals[54]

Rats: Chronic respiratory disease: 10 – 25 mg/kg PO every 12 hours[55]

REPTILES:

Susceptible respiratory infections for most species (extra-label): 5 mg/kg IM every 5 days for 25 days

Chronic respiratory infections (extra-label):

a) **Tortoises**: 15 mg/kg IM every 72 hours for 5 to 7 treatments[56]
b) **Bearded dragons**: 10 mg/kg IM once blood concentrations are high enough to kill susceptible bacteria[57]

Monitoring

- Clinical efficacy
- Adverse effects
- In cats, mydriasis and/or retinal changes may indicate retinal toxicity.

Client Information

- Enrofloxacin is best given on an empty stomach without food; however, if your animal vomits or acts sick, give with food or a small treat (no dairy products, antacids, or anything containing iron). If vomiting continues, contact your veterinarian.
- Do not crush film-coated tablets, as the drug is bitter, which may cause difficulty when getting your animal to take it.
- Do not give this medicine at the same time with other drugs or vitamins that contain certain minerals (eg, calcium, iron, magnesium, aluminum, zinc), as these products can reduce the amount of drug absorbed.
- This medicine may cause joint abnormalities if used in young, pregnant, or nursing animals.
- Most common side effects are vomiting, nausea, or diarrhea.
- Do not exceed prescribed dose in cats, as blindness can result. If your cat develops large pupils, contact your veterinarian immediately.

Chemistry/Synonyms

Enrofloxacin, a fluoroquinolone antibiotic, occurs as a pale-yellow crystalline powder. It is slightly soluble in water, but solubility is pH-dependent and altering the pH of the commercially available injections can cause precipitation. Enrofloxacin is related structurally to the human FDA-approved drug ciprofloxacin (enrofloxacin has an additional ethyl group on the piperazinyl ring).

Enrofloxacin may also be known as enrofloksasiini, enrofloxacine, enrofloxacino, enrofloxacinum, Bay-Vp-2674, *Baytril*®, *Baytril*® *100, Baytril*® *100-CA1, Enroflox*®, *Enroflox*®*-100*, *Enroquin*®, *Enrosite*®, or *Zobuxa*®.

Storage/Stability

Unless otherwise directed by the manufacturer, enrofloxacin tablets should be stored in tight containers at temperatures less than 25°C (77°F); excursions to 30°C (86°F) may be permitted for some products.

The canine FDA-approved injectable solution (2.27%) for IM injection should be stored protected from light at or below 25°C (77°F)[2]; do not freeze. Discard unused product 90 days from first vial puncture or after puncturing vial a maximum of 20 times.

The FDA-approved injectable solution (10%) for cattle and swine should be stored protected from sunlight at 20°C to 30°C (68°F-86°F), with excursions permitted to 40°C (104°F).[3,4] It should not be refrigerated or frozen. If exposed to cold temperatures, precipitation may occur; to redissolve, warm the solution, then shake the vial. Discard unused solution 30 days after first vial puncture, or after vial is punctured a maximum of 30 times with a needle or 4 times with a dosage delivery device.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Enrofloxacin 100 mg/mL injection may be diluted with sterile water for injection prior to IM or SC administration; use diluted solution within 24 hours of mixing.[3] Injectable enrofloxacin (both 22.7 mg/mL and 100 mg/mL) has been demonstrated to be physically **incompatible** with 1:1 dilution with 0.9% sodium chloride, lactated Ringer's solution (LRS), *Plasma-Lyte*® *A*, hydroxyethyl starch (HES) 6%, and potentially any drugs that have been reconstituted or diluted with those solutions (eg, ampicillin/sulbactam).[58] It must NOT be mixed with or come into contact with any IV solution containing calcium or magnesium (eg, *Normosol*®*-R*, *Plasma-Lyte*®*-R, -A,* or *-56*); morbidity and mortality secondary to microprecipitants lodging in patients' lungs have been reported.

Because physical incompatibilities may not be readily apparent to the naked eye or may develop 15 to 60 minutes after admixture or dilution (ie, during an infusion), it has been recommended to administer enrofloxacin injection only via labeled routes. If IV route must be used and suitable alternatives to enrofloxacin are not available, consider administration of undiluted enrofloxacin through a separate line.

For horses, an oral gel formulated from the bovine injectable product has been described[46]: 100 mL of the 100 mg/mL bovine injection (*Baytril*®*100*) is used. Stevia (0.35 g) is mixed with ≈15 mL of liquid enrofloxacin until dissolved. Apple flavoring (0.6 mL) is added until dissolved. Sodium carboxymethylcellulose (2 g) should be sprinkled over the mixture and stirred until incorporated, with immediate gradual addition of the remaining enrofloxacin (85 mL)

before the mixture solidifies. The resulting concentration is ≈100 mg/mL. The compounded gel should be stable for up to 84 days if kept refrigerated and protected from light.

For exotic animals, 3 compounded oral suspension preparations were shown to be stable for up to 56 days when stored at room temperature in amber-colored containers[59]:

1. Formulation A was made starting with 40 mL of corn syrup and 40 mL of distilled water mixed together; 30 mL of this solution was placed in a small mortar. Then, 27 film-coated tablets (68 mg) of commercially available enrofloxacin were added to the mortar and allowed to sit for 15 minutes. Once the film coating was dissolved, the tablets were pulverized in the mortar with a pestle until a homogeneous paste was formed. The mixture was then carefully transferred to a plastic amber-colored, 8 oz (240 mL) dispensing vial (bottle). Another 30 mL of the corn syrup-distilled water mixture was poured into the mortar and carefully stirred to facilitate the transfer of any remaining enrofloxacin residue in the mortar to the vial. A sufficient quantity of the corn syrup-distilled water vehicle was then added to the vial to bring the final volume of the suspension to 80 mL, which resulted in a final concentration of 22.95 mg/mL.
2. Formulation B was made following the same steps as Formulation A, but a 50:30 mixture of 50 mL of cherry syrup and 30 mL distilled water was used, which resulted in a final concentration of 22.95 mg/mL.
3. Formulation C was made using 40 mL of the 2.27% (22.7 mg/mL) injectable product and 40 mL of a liquid sweetener (*Ora-Sweet®*), which resulted in a final concentration of 11.35 mg/mL.

The authors concluded subjectively that although all 3 compounds were stable as described above, the cherry syrup mixture (Formulation B) best masked the smell and taste of enrofloxacin.

Enrofloxacin was found to elute from calcium sulfate hemihydrate (ie, plaster of Paris) beads over 30 days in experimental conditions.[60]

Enrofloxacin 2% in poloxamer 409 gel has been used as a safe and effective option for superficial corneal ulceration in California sea lions.[61] An in situ forming gel was prepared with poloxamers 407 and 188 and was bioavailable when administered IM to dogs.[62] The potency and stability of these formulations were not reported.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Enrofloxacin Tablets Oral Flavored Tablets, and Soft Chewable Tablets: 22.7 mg, 68 mg, and 136 mg; *Baytril®* Taste Tabs, *Zobuxa®* generic; (Rx). FDA-approved for use in dogs and cats

Enrofloxacin Tablets (film-coated): 22.7 mg, 68 mg, and 136 mg; *Baytril®*, (Rx). NADA #140-441. FDA-approved for use in dogs and cats

Enrofloxacin Injection: 22.7 mg/mL (2.27%) in 20 mL vials; *Baytril®*, generic; (Rx). NADA #140-913. FDA-approved for use in dogs only

Enrofloxacin Injection: 100 mg/mL in 100 mL and 250 mL bottles; *Baytril® 100*, generic; (Rx). FDA-approved for use in swine and cattle only. Not for use in calves to be processed for veal or for female dairy cattle 20 months or older, including dry dairy cows. Any extra-label use in food animals is banned by the FDA. Slaughter withdrawal in cattle is 28 days when used as labeled. A withdrawal period has not been established in preruminating calves. Slaughter withdrawal in swine is 5 days when the drug is used as labeled.

Enrofloxacin Injection: 100 mg/mL in 250 mL bottles; *Baytril® 100-CA1*;(Rx). Conditionally approved by the FDA pending a full demonstration of effectiveness under application number 141-527 for use in replacement dairy heifers under 20 months of age, all classes of beef cattle except beef calves less than 2 months of age, and beef bulls intended for breeding (any age). Not for use in any other class of dairy cattle, including dry dairy cows, or in veal calves. Slaughter withdrawal in cattle is 28 days; a withdrawal period has not been established in preruminating calves. Extra-label use of conditionally approved drugs, or of fluoroquinolones in food producing animals, is not permitted by the FDA.

There is also an otic preparation containing enrofloxacin and silver sulfadiazine: *Baytril® Otic*; (Rx). See ***Antibacterials, Otic*** for more information.

HUMAN-LABELED PRODUCTS: NONE

Ephedrine

(e-***fed***-rin)

Sympathomimetic Bronchodilator/Vasopressor

Prescriber Highlights

- ► Sympathomimetic used parenterally as a vasopressor agent for anesthesia-associated hypotension in dogs, cats, and horses.
- ► Contraindications include severe cardiovascular disease, especially with arrhythmias.
- ► Should be used with caution in patients with glaucoma, prostatic hypertrophy, hyperthyroidism, diabetes mellitus, cardiovascular disorders, or hypertension
- ► Adverse effects include CNS stimulation, arrhythmias, tachycardia, hypertension, vomiting, or anorexia.
- ► Crosses the placenta and is excreted into milk

Uses/Indications

Ephedrine can be used parenterally as a vasopressor agent in the treatment of anesthesia-associated hypotension in dogs, cats, and horses. In a study in horses with isoflurane-induced hypotension, ephedrine increased mean arterial pressure by increasing the cardiac index and systemic vascular resistance.[1] The authors concluded that ephedrine would be preferable to phenylephrine for this indication because ephedrine increases both blood flow and blood pressure. Mean arterial pressure, cardiac index, and systemic vascular resistance have also been shown to increase in isoflurane-anesthetized dogs treated with ephedrine.[2]

Ephedrine has been used in dogs and cats for the treatment of urinary incontinence due to urethral sphincter hypotonus, but the lack of available oral dosage forms limits the use of ephedrine for this indication.

Pharmacology/Actions

Ephedrine is a noncatecholamine that directly acts as an alpha- and beta-adrenergic receptor agonist and indirectly causes endogenous release of norepinephrine from sympathetic neurons[3, 4] and decreases the metabolism of norepinephrine by inhibiting the action of monoamine oxidase on norepinephrine.[5] Prolonged use or excessive dosing frequency can deplete norepinephrine from its storage sites and tachyphylaxis may ensue.[4] Tachyphylaxis has not been documented in dogs or cats when used for urethral sphincter hypotonus.

Pharmacologic effects of ephedrine include increased vasoconstriction, heart rate, coronary blood flow, and blood pressure; mild CNS stimulation; and decreased bronchoconstriction, nasal congestion, and appetite. Ephedrine can also increase urethral sphincter tone and produce closure of the neck of the urinary bladder.

Pharmacokinetics

Ephedrine is rapidly absorbed after oral and parenteral administration. In humans, ephedrine is thought to cross the blood–brain barrier by some researchers[6] and not others.[7-9] In dogs, ephedrine un-

dergoes rapid N-demethylation to norephedrine, which suggests that the activity of ephedrine is largely mediated through its metabolite.[10]

Ephedrine and norephedrine are both eliminated in the urine and urine pH may significantly alter excretion characteristics. In humans, at urine pH of 5, half-life is ≈3 hours; at urine pH of 6.3, half-life is ≈6 hours.

Compared with other vasopressor agents, IV ephedrine has a longer duration of action. When it is used to treat anesthesia-associated hypotension, it is recommended to administer as a bolus rather than as a CRI.

Contraindications/Precautions/Warnings

Ephedrine is contraindicated in patients with severe cardiovascular disease, particularly with arrhythmias. Ephedrine should be used with caution in patients with glaucoma, prostatic hypertrophy, hyperthyroidism, diabetes mellitus, or cardiovascular disorders. In humans, there is an increased risk of hypertension if ephedrine is used prophylactically.[4]

Tachyphylaxis secondary to depleted stores of endogenous norepinephrine can occur with repeated ephedrine doses.[4]

Renal impairment may increase elimination half-life and result in prolonged therapeutic or adverse effects.[4]

When this drug is administered as an IV bolus to humans, the drug concentration should be ≈5 – 10 mg/mL (see ***Compounding/Compatibility***);[4] it is assumed that this information also applies to veterinary patients.

Do not confuse ePHEDrine with EPINEPHrine.

Adverse Effects

The most common adverse effects include restlessness, irritability, tachycardia, or hypertension; nausea and vomiting may occur.[4] Anorexia may be a problem in some animals.

Reproductive/Nursing Safety

Limited data are available on the effects of ephedrine on fertility, pregnancy, and fetal safety. Use with caution during pregnancy. Ephedrine crosses the placental barrier and may have an effect on the fetuses.[4, 11] In humans, cases of potential metabolic acidosis in newborns at delivery with maternal ephedrine exposure have been reported.[4]

In humans, ephedrine is excreted in milk.[4] If ephedrine is absolutely necessary for the dam, consider using a milk replacer.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs of overdose result from sympathomimetic excess and may consist of an exacerbation of the adverse effects listed above or, with large overdoses, severe cardiovascular (hypertension to rebound hypotension, bradycardias to tachycardias, and cardiovascular collapse) and CNS effects (stimulation to coma).[12]

In acute oral overdoses, perform GI decontamination using the usual precautions and administer charcoal and a cathartic. Monitor blood pressure and treat clinical signs supportively (eg, antihypertensive agents).

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ephedrine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-Adrenergic Antagonists** (eg, **phentolamine**, **prazosin**): May inhibit the therapeutic effects of ephedrine
- **Alpha-2 Adrenergic Agonists** (eg, **clonidine, dexmedetomidine, xylazine**): May augment the pressor effects of ephedrine
- **Atropine**: May augment the pressor effects of ephedrine
- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, propranolol**): Concomitant use with ephedrine may diminish the effects of both drugs.
- **Cardiac Glycosides** (eg, **digoxin**): Concurrent use of cardiac glycosides with ephedrine may increase risk for arrhythmias.
- **Epidural Anesthesia**: Ephedrine may decrease the efficacy of epidural anesthesia.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, selegiline**): Ephedrine should not be given within 2 weeks of a patient receiving MAOIs as severe hypertension and hyperpyrexia are possible.
- **Oxytocin**: May result in additive hypertensive effect
- **Phenothiazines** (eg, **acepromazine**): Phenothiazines may antagonize effects of ephedrine.[13] Ephedrine may decrease neuroleptic effects of phenothiazines and may increase risk for cardiac arrhythmias, including QT interval prolongation and torsade de pointes. Combination should be avoided.
- **Propofol**: May augment the pressor effects of ephedrine
- **Quinidine**: May diminish the effects of both drugs
- **Reserpine**: May inhibit the pressor effects of ephedrine
- **Sodium Bicarbonate**: Concurrent use of ephedrine with sodium bicarbonate may result in ephedrine toxicity.
- **Sympathomimetic Agents** (eg, **phenylpropanolamine**): Ephedrine should not be administered with other sympathomimetic agents as increased toxicity may result.
- **Theophylline/Aminophylline**: Concurrent use of ephedrine with theophylline may increase the risk for GI and CNS toxicity.
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**): May decrease the pressor effects of ephedrine
- **Urinary Alkalinizers** (eg, **carbonic anhydrase inhibitors** [eg, methazolamide], **citrates**): May reduce the urinary excretion of ephedrine and prolong its duration of activity. Dosage adjustments may be required to avoid toxic clinical signs.
- **Vasopressin**: May result in additive hypertensive effect

Laboratory Considerations

- Ephedrine may cause a false-positive **amphetamine** when using EMIT assay.[14]

Dosages

DOGS:

Hypotension associated with anesthesia (extra-label):

a) For relatively short procedures in ASA I or II patients with hypotension nonresponsive to 1 or 2 crystalloid boluses: 0.1 – 0.25 mg/kg IV[2, 15] ; dilute ephedrine and administer incremental IV boluses until desirable blood pressure achieved (see ***Compatibility/Compounding Considerations***). Duration of action is ≈15 to 60 minutes after a single bolus.

b) 5 – 10 µg/kg/minute IV CRI[16]

Urinary incontinence responsive to adrenergic drugs (extra-label): 1.5 mg/kg PO every 12 hours.[17, 18] **NOTE**: Commercial oral dosage forms have been discontinued in the United States.

CATS:

Hypotension associated with anesthesia (extra-label):

a) 0.15 – 0.25 mg/kg diluted into 5 mL of a balanced electrolyte solution or saline and administer small increment IV boluses

until desirable blood pressure achieved (see ***Compatibility/Compounding Considerations***)[16]

b) 5 – 10 µg/kg/minute IV CRI[16]

HORSES:

Hypotension associated with anesthesia (extra-label):

a) 0.06 mg/kg IV as a bolus[19,20]

b) 0.02 mg/kg/minute IV CRI[1]

Monitoring

- Clinical effectiveness including resolution of hypotension or stabilization of blood pressure
- Adverse effects including CNS stimulation, arrhythmias, tachycardia, hypertension, vomiting, or anorexia, particularly in patients with impaired renal function
- Consider electrolyte monitoring in susceptible patients as beta-adrenergic agonists may decrease serum potassium concentrations.
- C-section neonates should be monitored for signs of metabolic acidosis.[4]

Client Information

- Ephedrine will be given to your animal by your veterinarian at the veterinary clinic. Effects of this medicine should wear off before your animal is sent home.
- Contact your veterinarian if you have any concerns about your animal's condition.

Chemistry/Synonyms

A sympathomimetic alkaloid, ephedrine sulfate occurs as fine, odorless, white crystals or powder. Approximately 770 mg are soluble in 1 mL of water. The commercially available injection has a pH of 4.5 to 7.[4]

Ephedrine sulfate may also be known as ephedrine sulphate. Many trade names are available.

Storage/Stability

Store ephedrine sulfate products at room temperature 25°C (77°F) with excursions permitted to 15°C to 30°C (59°F-86°F).[4] Discard unused portion.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

If using the 50 mg/mL product, it can be diluted 1:10 in 5% dextrose, 0.9% sodium chloride, or lactated Ringer's solution. Do not dilute the premixed 5 mg/mL product.

Ephedrine is **Y-site incompatible** with amphotericin B conventional form, diazepam, and pantoprazole.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Ephedrine Sulfate Injection: 50 mg/mL in 1 mL single-dose vials and ampules; generic; (Rx)

Ephedrine Sulfate Injection: 47 mg/mL in 1 mL vials; 4.7 mg/mL and 9.4 mg/mL in 5 mL vials; *Rezipres*®; (Rx)

Ephedrine Sulfate Injection: 5 mg/mL in 10 mL single-dose vials; *Emerphed*®; (Rx)

Oral ephedrine dosage forms have been discontinued in the United States, although oral combinations with guaifenesin (OTC) are available. The herbal supplement ma huang contains ephedrine as one of many active components.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Epinephrine

(ep-i-***nef***-rin) *Adrenalin*®, *Epi-Pen*®

Alpha-Adrenergic Agonist; Beta-Adrenergic Agonist

Prescriber Highlights

- ► Alpha- and beta-adrenergic agonist agent used systemically for treatment of anaphylaxis, cardiac resuscitation, and for refractory hypotension, as well as to prolong local effects of local anesthetic agents
- ► No absolute contraindications in life-threatening situations. Relative contraindications include closed-angle glaucoma, hypersensitivity to epinephrine, shock due to nonanaphylactic causes, during general anesthesia with inhalant anesthetics, during parturition (may delay the second stage), dilated cardiomyopathy or coronary insufficiency, thyrotoxicosis, acute or uncontrolled diabetes or hypertension, and toxemia of pregnancy.
- ► Use extreme caution in patients with a prefibrillatory cardiac rhythm. Caution is advised in patients with hypovolemia; this drug is not a substitute for adequate volume replacement.
- ► Do not inject into small appendages of the body (eg, toes, ears) either directly or combined with local anesthetic agents, as this may cause tissue necrosis and sloughing.
- ► Adverse effects include anxiety, tremors, excitability, vomiting, hypertension, tachycardia, pulmonary edema, arrhythmias, and lactic acidosis (with prolonged use or overdose situations).
- ► Do not confuse 1 mg/mL (formerly 1:1000) with 0.1 mg/mL (1:10,000) concentrations.
- ► Many drug interactions are possible.

Uses/Indications

In veterinary medicine, epinephrine is primarily used as treatment for anaphylaxis and cardiac resuscitation. Because of its vasoconstrictive properties, epinephrine can be added to local anesthetic agents to delay systemic absorption and prolong the local anesthetic effect. Epinephrine administered by IV continuous rate infusion may also be considered for the treatment of anesthetic-induced hypotension that is nonresponsive to other inotropic support.

Epinephrine has been used in reptiles to decrease recovery time after receiving inhalant anesthesia.[1,2]

Pharmacology/Actions

Epinephrine is an endogenous adrenergic agent with alpha- and beta-receptor activity. It relaxes smooth muscles in the bronchi and iris, antagonizes the effects of histamine, increases glycogenolysis, and raises blood sugar. If given IV at a low dose (0.01 mg/kg), epinephrine directly stimulates cardiac beta-1 receptors to cause increased heart rate and contractility with resultant increased cardiac output. As a result of these effects, myocardial work and oxygen consumption also increase. In the periphery, epinephrine activates beta-2 receptors, causing a decrease in peripheral vascular resistance, which lowers diastolic blood pressure. When administered at higher dosages (0.1 mg/kg), peripheral vascular resistance increases due to alpha-1-adrenergic effects.

Pharmacokinetics

Epinephrine is well-absorbed following IM or SC administration. IM injections are absorbed slightly faster than via the SC route; absorption can be expedited by massaging the injection site. The IM or SC routes are not used during cardiovascular resuscitation due to poor peripheral perfusion. Epinephrine is not effective when given PO, as it is rapidly metabolized in the GI tract and liver. Following SC injection, the onset of action is generally within 5 to 10 minutes. The onset of action following IV administration is immediate and intense.

Epinephrine does not cross the blood–brain barrier.

Epinephrine is metabolized in the liver and other tissues by monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) to inactive metabolites (3-methoxy-4-hydroxymandelic acid and metanephrine) that are then excreted in the urine after conjugation with glucuronic acid or sulfates.

Contraindications/Precautions/Warnings

In life-threatening situations there are no absolute contraindications to epinephrine use.

In nonemergent circumstances, epinephrine is contraindicated in patients with closed-angle glaucoma, hypersensitivity to epinephrine, shock due to nonanaphylactic causes, during general anesthesia with inhalant anesthetics, during parturition (may delay the second stage), and cardiac dilatation or coronary insufficiency. Epinephrine should not be injected either directly or with local anesthetics into small appendages of the body (eg, toes, ears) because of the degree of vasoconstriction that may lead to tissue necrosis and sloughing; administration through a central line is recommended.

Epinephrine should be used with extreme caution in patients with a prefibrillatory cardiac rhythm because of its excitatory effects on the heart. Epinephrine should be used with caution in patients in with thyrotoxicosis, acute or uncontrolled hypertension or diabetes, and toxemia of pregnancy. Use epinephrine with caution in patients with hypovolemia; this drug should not be used as a substitute for adequate fluid resuscitation.

Do not confuse EPINEPHrine with ePHEDrine or the 2 concentrations of commercially available epinephrine injection: 1 mg/mL (formerly labeled as 1:1000) and 0.1 mg/mL (formerly labeled as 1:10,000).

Adverse Effects

Epinephrine can induce tremors, excitability, vomiting, hypertension, tachycardia, other arrhythmias (especially if patient has organic heart disease or has received another drug that sensitizes the heart to arrhythmias), pulmonary edema, hyperglycemia, behavior changes (eg, anxiety, excitability), and lactic acidosis (with prolonged acute use or overdose situations). This information is largely extrapolated from the human label; application to veterinary species is assumed to be accurate. Repeated SC injections at or around the same site can cause tissue necrosis and sloughing at the injection site.[3] Administer through a central line, if possible, as administration through a peripheral vein may lead to local tissue necrosis if extravasation occurs. Phentolamine can be used locally for the treatment of extravasation.[4]

Reproductive/Nursing Safety

Epinephrine crosses the placenta but should not be withheld during life-threatening situations for the dam.

Although small amounts of epinephrine may be excreted into milk, it is unlikely to affect nursing offspring because it is rapidly destroyed in the GI tract and unlikely to be absorbed.

Overdose/Acute Toxicity

Clinical signs seen with overdose or inadvertent IV administration of SC or IM doses include cardiac arrhythmias, pulmonary edema and dyspnea, vomiting, and sharp rises in systolic, diastolic, and venous blood pressures.[3] Cerebral hemorrhages may result because of increased blood pressure. Renal failure, metabolic acidosis, and cold skin may also result.

Because epinephrine has a relatively short duration of effect, overdose treatment is mainly supportive.[3] If necessary, use of an alpha-adrenergic antagonist (eg, **phentolamine**) or a beta-adrenergic antagonist (eg, **propranolol**) can be considered for treatment of severe hypertension and cardiac arrhythmias. Prolonged periods of hypotension may follow, possibly requiring treatment with norepinephrine.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving epinephrine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Alpha-2 Adrenergic Agonists** (eg, **detomidine, dexmedetomidine, medetomidine, xylazine**): Epinephrine possesses alpha-agonist effects; thus, it should **NOT** be used to treat cardiac effects caused by alpha-2-adrenergic agonists.
- **Alpha-Adrenergic Antagonists** (eg, **phenoxybenzamine**, **phentolamine**, **prazosin**): May reverse the pressor effects of epinephrine due to alpha-1 blockade by the phenothiazine (ie, epinephrine reversal).
- **Anesthetics, Halogenated Inhalant** (eg, **isoflurane, sevoflurane**): An increased risk for developing arrhythmias can occur if epinephrine is administered to patients that have received a halogenated anesthetic agent; propranolol may be administered in these cases.
- **Antihistamines**: Certain antihistamines (eg, **chlorpheniramine, diphenhydramine**) may potentiate the effects of epinephrine.
- **Beta-Adrenergic Antagonist** (eg, **atenolol**, **propranolol**, **sotalol**): may potentiate hypertension and antagonize epinephrine's cardiac and bronchodilating effects by blocking the beta effects of epinephrine.
- **Digoxin**: An increased risk for arrhythmias may occur if epinephrine is used concurrently with digitalis glycosides.
- **Levothyroxine**: May potentiate the effects of epinephrine
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, selegiline**): May potentiate the pressor effects of epinephrine
- **Nitrates** (eg, **nitroglycerin**): May reverse the pressor effects of epinephrine
- **Oxytocic Agents**: Hypertension may result if epinephrine is used with oxytocic agents.
- **Phenothiazines** (eg, **acepromazine**): May reverse the pressor effects of epinephrine due to alpha-1 blockade by the phenothiazine (ie, epinephrine reversal)
- **Reserpine**: May potentiate the pressor effects of epinephrine
- **Sympathomimetic Agents, Other** (eg, **albuterol**, **dobutamine**, **isoproterenol**, **phenylpropanolamine**, **terbutaline**): Epinephrine should not be administered with other sympathomimetic agents as increased toxicity may result.
- **Tricyclic antidepressants** (eg, **amitriptyline**, **clomipramine**): May potentiate the effects of epinephrine

Dosages

NOTE: Epinephrine concentrations were formerly expressed us-

ing ratios (ie, 1:1000 and 1:10,000 strengths), but in 2017 the FDA mandated that ratios be removed from all labeling to reduce the risk for medication errors. Be certain when preparing the injection not to confuse 1 mg/mL (formerly 1:1000) with 0.1 mg/mL (1:10,000) concentrations.

DOGS/CATS:

Anaphylactoid shock (label-dosage; not FDA-approved): 0.1 – 0.5 mL (total dose, NOT mg/kg) IM or SC using epinephrine 1 mg/mL solution[5]

Cardiopulmonary resuscitation | asystole (extra-label): **NOTE**: Clinicians are strongly encouraged to obtain the *RECOVER CPR Initiative*, Part 7[6] available as open access via the Veterinary Emergency and Critical Care Society website (veccs.org); this publication (summarized directly below) includes more detailed information including treatment algorithms and drug dosage tables.

a) *Low-dose* epinephrine 0.01 mg/kg IV, IO administered every 3 to 5 minutes early in CPR is recommended. In order to minimize under- or overdosing during CPR, epinephrine should be administered during every other cycle of basic life support (BLS; 1 cycle is 2 minutes uninterrupted compression/ventilation). Administration of vasopressin 0.8 units/kg IV, IO every other cycle alternating with epinephrine may be considered (see ***Vasopressin***).
b) *High-dose* epinephrine 0.1 mg/kg IV, IO may be considered after prolonged CPR (greater than 10 minutes).
c) *In patients in which IV or IO access is not possible*, the intratracheal (IT) route may be considered. Dilute epinephrine with saline or sterile water and administer via a catheter longer than the endotracheal tube. Optimal dosages are not known, but dosages up to 10 times the standard have been recommended for IT administration. (In a subsequent reference, the IT dose is listed as 0.02 mg/kg for the low dose and 0.2 mg/kg for the high dose.[6,7]) **NOTE**: Blind intracardiac (IC) administration of resuscitation drugs is not recommended.

Anaphylaxis (extra-label): Initially, epinephrine 0.01 mg/kg IM using a 1 mg/mL solution; maximum dose of 0.3 mg (total dose; NOT mg/kg) in patients weighing less than 40 kg (88.2 lb) and 0.5 mg (total dose; NOT mg/kg) in patients weighing more than 40 kg (88.2 lb). Depending on episode severity and response to the initial injection, the dose can be repeated every 5 to 15 minutes as needed. However, if shock has already developed, epinephrine 0.05 µg/kg/minute should be given by slow IV infusion, ideally with the dose titrated to clinical response.[8] The SC route should be avoided.[9]

Hypotension associated with anesthesia (extra-label): 0.125 – 2 µg/kg/minute CRI[10]; **NOTE**: Because epinephrine can cause increased tissue oxygen demand and severe splanchnic vasoconstriction, it should be considered only when other interventions have failed.

Prolongation of local anesthetic effect (extra-label): Epinephrine may be added to local anesthetic formulations at a very low concentration (eg, epinephrine 5 µg/mL local anesthetic) to cause vasoconstriction at the site of administration, thereby reducing the rate of systemic absorption of the local anesthetic. Practically, remove 0.1 mL from 20 mL of local anesthetic solution and add 0.1 mL of 1 mg/mL epinephrine solution.

HORSES:

Anaphylactoid shock (label-dosage; not FDA-approved): 0.022 mg/kg (1 mL/100 lb) IM or SC using epinephrine 1 mg/mL solution[5]

Anaphylaxis (extra-label): 0.01 – 0.02 mg/kg IM, SC as a single dose; or 0.1 – 0.2 mg/kg IM, SC as a single dose[11,12]

Cardiopulmonary resuscitation of newborn foals (extra-label): 0.01 – 0.02 mg/kg IV every 3 minutes until return of spontaneous circulation. If given IT, 0.1 – 0.2 mg/kg[13,14]

RUMINANTS, SWINE:

Anaphylactoid shock (label-dosage; not FDA-approved): 0.022 mg/kg (1 mL/100 lb) IM or SC using epinephrine 1 mg/mL solution[5]

Anaphylaxis (extra-label): 0.01 – 0.02 mg/kg SC or IM; if using IV, dilute solution 10-fold; may be repeated at 15-minute intervals.[15]

BIRDS:

Cardiopulmonary resuscitation (extra-label):

a) mg/kg IV, IO[16]
b) 0.01 mg/kg using 1 mg/mL epinephrine diluted to 2 – 4 mL with saline or sterile water and administered via a catheter down the trachea. If there is tracheal obstruction, a sterile endotracheal tube needs to be inserted and stitched into the left abdominal air sac.[17,18]

SMALL MAMMALS

Cardiopulmonary resuscitation in small herbivores (eg, chinchillas, guinea pigs, rabbits; extra-label): 0.2 – 0.4 mg/kg IM, IV (bolus), or IT[19]

REPTILES:

Hasten recovery time after inhalant anesthesia (extra-label): 0.1 mg/kg IM significantly decreased the recovery time in American alligators[1] and common snapping turtles.[2]

Monitoring

- Heart rate, ECG, blood pressure; central venous pressure, if possible
- Respiratory rate and thoracic auscultation
- Urine production, if possible
- Blood gases
- Neurologic status (eg, mentation, pupillary light reflexes)
- If epinephrine is administered in a peripheral vein, monitor the site for signs of localized tissue necrosis

Client Information

- Note to pharmacist or veterinarian: Be sure to discuss clinical signs associated with anaphylaxis. Review proper use of using the injector including determining dosage (if required) and injection technique using manufacturer's patient insert. Incorrect device usage can lead to inadvertent human injection. In case of accidental human injection, seek emergency medical care immediately.
- Administering epinephrine is not a substitute for immediate veterinary care. Seek veterinary care as soon as possible after administering this medication.
- The best treatment for a severe allergic reaction is avoidance of situations that predispose your animal to triggers (eg, keep away from flowers if your animal has a severe allergy to bees).
- When avoidance cannot be prevented or when it happens unexpectedly, learn to recognize the early signs of a severe allergic reaction: collapse, pale gums, difficulty breathing (cats), noisy breathing (that is unusual for your animal), swelling of the face, vomiting, or diarrhea.
- Always have this medication easily accessible. Consider attaching it to the leash, crate, or something that always travels with your animal.
- Administer medication exactly as instructed by your veterinarian; refer to instructions that came with the product. Familiarize yourself with how the injector works before you need to use it.
- Absorption can be sped up by gently massaging the site of the shot.
- Store pre-filled injector pens in carrier tube at room temperature;

do not refrigerate. Do not store medication in a car where storage temperatures can be extreme. Do not use if liquid is discolored (pinkish or dark yellow) or particles are seen floating in it. Check expiration date and refill before expiration date.

- Contact your veterinarian or pharmacist for more information on safe disposal of used or expired epinephrine autoinjectors or needles.

Chemistry/Synonyms

Epinephrine, an endogenous catecholamine, occurs as white to nearly white, microcrystalline powder or granules. It is only very slightly soluble in water, but it readily forms water-soluble salts (eg, HCl) when combined with acids. Both the commercial products and endogenous epinephrine are in the levo-form, which is about 15 times more active than the dextro-isomer. The pH of the commercial injection ranges from 2.5 to 5.

Epinephrine is commonly called adrenalin.

Storage/Stability

Epinephrine HCl for injection should be stored 15°C to 30°C (59°F – 86°F) in tight containers protected from light. Epinephrine will darken (oxidation) when exposed to light and air. Do not use the injection if it is pink or brown or contains a precipitate. The stability of the injection depends on the form and the preservatives present and may vary among manufacturers. Epinephrine is rapidly destroyed by alkalis or oxidizing agents.

A study[20] investigated epinephrine stability when pre-drawn in syringes. Epinephrine 1 mg/mL solution containing sodium metabisulfite (antioxidant) was drawn under room air into 1 mL plastic syringes. Syringes were stored at 38°C with needles left attached and recapped. Epinephrine potency was maintained for 2 months when stored under low (15%) humidity and 4 months at high (95%) humidity.

Compatibility/Compounding Considerations

Epinephrine HCl is reported to be physically **compatible** with the following IV solutions and drugs: dextran 6% in dextrose 5%, dextran 6% in 0.9% sodium chloride, dextrose/Ringer's combinations, dextrose/lactated Ringer's combinations, dextrose/saline combinations, dextrose 2.5%, dextrose 5% (becomes unstable at a pH greater than 5.5), dextrose 10%, Ringer's injection, lactated Ringer's injection, 0.9% sodium chloride, sodium lactate 1/6 M, amikacin sulfate, cimetidine HCl, dobutamine HCl, and verapamil HCl.

Epinephrine HCl is reported to be physically **incompatible** with the following IV solutions and drugs: Ionosol-D-CM, Ionosol-PSL (Darrow's), Ionosol-T with dextrose 5% (**NOTE**: other Ionosol products are compatible), sodium chloride 5%, sodium bicarbonate 5%, aminophylline, hyaluronidase, sodium bicarbonate, and warfarin sodium.

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Dosage Forms/Regulatory Status

NOTE: Epinephrine concentrations were formerly expressed using ratios (ie, 1:1000 and 1:10,000 strengths), but in 2017 the FDA mandated that ratios be removed from all labeling to reduce the risk for medication errors. Be certain when preparing the injection not to confuse 1 mg/mL (formerly 1:1000) with 0.1 mg/mL (1:10,000) concentrations.

VETERINARY-LABELED PRODUCTS:

Epinephrine HCl for Injection 1 mg/mL in 1 mL amps and syringes and 10 mL, 30 mL, 50 mL, and 100 mL vials; generic; (Rx). Labeled for use in dogs, cats, cattle, horses, sheep, and swine.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Epinephrine HCl Solution for Injection: 1 mg/mL in 1 mL ampules and 1 mL, 10 mL, and 30 mL vials; generic; (Rx)

Epinephrine HCl Solution for Injection: 0.1 mg/mL 10 mL syringes and vials; generic; (Rx)

Epinephrine HCl Solution for Injection: 0.3 mg/0.3 mL; in prefilled single-dose syringes or in dual-dose autoinjectors; *EpiPen®*, *Twinject®*, *Adrenaclick®*, *Auvi-Q®*; *Symjepi®*; generic; (Rx)

Epinephrine HCl Solution for Injection: 0.15 mg /0.15 mL in single-dose or dual-dose autoinjectors; *Twinject®*, *Adrenaclick®*, *Auvi-Q®*, generic; (Rx)

Epinephrine HCl Solution for Injection: 0.15 mg/0.3 mL; *EpiPen Jr®*, *Symjepi®*; (Rx)

Epinephrine bitartrate is available as a powder form (aerosol) for inhalation, topical solution, and solution for nebulization; ophthalmic preparations are available.

Epirubicin

(ep-ee- ***roo***-bi-sin) *Ellence®*

Antineoplastic

Prescriber Highlights

- ► Injectable anthracycline antineoplastic agent that potentially could be used as a replacement for doxorubicin in dogs and cats.
- ► Limited published information is available for its use in animal patients.
- ► Adverse effect profile for animals is not well documented compared to doxorubicin. It may have less cardiotoxicity potential but more GI adverse effects. Otherwise, similar cautions and caveats as doxorubicin apply.
- ► Dexrazoxane may be used to manage extravasation or for prevention of cardiac toxicity.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies epirubicin as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Epirubicin could potentially be used as a replacement for doxorubicin in dogs and cats, but there is much less published on it for veterinary use compared to doxorubicin. Retrospective studies have evaluated epirubicin use in dogs for the adjuvant treatment of splenic hemangiosarcoma,[1] as part of a multi-agent protocol for lymphoma,[2] and in combination with lomustine or as a single agent rescue drug for histiocytic sarcoma;[3] another study specifically assessed epirubicin toxicity.[4] From this work, it appears that epirubicin has similar efficacy as doxorubicin and the potential for less cardiotoxicity but may have a higher incidence of adverse GI effects.

Epirubicin demonstrated tumor- and disease-free survival in cats with injection-site sarcoma.[4]

Pharmacology/Actions

Epirubicin has a similar mode of action as doxorubicin; it causes inhibition of DNA synthesis, DNA-dependent RNA synthesis, and

protein synthesis, but the precise mechanisms for these effects are not well understood. The drug acts throughout the cell cycle and also possesses some immunosuppressant activity.

Pharmacokinetics

No published data on epirubicin pharmacokinetics or pharmacodynamics in dogs or cats were located. Epirubicin, like doxorubicin, must be administered IV as it is not absorbed from the GI tract and is extremely irritating to tissues if administered SC or IM.

In humans after IV injection, epirubicin is rapidly and widely distributed but does not appreciably enter the CSF. It is marginally bound (77%) to tissue and plasma proteins and concentrates in red blood cells.

Epirubicin is metabolized extensively by the liver and other tissues via aldo-keto reductase primarily to epirubicinol, which is active, but only at 10% of the parent compound's activity; other inactive metabolites are also formed. Epirubicin and its metabolites are primarily excreted in the bile and feces, with lesser amounts excreted into the urine. Epirubicin is eliminated in a triphasic manner. In humans, average half-lives for the three elimination phases are the first phase (3 minutes), the second phase (2.5 hours), and the third phase (33 hours).

Contraindications/Precautions/Warnings

In humans, and likely in dogs as well, epirubicin is contraindicated or relatively contraindicated (measure risk vs benefit) in patients with myelosuppression (neutrophil count less than 1500 cells/µL), severe myocardial insufficiency, cardiomyopathy and/or heart failure, recent myocardial infarction, severe arrhythmias, or those already having received maximum cumulative anthracycline (eg, doxorubicin) doses. Epirubicin should be used with caution in patients with hyperuricemia, hyperuricuria, or impaired hepatic function. Dosage adjustments may be necessary for patients with hepatic impairment.

Epirubicin, like doxorubicin, should be administered IV slowly (over at least 3 to 5 minutes) in a free flowing IV line. Extreme care must be taken to avoid perivascular infusion (extravasation). IM or SC dosages are contraindicated.

Breeds predisposed to developing cardiomyopathy (eg, Doberman pinschers, Great Danes, rottweilers, boxers) should be monitored carefully while receiving epirubicin therapy.

P-glycoprotein actively transports doxorubicin and possibly epirubicin, and certain breeds susceptible to the *MDR1* mutation (also known as *ABCB1-1delta*; eg, collies, Australian shepherds, shelties, long-haired Whippets) may be at higher risk for toxicity. Bone marrow suppression (decreased blood cell counts, particularly neutrophils) and GI toxicity (anorexia, vomiting, diarrhea) are more likely to occur at normal doxorubicin dosages in dogs with the *MDR1* mutation. To reduce the likelihood of severe toxicity in these dogs (mutant/normal or mutant/mutant), the Veterinary Clinical Pharmacology Laboratory at Washington State University recommends reducing doxorubicin doses by 25% to 30% and carefully monitoring these patients.[5] A similar empiric dosage modification strategy should be considered for epirubicin.

Because epirubicin can be irritating to the skin, gloves should be worn when administering or preparing the drug. Ideally, doxorubicin injection should be prepared in a biological safety cabinet using standard chemotherapy preparation procedures. If accidental skin or mucous membrane contact occurs, wash the area immediately using soap and copious amounts of water. Spills or leakage of epirubicin solutions should be diluted with sodium hypochlorite solutions (with 1% available chlorine), preferably by soaking, and then diluted further with water.

Do not confuse EPIrubicin with DOXOrubicin or DAUNOrubicin.

The National Institute for Occupational Safety and Health (NIOSH) classifies epirubicin as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Epirubicin can cause several adverse effects similar to doxorubicin, including bone marrow suppression, cardiac toxicity, alopecia, gastroenteritis (vomiting, diarrhea), and stomatitis. Cardiotoxic effects may be less likely to occur than with doxorubicin, based upon preclinical toxicity studies.[6] After administration of doxorubicin in dogs (and probably epirubicin), nausea and vomiting commonly occur within the first 72 hours; diarrhea can occur within ≈4 to 5 days, and myelosuppression nadirs are generally seen 7 to 10 days after treatment. Many dogs receiving chemotherapy will have minor hair coat changes (eg, shagginess, loss of luster). Breeds with continuously growing hair coats (eg, poodles, terriers, Afghan hounds, or old English sheepdogs) are more likely to experience significant alopecia.

An immediate histamine-mediated hypersensitivity reaction may be seen characterized by urticaria, facial swelling, vomiting, arrhythmias (see below), and/or hypotension. The rate of infusion can have a direct impact on this effect, and generally, IV infusions should be administered no faster than over 10 to 20 minutes. Pretreatment with a histamine H_1 blocker such as diphenhydramine or an IV glucocorticoid may also reduce or eliminate these effects. This reaction has also been reported in one cat.[7]

For more information on cardiac toxicity of anthracycline antineoplastics, refer to the ***Doxorubicin*** monograph.

In cats, doxorubicin (and potentially epirubicin) is a potential nephrotoxin, and renal function should be monitored both before and during therapy.

Extravasation injuries secondary to perivascular administration of epirubicin can be quite serious, with severe tissue ulceration and necrosis possible. Prevention of extravasation should be a priority, and animals should be frequently checked during the infusion. Should extravasation occur, it is suggested to treat as per the recommendations for humans. There are currently two treatments recommended for doxorubicin (and epirubicin) extravasation injuries. Both have been shown to be effective, but no comparative trials have been published. **1)** Apply dimethyl sulfoxide (DMSO) 99% by saturating a gauze pad and painting on twice the area of the extravasation.[8] Allow the site to air dry and repeat the application every 6 hours for 14 days. Do not cover the area with a dressing. **2)** Dexrazoxane is FDA-approved for the treatment of extravasation resulting from anthracycline IV therapy; refer to the ***Dexrazoxane*** monograph for more information. Additionally, ice compresses applied to the affected area for 15 minutes every 6 hours for 3 days may be useful.

Reproductive/Nursing Safety

Epirubicin is teratogenic and embryotoxic in laboratory animals. It may reduce male and female fertility.[9] For sexually intact patients, verify pregnancy status prior to administration.

Epirubicin is excreted in milk in concentrations that may exceed those found in plasma. Because of risks to nursing offspring, consider using milk replacer if the dam is receiving epirubicin. In humans, nursing is contraindicated in patients receiving the drug.

Overdose/Acute Toxicity

Inadvertent acute overdose may be manifested by exacerbations of the adverse effects outlined above. For dogs, a lethal dose of epirubicin is not publicly available; however, 6-week daily repeated IV dose toxicity studies conducted in research dogs identified 0.4 mg/kg/day as the Lowest Observed Adverse Effect Level (LOAEL) with the kidney being the target organ.[10] Supportive and symptomatic therapy is suggested should an overdose occur. ***Dexrazoxane*** may be useful to help prevent cardiac toxicity.

For patients that have experienced or are suspected of having ex-

perienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving doxorubicin or epirubicin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antineoplastic Agents, Other**: May potentiate the toxic effects of doxorubicin
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem**): May result in an increased risk for heart failure
- **Cimetidine**: Can increase epirubicin levels; avoid using together
- **Cyclosporine**: Cyclosporine can increase doxorubicin and doxorubicinol (active metabolite) levels. Avoid using together.
- **Glucosamine**: May reduce doxorubicin effectiveness; use together is not recommended in humans.
- **Immunosuppressive Agents, Other** (eg, **leflunomide, tacrolimus**): Immunosuppressant effects may be enhanced.
- **Ketoconazole**: Can increase doxorubicin and doxorubicinol (active metabolite) levels and lead to toxicity. Avoid using together.
- **Paclitaxel**: Can increase epirubicin toxicity
- **Phenobarbital**: May increase elimination and reduce blood levels of doxorubicin
- **Spinosad**: Can increase doxorubicin and doxorubicinol (active metabolite) levels and lead to toxicity. Avoid using together.
- **Streptozocin**: May inhibit doxorubicin metabolism
- **Vaccines**: Live or live-attenuated vaccines may result in active infections in immunocompromised patients.
- **Verapamil**: May increase doxorubicin levels
- **Warfarin**: Increased risk for bleeding
- **Zidovudine**: Increased risk for neutropenia

Laboratory Considerations

- Epirubicin may significantly increase both blood and urine concentrations of **uric acid.**
- Handling of blood samples should pose no health hazard after 7 days.[11] **NOTE**: Reference pertains to doxorubicin; epirubicin not determined.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and since chemotherapy indications, treatment protocols, monitoring, and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[12–16] are strongly recommended.

DOGS:

Depending on the protocol used, epirubicin is usually dosed similarly to doxorubicin at 30 mg/m^2 (**NOT** mg/kg) IV[17] in a free-flowing line over at least 3 to 5 minutes. Smaller patients (eg, less than 10 kg [22 lb]) may be dosed at 1 mg/kg IV. The maximum cumulative epirubicin dose is probably similar to doxorubicin at 240 mg/m^2 (**NOT** mg/kg).

Lymphoma (extra-label): In a retrospective study, either a modified Wisconsin-Madison continuous chemotherapy protocol (CEOP-C; vincristine, prednisolone, cyclophosphamide, asparaginase, and epirubicin): Epirubicin 30 mg/m^2 (**NOT** mg/kg) or 1 mg/kg IV on weeks 4 and 9, followed by vincristine, chlorambucil, and methotrexate weeks 11 to 17, OR a modified Wisconsin-Madison discontinuous chemotherapy protocol (CEOP-25) used; same epirubicin dosage and frequency[2]

Splenic hemangiosarcoma (extra-label): In a retrospective study, after splenectomy, treated dogs received epirubicin at 30 mg/m^2 (**NOT** mg/kg) IV every 3 weeks for up to 4 to 6 treatments.[1]

Histiocytic sarcoma (extra-label): In a retrospective study, used in combination with lomustine or as a single-agent rescue drug, epirubicin was dosed at 25 – 30 mg/m^2 (**NOT** mg/kg), and in dogs less than 10 kg (22 lb) in weight, the drug was dosed at 1 mg/kg.[3]

CATS:

Injection site sarcoma: In one study, cats received 25 mg/m^2 (**NOT** mg/kg) IV every 21 days for 3 doses before undergoing surgical resection.[4]

Monitoring

- Efficacy
- CBC with platelet count. Neutrophil counts of less than 1500/µL generally require a delay in dosing.
- Dogs with pre-existing heart disease should be monitored with regular ECGs (insensitive to early toxic changes) and/or echocardiogram or surrogate biomarkers, such as cardiac troponin I.
- Evaluate hepatic function prior to therapy.
- Urinalysis, BUN, and creatinine in cats

Client Information

- Clients must be briefed on the possibilities of severe toxicity developing from this drug, including drug-related mortality. Clients should contact the veterinarian if the animal exhibits any clinical signs of profound depression, abnormal bleeding (including bloody diarrhea), and/or bruising.
- Epirubicin may cause urine to be colored orange to red for 1 to 2 days after dosing; although uncommon in animals, it is not harmful if it occurs.
- Mild anorexia and occasional vomiting are commonly seen 2 to 5 days posttherapy.
- Avoid skin contact with urine or feces of treated animals. After treatment, doxorubicin drug residues may be found in the treated dog's urine up to 21 days and feces for several days.[18]
- Although it is unknown how much drug is in the saliva of treated animals, do not allow treated animals to lick human skin while receiving chemotherapy treatment.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.
- Laboratory work must be monitored periodically while your animal is being treated with epirubicin; do not miss these important follow-up visits with your veterinarian.

Chemistry/Synonyms

Epirubicin (4-epidoxorubicin) is a semisynthetic stereoisomer of the anthracycline doxorubicin antibiotic antineoplastic and occurs as a red-orange powder soluble in water and methyl alcohol, slightly soluble in alcohol, and practically insoluble in acetone. The commercially available solution for injection has a pH of ≈3. CAS Registry: 56420-45-2 (epirubicin); 56390-09-1 (epirubicin hydrochloride); ATC: L01DB03.

Epirubicin HCl may also be known as 4-epidoxorubicin, 4-epiadriamycin HCl, IMI-28, or pidorubicin HCl. A common trade name is *Ellence*®.

Storage/Stability

Store lyophilized powder for injection at 25°C (77°F); excursions are permitted to 15°C to 30°C (59°F-86°F). Reconstituted solutions are stable for 24 hours when stored at 2°C to 8°C (36°F-46°F) and protected from light or 25°C (77°F) in normal lighting conditions. Discard any unused portion.

Store the commercially available solution in a refrigerator between 2°C and 8°C (36°F and 46°F). Do not freeze. Store protected from light, but no light protection is needed when administering the drug. The manufacturer recommends using the solution within 24 hours of removal from the refrigerator or first penetration of the rubber stopper and discarding any unused solution. When reconstituted, the solution should be clear and red in color. Do not use the solution if precipitation or significant discoloration is present.

Studies have shown that 2 mg/mL concentrations in sterile water for injection are stable for at least 43 days at 4°C (39°F) in plastic syringes.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

To reconstitute the lyophilized powder: Reconstitute 50 mg vial with 25 mL sterile water for injection, to a final concentration of 2 mg/mL. Shake vigorously; it may take up to 4 minutes for the mixture to completely dissolve. Epirubicin can be further diluted with sterile water for injection.

Epirubicin can be used in combination with other chemotherapy agents but should not be mixed with other drugs in the same syringe. Prolonged contact with any alkaline solution should be avoided as hydrolysis can occur. Epirubicin should not be mixed with heparin or fluorouracil due to chemical incompatibility that may lead to precipitation.

Epirubicin HCl is reportedly physically **compatible** with the following IV solutions and drugs: 3.3% dextrose in 0.3% sodium chloride, 5% dextrose, lactated Ringer's injection, 0.9% sodium chloride, and ifosfamide.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Epirubicin HCl for Injection: 2 mg/mL in 25 mL and 100 mL vials; *Ellence*®, generic; (Rx)

Epoetin Alfa

Erythropoietin (EPO)

Recombinant Human Erythropoietin (rHuEPO)

(eh-***poe***-ee-tin ***al***-fah) *Epogen®, Procrit®*

Erythropoietic Agent

Prescriber Highlights

- ► Hormone that regulates erythropoiesis; used for anemia associated with chronic kidney disease and myelosuppressive disorders.
- ► Concurrent iron supplementation is necessary for most patients.
- ► Contraindications include patients with uncontrolled hypertension or patients that are hypersensitive to the drug. Do not use in patients that have a history of forming autoantibodies with treatment.
- ► Adverse effects include autoantibody development that causes resistance to treatment, vomiting, hypertension, seizures, uveitis, iron depletion, local reactions at injection sites, fever, arthralgia, pure red cell aplasia (PRCA), and mucocutaneous ulcers.
- ► Adequate monitoring is vital.
- ► Because of decreased potential for development of antibodies and more favorable kinetics, darbepoetin is often recommended as a first-choice treatment for dogs and cats with anemia associated with chronic kidney disease as compared with erythropoietin.

Uses/Indications

Epoetin alfa, or recombinant human erythropoietin (rHuEPO), has been used for treatment of dogs and cats with anemia associated with end-stage chronic kidney disease (CKD) and myelosuppressive disorders. One group with experience treating more than 70 CKD cats with epoetin or darbepoetin reported that only ≈60% to 65% of cats had an adequate response.[1] Epoetin has also been used as part of a treatment regimen in cats and dogs with myelodysplasia, although evidence is limited to a small retrospective case study.[2] Because of concerns associated with expense and adverse effects (eg, pure red cell aplasia [PRCA]), most specialists do not recommend starting therapy in dogs or cats until there is development of clinical signs associated with the anemia (eg, lethargy, exercise intolerance), or when the packed cell volume (PCV) is less than 20% to 22%. It is hoped that canine and feline recombinant products will become commercially available in the future to reduce the risks for autoantibody formation.[3,4]

Many clinicians choose darbepoetin (instead of epoetin) because it may be less immunogenic and may require less frequent dosing compared with epoetin; however, the prohibitive cost of darbepoetin may preclude its use.

Pharmacology/Actions

Erythropoietin (EPO) is a hormone produced in the kidneys that regulates erythropoiesis. Under conditions of anemia and hypoxemia, EPO is secreted by interstitial cells surrounding renal tubules to promote erythrocyte precursor proliferation, maturation, and viability. The result is an increase in red blood cell mass and oxygen carrying capacity in the blood.[5]

Epoetin alfa (recombinant human EPO [rhEPO]) has an identical amino acid sequence as endogenous human EPO.

Pharmacokinetics

Epoetin alfa is only absorbed after parenteral administration. The

drug's metabolic fate is unknown. In patients with chronic kidney disease, half-lives are prolonged ≈20% over those with normal renal function.

In healthy dogs, epoetin alfa has an elimination half-life of ≈7 hours, which is ≈3 times shorter than darbepoetin.[6] The T_{max} of epoetin alfa appears to be ≈4 hours with otherwise variable kinetics. Correction of hematocrit may require 2 to 8 weeks, depending on initial hematocrit and dosage used.

Contraindications/Precautions/Warnings

Epoetin alfa is contraindicated in patients with uncontrolled hypertension or those that are hypersensitive to it (see ***Adverse Effects***); it should also not be used in patients that develop pure red cell aplasia (PRCA) after starting treatment with epoetin alfa or other erythropoietin (EPO) protein drug products. In animals with moderate to severe hypertension, epoetin alfa therapy should be started with caution or withheld until BP is controlled.

Adequate iron stores are necessary for efficacy; iron deficiency should be corrected prior to starting therapy with epoetin alfa. Providing iron supplementation concomitantly with epoetin alfa treatment is recommended[7] (some say it is imperative[8]); injectable iron dextran is preferable to oral iron products for this purpose because it has fewer adverse GI effects (eg, inappetence, vomiting, diarrhea).

Adverse Effects

The 2 most common adverse effects that occur in dogs and cats receiving epoetin alfa therapy are systemic hypertension (40% to 50% of patients[9]) and development of neutralizing antibodies to epoetin alfa, which could lead to a sudden worsening of anemia and/or pure red cell aplasia (PRCA).

Hypertension may be a result of increased blood viscosity and cardiac output and decreased anemia-mediated vasodilation. One study reported 40% of dogs and 50% of cats developed hypertension while being treated with EPO.[10] Targeting a quicker rise in PCV increases the risk for hypertension; a target of 1% to 3% PCV increase has been reported to balance clinical improvement while lowering the risk for adverse effects.[1] This finding echoes the risk described in humans—epoetin alfa has a black box warning from the FDA alerting prescribers to the increased risk for death, myocardial infarction, stroke, venous thromboembolism, and other serious cardiovascular events, especially when targeting a hemoglobin concentration greater than 11 g/dL.[11] In addition, underlying cardiac disease may be a result of, or compounded by, chronic kidney disease and hypertension. Seizures may be in response to hypertension.

An estimated 70% of dogs and cats receiving epoetin alfa (recombinant human erythropoietin [rHuEPO]) develop anti-rHuEPO antibodies, and up to 30% of all patients develop sufficient antibodies to cause PRCA with resultant profound anemia, arrest of erythropoiesis, and transfusion dependency.[9] A bone marrow aspirate should be considered in patients that develop refractory anemia while receiving adequate epoetin alfa doses and have normal iron metabolism. A myeloid:erythroid ratio of greater than 4 predicts significant autoantibody formation and contraindicates further EPO therapy.[8,9,12] Some clinicians believe that epoetin alfa should be withdrawn if packed cell volume (PCV) starts to decline while the patient is receiving therapy. Of note, some commercially available epoetin alfa contains 2.5 mg/mL human albumin, and, anecdotally, PRCA is reported to occur less often with darbepoetin, which does not contain human albumin. One study states that the incidence of PRCA is ≈25% to 30% in dogs and cats receiving epoetin alfa compared with less than 10% in those receiving darbepoetin.[1] Studies indicate that the incidence of PRCA can be seen in 25% to 40% of cats receiving epoetin alfa therapy.[1,7,9] Treatment of PRCA includes immediate discontinuation of epoetin, and immunosuppressive therapy and blood transfusions; however, the long-term prognosis once EPO antibodies have developed is grave regardless of these interventions.

Other adverse effects reported include high blood viscosity, polycythemia, seizures, and iron depletion. Local reactions at injection sites (which may be a predictor of antibody formation), fever, anorexia, cellulitis, arthralgia, and mucocutaneous ulcers are also possible.

Therapy should be discontinued if any of the above adverse effects occur.[13]

Reproductive/Nursing Safety

Little information is available for dogs and cats; it is unclear whether the drug crosses the placenta or enters milk. Some teratogenic effects (eg, decrease in body weight gain, delayed ossification) and implantation losses have been noted in pregnant rats given epoetin alfa 100 units/kg/day (which approximates initial human dosages).[11] Rabbits receiving 500 mg/kg IV during days 6 to 18 of gestation and rats receiving 500 mg/kg IV during days 7 to 17 of gestation showed no untoward effects on offspring. Use during pregnancy only when benefits outweigh the potential risks.

It is not known whether epoetin alfa is excreted in milk, but it is unlikely to pose much risk to nursing offspring due to digestion in the GI tract.

Overdose/Acute Toxicity

Acute overdoses do not appear to cause significant adverse or toxic effects. In humans, single doses of up to 1600 units/kg demonstrated no signs of toxicity. Chronic overdoses may lead to hypertension or polycythemia. Treatment includes drug discontinuation, cautious phlebotomy (if polycythemia occurs), and/or control of systemic hypertension.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving epoetin alfa and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Androgens** (eg, **danazol**): May increase the sensitivity of erythroid progenitors; this interaction has been used for therapeutic effect. **NOTE**: Neither this effect nor the safety of this combination has been confirmed in well-controlled studies.
- **Cyclosporine**: May cause additive increases in blood pressure and may alter cyclosporine blood levels, as cyclosporine is bound by RBCs
- **Desmopressin**: Use with epoetin alfa can decrease bleeding times.
- **Probenecid**: Probenecid has been demonstrated to reduce the renal tubular excretion of epoetin alfa; clinical significance of this remains unclear.

Laboratory Considerations

- No laboratory interactions of major clinical importance have been described.

Dosages

DOGS/CATS:

Adjunctive therapy for anemia associated with end-stage chronic kidney disease (extra-label):

a) *Initial dosage*: 100 units/kg SC 3 times per week[8,9]; continue this dose until the target packed cell volume (PCV) is reached,

typically within 3 to 4 weeks. Taking the RBC lag phase (ie, time for RBC maturation in bone marrow) into account, do not adjust dose more frequently than once every 3 weeks. Adjust the dose and frequency as necessary to find the lowest dose needed to control anemia. If adequate control is not achieved within 8 to 12 weeks, the dose can be increased by an additional 25 – 50 units/kg every 3 to 4 weeks while maintaining a dosing interval of 3 times per week.

b) *Maintenance dosage*: 50 – 100 units/kg once to twice weekly. Continue monitoring the PCV and If animal requires greater than 145 units/kg 3 times a week, evaluate for epoetin resistance.[1,12,16,17] Iron supplementation is highly recommended. See ***Iron Dextran***.

FERRETS:

Adjunctive therapy for anemia (extra-label): 50 – 150 units/kg IM 3 times weekly; may decrease to once weekly once PCV improves to desired range[18]

RABBITS/RODENTS/SMALL MAMMALS:

Adjunctive therapy anemia in rabbits (extra-label): 50 – 150 units/kg SC every 2 to 3 days until desired PCV is reached, then reduce to once weekly for at least 4 weeks[19]

Monitoring

- Baseline and periodic CBC with reticulocyte count to identify response to treatment.
- Baseline and periodic (weekly or every other week) packed cell volume (PCV) for the first 2 to 4 months of therapy. Target PCV is an increase by more than 10% or exceeds 30% for dogs,[8,14,15] and greater than 25% for cats.[7,8] Once the PCV is stable and a maintenance dose is established, recheck PCV every 1 to 3 months (frequency will depend on patient's clinical condition).
- Baseline and periodic renal serum chemistry
- Baseline and periodic blood pressure; begin with weekly, then every 1 to 3 months[1] (frequency will depend on patient's clinical condition)
- Baseline and periodic iron testing (eg, serum ferritin, total iron-binding capacity [TIBC]) during therapy to ensure adequate iron availability

Client Information

- Epoetin alfa is an injectable medication used to treat anemia (too few red blood cells) caused by chronic kidney disease.
- If you are giving this medicine at home, be sure you understand how and where to administer the shots. It may take several weeks before it works.
- Contact your veterinarian immediately if you notice skin reactions at the site of the shot, seizures (convulsions), low energy level, joint pain (difficulty walking), mouth ulcers (may appear as excessive drooling), or loss of appetite.
- Ongoing examinations and blood work are necessary while your animal receives this drug. Do not miss these important follow-up visits.

Chemistry/Synonyms

Epoetin alfa is a biosynthetic form of the glycoprotein human hormone erythropoietin with an identical amino acid sequence as endogenous human erythropoietin (EPO) but with different carbohydrate moieties. It is commercially available as a sterile, colorless solution adjusted for tonicity and pH (7 to 7.5). Commercial products may contain human albumin (2.5 mg/mL) or be formulated in an amino acid solution. Canine and feline EPO have an 81.3% and 83.3% amino acid homology, respectively, compared with human EPO. The relative conservation of amino acid sequencing allows for binding of recombinant human EPO to canine and feline EPO receptors.[1]

Epoetin may also be known as erythropoietin, rHuEPO, BI-71.052 (epoetin gamma), BM-06.019 (epoetin beta), EPO (epoetin alfa), EPOCH (epoetin beta), *Epogen®*, *Eprex®*, *Procrit®*, and *Retacrit*.

Storage/Stability

The injectable solution should be stored in the refrigerator at 2°C to 8°C (36°F-46°F); do not freeze. Do not use the product if there is discoloration or particulate matter present. Do not shake the solution, as denaturation of the protein with resultant loss of activity may occur. Protect from light; if light exposure is limited to 24 hours or less, no effects on potency should occur. Do not mix with other drugs or use the same IV tubing when other drugs are running.

Compatibility/Compounding Considerations

A method of diluting the Amgen product to facilitate giving very small dosages has been described.[20] Use of a 1:20 dilution (1 part *Epogen®* to 19 parts bacteriostatic normal saline) does not require any additional albumin to prevent binding of the drug to container. No data are available commenting on this dilution's stability.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance; it is also prohibited on the premises of a racing facility. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Epoetin Alfa, Solution for Injection (preserved; contains human albumin): 10,000 units/mL in 2 mL multi-dose vials and 20,000 units/mL in 1 mL multi-dose vials; *Epogen, Procrit*; (Rx)

Epoetin Alfa, Solution for Injection (preservative free; contains human albumin): 2000 units/mL, 3000 units/mL, 4000 units/mL, 10,000 units/mL, and 40,000 units/mL in 1 mL vials; *Epogen*, *Procrit*; (Rx)

Epoetin Alfa-epbx, Solution for Injection (preserved; contains amino acids): 10,000 units/mL in 2 mL multi-dose vials and 20,000 units/mL in 1 mL multi-dose vials; *Retacrit*; (Rx)

Epoetin Alfa-epbx, Solution for Injection (preservative free; contains amino acids): 2000 units/mL, 3000 units/mL, 4000 units/mL, 10,000 units/mL, and 40,000 units/mL in 1 mL vials; *Retacrit*; (Rx)

Eprinomectin/Praziquantel

(e-pri-no-***mek***-tin/pra-zi-***kwon***-tel) *Centragard®*

Topical Avermectin and Anticestodal Combination Antiparasitic Agent

Prescriber Highlights

- ► Topical feline heartworm preventive, also treats and controls roundworms, hookworms, and tapeworms
- ► For use in cats and kittens 7 weeks and older and 0.8 kg (1.8 lb) or greater
- ► Usually well tolerated. Salivation may occur if cats lick the application site.

Uses/Indications

Eprinomectin/praziquantel transdermal solution is indicated for the prevention of heartworm disease caused by *Dirofilaria immitis*, and for the treatment and control of roundworms (adult and fourth-stage larval *Toxocara cati*), hookworms (adult and fourth-stage larval *Ancylostoma tubaeforme*; adult *Ancylostoma braziliense*), and tapeworms (adult *Dipylidium caninum* and *Echinococcus multilocularis*) in cats and kittens 7 weeks of age and older and 0.8 kg (1.8 lb) or

greater. However, because the prepatent period for *E multilocularis* may be as short as 26 days, cats treated at the labeled monthly intervals may become reinfected and shed eggs between treatments.

Eprinomectin/praziquantel transdermal solution also has demonstrated activity in cats against *Toxascaris leonina,*[1] *Joyeuxiella* spp,[2] lungworms,[3–5] and bladder worms,[6] and is approved for several of these indications in countries outside of the United States.[7] Efficacy against GI nematodes and cestodes is comparable to the topical combination of emodepside/praziquantel.[8]

Pharmacology/Actions

Eprinomectin binds selectively to glutamate-gated chloride ion channels that occur in invertebrate nerve and muscle cells. This leads to an increase in cell membrane permeability to chloride ions, causing paralysis and death of the parasite. Like ivermectin, eprinomectin enhances the release of gamma aminobutyric acid (GABA) at presynaptic neurons. GABA acts as an inhibitory neurotransmitter and blocks the postsynaptic stimulation of the adjacent neuron in nematodes or the muscle fiber in arthropods. These compounds are generally not toxic to mammals, as they do not have glutamate-gated chloride channels and do not readily cross the blood–brain barrier.

Praziquantel's exact mechanism of action against cestodes has not been determined, but it may be the result of interaction with phospholipids in the integument, causing ion fluxes of sodium, potassium, and calcium. At low concentrations in vitro, the drug appears to impair sucker function and stimulates the worm's motility. At higher concentrations in vitro, praziquantel increases (irreversibly at very high concentrations) the contraction of the worm's strobilla (chain of proglottids). In addition, praziquantel causes irreversible focal vacuolization with subsequent cestodal disintegration at specific sites of the cestodal integument.

In schistosomes and trematodes, praziquantel directly kills the parasite, possibly by increasing calcium ion flux into the worm. Focal vacuolization of the integument follows, and the parasite is phagocytized by the host.

Pharmacokinetics

Following eprinomectin 0.4 mg/kg IV to cats, the average maximum plasma concentration (C_{max}) of eprinomectin $B1_a$ was 503 ng/mL. The drug distributed widely, with a steady-state volume of distribution of 2.39 L/kg and protein binding greater than 99%. Terminal elimination half-life (t½) was 23.1 hours. Eprinomectin was not conjugated in liver microsomal incubates, and although metabolism appeared to correlate with relative CYP3A4 activity, the drug undergoes minimal biotransformation and is excreted primarily in the feces as unchanged drug. In cats receiving eprinomectin 0.5 mg/kg in a multi-component transdermal solution, C_{max} averaged 20.1 ng/mL and was reached on average after 24 hours. Slow topical absorption prolonged its terminal half-life (114 hours). Topical bioavailability was 31%. Total drug exposure after topical application was proportionate to the dose administered.[9] An in vitro study determined that eprinomectin interacts with P-glycoprotein similar to ivermectin.[10]

Praziquantel is distributed throughout the body. It crosses the intestinal wall and blood–brain barrier into the CNS. Praziquantel is metabolized in the liver via CYP3A enzymes to metabolites of unknown activity. It is excreted primarily in the urine; elimination half-life is ≈3 hours in dogs.

Contraindications/Precautions/Warnings

Eprinomectin/praziquantel transdermal solution is contraindicated in patients with a known hypersensitivity to eprinomectin or praziquantel. The manufacturer does not recommend using eprinomectin/praziquantel transdermal solution in cats or kittens less than 7 weeks old or weighing less than 0.8 kg (1.8 lb). Do not administer the transdermal solution orally. In humans, praziquantel is contraindicated in patients that are hypersensitive to the drug, and it should not be administered to patients with a history of epilepsy.

Adverse Effects

Eprinomectin/praziquantel transdermal solution appears to be well tolerated. Vomiting, inappetence, and lethargy have been noted. Excessive salivation commonly occurs if cats lick the application site. Skin reactions (eg, itching, hair clumping, hair loss) may occur uncommonly after application of eprinomectin/praziquantel transdermal solution but are usually mild and temporary. Transient ataxia, disorientation, lethargy, and pupil dilation also have been noted at higher doses.

In cats, adverse effects were quite rare (less than 2%) in field trials using oral praziquantel, with salivation and diarrhea being reported.

Reproductive/Nursing Safety

Safe use of eprinomectin/praziquantel transdermal solution in breeding or pregnant cats has not been tested; however, praziquantel is considered safe to use during pregnancy. Praziquantel did not impair fertility or reproductive performance in rats at doses up to 300 mg/kg/day. The same dosage produced no harm to rabbit or rat fetuses.[11]

Safe use of eprinomectin/praziquantel transdermal solution in lactating cats has not been tested. Praziquantel appears in maternal milk at a concentration of ≈25% of that in maternal serum, and in humans it is recommended that women avoid nursing on the day of treatment and the subsequent 72 hours.[11]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Kittens that were exposed to 3 times and 5 times the eprinomectin/praziquantel transdermal solution label doses experienced ataxia, disorientation, lethargy, and pupil dilation that lasted 12 to 24 hours before recovering completely. Cats receiving 3 times the label dose orally immediately exhibited excessive salivation; vomiting and lethargy also were noted. Safety was also demonstrated when a similar transdermal solution was given to kittens at up to 15 times the label dose every 4 weeks for 6 treatments, and in adult cats receiving 5 times the label dose every 2 weeks for 3 treatments.[7]

Praziquantel has a wide margin of safety. In rats and mice, the oral LD_{50} is at least 2 g/kg. An oral LD_{50} could not be determined in dogs, as at doses greater than 200 mg/kg, the drug induced vomiting. Parenteral doses of 50 – 100 mg/kg in cats caused transient ataxia and depression; injected doses at 200 mg/kg were lethal in cats.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Eprinomectin is a P-glycoprotein substrate and inhibitor.[10] Praziquantel is a substrate of CYP 3A4 in humans. The following drug interactions either have been reported or are theoretical in humans or animals receiving eprinomectin or praziquantel and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but veterinarians should weigh the potential risks and perform additional monitoring when appropriate.

- **Albendazole**: Praziquantel may increase albendazole sulphoxide concentration.
- **Cimetidine**: May increase the serum concentration of praziquantel
- **CYP3A4 Inducers (**eg, **dexamethasone, phenobarbital, rifampin)**: May decrease eprinomectin and/or praziquantel concentrations. In humans, it is recommended to discontinue rifampin 4 weeks prior to praziquantel administration.

- **CYP3A4 Inhibitors** (eg, **amiodarone, clarithromycin, fluoxetine, itraconazole, ketoconazole, verapamil**): May increase eprinomectin and/or praziquantel concentrations
- **Grapefruit Juice**: Can significantly increase praziquantel serum concentrations in beagles.[12] May increase eprinomectin concentrations
- **P-Glycoprotein Inhibitors** (eg, **amiodarone, cyclosporine, digoxin, itraconazole, spironolactone**): May increase eprinomectin concentrations
- **P-Glycoprotein Substrates** (eg, **cyclosporine, doxorubicin, mitoxantrone, phenothiazines, vinca alkaloids**): Eprinomectin may inhibit P-glycoprotein and increase exposure to P-glycoprotein substrates.

Laboratory Considerations

- None noted

Dosages

CATS:

Prevention of heartworm disease, and for the treatment and control of roundworms, hookworms, and tapeworms (label dosage; FDA-approved): A minimum of 0.12 mL/kg (0.055 mL/lb), which delivers a minimum dose of eprinomectin 0.5 mg/kg (0.23 mg/lb) and praziquantel 10 mg/kg (4.55 mg/lb), is administered topically.[13] For the treatment of roundworms, hookworms, and tapeworms, administer once. For heartworm prevention, and for the control of roundworms, hookworms, and tapeworms, apply once monthly. Follow dosing table (see below) provided by the manufacturer. Part the hair and apply the entire applicator contents directly on the skin in 1 spot on the midline of the neck between the base of the skull and the shoulder blades. Cats weighing greater than 7.5 kg (16.5 lb) will require application of more than 1 unit.

Body weight in kg (lb)	Volume (mL)	Eprinomectin (mg)	Praziquantel (mg)
0.8-2.5 (1.8-5.5)	0.3	1.2	24.9
2.5-7.5 (5.6-16.5)	0.9	3.6	74.7
7.5-10 (16.6-22)	0.3 + 0.9	4.8	99.6
10-15 (22.1-33)	0.9 + 0.9	7.2	149.4

Monitoring

- Clinical efficacy; adverse effects

Client Information

- Dead tapeworms are typically not seen in feces after treatment.
- For heartworm prevention: This medicine may be administered year-round, or, at a minimum, treatment should start 1 month before the cat's first expected exposure to mosquitoes and continue at monthly intervals until at least 1 month after the cat's last exposure to mosquitoes. If a dose is missed and a 30-day interval between doses is exceeded, administer immediately and resume the monthly dosing schedule.
- Cats commonly scratch or groom the application site. Ingested product can cause excessive salivation or drooling, vomiting, and lack of energy.
- Apply this medicine directly to the skin, between the base of the skull and the shoulder blades where the cat cannot lick. Part the hair and place the tip of the applicator against the cat's skin during application. If 2 applicators are required, apply both in the same spot. Prevent treated cat and other cats in the household from grooming the application site. Avoid contact of the medicine with the cat's eyes.
- Caregivers should avoid contact with the application site for 5 hours following treatment and wash their hands after applying the product. If the product accidentally gets into the eyes, flush thoroughly with water. In case of accidental ingestion, or if skin or eye irritation occurs, contact a poison control center or physician for treatment advice.

Chemistry/Synonyms

Eprinomectin is a member of the avermectin class of antiparasitic agents, and the transdermal solution contains a mixture of eprinomectin $B1_a$ and $B1_b$. It is also known as MK-397, ML-635, or 4-epi-acetylamino-4-deoxy-avermectin B1.

A prazinoisoquinoline-derivative anthelmintic, praziquantel occurs as a white to practically white, hygroscopic, bitter tasting crystalline powder, either odorless or having a faint odor. It is very slightly soluble in water and freely soluble in alcohol. Praziquantel may also be known as EMBAY-8440 or praziquantelum, and it is sold under many trade names.

Eprinomectin/praziquantel transdermal solution is also known as *Centragard®*. In other countries, transdermal solutions containing eprinomectin/praziquantel combinations include *BROADLINE®* (also contains fipronil and S-methoprene and may be known as ML-635) and *NexGard® Combo* (also contains esafoxolaner).

Storage/Stability

Eprinomectin/praziquantel transdermal solution should be stored protected from light at or below 30°C (86°F) with excursions permitted to 40°C (104°F). Keep out of reach of children.

Compatibility/Compounding Considerations

No information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Eprinomectin/Praziquantel Transdermal Solution: Eprinomectin 4 mg/mL and praziquantel 83 mg/mL in 0.3- and 0.9-mL applicators; *Centragard®*; (Rx). For use on cats and kittens 7 weeks of age or older weighing at least 0.8 kg (1.8 lb). NADA #141-492

HUMAN-LABELED PRODUCTS: NONE

Eprinomectin

(e-pri-no-***mek***-tin) *Eprinex®; LongRange®*

Avermectin Antiparasitic Agent

Prescriber Highlights

- ► Topically applied (pour-on) or extended-release injection (for cattle on pasture only) avermectin antiparasiticide
- ► When pour-on is used as labeled, there are no milk or meat withdrawal times required.
- ► Injectable product has a 48-day slaughter withdrawal and specific syringe compatibilities. It must be administered SC in front of the shoulder (not for IV or IM use).
- ► Adverse effects of the pour-on product are rare but may include anorexia, hypogalactia, pruritus, and alopecia.
- ► Adverse effects of the injectable product include injection site reactions including granulomas and necrosis.

Uses/Indications

In cattle, topical eprinomectin is indicated for the treatment and control of the following:

- GI roundworms: *Haemonchus placei* (adult and L4 stages), *Ostertagia ostertagi* (L4), *Trichostrongylus axei, Trichostrongylus colubriformis, Trichostrongylus longispicularis* (adults only), *Cooperia oncophora, Cooperia punctate, Cooperia surnabada, Nematodirus*

helvetianus, Oesophagostomum radiatum, Bunostomum phlebotomum, *Strongyloides papillosus* (adults only), and *Trichuris* spp (adults only)
- Cattle grubs: *Hypoderma lineatum, Hypoderma bovis* (all parasitic stages)
- Lungworms: *Dictyocaulus viviparus* (adults and L4, for 21 days after treatment)
- Lice: *Damalinia bovis, Linognathus vituli, Haematopinus eurysternus, Solenopotes capillatus*
- Mange mites: *Chorioptes bovis, Sarcoptes scabiei*
- Horn flies: *Haematobia irritans* (for 7 days after treatment)

The extended-release eprinomectin 5% injection is indicated for the treatment and control of internal and external parasites (eg, susceptible GI roundworms, grubs, lungworms, mites) in cattle on pasture with persistent effectiveness. It has also shown efficacy for controlling *Rhipichephalus microplus* ticks.[1,2] Although one study reported the efficacy of SC eprinomectin in pastured dairy heifers,[3] it is not approved for use in female dairy cattle 20 months of age or older, including dry dairy cows, calves to be processed for veal, breeding bulls, calves less than 3 months of age, or cattle managed in feedlots or under intensive rotational grazing.

Various eprinomectin products are approved for use in sheep and goats in other countries. Topical eprinomectin has demonstrated efficacy against GI nematodes in lactating and nonlactating goats.[4–6] However, high variability in pharmacokinetic parameters and low bioavailability from this route of administration causes concern for suboptimal efficacy at recommended doses. SC administration in nonlactating goats at 0.2 mg/kg and 0.4 mg/kg had over 97.8% efficacy against *Haemonchus contortus and Trichostrongylus colubriformis*.[7] Eprinomectin has also shown efficacy against pulmonary and GI nematodes in sheep.[8] Small studies have shown a beneficial effect on milk yield when given SC at 0.2 mg/kg[9] or topically at 1 mg/kg.[10]

Topical eprinomectin may be useful in an extra-label manner for the topical treatment of psoroptic mange (*Psoroptes equi*) in horses or ear mites (*Psoroptes cuniculi*) in rabbits. One small study (6 subjects) showed a partial response when rabbits were dosed at 5 mg/kg topically, twice at 14-day intervals.[11]

Pharmacology/Actions

Eprinomectin binds selectively to glutamate-gated chloride ion channels that occur in invertebrate nerve and muscle cells. This leads to an increase in cell membrane permeability to chloride ions, causing paralysis and the death of the parasite. Like ivermectin, eprinomectin enhances the release of gamma-aminobutyric acid (GABA) at presynaptic neurons. GABA acts as an inhibitory neurotransmitter and blocks the postsynaptic stimulation of the adjacent neuron in nematodes or the muscle fiber in arthropods. These compounds are generally not toxic to mammals as they do not have glutamate-gated chloride channels and do not readily cross the blood–brain barrier.

Pharmacokinetics

When the injectable product is injected in cattle as labeled, a polymeric PLGA matrix is formed, allowing a gradual release of eprinomectin into the systemic circulation. Effective plasma concentrations may persist for at least 100 days, with an initial maximum eprinomectin concentration (C_{max}) reached within a few days after injection, followed by a second C_{max} ≈90 days later. A study comparing eprinomectin pharmacokinetic parameters of topical and long-acting injection administered to nonlactating dairy cattle demonstrated higher maximum eprinomectin concentration (C_{max}), longer half-life ($t_{½}$), and a greater area under the concentration-time curve with the long-acting injection. New world camelids experience a similar bi-phasic C_{max}. Administration of the pour-on formulation to goats prevented from grooming resulted in systemic absorption, with time to C_{max} noted at 1.1 days and $t_{½}$ of 4.18 days. Topical administration results in significantly lower systemic bioavailability in goats compared with cattle and has high variability between individuals.

Contraindications/Precautions/Warnings

The pour-on product must only be applied topically; do not give the pour-on orally or IV.

The injectable product's label states that "this product should not be used in other animal species" and that it is "not for intravenous or intramuscular use."

Underdosing and/or subtherapeutic concentrations of extended-release anthelmintic products are likely to encourage the development of parasite resistance. Resistance has been confirmed in *Haemonchus contortus* in geographic regions worldwide. Eprinomectin adversely affects fish and aquatic organisms; dispose of properly in an approved landfill or by incineration.[12–14]

Adverse Effects

Although no adverse reactions are listed in the pour-on product label, the FDA's Cumulative Adverse Drug Experience database for topical administration on cattle lists the 3 most common adverse effects as ineffective parasite control, anorexia, and udder hypogalactia.[15] It must be noted that incidence rates are not listed, and a causal effect is not established for listings in this database. Foreign labels report very rare incidences of pruritis and alopecia.[14]

The injectable product is likely to cause tissue damage at the site of injection, including possible granulomas and necrosis. Reactions have disappeared without treatment. Local tissue reaction may result in trim loss of edible tissue at slaughter. Observe cattle for injection site reactions.[13]

Reproductive/Nursing Safety

The label states that the injection is not for use in bulls, as reproductive safety testing has not been conducted in males intended for breeding or males actively breeding. Eprinomectin should not be used in calves less than 3 months of age because safety testing has not been conducted in calves in this age group. Administration at 3 times the recommended therapeutic dose had no adverse reproductive effects on beef cows at all stages of breeding, their pregnancy, or on their calves.

It is likely safe to use in nursing animals, but it is not approved for use in lactating dairy cattle.

Overdose/Acute Toxicity

For the pour-on formulation, calves given up to 5 times the recommended dosage showed no signs of adverse effects. One subject (of 6) showed signs of mydriasis when given 10 times the normal dose. The sustained-release injectable given at 3 to 5 times the recommended dose resulted in a statistically significant reduction in average weight gain when compared with the group tested at label dose. Treatment-related lesions observed in most cattle administered the product included swelling, hyperemia, or necrosis in the SC tissue of the skin.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving eprinomectin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Meloxicam**: Coadministration of eprinomectin and meloxicam in sheep resulted in increased systemic meloxicam concentrations due to the inhibition of ABCG2 transporters.[16]
- **P-Glycoprotein Inhibitors** (eg, **doxycycline**[17]): Eprinomectin has high affinity for P-glycoprotein. Use caution when administering with known P-gp inhibitors.

Dosages

HORSES:

Psoroptic (*Psoroptes equi*) mange (extra-label): 0.5 mg/kg topically once weekly for 4 treatments. The study authors suggest getting informed consent before use.[18]

CATTLE:

Labeled indications (pour-on; FDA-approved): 0.5 mg/kg (1 mL per 10 kg [22 lb]) applied topically along the backline in a narrow strip from the withers to the tailhead. For most effective results against grubs, treat cattle as soon as possible after the end of the heel fly (ie, warble fly) season.[19]

Labeled indications (extended-release injection; FDA-approved): 1 mg/kg (1 mL per 50 kg [110 lb]) SC under the loose skin in front of the shoulder. Divide doses greater than 10 mL between 2 injection sites. Inject using a 16- or 18-gauge, ½- to ¾-inch needle. See additional information on syringe compatibility and automatic syringes in the ***Compatibility/Compounding Considerations*** section below.[13] For most effective results against grubs, treat cattle as soon as possible after the end of the heel fly (ie, warble fly) season.

SHEEP/GOATS:

GI nematodes in nonlactating goats (extra-label): 0.2 – 0.4 mg/kg SC[7]

GI and pulmonary nematodes in sheep and goats (injection; extra-label): 0.2 mg/kg SC[20,21]

GI and pulmonary nematodes in sheep and goats (pour-on; extra-label): 1 mg/kg topically in a narrow strip from the withers to the tailhead[8]

NOTE: This dose may be suboptimal in goats due to high variability and low bioavailability of topical formulations.[22]

CAMELIDS:

Chorioptic mange (extra-label): Data conflict: 0.5 mg/kg topically once weekly for 4 weeks was effective in one field study,[23] but another study found a 10-week treatment to be ineffective.[24]

Client Information

For the pour-on formulation:

- When eprinomectin is used as labeled, there are no milk or meat withdrawal times required.
- Weather conditions (including rainfall) during administration do not affect efficacy.
- Do not apply this medicine to the backline if the animal is covered with mud or manure.
- Dispose of containers in an approved landfill or by incineration; do not contaminate water, as eprinomectin may adversely affect fish and aquatic organisms.

For the injectable formulation:

- 48-day withdrawal time
- Several restrictions on use. Eprinomectin is not approved for bulls, veal calves, or dairy cattle.
- Specific syringes required. Must be administered under the skin in front of the shoulder. Sanitize the injection site and administer with clean, properly disinfected needles.
- Observe for injection site reactions. If suspected, consult your veterinarian.

Chemistry/Synonyms

Eprinomectin is a member of the avermectin class of antiparasitic agents. It is also known as MK-397 or 4-epi-acetylamino-4-deoxy-avermectin B1.

Storage/Stability

Store the commercially available pour-on product at 30°C (86°F) or less, protected from light. Brief excursions up to 40°C (104°F) are permitted but should be minimized.

Store the injectable at 25°C (77°F) with excursions permitted between 15°C and 30°C (59°F and 86°F). Protect it from light. Do not store in automatic syringe equipment.

Compatibility/Compounding Considerations

For the injectable formulation: 100 mL bottle: Use only polypropylene syringes with the 100 mL bottle size. Not for use with polycarbonate syringe material. If syringe material is not known, contact the syringe manufacturer prior to use for identification. Do not use beyond 3 months after the stopper has been punctured. Discard bottle after 15 stopper punctures.

250 mL and 500 mL bottle sizes: Use only automatic syringe equipment provided by Merial. To obtain **compatible** equipment, contact Merial at 1-888-637-4251 or your veterinarian; should not be stored (left) in automatic syringe equipment. Automatic syringe equipment should be thoroughly cleaned after each use. Discard bottle after one stopper puncture with a draw-off spike. No special handling or protective clothing is necessary.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Eprinomectin Topical (Pour-On) Solution: 5 mg/mL in 250 mL/8.5 fl oz and 1 L/33.8 fl oz bottle with a squeeze-measure-pour-system, or a 2.5 L/84.5 fl oz and 5 L/169 fl oz collapsible pack or 20 L/ 676 oz container for use with appropriate automatic dosing equipment; *Eprinex®*, generic; (OTC). FDA-approved for use in beef or dairy cattle of all ages; not for use in calves to be processed for veal.

Eprinomectin 5% (50 mg/mL) Sustained-release Injectable: In 100, 250, and 500 mL bottles; *LongRange®*; (Rx). FDA-approved for use in cattle on pasture with persistent effectiveness. It is not approved for use in female dairy cattle 20 months of age or older, including dry dairy cows; calves to be processed for veal; breeding bulls; calves less than 3 months of age; or cattle managed in feedlots or under intensive rotational grazing. Animals intended for human consumption must not be slaughtered within 48 days of the last treatment. A withdrawal period has not been established for pre-ruminating calves. NADA #141-327

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Epsiprantel

(ep-si-***pran***-tel) *Cestex®*

Anticestodal Antiparasitic Agent

Prescriber Highlights

- ► Anticestodal for dogs and cats 7 weeks of age and older
- ► Limited oral absorption results in high concentration of the drug within the GI tract (ie, at the site of action).
- ► Adverse effects are uncommon due to limited oral absorption.
- ► Resistance to epsiprantel has been demonstrated in *Dipylidium caninum*.

Uses/Indications
Epsiprantel is FDA-approved for the removal of *Dipylidium caninum* and *Taenia pisiformis* in dogs, and *Dipylidium caninum* and *Taenia taeniaeformis* in cats. For *D caninum*, flea and louse control are mandatory, or tapeworm reinfestation is likely. Epsiprantel has demonstrated extra-label efficacy against adult stages of *Echinococcus* spp in dogs and cats.[1-3]

Pharmacology/Actions
Epsiprantel's exact mechanism of action against cestodes has not been determined. The tapeworm's ability to regulate calcium is apparently affected, causing tetany and disruption of attachment to the host. Alteration to the integument makes the worm vulnerable to digestion by the host animal. Isolated cases of resistance to epsiprantel have been demonstrated in *Dipylidium caninum*.[4]

Pharmacokinetics
Epsiprantel is absorbed poorly after oral administration. The bulk of the drug remains within the GI tract and is eliminated unchanged in the feces. Less than 0.1% of the drug is recovered in the urine after dosing. No metabolites have been identified.

Contraindications/Precautions/Warnings
There are no labeled contraindications to this drug. Epsiprantel should be considered contraindicated in patients hypersensitive to it. Do not use in puppies or kittens less than 7 weeks of age.

Adverse Effects
Adverse effects appear to be rare when epsiprantel is used at the labeled dosage.

Reproductive/Nursing Safety
Safety for use in pregnant, lactating, or breeding animals has not been determined, but adverse effects to the offspring would be highly unlikely because the drug is so poorly absorbed.

Overdose/Acute Toxicity
Acute toxicity resulting from an inadvertent overdose is highly unlikely. Dosages of up to 500 mg/kg (≈90 times recommended dose) given to dogs once daily for 14 days resulted in isolated instances of vomiting, increased alkaline phosphatase (ALP), and leukopenia. Dosages as high as 110 mg/kg (20 times recommended dose) given once daily for 4 days resulted in trembling and vomiting in some of the kittens tested. Dosages of 16.5 mg/kg (3 times recommended dose) given once daily for 3 days produced no adverse effects in adult greyhounds or in 7-week-old puppies. Dosages up to 13.75 mg/kg (2.5 times recommended dose) given once daily for 3 days produced no adverse effects in cats 4 to 5 months of age. [5]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions
- None reported; theoretically, prokinetic agents or fast-acting laxatives may reduce the drug's efficacy.

Laboratory Considerations
- None reported

Dosages
DOGS:

Treatment (removal) of tapeworms – *Dipylidium caninum* and *Taenia pisiformis* (label dosage; FDA-approved): 5.5 mg/kg PO once; round up to the next larger tablet size. For dogs over 46 kg (101 lb), round up to the next whole tablet combination.[5]

Treatment (removal) of *Echinococcus* spp (extra-label): 5 – 7.5 mg/kg PO once.[1-3] In one study,[3] total worm clearance occurred only in dogs given the higher dose.

CATS:

Treatment (removal) of tapeworms – *Dipylidium caninum* and *Taenia taeniaeformis* (label dosage; FDA-approved): 2.75 mg/kg PO once. Cats up to 4.5 kg (10 lb) should receive one 12.5 mg tablet; cats weighing 4.9 kg to 9 kg (11 to 20 lb) should receive one 25 mg tablet[5]

Treatment (removal) *Echinococcus multiocularis* (extra-label): 2.7 – 5.5 mg/kg PO once[2]

Monitoring
- Clinical efficacy

Client Information
- Oral medicine for treating tapeworms in dogs and cats
- Give this medicine with food
- Adverse effects are rare.
- Because the tapeworm may be partially or completely digested, worm fragments may not be seen in the feces after treatment.
- A single dose is usually effective. Talk with your veterinarian about measures (such as flea protection) that can be taken to prevent reinfection.

Chemistry/Synonyms
A pyrazino-benzazepine oral cestocide, epsiprantel occurs as a white powder that is sparingly soluble in water.

Epsiprantel may also be known as BRL-38705 or *Cestex*®.

Storage/Stability
Tablets should be stored at room temperature 20°C to 25°C (68°F-77°F) with excursions between 15°C to 30°C (59°F-86°F).

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:

Epsiprantel Oral Tablets (film-coated): 12.5 mg, 25 mg, 50 mg, and 100 mg; *Cestex*®; (Rx). NADA #140-893

HUMAN-APPROVED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Ergocalciferol
Vitamin D2
(er-goh-kal-***sif***-er-ole) *Drisdol*®

Vitamin D Analogue

Prescriber Highlights
► May be used to treat hypocalcemia associated with hypoparathyroidism, but calcitriol usually recommended first

► Less expensive than dihydrotachysterol (DHT) or calcitriol, but large initial doses are required, effects take longer to be seen, and if hypercalcemia develops, it takes longer (up to 18 weeks) to recover from

Uses/Indications
Ergocalciferol is sometimes used in dogs or cats to treat hypocalcemia secondary to parathyroid gland failure, particularly when dihydrotachysterol or calcitriol are too expensive for the owner. As compared with those agents, ergocalciferol takes longer to have

a maximal effect on serum calcium. Additionally, if hypercalcemia should develop, ergocalciferol's effects persist longer than either calcitriol or dihydrotachysterol.

Pharmacology/Actions

Ergocalciferol is first hydroxylated in the liver to 25-hydroxyvitamin D (has some activity) and then activated in the kidneys to 1,25-dihydroxyvitamin D, the primary active form of the drug. Vitamin D is considered a hormone and, in conjunction with parathormone (PTH) and calcitonin, regulates calcium homeostasis in the body. Active analogues (or metabolites) of vitamin D enhance calcium and phosphate absorption from the GI tract, promote reabsorption of calcium by the renal tubules, and increase the rate of accretion and resorption of minerals in bone. Ergocalciferol has ≈1/10 the activity of cholecalciferol for enhancing intestinal calcium absorption.

Pharmacokinetics

Specific pharmacokinetic values for dogs and cats were not located. The following information (human-based) generally applies: In the presence of bile salts, ergocalciferol is absorbed from the small intestine; after conversion to its 25-hydroxylated form in the liver and kidneys, it is stored in the liver and fat. Cats do not appear to convert ergocalciferol to its 25-hydroxylate form as well as cholecalciferol. Several days of therapy may be required until steady-state volume of distribution is achieved. In dogs and cats, maximal effect on calcium homeostasis is usually noted from 5 to 21 days after treatment begins; effects may persist for up to 18 weeks once treatment is discontinued.[1]

Contraindications/Precautions/Warnings

Ergocalciferol, at therapeutic dosages, is contraindicated in patients with hypercalcemia, vitamin D toxicity, malabsorption syndrome, or abnormal sensitivity to the effects of vitamin D. It should be used with extreme caution in patients with hyperphosphatemia. As patients with kidney dysfunction may not convert ergocalciferol into the primary active metabolite, calcitriol or DHT would be preferred because they do not require activation by the kidney. Chronic therapy should not be initiated unless owners are willing to commit to ongoing patient monitoring.

Adverse Effects

The primary concern with using ergocalciferol is exceeding the dosage with resultant hypercalcemia and, potentially, hyperphosphatemia or nephrocalcinosis. Hypercalcemia can persist for weeks to months.

Reproductive/Nursing Safety

Hypervitaminosis D in pregnant females has been implicated in causing teratogenic effects in animals and infants. Potential benefits of therapy must be weighed against the risks if considering use in pregnant dogs or cats.

As large doses of vitamin D can be excreted into milk, consider using milk replacer in offspring of dams receiving therapeutic dosages of ergocalciferol.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Because of the potential serious ramifications of overdoses, contacting an animal poison control center is strongly recommended. The toxic acute oral dose of ergocalciferol in dogs is reported as 4 mg/kg (160,000 units/kg).[2]

Acute ingestions should be managed using established protocols for GI decontamination if done within 6 hours of ingestion. Orally administered mineral oil may reduce absorption and enhance fecal elimination. Cholestyramine may also be beneficial.

Hypercalcemia secondary to chronic dosing of ergocalciferol should be treated by first temporarily discontinuing the drug and exogenous calcium therapy. If hypercalcemia is severe, furosemide, calcium-free IV fluids (eg, normal saline), urine acidification, bisphosphonates, and corticosteroids may be employed. Because of the long duration of action of ergocalciferol (potentially up to 18 weeks), hypercalcemia may persist. Restart ergocalciferol therapy (if desired) at a reduced dosage only when serum calcium concentrations return to the normal range. Diligent monitoring (eg, serum PTH, ionized calcium, phosphorus, vitamin D concentrations, renal function) is required.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ergocalciferol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Cimetidine**: May result in decreased vitamin D exposure
- **Cholestyramine**: May decrease vitamin D absorption
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Can reduce the effects of vitamin D
- **Digoxin** or **Verapamil**: Patients on these drugs are sensitive to the effects of hypercalcemia; intensified monitoring is required
- **Mineral Oil**: May reduce the amount of ergocalciferol absorbed
- **Phenobarbital**: May result in decreased systemic vitamin D exposure
- **Thiazide Diuretics** (eg, **hydrochlorothiazide**): May cause hypercalcemia when given in conjunction with vitamin D

Laboratory Considerations

- **Serum cholesterol** levels may be falsely elevated by vitamin D analogues when using the Zlatkis-Zak reaction for determination.

Dosages

DOGS/CATS:

Maintenance therapy of parathyroid failure after using parenteral calcium to control hypocalcemic tetany (extra-label): Calcitriol is generally preferred due to a more rapid effect and a risk of overshooting the ergocalciferol dosage leading to persistent hypercalcemia; however, ergocalciferol can be a less expensive option. The ergocalciferol dosage is 4000 – 6000 units/kg PO once daily. Effect is usually seen between 5 and 14 days after initiation of treatment. After 1 to 5 days, parenteral calcium can usually be discontinued. Patient should remain hospitalized until serum calcium concentration remains between 8 and 10 mg/dL without parenteral calcium support. Continue ergocalciferol but administer every other day. Weekly serum calcium concentrations should be measured and ergocalciferol dosage adjusted to maintain serum calcium concentrations between 8 and 9.5 mg/dL. Maintenance dosages usually range from 1000 – 2000 units/kg PO once daily to once weekly. Goal is to prevent hypocalcemic tetany, but not induce hypercalcemia.[3] Once animal is stable, monthly rechecks for 6 months are strongly advised; then every 2 to 3 months thereafter.[1,3]

Monitoring

- See dosage information above.

Client Information

- Using vitamin D products may require lifelong treatment and regular laboratory monitoring.

- Although this agent can be used to treat low calcium concentrations, excessive ergocalciferol doses can cause calcium concentrations in the blood to become too high. This effect can last for many weeks, even after the medication is discontinued.

Chemistry/Synonyms

Ergocalciferol is obtained by irradiating (with ultraviolet light) ergosterol, a sterol present in fungi and yeasts. It occurs as white or almost white crystals or yellowish crystalline powder and is practically insoluble in water but is soluble in fatty oils. One mg of ergocalciferol provides 40,000 units of vitamin D activity.

Ergocalciferol may be known as calciferol, vitamin D_2, viosterol, activated ergosterol, or irradiated ergosterol; there are many international trade names.

Storage/Stability

Ergocalciferol is sensitive to light, heat, and air. Store capsules or liquid at room temperature (15°C-30°C [59°F-86°F]) and protect from light.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Ertapenem

(er-ta-***pen***-um) *Invanz®*

Carbapenem Antibiotic

Prescriber Highlights

- ► Carbapenem antibiotic similar to imipenem and meropenem but with a narrower spectrum of activity
- ► Not effective against *Pseudomonas* spp or *Acinetobacter* spp
- ► Rarely used in veterinary medicine; must be considered investigational, as there is limited information available for use in dogs and cats
- ► Use in veterinary medicine is controversial because of the drug's importance in human medicine. Veterinary infectious disease specialists should be consulted prior to treatment. Use should be reserved for infections with confirmed susceptibility that are resistant to lower-tier options.

Uses/Indications

Because ertapenem is used for multidrug-resistant infections in humans, its use in veterinary medicine should be reserved for confirmed infections where culture and susceptibility testing demonstrate resistance to all other options, the infection is considered treatable, and consultation with an infectious disease expert has concluded that ertapenem is a viable and reasonable treatment.[1,2] Empirical use should be discouraged. If a carbapenem is required, the use of meropenem or imipenem would be preferred because of greater information available regarding the use of these antibiotics in animals.

Ertapenem may be useful in treating resistant gram-negative bacterial infections, particularly when aminoglycoside use would be risky (eg, renal failure) or not effective (eg, resistance or CNS infections). Although ertapenem has a broad spectrum of antibacterial activity, it is not active against *Pseudomonas aeruginosa*. It potentially could be useful against mixed anaerobic and gram-negative aerobic infections when *Pseudomonas spp* is not considered a likely pathogen.

The World Health Organization (WHO) has designated ertapenem as a Critically Important, High Priority antimicrobial for human medicine.[3]

Pharmacology/Actions

Ertapenem is a carbapenem antibiotic similar to imipenem and meropenem. Like other beta-lactams, it inhibits bacterial cell wall synthesis, is time-dependent, and is usually bactericidal.

Ertapenem has a broad antibacterial spectrum similar to that of imipenem, but it is more active against Enterobacteriaceae and anaerobes. It has equivalent activity against gram-positive bacteria and minimal activity against *Pseudomonas aeruginosa* and *Acinetobacter* spp. Methicillin-resistant *Staphylococcus* spp and *Enterococcus faecium* are resistant to the effects of ertapenem. Because ertapenem (like meropenem) is more stable than imipenem to renal dehydropeptidase I, it does not require the addition of cilastatin to inhibit that enzyme.

Pharmacokinetics

No pharmacokinetic data have been published for dogs or cats. Anecdotally, it has been reported that the pharmacokinetics in dogs and cats do not mimic those values seen in humans.

In humans, ertapenem must be administered parenterally as it is not appreciably absorbed after oral administration. Intramuscular bioavailability is about 90%, and peak plasma concentrations occur in ≈2.3 hours.[2] Ertapenem exhibits concentration-dependent binding to human plasma proteins. At plasma concentrations of less than 100 µg/mL, it is 95% bound; at 300 µg/mL, it is 85% bound. Ertapenem biotransformation is not dependent on hepatic mechanisms, as the major metabolite (inactive) is formed by hydrolysis of the beta-lactam ring. Approximately 80% of an IV dose is excreted in the urine, evenly split between inactive metabolites and an unchanged drug. Approximately. 10% is excreted in the feces. In young, healthy adults, the elimination half-life is about 4 hours and about 2.5 hours in pediatric patients.[2]

Contraindications/Precautions/Warnings

Ertapenem is contraindicated in patients that are hypersensitive to it and other carbapenems and in those patients that have developed anaphylaxis after receiving any beta-lactam antibiotic.[2] It is contraindicated in patients that are hypersensitive to lidocaine or other amide-type local anesthetics (if used IM with 1% lidocaine as the diluent).[2]

Consider the use of ertapenem investigational since it has not been widely used clinically in veterinary medicine and has little published information for its use in dogs or cats. See ***Uses/Indications***.

Adverse Effects

The adverse effect profile for ertapenem in dogs or cats is unknown. In humans, IV injection site reactions and diarrhea are the most common adverse effects.[2] Other GI effects (eg, nausea, vomiting), headache, or tachycardia have occasionally been reported. Rarely, hypersensitivity or CNS effects (eg, hallucinations, agitation, seizures) have been seen.

Reproductive/Nursing Safety

Ertapenem has been shown to cross the placenta in rats, but no teratogenic effects have been reported.[2]

Ertapenem is distributed into breast milk.

Because safety has not been established in animals, this drug

should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Clinical signs as a result of an overdose are unlikely. Humans receiving ertapenem 3 g IV had an increased incidence of nausea and diarrhea.[2] If an overdose occurs and adverse effects are noted, treat supportively.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ertapenem and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Probenecid**: In humans, coadministration of ertapenem with probenecid can increase ertapenem AUC by 25% and the elimination half-life by about 20%.[2] Because of these relatively small effects, the manufacturer does not recommend using probenecid to extend the half-life of ertapenem.

Laboratory Considerations

- No specific laboratory interactions or concerns were noted.

Dosages

DOGS/CATS:

IMPORTANT: Because ertapenem is used for multidrug-resistant infections in humans, its use in veterinary medicine should be reserved for confirmed infections where culture and susceptibility testing demonstrate resistance to all other options, the infection is considered treatable, and consultation with an infectious disease expert has concluded that ertapenem is a viable and reasonable treatment.[1,2] Empirical use should be discouraged. If a carbapenem is required, the use of meropenem or imipenem would be preferred because of greater information available regarding the use of these antibiotics in animals.

Susceptible infections (extra-label): Anecdotally, 30 mg/kg IV or SC every 8 hours

Monitoring

- Clinical efficacy
- Adverse effects (eg, GI, neurotoxicity, hypersensitivity)
- In humans receiving ertapenem for a prolonged period, hepatic, hematopoietic, and renal function tests are suggested for periodic assessment.[2]

Client Information

- This medicine must be injected into a vein (*intravenous* [IV]; only done in the hospital) or under the skin (*subcutaneously [SC]*).
- Your veterinarian or pharmacist will give you all of the items you need to give the shots (eg, needles, syringes, diluent). If there is a need to mix the medicine before you give it, mix it exactly as your veterinarian or pharmacist tells you.
- Because of the need to inject this medicine, be sure you understand the correct amount to give the shot (*injection*), where to give it, and how to give it. Injections may sting when given. If your animal objects too much, your veterinarian may be able to give you something to mix with the liquid to help it sting less.

Chemistry/Synonyms

Ertapenem sodium is a synthetic 1-(beta) methyl carbapenem antibiotic that occurs as a white to off-white, hygroscopic, crystalline powder. It is soluble in water and normal saline. The 1 g injectable product contains ≈6 mEq of sodium and 175 mg of sodium bicarbonate (as an excipient).

Ertapenem may also be known as L-749345, ML-0826, ZD-4433, ertapenemum, or *Invanz*®.

Storage/Stability

Store unreconstituted ertapenem vials at temperatures at or below 25°C (77°F).[2] Once reconstituted and diluted in 0.9% sodium chloride for IV use, ertapenem is stable at room temperature for 6 hours. If refrigerated, it can be stored for 24 hours and used within 4 hours after removal from the refrigerator. Do not freeze reconstituted solutions.

Compatibility/Compounding Considerations

For IV use, reconstitute vial contents with 10 mL of water for injection, bacteriostatic water for injection, or 0.9% sodium chloride injection. After shaking to dissolve the powder, immediately transfer to a 50 mL bag of 0.9% sodium chloride. Do not use diluents containing dextrose.

The manufacturer advises to avoid mixing ertapenem with other medications or using IV solutions containing dextrose. Ertapenem is **compatible** with lactated Ringer's solution. Ertapenem is **Y-site compatible** with some medications; please consult a hospital pharmacist or an appropriate pharmacy reference for further information about Y-site compatibility of ertapenem.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Ertapenem Sodium Lyophilized Powder for Injection: 1 g (as 1.045 g ertapenem) in single-dose vials; *Invanz*®, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Erythromycin

(er-ith-roe-***mye***-sin) *Gallimycin*®

Macrolide Antibiotic; Prokinetic

For ophthalmic use, refer to ***Erythromycin, Ophthalmic***

Prescriber Highlights

- ► Prokinetic agent; effect occurs at doses much lower than required for treating bacterial infections
- ► May be used in combination with rifampin for treatment of *Rhodococcus equi* infections in foals
- ► Contraindications include use in rabbits, gerbils, guinea pigs, and hamsters; oral use in ruminants and adult horses at antimicrobial doses; and animals with a hypersensitivity to erythromycin or related drugs (eg, azithromycin, clarithromycin).
- ► Adverse effects include GI distress (with oral administration), pain on IM injection, thrombophlebitis (with IV administration), and hyperthermia in foals. Erythromycin may cause neurologic signs in dogs with *MDR1* mutation (also known as *ABCB1-1delta*).
- ► Many documented drug interactions

Uses/Indications

Erythromycin may be used for treatment of susceptible infections and as a prokinetic agent to increase gastric emptying. In healthy cats, erythromycin and metoclopramide demonstrated similar shortening of gastric emptying time.[1] Erythromycin may also be beneficial in treating reflux esophagitis, especially in cats,[2] and colonic motility disorders in dogs[3] and horses.[4, 5]

Erythromycin in combination with rifampin is used to treat foals with *Rhodococcus equi* infections. Erythromycin estolate[6] and a microencapsulated base[7] appear to be the most efficacious form of the drug in foals due to better absorption and less frequent adverse effects. Other macrolides (ie, clarithromycin or azithromycin ± rifampin/rifampicin)[8, 9] are more commonly used because they are better tolerated, have more favorable pharmacokinetics (eg, bioavailability, tissue penetration, half-life). The combination of clarithromycin/rifampin appears to be more effective than erythromycin/rifampin or azithromycin/rifampin for treating *R equi* infections in foals.[8]

Erythromycin is uncommonly used systemically because of its narrow spectrum of activity, high risk for adverse effects in hindgut fermenters (eg, adult horses, rabbits, hamsters), and increasing resistance in target bacteria.

A previously available injectable erythromycin product was approved for treatment of infections caused by susceptible organisms in cats, dogs, and cattle; however, it is no longer commonly used for this purpose in these species.

The World Health Organization (WHO) has designated erythromycin as a Critically Important, Highest Priority antimicrobial for human medicine. The Office International des Epizooties (OIE) has designated macrolides as Veterinary Critically Important Antimicrobial (VCIA) Agents in veterinary species.[10]

Pharmacology/Actions

Erythromycin, a time-dependent antibiotic, is usually a bacteriostatic agent, but it may be bactericidal at high concentrations or against highly susceptible organisms (eg, streptococci). Macrolides (eg, erythromycin, tylosin) are believed to act by binding to the 50S ribosomal subunit of susceptible bacteria, thereby inhibiting peptide bond formation and protein synthesis.

Erythromycin has in vitro activity predominantly against gram-positive cocci (eg, staphylococci, streptococci), gram-positive bacilli (eg, *Bacillus anthracis, Corynebacterium* spp, *Clostridium* spp, [not *C difficile*], *Listeria* spp, *Erysipelothrix* spp), and some strains of gram-negative bacilli (eg, *Campylobacter* spp, *Haemophilus* spp, *Pasteurella* spp, *Bartonella* spp, *Brucella* spp). Some strains of *Actinomyces* spp, *Mycoplasma* spp, *Chlamydia* spp, *Ureaplasma* spp, and rickettsial organisms are also inhibited by erythromycin. Most strains of the Enterobacteriaceae family (eg, *Pseudomonas* spp, *Escherichia coli, Klebsiella* spp) are intrinsically resistant to erythromycin and acquired erythromycin resistance occurs frequently in methicillin-resistant staphylococci. Tolerance (ie, increasing minimum inhibitory concentrations [MICs]) by *Rhodococcus equi* to both erythromycin and rifampin is problematic, and resistance has been documented in some isolates. One study suggests biofilm formation as a cause of *R equi* erythromycin resistance.[11]

Like other macrolides, antimicrobial activity is reduced at lower pH, in abscesses, and in necrotic tissues.

At subantimicrobial doses, erythromycin mimics the effects of motilin (in cats, humans, and rabbits) and 5-hydroxytryptophan type 3 (5-HT_3) (in dogs) and can stimulate migrating motility complexes and antegrade peristalsis.[12] By inducing antral contractions, gastric emptying is enhanced. Erythromycin also increases lower esophageal sphincter pressure and could be useful in treating cats (and possibly dogs) with gastroesophageal reflux and reflux esophagitis. Erythromycin is reported to stimulate colonic activity in dogs and horses but not in cats. Erythromycin's prokinetic mechanism of action in dogs is not completely understood but is probably via activation of 5-HT_3 receptors. Erythromycin increases abomasal motility and emptying rate in calves and adult cattle.[13-15] Prokinetic activity may diminish with chronic use (tachyphylaxis). It has been suggested that combining erythromycin with metoclopramide could lessen this effect.[16]

Pharmacokinetics

Erythromycin is absorbed after oral administration in the upper small intestine. Several factors can influence the bioavailability of erythromycin, including salt form, dosage form, GI acidity, presence of food in the stomach, and gastric emptying time. Both the erythromycin base and stearate are susceptible to acid degradation; enteric coatings are often used to alleviate this. In most species, ethylsuccinate and estolate forms are dissociated in the upper small intestine and then absorbed, but a study in cats found that oral administration of erythromycin ethylsuccinate tablets or suspension did not result in measurable serum concentrations.[17] Fasting increases oral bioavailability in foals, and estolate[6] and a microencapsulated base[7] formulations appear to be better absorbed than other formulations.[7] After IM or SC injection of the polyethylene-based veterinary product in cattle, absorption was very slow. Bioavailability is ≈40% after SC injection and 65% after IM injection.

Erythromycin is distributed throughout the body into most fluids and tissues including the prostate, macrophages, and leukocytes. CSF concentrations are poor. In foals, erythromycin concentrations in bronchiolar lavage cells are equivalent to those found in the serum, but concentrations in pulmonary epithelial lining fluid are lower. Protein binding of erythromycin and the estolate salt are 73% to 81%, and 96%, respectively. The volume of distribution for erythromycin is reportedly 2 L/kg in dogs, 3.7 to 7.2 L/kg in foals, 2.3 L/kg in mares, 2.34 L/kg in cats, and 0.8 to 1.6 L/kg in cattle. In lactating dairy cattle, the milk:plasma ratio is 6:7.

Erythromycin is primarily excreted unchanged in the bile but is also partly metabolized by the liver via N-demethylation to inactive metabolites. Some of the drug is reabsorbed after biliary excretion. Only ≈2% to 5% of a dose is excreted unchanged in the urine.

The reported elimination half-life of erythromycin in various species is 60 to 90 minutes in dogs[18] and cats,[17] 60 to 70 minutes in foals and mares,[19, 20] and 190 minutes in cattle.[21]

Contraindications/Precautions/Warnings

Erythromycin is contraindicated in patients that are hypersensitive to it. In humans, erythromycin should be used with caution in patients with hepatic dysfunction or pre-existing liver disease; repeated courses or prolonged treatment with the estolate form have been rarely associated with the development of reversible cholestatic hepatitis. This effect has not been reported in veterinary species, but given the availability of other salt formulations, the estolate should probably be avoided in patients with pre-existing liver dysfunction. Erythromycin rarely causes prolongation of the QT interval and development of ventricular arrhythmias in humans, including atypical ventricular tachycardia (torsades de pointes). Caution is advised when using erythromycin in patients with pre-existing arrhythmias or in conjunction with other QT prolongation drugs. See ***Drug Interactions***.

Many clinicians consider erythromycin contraindicated in adult horses (see ***Adverse Effects***). Unless *Rhodococcus equi* is confirmed, erythromycin should be used with caution in horses older than 4 months of age.[22] In foals with *R equi* infections, prolonged monotherapy could potentially induce *R equi* resistance; treatment with concomitant rifampin is recommended. Because erythromycin is implicated in causing hyperthermia and fatal respiratory distress in foals treated during hot weather,[23, 24] provision of shade and close observation is advised, or an alternate macrolide should be used.

Oral erythromycin should not be used in ruminants, as severe diarrhea may result. Erythromycin and other macrolides are contraindicated in rabbits, gerbils, guinea pigs, and hamsters, as toxic enterocolitis may be induced.

Although erythromycin can be used to improve GI motility, the use of antimicrobial agents for noninfectious indications is discouraged.[25]

As a P-glycoprotein substrate, erythromycin should be used with caution in patients with confirmed *MDR1* gene mutation (also known as *ABCB1-1delta*).[26]

Adverse Effects

When erythromycin is injected IM, local reactions and pain at the injection site may occur. Oral erythromycin may cause GI disturbances (eg, diarrhea, anorexia, vomiting). IV injections must be given slowly (ie, over 20 to 60 minutes), as they may cause thrombophlebitis.[27]

Hyporexia; bruxism; and a mild, self-limiting diarrhea can occur in foals treated with erythromycin. These effects generally resolve after treatment is temporarily stopped. However, severe enterocolitis is possible. Erythromycin may induce anhidrosis, which alters temperature homeostasis in foals.[24] Foals 2 to 4 months of age have reportedly developed hyperthermia with associated respiratory distress and tachypnea.[23] Physically cooling off these animals has been successful in controlling this effect. Mares of treated foals can develop clostridial enterocolitis, presumably via ingestion of the foal's feces.[28]

Adult horses may develop severe, sometimes fatal, diarrhea, making use of erythromycin in adults controversial.

Erythromycin used as a prokinetic agent may increase clinical signs of intestinal distress because it can stimulate emptying of larger food particles into the intestine than is normal. Rectal edema and partial anal prolapse have been associated with erythromycin in swine.[29]

Reproductive/Nursing Safety

Erythromycin crosses the placenta, with fetal serum concentrations being 5% to 20% of maternal concentrations. Erythromycin fed to rats did not reveal evidence of impaired fertility.[30] Although erythromycin has not demonstrated teratogenic effects in rats, and the drug is not thought to possess serious teratogenic potential, it should only be used during pregnancy when the benefits outweigh the risks.

Erythromycin is excreted in milk in small amounts, with an observed milk:plasma ratio of 0.5 in humans; it is considered compatible with breastfeeding.

Overdose/Acute Toxicity

Except in the situations listed in ***Adverse effects***, erythromycin is relatively nontoxic; however, shock reactions have been reported in neonatal pigs receiving erythromycin overdoses.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving erythromycin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antiarrhythmic Agents** (eg, **amiodarone, procainamide, quinidine, sotalol**): Concurrent use may increase plasma concentration of antiarrhythmic agents and also enhance QT prolonging effect. In humans, cases of adverse cardiovascular events including cardiac arrest and arrythmias have been reported. Avoid combination.
- **Cisapride**: Erythromycin can inhibit the metabolism of cisapride, and the manufacturer states that use of these drugs together (in humans) is contraindicated; however, in one study in dogs, erythromycin did not alter the pharmacodynamics of cisapride.[31]
- **Clindamycin, Lincomycin**: In vitro evidence of antagonism
- **Colchicine**: Erythromycin may inhibit P-glycoprotein and increase the serum colchicine concentration.
- **Digoxin**: Erythromycin may inhibit P-glycoprotein and increase the serum digoxin concentration.
- **Loperamide**: Loperamide may reduce promotility effects of erythromycin. Erythromycin may inhibit P-gp, theoretically increasing the risk for loperamide toxicity in dogs homozygous for the *MDR1* genetic mutation (also known as *ABCB1-1delta*).
- **Sucralfate**: May reduce absorption of erythromycin; separate doses by 2 hours if possible

Erythromycin is a potent CYP3A4 inhibitor that can inhibit the metabolism of other drugs that use the CYP3A subfamily of the cytochrome P450 enzyme system. Depending on the therapeutic index of the drug(s) involved, therapeutic drug monitoring and/or dosage reduction may be required if the drugs must be used together. These drugs include:

- **Anticoagulants** (eg, **rivaroxaban, warfarin**)
- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): Possible increased erythromycin concentrations and increased risk for QT interval prolongation and cardiac arrhythmias
- **Benzodiazepines** (eg, **alprazolam, midazolam, triazolam**)
- **Bromocriptine**
- **Buspirone**
- **Calcium Channel Blockers** (eg, **amlodipine, diltiazem, verapamil**)
- **Cannabidiol**
- **Carbamazepine**
- **Cyclosporine**
- **Disopyramide**: Risk for increased QT interval
- **Doxorubicin**
- **Maropitant**
- **Methylprednisolone**
- **Opioids** (eg, **alfentanil, fentanyl, methadone, morphine**)
- **Quinidine**: Risk for prolonged QT interval
- **Sildenafil**: Erythromycin may increase the serum concentration of sildenafil. Consider therapy modification and monitor pulmonary arterial hypertension.
- **Tacrolimus, Systemic**
- **Theophylline/Aminophylline**
- **Vinca Alkaloids** (eg, **vinblastine, vincristine, vinorelbine**)

Laboratory Considerations

- Erythromycin may cause falsely elevated values of **AST** and **ALT** when using colorimetric assays.
- Fluorometric determinations of **urinary catecholamines** can be altered by concomitant erythromycin administration.

Dosages

NOTE: IV injections should be given slowly (ie, over 20-60 minutes). See ***Adverse Effects***.

DOGS:

Susceptible infections (extra-label): 10 – 20 mg/kg PO every 8 to 12 hours

Prokinetic agent (extra-label): 0.5 – 1 mg/kg PO, IV every 8 hours[32-34]

CATS:

Susceptible infections (extra-label): 10 – 20 mg/kg PO every 8 to 12 hours

Prokinetic agent (extra-label): 0.5 – 1 mg/kg PO or IV every 8 hours[32, 33] has been suggested; however, erythromycin does not appear to have colonic motility stimulating effects in cats.

HORSES:

***Rhodococcus equi* infections in foals** (extra-label): Most clinicians recommend using the estolate or enteric-coated (base) forms of erythromycin 20 – 25 mg/kg PO every 8 hours with rifampin 5 mg/kg PO every 12 hours or 10 mg/kg PO once daily (every 24 hours).[9] Treatment may be required for 1 to 3 months. Early diagnosis and treatment may reduce treatment duration.

Proliferative enteropathy caused by *Lawsonia intracellularis* infections in foals (extra-label): Erythromycin estolate 25 mg/kg PO every 6 to 8 hours with rifampin 10 mg/kg PO every 12 hours for a minimum of 21 days[35]

Regional limb perfusion (extra-label): 2000 mg administered via catheter inserted into cephalic or saphenous vein[36]

Prokinetic agent (extra-label):

a. 0.1 - 1 mg/kg diluted in saline and administered IV over 1 hour[37, 38]
b. 1 mg/kg IV every 6 to 8 hours[39]

CATTLE:

Bovine respiratory disease (ie, shipping fever complex, bacterial pneumonia) associated with *Pasteurella multocida* organisms susceptible to erythromycin in beef and dairy (not breeding age) cattle (label dosage; FDA-approved): 4 mL/100-lb body weight (4 mg/lb or 8.8 mg/kg) once daily for up to 5 days as needed. Administer via deep IM injection (no more than 10 mL per site) into the heavy neck muscles or, if necessary for alternating injection sites, into the heavy muscular portion of the hind legs (semitendinosus muscles). In calves weighing less than 90 kg (200 lb), no more than 4 mL/site deep IM injection into the heavy muscles of the hind legs only. Use a 1- to 2-inch, 16- or 18-gauge needle, depending on the animal's size. Do not use in female dairy cattle older than 20 months of age or in calves to be processed for veal.[40]

Prokinetic agent (extra-label):
Calves: 8.8 mg/kg IM or 20 mg/kg PO as a single dose[15, 41, 42]
Adults: 8.8 – 10 mg/kg IM once daily for up to 3 days[43]

BIRDS:

Susceptible infections (extra-label): Oral suspension, 60 mg/kg PO every 12 hours[44]

FERRETS:

Susceptible infections (extra-label): 10 mg/kg PO 4 times daily[45]

Monitoring

- Clinical efficacy
- Culture and susceptibility testing when used for antimicrobial indications
- Adverse effects
- Baseline and periodic hepatic enzymes (eg, ALT, AST, ALP) for patients receiving erythromycin estolate long-term

Client Information

- The intramuscular 100 mg/mL (*Erythro-100®*) product has specific instructions on where and how to inject the drug in cattle. Refer to the label directions or package insert for more information before using.
- When administering the medicine orally to small animal species, give it on an empty stomach. If gastrointestinal signs (eg, vomiting, lack of appetite, diarrhea) occur, then give medicine with food. Administer the medicine to foals prior to offering hay.
- If gastrointestinal side effects are severe or persist, contact your veterinarian.

Chemistry/Synonyms

Erythromycin, a macrolide antibiotic produced from *Streptomyces erythreus*, is a weak base that is available commercially in several salts and esters and has a pK_a of 8.9. Erythromycin base occurs as a bitter-tasting, odorless or practically odorless, white to slight yellow, crystalline powder. Approximately 1 mg is soluble in 1 mL of water; it is soluble in alcohol.

Erythromycin estolate occurs as a practically tasteless and odorless, white, crystalline powder. It is practically insoluble in water and ≈50 mg is soluble in 1 mL of alcohol. Erythromycin estolate may also be known as erythromycin propionate lauryl sulfate.

Erythromycin ethylsuccinate occurs as a practically tasteless and odorless, white to slight yellow, crystalline powder. It is very slightly soluble in water and freely soluble in alcohol.

Erythromycin lactobionate occurs as white to slightly yellow crystals or powder. It may have a faint odor and is freely soluble in water and alcohol.

Erythromycin may also be known as eritromicina and erythromycinum; many trade names are available.

Storage/Stability

Erythromycin (base) capsules and tablets should be stored in airtight containers at room temperature of 15°C to 30°C (59°F-86°F). Erythromycin estolate preparations should be protected from light. To retain palatability, the oral suspensions should be refrigerated.

Erythromycin ethylsuccinate tablets and powder for oral suspension should be stored in airtight containers at room temperature. The commercially available oral suspension should be stored in the refrigerator to preserve palatability. After dispensing, the oral suspensions are stable for at least 14 days at room temperature, but individual products may have longer labeled stabilities.

Erythromycin lactobionate powder for injection should be stored at room temperature. For initial reconstitution (vials), use only sterile water for injection. After reconstitution, the drug is stable for 24 hours at room temperature and for 2 weeks if refrigerated. To prepare for administration via continuous or intermittent infusion, the drug is further diluted in 0.9% sodium chloride, lactated Ringer's solution, or *Normosol®-R*. Other infusion solutions may be used but first must be buffered with 4% sodium bicarbonate injection (1 mL per 100 mL of solution). At a pH of less than 5.5, the drug is unstable and loses potency rapidly.

Compatibility/Compounding Considerations

Many drugs are physically **incompatible** with erythromycin lactobionate. Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Although many products continue to be listed in the FDA Green Book, there are currently no approved veterinary products available.

HUMAN-LABELED PRODUCTS:

Erythromycin Base Delayed-release Oral Tablets enteric-coated: 250 mg, 333 mg, and 500 mg; *Ery-Tab®*; (Rx)

Erythromycin Base Tablets Film-coated: 250 mg and 500 mg; generic; (Rx)

Erythromycin Base Delayed-release Oral Capsules enteric-coated pellets: 250 mg; *ERYC®*, generic; (Rx)

Erythromycin Stearate Film-coated Tablets: 250 mg; generic; (Rx)

Erythromycin Ethylsuccinate Tablets: 400 mg; *E.E.S. 400®*, generic; (Rx)

Erythromycin Ethylsuccinate Powder for Oral Suspension: 200 mg/5 mL (40 mg/mL) when reconstituted 100 mL and 200 mL; *EryPed®* 200 and 400, *E.E.S. Granules®*; (Rx)

Erythromycin Ethylsuccinate Powder for Oral Suspension: 400 mg/5 mL (80 mg/mL) in 100 mL; *EryPed* ®; (Rx)

Erythromycin Lactobionate Lyophilized Powder for Injection Solution: 500 mg (as lactobionate) vial; *Eythrocin*®; (Rx)

Erythromycin and Sulfisoxazole Granules for Oral Suspension: erythromycin ethylsuccinate (equivalent to 200 mg erythromycin activity) and sulfisoxazole acetyl (equivalent to sulfisoxazole 600 mg/5 mL [120 mg/mL] when reconstituted in 100 mL, 150 mL, and 200 mL); *Eryzole*®, *Pediazole*®, generic; (Rx)

Topical and ophthalmic preparations are also available.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Esmolol

(***ess***-moe-lol) *Brevibloc*®

Beta-1-Adrenergic Blocker

Prescriber Highlights

- ► Ultra-short-acting beta-1 blocker used IV for short-term treatment of supraventricular tachycardias or to determine if beta-blockers are effective for controlling arrhythmias
- ► Beta-blocker of choice for use under general anesthesia
- ► Contraindications include patients with overt cardiac failure, second- or third-degree AV block, sinus bradycardia, or cardiogenic shock.
- ► Use caution in patients with congestive heart failure (CHF), bronchoconstriction, or diabetes mellitus.
- ► Adverse effects: hypotension and bradycardia are most common
- ► Many possible drug interactions

Uses/Indications

Esmolol may be used as a test drug to indicate whether beta-blocker therapy is warranted, as an antiarrhythmic agent (particularly in cats with hypertrophic cardiomyopathy), or as an infusion in the short-term treatment of supraventricular tachyarrhythmias (eg, atrial fibrillation/flutter, sinus tachycardia). Esmolol may also be used to manage hyperdynamic right ventricular outflow tract obstruction following balloon valvuloplasty in dogs with pulmonary valve stenosis.[1]

Pharmacology/Actions

Esmolol is classified as a class II antiarrhythmic drug. It primarily blocks beta-1-adrenergic receptors in the myocardium. At clinically used doses, esmolol does not have any intrinsic sympathomimetic activity (ISA) and, unlike propranolol, does not possess membrane-stabilizing effects (quinidine-like) or bronchoconstriction. Cardiovascular effects secondary to esmolol include negative inotropic and chronotropic activity that can lead to reduced myocardial oxygen demand. Systolic and diastolic blood pressures are reduced at rest and during exercise.[2] The antiarrhythmic effect is thought to be due to its blockade of adrenergic stimulation of the cardiac pacemaker potential. Esmolol increases sinus cycle length, slows AV node conduction, and prolongs sinus node recovery time.[3]

Esmolol is considered the beta-blocker of choice in animals under general anesthesia that might develop hypertension and supraventricular tachycardia due to inappropriate sympathetic activity.

Pharmacokinetics

After IV injection, esmolol is rapidly and widely distributed but not appreciably to the CNS, spleen, and testes.[4] The distribution half-life is ≈2 minutes. Steady-state blood concentrations occur in ≈5 minutes if a loading dose is given or ≈30 minutes without it. Esmolol is rapidly metabolized in the blood by esterases to a practically inactive metabolite. Renal or hepatic dysfunction does not appreciably alter elimination characteristics. Terminal half-life is ≈10 minutes and duration of action after discontinuing IV infusion is usually ≈20 minutes postinfusion in dogs.

Contraindications/Precautions/Warnings

Esmolol is contraindicated in patients with overt cardiac failure, second- or third-degree AV block, sinus bradycardia, or in cardiogenic shock. It should be used with caution (weigh benefit vs risk) in patients with CHF, bronchoconstriction, or diabetes mellitus.

In humans with tachycardia secondary to pheochromocytoma, it is recommended that esmolol be given in combination with (or after) an alpha-blocker, or a paradoxical increase in blood pressure can occur secondary to attenuation of beta-mediated vasodilation in skeletal muscle.[5]

Adverse Effects

At usual dosages, adverse effects are uncommon and generally an extension of the pharmacologic effects. Hypotension (with resultant clinical signs) and bradycardia are the most likely adverse effects seen. These usually prove to be mild and transient in nature. Esmolol may mask certain clinical signs of developing hypoglycemia (such as increased heart rate or blood pressure).

Reproductive/Nursing Safety

It is unknown whether esmolol crosses the placenta. Studies done in rats and rabbits demonstrated no teratogenic effects at doses up to 3 times the maximum human maintenance dose (MHMD). Higher doses (8 times or more than the MHMD) demonstrated some maternal death and fetal resorption.

It is unknown if esmolol is excreted in milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The IV LD_{50} in dogs is ≈32 mg/kg. Dogs receiving 2 mg/kg/minute for 1 hour showed no adverse effects; doses of 3 mg/kg/minute for 1 hour produced ataxia and salivation; and 4 mg/kg/minute for 1 hour caused muscular rigidity, tremors, seizures, ptosis, vomiting, hyperpnea, vocalizations, and prostration. These effects all resolved within 90 minutes of the end of infusion. Because of the short duration of action of the drug, discontinuation or dosage reduction may be all that is required; otherwise, clinical and supportive treatment may be initiated.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving esmolol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetylcholinesterase Inhibitors** (eg, **physostigmine**): Concurrent use may increase risk for severe bradycardia.
- **Alpha-2 Agonists** (eg, **dexmedetomidine**): Concurrent use may increase risk for AV block.
- **Amiodarone**: Concurrent use may result in bradycardia, hypotension, sinus arrest, and AV block.
- **Anesthetic Agents, General**: Additive myocardial depression may occur with the concurrent use of propranolol and myo-

cardial depressant anesthetic agents.

- **Anticholinergics** (eg, **atropine**): May negate bradycardic effects of beta-blockers
- **Beta-2-Adrenergic Agonists** (eg, **albuterol, terbutaline**): At higher doses, atenolol may impair bronchodilation.
- **Calcium Channel Blockers** (eg, **diltiazem, verapamil**): Myocardial depressant effects of both classes of agents may be potentiated. IV administration in close proximity is contraindicated. Monitor cardiac function and adjust therapy as needed. Generally, drugs such as diltiazem can be safely administered 30 minutes after esmolol administration has been discontinued.
- **Digoxin**: Esmolol may increase serum digoxin levels up to 20%; concurrent use increases the risk for bradycardia.
- **Hypotensive Agents** (eg, **amlodipine**, **enalapril**, **telmisartan**): Concurrent use may result in increased risk for hypotension.
- **Monoamine Oxidase Inhibitors (MAOIs)**: Concurrent use of MAOIs with esmolol is not recommended due to potential risk for hypertension.
- **Morphine**: Titrate esmolol dosage carefully in patients also receiving morphine, as it may increase steady-state esmolol serum concentrations up to 50%.
- **Phenothiazines** (eg, **acepromazine**, **chlorpromazine**): May increase risk for hypotension
- **Reserpine**: May see additive effects (eg, hypotension, bradycardia) if used with esmolol
- **Theophylline, Aminophylline**: Esmolol may cause severe bronchospasm and reduce the therapeutic effects of theophylline.
- **Vasoconstrictors and Inotropes** (eg, **dopamine**, **epinephrine**, **norepinephrine**): If systemic vascular resistance is high, there is an increased risk for blocked cardiac contractility; esmolol is not recommended to control supraventricular tachycardias in patients receiving these drugs.

Laboratory Considerations

- None noted

Dosages

DOGS/CATS:

Ultra-short-acting beta-blocker (for treating or assisting in treatment of ventricular arrhythmias) (extra-label): Dosage recommendations vary somewhat and there does not appear to be clear evidence supporting any dosage. Often an initial IV loading dose of 0.25 – 0.5 mg/kg (250 – 500 µg/kg) is administered IV over 2 to 5 minutes and then a CRI of 10 – 200 µg/kg/minute IV is started.[6–9] Some clinicians recommend initial dosages as low as 0.05 – 0.1 mg/kg (50 – 100 µg/kg) with intermittent IV bolus doses of 0.05 – 0.1 mg/kg (50 – 100 µg/kg) administered every 5 minutes up to a maximum dose of 0.5 mg/kg (500 µg/kg). If esmolol is to be used in animals with severe heart failure or mitral regurgitation, it is best dosed without an initial bolus and at the lower end of the CRI rates. CRI can be adjusted upwards every 10 minutes while the patient is continuously monitored.

Monitoring

- Blood pressure
- ECG
- Heart rate

Client Information

- Esmolol should only be used in an inpatient setting where appropriate monitoring is available.

Chemistry/Synonyms

A short-acting beta-1-adrenergic blocker, esmolol occurs as a white or off-white crystalline powder. It is not as lipophilic as either labetalol or propranolol but is comparable to acebutolol. 650 mg is soluble in 1 mL of water, and 350 mg is soluble in 1 mL of alcohol.

Esmolol HCl may also be known as ASL-8052, *Brevibloc®*, or *Miniblock®*.

Storage/Stability

The concentrate for injection should be stored at room temperature 25˚C (77˚F), with excursions permitted to 15˚C to 30˚C (59˚F-86˚F). Do not freeze; protect this product from excessive heat. It is a clear, colorless to light yellow solution.

After dilution to a concentration of 10 mg/mL, esmolol HCl is stable (at refrigeration temperatures or room temperature) for at least 24 hours in commonly used IV solutions.

Compatibility/Compounding Considerations

Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Esmolol may be diluted in standard 5% dextrose, lactated Ringer's solution, or saline (or combinations thereof) IV fluids. At 10 mg/mL, esmolol is reportedly physically **compatible** with digoxin, dopamine, fentanyl, lidocaine, morphine sulfate, nitroglycerin, and nitroprusside.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Esmolol HCl Injection: 10 mg/mL regular and preservative free in 10 mL vials; 20 mg/mL preservative free in 100 mL bags; *Brevibloc®*; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Esomeprazole

(ess-oh-***meh***-prah-zahl) *NexIUM®*

Proton Pump Inhibitor

Prescriber Highlights

- ► Used for GI ulcers and erosions; limited information on its use in veterinary species
- ► Available in oral capsules and suspensions as well as IV forms
- ► Oral doses should be given on an empty stomach (preferably 1 hour before food).
- ► Adverse effects: Small animal species: Likely to be well tolerated; potentially GI distress (eg, anorexia, colic, nausea, vomiting, flatulence, diarrhea), hematologic abnormalities, UTIs, proteinuria, or CNS disturbances. Horses: Unlikely; potential hypersensitivity

Uses/Indications

Esomeprazole, the S-enantiomer of omeprazole, is a proton pump inhibitor (PPI) that is potentially useful in treating both gastroduodenal ulcer disease and to prevent and treat gastric erosions caused by ulcerogenic drugs (eg, aspirin).

A study to determine whether preanesthetic IV administration of esomeprazole alone or esomeprazole with cisapride increased esophageal pH and decreased frequency of GI reflux (GER) in anesthetized dogs found that although esomeprazole alone increased gastric and esophageal pH, it did not alter the incidence of GER as compared with the control group.[1] In the study, gastric and esopha-

geal pH was measured in anesthetized dogs at 12 to 18 hours before induction and again 1 to 1.5 hours before induction. The combination of esomeprazole and cisapride significantly increased pH and reduced reflux events.[1] Esomeprazole also increased intragastric pH after SC and PO administration in dogs.[2] In a study evaluating the efficacy of three acid-suppressing medications over 72 hours of treatment in 9 healthy beagles (esomeprazole 1 mg/kg IV every 12 hours; pantoprazole 1 mg/kg IV every 12 hours; famotidine loading dose of 1 mg/kg IV followed by 8 mg/kg IV CRI), significant increases in mean intragastric pH were noted over time for all 3 treatments; however, only esomeprazole and famotidine CRI achieved the goals for treatment of gastroduodenal ulcers in humans.[3] The conclusions were that the famotidine CRI and IV esomeprazole might be superior acid suppressants compared with standard doses of pantoprazole for the first 72 hours of treatment.

In a study evaluating the efficacy of 3 oral acid-suppressing medications in 12 healthy cats (esomeprazole 1 mg/kg every 12 hours; lansoprazole 1 mg/kg every 12 hours; dexlansoprazole 6 mg/kg every 12 hours), only esomeprazole achieved the established goals for treatment of gastroduodenal ulcers in humans.[4] Orally administered esomeprazole may be a superior acid-suppressant in cats compared with PO lansoprazole or PO dexlansoprazole.

Two studies in horses (PO/NGT and IV) found that esomeprazole caused significant increases in gastric pH.[5,6] It has been shown that both dosage (0.5 mg/kg/day vs 2 mg/kg/day) and diet (high grain with low fiber vs ad libitum hay) had an inconsistent effect on gastric pH in horses.[7] A study evaluating oral enteric-coated esomeprazole paste (0.5 mg/kg once daily) with oral enteric omeprazole paste (1 mg/kg once daily) in 9 adult standardbred horses found both treatments were equally effective in increasing gastric pH, with no difference in mean pH between treatments, and that enteric-coated esomeprazole may be a therapeutic alternative to omeprazole for prevention of gastric ulcers in horses.[8]

An advantage of esomeprazole is the large variety of dosage forms (eg, oral capsules, oral suspensions, IV) and strengths that are commercially available.

Pharmacology/Actions

Esomeprazole is a substituted benzimidazole proton pump inhibitor (PPI). It binds irreversibly at the secretory surface of parietal cells to the enzyme H^+/K^+ ATPase, where it inhibits hydrogen ion transport into the stomach. Esomeprazole reduces acid secretion during both basal and stimulated conditions. There is a lag time between administration and efficacy in most species, but it appears that in both dogs and horses, effects can be rapid. Esomeprazole may also inhibit some hepatic cytochrome P450 oxidase system isoenzymes (see ***Drug Interactions*** below).

Pharmacokinetics

In dogs, after administration of 1 mg/kg IV, terminal elimination half-life, systemic plasma clearance, and steady state volume of distribution were 0.73 hours, 0.3 L/hour/mL, and 0.27 L/kg, respectively. When the same dose was administered SC and PO, time until maximum concentration, peak plasma concentration, terminal elimination half-life, and bioavailability were 0.38 hours (SC) and 1.81 hours (PO), 2.62 µg/mL (SC) and 1.34 µg/mL (PO), 0.9 hours (SC) and 0.98 hours (PO), and 106% (SC) and 71.4% (PO), respectively.[2]

In humans, oral esomeprazole is well absorbed when taken on an empty stomach, but the presence of food can reduce bioavailability from ≈90% to ≈50%. Peak concentrations occur ≈1.5 hours after dosing. Esomeprazole is 97% bound to human plasma proteins and in healthy human adults, the apparent volume of distribution at steady state is ≈16 L. Esomeprazole is predominantly metabolized in the liver by the cytochrome P450 (CYP-450) enzyme system with the isoenzyme CYP2C19 forming the majority of metabolites (hydroxy and desmethyl forms) and, to a lesser extent, the CYP3A4 isoenzyme forming the sulphone metabolite. Plasma elimination half-life of esomeprazole in humans is ≈1 to 1.5 hours. Less than 1% of the parent drug is excreted in the urine unchanged with ≈80% of the dose excreted into the urine as metabolites. The remainder is excreted in the feces as unabsorbed drug or its metabolites.

Contraindications/Precautions/Warnings

Esomeprazole is contraindicated in patients that are hypersensitive to it. In patients with severe hepatic disease, the drug's half-life may be prolonged and dosage adjustment may be necessary. In humans, hypomagnesemia is rarely reported with prolonged treatment. Cutaneous lupus erythematosus and systemic lupus erythematosus have also been reported in patients taking proton pump inhibitors (PPIs) and have occurred both as new onset and as an exacerbation of existing autoimmune disease.[9]

Do not confuse ESOmeprazole with omeprazole or other similar-sounding PPIs.

Adverse Effects

There is little clinical experience or published data on the safety of esomeprazole in animal patients, but it is likely to be well tolerated, similar to other proton pump inhibitors (PPIs). Vomiting has been observed after oral and parenteral administration. Potentially, other GI signs (eg, anorexia, colic, nausea, flatulence, diarrhea, *Clostridium difficile* infection) could occur, as well as hematologic abnormalities (rare in humans), UTI, proteinuria, increased liver enzymes, or CNS disturbances.[10]

Reproductive/Nursing Safety

Esomeprazole did not demonstrate teratogenicity in laboratory animals.[10] Reduced body weight, neurodevelopmental delays, and embryolethality were observed in rats receiving doses 17 to 34 times the human dose.

It is not known whether esomeprazole is excreted in maternal milk. For humans, because of the potential for serious adverse effects in nursing infants, and the potential for tumorigenicity shown in rat carcinogenicity studies, nursing is discouraged if the drug is required.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Little information is available on acute toxicity. The LD_{50} of esomeprazole in rats after oral administration is reportedly more than 4 g/kg. Humans have tolerated oral dosages of 360 mg/day of esomeprazole without significant toxicity. If a massive overdose occurs, treat symptomatically and supportively.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving esomeprazole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Azole Antifungals** (eg, **itraconazole, ketoconazole**): Esomeprazole can reduce absorption, and azoles can potentially increase esomeprazole exposure.
- **Benzodiazepines** (eg, **diazepam**): Esomeprazole may potentially alter benzodiazepine metabolism and prolong CNS effects.

- **Cefpodoxime, Cefuroxime**: Esomeprazole may decrease cefpodoxime or cefuroxime absorption; consider use of an alternative antibiotic.
- **Clarithromycin**: Increased concentrations of esomeprazole, clarithromycin, and 14-hydroxyclarithromycin are possible.
- **Clopidogrel**: In humans, concurrent use of omeprazole and esomeprazole (but not other proton pump inhibitors [PPIs]) may decrease the efficacy of clopidogrel and increase the risk for thrombosis[10]; however, a study in dogs found omeprazole combined with clopidogrel did not alter antiplatelet effects in healthy dogs.[11]
- **Cyanocobalamin** (oral form): Esomeprazole may decrease oral absorption.
- **Cyclosporine**: Esomeprazole may reduce cyclosporine metabolism.
- **Digoxin**: Esomeprazole may increase digoxin concentrations.
- **Diuretics (loop** or **thiazides)**: Increased risk for hypomagnesemia; increased monitoring suggested, particularly in susceptible patients
- **Iron, Oral**: Esomeprazole may decrease iron absorption.
- **Levothyroxine**: May result in increased TSH concentrations
- **Methotrexate**: Esomeprazole may increase and prolong methotrexate (and its metabolite) concentrations.
- **Mycophenolate**: Esomeprazole may reduce mycophenolic acid (MPA; active metabolite) concentrations.
- **Propranolol**: May result in increased propranolol exposure
- **Sucralfate**: May inhibit absorption of esomeprazole; stagger doses
- **Tacrolimus**: May result in increased tacrolimus exposure
- **Warfarin**: Esomeprazole may increase anticoagulant effect.

Laboratory Considerations

- Esomeprazole will increase **serum gastrin** concentration early in therapy, potentially interfering with secretin stimulation test.[10]

Dosages

DOGS:

Reduce gastric acid production (extra-label):

a) 0.5 – 1 mg/kg IV slowly over 3 minutes every 12 hours[3,12]
b) 1 mg/kg PO once daily on an empty stomach[2]

Reduce gastroesophageal reflux events during anesthesia (extra-label): 1 mg/kg IV over 3 minutes in combination with cisapride 1 mg/kg IV administered 1 to 1.5 hours prior to induction[1]

CATS:

Reduce gastric acid production (extra-label): 1 mg/kg PO every 12 hours[4]

HORSES:

Reduce gastric acid production (extra-label):

a) 40 – 80 mg/horse (NOT mg/kg) PO once daily[5]
b) 0.5 – 2 mg/kg PO once daily[7]
c) 0.5 mg/kg IV once daily[6]

Monitoring

- Efficacy
- Adverse effects (eg, GI distress)

Client Information

- This medicine is best given on an empty stomach, preferably in the morning 1 hour before feeding.
- Do not crush capsules unless instructed to. Capsules may be opened, and the contents mixed with applesauce or similar foods. Be sure to give the medicine to your animal immediately after preparing.
- If you have difficulty getting your animal to take the medicine, contact your veterinarian or pharmacist for tips to help with dosing and reduce the stress of medication time for both you and your animal.

Chemistry/Synonyms

A substituted benzimidazole proton pump inhibitor, esomeprazole is the S-isomer of omeprazole and is available commercially as 2 primary salts: magnesium (PO use) and sodium (IV use). Esomeprazole magnesium (CAS Registry: 217087-09-7; ATC: A02BC05) occurs as a white to slightly colored powder. It is slightly soluble in water, soluble in methyl alcohol, and practically insoluble in heptane. Esomeprazole sodium (CAS Registry: 161796-78-7; ATC: A02BC05) commercially available injection is a lyophilized powder with edetate disodium 1.5 mg and sodium hydroxide added to adjust pH (9 to 11) during manufacturing.

NexIUM® 20 and 40 mg capsules contain sugar spheres. *NexIUM*® 2.5, 5, 10, 20, and 40 mg powder for oral suspension also contains dextrose.

Esomeprazole may also be known as *(S)*-omeprazole, H199/18I, or perprazole. A common trade name is *NexIUM*®.

Storage/Stability

Oral capsules should be stored in tightly closed containers at 25°C (77°F) and may be exposed to 15°C-30°C (59°F-86°F) in tightly closed containers.

Intact vials of esomeprazole sodium for injection should be stored at controlled room temperature and protected from light. After reconstitution and dilution with 0.9% sodium chloride, it should be administered within 12 hours when stored at room temperature. The manufacturer states that refrigeration is not required. Stability of esomeprazole sodium in solution is strongly dependent on pH; stability of the drug decreases with decreasing pH.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Esomeprazole sodium for injection should be reconstituted only with sterile 0.9% sodium chloride when being administered as an IV injection over 3 minutes, although lactated Ringer's injection, or dextrose 5% may be used when administering as an IV infusion over 10 to 30 minutes (see ***Storage/Stability*** above). Flushing the administration line with sodium chloride 0.9%, Ringer's injection, lactated Ringer's, or dextrose 5% is required both before and after administering the drug. Mixing or giving with other drugs is not recommended.

If mixing capsule contents with food, only cold or room temperature applesauce is recommended, and administration should occur immediately after mixing.

Use of the esomeprazole delayed-release oral suspension packets: Empty the contents of a 2.5 mg or 5 mg packet into a container with 5 mL of water; empty the contents of a 10 mg, 20 mg, or 40 mg packet into a container with 15 mL of water. Stir, then leave for 2 to 3 minutes to thicken. Stir and drink within 30 minutes. If any material remains after drinking, add more water, stir, and drink immediately. In cases where there is a need to use 2 packets, they may be mixed in a similar way by adding twice the required amount of water or follow the mixing instructions provided.

Nasogastric/gastric tube administration: Add 5 mL of water to a catheter-tipped syringe and then add the contents of a 2.5 mg or 5 mg packet; for the 10 mg, 20 mg, or 40 mg packet, the volume of water in the syringe should be 15 mL. It is important to only use a catheter-tipped syringe when administering esomeprazole through a nasogastric or gastric tube. Immediately shake the syringe and leave

for 2 to 3 minutes to thicken. Shake the syringe and inject through the nasogastric or gastric tube (French size 6 or larger) into the stomach within 30 minutes. Refill the syringe with an equal amount of water (5 or 15 mL). Shake and flush any remaining contents from the nasogastric or gastric tube into the stomach.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Esomeprazole Magnesium Oral Delayed-Release Capsules (containing enteric-coated granules): 20 mg and 40 mg; *NexIUM*®; generic; (Rx)

Esomeprazole Magnesium Oral Delayed-Release Tablets: 20 mg; *NexIUM*® *24HR*; generic; (OTC)

Esomeprazole Magnesium Powder for Oral Delayed-Release Suspension (containing enteric-coated granules): 2.5 mg, 5 mg, 10 mg, 20 mg, and 40 mg packets. *NexIUM*®; (Rx)

Esomeprazole Strontium Oral Delayed-Release Capsules: 24.65 mg and 49.3 mg; generic; (Rx)

Esomeprazole Sodium for Injection: 20 mg and 40 mg; *NexIUM I.V.*®; generic; (Rx)

There is also an oral product combined with naproxen, but it is not appropriate for veterinary use.

Estradiol

(ess-tra-***dye***-ole) *ECP*®

Hormonal Agent (Estrogen)

Prescriber Highlights

- ► Natural estrogen salt used primarily to induce estrus; has been used as an abortifacient (rarely recommended today)
- ► Contraindicated during pregnancy; do not use in ferrets because of the risk for myelosuppression.
- ► Adverse effects in cats and dogs include myelotoxicity, cystic endometrial hyperplasia, pyometra, feminization in males, and signs of estrus in females.
- ► Feminization may occur in male animals; in female animals, signs of estrus may occur.
- ► Use of estradiol in food animals is prohibited by the FDA.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies estrogens as group II hazardous drugs; use appropriate precautions when handling.

Uses/Indications

Estradiol is used to enhance estrus behavior and receptivity in noncycling or ovariectomized mares and to hasten the onset of ovulation in transitional mares. It is also used in mares to synchronize estrus (when used in combination with progesterone), to induce lactation (when used in combination with domperidone), and to treat placentitis[1] and estrogen-responsive urinary incontinence.[2]

Historically, estradiol has been used to treat estrogen-responsive urinary incontinence in dogs, but safer estrogens (eg, diethylstilbestrol [DES], estriol) are now preferred; its use as an abortifacient in small animal species is no longer recommended.

Estradiol has previously been used as an abortifacient agent in cattle; however, the manufacturing and compounding of estradiol for use in food-producing animals is now prohibited by the FDA.

Pharmacology/Actions

Estradiol is the most active endogenous estrogen. Estrogens are necessary for the normal growth and development of female sex organs and, in some species, contribute to the development and maintenance of secondary female sex characteristics. Estrogens cause increased cell height and secretions of the cervical mucosa, thickening of the vaginal mucosa, endometrial proliferation, and increased uterine tone.

Estrogens also have effects on the skeletal system; they increase calcium deposition, accelerate epiphyseal closure, and increase bone formation. Estrogens have a slight anabolic effect and can increase sodium and water retention. Estrogens affect the release of gonadotropins from the pituitary gland, which can cause inhibition of lactation, ovulation, and androgen secretion.

Pharmacokinetics

No specific information was located regarding the pharmacokinetics of estradiol in veterinary species. In humans, estrogen in oil solutions after IM administration is absorbed promptly and absorption continues over several days. Esterified estrogens (eg, estradiol) have delayed absorption after IM administration. Estrogens are distributed throughout the body and accumulate in adipose tissue. Elimination of steroidal estrogens occurs principally by hepatic metabolism. Estrogens and their metabolites are primarily excreted in the urine, but they are also excreted into bile and undergo enterohepatic recirculation.

Contraindications/Precautions/Warnings

Estradiol is contraindicated in patients hypersensitive to the drug formulation and during pregnancy, as it can cause fetal malformations of the genitourinary system and induce bone marrow depression in the fetus. In humans, the drug is contraindicated in patients with abnormal genital bleeding of unknown etiology, breast cancer or estrogen-dependent neoplasia, hepatic dysfunction or disease, or with a history of arterial or deep vein thrombosis or pulmonary embolism. Use with caution in patients with diabetes mellitus or hypoparathyroidism.

Estradiol should not be used to treat estrogen-responsive incontinence in small animals; other estrogens (eg, diethylstilbestrol [DES], estriol) are less toxic.

When estradiol is used for treatment of a prolonged corpus luteum, a thorough uterine examination should be completed to determine if endometritis or a fetus is present.

In ferrets, estradiol is reportedly extremely toxic to bone marrow; therefore, estradiol should be avoided in this species.

The National Institute for Occupational Safety and Health (NIOSH) classifies estrogens as hazardous drugs representing an occupational hazard to healthcare workers; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[3]

Do not confuse estriol with estrADiol.

Adverse Effects

Estrogens have been associated with severe adverse effects in small animals. In cats and dogs, estrogens are considered toxic to the bone marrow and can cause blood dyscrasias. Blood dyscrasias are more prevalent in older animals and when higher dosages are used. Initially, a thrombocytosis and/or leukocytosis may be noted, but thrombocytopenia and leukopenia will gradually develop. Changes in a peripheral blood smear may be apparent within 2 weeks after estrogen administration. Chronic estrogen toxicity is characterized by a normochromic, normocytic anemia; thrombocytopenia; and neutropenia. Myelosuppression may be transient and begin to resolve within 30 to 40 days after discontinuation, or it may persist and progress to a fatal aplastic anemia.

Estrogens may cause cystic endometrial hyperplasia and pyometra.[4-6] After therapy is initiated, an open-cervix pyometra may be noted 1 to 6 weeks after therapy.

Estrogens have been shown to induce mammary neoplasia.[7, 8]

When estradiol is used chronically in male animals, feminization may occur. In females, signs of estrus may occur and persist for 7 to 10 days. In cattle, prolonged estrus, genital irritation, decreased milk flow, precocious development, and follicular cysts may develop after estrogen therapy. These effects may be secondary to overdose; dosage adjustment may reduce or eliminate them.

Reproductive/Nursing Safety

Estradiol is contraindicated during pregnancy. Estrogens are present in breast milk and have been shown to decrease the quantity and quality of maternal milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Dogs exposed to estrogens at excessive doses may develop myelotoxicity characterized by normocytic, normochromic anemia; thrombocytopenia; and leukocytosis. Common clinical signs associated with overdose include inappetence, pallor, exercise intolerance, vulvar edema, vaginal bleeding, respiratory distress, hematuria, melena, fever, epistaxis, and petechiation of the skin or mucous membranes.[9] Treatment is supportive including cessation of estrogen therapies, correction of anemia and thrombocytopenia, and administration of antibiotics if the patient is severely leukopenic.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving estradiol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticoagulants** (eg, **heparins, rivaroxaban, warfarin**): Concurrent use may diminish anticoagulant effect.
- **Ascorbic Acid**: Ascorbic acid may increase estrogen concentration.
- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): May increase estrogen concentration
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Enhanced glucocorticoid effects may result if estrogens are used concomitantly with corticosteroid agents. It has been postulated that estrogens may either alter the protein binding of corticosteroids and/or decrease their metabolism; corticosteroid dosage adjustment may be necessary when estrogen therapy is either started or discontinued.
- **Cyclosporine**: Estrogens may increase cyclosporine serum cyclosporine concentration.
- **Estrogens, Other** (eg, **diethylstilbestrol [DES]**): Possible additive effects. Do not use with other estrogens; concomitant use with other estrogens has not been evaluated.
- **Hypoglycemic Agents** (eg, **glipizide, insulin, metformin**): Estrogens may increase blood glucose concentration.
- **Levothyroxine**: Estrogens may diminish the therapeutic effect of levothyroxine, and an increase in levothyroxine dose may be needed. Monitor thyroid status when using these drugs in combination and adjust levothyroxine dose accordingly. See ***Monitoring*** in ***Levothyroxine***.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May increase estrogen concentration
- **Mitotane**: May decrease estrogen concentration if administered concomitantly
- **Phenobarbital**: May decrease estrogen concentration if administered concomitantly
- **Rifampin**: May decrease estrogen concentration if administered concomitantly
- **St. John's Wort**: May decrease estrogen concentration if administered concomitantly
- **Theophylline, Aminophylline**: Estrogens may increase theophylline concentration.
- **Thyroid Hormones**: Possible alteration of thyroxine and thyrotropin serum concentrations
- **Ursodiol**: Estrogens may diminish ursodiol efficacy.

Laboratory Considerations

- Estrogens have been demonstrated to increase **thyroxine-binding globulin** (**TBG**) in humans, with resultant increases in total circulating thyroid hormone. Decreased T_3 resin uptake also occurs, but **free T_4** concentration is unaltered. It is unclear if estradiol affects these laboratory tests in veterinary patients.
- Estrogens may decrease the diagnostic effect of **cosyntropin**[10] and **metyrapone**.[11]

Dosages

HORSES:

NOTE: All dosages are for estradiol cypionate (ECP) unless otherwise noted.

Estrus synchronization (extra-label): Estradiol 50 mg/mare (NOT mg/kg) in combination with progesterone 150 mg/mare (NOT mg/kg) IM once daily for 10 days. Concurrently, administer dinoprost 5 mg/mare (NOT mg/kg) SC as a single dose on the last treatment day.[12]

Enhance estrus behavior and receptivity in ovariectomized mares (extra-label): 5 – 10 mg/horse (NOT mg/kg) IM once[13]

Induction of ovulation in anovulatory mares (extra-label):

a) Estradiol 50 mg/horse (NOT mg/kg) IM once on January 21; sulpiride 3 g/horse (NOT mg/kg) SC was administered on the 5th and 12th days after ECP injection[14, 15]

b) Estradiol benzoate: 11 mg/mare (NOT mg/kg) IM every other day (beginning January 11) for a total of 10 injections. On the day after the 6th estradiol dose, begin sulpiride 250 mg/mare (NOT mg/kg) SC daily; continue sulpiride until the mare ovulates or for 35 doses (whichever occurs first)[16]

Ascending placentitis (extra-label): 10 mg/horse (NOT mg/kg) IM every 3 days for 3 treatments was beneficial under experimental conditions[1]

Induction of lactation in nonpregnant mares (extra-label): Estradiol 50 mg/mare (NOT mg/kg) in combination with progesterone 150 mg (NOT mg/kg) IM once daily for 7 days; administer dinoprost 5 mg/mare (NOT mg/kg) IM as a single dose on treatment day 7. Throughout treatment, also administer sulpiride 500 mg/mare (NOT mg/kg) IM twice daily for 10 days.

Mares with estrogen-responsive urinary incontinence (extra-label): 5 – 12 µg/kg IM daily for 3 days and then every other day.[2, 17] Some mares will improve, but treatment does not cure the condition.

Monitoring

When therapy is chronic or used at high doses, perform baseline and periodic (eg, monthly):

- CBC: The frequency of monitoring with chronic therapy depends on the underlying clinical presentation.
- Hepatic enzymes (eg, ALT, AST, ALP)

Client Information

- Injectable estrogen should only be administered by a veterinarian. Estrogen hormone is used in mares to induce estrus (heat) and for long-term treatment of urinary incontinence.
- This hormone may be used (rarely) in dogs and cats as a mismate treatment to avoid pregnancy.
- Avoid use in pregnant animals as this medicine will cause loss of pregnancy.
- Contact your veterinarian immediately if your animal develops a decrease in appetite, pale gums, lethargy, vaginal bleeding or other vaginal discharge, swelling of the vulva, difficulty breathing, bloody urine, dark stool, fever, bloody nose, and bruising on the skin or gums.
- Pregnant women and those who are breastfeeding should use caution when handling this medicine. Wear disposable gloves when handling this drug.
- Estradiol use in food-producing animals is illegal.
- Your veterinarian will need to periodically examine your animal and perform blood tests while your animal is on this treatment. Do not miss these important follow-up visits.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Estradiol cypionate is a naturally occurring steroidal estrogen. Estradiol cypionate is produced by esterifying estradiol with cyclopentanepropionic acid and occurs as a white to off-white, crystalline powder. It is either odorless or has a slight odor and has a melting range of 149°C to 153°C (300°F-307°F). Less than 0.1 mg/mL is soluble in water, and 25 mg/mL is soluble in alcohol. Estradiol cypionate is sparingly soluble in vegetable oils.

Estradiol may also be known as beta-oestradiol, dihydrofolliculin, dihydrotheelin, dihydroxyoestrin, estradiolum, NSC-9895, NSC-20293 (α-estradiol), and oestradiol; many trade names are available.

Estradiol cypionate may also be known as oestradiol cyclopentylpropionate, oestradiol cypionate, *Delestrogen®*, *Depo-Estradiol®*, *DepoGen®*, *Dura-Estrin®*, *ECP®*, *E-Cypionate®*, *Estra-D®*, *Estrace®*, *Estro-Cyp®*, *Estroject®*, *depGynogen®*, *Femtrace®*, or *Gynodiol®*.

Storage/Stability

Estradiol cypionate should be stored in light-resistant containers at controlled room temperature (20°C-25°C [68°F-77° F]); avoid freezing.

Commercially available injectable solutions of estradiol cypionate are sterile solutions in a vegetable oil (usually cottonseed oil); they may contain chlorobutanol as a preservative.

Compatibility/Compounding Considerations

Do not mix estradiol cypionate with other medications.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Several estradiol-containing implants are available for use in beef cattle, but in 2006, the FDA stated that the use of estradiol cypionate (ECP) in food-producing animals is illegal, and manufacturing and compounding of ECP for such use is illegal. In the United States, it is illegal to compound estradiol for use in food-producing animals.

HUMAN-LABELED PRODUCTS:

Estradiol Cypionate in Oil for Injection: 5 mg/mL in 5 mL vials; *Depo-Estradiol®*; (Rx)

Estradiol Valerate in Oil for Injection: 10 mg/mL, 20 mg/mL, and 40 mg/mL in 5 mL multidose vials; *Delestrogen®*, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Estriol

(ess-***trye***-ole) *Incurin®*

Hormonal Agent (Estrogen)

Prescriber Highlights

- ► Short-acting estrogen approved for treating estrogen-responsive urethral sphincter mechanism incompetence (USMI) in ovariohysterectomized female dogs
- ► Not dosed by animal's weight. Dosage should be tapered to the lowest effective dose.
- ► Use is contraindicated in male dogs, intact female dogs, dogs less than 1 year of age, pregnant or lactating dogs, dogs that have polyuria and polydipsia (PU/PD), dogs that are pregnant or lactating, or dogs receiving other estrogen medications.
- ► Use caution in dogs with liver disease or when using in combination with glucocorticoids.
- ► Most common adverse effects are GI (eg, hyporexia, vomiting) and estrogen-related (eg, swollen vulva); myelotoxicity risk appears to be low.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies estrogens as hazardous drugs; use appropriate precautions when handling.

Uses/Indications

Estriol tablets are FDA-approved for control of estrogen-responsive urethral sphincter mechanism incompetence (USMI) in ovariohysterectomized female dogs. At present, estriol is the only estrogen approved in the US for this use.

No clinical studies were found that compared efficacy or adverse effects of estriol with other estrogens (eg, diethylstilbestrol) or α-adrenergic drugs (eg, phenylpropanolamine) in female dogs with USMI. Some have proposed that using an estrogen with an α-adrenergic may be more effective[1] and allow dosage reductions for both drugs; however, one study compared use of estriol alone with use of estriol in combination with phenylpropanolamine in female dogs with USMI and showed no difference in urethral resistance.[2]

Pharmacology/Actions

Estriol is a short-acting estrogenic drug. By binding to estrogen receptors in the female canine lower urinary tract, estriol can improve urinary continence in ovariohysterectomized dogs. This effect is thought to occur through enhanced urethral sphincter tone via increased sensitivity of urethral smooth muscle receptors to norepinephrine and thus, increased smooth muscle contractility. In comparison to other estrogen analogues (eg, 17 beta-estradiol, diethylstilbestrol [DES]), estriol binds to estrogen receptors for a much shorter period but still yields therapeutic effects and apparently reduces the risk for tumorigenic effects and myelotoxicity.

Pharmacokinetics

After oral administration, estriol is nearly completely absorbed from the GI tract, and peak plasma concentrations occur in about one hour. Absorbed estriol is highly, but weakly, bound to plasma proteins, which partly explains its short acting duration. In dogs, it is

not known how the drug is biotransformed, but in other species it is oxidated, sulfated, and glucuronidated in the liver. Half-life is roughly 8 to 12 hours but is difficult to determine as most pharmacokinetic studies produce multiple concentration peaks, suggesting that enterohepatic recirculation occurs. Estriol and its conjugated forms are excreted in the urine.

Contraindications/Precautions/Warnings

Estriol is contraindicated in animals that are hypersensitive to it and in animals receiving other estrogens (eg, diethylstilbestrol [DES]).

In some countries, estriol is labeled as contraindicated in male dogs, intact female dogs, dogs less than one year of age, pregnant or lactating dogs, or dogs with signs of polyuria and polydipsia (PU/PD).[3,4]

Estriol should be used with caution in dogs with liver disease or when used in combination with glucocorticoids as the safety has not been established.[5]

The National Institute for Occupational Safety and Health (NIOSH) classifies estrogens as hazardous drugs representing an occupational hazard to healthcare workers; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.[6]

Do not confuse estriol with estrADiol.

Adverse Effects

Estriol may cause adverse GI effects (eg, anorexia, vomiting) and adverse estrogenic effects (eg, swollen vulva [most common],[7] vulvovaginitis, mammary hyperplasia, behavioral changes, and enhanced attractiveness to male dogs).[5] Rarely, polydipsia, lethargy, hyperactivity, aggression, and local alopecia have been reported. Very rarely, blood dyscrasias, vaginal bleeding, and an increased incidence of seizures have been noted. Most adverse effects are reversible by lowering the dose of estriol.

Estrogens may increase the risk of mammary tumors and may cause myelotoxicity[8]; the risk for these effects in dogs at recommended dosages of estriol appears to be low, likely owing to its relatively short duration of action.[5] No hematologic abnormalities were associated with estriol therapy in a study with 114 dogs.[9]

Reproductive/Nursing Safety

Exogenously administered estrogens are contraindicated for use during pregnancy. Some estrogens (eg, diethylstilbestrol [DES]) have been associated with significant fetal malformations or tumorigenic effects in humans.

Exogenous estrogen administration during nursing is generally not recommended because of the potential for milk transmission and reduction in milk quality and quantity.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute oral overdoses may cause emesis or other GI effects. Estrogenic effects (see ***Adverse Effects***) are possible in both males (ie, feminization) and females. Clinical signs in female beagles given estriol for 6 months at up to 10 mg/day included estrogenic effects; pathology showed vulvar and vaginal tissue with a proestrus-like appearance with or without lymphoplasmacytic infiltrate and urothelial hyperplasia of the renal pelvis.[10] Increased white blood cell and platelet counts were observed in dogs receiving 6 mg/day and 10 mg/day doses.[5] In 2 acute toxicity trials performed in rats, LD_{50} after oral administration was greater than 2 g/kg,[11] suggesting that an acute overdose is unlikely to cause mortality.

Long-term (26 weeks) overdoses of 6 to 10 mg/day (3 to 5 times the recommended dose) demonstrated redness and swelling of the vulva, vulvar discharges, mammary hyperplasia, and higher white blood cell counts.[12]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to the ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving oral estrogens and potentially could be of significance in veterinary patients:

- **Anticoagulants** (eg, **heparins, rivaroxaban, warfarin**): Concurrent use may diminish anticoagulant effect.
- **Ascorbic Acid**: Ascorbic acid may increase estrogen concentration.
- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): May increase estrogen concentration
- **Cimetidine**: May increase estrogen concentration
- **Cyclosporine**: Estrogens may increase serum cyclosporine concentration.
- **Hypoglycemic Agents** (eg, **glipizide, insulin, metformin**): Estrogens may increase blood glucose concentration.
- **Estrogens, Other** (eg, **diethylstilbestrol [DES]**): Possible additive effects. Do not use with other estrogens; concomitant use with other estrogens has not been evaluated.[5]
- **Levothyroxine**: Estrogens may diminish the therapeutic effect of levothyroxine, and an increase in levothyroxine dose may be needed. Monitor thyroid status when using these drugs in combination and adjust levothyroxine dose accordingly. See ***Monitoring*** in ***Levothyroxine***.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May increase estrogen concentration
- **Mitotane**: May decrease estrogen concentration if administered concomitantly
- **Phenobarbital**: May decrease estrogen concentration if administered concomitantly
- **Rifampin**: May decrease estrogen concentration if administered concomitantly
- **Theophylline, Aminophylline**: Estrogens may increase theophylline concentration.
- **Thyroid Hormones**: Possible alteration of thyroxine and thyrotropin serum concentrations
- **Ursodiol**: Estrogens may diminish ursodiol efficacy.

Laboratory Considerations

- In humans, estrogens have been demonstrated in humans to increase **thyroxine-binding globulin** (**TBG**) concentrations with resultant increases in total circulating thyroid hormone. Decreased $\mathbf{T_3}$ resin uptake also occurs, but **free** $\mathbf{T_4}$ concentration is unaltered. It is unclear if estradiol affects these laboratory tests in veterinary patients.
- Estrogens may decrease the diagnostic effect of **cosyntropin**[13] and **metyrapone.**[14]

Dosages

DOGS:

Estrogen-responsive urinary incontinence in ovariohysterectomized female dogs (label dosage; FDA approved): Initially, 2 mg/dog (NOT mg/kg) PO once daily for a minimum of 14 days.[5] After urinary incontinence is controlled, decrease the dose to 1 mg/dog (NOT mg/kg) PO once daily, then 0.5 mg/dog (NOT mg/kg) PO once daily, then 0.5 mg/dog (NOT mg/kg) PO every other day until the lowest effective dose is determined. Allow a minimum of 7 days between each dose adjustment. The maxi-

mum daily dose is 2 mg/dog (NOT mg/kg). If the dog does not respond to this dosage, the diagnosis should be re-assessed.

Hormone-dependent urinary incontinence caused by sphincter mechanism incompetence in ovariohysterectomized female dogs (extra-label): Initially, 1 mg/dog (NOT mg/kg) PO once daily for 7 to 14 days.[3, 4]

- If 1 mg/dog (NOT mg/kg) PO once daily is *effective*, decrease to 0.5 mg/dog (NOT mg/kg) PO once daily. When the lowest effective daily dose is determined, treatment every other day may be tried. Seven days should be allowed between dosage adjustments before judging the full effect of the dosage change. Ensure the dosage used to achieve the therapeutic effect is as low as possible; dosage should not be less than 0.5 mg/dog (NOT mg/kg) per day.
- If 1 mg/dog (NOT mg/kg) PO once daily was *ineffective*, increase dosage to 2 mg/dog (NOT mg/kg) PO once daily. The maximum dosage should not exceed 2 mg/dog (NOT mg/kg) per day. If 2 mg/dog (NOT mg/kg) per day is successful, reduce dosage to 2 mg/dog (not mg/kg) PO every other day. If treatment with 2 mg/dog (NOT mg/kg) PO once daily is ineffective, reassess diagnosis.[3, 15]

Monitoring

- Clinical efficacy
- Adverse effects (eg, inappetence, vomiting, polydipsia, swollen vulva, vulvovaginitis, mammary hyperplasia, behavioral changes)
- Baseline CBC and urinalysis; recheck CBC after 1 month of therapy[16]

Client Information

- Estriol is used in dogs to treat estrogen-responsive urinary incontinence.
- The most common side effects include lack of appetite, vomiting, greater thirst, and swollen vulva.
- This medicine may be given with or without food. If your dog vomits or acts sick after getting estrogen on an empty stomach, give with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Treatment will likely continue for the remainder of the life of the dog.
- Your veterinarian will need to monitor your dog with periodic examinations and laboratory testing. Do not miss these important follow-up visits.
- Pregnant women and those who are breastfeeding should use caution when handling. Wash your hands with soap and water thoroughly after administration to avoid exposure to the drug.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Estriol is a natural estrogenic sex hormone that occurs as a white to off-white, odorless, crystalline powder. It is insoluble in water; sparingly soluble in alcohol; and soluble in acetone, chloroform, dioxan, ether, and vegetable oils. Its molecular weight is 288.4 g/mol.

The commercially available veterinary tablets contain amylopectin, magnesium stearate, potato starch, and anhydrous lactose.

Estriol may also be known as E3, oestriol, follicular hormone hydrate, theelol, or *Incurin*®.

Storage/Stability

Store estriol tablets at or below 25°C (77°F) with excursions permitted to 40°C (104°F). Protect from light.

Compatibility/Compounding Considerations

No specific information has been noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Estriol Tablets: 1 mg scored tablets in 30- or 90-count foil-sealed blister packs; *Incurin*®; (Rx). FDA-approved for oral use in dogs. NADA #141-325

Estriol should not be used in food-producing animals.

HUMAN-LABELED PRODUCTS: NONE

Ethambutol

(e-***tham***-byoo-tole) *Myambutol*®

Antimycobacterial Agent

Prescriber Highlights

- ► Can be used as part of an antimycobacterial drug combination protocol for dogs, cats, and birds
- ► Treating *Mycobacterium tuberculosis* complex infections in veterinary species is controversial because of potential risk for public health.
- ► Contraindicated in patients hypersensitive to the drug
- ► Caution is advised in patients with renal disease and preexisting optic neuritis.
- ► Adverse effects include optic neuritis, peripheral neuritis, and neurotoxicity.

Uses/Indications

In combination with other antimycobacterial drugs, ethambutol may be useful in treating mycobacterial infections caused by *Mycobacterium bovis*, *Mycobacterium tuberculosis*, *Mycobacterium genavense*, *Mycobacterium avium-intracellulare* complex (MAC) in dogs or cats, particularly when the organism is resistant to treatment with other drug combinations (eg, rifampin, fluoroquinolones, macrolides). In birds, ethambutol has been used in combination with other agents for treating mycobacterial (eg, *M avium*) infections.

Because of public health risks, particularly in the face of increased populations of immunocompromised humans, and the possible contribution to development of antimicrobial resistance, treatment of *Mycobacterium tuberculosis* complex infections (eg, *M bovis, M tuberculosis, Mycobacterium microti,* among others) in domestic or captive animals is controversial.

The World Health Organization has designated ethambutol as a Critically Important, High Priority antimicrobial for human medicine.[1]

Pharmacology/Actions

A synthetic, bacteriostatic, antimycobacterial agent, ethambutol only acts against actively dividing mycobacteria. It enters mycobacterial cells and interferes with RNA synthesis and appears to interfere with the incorporation of mycolic acid into cell walls, allowing other antimycobacterial agents to penetrate the cell wall. Ethambutol does not have appreciable activity against other bacteria or fungi. Resistance can occur and is thought to develop in a stepwise manner; resistance is more likely with monotherapy. Cross-resistance with other antimycobacterial agents has not been reported.

Pharmacokinetics

Pharmacokinetic values for cats or birds were not located. In dogs, ethambutol is reported to have a volume of distribution of 3.8 L/kg, a total body clearance of 13.2 mL/minute/kg, and an elimination half-life of 4.1 hours. Nephrectomized dogs had an elimination half-life of 5 hours.

In humans, ethambutol is rapidly absorbed after PO administra-

tion and bioavailability is around 75%. The drug is distributed widely in the body, but CSF concentrations only range from 10% to 50% of those found in serum. Erythrocyte concentrations are about twice that of the serum and can serve as a depot for the drug. About 15% of absorbed drug is hepatically metabolized to inactive metabolites. The majority of the drug is eliminated both by tubular secretion and glomerular filtration as unchanged drug in the urine. Elimination half-life in humans with normal renal function is about 3 to 4 hours; up to 8 hours if renal function is impaired.

Contraindications/Precautions/Warnings

Ethambutol should not be used in patients with a history of prior hypersensitivity reactions to it. In humans, the drug is contraindicated in patients with optic neuritis.

Patients with markedly reduced renal function may need dosage adjustment.

To help ensure human health, it is recommended to contact local public health authorities and obtain their recommendations before treating *Mycobacterium tuberculosis* complex infections in companion animals.

Adverse Effects

Well-described adverse effect profiles for ethambutol in dogs, cats, or birds are not available. Because ethambutol is used in combination with other medications, adverse effects associated with treatment may not be a result of ethambutol. In pre-clinical studies, some dogs receiving ethambutol over prolonged periods developed non-dose related degenerative changes in the central nervous system. In toxicology studies, dogs receiving large, prolonged doses developed signs of myocardial toxicity and depigmentation of the tapetum lucidum of the eyes. However, dosages as large as 400 mg/kg/day for 4 weeks in dogs demonstrated no significant abnormalities in electroretinogram or visual evoked potential. In humans, optic neuritis (usually reversible after drug discontinuation) causing decreased visual acuity has been reported; optic neuritis may respond to treatment with vitamin B_{12} injections.

Hepatotoxicity, sometimes fatal, has been noted in humans taking ethambutol. Peripheral neuritis, blood dyscrasias, and hyperuricemia also have occurred.

Because antimycobacterial therapy involves multiple drugs for extended periods of time, bacterial or fungal overgrowth infections can occur. Antifungal medications may be required.

Reproductive/Nursing Safety

Ethambutol crosses the placenta; fetal levels are reported to range from 30% to 75% of that found in maternal serum. Teratogenic effects associated with ethambutol have not been reported in humans, but studies in mice, rats, and rabbits given high doses yielded a variety of abnormalities in offspring.

Ethambutol is excreted into milk in levels approximating those found in maternal serum. In humans, ethambutol is considered compatible with pregnancy.[2]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Very limited information exists. Acute overdoses of greater than 10 grams in humans have caused optic neuritis. Other adverse effects noted with human overdoses include CNS effects (confusion, visual hallucinations), abdominal pain, nausea, fever, and headache; treatment is supportive.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving ethambutol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Aluminum-containing Antacids**: In humans, it has been documented that coadministration can reduce oral absorption of ethambutol; it is suggested to separate dosing by at least 4 hours if both drugs are necessary.

Laboratory Considerations

- No specific concerns; in humans, increased **serum uric acid** levels have been noted.

Dosages

DOGS:

Disseminated *Mycobacterium tuberculosis* (extra-label): Ethambutol 10 – 25 mg/kg PO once daily, in combination with rifampin 5 – 10 mg/kg PO every 12 to 24 hours (maximum of 600 mg/day) and isoniazid 10 – 20 mg/kg PO once daily (maximum of 300 mg/day). May also add pyrazinamide 15 – 40 mg/kg PO once daily. Treatment must continue for more than 9 months.[3] **NOTE**: Pyrazinamide is ineffective for *Mycobacterium bovis*.

CATS:

Mycobacterial infections (extra-label): 10 – 25 mg/kg PO once daily, in combination with 1 or preferably 2 antimycobacterial drugs (eg, rifampin, isoniazid, clarithromycin or azithromycin, marbofloxacin or pradofloxacin).[4] **NOTE**: Ethambutol is not recommended in the current guidelines for treating *Mycobacterium tuberculosis* complex infections in cats. [5]

BIRDS:

***Mycobacterium avium* infections in caged birds** (extra-label): Several protocols have been used, but controlled trials have not been performed. Combination therapy and treatment for 6 to 12 months is required.

Protocol 1: Ciprofloxacin 20 mg/kg PO every 12 hours or enrofloxacin 15 mg/kg PO or IM (**NOTE**: Repeated IM injections can cause muscle necrosis) for 10 days; clofazimine 1.5 mg/kg PO once daily; cycloserine 5 mg/kg PO every 12 hours; and ethambutol 20 mg/kg PO every 12 hours

Protocol 2: Clofazimine 6 mg/kg PO once daily; ethambutol 30 mg/kg PO once daily; rifampin 45 mg/kg PO once daily

Protocol 3: Ciprofloxacin 80 mg/kg PO once daily or enrofloxacin 30 mg/kg PO once daily; ethambutol 30 mg/kg PO once daily; rifampin 45 mg/kg PO once daily or rifabutin 15 mg/kg PO once daily[6]

Protocol 4: Clarithromycin 61 mg/kg, moxifloxacin 25 mg/kg and ethambutol 60 mg/kg administered by crop gavage every 12 hours for 18 weeks[7]

Monitoring

- Clinical efficacy
- With long-term therapy, consider periodic monitoring of CBC, liver enzymes, and renal parameters.
- Routine ophthalmologic examinations are recommended for humans taking this medication long term.
- Monitor for fungal or bacterial overgrowth infections

Client Information

- Animals that have certain forms of mycobacterial infections may be contagious to humans. Discuss this with your veterinarian and

your physician for more information.
- The length of treatment with ethambutol may be very long (months to years). Be sure to give all of the medication that is prescribed as directed and until it is all gone.
- This medication can be administered with or without food.
- Report any changes noted with your animal's eyes or vision, or any other new concerns to your veterinarian.
- Periodic monitoring of bloodwork and response to treatment is recommended. Do not miss important follow up visits with your veterinarian.

Chemistry/Synonyms
Ethambutol HCl occurs as a white, crystalline powder that is freely soluble in water and soluble in alcohol.

Ethambutol may also be known as: CL-40882, etambutol, or ethambutoli; there are many trade names for international products.

Storage/Stability
Ethambutol tablets should be stored at 20°C to 25°C (68°F-77°F) in well-closed, light-resistant containers.

Compatibility/Compounding Considerations
No specific information was noted.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Ethambutol HCl Tablets: 100 mg and 400 mg (scored); *Myambutol*®, generic; (Rx)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Ethanol
Ethyl Alcohol
(***eth***-a-nol)
Antidote

Prescriber Highlights
- ► Used as second-line treatment of ethylene glycol (EG) toxicity for dogs and cats (fomepizole recommended as first-line)
- ► Adverse effects include CNS and respiratory depression, hypoglycemia, diuresis, as well as pain and infection at the injection site.
- ► No absolute contraindications when used for treatment of ethylene glycol toxicity; use caution in animals with CKD and hepatic disease
- ► Avoid extravasation. Monitor fluid, electrolyte, and respiratory status; consider measuring alcohol and toxin levels (if possible).
- ► No FDA-approved products exist; must be compounded

Uses/Indications
The principal use of ethanol in veterinary medicine is for the treatment of ethylene glycol toxicity. Although fomepizole (4-methylpyrazole; 4 MP) is the treatment of choice for ethylene glycol poisoning, ethanol is more readily available and a more economical alternative when patients present within a few hours after ingestion.

Ethanol is used in the management of methanol poisoning in humans but is not recommended for methanol toxicity in dogs and cats as it exacerbates CNS depression and prolongs toxicity by delaying methanol elimination.[1]

Percutaneous injection of ethanol 95% to 96% has been used successfully to treat canine[2] and feline[3] hyperparathyroidism. Percutaneous injection of 96% ethanol has also been used for feline hyperthyroidism with varying results. In one study of 4 cats with unilateral thyroid nodules, percutaneous ethanol injection (PEI) successfully decreased serum total T_4 concentrations, which remained within or below the reference range for 12 months.[4] Another study of 7 cats with bilateral thyroid nodules showed only transient decreases in serum total T_4.[5]

In horses, ethanol has been used in aerosol form as a mucokinetic agent and for intraarticular administration to promote distal tarsal joint ankylosis with osteoarthritis.

Pharmacology/Actions
Ethanol competitively inhibits alcohol dehydrogenase, preventing the conversion of ethylene glycol to its toxic metabolites (glycoaldehyde, glycolate, glyoxylate, and oxalic acid). This inhibition allows ethylene glycol to be principally excreted in the urine unchanged. For ethanol to be effective, it must be given early after ethylene glycol ingestion, ideally sooner than 4 to 8 hours after ingestion. It is seldom useful if started 8 hours after significant ingestion.

When injected into a thyroid or parathyroid mass, ethanol causes necrosis of the nodule tissue.

Pharmacokinetics
Alcohol is well absorbed orally, but it is administered intravenously for toxicity treatment. It rapidly distributes throughout the body and crosses the blood–brain barrier.

Contraindications/Precautions/Warnings
As ethylene glycol intoxication is life-threatening, there are no absolute contraindications to ethanol's use for this indication. Use it with caution in animals with chronic kidney disease, as the unmetabolized parent compound will not be eliminated unless hemodialysis is available. Ethanol may exacerbate hepatic disease.

Prior to ethanol ablation in cats, laryngeal function should be assessed and should be normal due to the possibility of laryngeal paralysis.[5,6]

The use of ethanol with fomepizole is usually contraindicated; see ***Drug Interactions*** for more information.

Adverse Effects
General adverse effects associated with ethanol are CNS depression and respiratory depression. A high risk for hypothermia and respiratory arrest is associated with high blood levels. Ethanol's effects on antidiuretic hormone (ADH; vasopressin) may enhance diuresis. As ethylene glycol may also cause diuresis, fluid and electrolyte therapy requirements need to be monitored and managed. Hypoglycemia, hypocalcemia, and metabolic acidosis may be seen; pulmonary edema can also occur. Orally administered ethanol is a gastric irritant, and vomiting may result. The risk of aspiration is increased due to ethanol's inhibitory effect on the epiglottis.

Following ethanol treatment for ethylene glycol exposure, animals will be depressed and lethargic during recovery. Other adverse effects include pain and infection at the injection site, phlebitis, and intravascular hemolysis. Extravasation should be watched for and avoided; use of a central catheter may reduce this risk.

Dysphonia can occur following ethanol ablation in dogs and cats. In humans, transient injection site pain has been reported.

When aerosolized in horses, irritation and bronchoconstriction may result. With intraarticular administration in horses, mild swelling at the injection site can occur; severe swelling with secondary cellulitis and fibrosis occurs rarely.

Reproductive/Nursing Safety
Alcohol crosses the placenta. Alcohol's safety during pregnancy has not been established for short-term use. Use only when necessary.

Alcohol passes freely into milk to levels that approximate maternal serum levels.

Because safety has not been established in animals, this drug

should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The lowest lethal IV dose in dogs is 1600 mg/kg.[7] The oral lethal dose of ethanol in dogs is 5 – 8 g/kg. If clinical signs of overdose occur (lateral nystagmus, hypothermia, respiratory depression, profound obtundation), either slow the infusion or discontinue temporarily. Alcohol blood levels may be used to monitor both the efficacy and toxicity of alcohol.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ethanol and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Bromocriptine**: Alcohol may increase the severity of adverse effects seen with bromocriptine.
- **Charcoal, Activated**: Will inhibit the absorption of orally administered ethanol; do not use activated charcoal if administering ethanol orally for methanol or ethylene glycol intoxication.
- **CNS Depressant Drugs** (eg, **barbiturates, benzodiazepines, phenothiazines, opioid analgesics**, **antihistamines, tricyclic antidepressants**): Alcohol may cause additive CNS depression when used with other CNS depressant drugs.
- **Fomepizole** (**4-methylpyrazole; 4-MP**): Inhibits alcohol dehydrogenase; ethanol metabolism is reduced significantly, and alcohol poisoning (CNS depression, coma, death) can occur. Use together is generally not recommended, but if both drugs are used, monitoring of ethanol blood levels is mandatory.
- **Insulin**: Alcohol may affect glucose metabolism and the actions of insulin or oral antidiabetic agents.
- **Sulfonylureas** (eg, **glipizide, glyburide**): Increased risk for hypoglycemia
- **Chlorpropamide and Metronidazole**: A disulfiram reaction (increased acetaldehyde with tachycardia, vomiting, weakness) may occur if alcohol is used concomitantly with these drugs.
- **Antihypertensive Agents** (eg, **amlodipine, enalapril, telmisartan**): Ethanol may enhance the hypotensive effect of antihypertensive drugs.

Laboratory Considerations

Ethylene Glycol Testing Kits: Ethanol may cause false-positive reports on ethylene glycol screening tests. Refer to the label of the testing kit for more information.

Dosages

DOGS:

Ethylene glycol poisoning (extra-label): **NOTE**: Fomepizole is generally preferred, but availability and/or cost may be an issue.

When using ethanol, a CRI is preferred as it results in more stable blood ethanol concentrations.[8] **See *Compatibility/Compounding Considerations*** for detailed ethanol dilution instructions**.**

a) Using a 20% ethanol solution: give 5.5 mL/kg dose over 1 hour IV every 4 hours for 5 treatments, then every 6 hours for four additional treatments (each treatment is dosed as a CRI over 1 hour).[9,10,11]

b) Using a 7% ethanol solution: give 8.6 mL/kg slowly IV, followed by 1.43 mL/kg/hour IV CRI for at least 36 hours (48 hours of treatment is optimal). If the EG test was positive initially, then check it before stopping treatment. Discontinue treatment when it converts to negative.[12]

c) If IV administration is not possible, ethanol can be given orally (via an indwelling nasogastric tube). Using a 40% ethanol solution (80 proof), a typical dosage is ≈1 – 1.4 mL/kg PO. The solution can be diluted as gastric irritation may result in vomiting.[13]

Percutaneous ultrasound-guided ethanol ablation of presumed functional parathyroid nodules (extra-label): 95% ethanol injected into the center of the nodule; target injected volume equal to the measured volume of the nodule. Hypercalcemia resolved in 85% of cases; 22% of treated cases developed hypocalcemia, but only 1 was symptomatic.[2]

CATS:

Ethylene glycol poisoning (extra-label): **NOTE**: High-dose fomepizole is generally preferred, but availability and/or cost may be an issue.

When using ethanol, a CRI is preferred as it will result in more stable blood ethanol concentrations.[8] **See *Compatibility/Compounding Considerations*** for detailed ethanol dilution instructions**.**

a) Using a 20% ethanol solution[11]: give 5 mL/kg dose over 1 hour IV every 6 hours for 5 treatments, then every 8 hours for four additional treatments (each treatment is dosed as a CRI over 1 hour).[9,10]

b) Using a 7% ethanol solution: give 8.6 mL/kg slowly IV, followed by 1.43 mL/kg/hour IV CRI for at least 36 hours (48 hours of treatment is probably better). If the EG test was positive initially, then check it before stopping treatment. Discontinue treatment when it converts to negative.[12]

c) If IV administration is not possible, ethanol can be given orally (via an indwelling nasogastric tube). Using a 40% solution (80 proof), a typical dosage is ≈1 – 1.4 mL/kg PO. The solution can be diluted as gastric irritation may result in vomiting.[13]

Percutaneous ultrasound-guided ethanol ablation of hyperplastic thyroid nodule (extra-label): 96% ethanol injected into the nodule. Injected ethanol volume is based on nodule size; 50% to 100% of the calculated nodule volume has been used as targets. If bilateral nodules are present, only one nodule should be treated at a time.[4,5]

HORSES:

Promote ankylosis in horses with distal tarsal joint osteoarthritis (extra-label): In the study, joints were treated if there was no contrast-mediated radiographic evidence of communication with the proximal intertarsal joint (PITJ). The same needle was kept in the joint space, and either 70% ethanol solution in sterile water or 100% ethanol was injected until minor resistance was felt (2 to 4 mL). In their conclusion, the authors stated: …*findings of this study support the use of 70% ethanol solution for treatment of distal tarsal joint OA in cases that do not respond to corticosteroid medication. Careful case selection and accurate contrast-facilitated injection technique are mandatory to minimize potential complications of this treatment.*[14]

Monitoring

- Alcohol blood levels (and ethylene glycol or methanol levels). **NOTE**: In humans, blood ethanol levels should be maintained at 100 – 130 (some say up to 200) mg/dL (21.7 – 28.2 milliMoles/L). It is safer to maintain a blood ethanol concentration greater than 130 mg/dL than to have it fall below 100 mg/dL. (*POISINDEX® Managements*, Thompson; *MICROMEDEX®* Healthcare Series, 2007)
- Degree of CNS and respiratory depression (eg, respiratory rate,

SpO2, venous CO_2 if available)
- Body temperature
- Fluid, electrolyte, acid/base, and blood glucose status

Client Information
- Give systemically administered alcohol in a controlled clinical environment.
- There are no FDA-approved ethanol products. Emergencies may require the use of non-pharmaceutical-grade ethanol.

Chemistry/Synonyms
Ethanol is a transparent, colorless, volatile liquid having a characteristic odor and a burning taste. Ethyl alcohol is miscible with water and many other solvents.

"Proof" is considered 2 times the percentage of ethanol. For example, 100 proof vodka is 50% ethanol; 80 proof vodka is 40% ethanol. In some states, pure grain alcohol (often called "Everclear"), which is a 95% ethanol (190 proof) product, can be purchased.

Ethanol may also be known as aethanolum, alcohol, grain alcohol, ethanolum, and ethyl alcohol.

Storage/Stability/Preparation
Protect alcohol from extreme heat or freezing. Do not use it unless the solution is clear. Alcohol may precipitate many drugs; do not administer other medications in the alcohol infusion solution unless compatibility is documented (consult specialized references or a hospital pharmacist for more specific information).

Compatibility/Compounding Considerations
Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

NOTE: Since alcohol infusions are generally only used in veterinary medicine for the treatment of ethylene glycol and methanol toxicities, obtaining medical/pharmaceutical grade or laboratory-grade alcohol can be difficult in an emergency. One improvised method that has been successful, albeit not pharmaceutically elegant, is to use commercially available vodka (40% [80 proof] or 50% [100 proof]) or grain alcohol ("Everclear"; 95% [190 proof]) diluted in an appropriate IV solution (eg, 5% dextrose or 0.9% sodium chloride).

To make an ethanol dilution:

1. Determine the volume of ethanol to dilute:

$$\textit{volume of stock ethanol needed} = \left(\frac{\%\ \textbf{\textit{desired}}}{\%\ \textbf{\textit{stock}}}\right) \times \textbf{\textit{total}}\ \text{volume desired}$$

2. Remove the volume determined in Step 1 from the fluid bag before adding the ethanol to the diluent

Example: make a 20% ethanol solution using 80 proof vodka (40% ethanol) in a one-liter bag of fluids

1. Determine the volume of vodka to dilute:

$$\textit{Volume of vodka needed} = \left(\frac{20\%}{40\%}\right) \times 1000\ mL$$

2. Volume of vodka needed is 500 mL. Remove 500 mL from 1 L bag of fluids, then add 500 mL of vodka.

Use an in-line filter to administer IV. The client should give informed consent regarding the use of this non-pharmaceutical product before use.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS: NONE

Alcohol (ethanol) 5% and 10% in dextrose 5% IV solutions that were commercially available have been discontinued.

For information on obtaining tax-free alcohol for medicinal purposes, contact a regional office of the Bureau of Alcohol, Tobacco, and Firearms.

In the UK: Dehydrated Alcohol (absolute alcohol) BP for Injection, Ethanol BP 100% v/v; 2 mL, 5 mL, 10 mL, 20 mL, and 50 mL ampules. (Martindale Pharma)

Etodolac
(ee-toe-***doe***-lak) *EtoGesic®, Lodine®*

Nonsteroidal Anti-inflammatory Agent (NSAID)

Prescriber Highlights
- ► A second-generation NSAID used in dogs; uncommonly used today. The veterinary-approved dosage forms of etodolac are not commercially available.
- ► Contraindicated in patients that are hypersensitive to it or other NSAIDs. Use this drug with caution in patients with preexisting or occult GI, hepatic, renal, cardiovascular, or hematologic abnormalities.
- ► Adverse effects include vomiting, diarrhea, lethargy, surgical bleeding, hypoproteinemia, keratoconjunctivitis sicca (KCS), and localized pain and tissue reactions at the injection site.
- ► Many potential drug interactions

Uses/Indications
Etodolac is labeled for the management of pain and inflammation associated with osteoarthritis in dogs. Etodolac appeared to provide analgesia to chronically lame horses with navicular syndrome.[1]

Pharmacology/Actions
Like other NSAIDs, etodolac has analgesic, anti-inflammatory, and antipyretic activity. Etodolac appears to be more selective for inhibition of cyclooxygenase-2 than cyclooxygenase-1, but studies conflict on this, and a definitive answer is not presently agreed upon. It may be better to describe etodolac as a COX-1–sparing drug rather than a COX-2–selective drug. In dogs, etodolac dosage affects whether the drug causes GI (COX-1 related) adverse effects. Dosages as little as 2.7 times the labeled dose can produce GI lesions.[2] Etodolac is also thought to inhibit macrophage chemotaxis, which may explain some of its anti-inflammatory activity.

In horses, etodolac does not exhibit much COX-2 selectivity.

Pharmacokinetics
The S(+) enantiomer is thought to provide the bulk of the pharmacologic activity, but the drug is supplied as a racemic mixture. Pharmacokinetic studies that measure both forms as one are not clinically relevant. After oral administration to healthy dogs, etodolac is rapidly and nearly completely absorbed.[2] The presence of food may alter the rate, but not the extent, of absorption. Peak serum concentrations occur 1 to 2 hours postdosing. Etodolac is highly bound to serum proteins. The drug is primarily excreted via the bile into the feces.[2] Glucuronide conjugates have been detected in the bile but not the urine. Elimination half-life in dogs varies depending on whether food is present in the gut, which may affect the rate of enterohepatic circulation of the drug.[2] These values range from about 8 hours (fasted) to 12 hours (non-fasted). Serum half-life is not necessarily a good predictor for the duration of efficacy, possibly due to the drug's high protein binding.

In horses, etodolac has an oral bioavailability of about 77%.[3] After

IV dosing, the volume of distribution was 0.29 L/kg, and the clearance was 235 mL/kg/hour. Elimination half-life (after IV dosing) was ≈2.5 to 3 hours.

Contraindications/Precautions/Warnings

Etodolac is contraindicated in dogs that are hypersensitive to it. It should be used with caution in dogs with preexisting or occult GI, hepatic, cardiovascular, or hematologic abnormalities (eg, von Willebrand disease or receiving anticoagulant therapy), as NSAIDs may exacerbate these conditions. Patients may be more susceptible to renal injury from etodolac if they are dehydrated, on diuretics, or have preexisting renal, hepatic, or cardiovascular dysfunction.

Safety of etodolac has not been established in dogs less than 12 months of age.

Adverse Effects

In clinical field studies, etodolac's primary adverse effects were vomiting and regurgitation,[4–6] and these effects were reported in about 5% of dogs tested.[2] Diarrhea, lethargy, and hypoproteinemia have also been reported in dogs. Urticaria, behavioral changes, and inappetence were reported in less than 1% of dogs treated. Hepatotoxicity and/or nephrotoxicity are possible but are not well-documented problems in dogs.

Therapy with etodolac should be terminated if inappetence, vomiting, fecal abnormalities, or anemia are observed.[2]

Etodolac injection may cause localized pain or tissue reactions at the injection site.

Etodolac may decrease total serum T_4 in some dogs.[7] However, its clinical significance is unclear.[8]

Etodolac appears to have less impact on clotting times than some other canine FDA-approved NSAIDs, but bleeding during surgery has been reported.

Cases have been reported of dogs developing keratoconjunctivitis sicca (KCS) after receiving etodolac treatment,[9] and the incidence rate is unknown at this time.

GI distress is the primary adverse effect of etodolac in horses.[10]

Reproductive/Nursing Safety

Safe use has not been established in breeding, pregnant, or lactating dogs.

Most NSAIDs are excreted in the milk; use with caution.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available, but in a safety study where dogs were given 40 mg/kg/day (2.7 times the label dosage), GI ulcers, weight loss, emesis, and fecal occult blood were noted.[2] Dosages of 80 mg/kg/day (5.3 times the label dosage) caused 6 of 8 dogs to either die or become moribund secondary to GI ulceration. It should be noted that these were not single-dose overdoses; however, they demonstrate that there is a relatively narrow therapeutic window for the drug in dogs and that dosages should be carefully determined (ie, do not confuse mg/kg dosages with mg/lb).

Common clinical signs include acute renal failure, anorexia, collapse, hyperkalemia, and hypersalivation. As with any NSAID, overdosage can lead to GI and renal effects. GI decontamination with emetics and/or activated charcoal may be appropriate. For doses where GI effects are expected, the use of GI protectants is warranted. If renal effects are also expected, fluid diuresis is warranted.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

NOTE: Although the manufacturer does not list any specific drug interactions in the package insert, it does caution to avoid or closely monitor etodolac's use with other drugs, especially those that are also highly protein bound. It also recommends close monitoring or avoiding **using etodolac with any other ulcerogenic drugs** (eg, **corticosteroids, other NSAIDs**). Although some clinicians advocate a multi-day washout period when switching from one NSAID to another (not aspirin—see below), there does not appear to be any substantial evidence that this is required. Until there is more evidence, consider starting the new NSAID when the next dose would be due for the old one.

The following drug interactions have either been reported or are theoretical in humans or animals receiving etodolac and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **enalapril, benazepril**): Etodolac may reduce the antihypertensive effects of ACE inhibitors. Because ACE inhibitors potentially reduce renal blood flow, use with NSAIDs could increase the risk for renal injury
- **Aminoglycosides** (eg, **gentamicin, amikacin**): Concurrent use may increase the risk for nephrotoxicity.
- **Angiotensin Receptor Blockers** (**ARB;** eg, **telmisartan**): Etodolac may reduce the antihypertensive effects of ARBs. Because ARBs potentially reduce renal blood flow, use with NSAIDs could increase the risk for renal injury
- **Anticoagulants** (eg, **heparin, LMWH, rivaroxaban, warfarin**): Concurrent use may increase the risk for bleeding.
- **Aspirin**: Concurrent use may increase the risk for GI ulceration.
- **Bisphosphonates** (eg, **alendronate**): Concurrent use may increase the risk for GI ulceration and nephrotoxicity.
- **Cholestyramine**: May reduce etodolac absorption
- **Cisplatin**: Etodolac may potentiate the renal toxicity of cisplatin when it is used in combination with cisplatin.
- **Clopidogrel**: Concurrent use may increase the risk for bleeding.
- **Corticosteroids** (eg, **dexamethasone**, **fludrocortisone**, **prednis(ol)one**): Concomitant administration with NSAIDs may significantly increase the risk for GI adverse effects.
- **Cyclosporine**: Concurrent use may result in an increased risk for cyclosporine nephrotoxicity.
- **Digoxin**: Concurrent use may result in increased serum concentration of digoxin and prolonged digoxin half-life.
- **Diuretics** (eg, **furosemide**): Concurrent use may result in reduced diuretic efficacy and possible nephrotoxicity.
- **Methotrexate**: Serious toxicity has occurred when NSAIDs have been used concomitantly with methotrexate; use together with caution.
- **Nephrotoxic Agents** (eg, **amphotericin B, aminoglycosides, cisplatin**): Potential for increased risk for nephrotoxicity if used with NSAIDs
- **nonsteroidal anti-inflammatory drugs (NSAIDs), Other**: Concurrent use of multiple NSAIDs should be avoided.
- **Phenobarbital**: Concurrent use may increase the metabolism of etodolac in dogs.
- **Probenecid**: May cause a significant increase in serum levels and half-life of etodolac
- **Selective serotonin reuptake inhibitors (SRIs;** eg, **fluoxetine)**: Concurrent use with etodolac may result in an increased risk for bleeding.

- **Tacrolimus**: Concurrent use with etodolac may result in acute renal failure.
- **Tigilanol Tiglate**: Because tigilanol tiglate must be used concomitantly with a glucocorticoid medication, NSAIDs must be avoided.

Laboratory Considerations

- Etodolac may cause false-positive determinations of **urine bilirubin**.
- Etodolac therapy may alter **thyroid function tests** and their interpretation; falsely low values may occur in dogs receiving etodolac.

Dosages

DOGS:

Treatment of pain and inflammation associated with osteoarthritis (labeled-dose; FDA-approved):

Oral tablets: 10 – 15 mg/kg PO once daily[2]. Dogs less than 5 kg (11 lb) cannot be accurately dosed with *EtoGesic®* tablets. Adjust the dose to obtain a satisfactory response, but do not exceed 15 mg/kg.[2] For long-term therapy, reduce dose level to minimum effective dosage.

Injection: 10 – 15 mg/kg SC as a single dorsoscapular injection. If needed, daily dosing with tablets may begin 24 hours after the last injectable treatment.

HORSES:

Navicular pain (extra-label): 23 mg/kg PO every 24 hours[11]

Monitoring

- Baseline (especially in geriatric dogs, dogs with chronic diseases, or those where prolonged treatment is likely): physical examination, CBC, serum chemistry panel (including liver enzymes and renal values), and urinalysis. It is recommended to reassess liver enzymes after 1 week of therapy. If liver enzyme elevations occur, recommend discontinuing the drug.
- Schirmer tear test prior to and periodically during therapy
- Clinical efficacy
- Signs of potential adverse reactions: inappetence, diarrhea, mucoid feces, vomiting, melena, polyuria, polydipsia, anemia, jaundice, lethargy, behavior changes, ataxia, or seizures
- Long-term therapy: Consider repeating CBC, urinalysis, and serum chemistries on an ongoing basis

Client information

- This medicine can be given with or without food; however, giving medicine with food may reduce the chances for stomach problems. If your animal vomits or acts sick after getting it on an empty stomach, give your animal the medicine with food or with a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Most dogs usually tolerate etodolac well, but rarely, some dogs will develop ulcers or serious kidney and liver problems. Watch for the following signs: not eating (as much as usual), vomiting, changes in bowel movements; changes in behavior or activity levels (more or less active than normal), incoordination (eg, stumbling, clumsiness), seizures (convulsions), or aggression; yellowing of gums, skin, or whites of the eyes (jaundice); changes in drinking (frequency, amount consumed) or urination habits (frequency, color, or smell).
- Periodic laboratory tests to check for liver and kidney side effects are required; do not miss important follow up visits with your veterinarian.

Chemistry/Synonyms

Etodolac is an indole acetic acid derivative and an NSAID that occurs as a white, crystalline compound that is insoluble in water but soluble in alcohol or DMSO. Etodolac has a chirally active center with a corresponding S (+) enantiomer and an R (-) enantiomer. The commercially available product is supplied as a racemic mixture of the forms.

Etodolac may also be known as AY-24236, etodolacum, etodolic acid, *Acudor®*, *Articulan®*, *Dualgan®*, *Eccoxolac®*, *Edolan®*, *Elderin®*, *EtoGesic®*, *Etonox®*, *Etopan®*, *Flancox®*, *Hypen®*, *Lodot®*, *Lonine®*, *Metazin®*, *Sodolac®*, *Todolac®*, *Ultradol®*, and *Zedolac®*.

Storage/Stability

Store the commercially available veterinary tablets at controlled room temperature (15°C to 30°C [59°F to 86°F]).

Store the commercially available injection at or below 25°C (77°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

NOTE: Although etodolac is still listed in FDA's Green Book of approved animal drugs, it is not commercially available in the United States.

Etodolac Scored Tablets: 150 mg, 300 mg and 500 mg; *EtoGesic®*; (Rx). FDA-approved for use in dogs. Do not use in cats. NADA #141-108

Etodolac Injection 10% (100 mg/mL); *EtoGesic® Injectable*; (Rx). FDA-approved for use in dogs. NADA #141-274

HUMAN-LABELED PRODUCTS:

Etodolac Tablets: 400 and 500 mg; extended-release tablets: 400, 500, and 600 mg; capsules: 200 and 300 mg; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Etomidate

(ee-***tom***-i-date) *Amidate®*

Injectable Anesthetic

Prescriber Highlights

- ► Injectable nonbarbiturate anesthetic agent that may be useful as an alternative to alfaxalone or propofol for induction of general anesthesia, particularly in patients with preexisting cardiac dysfunction, or that are critically ill
- ► Can inhibit cortisol production; may need to supplement corticosteroids in critically ill patients
- ► Not a controlled substance
- ► Relatively expensive, especially for large-sized dogs

Uses/Indications

Etomidate may be useful as an alternative to alfaxalone or propofol for anesthetic induction in small animals, particularly in patients with preexisting cardiac dysfunction, or those that are critically ill.

Pharmacology/Actions

Etomidate acts at the GABA receptor in the CNS to increase chloride conductance, causing hyperpolarization of postsynaptic neurons and resulting in hypnosis and CNS depression.[1] Etomidate causes minimal hemodynamic changes and little effect on the cardiovascular system as compared with other injectable anesthetic agents. At clinical doses, etomidate has little effect on respiratory rate or

rhythm.[2] Etomidate decreases cerebral blood flow and oxygen consumption.[2] It usually lowers intraocular pressure (IOP) and causes slight decreases in intracranial pressure[2,3]; however, when combined with other drugs, IOP may increase.[4] Etomidate reportedly does not induce malignant hyperthermia, but can speed its onset in susceptible patients secondary to a triggering agent.[5]

The reported therapeutic index (toxic dose/therapeutic dose) for etomidate is 26.[6] For comparison, therapeutic indexes for propofol and thiopental are ≈3 and 5, respectively.

When comparing etomidate to propofol for inductions in dogs, patients receiving etomidate had higher systolic arterial pressures and mean arterial pressures, but etomidate caused longer and poorer recoveries than propofol.[7]

Pharmacokinetics

No specific information on the pharmacokinetics of etomidate in domesticated animals was located. In humans, after IV injection, etomidate is rapidly distributed into the CNS and then rapidly cleared from the brain back into systemic tissues. Duration of hypnosis is short (3 to 5 minutes) and is dependent on dose. Recovery from anesthesia appears to be as fast as with thiopental, but slower than propofol. Etomidate is 75% bound to plasma proteins. The drug is rapidly metabolized in the liver, primarily via hydrolysis or glucuronidation to inactive metabolites. The majority of the drug and metabolites are excreted into the urine. Elimination half-life ranges from 1.25 to 5 hours.

Contraindications/Precautions/Warnings

Etomidate is contraindicated in patients that are known to be hypersensitive to it.[8]

Etomidate can inhibit adrenocortical function[9–11]; it should not be used for purposes other than induction. Use with caution in patients with impaired adrenocortical function, particularly those with septic shock. Exogenous glucocorticoid administration may be considered in severely compromised animals.

Etomidate does not provide analgesia.[8]

Limited studies in patients with impaired hepatic or renal function have shown that elimination half-lives may be significantly increased in these patients, and the propylene glycol carrier in the injection may be problematic in patients with liver dysfunction.

A study in dogs concluded that etomidate/midazolam induction of anesthesia be used with caution in dogs undergoing ocular surgery, as it caused clinically relevant miosis, significant increases in intraocular pressure (IOP), and commonly caused ptyalism, gagging, and abdominal heaving.[12]

Do not confuse etomidate with etidronate. Etomidate is considered a high-alert medication (medication that requires special safeguards to reduce the risk for errors).[13] Consider instituting practices such as redundant drug dosage and volume checking, and special alert labels.

Adverse Effects

Common adverse effects include pain at IV injection site, phlebitis, vomiting, regurgitation, hypersalivation, skeletal muscle movements (myoclonus), eye movements, apnea, tachypnea, pigmenturia, and postoperative retching.[14,15] Preanesthetic medications administered prior to etomidate can decrease these effects.

Some hemolysis may occur due to the propylene glycol content of the injection, especially in cats.[16] Anecdotally, it may be beneficial to dilute etomidate (eg, inject into a running IV line) to decrease the pain associated with injection and, potentially, reduce hemolysis. Hemoglobinuria and intravascular hemolysis occurred in 2 dogs receiving etomidate infusion.[17]

Although etomidate causes minimal cardiopulmonary depression, a brief period of hypoventilation and decreased arterial blood pressure can occur after administration.

Apnea, laryngospasm, hiccups, hyperventilation, hypoventilation, hypertension, hypotension, lactic acidosis, arrhythmias, and postoperative vomiting have been reported in humans that have received etomidate.[8] Seizures have been reported in a few humans receiving etomidate; this adverse effect may be reduced if an opioid premedication is administered prior to etomidate.

Reproductive/Nursing Safety

Etomidate has caused embryocidal effects in rats and maternal toxicity in rabbits and rats.[8]

Some etomidate is excreted into maternal milk; use with caution in nursing patients.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Acute overdoses would be expected to cause enhanced pharmacologic effects of the drug. Treatment would be supportive (eg, mechanical ventilation), until the effects of the medication are diminished.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving etomidate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **CNS and Respiratory Depressants** (eg, **barbiturates, opiates, anesthetics**): Additive pharmacological effects can occur if etomidate is used concurrently with other drugs that depress CNS or respiratory function.
- **Verapamil**: Has been associated with potentiating the anesthetic and respiratory depressant effects of etomidate

Laboratory Considerations

- The effects of etomidate on inhibiting cortisol may invalidate **ACTH stimulation** and **glucose tolerance** tests. Cortisol function may be affected for 2 to 6 hours in dogs, and up to 5.5 hours in cats after etomidate administration.

Dosages

DOGS & CATS:

Induction agent (extra-label): Dosing recommendations vary somewhat but generally range from 0.5 – 2 mg/kg IV,[7,14,18–23] although dosages up to 4 mg/kg IV have been noted.[23] A suitable premedication is required and can help reduce the incidence and severity of vomiting and myoclonic tremors. A benzodiazepine (eg, midazolam) ± low-dose ketamine administered prior to use can further reduce adverse effects and potentially allow lower etomidate induction dosages of 0.25 – 1 mg/kg.[24] Some clinicians also recommend administering a short-acting IV glucocorticoid to help offset etomidate's effects on cortisol production.

FERRETS:

Induction agent in the cardiovascular unstable patient (extra-label): Etomidate 1 – 2 mg/kg IV after diazepam 0.5 mg/kg IV[25]

SMALL MAMMALS:

Induction agent (extra-label):

a) **Rabbits**: As an induction agent in the cardiovascular unstable patient, etomidate 1 – 2 mg/kg IV after diazepam 0.5 mg/kg IV[25]

b) 1 – 2 mg/kg IV; must use with a benzodiazepine to prevent seizures[26]

Monitoring

- Depth of anesthesia and CNS effects (eg, seizures, paddling,

myoclonus)
- Respiratory depression (eg, respiratory rate, pulse oximetry, end-tidal CO_2 ($ETCO_2$)
- Cardiovascular status (eg, cardiac rate and rhythm; blood pressure)

Client Information
- Etomidate is a potent sedative-hypnotic that should only be used by professionals in a setting where adequate patient monitoring is available.

Chemistry/Synonyms
An injectable, carboxylic imidazole anesthetic, etomidate occurs as a white or almost white powder. It is very slightly soluble in water and freely soluble in alcohol. The commercially available injection has a pH of 8.1, contains 35% propylene glycol, and is hyperosmolar (4640 mosm/L).

Etomidate may also be known as R-16659, *Amidate®*, *Hypnomidate®*, *Radenarcon®*, or *Sibul®*.

Storage/Stability
Unless otherwise labeled, store etomidate injection at room temperature and protected from light.

Compatibility/Compounding Considerations
No specific information was noted.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Etomidate Injection: 2 mg/mL in 10 mL and 20 mL single-dose vials; 10 mL and 20 mL ampules; and 20 mL *Abbojject®* syringes; *Amidate®*; generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Euthanasia Agents with Pentobarbital

(yoo-thon-***ayzh***-ya; pen-toe-***barb***-i-tal) *Beuthanasia-D®*

*See **Pentobarbital** monograph for therapeutic uses (other than euthanasia)*

Prescriber Highlights
- ► Used for humane euthanasia in animals not intended for food purposes
- ► Store product separately and securely so it is not confused with therapeutic agents.
- ► Use care in handling filled syringes; avoid accidental injection and any contact with open wounds. Dispose of used needles and syringes properly.
- ► A sedative, analgesic, and/or anesthetic agent may be required prior to injection with this agent in painful, distressed, or fractious animals.
- ► Minor muscle twitching, agonal breathing, urination, defecation, vocalization, and dysphoria can occur during and after injection.
- ► Pentobarbital is a DEA schedule II (C-II) controlled substance when used as a single agent; pentobarbital with phenytoin is a DEA schedule III (C-III) controlled substance.

Uses/Indications
Euthanasia agents with pentobarbital can be used for rapid, humane euthanasia in animals not intended for food purposes. Individual products may be labeled for use in specific species. Euthanasia induced by pentobarbital occurs rapidly, smoothly, and is relatively painless, particularly when administered IV (preferred).[1] See ***Dosages.***

Pharmacology/Actions
Pentobarbital administered at high doses causes rapid loss of consciousness with simultaneous collapse of the animal. This stage rapidly progresses to deep anesthesia with concomitant reduction in blood pressure. Subsequent depression of the medullary respiratory center terminates breathing; encephalographic activity becomes isoelectric, indicating cerebral death; and then cardiac activity ceases.

Some euthanasia solutions contain phenytoin for its cardiac depressant effects, which hastens cessation of cardiac electrical activity.

Contraindications/Precautions/Warnings
Euthanasia agents with pentobarbital must not be used in animals intended for food purposes (human or animal consumption); care must be taken to prevent scavenging wildlife from consuming carcasses. Contact the US Fish and Wildlife Service for additional advice for prevention of relay pentobarbital toxicity in wildlife.

Use extreme care in handling filled syringes and properly disposing of used injection equipment. Avoid accidental injection and any contact with open wounds.

Death may be delayed in animals with cardiac or circulatory deficiency[2]; death may be delayed or not accomplished if injection is given perivascularly. Prior use of a sedative, analgesic, and/or anesthetic agent may be required in painful, distressed, or fractious animals. Do not combine neuromuscular blockers with pentobarbital-containing injection, as paralysis may occur prior to onset of unconsciousness.[3]

Dosage forms of pentobarbital-containing euthanasia solutions are not indicated or formulated (eg, denatured, nonsterile) for therapeutic use.

Do not confuse PHENObarbital with PENTObarbital.

Adverse Effects
Minor muscle twitching may occur after injection. Reflex responses may cause motor activity to continue; however, the unconscious animal does not experience pain or distress because the cerebral cortex is not functioning. In a study of dogs euthanized with pentobarbital-phenytoin combination,[4] the incidence of muscle activity was 14%. Other reported adverse events included agonal breaths (≈10%), urination (≈8%), vocalization (5%), and dysphoria (4%).[4]

Reproductive/Nursing Safety
Pentobarbital readily crosses the placenta and fetal depression occurs following administration of pentobarbital euthanasia; however, it is not considered a viable method of fetal euthanasia.[1]

Dosages
NOTES:
1. For a thorough discussion of the use of pentobarbital (and other methods) for humane euthanasia in a variety of species, refer to the most recent version of the AVMA Guidelines for the Euthanasia of Animals.[3]
2. Because different products may contain different concentrations of pentobarbital, refer to the specific information provided with the product being used.
3. IV injection is the preferred route for euthanasia of dogs, cats, other small animals, and horses.[3] Intraperitoneal or intracoelomic injection may be used in situations when an IV injection would be distressful, dangerous, or difficult because of small patient size. Administration of pentobarbital via intraorgan routes (eg, intraosseous, intracardiac, intrahepatic, intrarenal) generally should be performed only in unconscious or anesthetized animals.
4. Because of the viscous nature of these compounds, many cli-

nicians dilute the euthanasia solution with commonly used isotonic fluids (eg, lactated Ringer's solution, 0.9% sodium chloride). No studies have confirmed the stability of these dilutions; administration should occur immediately after mixing.

DOGS:

Humane euthanasia:

a) **Pentobarbital with phenytoin** (label dosage; FDA-approved): pentobarbital 390 mg with phenytoin 50 mg (1 mL) for each 4.5 kg (10 lb) of body weight IV[5]

b) **Pentobarbital as a single agent** (label dosage; not FDA-approved): pentobarbital 390 mg (1 mL) for each 4.5 kg (10 lb) of body weight IV[6]

CATS:

Humane euthanasia:

a) **Pentobarbital sodium as a single agent** (label dosage; not FDA-approved): pentobarbital 390 mg (1 mL) for each 4.5 kg (10 lb) of body weight IV[6]

b) **Pentobarbital with phenytoin** (extra-label): pentobarbital 390 mg with phenytoin 50 mg (1 mL) for each 4.5 kg (10 lb) of body weight IV[5]

LARGE ANIMALS:

Humane euthanasia:

a) **Pentobarbital as a single agent** (label-dosage; not FDA-approved): pentobarbital 390 mg [or 6 grains] (1 mL) for each 4.5 kg (10 lb) of body weight IV[6, 7]

b) **Pentobarbital with phenytoin**(extra-label): pentobarbital 390 mg with phenytoin 50 mg (1 mL) for each 4.5 kg (10 lb) of body weight IV.[6] Use of an IV catheter is suggested due to the large volume to be injected.[3] **NOTE**: This drug must not be used in animals to be consumed by humans or other animals.

Monitoring

Verification of death in some species (eg, reptiles, amphibians) can be challenging; species-specific references should be consulted. Using a combination of criteria to confirm death is recommended[1] and may include:

- The absence of respirations and heart sounds
- Graying of mucous membranes
- Fixed, dilated pupils
- Rigor mortis

Client Information

- Administration of euthanasia agents must only be performed by authorized veterinary professionals.
- Clients should be forewarned about the possibility of agonal breathing, muscle twitching, dysphoria during injection, elimination of bodily fluids, and eyes not closing once unconscious. The animal is unconscious and not experiencing any pain during these events.
- Euthanized animals must be properly disposed of (eg, by deep burial; local laws and regulations may apply) to prevent toxicity to scavenging animals that may consume carcass material.

Storage/Stability

Unless stated otherwise on the product label, store pentobarbital euthanasia agents at controlled room temperature of 20°C to 25°C (68°F-77°F) with excursions of 15°C to 30°C (59°F-86°F).

Euthanasia agents with pentobarbital are schedule 2 (C-II) or schedule 3 (C-III) controlled substances that should be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal laws regarding disposal of unused or wasted controlled drugs. Euthanasia agents should be stored separately in a manner that will not be confused with therapeutic agents. Diversion of euthanasia solution for suicide has occurred.[8, 9]

Dosage Forms/Regulatory Status

Information on lower concentration products used therapeutically can be found in ***Pentobarbital***. Pentobarbital-only products have not been approved by the FDA.

VETERINARY-LABELED PRODUCTS:

NOTE: Report dispensing to state monitoring programs as required. Properly dispose of euthanized animals. Renderers may not accept carcasses euthanized with pentobarbital.

Pentobarbital Sodium 390 mg/mL and Phenytoin Sodium 50 mg/mL for Injection (Euthanasia) in 100 mL vials; nonsterile; *Beuthanasia*®-D Special, [5] generic; (Rx, C-III). FDA-approved for use in dogs. NADA #119-807

Pentobarbital Sodium Powder for Reconstitution and Injection: 392 mg/mL when constituted with 250 mL of water; nonsterile; *Fatal-Plus*® *Powder*[10]; (Rx, C-II). Labeled for use in animals regardless of species.

Pentobarbital Sodium for Injection: 390 mg/mL_in 250 mL vials; nonsterile; *Socumb*®[7]; *Fatal-Plus*® *Solution*[6]; (Rx, C-II). Some products labeled for use in animals regardless of species.

HUMAN-LABELED PRODUCTS: NONE

Exenatide

(ex-***en***-a-tide) *Bydureon*®*, Byetta*®

Glucagon-like Peptide-1 (GLP-1) Receptor Agonist

Prescriber Highlights

- ► An incretin mimetic that is administered SC for adjunctive management of diabetes mellitus in cats
- ► Exenatide is NOT an insulin substitute and cannot be used to treat diabetic ketoacidosis; it should not be used as monotherapy to manage type 1 diabetes mellitus.
- ► Contraindications include hypersensitivity, severe GI disease, severe or end-stage renal disease, medullary thyroid carcinoma, and multiple endocrine neoplasia syndrome type 2.
- ► Use with caution in patients with impaired renal function or history of renal transplant, history of pancreatitis, or drug-induced immune-mediated thrombocytopenia (DIIMT); occurrence of pancreatitis or DIIMT precludes further exenatide use.
- ► Adverse effects include nausea, vomiting, diarrhea, anorexia, and weight loss. Hypoglycemia is unlikely unless exenatide is used in conjunction with other hypoglycemic agents (eg, insulin).
- ► The National Institute for Occupational Safety and Health (NIOSH) has determined that exenatide meets the definition of a hazardous drug; use appropriate precautions when handling.
- ► Obtaining doses for cats from exenatide formulations intended for use in humans may prove challenging.
- ► Exenatide immediate-release (IR) solution is not interchangeable with exenatide extended-release (ER) formulation.

Uses/Indications

Exenatide is used for the adjunctive treatment of uncomplicated diabetes mellitus in cats. In studies using exenatide immediate-release (IR) solution, median or average changes in study parameters (eg, fasting blood glucose, insulin concentration) in obese or diabetic cats were not significant but tended toward improvement, and positive responses were apparent in individual cats.[1,2] When exenatide

extended-release (ER) was administered with glargine insulin to newly diagnosed diabetic cats, glucose variability was reduced, and remission rates and metabolic control appeared improved compared with cats that received only glargine; however, these results were significant only at interim study analyses, and were not statistically different from placebo at the study conclusion.[3,4]

Pharmacology/Actions

Exenatide is an incretin mimetic. As a glucagon-like peptide-1 (GLP-1)–receptor agonist, exenatide augments glucose-dependent insulin synthesis and secretion, enhances pancreatic endocrine beta-cell proliferation and survival, and inhibits glucagon secretion (without impeding glucagon secretion in response to hypoglycemia).[5] The drug improves insulin sensitivity in muscles and reduces hepatic gluconeogenesis.[6] Exenatide efficacy depends on an adequate mass of functional pancreatic endocrine beta cells.[7] Because exenatide amplifies the insulin response to food within the lumen of the GI tract, the risk for hypoglycemia is low.

Exenatide immediate-release (IR) was administered to healthy cats and increased insulin secretion in response to glucose,[8–10] and one study noted variable effects on glucagon secretion.[10] No significant changes in glucose, insulin, or glucagon concentrations were observed in obese[1] or diabetic[2] cats.

In healthy cats that received exenatide extended-release (ER), fasting blood glucose and glucagon concentration were reduced, and insulin secretion increased (including first-phase insulin response).[10,11] After a single dose of exenatide ER, readings from continuous glucose monitors were below baseline at 2 and 6 weeks after injection.[11] However, studies returned conflicting results for glucose, insulin, and glucagon responses to meals.[10,11] At the time of writing, no publications describing the effects of exenatide ER on glucose, insulin, or glucagon concentrations in diabetic cats were located.

GLP-1 activity in the CNS may help regulate satiety.[6] In the GI tract, GLP-1 agonists delay gastric emptying and reduce GI motility, an effect that may help attenuate postprandial hyperglycemia.[6] Exenatide delays gastric emptying in cats,[12] and has resulted in colic in alpacas.[13,14]

Pharmacokinetics

Exenatide concentration peaked 45 minutes after SC administration of exenatide immediate-release (IR) to healthy fasted cats and was no longer significantly different from baseline after 90 minutes.[8]

Exenatide extended-release (ER) formulation was administered to healthy cats and resulted in measurable exenatide concentrations after 15 minutes. An initial peak exenatide concentration was noted after 1 hour; a second, higher peak occurred 4 weeks after injection. Exenatide concentration was no longer significantly different from baseline 6 weeks after injection.[11]

In humans, exenatide is renally eliminated, undergoing glomerular filtration and proteolytic degradation. The half-life of exenatide IR solution is 2.4 hours,[5] whereas the ER formulation has a half-life of ≈14 days. Unlike endogenous glucagon-like peptide-1 (GLP-1), dipeptidyl peptidase-4 (DPP-4) is not involved in exenatide metabolism.

Contraindications/Precautions/Warnings

Exenatide is NOT an insulin substitute and cannot be used to treat diabetic ketoacidosis; it should not be used as monotherapy for treatment of type 1 diabetes mellitus. Because exenatide use in cats is emerging, the safety profile is still being studied; current information for use in cats is limited to small sample-size studies and extrapolation from known human information.

Exenatide is contraindicated in patients with known hypersensitivity to it or any components of the formulation. Exenatide extended-release (ER) is contraindicated for use in humans with medullary thyroid carcinoma or multiple endocrine neoplasia syndrome type 2.[15] In humans, exenatide immediate-release (IR) should not be used in patients with severe GI disease (eg, gastroparesis, inflammatory bowel disease), or with severe or end-stage renal disease.[5] In humans, development of either pancreatitis or drug-induced immune-mediated thrombocytopenia is considered a contraindication to continued exenatide use.[5,15] Pancreatitis is more likely to occur in humans with concurrent risk factors (eg, cholelithiasis, hypertriglyceridemia).

Acute kidney injury has occurred in humans taking exenatide.[5,15] The drug should be used with caution in patients with impaired renal function or in renal transplant recipients.

Absorption of orally administered medication may be impacted (eg, delayed time to peak concentration) as exenatide may slow GI transit times. Orally administered medication should be administered at least one hour prior to exenatide administration.

Exenatide ER caused dose- and duration-dependent thyroid C-cell tumors in rats.[15] The National Institute for Occupational Safety and Health (NIOSH) has determined this carcinogenicity meets the definition of a hazardous drug, and personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Exenatide may cause adverse GI effects (eg, diarrhea, vomiting, anorexia) in cats; obese cats had a reduced appetite, as noted by owners using a 5-point assessment scale.[1] Weight loss (≈0.7 kg[1.5 lb]) has been documented in healthy,[9] obese,[1] and diabetic[2] cats that have received exenatide immediate-release (IR); however, when exenatide extended-release (ER) was administered with glargine insulin to newly diagnosed diabetic cats, it had a variable effect on weight and no effect on body condition score.[3] Although subclinical hypoglycemia occurred in 63% of diabetic cats that were treated with exenatide IR and glargine insulin,[2] hypoglycemia rates were similar in diabetic cats that received either glargine insulin alone or in combination with exenatide ER.[3]

Injection site reactions are common in humans but have not been reported in cats with either exenatide formulation.[2,3,8,11,16] Increased aggression during injection of exenatide IR was noted in one study of obese cats,[1] and increased sleeping and hiding in dark places were noted in newly diagnosed diabetic cats treated with exenatide ER and glargine insulin.[3] Exenatide-induced pancreatitis or increased feline pancreatic lipase has not been identified in cats, although the number of cats with exposure to exenatide formulations remains small.

In humans, severe hypersensitivity reactions (eg, angioedema and anaphylaxis) are rare, whereas less severe reactions (eg, rash, urticaria, pruritus) are more common.[5] Antibodies to exenatide developed in 44% to 49% of patients who were treated with either exenatide formulation.[5,15] In most of the patients, antibodies occurred at low levels and did not impact glycemic control; however, 6% of patients had high antibody titers associated with an attenuated glycemic response.

Reproductive/Nursing Safety

Exenatide is unlikely to cross the placenta.[17] However, administration of high doses (12 to 390 times the recommended human dose) of exenatide immediate-release (IR) to pregnant mice and rabbits during periods of fetal organogenesis resulted in skeletal abnormalities, cleft palate, and reduced fetal and neonatal growth. Neonatal deaths were observed in mice receiving 6 µg/kg/day (≈3 times the recommended human dose).[5] Exenatide extended-release (ER) administered to rats during organogenesis reduced fetal growth and delayed fetal ossification.[15]

Exenatide is excreted in the maternal milk of mice with concentrations in milk 2.5% that of maternal plasma.[5] Because exenatide is not orally absorbed, the risk to nursing offspring is likely negligible.[17]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

An overdose of exenatide may result in severe nausea, vomiting, and hypoglycemia. Based on pharmacokinetic data,[8,11] clinical signs caused by overdoses of exenatide immediate-release (IR) would be expected to be short-lived, whereas overdoses of exenatide extended-release (ER) could have effects for many weeks. Patients should be treated supportively based on clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving exenatide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, propranolol**): Can have variable effects on glycemic control and can mask the signs associated with hypoglycemia
- **Clonidine**: Can mask the signs associated with hypoglycemia
- **Digoxin**: Peak concentration may be delayed and reduced but overall steady-state digoxin exposure (AUC) is unchanged.[5]
- **Orally Administered Medications**: By slowing gastric emptying, exenatide may change the rate and extent of absorption of all concomitantly administered oral medications. Oral medications should be administered at least 1 hour prior to exenatide.
- **Reserpine**: Can mask the signs associated with hypoglycemia
- **Warfarin**: Concurrent use may prolong prothrombin time.

The following drugs or drug classes may potentiate exenatide hypoglycemic activity:

- **Anabolic Steroids** (eg, **boldenone, stanozolol, testosterone**)
- **Angiotensin II Receptor Blockers** (**ARBs**; eg, **telmisartan**)
- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril, enalapril**)
- **Disopyramide**
- **Fenofibrate**
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin, pradofloxacin**)
- **Fluoxetine**
- **Hypoglycemics, Oral** (eg, **acarbose, glipizide, metformin**)
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**)
- **Pentoxifylline**
- **Salicylates** (eg, **aspirin, bismuth subsalicylate**)
- **Somatostatin Derivatives** (eg, **octreotide**)
- **Sulfonamides** (eg, **sulfadimethoxine, sulfamethoxazole**)

The following drugs or drug classes may diminish exenatide hypoglycemic activity:

- **Alpha-2-Adrenergic Receptor Agonists** (eg, **dexmedetomidine, xylazine**): May cause hyperglycemia and temporarily interfere with glycemic control
- **Beta-Adrenergic Receptor Agonists** (eg, **albuterol, terbutaline**)
- **Corticosteroids** (eg, **dexamethasone, prednis[ol]one**)
- **Cyclosporine**
- **Danazol**
- **Diazoxide**
- **Diuretics** (eg, **furosemide, hydrochlorothiazide**)
- **Estrogens** (eg, **diethylstilbestrol [DES], estriol**)
- **Isoniazid**
- **Leuprolide**
- **Niacin**
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**)
- **Progestins** (eg, **megestrol**)
- **Sympathomimetic Agents** (eg, **epinephrine**, **phenylpropanolamine**)
- **Thyroid Hormones**: Can elevate blood glucose levels in diabetic patients when thyroid hormone therapy is first initiated

Laboratory Considerations

- None noted

Dosages

NOTE: Exenatide immediate-release (IR) and exenatide extended-release (ER) are NOT interchangeable.

CATS:

Adjunctive therapy for diabetes mellitus (extra-label):

- Using exenatide IR: 1 µg/kg SC twice daily in combination with twice-daily glargine insulin and a low-carbohydrate diet.[2] Administer *before* feeding; do not administer after a meal. Injecting exenatide into the same body region as insulin injection is acceptable as long as injection sites are not adjacent (ie, separate injections by 1 inch or more if possible[18]). Glargine dose reduction of 25% to 50% was required in some cats.
- Using exenatide ER: 200 µg/kg SC every 7 days in combination with twice-daily glargine insulin and a low-carbohydrate diet[3]

Monitoring

The overarching goal when monitoring diabetic patients is control of clinical signs related to hyperglycemia (eg, polyuria, polydipsia) while avoiding hypoglycemia.[19] All monitoring strategies should be interpreted based on clinical signs. Results from the monitoring options listed below may conflict in regard to achieving good glycemic and clinical control. Diabetic patients should be closely monitored.

- Patient status and control of clinical signs: Body weight, appetite, fluid intake, urine output
- Blood glucose curve. It is encouraged to refer to additional information on regulating diabetic patients and insulin adjustments. Flash glucose monitoring systems (eg, *FreeStyle Libre* system) are easy to apply, are user-friendly, and provide useful information surrounding glycemic control when the patient is in the hospital or home environment.[20–23] A blood glucose curve can be considered at the following times[19]:
  - After the first dose of a new insulin type
  - 7 to 14 days after starting insulin or an insulin dose change
  - At least every 3 months, even in animals with well-controlled diabetes
  - Any time clinical signs recur in an animal with previously well-controlled diabetes
  - When hypoglycemia is suspected
- Urine glucose monitoring is typically only helpful for documenting prolonged hypoglycemia (eg, persistently negative urine glucose testing when monitoring for diabetic remission in cats). Because most diabetic patients spend time above the renal threshold for urinary glucose spillage, even patients with well-controlled diabetes may be intermittently glucosuric throughout the day.
- Fructosamine or glycosylated hemoglobin can be measured if

available and warranted.
- Pancreatitis, acute kidney injury, and drug-induced immune-mediated thrombocytopenia (DIIMT) are uncommon but significant concerns in humans. It is recommended to monitor feline pancreatic lipase immunoreactivity (fPLI) concentration, BUN, creatinine, and CBC with platelet count.
- Injection sites, for local reactions
- As exenatide may slow GI transit and alter oral drug absorption, response to orally administered medication should be monitored closely for intended effect.
- For patients that have experienced or are suspected to have experienced repeated or unexplained hypoglycemia, it is strongly encouraged to consult with a veterinary emergency and critical care and/or endocrinology specialist or reference text that specializes in providing information specific for treatment of hypoglycemia.

Client Information

- Exenatide is administered by injection under the skin (subcutaneous). Your veterinarian should demonstrate and allow practice of correct injection techniques.
- Always double-check the dose in the syringe before you inject your animal.
- The injection site should be frequently changed, with the main sites being the back of the neck or shoulder area.
- Nausea, vomiting, and lack of appetite are common side effects. Report significant or prolonged changes in appetite, abnormal feces, or weight loss to your veterinarian.
- This medication requires frequent monitoring by your veterinarian, including blood work. Do not miss these important follow-up visits.
- When using exenatide immediate-release (IR) solution:
  - The pen device requires priming before the first use.
  - The needle must be removed before storing to prevent leakage.
  - Store refrigerated until first use; once in use, it may be stored in the refrigerator or at room temperature. Discard 30 days after first use.
  - Do not freeze; the drug must be discarded if it freezes.
  - Missed doses should be omitted, and the next dose resumed at the scheduled time.
- When using exenatide extended-release (ER) solution:
  - Store refrigerated until ready to use; allow it to come to room temperature prior to injection. Exenatide ER may be stored at room temperature for up to 4 weeks. Do not freeze; the drug must be discarded if it freezes.
  - Wear gloves and eye protection when preparing and administering. Wash hands thoroughly after administration.
  - Vials are single-use only and any unused portion must be discarded.
- Use a new needle for each dose. Place used needles and syringes in a puncture-resistant ("sharps") disposal container immediately after use, making sure you do not attempt to disconnect the needle from the syringe or recap the needle. Your veterinarian or pharmacist can help you obtain these containers.
- This medicine is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Exenatide is a synthetic 39-amino-acid protein originally identified in the saliva of the Gila monster (*Heloderma suspectum*). It has a molecular weight of 4187. The amino acid sequence has 53% similarity to mammalian glucagon-like peptide-1 (GLP-1). Exenatide immediate-release (IR) is clear and colorless with a pH of 4.5. Exenatide extended-release (ER) contains exenatide incorporated into a microsphere polymer formulation that appears as a white to off-white powder and requires reconstitution with the manufacturer-provided diluent. After reconstitution, exenatide ER is cloudy and white to off-white.

Exenatide may also be known as AC 2993, LY2148568, exendin-4, *Bydureon*®, and *Byetta*®.

Storage/Stability

Store all unused exenatide products refrigerated at 2°C to 8°C (36°F-46°F). Protect from light and freezing; discard exenatide if it has been frozen.

After first use, store exenatide immediate-release (IR) between 2°C and 25°C (36°F-77°F); do not store pen device with a needle attached as the solution may leak from the device and air bubbles may form. The manufacturer states that exenatide IR is to be discarded 30 days after first use.

Exenatide extended-release (ER) may be stored unmixed at room temperature for no more than 4 weeks. Once reconstituted, it must be administered immediately.

Compatibility/Compounding Considerations

Do not mix exenatide immediate-release (IR) with insulin.[5]

Studies have described dilution of exenatide IR with saline or with a diluent composed of the same excipients as commercial exenatide solution.[1,9] Despite plasma exenatide being measurable in the participants of one study,[1] dilution of exenatide IR is not recommended as potency and stability were not assessed. Exenatide IR was diluted 1:10 using a diluent composed of the same excipients as commercial exenatide solution and stored at room temperature for a maximum of 30 days.[1] Despite plasma exenatide being measurable in the study participants,[1] dilution of exenatide IR is not recommended as potency and stability analyses were not performed. Another study used a 1:10 to 1:100 dilution of exenatide IR with 0.9% sodium chloride, which was mixed prior to each dose (dilution technique and storage [if any] was not described).[9]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Exenatide Immediate-Release (IR) Injection: 250 µg/mL in prefilled pens that deliver 60 doses of either 5 µg (1.2 mL total) or 10 µg (2.4 mL total); *Byetta*®; (Rx)

Needles for pen device are sold separately.

Exenatide Extended-Release (ER) Injection: 2 mg single-dose vial in a kit with a prefilled syringe containing 0.65 mL diluent, a vial connector, and custom needles specific to the delivery system; 4 vial-diluent pairs per unit; *Bydureon*®; (Rx). It is also available as a pen device containing 2 mg exenatide and 0.65 mL diluent in separate compartments, and as an autoinjector (*Bydureon*® *BCise*); however, these presentations are not practical for feline dosages.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Famciclovir

(fam-***sye-kloe***-veer) *Famvir®*

Antiviral (Herpes)

Prescriber Highlights

- ► May be effective in treating feline herpes (FHV-1) infections and equine herpesvirus myeloencephalopathy (EHM). Dosage recommendations still in flux
- ► Appears to be well tolerated when used short-term (2 to 3 weeks)
- ► May administer without regard to meals
- ► Dosage reduction recommended for human patients with renal impairment; veterinary significance is uncertain

Uses/Indications

Famciclovir improved clinical signs and reduced viral shedding in cats experimentally infected with herpesvirus type 1 (FHV-1),[1] and in a retrospective case series of cats with naturally occurring FHV-1, 85% of owners reported improved clinical signs.[2] However, in shelter cats neither a single dose[3] nor a 7-day course of famciclovir[4] improved clinical signs following shelter admission, but the 7-day treatment reduced conjunctival FHV-1 shedding.[4]

Famciclovir may also prove beneficial in horses with equine herpesvirus-1 (EHV-1) myeloencephalopathy, but additional research is needed before it can be confidently recommended.

Pharmacology/Actions

In most species, famciclovir is rapidly converted in vivo to penciclovir. In cells infected with susceptible herpesvirus or varicella zoster virus, viral thymidine kinase phosphorylates penciclovir to penciclovir monophosphate. Cellular kinases further convert penciclovir monophosphate to penciclovir triphosphate, which inhibits herpesvirus DNA polymerase via competition with deoxyguanosine triphosphate, thereby selectively inhibiting viral DNA synthesis. Famciclovir is considered a virostatic agent and therefore does not affect latent virus and doesn't necessarily clear the virus.

Viral resistance can occur by mutation of viral thymidine kinase or DNA polymerase.

Pharmacokinetics

Famciclovir is deacetylated in the intestinal wall and blood and then oxidized via aldehyde oxidase in the liver to the active compound, penciclovir. Although deacetylation occurs rapidly and completely, cats are deficient in aldehyde oxidase and extrapolating pharmacokinetic data from other species to cats is not reliable because of this. Pharmacokinetics are non-linear in cats probably due to saturation of biotransformation enzymatic systems.[5]

Oral administration of 40 mg/kg or 90 mg/kg famciclovir to cats demonstrated variable famciclovir absorption and low bioavailability of penciclovir (7%-13%).[6] Food may reduce oral bioavailability. Both dosages had similar peak concentrations of penciclovir (C_{max}, ≈1.3 µg/mL) and peak times (T_{max}, 3 hours). Penciclovir elimination half-life was between 4 and 5 hours at both doses. Penciclovir administered IV demonstrated a volume of distribution that approximated the total body water of cats.[6]

In another pharmacokinetic study in cats given 40 mg/kg and 90 mg/kg oral doses, plasma penciclovir C_{max} was 2 µg/mL and 2.7 µg/mL respectively and elimination half-life was ≈4 to 5 hours at both doses.[5] Penciclovir concentration in tears was significantly higher with 90 mg/kg dosages, and C_{max} in tears was ≈25% that of plasma.

In horses, after oral famciclovir doses of 20 mg/kg, peak plasma penciclovir concentrations occurred ≈1 hour after dosing with peak concentrations of ≈3 µg/mL. Elimination was biphasic with a slow terminal half-life of ≈33 hours.[7]

In humans, famciclovir is well absorbed after oral administration, but undergoes extensive first-pass metabolism (not by CYP enzymes). Food can decrease peak concentrations but does not significantly impact clinical efficacy. Penciclovir is only marginally bound to plasma proteins. In humans, penciclovir elimination half-life is ≈2 to 3 hours; excretion is primarily via renal mechanisms. Intracellular half-lives of penciclovir in infected cells are significantly longer.

Contraindications/Precautions/Warnings

Famciclovir is contraindicated in patients known to be hypersensitive to it or penciclovir.

It should be used with caution (and dosage adjustment) in patients with renal dysfunction. Dosage adjustments are recommended in human patients with creatinine clearance less than 60 mL/min; significance in veterinary species is unclear.

Do not confuse famciclovir with acyclovir.

Adverse Effects

One study[2] noted adverse effects in 17% of cats receiving famciclovir, including diarrhea (7%), polydipsia (5%), weight loss (1.7%), vomiting (1.7%), and hiding behavior (1.7%). Urethral obstruction occurred in one cat receiving 90 mg/kg every 8 hours for 3 days, but the investigators determined the obstruction was not caused by famciclovir.[5]

In a small (n = 4) pharmacokinetic study in horses, adverse effects were not observed following a single oral dose of 20 mg/kg.[7]

In humans, famciclovir can cause nausea, vomiting, diarrhea, pruritus, and headache. Neutropenia, electrolyte disturbances, and increased liver transaminases have been reported and renal failure can occur, particularly when doses are not adjusted in patients with renal dysfunction.

Reproductive/Nursing Safety

In laboratory animals, doses up to 1000 mg/kg/day did not cause any observed effects on developing embryos or fetuses.[8] Dose-related testicular toxicity (reduced and abnormal sperm, seminiferous tubule atrophy) and reduced male fertility was observed in laboratory animals; no effect on females was observed.

Famciclovir (as penciclovir) is excreted in the milk of rats at concentrations 8 times higher than in plasma. Recommendations for humans is to avoid famciclovir use in nursing mothers.[9]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Little information is available. Supportive treatment has been recommended. Penciclovir can be removed by hemodialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to the ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving famciclovir and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Probenecid**: Can reduce the amount of penciclovir excreted by the kidneys and increase penciclovir plasma concentrations

Laboratory Considerations

- No specific information found.

Dosages

CATS:

Feline herpesvirus type 1 (FHV-1; extra-label): 90 mg/kg PO every 12 hours may be most reliable at achieving therapeutic active metabolite (penciclovir) concentrations in the superficial cornea; dosages ranging from 30 – 90 mg/kg PO every 8 to 12 hours have been studied.[2,4-6,10,11] Treatment duration recommendations can vary somewhat with 2 to 4 week durations often suggested. Kittens (at least 5 days old) may only require treatment for 2 weeks. Available human oral dosage forms may limit options for doses that can be practically administered. Treatment with famciclovir may preclude the need for topical ocular antiviral medications; however, other topical drugs such as an antibacterial agents or mucinomimetic artificial tear replacement may be critical.[12]

Monitoring

- Clinical efficacy
- Adverse effects most frequently seen in cats include diarrhea, polydipsia, inappetence, and vomiting.
- Baseline CBC, electrolytes, and renal panel with periodic recheck examinations if the drug is being administered chronically

Client Information

- Medicine used to control, but not cure, herpesvirus infections in cats
- Try giving medicine without food, but if your cat vomits or acts sick after getting the medicine, give with a small amount of food. Because there is limited experience with this medicine in veterinary medicine, be sure to report any concerns about your cat to your veterinarian while your cat is taking it.
- Usually well tolerated.

Chemistry/Synonyms

A prodrug, famciclovir is a purine-derived, synthetic, acyclic purine nucleoside analogue. It is white to pale-yellow solid, freely soluble in acetone and methanol, and sparingly soluble in ethanol and isopropanol. At 25°C famciclovir is freely soluble (greater than 25% w/v) in water initially, but rapidly precipitates.

Famciclovir may also be known as AV 42810, BRL 42810, famciclovirum, or by the trade name *Famvir®*.

Storage/Stability

Famciclovir tablets should be stored at room temperature (20°C-25°C [68°F-77°F]) in an airtight, light-resistant container.

Compatibility/Compounding Considerations

The film-coated tablets may be split.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Famciclovir Oral Tablets (film-coated): 125 mg, 250 mg, and 500 mg; *Famvir®*, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Famotidine

(fa-***moe***-ti-deen) *Pepcid®*

H_2-Receptor Antagonist

Prescriber Highlights

- Used to reduce gastric acid production. Studies in dogs and cats suggest omeprazole is superior to famotidine for increasing gastric pH.
- Longer duration of action and fewer drug interactions than cimetidine
- Adverse effects include possible bradycardia with rapid IV infusion. Potential for GI effects or dry mouth or skin; rare idiopathic intravascular hemolysis anecdotally reported when given IV to cats

Uses/Indications

Famotidine may be useful for the treatment and/or routine prophylaxis of gastric, abomasal, and duodenal ulcers; stress-related or drug-induced erosive gastritis; esophagitis; duodenal gastric reflux; and esophageal reflux. However, oral omeprazole provided superior gastric acid suppression as compared with oral famotidine,[1] and omeprazole was also deemed superior to famotidine when used to prevent exercise-induced gastritis in racing Alaskan sled dogs.[2] Coadministration of famotidine and pantoprazole in dogs was not superior to pantoprazole alone for increasing intragastric pH, so combining these drugs is likely not necessary.[3] A recent study reported diminished effect on intragastric pH in dogs when oral famotidine 1 mg/kg was repeatedly administered every 12 hours for 14 days.[4]

Famotidine could be considered for immediate relief of signs when used on an as needed basis, and when used in the short term (eg, prevention of esophageal reflux under anesthesia[5,6]).[7]

In dogs, famotidine did not improve outcomes (eradication) of *Helicobacter* spp infections when added to triple antibiotic therapy.[8]

When famotidine was administered to cats for 14 days, a diminished effect on intragastric pH was observed, indicating decreased effectiveness with prolonged administration.[9]

In cattle, famotidine significantly increased the pH of abomasal outflow fluid for up to 4 hours after a single dose. When famotidine was administered every 8 hours for 3 doses, tachyphylaxis appeared to occur, as the duration of increased pH progressively diminished after each dose. The total time of increased pH was ≈7 hours (30% of a 24 hour period).[10]

Pharmacology/Actions

At the H_2 receptors of the parietal cells, famotidine competitively inhibits histamine, thereby reducing gastric acid output, both during basal conditions and when stimulated by food, pentagastrin, histamine, or insulin. Gastric emptying time, pancreatic or biliary secretion, and lower esophageal pressures are not altered by famotidine. By decreasing the amount of gastric juice produced, H_2 blockers reduce the amount of pepsin secreted. Famotidine leads to transient increases in serum gastrin, which returns to baseline concentrations a week after discontinuation.[11]

Pharmacokinetics

Famotidine is not completely absorbed after oral administration but undergoes minimal first-pass metabolism. In humans, systemic bioavailability is ≈40% to 50%. Distribution characteristics are not well described. In rats, only ≈15% to 20% is bound to plasma proteins; the drug does not cross the blood–brain barrier or the placenta. When the drug is administered orally, ≈⅓ is excreted unchanged in the urine, and the remainder is primarily metabolized in the liver and then excreted in the urine. After IV dosing, ≈⅔ is excreted unchanged.

The pharmacokinetics of famotidine, ranitidine, and cimetidine have been investigated in horses.[12] After administration of a single IV dose, elimination half-lives of famotidine, ranitidine, and cimetidine ranged from 2 to 3 hours and were not significantly different. Bioavailability of each of the drugs was low in horses (ie, famotidine, 13%; ranitidine, 13.5%; cimetidine, 30%).

After administration of a single famotidine dose (0.4 mg/kg IV) to adult steers, the half-life was 3.33 hours.[10]

Contraindications/Precautions/Warnings

Famotidine is contraindicated in patients with known hypersensitivity to the drug.

Consider dosage reduction in patients with significant renal dysfunction.

Do not confuse famotidine with fluoxetine or furosemide.

Adverse Effects

Rapid IV infusion may cause bradycardia. H_2 blockers have been demonstrated to be relatively safe and exhibit minimal adverse effects. In humans, agranulocytosis, pancytopenia, and leukopenia have been rarely reported.[13,14] Other reported rare to infrequent adverse effects in humans include fever, fatigue, vomiting, nausea, headache, dizziness, constipation, diarrhea, abdominal discomfort, arrhythmias, hypotension, AV block, elevated liver enzymes, elevated bilirubin, hypersensitivity skin reactions, and CNS signs (confusion, agitation).

There have been rare anecdotal reports of famotidine causing intravascular hemolysis when given IV to cats. A retrospective study evaluating IV famotidine in 56 hospitalized cats did not show any evidence of hemolysis. The authors concluded that IV famotidine appeared safe in cats when administered over 5 minutes.[15]

Reproductive/Nursing Safety

In laboratory animal studies, famotidine demonstrated no detectable harm to offspring.[13,14] Large doses could affect the mother's food intake and weight gain during pregnancy, which could indirectly be harmful to developing fetuses.

Famotidine enters into milk. It is unclear if there is any clinical significance for nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The minimum acute lethal dose in dogs is reported to be more than 2 g/kg for oral doses and ≈300 mg/kg for IV doses.[13,14] In dogs, IV doses of 5 – 200 mg/kg caused vomiting, restlessness, mucous membrane pallor, and redness of the mouth and ears. Higher doses caused hypotension, tachycardia, and collapse.

Because of the wide margin of safety associated with the drug, most overdoses should require only monitoring. In massive oral overdoses, gut-emptying protocols should be considered, and supportive therapy should be initiated when warranted.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Unlike cimetidine or ranitidine, famotidine does not appear to inhibit hepatic cytochrome P450 enzyme systems, and dosage adjustments of other drugs (eg, warfarin, theophylline, diazepam, procainamide) that are metabolized by these metabolic pathways are usually not required.

The following drug interactions have either been reported or are theoretical in humans or animals receiving famotidine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): By increasing gastric pH, famotidine may decrease the absorption of these agents; if both drugs are required, the azole should be administered 1 hour before famotidine.
- **Cefpodoxime, Cefuroxime**: Famotidine may decrease the absorption of these cephalosporins; separating doses by 2 hours may alleviate this effect.
- **Dichlorphenamide**: Increased famotidine exposure may occur.
- **Iron Salts, Oral**: Famotidine may decrease the absorption of oral iron; iron should be administered at least 1 hour before famotidine.

Laboratory Considerations

- H_2 blockers may antagonize the effects of **histamine** and **pentagastrin** in the evaluation of gastric acid secretion.
- A study in dogs showed that famotidine only had transient effects on **serum gastrin** concentrations. The authors concluded that in dogs with clinical features consistent with gastrinomas, chronic famotidine administration would likely not contribute to increases in serum gastrin concentration.[16]
- After use of allergen extract **skin tests**, H_2 antagonists may inhibit histamine responses. It is recommended that H_2 blockers be discontinued at least 24 hours before these tests are performed.

Dosages

DOGS & CATS:

Reduce gastric acid production (extra-label):

a) 1 mg/kg IV slowly (over at least 5 minutes) as a loading dose followed by 8 mg/kg/day IV as a CRI may provide the best antacid efficacy in dogs.[17,18]

b) 1 mg/kg PO, SC, or IV (slowly over at least 5 minutes) every 12 hours. Rounding oral doses up to the nearest 5 mg increment (eg, 5 mg/cat [NOT mg/kg]) is reasonable. Once daily administration should be considered in patients with significantly diminished renal function.

HORSES:

Adjunct in ulcer treatment (extra-label): 0.23 mg/kg IV every 8 hours or 0.35 mg/kg IV every 12 hours; 1.88 mg/kg PO every 8 hours or 2.8 mg/kg PO every 12 hours[12]

CATTLE:

Reduce gastric acid production (extra-label): From a pharmacokinetic study in 4 adult steers: 0.4 mg/kg IV every 8 hours for 3 doses increased abomasal outflow fluid pH for 3 hours, 2 hours, and 1 hour after each respective dose.[10] Further studies are needed to support clinical efficacy.

FERRETS:

Stress-induced ulcers (extra-label): 0.25 – 0.5 mg/kg PO or IV every 24 hours[19]

In combination with antibiotics for *Helicobacter* spp treatment (extra-label): 0.25 – 0.5 mg/kg PO or IV every 24 hours[20]

SMALL MAMMALS:

Rabbits: **Stress-induced ulcer prevention once critically ill animal has stabilized** (extra-label): 1 mg/kg IV every 24 hours[21]

Monitoring

- Clinical efficacy (dependent on reason for use); monitored by decrease in signs, endoscopic examination, blood in feces
- Adverse effects, if noted

Client Information

- This medicine is used to treat or prevent stomach ulcers. Give this medicine as directed by your veterinarian. Clinical signs may recur if doses are missed.
- This medicine works best if given before the first meal of the day. If your animal vomits or appears sick after giving this medicine on an empty stomach, give it with food or a small treat. If vomiting continues, contact your veterinarian.
- Famotidine is available over the counter (ie, without a prescription), but you should only give it to your animal if your veterinarian recommends its use.

Chemistry/Synonyms

Famotidine is an H_2-receptor antagonist. It occurs as a white to pale yellow crystalline powder and is odorless but has a bitter taste. 740 µg are soluble in 1 mL of water.

Famotidine may also be known as famotidinum, L-643341, MK-208, and YM-11170; many trade names are available.

Storage/Stability

Tablets should be stored in well-closed, light-resistant containers at room temperature (20°C-25°C [68°F-77°F]).[14]

The oral suspension dry powder and suspension should be stored in well-closed, light-resistant containers at 25°C (77°F); excursions permitted to 15°C to 30°C (59°F-86°F). After reconstitution, the resultant suspension is stable for 30 days when stored at temperatures below 30°C (86°F); do not freeze.

Famotidine injection should be stored in the refrigerator at 2°C to 8°C (36°F-46°F).[13]

Compatibility/Compounding Considerations

Commercially available famotidine tablets can be split or crushed but have a bitter taste.

Famotidine for injection is physically **compatible** with most commonly used IV infusion solutions and is stable for 48 hours at room temperature when diluted in these solutions.

Compounded preparation stability: Famotidine oral suspension compounded from commercially available tablets has been published.[22] Triturating 24 famotidine 40 mg tablets with 60 mL of *Ora-Plus®* and qs ad to 120 mL with *Ora-Sweet®* (or *Ora-Sweet® SF*) brought to a favorable pH of 5.8 yields an 8 mg/mL oral suspension that retains more than 90% potency for 95 days when stored at 25°C (77°F). Famotidine is stable in buffered solutions at a pH of 4 to 6, but rapid and extensive drug degradation occurs at a pH less than 2.

Another recipe to make a 4 mg/mL flavored, oral aqueous-based suspension from 10 mg tablets: To make a 30 mL suspension: Pulverize twelve (12) 10 mg tablets (0.12 g; 120 mg) to a fine powder in a mortar and pestle. Wet with glycerin (1 – 2 mL) to make a thick paste. Add up to 1 mL of a water-soluble flavoring agent. Add enough oral suspending vehicle (OSV; eg, *Ora-Plus®*, *Ora-Sweet®*) and mix to allow transfer to an amber prescription bottle. This process may need to be repeated several times to wash the mortar; qs ad to 30 mL with additional OSV. Shake well before use; store in the refrigerator and dispose of any unused amount after 30 days.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 5 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Famotidine Oral Tablets (plain, film-coated, chewable): 10 mg and 20 mg, gelcaps 40 mg; *Pepcid®*, *Pepcid® AC®*, and *Pepcid RPD®*, generic; (Rx and OTC)

Famotidine Powder for Oral Suspension: 8 mg/mL when reconstituted in 400 mg bottles; *Pepcid®*, generic; generic; (Rx)

Famotidine Injection: 10 mg/mL in 1 mL and 2 mL single-dose vials and 4 mL, 20 mL, and 50 mL multidose vials (may contain mannitol or benzyl alcohol); generic; (Rx)

Fatty Acids, Omega-3

Nutritional Supplement

Prescriber Highlights

- ► Most commonly used orally for adjunctive treatment of pruritus associated with a variety of inflammatory skin conditions in dogs and cats; may be useful as an anti-inflammatory associated with other chronic conditions (eg, chronic kidney disease, osteoarthritis).
- ► In horses, may also be used for adjunctive therapy for chronic lower airway inflammation associated with equine asthma.
- ► Safety in pregnancy has not been established.
- ► May affect platelet function and bleeding times in dogs and cats; use caution in patients with primary or secondary hemostatic disorders or in those patients concurrently receiving medication to alter these systems.
- ► Adverse effects include GI distress with high doses; rarely, some dogs may become lethargic or more pruritic.

Uses/Indications

Fatty acid products are often used for the adjunctive treatment of pruritus associated with atopy, idiopathic seborrhea, miliary dermatitis, and eosinophilic granuloma complex; however, it is important to note that they are not helpful to treat acute flares of pruritis as prolonged periods (ie, weeks to months) are required for their actions to take effect.[1] Omega-3 fatty acids may be added to commercial veterinary diets to improve coat quality, as well as to commercial veterinary prescription diets specifically formulated for a variety of inflammatory conditions (eg, osteoarthritis; cardiac, liver, and kidney disease; neurologic conditions).

Polyunsaturated fatty acids (PUFA n-3s), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) are commonly found in higher concentrations in fish oil-containing products and are often chosen for their anti-inflammatory properties, which may be beneficial as adjunctive treatment for chronic kidney disease, arthritis (both degenerative and autoimmune), cardiovascular disease (hypercoagulable states, heart failure, dysrhythmias, boxer dogs with arrhythmogenic right ventricular cardiomyopathy[2]), inflammatory bowel disease, hepatic fibrosis, steatosis, and some neoplastic diseases. Omega-3 fatty acid supplementation may also reduce the incidence of lipemic aqueous in miniature schnauzers.[3]

Essential fatty acids may provide benefit when used as adjunctive therapy in dogs with atopic dermatitis.[4-6] When they are used for pruritus, significant therapeutic effects may be noted in only 25% to 50% of treated patients. Several months of treatment are required before evaluating efficacy.[1] Antihistamine and fatty acid therapy may be synergistic for treatment of pruritus.

One study in dogs with chronic osteoarthritis fed a diet supplemented with fish oil omega-3 fatty acids suggested that carprofen dosage reductions could be possible.[7] In another study, dogs with osteoarthritis fed a diet with a high omega-3 to omega-6 ratio (compared with the control diet, omega-3 levels were 31 times greater,

and omega-6 levels were 34 times lower) had significantly lower serum levels of arachidonic acid and owners reported subjective improvement in arthritic condition.[8]

A supplement containing omega-3 fatty acids, magnesium citrate, and zinc sulfate reduced behavioral disorders in dogs.[9]

Dietary supplementation with omega-3 polyunsaturated fatty acids or feeding animals a diet that has a reduced omega-6:omega-3 ratio that is close to 5:1 (as found in most commercially available renal diets) is expected to alter the long-term course of renal injury and decrease the magnitude of proteinuria.[10,11]

In a study of horses with chronic lower airway disease, addition of an omega-3 PUFA supplement resulted in clinically significant improvement in pulmonary function, airway inflammation, and clinical signs compared with the control group. All horses in the study also were fed a low-dust pelleted diet.[12]

Pharmacology/Actions

The most commonly supplemented fatty acids are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which, along with α-linoleic acid, are considered essential fatty acids. They are an integral part of the cellular framework of all cells and help to maintain normal cellular function; however, it remains difficult to ascertain which compounds may be responsible for their proposed efficacy, particularly when considering the combination nature of the commercial products being marketed. The therapeutic benefits and optimal ratios of EPA versus DHA remain unclear.

Omega-3 fatty acids affect arachidonic acid concentrations in plasma lipids and cellular membranes, and affect the degree of inflammatory prostaglandins, leukotrienes, and thromboxane production in the body.

Contraindications/Precautions/Warnings

Most commercial pet foods contain a source of omega-3 fatty acids. Before supplementation, determine the amount of omega-3 fatty acids already in the animal's diet to determine the appropriate amount to be supplemented.

Fatty acids should be used with caution in dogs that have had previous bouts of pancreatitis or protracted diarrhea.[13]

Because of potential effects on platelet function and bleeding times, use with caution in patients with primary or secondary hemostatic disorders or in those receiving medications to alter these systems.[13,14]

Adverse Effects

At high dosages, GI disturbances (eg, belching, vomiting, diarrhea) may be seen.[13] Rarely, some dogs become lethargic, have impaired wound healing, or become more pruritic. Omega-3 fatty acids may alter immune function, but any clinical significance of these effects is not clearly known. Omega-3 fatty acids may decrease platelet activity and increase the risk of bleeding.

Reproductive/Nursing Safety

In humans, women are encouraged to consume omega-3 fatty acids during pregnancy. Omega-3 fatty acid supplements are considered compatible with pregnancy and during lactation[15]; the relevance of this recommendation for veterinary patients is unclear.

Overdose/Acute Toxicity

Acute ingestions may produce clinical signs that mirror omega-3 fatty acid adverse effects. Acute toxicosis may result after accidental overdoses of fatty acid products containing vitamin A. See ***Vitamin A*** for more information.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving omega-3 fatty acids and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticoagulants** (eg, **aspirin, clopidogrel, warfarin, heparin**): Because of potential effects on bleeding times, use with caution in patients receiving anticoagulant medication. Omega-3 fatty acids have been shown to augment the antiplatelet effect of aspirin.[14]
- **Corticosteroids** (eg, **prednis(ol)one**): May have a steroid-sparing effect in dogs with atopic dermatitis[5]
- **Cyclosporine**: May have a cyclosporine-sparing effect in dogs with atopic dermatitis[4]
- **Nonsteroidal Anti-inflammatory Drugs (NSAIDs**; eg, **carprofen, meloxicam, robenacoxib**): May increase the risk of bleeding

Laboratory Considerations

None

Dosages

NOTE: Fish oil should contain vitamin E as an antioxidant; however, to avoid toxicities, supplements that contain other nutrients are not recommended. Cod liver oil and flax oil should not be used.[13,16,17]

DOGS:

Omega-3 nutritional supplement (extra-label): The National Research Council (NRC) recommended daily allowances (indicating safe upper limits) and suggested dosages for therapeutic use are determined using metabolic weight (not actual body weight) and the *combined* weight of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). To calculate this, first convert the dog's body weight in kg to the metabolic body weight by taking the actual weight in kg and raising it to the power of 0.75. For example, a dog weighing 10 kg would convert to 5.62. (***Plumb's note**: Those not adept at using a scientific calculator for this purpose can use a calculator that has a square root function key. In the example above of a dog weighing 10 kg; cube the bodyweight in kg [10 x 10 x 10 = 1000], then take the square root of 1000 twice = 5.62.*) This value is then multiplied by the recommended dosage for a particular condition. Consider the amount of EPA/DHA already present in the diet when determining daily dose. The following are suggested daily dosages of *combined* EPA/DHA per metabolic weight:

- **NRC recommended daily allowance**: 30 mg/kg$^{0.75}$ PO
- **NRC safe upper limit**: 370 mg/kg$^{0.75}$ PO

Idiopathic hyperlipidemia (extra-label):

a) 120 mg/kg$^{0.75}$ PO once daily
b) Alternatively, 200 – 300 mg/kg PO once daily, with a suggested upper limit of 4 – 5 g daily[18]

Kidney disease (extra-label):

a) 140 mg/kg$^{0.75}$ PO; may be increased to the NRC safe upper limit
b) **Adjunctive treatment of glomerular disease**: In combination with a diet containing a reduced omega-6:omega-3 polyunsaturated fatty acids (PUFA) ratio, approximating 5:1. Where dietary supplementation with an omega-3 PUFA is used to alter this ratio, a dosage of EPA in combination with DHA 250 – 500 mg/kg of should be considered appropriate for most canine diets.[10]
b) **Proteinuria** (extra-label): Anecdotal dosage extrapolated from human data suggest a minimum of omega-3 fatty acids

1 g/4.55 kg body weight PO every 24 hours.[19]

Cardiovascular disorder (extra-label): EPA 40 mg/kg in combination with DHA 25 mg/kg PO once daily[17]

Osteoarthritis (extra-label):

a) 310 mg/kg$^{0.75}$ PO; may be increased to the NRC safe upper limit
b) EPA 90 mg/kg in combination with DHA 20 mg/kg PO once daily significantly improved indicators of pain and quality of life.[20]

Inflammatory or immunologic disorders (eg, inflammatory bowel disease, atopy; extra-label): 125 mg/kg$^{0.75}$ PO[21,22]

Cyclosporine-sparing effect in atopic dermatitis (extra-label): EPA 36 mg/kg in combination with DHA 25 mg/kg PO once daily resulted in ≈35% reduction in the median daily cyclosporine dosage over the 12-week study period.[4] Pruritus also was improved. The product used in this study also contained α-linolenic acid, linoleic acid, and docosapentaenoic acid.

Symmetrical lupoid onychodystrophy (extra-label): EPA 82.5 mg/kg in combination with DHA 53 mg/kg (average dosage) PO once daily was equivalent to cyclosporine in improving the number of healthy claws and long-term hunting abilities; note that the study sample size was limited to 6 dogs per treatment arm.[23]

CATS:

NOTE: There is less evidence supporting safety and efficacy use of omega-3 fatty acids in cats than in dogs; optimal dosages are not yet known. Dosages greater than EPA + DHA 75 mg/kg$^{0.67}$ per day should be used with caution and under veterinary supervision until further evaluations of long-term safety are performed.[21]

Kidney disease | Proteinuria (extra-label): anecdotal dosage extrapolated from human data suggest a minimum of omega-3 fatty acids 1 g/4.55 kg body weight PO every 24 hours[19]

Adjunctive treatment of CHF (extra-label): EPA 40 mg/kg in combination with DHA 25 mg/kg PO once daily has been recommended. Practically, capsules that contain EPA ≈180 mg in combination with DHA 120 mg DHA can be administered at a dose of 1 capsule/4.5 kg (10 lb) body weight.[16,17]

HORSES:

Chronic lower airway inflammatory disease (extra-label): 30 g or 60 g omega-3 fatty acid feed supplement added to pellet-only diet for 2 months improved cough and lung function in horses with severe equine asthma (SEA; formerly known as recurrent airway obstruction) and inflammatory airway disease.[12]

Monitoring

- Efficacy for treated indication
- Adverse effects (eg, vomiting, diarrhea)

Client Information

- Omega-3 fatty acids are also known as fish oils.
- This medicine may be given with or without food.
- Often used in addition to other treatments for controlling skin diseases, arthritis, and some heart conditions
- When this medicine is used to control itching, treatment may require 2 to 3 months to see if it will be effective.
- Usually tolerated well. Upset stomach and loose stools/diarrhea are the most common side effects, especially when higher doses are used. Some animals may bruise or bleed more easily. If this occurs, contact your veterinarian.
- Be sure to read product labels closely as fatty acid content varies widely between products. It is recommended to purchase a product from a reputable manufacturer. Consult your veterinarian or pharmacist to find a safe and reliable product selection for your animal.

Chemistry/Synonyms

The commercially available veterinary products generally contain a combination of eicosapentaenoic acid [EPA] and docosahexaenoic acid (DHA) derived from fish oil and vegetable oil (gamma-linolenic acid) that serve as essential fatty acids. They may also contain vitamin E (d-α-tocopherol) and vitamin A.

Storage/Stability

Because fatty acids are susceptible to oxidation and breakdown by exposure to elevated temperatures, light, and air, products should be stored in an airtight container in a cool, dry place, protected from heat.

Compatibility/Compounding Considerations

No specific information has been noted.

Dosage Forms/Regulatory Status

NOTE: Fish oil supplements should contain vitamin E as an antioxidant. Use of a high-quality product, preferably one certified free of heavy metals or other environmental contaminants, is suggested.[13]

VETERINARY-LABELED PRODUCTS:

There are many combination products available without prescription having various trade names, including (partial listing): *Dermapet Eicosderm®, Dermapet OFA plus EZ-C Caps®, F.A. Caps®, F.A. Caps ES®, Omega EFA® Capsules, Omega EFA® Capsules XS, Performer® OFA Gel Capsules Extra Strength, Aliera®*.

HUMAN-LABELED PRODUCTS:

There are many fish oil capsules available without prescription having various trade names.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Felbamate

(***fell***-ba-mate) *Felbatol®*

Anticonvulsant

Prescriber Highlights

- ► Second- or third-line antiepileptic medication for dogs
- ► Contraindicated in patients hypersensitive to it or other carbamates
- ► Use caution in patients with pre-existing hepatic dysfunction or blood dyscrasias.
- ► Adverse effects may include KCS, liver enzyme induction, tremors, limb rigidity, salivation, restlessness, and agitation; use in dogs appears to be relatively safe, but because of limited use, adverse effect profile and incidence may be incomplete.
- ► Cost and accessibility may be issues.

Uses/Indications

Felbamate is an anticonvulsant agent that may be useful for treating seizure disorders (generalized seizures, but especially complex partial seizures) in dogs. A potential advantage of felbamate therapy is that when used alone or in combination with phenobarbital and/or bromides, it does not appear to cause additive sedation.

Pharmacology/Actions

Felbamate's anticonvulsant activity is thought to be due to its ability to reduce excitatory neurotransmission; its exact mechanism is unknown, but it is believed to increase activation of sodium channels, thereby decreasing sustained high-frequency firing of action potentials.

Pharmacokinetics

Felbamate is well absorbed after oral administration in dogs. Felbamate is both excreted unchanged and as metabolites in the urine. The half-life in adult dogs averages around 4 to 6 hours. Because the drug can induce liver enzyme induction, half-lives may decrease with time, and dosages may need adjustment.

Contraindications/Precautions/Warnings

Felbamate is contraindicated in patients hypersensitive to it or other carbamates (eg, meprobamate). In humans, felbamate has caused aplastic anemia and acute hepatic failure, and should not be used in patients with a history of blood dyscrasias or hepatic dysfunction.

Adverse Effects

Adverse reactions in the dog include keratoconjunctivitis sicca (KCS), liver enzyme induction, tremor, limb rigidity, salivation, restlessness, and agitation (at high doses). Sedation is not reported in the dog when used as a monotherapy, but excitability does occur at high doses. In humans, aplastic anemia and hepatic necrosis have been noted and could be a factor in canine medicine. There apparently have not been any case reports yet of aplastic anemia in dogs, but blood dyscrasias (thrombocytopenia, lymphopenia, and leukopenia) have anecdotally been reported. Additionally, sedation, vomiting, and nausea have been reported in dogs but usually in those receiving other anticonvulsants as well.

Reproductive/Nursing Safety

Felbamate crosses the placenta. Teratogenicity was not documented in pregnant laboratory animals exposed to felbamate.[1]

The drug is excreted into maternal milk. Decreased pup weight and increased pup death were observed in rats during lactation.[1]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available. One human subject taking 12 g over 12 hours only developed mild gastric distress and a slightly increased heart rate.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving felbamate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Clopidogrel**: Concurrent use may result in a reduction in the clinical efficacy of clopidogrel.
- **Phenobarbital, Primidone**: When felbamate is added to patients taking phenobarbital, it may cause increases in phenobarbital levels. When phenobarbital is added to patients taking felbamate, felbamate levels may decrease.
- **QTc Prolonging Drugs** (eg, **amiodarone**, **cisapride, quinidine, sotalol**): Concurrent use may increase the risk for QT-interval prolongation.
- **Valproate**: Felbamate can cause increases in valproic acid levels.

Dosages

DOGS:

Seizure control[2]; second- to third-line agent; (extra-label): Felbamate is not commonly used, but it can be considered as an add-on drug when acceptable seizure control is not attained or adverse effects are not tolerated with other standard treatments. Evidence supporting any dosage regimen was not located. Most recommend using initially at 15 – 20 mg/kg PO every 8 hours, with gradual dosage increases of ≈15 mg/kg PO every 2 weeks, if required and tolerated. Some start at lower dosages 5 – 10 mg/kg PO every 12 hours and titrate to every 8 hours. Upper limits of 60 – 70 mg/kg PO every 8 hours have been noted.

Monitoring

- CBC, chemistry panel; baseline and regularly during treatment
- Therapeutic drug levels for felbamate in dogs are not known but appear to be in the 25 – 100 µg/mL range. The usefulness of monitoring serum levels is uncertain.

Client Information

- Anticonvulsant that may be useful to treat seizure disorders (eg, epilepsy) in dogs. Limited experience using it in veterinary medicine. It usually does not cause sleepiness or sedation.
- May be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give it with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Appears to be relatively safe in dogs, but report anything out of the ordinary to your veterinarian. Possible side effects include tremors, shaking, stiff legs, excessive salivation (drooling), restlessness, agitation, dry eyes, or increases in liver enzymes.
- Requires dosing several times a day. It will not be effective if dosages are missed.
- While your animal is taking this medication, it is important to return to your veterinarian for periodic monitoring of lab work. Do not miss these important follow-up visits.

Chemistry/Synonyms

Felbamate is a unique dicarbamate anticonvulsant agent that is slightly soluble in water.

Felbamate may also be known as AD-03055, W-554, *Felbamyl*®, *Felbatol*®, and *Taloxa*®.

Storage/Stability

Store felbamate preparations at room temperature 20°C to 25°C (68°F-77°F) in tight containers. Shake the suspension well before use.

Compatibility/Compounding Considerations

No specific information has been noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

Association of Racing Commissioners International (ARCI) Uniform Classification Guidelines for Foreign Substances (UCGFS) Class 3 Drug). Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Felbamate Tablets: 400 and 600 mg; *Felbatol*®, generic; (Rx).

Felbamate Suspension: 120 mg/mL in 240 and 960 mL; *Felbatol*®, generic; (Rx).

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Fenbendazole

(fen-**ben**-da-zole) *Panacur®, Safe-Guard®*

Antiparasitic Agent

Prescriber Highlights

- ► Anthelmintic useful for reduction and removal of nematode and protozoal parasites in a variety of species
- ► Adverse effects are uncommon; vomiting can occur infrequently in dogs and cats. Hypersensitization reactions caused by antigen release from dying parasites are possible, particularly at high doses.
- ► Generally safe to use during pregnancy
- ► In dogs, this drug should be given with food to increase bioavailability.

Uses/Indications

In dogs, fenbendazole is labeled for removal of the following parasites: roundworms (*Toxocara canis, Toxascaris leonina*), hookworms (*Ancylostoma caninum, Uncinaria stenocephala*), whipworms (*Trichuris vulpis*), and tapeworms (*Taenia pisiformis*). It is not effective against *Dipylidium caninum*. Fenbendazole has also been used clinically to treat *Eucoleus aerophilus* (formerly known as *Capillaria aerophila*), *Filaroides hirthi*, and *Paragonimus kellicotti* infections in dogs; it may be useful in combination with praziquantel for some cases of subclinical schistosomiasis caused by *Heterobilharzia americana*.[1,2]

Fenbendazole has been used extra-label in domestic cats, sheep, camelids, small mammals, pet birds, and reptiles and may be approved in countries outside the United States for these species. See ***Dosages*** for more information.

In horses, fenbendazole is labeled for removal of the following parasites: large strongyles (*Strongylus edentatus, Strongylus equinus, S vulgaris, Triodontophorus* spp), small strongyles (also known as cyathostomes; eg, *Cylicocyclus* spp, *Cylicostephanus* spp, *Cylicodontophorus* spp), ascarids (*Parascaris equorum*), and pinworms (*Oxyuris equi*). Benzimidazole resistance is a concern when treating horses for cyathostomes.[3–6]

In cattle, fenbendazole is labeled for removal of the following parasites in their adult forms (and most immature stages): *Haemonchus contortus, Ostertagia ostertagi, Trichostrongylus axei, Bunostomum phlebotomum, Nematodirus helvetianus, Cooperia* spp, *Trichostrongylus colubriformis, Oesophagostomum radiatum,* and *Dictyocaulus viviparus*. In beef cattle only, fenbendazole is FDA-approved for removal and control of *Moniezia* spp and arrested fourth-stage forms of *O ostertagi*.

In nonlactating goats, fenbendazole is labeled for removal of adult stomach worms (*H contortus, Teladorsagia circumcincta*).

In swine, fenbendazole is labeled for removal of the following parasites: large roundworms (*Ascaris suum*), lungworms (*Metastrongylus apri, Metastrongylus pudendotectus*), nodular worms (*Oesophagostomum dentatum, Oesophagostomum quadrispinulatum*), small stomach worms (*Hyostrongylus rubidus*), whipworms (*Trichuris suis*), and kidney worms (*Stephanurus dentatus*; both mature and immature).

In broiler chickens and replacement chickens intended to become breeding chickens, fenbendazole is indicated for the treatment and control of adult *Ascaridia galli* and in breeding chickens for the treatment and control of adult *A galli* and *Heterakis gallinarum*.

Fenbendazole is approved for control of ascarids in big cats (eg, lions, leopards, tigers) and in bears; in some of those species, it is also labeled for control of hookworms and/or tapeworms.

Fenbendazole resistance is a growing concern for canine hookworms,[7–10] and *Ostertagia* spp.[11–13]

Pharmacology/Actions

Benzimidazole antiparasitic agents have a broad spectrum of activity against a variety of pathogenic internal parasites. In susceptible parasites, their mechanism of action disrupts intracellular microtubular transport systems by binding tubulin, preventing tubulin polymerization, and inhibiting microtubule formation. Benzimidazoles are also believed to act at higher concentrations to disrupt metabolic pathways within the helminth, and inhibit metabolic enzymes, including malate dehydrogenase and fumarate reductase.

Benzimidazoles may be considered time-dependent antiparasitic agents.

Fenbendazole has activity against adult life cycle stages of susceptible parasites and may have larvicidal and ovicidal activity against certain parasites.[14,15]

Benzimidazoles appear to exert anticancer effects through multiple mechanisms. In vitro and preclinical studies have demonstrated that benzimidazoles destabilize microtubules, increase the stability of p53 tumor suppressor proteins, induce apoptosis, and reduce glucose uptake in cancer cells.[16–18] Additional research is required to determine clinical relevance.

Pharmacokinetics

Fenbendazole is only marginally absorbed after oral administration in dogs.[19] The amount absorbed from the gut is associated more with the solubility of the drug and not the dosage given. In dogs, when administered doses ranged from 25 – 100 mg/kg, the area under the curve (AUC) was similar. Bioavailability is increased in dogs when fenbendazole is administered with food; the fat content of the food does not significantly alter bioavailability.[20] The absorbed drug is sequentially converted to sulfoxide (active) and sulfone (inactive) metabolites. Fenbendazole and metabolites are excreted in the feces.

After PO administration in calves and horses, peak blood concentrations of 0.11 µg/mL and 0.07 µg/mL, respectively, were measured. After 10 mg/kg PO in sheep and goats, maximum concentrations were 128 and 146 µg/mL, respectively.[21] Absorbed fenbendazole is metabolized to the active compound, oxfendazole (sulfoxide), and sulfone (inactive). In cattle, sheep, and pigs, 44% to 50% of a dose of fenbendazole is excreted unchanged in the feces and less than 1% in the urine.

Contraindications/Precautions/Warnings

Fenbendazole is not FDA-approved for use in horses intended for food purposes.

Adverse Effects

At labeled dosages, fenbendazole does not typically cause any adverse effects. Hypersensitivity reactions secondary to antigen release by dying parasites may occur, particularly at high doses. Salivation, vomiting, and diarrhea may infrequently occur in dogs or cats that have been given fenbendazole. Pancytopenia was reported in 1 dog.[22] Fenbendazole may cause intestinal problems and myelosuppression in some birds.[23,24]

Reproductive/Nursing Safety

Fenbendazole is considered generally safe to use in all species during pregnancy and is the drug of choice for treatment of giardiasis in pregnant animals.[25] Fenbendazole administered to males and pregnant and nonpregnant females (including *Felidae* and *Ursidae*) at 10 times the recommended dose for twice the recommended treatment period did not have an effect on reproduction.[26] Fenbendazole may interfere with implantation in pigs during early pregnancy.[27]

Fenbendazole should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Fenbendazole is well tolerated at doses up to 100 times what is recommended. The LD_{50} in laboratory animals exceeds 10 g/kg when

administered PO.[28] It is unlikely that an acute overdose will lead to clinical signs.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions with fenbendazole have either been reported or are theoretical in humans or animals and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Bromsalan Flukicides** (eg, **dibromsalan**, **tribromsalan**; not available in the United States): Oxfendazole or fenbendazole should not be given concurrently with bromsalan flukicides; abortions in cattle and death in sheep have been reported when these compounds are used together.
- **Methimazole**: In sheep, methimazole has increased fenbendazole (parent) concentration and delayed the formation of sulfoxide and sulfone metabolites.[29]
- **Triclabendazole**: In an in vitro study, triclabendazole reduced the rate of oxfendazole formation but increased oxfendazole accumulation.[30]

Laboratory Considerations

None were noted.

Dosages

DOGS:

Treatment and control of roundworms (*Toxocara canis, Toxascaris leonina*), hookworms (*Ancylostoma caninum, Uncinaria stenocephala*), whipworms (*Trichuris vulpis*), and tapeworms (*Taenia pisiformis*) (label dosage; FDA approved): 50 mg/kg PO daily for 3 consecutive days. It is recommended to give with food. Puppies (6 weeks or older) should be dewormed at ages 6, 8, 10, and 12 weeks. The dam should be treated at the same time as the puppies.[26,31]

Dosing Table for Premeasured Powder Packets[31]

Body weight kg (lb)	Packet size (222 mg/g)*
4.5 (10)	1 g
5-9.1 (11-20)	2 g
9.5-13.6 (21-30)	1 g + 2 g
14.1-18.2 (31-40)	4 g
18.6-22.7 (41-50)	1 g + 4 g
23.2-27.3 (51-60)	2 g + 4 g
27.7-36.4 (61-80)	Two 4 g
Over 36.4 (80)	Combinations should be used to obtain recommended daily dose.

**Packet size is the daily dose. The dog must be given this dose for 3 consecutive days.*

Alternative dosages for the labeled indications above (extra-label):

a) **Treatment of *T vulpis***: Some clinicians suggest treatment be repeated after 2 weeks and then after 3 months.

b) 100 mg/kg PO once for adult dogs[32]

Treatment for a variety of other parasites (extra-label):

a) **Slow adulticide kill of *Angiostrongylus vasorum***: For animals in which severe clinical signs and pulmonary hypertension have occurred: 50 mg/kg PO every 24 hours for 3 to 5 days, discontinue for a few days, then repeat course of fenbendazole 50 mg/kg PO every 24 hours for 3 to 5 days.[33]

b) ***Crenosoma vulpis***: 25 – 50 mg/kg PO every 24 hours for 3 to 14 days[34]

c) ***Eucoleus* spp (formerly *Capillaria* spp)**: 50 mg/kg PO every 24 hours for 10 days[34]

d) ***Filaroides* spp**: 50 mg/kg PO every 24 hours for 14 to 21 days or 100 mg/kg PO every 24 hours for 7 days[34]

e) ***Giardia* spp**: 50 mg/kg PO every 24 hours for 3 to 5 days[32,35,36]

f) ***Mesocestoides* spp**: 100 mg/kg PO every 12 hours for at least 4 weeks[37]

g) ***Oslerus osleri***: 50 mg/kg PO every 24 hours for 7 to 14 days[32,34]

h) ***Paragonimus kellicotti***: 50 mg/kg PO every 24 hours for 10 to 14 days[38]

i) ***Physaloptera* spp**: Fenbendazole 75 – 90 mg/kg PO every 24 hours for 5 days in combination with pyrantel pamoate 7.5 mg/kg PO once; repeat in 3 weeks[39]

j) ***Heterobilharzia americana***: Fenbendazole 24 mg/kg PO every 24 hours for 7 days in combination with praziquantel 10 mg/kg PO every 8 hours for 2 days[1,2]

k) **Persistent or suspected resistant *A caninum* using a 3-drug regimen**: fenbendazole 50 mg/kg PO once daily for 3 days in combination with pyrantel 5 mg/kg PO once and moxidectin 2.5 mg/kg topically[40]

Preventing transplacental and transmammary transmission of somatic *T canis* and *A caninum* (extra-label):

a) 50 mg/kg PO every 24 hours from day 40 of gestation to day 14 of lactation[41]

b) 25 mg/kg PO once daily from day 40 of gestation to 2 days postwhelping[32]

CATS:

Treatment for a variety of parasites (extra-label):

a) **Ascarids (*Toxocara* spp), *Ancylostoma* spp, *Trichuris* spp, *Uncinaria* spp, and *Taenia* spp** (extra-label): Cats older than 6 months and pregnant cats: 100 mg/kg PO once.[32] Kittens younger than 6 months: 50 mg/kg PO every 24 hours for 3 days[32]

b) ***Aelurostrongylus abstrusus*** (extra-label): 50 mg/kg PO every 24 hours for 3 days[32]; longer treatments (ie, 10 to 14 days) may be required[42]

c) ***Eurytrema procyonis* (pancreatic fluke;** extra-label): 30 mg/kg PO every 24 hours for 6 days[43]

d) ***Giardia* spp** (extra-label): 50 mg/kg PO once daily for 5 to 7 days[44,45]

e) ***Strongyloides* spp** (extra-label): 50 mg/kg PO every 24 hours for 3 to 5 days

f) ***Paragonimus kellicotti*, *Pearsonema feliscati* (formerly *Capillaria feliscati*), or *Eucoleus aerophilus* (formerly *Capillaria aerophila*) infections** (extra-label): 25 – 50 mg/kg PO every 12 hours for 10 or more days

HORSES:

Control of large strongyles (*Strongylus edentatus, Strongylus equinus, Strongylus vulgaris, Triodontophorus* spp), small strongyles (*Cyathostomum* spp, *Cylicocyclus* spp, *Cylicostephanus* spp, *Cylicodontophorus* spp), pinworms (*Oxyuris equi*), and ascarids (*Parascaris equorum*) (label dosage; FDA-approved): Adult horses: 10 mg/kg PO for ascarids, 5 mg/kg PO for all other indications; regular deworming at intervals of 6 to 8 weeks may be

required because of the possibility of reinfection. Foals and weanlings younger than 18 months, in which ascarids are a common problem: 10 mg/kg PO; regular deworming at intervals of 6 to 8 weeks may be required because of the possibility of reinfection.[28]

Treatment of encysted early third-stage, late third-stage, and fourth-stage cyathostome larvae as well as fourth-stage *S vulgaris* larvae (label dosage; FDA-approved): 10 mg/kg PO once daily for 5 consecutive days. In the case of fourth-stage larvae *S vulgaris*, treatment and re-treatment should be based on life cycle and epidemiology. Treatment should be initiated in the spring and repeated in the fall after a 6-month interval.[28,46]

CATTLE:

Removal and control of lungworms (*Dictyocaulus viviparus*); adult stomach worms (ie, brown stomach worms [*Ostertagia ostertagi*]); adult and fourth-stage larvae stomach worms (ie, Barber's pole worms [*Haemonchus contortus* and *Haemonchus placei*]); small stomach worms (*Trichostrongylus axei*); adult and fourth-stage larvae intestinal worms (ie, hookworm [*Bunostomum phlebotomum*], thread-necked intestinal worms [*Nematodirus helvetianus*], small intestinal worms [*Cooperia punctata* and *Cooperia oncophora*], bankrupt worms [*Trichostrongylus colubriformis*], and nodular worms [*Oesophagostomum radiatum*]) (label dosage; FDA-approved): 5 mg/kg PO once. Re-treatment may be necessary after 4 to 6 weeks.[47]

Removal and control of stomach worms (fourth-stage inhibited larvae; *O ostertagi*) and tapeworms (*Moniezia benedeni*) in beef cattle *only* (label dosage; FDA-approved): 10 mg/kg PO once. Should not be used in dairy cattle at 10 mg/kg.[46]

***Giardia* spp in calves** (extra-label): 15 mg/kg/day PO for 3 consecutive days; animals should then be moved to a pen that has been thoroughly cleaned and disinfected with ammonia 10%.[48]

GOATS:

Removal and control of adult stomach worms (*H contortus* and *Teladorsagia circumcincta*) in nonlactating goats (label dosage; FDA-approved): 5 mg/kg PO; re-treatment may be necessary after 4 to 6 weeks.[46]

Removal and control of adult stomach worms in nonlactating goats (extra-label): 10 mg/kg; extended withdrawal times required.

CAMELIDS:

Susceptible parasites in new world camelids (extra-label): 10 – 20 mg/kg PO for 3 to 5 days[49]

Adjunctive treatment of meningeal worm infestation (*Parelaphostrongylus tenuis*) (extra-label): 50 mg/kg PO once daily for 5 days with ivermectin at 0.3 mg/kg SC for 5 days. Fluids, nutritional support, prophylactic treatment (ranitidine, omeprazole), and anti-inflammatories (flunixin, dexamethasone, dimethylsulfoxide [DMSO]) should also be used for stress ulcers.[50]

SWINE:

NOTE: There are also medicated feed/premix products labeled for use in swine.

Large roundworms (*Ascaris suum*), lungworms (*Metastrongylus apri, Metastrongylus pudendotectus*), nodular worms (*Oesophagostomum dentatum, Oesophagostomum quadrispinulatum*), small stomach worms (*Hyostrongylus rubidus*), whipworms (*Trichuris suis*), and kidney worms (*Stephanurus dentatus*; both adult and larvae) (label dosage; FDA-approved): Must be administered PO to swine via drinking water at 2.2 mg/kg/day for 3 consecutive days. Not for use in nursing piglets.[51] Alternatively, 9 mg/kg PO (as a 20% medicated feed/premix) can be fed as a sole ration for 3 to 12 consecutive days.[52]

A suum (extra-label): 2.5 mg/kg PO in drinking water once daily for 2 consecutive days 1 week after arriving at fattening mill; treatment course repeated 6 weeks after arriving at fattening mill.[53]

Whipworms in potbellied pigs (extra-label): 10 mg/kg PO once daily for 3 days[54,55]

BIRDS:

NOTE: Fenbendazole may cause severe toxicity in some birds.

Routine deworming (extra-label):

a) **Labeled indications in breeding, broiler, and replacement chickens** (FDA-approved): 1 mg/kg PO daily in drinking water for 5 consecutive days. The required daily volume of fenbendazole suspension is calculated from the total estimated body weight (kg) of the entire group of chickens to be treated. Formula on product label contains calculations for daily requirements and mixing instructions.[51]

b) **Raptors**: 20 mg/kg PO every 24 hours for 5 days[56]

c) **Psittacines, passerines**: 20 mg/kg PO every 24 hours for 3 days[56]

d) **Pigeons**: 10 mg/kg PO once daily for 3 days[56]

FERRETS:

Routine deworming (extra-label): 20 mg/kg PO every 24 hours for 5 days, repeated every 3 months[56]

SMALL MAMMALS & RODENTS:

a) **Mice, rats, gerbils, hamsters, guinea pigs, chinchillas** (extra-label): 20 – 50 mg/kg PO every 24 hours for 5 days; the higher end of the dose range is needed for *Giardia* spp[57]

b) **Rabbits**:

i. **Treatment and prevention of *Encephalitozoon cuniculi*** (extra-label): 20 mg/kg PO every 24 hours for 28 days; single treatment course only[58]

ii. **Routine deworming** (extra-label): 20 mg/kg PO once daily for 9 days, repeated 2 to 4 times per year[58]

c) ***Giardia* spp in chinchillas** (extra-label): 25 mg/kg PO every 24 hours for 3 days[59]

d) **Nematodes in hedgehogs** (extra-label): 25 mg/kg PO, repeated at 14 and 28 days[60]

e) **Nematodes, Tapeworms in sugar gliders** (extra-label): 20 – 50 mg/kg every 24 hours for 3 days, repeated in 14 days[61]

REPTILES:

Routine deworming (extra-label):

a) 25 mg/kg PO once daily for 3 days

b) **Tortoises**: 50 mg/kg PO once[56]

Nematodes (extra-label): 50 – 100 mg/kg PO, repeated in 2 weeks

Trematodes (extra-label): 100 mg/kg repeated in 2 weeks[62]

BIG CATS/EXOTIC CATS:

Susceptible parasites (label dosage; FDA-approved): 10 mg/kg PO every 24 hours for 3 consecutive days[26]

BEARS (*URSIDAE*):

Susceptible parasites (label dosage; FDA-approved): 10 mg/kg PO every 24 hours for 3 consecutive days[26]

Monitoring

- Efficacy via fecal flotation, fecal egg count (FEC), fecal egg count reduction test (FECRT)

Client Information

- This oral dewormer is used in many species.
- This medicine may need to be given for several days to be effective. Follow the instructions from your veterinarian and do not miss doses or stop giving it to your animal early.

- This medicine is best given with food in small animals.
- Although there are usually no side effects, gastrointestinal effects (eg, vomiting, drooling, diarrhea) can occur. Rarely, allergic reactions can develop.

Chemistry/Synonyms

Fenbendazole, a benzimidazole anthelmintic, occurs as a white crystalline powder. It is only slightly soluble in water.

Fenbendazole may also be known as Hoe-881V, *Panacur®*, and *Safe-Guard®*.

Storage/Stability

Fenbendazole products should be stored at room temperature.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Fenbendazole Granules: 222 mg/g (22.2%) in 0.18 oz and 1 g, 2 g, and 4 g packets and 1 lb jars; *Panacur® Granules 22.2%*; (Rx). *Safeguard® Canine Dewormer*, *Panacur® C* (OTC). FDA-approved for use in dogs, horses, large exotic cats (eg, lions), and bears (eg, black bears, polar bears)

Fenbendazole Suspension: 100 mg/mL (10%); there are products labeled for use in horses, cattle, and goats: *Panacur® Suspension*; (Rx). FDA-approved for use in horses (not intended for food) and cattle. Slaughter withdrawal is 8 days and milk withdrawal is 48 hours in cattle. *Safe-Guard® Suspension*; (OTC). FDA-approved for use in beef and dairy cattle and nonlactating goats. Cattle must not be slaughtered within 8 days following treatment; there is no milk withdrawal in cattle for this product. A withdrawal period has not been established for this product in preruminating calves. Should not be used in calves to be processed for veal. Goats must not be slaughtered for food within 6 days following treatment. Because a withdrawal time in milk has not been established, this drug should not be used in lactating goats.

Fenbendazole Paste: 100 mg/g (10%); available in both equine and bovine labeled products and sizes. *Panacur® Paste*; *Safe Guard® Paste;* (OTC). FDA-approved for use in horses not intended for food and in cattle. Slaughter withdrawal for cattle at labeled dosages is 8 days; milk withdrawal time at labeled dosages is 96 hours.

Fenbendazole Pellets: *Safe-Guard® 0.5% Alfalfa-Based Pellets*; (OTC). FDA-approved for use in beef and dairy cattle and swine. There is no milk withdrawal time at labeled dosages; slaughter withdrawal time at labeled dosages for cattle is 13 days and 0 days for swine (no withdrawal period for swine).

Fenbendazole Pellets: *Safe-Guard® Equi-Bits* 0.5% (OTC)

Fenbendazole Suspension: 200 mg/mL in 1 L bottles. *Safe-Guard® AquaSol*; (OTC). For use in swine and in breeding and broiler chickens and replacement chickens intended to become breeding chickens. Withdrawal period for swines is 2 days. Not for use in nursing piglets. No withdrawal period required for chickens when used according to label.

Fenbendazole Premix 20% Type A (200 mg/g): *Safe-Guard® Premix*; (OTC). FDA-approved for use in swine, growing turkeys, dairy and beef cattle, and zoo and wildlife animals. Slaughter withdrawal for cattle is 13 days; no milk withdrawal time is noted. There is no slaughter withdrawal for turkey or swine at labeled dosages. Wildlife animal slaughter (hunting) withdrawal is 14 days at labeled dosages.

There may also be Type B and C medicated feeds available.

HUMAN-LABELED PRODUCTS: NONE

Fenofibrate

(fen-oh-***fye***-brate) *TriCor®*

Fibric acid derivative; anti-lipemic agent

Prescriber Highlights

- ► May be useful as adjunctive therapy, along with a low-fat diet, to treat hypertriglyceridemia in dogs
- ► Limited experience and no published clinical studies in cats; efficacy or safety is not established
- ► Avoid use in patients with preexisting gallbladder disease, severe renal impairment, or active liver disease
- ► Many preparations are available; not bioequivalent.

Uses/Indications

Fenofibrate could be useful to lower triglycerides in dogs when diet modifications alone have been unsuccessful. In dogs with hypertriglyceridemia, triglycerides were normalized in 86% to 100% of dogs treated with fenofibrate.[1,2] After 3 to 4 weeks of initiating fenofibrate treatment, a 73% to 88% median reduction in triglycerides and a 10% to 20% reduction in total cholesterol were observed. Under experimental conditions, fenofibrate reduced both total cholesterol and triglycerides in obese beagles by ≈30% after 1 to 2 weeks of use[3]; dogs with the highest pretreatment values experienced the greatest reductions.

In humans, fenofibrate is used as adjunctive therapy to lifestyle changes in the management of dyslipidemia primarily to reduce triglycerides; with treatment, HDL-cholesterol concentrations are typically increased, and reductions in total- and LDL-cholesterol may occur. It is recommended to discontinue treatment in humans if an adequate response is not achieved with 2 to 3 months.[4]

Pharmacology/Actions

Fenofibric acid, the active form of fenofibrate, activates peroxisome proliferator-activated receptors, which increases lipoprotein lipase concentrations and activity. The resulting increased clearance of very low-density lipoproteins and triglycerides causes LDL-cholesterol to be less atherogenic and more easily eliminated. Fenofibrate also increases urinary uric acid excretion. Increased biliary cholesterol saturation contributes to the increased risk for cholelithiasis.

Pharmacokinetics

Fenofibrate is a prodrug that must be converted to its active form, fenofibric acid, but dogs may produce other metabolites.[5] The oral bioavailability varies by dosage form and fed state; fenofibrate nanocrystal tablets have a bioavailability of ≈30% in dogs.[6] In dogs receiving radiolabeled fenofibrate (5 mg/kg PO once), 9% of the dose was eliminated in urine and 81% in feces, primarily within 24 hours of administration.[7]

In humans, peak concentrations occur 4 to 6 hours after administration. Certain preparations must be given with food to increase absorption, whereas others may be taken without regard to meals. Fenofibrate is completely hydrolyzed to its active form, fenofibric acid. Protein binding is 99%, primarily to albumin. The drug is renally eliminated (≈60%), and elimination half-life is ≈20 hours with normal renal function.

Contraindications/Precautions/Warnings

Fenofibrate is contraindicated in patients that are hypersensitive to it or fenofibric acid and with current liver disease or preexisting gallbladder disease.

In humans, hypersensitivity reactions (eg, toxic epidermal

necrolysis, Stevens-Johnson syndrome) have been reported, as have increased liver enzymes, hepatitis, pancreatitis, cholelithiasis, and increased serum creatinine.[8] Serious drug-induced liver injury has been reported. The risk for muscle toxicity (eg, myopathy, rhabdomyolysis) may be increased in geriatric patients and those with diabetes mellitus, hypothyroidism, or renal disease. A paradoxical reduction in HDL-cholesterol may occur.

The role and safety of fenofibrate in humans with preexisting hepatobiliary disease are not clear, and data in dogs are absent. Fenofibrate may contribute to the progression of cholelithiasis in humans with preexisting choleliths; however, its use has been recommended in humans with primary biliary cirrhosis. Fenofibrate should be used with care in dogs with gallbladder mucocele. There is an association between hypercholesterolemia and gallbladder mucocele that could be ameliorated by decreasing serum cholesterol; however, fenofibrate may also increase secretion of cholesterol into the bile, which could contribute to cholelith or mucocele formation. Fenofibrate should be discontinued if liver enzymes persistently exceed 3 times the upper limit of normal, if choleliths are found, or if myopathy or myositis occurs.

Fenofibrate is contraindicated in humans with severe renal impairment, and dosage reduction should be considered in the presence of decreased renal function. Renal elimination is minimal in dogs, but safety in patients with preexisting renal disease has not been determined. Until further research demonstrates safe use of fenofibrate in dogs with preexisting renal disease, this drug should be used with caution in these patients (see ***Monitoring***).

There are several fenofibrate/fenofibric acid preparations, all of which are not bioequivalent. Be sure to specify the intended product when ordering fenofibrate (see ***Dosage Forms/Regulatory Status***).

Adverse Effects

Diarrhea and flatulence have been reported in dogs that received fenofibrate; however, these effects are reduced by temporarily withholding the drug, followed by reinstating at a lower dose for 1 week before resuming the full dose.[2] Increased ALT (2.5 times normal) was noted in 1 dog, and 2 dogs experienced increased creatine kinase.[1]

In humans, adverse effects include nausea, reduced appetite, headache, malaise, back pain, and myalgia.[8] Increases in liver enzymes and serum creatinine are possible. Cholelithiasis and pancreatitis have been reported. Mild or moderate reductions in hemoglobin and white blood cells may occur, as may thrombocytopenia and agranulocytosis.

Reproductive/Nursing Safety

Administration of fenofibrate to pregnant laboratory animals during periods of organogenesis did not result in embryo- or fetal toxicity.[8]

Fenofibrate is contraindicated in nursing women due to the potential to disrupt lipid metabolism in the infant.[8] In veterinary patients, use of milk replacer can be considered if the drug must be continued.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No information found. The drug is not removed by dialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

In humans, fenofibrate may inhibit CYP2C9; it is not a CYP isoenzyme substrate. The following drug interactions either have been reported or are theoretical in humans or animals receiving fenofibrate or fenofibric acid and may be of significance in veterinary patients; unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring should be performed when appropriate.

- **Cannabidiol**: Concurrent use may increase cannabinoid exposure.
- **Cholestyramine**: Administer fenofibrate 1 hour before or 4 to 6 hours after cholestyramine.
- **Colchicine**: Concurrent use may increase risk for serious muscle toxicity.
- **Cyclosporine**: Concurrent use may increase risk for nephrotoxicity in humans. Fenofibrate may decrease serum concentrations of cyclosporine.
- **HMG CoA Reductase Inhibitors** (**"statins"**; eg, **atorvastatin, lovastatin**): Concurrent use may increase risk for serious myopathy.
- **Mycophenolate**: Concurrent use may increase risk for neutropenia and other adverse effects of mycophenolate.
- **Omeprazole**: Concurrent omeprazole with fenofibric acid preparations may modestly increase fenofibric acid exposure.
- **Sulfonylureas** (eg, **glipizide**): Concurrent fenofibrate may increase sulfonylurea exposure and risk for hypoglycemia.
- **Ursodiol**: Concurrent fenofibrate may increase biliary cholesterol secretion and reduce ursodiol effectiveness.
- **Warfarin**: Concurrent use may potentiate anticoagulant effect and risk for bleeding.

Laboratory Considerations

No specific laboratory interactions or considerations were noted.

Dosages

NOTE: There are many fenofibrate/fenofibric acid preparations that, except for generic equivalents, are not bioequivalent (ie, they cannot be interchanged/substituted). Be sure to specify the intended product when ordering fenofibrate.

DOGS:

Reduce serum triglycerides (extra-label): 6.5 – 10 mg/kg PO once daily with the first meal of the day.[1–3,9] Fenofibrate nanocrystal tablets were used in one study,[1] while the other studies used fenofibrate tablets.

Monitoring

- Fasting cholesterol panel (including triglyceride measurement)
- Adverse effects, including signs of muscle toxicity and gallbladder disease (eg, weakness, exercise intolerance, lethargy, appetite loss, vomiting, or diarrhea)
- Baseline and periodic serum chemistry panel to include evaluation of renal, liver, and muscle parameters (eg, BUN, creatinine, AST, ALT, bilirubin, CK)

Client Information

- *Fenoglide®*, *Lofibra®*, *Lipofen®*, and their generic equivalents must be taken with food. All other preparations may be taken without regard to food or meals.
- *Antara®*, *Fenoglide®*, *Lipofen®*, *Trilipix®*, and their generic equivalents should be administered whole, without crushing or chewing.
- Report to your veterinarian any vomiting, diarrhea, yellowing of the eyes or skin, and significant lethargy (weakness) or change in activity level.

Chemistry/Synonyms

Fenofibrate occurs as a white to almost-white, solid, nonhygroscopic, odorless, nonbitter-tasting substance. It is practically insoluble in water.

Storage/Stability
Store fenofibrate protected from light and moisture at controlled room temperature (25°C [77°F]) with excursions of 15°C to 30°C (59°F-86°F) permitted.

Compatibility/Compounding Considerations
No specific information was noted.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
NOTE: There are several fenofibrate/fenofibric acid preparations which are not bioequivalent. Be sure to specify the intended product when prescribing fenofibrate.

Fenofibrate Oral Tablets: 35 mg, 40 mg, 50 mg, 54 mg, 105 mg, 120 mg, and 160 mg; *Fenoglide®*, *Fibricor®*, *Lipofen®*, *Lofibra®*, *Triglide®*, generic; (Rx)

Fenofibrate Oral Tablets (nanocrystal): 48 mg and 145 mg; *Tricor®*, generic; (Rx)

Fenofibrate Oral Capsules: 30 mg, 43 mg, 50 mg, 67 mg, 90 mg, 130 mg, 134 mg, 150 mg, and 200 mg; *Antara®*, *Lipofen®*, *Lofibra®*, generic; (Rx)

Fenofibrate Oral Capsules (micronized): 43 mg, 67 mg, 130 mg, 134 mg, and 200 mg; *Antara®*, *Lofibra®*, generic; (Rx)

Fenofibric Acid Delayed-Release Oral Capsules: 45 mg and 135 mg; *Trilipix®*;(Rx)

Fenofibric Acid Capsules: 30 mg, 35 mg, 90 mg, and 105 mg; *Antara®*, *Fibricor®*

Fenoldopam
(fe-***nol***-doe-pam) *Corlopam®*
Dopamine Agonist (D_1); Antihypertensive

Prescriber Highlights
- ► May be useful in treating hypertensive emergencies in dogs and cats and nonpolyuric acute kidney injury in dogs, cats, and foals.
- ► No known contraindications; it can cause tachycardia and hypokalemia.
- ► Blood pressure, heart rate, urine output, and serum electrolytes should be monitored closely.
- ► Must be administered as a CRI with an accurate infusion pump; it must not be given as an IV bolus.

Uses/Indications
Fenoldopam may be used for the management of hypertensive emergencies in dogs and cats.[1] It is also used as adjunctive treatment of nonpolyuric acute kidney injury (AKI) in dogs, cats, and foals.

In healthy, anesthetized dogs with experimentally-induced hypovolemia, fenoldopam was shown to be renoprotective and helped to maintain renal blood flow, glomerular filtration rate, and natriuresis without causing hypotension.[2,3] However, in a prospective study of dogs with heatstroke, fenoldopam did not demonstrate a clinically relevant effect on the occurrence of acute kidney injury, kidney function parameters, or mortality.[4] An experimental study in young, healthy cats, a 2-hour infusion of 0.5 µg/kg/minute induced diuresis (delayed effect) and natriuresis, with creatinine clearance significantly increasing 6 hours after the infusion was stopped.[5] A retrospective study of 62 dogs and cats with AKI receiving fenoldopam demonstrated that the treatment was safe but there was no improvement in length of hospital stay, survival to discharge, or renal biochemical parameters compared to those that did not receive fenoldopam.[6]

In normotensive neonatal foals, low-dosage fenoldopam (0.04 µg/kg/min IV CRI) had no significant effects on systemic hemodynamics, creatinine clearance, sodium, chloride, or potassium excretion, but it did significantly increase urine output. High-dosage fenoldopam (0.4 µg/kg/min IV CRI) increased heart rate, decreased systemic arterial blood pressure, and had no significant effects on renal function. The authors concluded that low-dosage fenoldopam had a potential clinical application for prophylaxis or treatment of acute kidney injury in neonatal foals, but additional studies were warranted.[7]

In humans, fenoldopam is labeled for the treatment of severe hypertension; it is also used as a renoprotectant following cardiovascular surgery to improve GI oxygen flow in hypovolemic patients.[8] Due to its selectivity and lower risk for adverse effects, fenoldopam has largely replaced dopamine for adjunctive treatment of acute kidney injury. No beneficial effect on renal function has been noted in human patients with severe chronic kidney disease, heart failure, or hepatic disease.

Pharmacology/Actions
Fenoldopam is a selective postsynaptic dopamine agonist at D_1-receptors, resulting in peripheral arterial vasodilation, increased mesenteric and renal blood flow, diuresis, and reduced total peripheral resistance and systemic blood pressure. In humans, it has been shown to be renoprotective after cardiovascular surgery. Heart rates can increase secondary to a reflex-response to vasodilatory effects. Fenoldopam causes dose-related increases in renal plasma flow, decreases in renal vascular resistance, and produces diuresis, natriuresis, and kaliuresis without significantly affecting the glomerular filtration rate.

Fenoldopam antagonizes alpha-receptors ($alpha_2$ greater than $alpha_1$) at dosages higher than those that activate D_1-receptors, which also contributes to vasodilation. Fenoldopam has no affinity for D_2-receptors, beta-adrenergic receptors, serotonin receptors, or muscarinic receptors.

Pharmacokinetics
A pharmacokinetic study, conducted in 6 healthy beagles given fenoldopam 0.8 µg/kg/minute IV CRI for 3 hours, showed highly variable values of plasma concentrations and clearance, but the drug achieved steady-state plasma concentrations within 10 minutes of the infusion start and was rapidly eliminated with the drug becoming undetectable within 10 minutes of discontinuation. The authors suspected fenoldopam undergoes complete first-pass hepatic elimination in dogs and may undergo additional extra-hepatic clearance, including metabolism and/or renal excretion of unchanged drug.[9]

Six healthy cats given fenoldopam 0.8 µg/kg/minute IV CRI for 2 hours showed a pharmacokinetic profile similar to humans with the volume of distribution, clearance, and half-life of 198 mL/kg, 46 mL/kg/minute, and 3 minutes, respectively.[9]

In humans, fenoldopam has a rapid onset of action, with the antihypertensive effect occurring within 15 minutes. It is about 88% bound to plasma proteins, and almost no drug crosses the blood–brain barrier. The duration of action is ≈1 hour, and the elimination half-life is ≈5 minutes. Fenoldopam is metabolized in the liver with an extensive first-pass effect. The majority of a dose is excreted into the urine, primarily as the inactive glucuronide metabolite.

Contraindications/Precautions/Warnings
There are no known contraindications, but fenoldopam should be used with caution in patients with a history of sulfite sensitivity and glaucoma as increased intraocular pressure has been reported.[8] Additionally, cases of tachycardia and hypokalemia have been reported.

The drug must not be given as an IV bolus. Some preparations contain propylene glycol.

Adverse Effects

The adverse effect profile for fenoldopam is not well documented in animals. The majority of experimental studies were conducted in healthy dogs and cats and did not show any overt adverse effects.[3,5] Foals administered high-dose fenoldopam (0.4 µg/kg/minute) had significantly higher heart rates compared to low-dose fenoldopam or baseline values; 3/6 foals showed signs of restlessness.[7]

In humans, fenoldopam has caused tachycardia (dose-related), headache, flushing, nausea, vomiting, hypotension, and hypokalemia.

Reproductive/Nursing Safety

Fenoldopam was not teratogenic or fetotoxic when administered orally to laboratory animals during periods of organogenesis.[8] Fenoldopam is excreted in milk, but its effects on offspring have not been determined.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses of fenoldopam would likely produce hypotension and reflex tachycardia. The drug effects are generally short-lived (up to 1 hour). Monitoring heart rate, blood pressure, and electrolytes are mandatory. Data suggests it is unlikely to be removed via dialysis.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fenoldopam and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- Beta-Adrenergic Receptor Antagonists (eg, **atenolol, propranolol**): Can inhibit sympathetic reflex response to fenoldopam; concurrent use is not recommended.
- Hypotensive Drugs (eg, **amlodipine**, **hydralazine**, **nitroprusside, telmisartan**): Hypotensive effects of fenoldopam may be enhanced.

Laboratory Considerations

None noted

Dosages

NOTES:

1. Do NOT administer fenoldopam as an IV bolus; it must be diluted with 0.9% sodium chloride or 5% dextrose to a concentration of 40 to 60 µg/mL and administered IV as a CRI. See ***Compatibility/Compounding Considerations.***
2. CRI administration should be done with a calibrated, mechanical infusion pump.
3. Fenoldopam infusions can be discontinued abruptly or slowly withdrawn.

DOGS:

Adjunctive treatment of acute, nonpolyuric kidney injury (extra-label): 0.8 µg/kg/minute IV CRI for 5 hours has been suggested.[3,10]

Hypertensive emergency (extra-label): 0.1 µg/kg/minute IV CRI; monitor blood pressure carefully, and increase dosage by 0.1 µg/kg/minute every 15 minutes until the desired systolic blood pressure is reached, or to a maximum of 1.6 µg/kg/minute.[1]

CATS:

Adjunctive treatment of acute kidney injury (oliguric, anuric) (extra-label): 0.1 – 1 µg/kg/minute IV CRI for 2 hours has been recommended.[11] In a study in healthy cats, 0.5 µg/kg/minute IV CRI documented an increase in urine output.[5]

Hypertensive emergency (extra-label): 0.1 µg/kg/minute IV CRI; monitor BP carefully, and increase dosage by 0.1 µg/kg/minute every 15 minutes until the desired systolic blood pressure is reached, or to a maximum of 1.6 µg/kg/minute.[1]

FOALS:

Adjunctive treatment of acute kidney injury (extra-label): 0.04 – 0.4 µg/kg/minute IV CRI for 30 minutes has been used.[7]

Monitoring

- Blood pressure, heart rate
- Urine output
- Serum electrolytes, especially potassium. Infusions of fenoldopam have caused hypokalemia in human patients receiving infusions lasting less than 6 hours.

Client Information

Use fenoldopam only in an inpatient setting.

Chemistry/Synonyms

Fenoldopam mesylate (CAS Registry: 67227-56-9 fenoldopam, 67227-57-0 fenoldopam mesylate; ATC: C01CA190) occurs as a white to off-white powder and is soluble in water. The injectable solution contains propylene glycol and sodium metabisulfite. Unlike nitroprusside, fenoldopam is not degraded by light, nor does it cause thiocyanate toxicity.

Fenoldopam mesylate may also be known as fenoldopam mesilate, SKF-82526-j, or *Corlopam*®.

Storage/Stability

Store ampules and vials at 2°C to 30°C (36°F-86°F). Following dilution, discard solution after 4 hours at room temperature or 24 hours under refrigeration.

Compatibility/Compounding Considerations

Compatibility is dependent on factors, such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Before administration, the 10 mg/mL injectable concentrate should be diluted and is **compatible** with 0.9% sodium chloride injection or 5% dextrose injection for dilution. To dilute to 60 µg/mL (the usual dilution guideline for human pediatric patients and recommended for small animal species to reduce the risk for volume overload): add fenoldopam 30 mg (3 mL of concentrate) to 500 mL 0.9% sodium chloride or 5% dextrose, or add fenoldopam 15 mg (1.5 mL of concentrate) to 250 mL 0.9% sodium chloride or 5% dextrose. Fenoldopam should be administered as an IV CRI using a calibrated, mechanical infusion pump.

Drugs that are **Y-site compatible** with fenoldopam infusions include alfentanil, amikacin, atracurium, atropine, butorphanol, calcium gluconate, dexmedetomidine, diltiazem, diphenhydramine, dolasetron, epinephrine, fentanyl, heparin, hydrocortisone sodium succinate, hydromorphone, mannitol, naloxone, ondansetron, potassium chloride, and propofol.[12]

Drugs that are **Y-site incompatible** with fenoldopam infusions include ampicillin sodium, bumetanide, dexamethasone sodium phosphate, diazepam, fosphenytoin, furosemide, methylprednisolone sodium succinate, and sodium bicarbonate.[13]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 3 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information. The FEI (International Federation for Equestrian Sports) lists this drug as a "prohibited substance - banned".

HUMAN-LABELED PRODUCTS:
Fenoldopam injection solution: 10 mg/mL in 1 or 2 mL single-use ampules or vials; *Corlopam*®; (Rx)

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Fentanyl, Injection

(***fen***-ta-nil) *Sublimaze*®
Opioid

Prescriber Highlights
- ► Opioid analgesic used parenterally in small animals; potentially useful as a CRI in horses
- ► Contraindications: scorpion stings; use extreme caution when additional respiratory or CNS depression would be detrimental.
- ► Use caution in geriatric, ill, or debilitated patients and in those with GI obstruction, pre-existing respiratory problems, or renal or hepatic impairment.
- ► Adverse effects include dose-dependent respiratory, CNS, and circulatory depression (eg, bradycardia); urine retention; constipation; dysphoria; and agitation.
- ► Schedule II controlled substance in the United States
- ► See also ***Fentanyl, Transdermal Patch***

Uses/Indications
In veterinary medicine, fentanyl injection is used primarily in dogs and cats for the adjunctive control of postoperative pain and in the control of severe pain associated with nonspecific, widespread pain (eg, associated with cancer, pancreatitis, aortic thromboemboli, peritonitis). Perioperative injectable fentanyl may also reduce the requirements for inhalational anesthetics during surgery, which could be particularly advantageous in patients with compromised cardiac function. In healthy beagles, fentanyl decreased isoflurane and sevoflurane MAC by ≈40%.[1,2] Because of its short duration of action, fentanyl CRIs are particularly useful in critically ill or postsurgical patients, as it can be adjusted to meet the analgesia needs of the patient, minimize adverse effects, and be temporarily halted to assess neurologic status. Injectable fentanyl may be particularly useful in cats for perioperative pain control, especially when higher analgesic doses are required, as it appears to have fewer adverse effects in this species than either hydromorphone or morphine.

Pharmacology/Actions
Fentanyl is a mu-opioid agonist that is short acting and ≈80 to 100 times more potent than morphine. Mu receptors are found primarily in the pain-regulating areas of the brain, dorsal horn of the spinal cord, and different peripheral tissues; they are thought to contribute to the analgesia, euphoria, respiratory depression, physical dependence, miosis, and hypothermic actions of opioids. Receptors for opioid analgesics are found in high concentrations in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain; they are also found in tissues such as the GI tract, urinary tract, and other smooth muscles.

Pharmacokinetics
Fentanyl used via a single dose IV injection has a relatively short duration of effect in most species.

In dogs, a fentanyl 10 µg/kg IV bolus rapidly distributes and exhibits a large volume of distribution (ie, 5 L/kg). The terminal elimination half-life is ≈45 minutes; total clearance is 78 mL/min/kg. After dogs received a fentanyl 10 µg/kg IV bolus followed by a fentanyl 10 µg/kg/hour IV CRI, fentanyl blood concentrations were maintained ≈1 ng/mL, which is the assumed but not verified therapeutic analgesic level for this species.[3]

In cats, an elimination half-life of 2.4 hours, mean systemic clearance of 1.4 L/kg/hour, and an apparent volume of distribution of 4.42 L/kg were recorded after administration of a 5 µg/kg IV bolus, followed by 5 µg/kg/hour IV CRI for 2 hours.[4]

One study looked at pharmacokinetics of IV fentanyl in foals at 6 to 8, 20 to 22, and 41 to 42 days of age.[5] In this study, the average volumes of distribution were 3.55, 1.53, and 1.82 L/kg, respectively. The elimination half-lives were 49.3 minutes, 25.8 minutes, and 33.7 minutes, respectively.

Contraindications/Precautions/Warnings
Fentanyl is contraindicated in patients with known hypersensitivity to it or other opioids.

Because of its potency, fentanyl injection should be used only by those familiar with its use and when patients can be adequately monitored and supported.

Use with extreme caution in patients with CNS or respiratory depression or when using in conjunction with other CNS, respiratory, or cardiac depressants; adequate monitoring should be used. Use cautiously in geriatric, ill, or debilitated patients and in those with GI obstruction, pre-existing respiratory problems, or renal or hepatic impairment.

Opioid analgesics are contraindicated in patients stung by scorpions (eg, *Centruroides* spp), as it may potentiate venom effects.[6]

Opioids may cause mydriasis in cats. Approach patients slowly so as not to startle them, and keep patients out of bright light while pupils are dilated.

Do not confuse fentaNYL with ALFentanil, CARFentanil, REMIFentanil, or SUFentanil.

Adverse Effects
The primary adverse effects are dose-related respiratory (eg, bradypnea, hypercapnia), CNS (eg, sedation), and circulatory depression (eg, bradycardia, hypotension). Hypothermia is possible in dogs. Anticholinergic agents may be required to treat bradycardia when fentanyl is used intraoperatively. Dogs and cats appear to be susceptible, but less prone than humans, to opioid-induced respiratory depression. In a study[7] in healthy, young-adult dogs, concurrent administration of fentanyl and isoflurane resulted in significant decreases in mean arterial blood pressure, heart rate, cardiac index, and a significant increase in partial pressure of carbon dioxide ($PaCO_2$); all of which, except $PaCO_2$ returned to pretreatment levels over time. Dysphoria has been reported in ≈25% of dogs treated with fentanyl IV CRI postoperatively.[8] Fentanyl-induced asystole has been reported in 2 dogs under isoflurane anesthesia.[9] Data regarding fentanyl's effect on intraocular pressure in dogs are conflicting.[10,11]

Some patients exhibit dysphoria or agitation after receiving fentanyl; acepromazine or other mild tranquilizers may alleviate these effects.

In horses, fentanyl, like morphine, can initially stimulate then inhibit cecocolic activity. Horses heterozygous for the G57C polymorphism of the mu-opioid receptor had an increased locomotor response to fentanyl in one study.[12]

In humans, fentanyl can cause a rare syndrome called wooden chest, which is characterized by chest wall rigidity[13,14]; however, this syndrome has never been reported in dogs.[15]

Reproductive/Nursing Safety

Opioids cross the placenta. Embryocidal effects and reduced pup survival have been noted in rats.[16]

Most narcotic agonist analgesics are excreted into milk, but effects on nursing offspring may not be significant.

Overdose/Acute Toxicity

Overdoses may produce profound respiratory and/or CNS depression in most species. Newborns may be more susceptible to these effects than adult animals. Other toxic effects may include hypersalivation, ataxia, bradycardia, hypothermia, diarrhea, cardiovascular collapse, tremors, neck rigidity, and seizures.

Naloxone is the agent of choice when treating fentanyl-related respiratory and circulatory depression. In massive overdoses, naloxone may need to be repeated; mechanical respiratory support should be considered in patients with severe respiratory depression. Patients should be closely observed, as naloxone's effects sometimes diminish before subtoxic levels of fentanyl are attained.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fentanyl and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **enalapril**): Concurrent use may increase the risk for bradycardia, hypotension, and orthostasis.
- **Alfaxalone**: Fentanyl reduced alfaxalone dosage requirements in dogs.[17,18]
- **Anesthetic, Inhalant**: Isoflurane anesthesia reduced fentanyl clearance in horses, and increased mean arterial pressure was noted.[19] Fentanyl reduces MAC by ≈40%.[1,2] Combination increases the risk for bradycardia or hypotension.
- **Anticholinergic Agents** (eg, **acepromazine, amitriptyline, atropine, clomipramine, hyoscyamine**): Concurrent use may increase the risk for urinary retention, constipation, and CNS and respiratory depression.
- **Angiotensin Receptor Blockers** (**ARBs,** eg, **telmisartan**): Concurrent use may increase the risk for bradycardia, hypotension, and orthostasis.
- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk of respiratory depression. However, a study in dogs showed that ketoconazole did not significantly alter the elimination of fentanyl.[20]
- **Barbiturates** (eg, **pentobarbital, phenobarbital**): Concurrent use may increase the risk for CNS and/or respiratory depression. Monitor, and adjust doses accordingly.
- **Benzodiazepines** (eg, **diazepam, midazolam**): Concurrent use may increase the risk for CNS and/or respiratory depression. Monitor, and adjust doses accordingly.
- **Beta-Blockers** (eg, **atenolol, esmolol, propranolol**): May produce bradycardia or hypotension if used concurrently with fentanyl
- **Bethanechol**: Concurrent use may antagonize the beneficial effects of bethanechol on GI motility; avoid combination of these drugs.
- **Calcium Channel Blockers** (eg, **amlodipine**, **diltiazem**): Concurrent use may increase the risk for bradycardia, hypotension, and orthostasis. Diltiazem may increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression.
- **Cannabidiol**: Concurrent use may increase the risk for CNS depression.
- **Cimetidine**: May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression.
- **Desmopressin**: Concurrent use may increase levels of oral desmopressin and increase the risk for water intoxication and/or hyponatremia, which can progress to seizures, coma, respiratory arrest, and death. Monitor electrolytes and renal function.
- **Dextromethorphan**: Concurrent use may increase the risk for serotonin syndrome.
- **Diuretics** (eg, **furosemide**): Opioids may decrease therapeutic effects of diuretics.
- **Domperidone**: Concurrent use may antagonize the GI effects of domperidone.
- **Hepatic Enzyme Inducers** (eg, **griseofulvin, mitotane, phenobarbital**): Concurrent use may decrease levels of fentanyl. Monitor clinical response and adjust doses accordingly.
- **Grapefruit Juice**: May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression
- **Ifosfamide**: Concurrent use may increase the risk for neurotoxicity, including somnolence, confusion, hallucinations, blurred vision, urinary incontinence, seizures, and coma. Use cautiously and monitor.
- **Iohexol**: Concurrent use of opioids with intrathecal iohexol may increase the risk for seizures. Opioids should be withheld for 48 hours before and 24 hours after intrathecal administration of iohexol.
- **Loperamide**: Concurrent use may increase the risk for constipation.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, selegiline**): Concurrent use may increase the risk for anxiety, confusion, hypotension, respiratory depression, cyanosis, and coma. MAOIs inhibitors should be withheld for 14 days prior to administration of opioids; avoid combination of these drugs.
- **Metoclopramide**: Concurrent use may antagonize the prokinetic effects of metoclopramide.
- **Neuromuscular Blocking Agents** (eg, **atracurium, pancuronium**): Concurrent use may increase the risk for tachycardia, bradycardia, and/or hypotension. Use cautiously and monitor.
- **Propofol**: Increased risk for CNS and cardiorespiratory depression
- **Serotonergic Agents** (eg, **fluoxetine, ondansetron**): Concurrent use may increase the risk for serotonin syndrome; avoid combination of these drugs.
- **Tramadol**: Concurrent use may increase the risk for seizures, serotonin syndrome, urine retention, and constipation. The risk for CNS and respiratory depression may be additive.

Laboratory Considerations

- Because opioids may increase biliary tract pressure, plasma **amylase** and **lipase** values can be increased up to 24 hours following drug administration.

Dosages

NOTES:

1. **Adequate patient monitoring is essential. Be sure to have naloxone readily available when administering fentanyl.**
2. Do not confuse dosages listed as µg/kg or mg/kg; CRI dosages may be reported as mg/kg/hour, µg/kg/hour, or µg/kg/minute.

3. Always double-check dosages and resulting volumes when using injectable fentanyl.
4. All dosages are extra-label.

DOGS/CATS:

Perioperative analgesia: Fentanyl 10 µg/kg IV loading dose, followed by fentanyl 10 µg/kg/hour IV CRI may be a guideline during general anesthesia to provide analgesia in dogs.[3] Others have recommended loading doses ranging from 2 – 10 µg/kg IV, followed by 2 – 10 µg/kg/hour IV CRI for dogs.[21] In cats, fentanyl 5 µg/kg IV loading dose followed by 5 µg/kg/hour IV CRI.[22] If bolus IV, IM, or SC doses (usually 5 – 8 µg/kg) are administered without a follow-up CRI, duration of action is very short and re-administration may need to be repeated at 1 to 2 hour intervals.

Severe pain in the emergent patient: Fentanyl 10 – 50 µg/kg IV titrated to effect; use the effective dose as an hourly IV CRI. Give CRI in conjunction with NSAIDs when they are not contraindicated. Ketamine 4 mg/kg IV as a bolus can be used with fentanyl to provide additional analgesia. In addition, the following can be added: *in dogs*, lidocaine 2 – 4 mg/kg IV bolus, followed by lidocaine 2 – 4mg/kg/hour IV CRI; *in cats*, lidocaine 0.25 – 1 mg/kg IV bolus, followed by lidocaine 0.5 – 2 mg/kg/hour IV CRI. Use caution to avoid toxicity if local anesthetics have been administered by means of a different route. Consider combining this regimen with other analgesic modalities (eg, epidural analgesia, local nerve blocks), or anesthetize the patient while attempting to find or treat the inciting cause.[23]

Epidural analgesia: Fentanyl 4 µg/kg, diluted with 0.2 mL preservative-free saline or local anesthetic, and placed in the epidural space. This has predominantly supraspinal effects, with onset occurring in less than 10 minutes, with a ½-hour duration.[24]

Anesthetic agent: Fentanyl 20 – 40 µg/kg IV (or SC, IM) bolus has been noted when used a sole agent; decrease the dose if using with other cardio- or respiratory depressant agents. Dosages are generally higher than those used for analgesia but, like all anesthetic agents, vary depending on comorbidities, patient response, and other coadministered drugs and anesthetic agents. To reduce MAC and provide intraoperative pain control, fentanyl may then be administered as a CRI. CRI dosage recommendations vary considerably, but usually are in the 5 – 20 µg/kg/hour (up to 40 µg/kg/hour in dogs) range.

FERRETS:

Perioperative analgesia and adjunctive anesthetic agent: fentanyl 5 – 10 µg/kg IV preoperatively followed by fentanyl 10 – 20 µg/kg/hour IV CRI with ketamine 0.3 – 0.4 mg/kg/hour IV CRI intraoperatively. Postoperatively, fentanyl 2 – 5 µg/kg/hour IV CRI with ketamine 0.3 – 0.4 mg/kg/hour IV CRI.[25]

RABBITS/RODENTS/SMALL MAMMALS:

Perioperative analgesia: 5 – 20 µg/kg IV bolus for a 30 to 60 minute duration.[26] In rabbits, fentanyl has been shown to reduce isoflurane MAC when used intraoperatively.[27]

HORSES:

Analgesia: 10 µg/kg IV over 5 minutes produced analgesia for up to 30 minutes.[28]

Partial intravenous anesthesia (PIVA) protocol: A study in anesthetized horses showed that a fentanyl IV CRI ranging from 6 – 8 µg/kg/hour (plasma concentration 13 ng/mL) must be administered to decrease the MAC of isoflurane by 18%.[29] In another study, the authors used a loading dose of fentanyl 4 – 8 µg/kg IV over 12 minutes, followed by fentanyl 6 – 12 µg/kg/hour IV CRI (plasma concentration was 13 – 24 ng/mL).[30] These doses did not significantly decrease the MAC of isoflurane. Several horses showed undesirable and potentially injurious behavior during recovery. The authors concluded that the study results did not support use of fentanyl as an anesthesia adjuvant.

SHEEP/GOATS:

Anesthetic agent: One study determined that 5 µg/kg/hour IV CRI did not reduce isoflurane MAC.[31] Another study suggested that 10 µg/kg/hour IV CRI with isoflurane in oxygen reduced the isoflurane requirements without clinically affecting the cardiorespiratory stability or postoperative recovery.[32] In goats, dosages of 15 µg/kg/hour IV CRI or greater have been associated with severe excitatory behavior.[33]

Epidural analgesia: fentanyl 4 µg/kg with bupivacaine 0.25 mg/kg for lumbosacral epidural provided analgesia for 180 minutes.[34]

Monitoring

- Analgesic efficacy
- Heart rate, blood pressure, pulse oximetry, respiratory rate, $ETCO_2$
- CNS effects (eg, sedation, dysphoria, excitement)

Chemistry/Synonyms

Fentanyl citrate, a potent opioid agonist, occurs as a white crystalline powder. It is sparingly soluble in water and soluble in alcohol. It is odorless and tasteless (not recommended for taste test because of extreme potency) with a pK_a of 8.3 and a melting point between 147°C to 152°C (296.6°F-305.6°F). Fentanyl citrate injection has a pH between 4 to 7.5.

Fentanyl and fentanyl citrate may also be known as fentanylum, fentanyli citras, McN-JR-4263-49, phentanyl citrate, R-4263, or *Sublimaze®*.

Storage/Stability

Fentanyl injection should be stored protected from light at controlled room temperature. It is hydrolyzed in an acidic solution.

Fentanyl is a schedule 2 (C-II) controlled substance that should be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

The injection is **compatible** with normal saline and D_5W. Fentanyl citrate injection is reported to be **compatible** with clonidine, bupivacaine, ropivacaine, and ketamine.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 1 substance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Fentanyl Injectable: 0.05 mg/mL (50 µg/mL) in 1 mL, 2 mL, 5 mL, 10 mL, 20 mL, and 50 mL preservative-free ampules and vials; *Sublimaze®*, generic; (Rx, C-II)

All fentanyl products are schedule 2 controlled substances. Report dispensing to state monitoring programs where required.

For the complete list of references, see **wiley.com/go/budde/plumb**

Fentanyl, Transdermal Patch

(***fen***-ta-nil) *Duragesic®, Ionsys®*

Opioid

See also ***Fentanyl, Injection***

Prescriber Highlights

- ► Opioid analgesic used transdermally (extra-label) in veterinary patients
- ► Contraindications include scorpion stings; use extreme caution when additional respiratory or CNS depression would be detrimental.
- ► Use caution in geriatric, ill, febrile, or debilitated patients and in those with GI obstruction, pre-existing respiratory problems, or renal or hepatic impairment.
- ► Adverse effects include dose-dependent respiratory, CNS, and circulatory depression (eg, bradycardia); rashes at the patch site; urine retention; constipation; dysphoria; and agitation.
- ► Delayed onset of analgesia (eg, 6 hours in cats, 12 to 24 hours in dogs) precludes use for acute pain.
- ► Body temperature and application site influence transdermal absorption of fentanyl; inadequate patch adherence increases risk for detachment or ingestion.
- ► Schedule II controlled substance in the United States

Uses/Indications

In veterinary medicine, transdermal patches are used primarily in dogs[1,2] and cats[3] and have been shown to be useful for the adjunctive control of postoperative pain, severe pain associated with chronic pain, and nonspecific, widespread pain (eg, associated with cancer, pancreatitis, aortic thromboemboli, peritonitis).

Overall, transdermal fentanyl is thought to be clinically effective and has not demonstrated substantial adverse effects. A noncontrolled study in 10 dogs following spinal surgery measured plasma fentanyl concentrations after transdermal patch application (mean patch concentration, 4.1 ± 0.8 µg/kg/hour) and concluded that fentanyl patches may represent a valid aid for pain relief in small animals and can contribute to the postoperative well-being of patients undergoing major surgery.[1] However, one study in dogs comparing transdermal (patch) fentanyl with morphine IM for pain control during the first 24 hours after orthopedic surgery did not show any significant pain control benefit from the patch, which is considerably more expensive than morphine IM.[4]

In humans, significant respiratory depression with fentanyl patches after surgery has precluded postoperative use, but this has not been a significant problem in veterinary medicine.

Pharmacology/Actions

Fentanyl is a mu-opioid agonist that is short acting and ≈80 to 100 times more potent than morphine. Mu receptors are found primarily in the pain-regulating areas of the brain, dorsal horn of the spinal cord, and different peripheral tissues; they are thought to contribute to the analgesia, euphoria, respiratory depression, physical dependence, miosis, and hypothermic actions of opioids. Receptors for opioid analgesics are found in high concentrations in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain; they are also found in tissues such as the GI tract, urinary tract, and other smooth muscles.

Pharmacokinetics

There have been limited pharmacokinetic studies performed with transdermal fentanyl patches in dogs, cats, horses, sheep, chickens, rabbits, goats, alpacas, and ball pythons. Although therapeutic concentrations of fentanyl are usually attained, there is significant interpatient variability for both the time to achieve therapeutic concentrations and the concentrations themselves. Some animals may not achieve serum concentrations thought to be therapeutic (ie, 0.6 – 1 ng/mL). In an in vitro study of canine skin, fentanyl penetrated skin from the groin region more rapidly and with a shorter lag time than skin from the neck and thorax.[5] In dogs, the patch should be applied 24 hours in advance of need if possible, with a minimum of 12 hours before the patch is needed; for continued use, patches may need to be changed every 48 to 72 hours. Cats tend to achieve therapeutic concentrations faster than dogs. Most cats attain therapeutic benefit ≈6 hours after application; duration of action persists for at least 72 hours (usually for at least 104 hours). Duration of action is generally longer in cats than in dogs.

In horses, fentanyl from patches is rapidly absorbed, with therapeutic concentrations (thought to be 0.6 – 1 ng/mL) achieved ≈6 hours after application and persisting for 48 hours or more; however, in ≈⅓ of the horses, plasma concentrations never reached greater than 1 ng/mL.[6]

In sheep, patches applied at a mean dose of 2.05 µg/kg/hour had an average T_{max} of 12 hours (range, 4-24 hours) and a C_{max} of 1.3 ng/mL (range, 0.62 – 2.73 ng/mL); concentrations remained above 0.5 ng/mL for 40 hours after application.[7] A study showed that fentanyl patches delivering 1.1 – 1.4 µg/kg/hour did not affect thermal or mechanical nociceptive threshold in sheep.[8] A more recent study suggested that a 2 µg/kg/hour patch should be applied 24 to 36 hours prior to surgery.[9]

In goats, a target dose of 2.5 µg/kg/hour resulted in a peak fentanyl concentration 12 hours after application, and concentrations were maintained above 0.5 ng/mL for 40 hours.[10]

Contraindications/Precautions/Warnings

Fentanyl is contraindicated in patients with known hypersensitivity to it, other opioids, or any component of the product (including the adhesive for the patch).

Absorption and efficacy can be highly variable between patients wearing transdermal patches; injectable rescue analgesia should be available.

Use with extreme caution in patients with CNS or respiratory depression or when using with other CNS, respiratory, or cardiac depressants; adequate monitoring should be used. Doses of other opioids may need to be reduced when given in conjunction with transdermal fentanyl, particularly several hours after application of the patch. Transdermal fentanyl should be used cautiously in geriatric, ill, or debilitated patients and in those with GI obstruction, pre-existing respiratory problems, or renal or hepatic impairment. Febrile patients may have increased absorption of fentanyl and will require increased monitoring.

Opioid analgesics are contraindicated in patients stung by scorpions (eg, *Centruroides* spp), as it may potentiate venom effects.[11]

Opioids may cause mydriasis in cats. Approach these patients slowly in order to not startle them, and keep the patient out of bright light while pupils are dilated.

In a study, 4 out of 7 calves displayed adverse cardiac and behavioral effects after application of patches with 1 – 2 µg/kg/hour; 2 calves required reversal with naloxone.[12]

Previously, fentanyl patches were only available in a gel-matrix form that could not be cut. Although brands are now available that potentially can be cut, it is recommended to prescribe appropriately sized patches that do not require cutting. Consult a veterinary pharmacist before cutting patches.

Increased body temperature increases fentanyl absorption. Consider removing the patch if the patient develops a fever; if the patch is left in place, the patient must be closely monitored for adverse effects. Do not allow an applied fentanyl patch to be exposed to exogenous heat sources (eg, heating pads). Increased drug release and

absorption have occurred with fatal results.

Used fentanyl patches must be disposed of safely, as they can contain significant amounts of residual drug and can pose a risk for intoxication of exposed humans, especially children, if placed in the regular trash.[13] To avoid this risk, and the risk of diversion, the FDA recommends that used patches be disposed of promptly via a drug take-back program or be flushed down the toilet.

Do not confuse fentanyl with ALFentanil, CARFentanil, REMIFentanil, or SUFentanil.

Adverse Effects

The primary adverse effects of most concern are respiratory (eg, bradypnea), CNS (eg, sedation), and circulatory depression (eg, bradycardia, hypotension); however, the incidence of these effects has not been widespread when fentanyl patches are used alone (ie, without other opioids or respiratory and cardiac depressant medications). Rashes at the patch site have been reported. If a rash occurs, the patch should be removed, and a different application site should be chosen if an additional patch is warranted. Urine retention and constipation may occur. Consider removing the patch in patients that develop a fever after application, as fentanyl absorption may increase. Some patients exhibit dysphoria or agitation after application; acepromazine or other mild tranquilizers may alleviate these effects.

Reproductive/Nursing Safety

Opioids cross the placenta. Embryocidal effects and reduced pup survival have been noted in rats.[14] Prolonged opioid use during pregnancy may result in neonatal withdrawal symptoms. Fentanyl may reduce fertility in males and females.

Most narcotic agonist analgesics are excreted into milk, but effects on nursing offspring may not be significant.

Overdose/Acute Toxicity

Overdoses may produce profound respiratory and/or CNS depression in most species. Neonates may be more susceptible to these effects than adult animals. Other toxic effects may include hypersalivation, ataxia, bradycardia, hypothermia, diarrhea, cardiovascular collapse, tremors, neck rigidity, and seizures.

Naloxone is the agent of choice when treating respiratory and circulatory depression. In massive overdoses, naloxone may need to be repeated; mechanical respiratory support should be considered in patients with severe respiratory depression. Patients should be closely observed, as naloxone's effects sometimes diminish before subtoxic levels of fentanyl are attained.

Drug Interactions

In humans, fentanyl is a substrate of CYP3A4. The following drug interactions have either been reported or are theoretical in humans or animals receiving fentanyl and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Agents** (eg, **acepromazine, amitriptyline, atropine, clomipramine, hyoscyamine**): Concurrent use may increase the risk for urinary retention, constipation, and CNS and respiratory depression.
- **Anesthetic Agents** (eg, **isoflurane, propofol**): May produce bradycardia or hypotension
- **Angiotensin Receptor Blockers** (**ARBs,** eg, **telmisartan**): Concurrent use may increase the risk for bradycardia, hypotension, and orthostasis
- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression. However, a study in dogs showed that ketoconazole did not significantly alter the elimination of fentanyl.[15]
- **Barbiturates** (eg, **pentobarbital, phenobarbital**): Concurrent use may increase the risk for CNS and/or respiratory depression. Monitor, and adjust doses accordingly.
- **Benzodiazepines** (eg, **diazepam, midazolam**): Concurrent use may increase the risk for CNS and/or respiratory depression. Monitor, and adjust doses accordingly.
- **Beta Blockers** (eg, **atenolol, esmolol, propranolol**): May produce bradycardia or hypotension if used concurrently with fentanyl
- **Bethanechol**: Concurrent use may antagonize the beneficial effects of bethanechol on GI motility; avoid combination of these drugs.
- **Calcium Channel Blockers** (eg, **amlodipine**, **diltiazem**): Concurrent use may increase the risk for bradycardia, hypotension, and orthostasis. Diltiazem may increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression.
- **Cannabidiol**: Concurrent use may increase the risk for CNS depression.
- **Cimetidine**: May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression.
- **Desmopressin**: Concurrent use may increase levels of oral desmopressin and increase the risk for water intoxication and/or hyponatremia, which can progress to seizures, coma, respiratory arrest, and death. Monitor electrolytes and renal function.
- **Dextromethorphan**: Concurrent use may increase the risk for serotonin syndrome.
- **Diuretics** (eg, **furosemide**): Opioids may decrease therapeutic effects of diuretics.
- **Domperidone**: Concurrent use may antagonize the GI effects of domperidone.
- **Hepatic Enzyme Inducers** (eg, **griseofulvin, mitotane, phenobarbital**): Concurrent use may decrease levels of fentanyl. Monitor clinical response and adjust doses accordingly.
- **Grapefruit Juice**: May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk for respiratory depression.
- **Ifosfamide**: Concurrent use may increase the risk for neurotoxicity, including somnolence, confusion, hallucinations, blurred vision, urinary incontinence, seizures, and coma. Use cautiously and monitor.
- **Iohexol**: Concurrent use of opioids with intrathecal iohexol may increase the risk for seizures. Opioids should be withheld for 48 hours before and 24 hours after intrathecal administration of iohexol.
- **Loperamide**: Concurrent use may increase the risk for constipation.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): May increase the half-life and decrease the clearance of fentanyl, leading to prolonged effects and an increased risk of respiratory depression
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, selegiline**): Concurrent use may increase the risk for anxiety, confusion, hypotension, respiratory depression, cyanosis, and coma. MAOIs should be withheld for 14 days prior to administration of opioids; avoid combination of these drugs.
- **Metoclopramide**: Concurrent use may antagonize the prokinetic effects of metoclopramide.
- **Neuromuscular Blocking Agents** (eg, **atracurium, pancuronium**): Concurrent use may increase the risk for tachycardia, bradycardia, and/or hypotension. Use cautiously and monitor.

- **Serotonergic Agents** (eg, **fluoxetine, ondansetron**): Concurrent use may increase the risk for serotonin syndrome; avoid combination of these drugs.
- **Tramadol**: Concurrent use may increase the risk for seizures, serotonin syndrome, urinary retention, and constipation. The risk for CNS and respiratory depression may be additive.

Laboratory Considerations

- Because opioids may increase biliary tract pressure, serum **amylase** and **lipase** values can be increased up to 24 hours following drug administration.

Dosages

NOTES:

1. Do not confuse total amount of fentanyl per patch with the fentanyl delivery rate (eg, 75 mcg/hr patches contains 7.65 mg fentanyl).
2. Always double-check dosages when using fentanyl.
3. Human-labeled fentanyl patches are used in an extra-label manner in all veterinary species.

Postoperative pain control or palliative short-term control of cancer pain: There is significant interspecies and interpatient variability of response to the transdermal product. Application prior to surgery is advised when used as the primary analgesic for postoperative pain, as many hours may be required for therapeutic concentrations to be achieved. In general, therapeutic concentrations may be reached in 12 to 24 hours in dogs, 6 to 24 hours in cats, and 12 hours in horses. Patches used for short-term cancer pain control generally need to be replaced every 4 to 5 days in dogs and cats.

To transition from fentanyl infusions to a fentanyl patch in cats: Adjust fentanyl IV CRI rate to reach optimal effect before patch is applied; after patch application, the infusion should then be tapered and discontinued over the next 8 to 24 hours and the patient response observed. Failure of the patch is suspected if the patient responds well on the infusion but poorly on the patch. In cats, fentanyl delivery from the patch is highly variable. A 25 µg patch provides ≈10 µg/hour.[16]

Dosage range recommendations are typically 2 – 2.5 µg/kg/hour but may range from 1 – 5 µg/kg/hour. The following table can be used as a general guide:

Species	Body weight	Dose, patch size (µg/hour)	Patch location
Cats	Less than 4 kg[17] (11 lb)	12 (a 25 µg/hour patch may be used in larger cats)	Lateral thorax, inguinal area, metatarsal/carpal areas, or base of tail. Cervical area is not recommended, as the patch tends to fall off.
Dogs	Less than 5 kg (11 lb)	12 µg/hour	Thorax, inguinal area, metatarsal/carpal areas, or base of tail. Dorsal or lateral cervical area has been used, but leashes must not be placed around the neck if fentanyl patches are in place.
Dogs	5-10 kg (11-22 lb)	25 µg/hour	Thorax, inguinal area, metatarsal/-carpal areas, or base of tail. Dorsal or lateral cervical area has been used, but leashes must not be placed around the neck if fentanyl patches are in place.
Dogs	10-20 kg (22-44 lb)	50 µg/hour	Thorax, inguinal area, metatarsal/-carpal areas, or base of tail. Dorsal or lateral cervical area has been used, but leashes must not be placed around the neck if fentanyl patches are in place.
Dogs	20-30 kg (44-66 lb)	75 µg/hour	Thorax, inguinal area, metatarsal/-carpal areas, or base of tail. Dorsal or lateral cervical area has been used, but leashes must not be placed around the neck if fentanyl patches are in place.
Dogs	Greater than 30 kg (66 lb)	100 µg/hour	Thorax, inguinal area, metatarsal/-carpal areas, or base of tail. Dorsal or lateral cervical area has been used, but leashes must not be placed around the neck if fentanyl patches are in place.
Horses	350-500 kg (772-1102 lb)	Two 100 µg/hour applied simultaneously	Neck, antebrachium (foals), thorax (adults)
Pigs	17-30 kg (38-66 lb)	50 - 100 µg/hour	Lateral thorax
Sheep	55-70 kg (121-154 lb)	50 – 100 µg/hour	Abdomen, cervical, antebrachial area
Goats	20-40 kg (44-88 lb)	50 – 100 µg/hour	Abdomen, cervical, antebrachial area
Alpacas	60 kg (132 lb)	100 + 25 µg/hour	Antebrachium
Rabbits	3.5-4 kg (7.7-8.8 lb)	12 – 25 µg/hour	Lateral thorax
Chickens	2.2-3.6 kg (4.8-7.9 lb)	25 µg/hour	Iliopsoas muscle, feathers plucked from 4 cm^2 area[18]

PATCH APPLICATION

NOTE: Direct patch contact with heating pads can significantly increase fentanyl absorption and the risk for toxicity. The patch should be kept dry.

1) Carefully shave or closely clip the site. DO NOT use depilatory (ie, hair removal) agents in preparation of the site. Clip at least a 1- to 2-cm margin around the patch.
2) Gently wipe (do not scrub) the site with a damp cloth (use water only) to remove hair and any debris; allow the skin to completely dry. This step is absolutely necessary, or the patch will not stick to the skin. DO NOT wipe the area with alcohol or surgical scrub solution, as they may remove surface lipids from the skin and alter drug absorption.
3) Place the patch on the skin and hold it in place with the palm of your hand for 2 to 3 minutes. The heat of your hand will help the adhesive bond to the skin. Failure to perform this step will result in the patch falling off. Fentanyl will not be absorbed properly if the patch is not fully adhered to the skin.
4) Although not required, patches may be secured in place with a transparent adhesive film dressing or first aid tape *around the edges only*; never cover fentanyl patches with any other bandage or tape.[19] If *Bioclusive®* is used, apply the fentanyl patch as described above, then spray around the perimeter and over the patch with medical adhesive spray (eg, *Medical Adhesive®*), place *Bioclusive®* over the site, and press it down firmly. Be sure to clip an area large enough so *Bioclusive®* can adhere to the patch and the skin. If *Bioclusive®* only adheres to the patch and fur without good adherence to the skin, the patch tends to peel up and dislodge.
5) Using a permanent marker, label the patch with the patch size (eg, 12, 25, 50, 75, 100 µg/hour) and the date and time the patch was placed. Patches have been shown to release effective fentanyl levels for up to 5 days in cats, 3 days in dogs, and 2 days in horses. Patches can potentially be left on longer, especially in dogs.
6) The person applying or removing the patch must thoroughly wash their hands with soap and water to remove any drug residue. Surgical gloves may be worn to place or remove patches, as skin contact does occur when handling the adhesive edges.
7) Dispose of used patches by flushing them down the toilet if drug take-back programs are not available.

Monitoring

- Analgesic efficacy
- Heart rate and respiratory rate
- CNS effects (eg, sedation, dysphoria, excitement)
- Security of patch placement

Client Information

Explain carefully to owners how to apply (if applicable), remove, and dispose of patches. Consider making application, removal, and disposal an outpatient procedure, thereby bypassing owner concerns.

- This drug is a narcotic pain reliever in the form of a topical patch. It may take several hours after application before the drug starts working. Pain relief may be provided for 3 to 5 days in dogs and cats.
- Fentanyl is a C-II controlled drug and requires a new written prescription for refills. Use of this medication in animals or humans other than those for whom they are prescribed is illegal.
- This drug is usually tolerated well by animals. High doses can cause sedation, dysphoria (eg, howling, whining), slowed heart rate, constipation, and slow breathing. Contact your veterinarian if you feel your animal is too sedated or if you notice skin irritation or redness in the area of the patch application.
- Increased body temperature (eg, fever, overheating, warm compresses) may cause your pet to receive too much of this medicine at one time and increase the risk for side effects and toxicity. Use caution with warming blankets, increased exercise, and exposure to hot surrounding temperatures.
- Patches (new, on the animal, or used) must be kept away from children; use cautiously in households in which young children or animals could remove, ingest, or be exposed to patches. If human skin comes into contact with the patch, wash the area with water only (do not use soap).
- Dispose of the patch using a drug take-back program (preferred) or by flushing the patch down the toilet if a take-back program is not available.

Chemistry/Synonyms

Fentanyl citrate, a very potent opioid agonist, occurs as a white crystalline powder. It is sparingly soluble in water and soluble in alcohol. It is odorless and tasteless (not recommended for taste test because of extreme potency) with a pK_a of 8.3 and a melting point between 147°C to 152°C (296.6°F-305.6°F).

Fentanyl and fentanyl citrate may also be known as fentanylum, fentanyli citras, McN-JR-4263-49, phentanyl citrate, R-4263, *Actiq®*, *Fenodid®*, *Fenta-Hameln®*, *Fentabbott®*, *Fentanest®*, *Fentax®*, *Fentora®*, *Haldid®*, *Ionsys®*, *Leptanal®*, *Nafluvent®*, *Sintenyl®*, *Sublimaze®*, *Tanyl®*, or *Trofentyl®*.

Storage/Stability

Fentanyl transdermal patches should be stored at temperatures less than 25°C (77°F) and applied immediately after being removed from the individually sealed package. Do not freeze. Do not cut patches without first verifying the patch matrix.

Fentanyl is a schedule 2 (C-II) controlled substance that should be stored in an area that is substantially constructed and securely locked. Follow applicable local, state, and federal rules regarding disposal of unused or wasted controlled drugs.

Compatibility/Compounding Considerations

Most modern transdermal fentanyl patches can be cut, but it is advised to obtain the opinion of a pharmacist before doing so.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 1 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Fentanyl Transdermal System (Patch):

Fentanyl delivery rate (µg/hour)	Patch physical size (varies by manufacturer [cm^2])	Total fentanyl content (varies by manufacturer [mg])
12.5	3.1-5.4	1.3-1.5
25	6.25-10.7	2.5-3.1
37.5	9.4-16.4	3.8-4.1
50	12.5-21.4	5-6.9
62.5	15.6-26.8	6.4-6.9
75	15.7-32.1	7.5-9.3
87.5	18.8-37.5	8.9-9.7
100	25-42.8	10-12.4

Duragesic®-12, - 25, -50, -75 and *-100*; generic; (Rx, C-II) Patch dimensions and fentanyl content vary by manufacturer.

The following human product is available, but there is currently no information on their clinical usefulness or safety in animals:

Fentanyl Iontophoretic Transdermal System: 40 **µg**/dose fentanyl hydrochloride (equivalent to 44.4 **µg** of fentanyl) delivered over a 10-minute period after each activation of the dose button. Each system contains fentanyl hydrochloride 10.8 mg; *Ionsys®*; (Rx; C-II)

All fentanyl products are schedule II controlled substances. Report dispensing to state monitoring programs where required.

References

Ferrous Sulfate

(***fair***-us sul-***fayte***)

Nutritional, Hematinic

Prescriber Highlights

- ► Oral iron supplement for the treatment of iron deficiency anemia or as an iron supplement
- ► The most common adverse effect is GI upset.
- ► Overdoses can be life-threatening.
- ► A wide variety of products exist, and none are FDA-approved; use caution when choosing a product.

Uses/Indications

Ferrous sulfate can be used to treat iron deficiency anemia in dogs due to chronic blood loss, as iron is a necessary trace element in all hemoglobin-utilizing animals. Additionally, it has been used as adjunctive therapy in dogs or cats when receiving epoetin (erythropoietin) or darbepoetin therapy.

Pharmacology/Actions

Iron is necessary for the formation of hemoglobin and myoglobin and for the transport and utilization of oxygen. If an iron deficiency exists, iron administration will correct physical signs of iron deficiency and will correct decreased hemoglobin concentrations secondary to iron deficiency. Iron will not stimulate erythropoiesis or correct hemoglobin abnormalities that are not caused by iron deficiency.

Ferrous sulfate is one of many available iron salts. Ferrous sulfate contains 20% elemental iron by weight (325 mg ferrous sulfate = 65 mg elemental iron).

Pharmacokinetics

Oral absorption of iron salts is complex and determined by a variety of factors, including diet, iron stores present, degree of erythropoiesis, and dose. Iron is thought to be absorbed throughout the GI tract but is primarily absorbed in the duodenum and proximal jejunum. Food in the GI tract may reduce the amount absorbed but can help manage GI upset.

After absorption, the ferrous iron is immediately bound to transferrin, transported to the bone marrow, and eventually incorporated into hemoglobin. Iron metabolism occurs in a nearly closed system. Because iron liberated by the destruction of hemoglobin is reused by the body and only small amounts are lost by the body via hair and nail growth, normal skin desquamation, and GI tract sloughing, normal dietary intake usually is sufficient to maintain iron homeostasis.

Contraindications/Precautions/Warnings

Ferrous sulfate and other oral iron products are considered contraindicated in patients with known hypersensitivity to any component of the product and should be used with caution in patients with hemosiderosis, hemochromatosis, or hemolytic anemia. Due to its GI-irritating properties, oral iron products are not used by some clinicians in patients with GI ulcerative diseases.

No FDA-approved products exist; use caution when choosing a product. Some preparations contain alcohol and propylene glycol.

Adverse Effects

Adverse effects are usually limited to mild GI upset, including discomfort, constipation, nausea, and diarrhea. Division of the daily dose or administration with food may reduce this effect, but dose reduction may be necessary for some animals.

Reproductive/Nursing Safety

Iron requirements increase during pregnancy, and oral iron supplements may be used to correct iron deficiency in pregnant females.

Breast milk naturally contains iron, but the level does not appear to correspond with maternal iron status. In women, ferrous sulfate is considered compatible with breastfeeding.[1]

Overdose/Acute Toxicity

Ingestion of iron-containing products may result in serious toxicity, and acute intoxication should be considered an emergency. As little as 400 mg of elemental iron is potentially fatal in a child, and the reported LD_{50} of ferrous sulfate in dogs following IV administration was 79 mg/kg.[2] Initial clinical signs of acute iron poisoning usually present with an acute onset of GI irritation and distress (vomiting—possibly hemorrhagic, abdominal pain, diarrhea). The onset of these effects may be seen within 30 minutes of ingestion but can be delayed several hours. Peripheral vascular collapse may rapidly follow with clinical signs of depression, weak and/or rapid pulse, hypotension, cyanosis, ataxia, and coma possible. Some patients do not exhibit this phase of toxicity and may be subclinical for 12 to 48 hours after ingestion, when another critical phase may occur. This phase may be exhibited by pulmonary edema, vasomotor collapse, cyanosis, pulmonary edema, fulminant hepatic failure, coma, and death. Animals that survive this phase may exhibit long-term sequelae (including gastric scarring, contraction) and have persistent digestive disturbances.

Because the acute onset of gastroenteritis may be associated with a multitude of causes, diagnosis of iron intoxication may be difficult unless the animal has been observed ingesting the product or physical evidence suggests ingestion. Ferrous sulfate (and gluconate) tablets are radiopaque and often can be observed on abdominal radiographs. Serum iron levels and total iron-binding capacity (TIBC) may also be helpful in determining the diagnosis but must be done on an emergency basis to have any clinical benefit.

Deferoxamine is useful in chelating iron that has been absorbed. See ***Deferoxamine*** for further information.

In addition to chelation therapy, other supportive measures may be necessary, including treatment of acidosis, prophylactic antibiotics, oxygen, treatment for shock, coagulation abnormalities, seizures, and/or hyperthermia. After the acute phases have been resolved, dietary evaluation and management may be required.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving ferrous sulfate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Alendronate**: Oral iron may reduce the absorption of oral bisphosphonates; administer at least 2 hours apart.

- **Antacids, Aluminum- or Magnesium- Containing**: May bind and decrease oral iron absorption; administer at least 2 hours apart
- **Calcium Supplements, Antacids**: May bind and decrease oral iron absorption; administer at least 2 hours apart
- **Chloramphenicol**: May delay the response to iron administration; avoid the use of chloramphenicol in patients with iron deficiency anemia
- **Fluoroquinolones** (eg, **enrofloxacin, marbofloxacin**): Iron may reduce the absorption of oral fluoroquinolones; administer 2 to 4 hours apart**.**
- **H_2-Receptor Antagonists** (eg, **famotidine, ranitidine**): May decrease iron absorption
- **Levothyroxine**: Oral iron may reduce the absorption of levothyroxine; administer at least 4 hours apart.
- **Mycophenolic Acid**: Concurrent use may result in decreased mycophenolate efficacy; separate administration by at least 2 hours.
- **Penicillamine**: Oral iron can decrease the absorption of penicillamine; administer at least 1 hour apart.
- **Proton Pump Inhibitors** (eg, **omeprazole**): May decrease iron absorption
- **Tetracyclines**: Oral iron preparations can bind to orally administered tetracyclines, thereby decreasing the absorption of both compounds.
- **Vitamin C**: May enhance the absorption of iron

Laboratory Considerations

- Large doses of oral iron can color the feces black and cause false positives with the **guaiac test** for occult blood in the feces.

Dosages

CAUTION: Use caution when dosing oral iron products; some authors state dosages in terms of the iron salt (ferrous sulfate), and some state doses in terms of elemental iron. Dosages below are for ferrous sulfate, *not* elemental iron.

DOGS:

Iron deficiency anemia or patients treated with epoetin or darbepoetin (extra-label): Oral ferrous sulfate may be considered, although injectable iron dextran is more commonly used. Recommended dosages are 11 mg/kg or 100 – 300 mg/dog PO once daily.[3,4] If underlying blood loss is the cause of iron deficiency, it must be corrected before treatment.

CATS:

Iron deficiency anemia or patients treated with epoetin or darbepoetin (extra-label): Oral ferrous sulfate may be considered, although injectable iron dextran is more commonly used, as cats do not tolerate oral iron products well. Usual recommended dosages are 50 – 100 mg/cat PO once daily,[5] but doses range from 30 – 200 mg/cat/day PO.[3] If underlying blood loss is the cause for iron deficiency, it must be corrected before treatment.

Monitoring

- Baseline and periodic CBC, including RBC indices (eg, MCV, MCHC). **NOTE**: RBC indices may take months to normalize.[6]
- Serum iron parameters (eg, ferritin) can be measured to monitor and approximate total body iron concentrations.[6]
- Adverse reactions

Client Information

- This medicine can be given with food to minimize GI upset, but do not give with dairy products, including cheese.
- Side effects can include constipation, diarrhea, vomiting, or nausea. In case of black tarry stools or bloody vomit, contact your veterinarian immediately.
- Keep this medicine out of reach from other animals and children, as accidental overdoses can be very toxic.

Chemistry/Synonyms

Ferrous sulfate, an orally available iron supplement, occurs as odorless, pale-bluish-green crystals or granules having a saline, styptic taste. In dry air, the drug is efflorescent.

If exposed to moisture or moist air, the drug is rapidly oxidized to a brownish-yellow ferric compound that should not be used medicinally. Exposure to light or an alkaline medium will enhance the conversion from the ferrous to the ferric state.

Ferrous sulfate is available commercially in 2 forms: regular and dried. Regular ferrous sulfate contains 7 molecules of water of hydration and is freely soluble in water and insoluble in alcohol. Ferrous sulfate contains ≈200 mg of elemental iron per gram. Dried ferrous sulfate consists primarily of the monohydrate with some tetrahydrate. It is slightly soluble water. Dried ferrous sulfate contains 300 mg of elemental iron per gram. Ferrous sulfate, dried may also be known as ferrous sulfate, exsiccated.

Ferrous sulfate may also be known as eisen(II)-sulfat, ferreux (sulfate), ferrosi sulfas heptahydricus, ferrous sulphate, ferrum sulfuricum oxydulatum, iron (II) sulphate heptahydrate, iron sulphate; many trade names are available.

Storage/Stability

Unless otherwise instructed, store ferrous sulfate preparations in tight, light-resistant containers. Store tablets at 15°C to 30°C (59°F-86°F). Store liquid preparations at 20°C to 25°C (68°F-77°F).

Compatibility/Compounding Considerations

None were noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

There are many available multivitamin products containing iron.

HUMAN-LABELED PRODUCTS:

There are no ferrous sulfate products regulated by the FDA. To ensure that the product contains the labeled amount of ferrous sulfate and does not contain contaminants, look for third-party verification marks, such as USP or NSF, on the bottle.

Ferrous Sulfate Oral Tablets: several strengths available, most commonly as 325 mg (65 mg elemental iron); *Feosol*®, *FeroSul*®, generic; (OTC)

Ferrous Sulfate Oral Elixir/Liquid: 220 mg/5 mL (44 mg iron/5 mL) and 300 mg/5 mL (60 mg iron/5 mL); generic; (OTC)

Ferrous Sulfate Oral Drops: 15 mg iron/mL and 5 mg iron/20 mL; *Enfamil Fer-In-Sol*®, *Fer-Gen-Sol*®, generic; (OTC)

Many other oral iron salts are available that contain different percentages of elemental iron, such as ferrous fumarate and ferrous gluconate. Exercise caution when choosing iron products.

For the complete list of references, see **wiley.com/go/budde/plumb**

Fexofenadine

(fex-oh-***FEN***-ah-deen) *Allegra®*

Antihistamine, Second Generation

Prescriber Highlights

- ► May be useful in treating or preventing allergy-related conditions
- ► Limited published data to support use
- ► Incidence of adverse effects appears minimal, but sedation, CNS depression, and GI effects are possible
- ► Do not confuse with, or use combination products containing, pseudoephedrine (*Allegra-D®*). Human fexofenadine oral suspension contains xylitol, which is toxic to dogs.

Uses/Indications

Fexofenadine is a second-generation, nonsedating antihistamine. It may be useful in small animal species for controlling clinical signs associated with histamine-mediated conditions, including atopic dermatitis, allergic pruritus, and rhinitis. However, limited scientific evidence exists to support antihistamines for these uses in animals, or the use of any one antihistamine over another. Oral H_1-antihistamines might be of some benefit in dogs with mild signs of atopic dermatitis; however, there is insufficient evidence in favor of or against recommending H_1-antihistamines to treat active or chronic atopic dermatitis in dogs.[1–3] Antihistamines appear to be more effective if given consistently and before dogs become moderately pruritic.[1,4] One small, randomized controlled noninferiority trial suggested consistent benefit from fexofenadine in treated dogs with atopic dermatitis[5,6]; however, this study was likely underpowered.[7]

Pharmacology/Actions

Fexofenadine, a second-generation H_1-antihistamine, is a selective peripheral histamine$_1$-receptor antagonist. Second-generation antihistamines are more lipophobic than first-generation antihistamines (eg, diphenhydramine, chlorpheniramine). Therefore, they do not readily cross into the CNS and do not cause sedation or have substantial anticholinergic effects. Fexofenadine may have other anti-inflammatory effects, including mast cell stabilization, and effects on inflammatory mediators such as leukotrienes and prostaglandins that are associated with allergic responses.

Fexofenadine is an active metabolite of terfenadine, which was withdrawn from the market secondary to concerns that it could prolong QTc intervals in humans. Fexofenadine did not prolong the QTc interval in dogs at plasma concentrations many times higher than those seen after administration of recommended dosages.[8]

Pharmacokinetics

Fexofenadine is a P-glycoprotein substrate drug and theoretically could have altered bioavailability in dogs with deficient P-glycoprotein function (*MDR-1* mutation); however, it is unclear if fexofenadine pharmacokinetics are altered in these dogs. One study found that plasma concentrations of fexofenadine were significantly higher at 4 and 8 hours postdose in *MDR-1* dogs,[9] but the results are in question as dogs also received famotidine (another P-glycoprotein substrate) 1 hour before dosing and additional P-glycoprotein/CYP-3A substrates (quinidine, loperamide) were administered at the same time as fexofenadine.[10]

A pharmacokinetic study in horses[11] showed low oral bioavailability (median = 2.6% alone; 1.5% when ivermectin was given PO 12 hours prior), a volume of distribution (steady-state) of 0.8 L/kg, plasma clearance of 0.75 mL/hour/kg, and a terminal half-life of 5 hours after oral administration. The authors concluded that despite fexofenadine having antihistaminic effects in the horse at low plasma concentrations, extended studies are needed to determine its therapeutic value. Low bioavailability in horses may mean that oral treatment is not suitable.

In humans, fexofenadine is rapidly absorbed following oral administration, with peak concentrations occurring between 2 and 3 hours after dosing.[12] Elimination half-life is ≈14.4 hours when dosed twice daily. Approximately 5% of the total dose is eliminated by hepatic metabolism. The majority of an oral dose is eliminated in the feces, which may be due to low oral absorption or biliary excretion. Dose adjustments are recommended for moderate to severe renal function impairment, as plasma concentrations can increase by 100% or more.

Contraindications/Precautions/Warnings

Do not use fexofenadine in patients hypersensitive to it.

In humans, dosage adjustment is recommended in patients with severe renal impairment.

Adverse Effects

Although there has been limited clinical experience with fexofenadine in veterinary patients, adverse effects are not common. Sedation, CNS depression, and GI effects are possible.

Reproductive/Nursing Safety

No evidence of teratogenicity was seen in rats or rabbits given 300 mg/kg doses; however, dose-related decreases in implantation and an increased incidence of postimplantation losses have been noted in rats,[13] and rats given dosages of 3 times the recommended human dose were associated with decreased pup weights and survival rates. In humans, other second-generation antihistamines have more available information regarding use in pregnant or nursing patients and are therefore preferred over fexofenadine.[14,15]

It is unknown if fexofenadine is excreted into milk, but it is unlikely to pose much risk to nursing offspring. In humans, it is recommended that infants exposed to fexofenadine through nursing be monitored closely for irritability or drowsiness.[14,15]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In laboratory studies, dogs receiving oral doses up to 2 g/kg (300 times the maximum recommended adult human oral daily dose) showed no evidence of toxicity. QT intervals were not prolonged in dogs receiving 30 mg/kg PO twice daily for 5 days, despite fexofenadine plasma concentrations being ≈9 times those of humans receiving the maximum recommended dose (180 mg/day).[8]

Clinical signs associated with a fexofenadine overdose may include lethargy, facial edema, and vomiting; CNS depression may also occur. Because fexofenadine may be found in combination with other drugs (eg, pseudoephedrine), it is important to determine what product was actually ingested.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fexofenadine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Antacids Containing Aluminum or Magnesium**: Reduced oral bioavailability of fexofenadine; separate dosing by at least one hour

- **Erythromycin, Ketoconazole**: May increase fexofenadine concentrations by enhancing its absorption. This effect is unlikely to be clinically significant due to the wide margin of safety of fexofenadine.
- **Fruit Juices**: In humans, grapefruit, apple, or orange juice may reduce bioavailability; therefore, it is recommended that fexofenadine be taken with water.
- **Ivermectin**: In a small pharmacokinetic study in horses, oral ivermectin decreased the oral bioavailability of fexofenadine.[16]

Laboratory Considerations

- **Allergy testing (intradermal tests)**: Most veterinary dermatologists recommend discontinuing oral antihistamines 1 to 2 weeks prior to intradermal skin tests in dogs or cats; however, one pharmacokinetic/pharmacodynamic study with hydroxyzine and cetirizine in dogs[17] suggests that when tests cannot be delayed, a minimum wait time of 2 days may be acceptable for some drugs in dogs.[7]
- **Allergy testing (IgE serological tests)**: Withdrawal of antihistamines prior to testing is theoretically not necessary, but this has not been proven.[7]

Dosages

DOGS:

Antihistamine for treatment of allergic (histamine-mediated) conditions (extra-label): 2 – 5 mg/kg PO every 12 to 24 hours. Higher doses have been recommended, including one study that used 18 mg/kg PO once daily and reported positive results in dogs with atopic dermatitis.[6] Practically, because of available tablet dosage forms, initial doses should be rounded to the nearest multiple of 15 mg (small dogs) and 30 mg (large dogs). As with other antihistamines, patient response is individualized and unpredictable. When evaluating efficacy for any antihistamine, a minimum trial period of 2 weeks has been recommended.[4] In patients exhibiting benefit, response may be improved when used prior to allergen exposure and on a regular, ongoing basis.

CATS:

Antihistamine for treatment of allergic (histamine-mediated) conditions (extra-label): 10 – 15 mg/cat (NOT mg/kg) PO every 12 to 24 hours. Higher dosages up to 30 mg/cat (NOT mg/kg) PO every 12 hours have been recommended. The oral 30 mg disintegrating tablets may be a useful dosage form for cats as they dissolve rapidly inside the mouth. When splitting tablets of this dosage form, protect remaining tablet from moisture.

Monitoring

- Improvement of clinical signs related to allergies (eg, pruritis, rhinitis)
- Adverse effects (eg, sedation, GI effects)

Client Information

- Antihistamines should be used on a regular, ongoing basis in animals that respond to them. They work better if they are given to your animal before exposure to an allergen or allergy flare.
- This medicine may take several days to 2 weeks to determine if it is effective.
- Fexofenadine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- This medicine is less likely to cause drowsiness (sleepiness) than some other antihistamines, but it can still occur.
- Use caution with over-the-counter formulations of this medicine, as other potentially toxic ingredients may be combined in the products (eg, decongestants, such as pseudoephedrine or acetaminophen). Be sure the product used only contains fexofenadine as the active ingredient. Liquid formulation of this product may contain xylitol, an artificial sweetener, which can be toxic to animals.

Chemistry/Synonyms

Fexofenadine HCl (CAS Registry: 138452-21-8; ATC: R06AX26) occurs as a white to off-white powder. It is slightly soluble in water, freely soluble in ethanol, and very slightly soluble in acetone.

Fexofenadine may also be known as terfenadine carboxylate hydrochloride or MDL-16455A. A common trade name is *Allegra*® or *Telfast*®.

Storage/Stability

Fexofenadine tablets, orally dispersible (disintegrating) tablets, and oral suspension should be stored at room temperature (20°C-25°C [68°F-77°F]).

Orally dispersible tablets should be protected from moisture and are recommended for use immediately after opening individual tablet blisters.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Oral Tablets: 60 mg and 180 mg; *Allegra Allergy*®, generic; (OTC)

Oral Disintegrating Tablets (ODT): 30 mg; *Allegra Allergy Children's*®; (OTC). **NOTE**: The orally disintegrating tablet is designed to disintegrate on the tongue and may be of use in animals difficult to pill.

Oral Gelcaps (Gel Coated Tablets): 180 mg; *Allegra Allergy*®, generic; (OTC)

Oral Suspension: 30 mg/5 mL (6 mg/mL); *Allegra Allergy Children's*®; (OTC). **CAUTION**: Oral suspensions contain xylitol; do not use in dogs.

There are also fexofenadine/pseudoephedrine combination products available (eg, *Allegra D*®), but they are **NOT** recommended for use in animal patients.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Filgrastim (Granulocyte Colony Stimulating Factor; GCSF)

(fill-***grass***-stim) *Neupogen*®

Cytokine Hematopoietic Agent

Prescriber Highlights

- ► Cytokine that, in the bone marrow, primarily increases the proliferation, differentiation, and activation of progenitor cells in the neutrophil-granulocyte line
- ► Human origin product; antibodies may form that can cause prolonged neutropenia
- ► Biosimilar products are available, but are not considered interchangeable by the FDA; intended product must be specified on the prescription

Uses/Indications

Filgrastim may be of benefit in managing neutropenic complications (eg, infections) in dogs, cats, horses, and alpacas. It should only be used when the intrinsic response to endogenously produced cytokines is thought to be inadequate and when there is evidence that granulocyte precursors are available in the bone marrow. The use of filgrastim in veterinary medicine is controversial because of the drug's cost, potential for antibody development, and the lack of evidence for its efficacy in reducing mortality versus using antibiotic therapy alone.

Pharmacology/Actions

Filgrastim is a hematopoietic agent that primarily affects bone marrow to increase the proliferation, differentiation, and activation of progenitor cells in the neutrophil-granulocyte line. Filgrastim increases neutrophil precursor cells, neutrophil production rate, and shortens maturation time. A dose-dependent increase in neutrophil counts is observed within a few hours of filgrastim administration and persists for the duration of filgrastim exposure. Chemotherapy-induced neutropenia is shortened in duration and severity.[1] Although derived from human DNA, the product is not species-specific for its bone marrow effects.

Pharmacokinetics

After subcutaneous injection, filgrastim is rapidly absorbed and distributed with highest concentrations found in the bone marrow, liver, kidneys, and adrenal glands. The elimination half-life is ≈3.5 hours in humans. Filgrastim undergoes non-hepatic metabolism and renal elimination.

Contraindications/Precautions/Warnings

Filgrastim is contraindicated in patients hypersensitive to it. Animals that have developed antibodies to filgrastim with resultant neutropenia, or animals that experienced severe allergic reactions to filgrastim should probably not receive it in the future. Filgrastim may support or accelerate acute leukemia and myelodysplastic syndromes, and its use in these patients is considered controversial.

Filgrastim should not be given in the 24 hours before or after chemotherapy administration.

Do not confuse filgrastim with pegfilgrastim, tbo-filgrastim, or sargramostim. Biosimilar filgrastim products have not been determined to be interchangeable.

Adverse Effects

Because the human DNA origin product can be immunogenic to other species, some patients may develop severe neutropenia by mounting an immune response against both endogenously produced and exogenously administered G-CSF. Studies in cats have demonstrated that short pulse doses of filgrastim for 3 to 5 days, during the time of neutropenia, may be safe and may minimize development of neutrophil neutralizing antibodies. Preliminary studies using canine origin G-CSF have not demonstrated autoantibody formation in either dogs or cats.

Additionally, there are concerns that exogenously administered filgrastim can cause undesirable responses in other tissues, including myelofibrosis and medullary histiocytosis.

Occasionally, irritation at the injection site may occur. Bone or musculoskeletal pain, splenomegaly (including splenic rupture), glomerulonephritis, capillary leak syndrome, and hypotension have been reported in humans.

Reproductive/Nursing Safety

Adverse effects in females and offspring have been demonstrated after filgrastim was administered to pregnant laboratory animals at high doses. Interpretation of this data for use in a clinical setting is difficult, but filgrastim should only be used in pregnant females when the benefits of treating outweigh the potential risks.

Filgrastim is excreted in milk, but as the drug is not absorbed orally it is unlikely to pose significant risk to nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available. Filgrastim has limited acute toxic potential and clinically significant overdoses are unlikely.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving filgrastim and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Antineoplastic Agents**: Although filgrastim was developed primarily to prevent neutropenia associated with some chemotherapeutic agents, avoid filgrastim use within 24 hours before or after antineoplastic drugs.[1]
- **Bleomycin**: Concurrent use may increase the risk for pulmonary toxicity.
- **Cyclophosphamide**: Concurrent use may increase the risk for pulmonary toxicity.
- **Vincristine**: Concurrent use may increase the risk for peripheral neuropathy.

Laboratory Considerations

- Positive **bone imaging** changes have been noted due to increased hematopoietic activity.

Dosages

NOTE: To avoid the development of autoantibody formation, most clinicians that prescribe this agent in dogs or cats recommend a pulse therapy of no more than 5 days in duration.

DOGS/CATS:

Adjunctive treatment of neutropenia (extra-label): No consensus or evidence was located on any dosing strategy for this agent in animals. Most commonly, a dosage of 5 – 10 µg/kg SC daily is recommended.[2]

HORSES:

Neutropenia in foals (extra-label): From a retrospective study (abstract) of 13 foals dosed with filgrastim 5 µg/kg SC, 8 were discharged and 5 died or were euthanized. From the data, the authors concluded that the use of filgrastim in foals was safe; adverse effects were not observed. Leukopenic foals treated with filgrastim that survived to discharge tended to have higher mean WBC counts, higher percentages of neutrophils, and lower percentages of band neutrophils than the foals that did not survive.[3]

Adjunctive treatment for the prevention of shipping fever in yearlings (extra-label): 0.23 µg/kg SC given once prior to transportation sustained neutrophil counts within the reference range for 48 hours during long-distance transportation; however, no cases of shipping fever developed in either treatment or control groups.[4]

CAMELIDS:

Adjunctive treatment of neutropenia in alpaca (extra-label): 5 µg/kg SC daily for 3 days given to healthy alpacas increased neutrophil counts within 24 hours of the first dose and returned to pretreatment values 72 hours after the last dose.[5]

Monitoring
- Baseline and periodic CBC with platelets as indicated by clinical condition

Client Information
- Clients should be informed of the cost of filgrastim as well as the possibility that it may cause antibodies to form against endogenously produced G-CSF, thereby causing a potentially life-threatening neutropenia.

Chemistry/Synonyms
Prepared via recombinant DNA technology from human DNA, filgrastim is a single chain polypeptide consisting of G-CSF plus a N-terminal methionine. Its 175 amino acids are not glycosylated, and it has a molecular weight of ≈18,800 daltons. The commercially available injection occurs as a clear solution buffered to a pH of ≈4. Filgrastim 10 µg is equivalent to 1 million units.

Filgrastim may also be known as: granulocyte colony-stimulating factor, G-CSF, XM-02; *Filgen®*, *Gran®*, *Granulen®*, *Granulokine®*, *Neupogen®*, *Nivestym®* (filgrastim-aafi), *Releuko®* (filgrastim-ayow), *Neutromax®*, and *Zarxio®* (filgrastim-sndz).

Storage/Stability
Filgrastim injection should be stored in the refrigerator (2°C-8°C [36°F-46°F]), and at room temperature for up to 24 hours. Do not freeze or shake contents of vial; protect from light.

Compatibility/Compounding Considerations
If necessary, filgrastim may be diluted into 5% dextrose for injection, but if diluted to concentrations between 5 and 15 µg/mL, it is recommended that albumin be added to the solution to a concentration of 2 mg/mL to reduce adsorption to plastic IV tubing. It is not recommended to dilute to concentrations of less than 5 µg/mL. Filgrastim should never be diluted with saline as a precipitate may form.

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Filgrastim Injection: 300 µg/mL preservative free in 1 mL and 1.6 mL single dose vials; 300 µg/0.5 mL preservative free in 0.5 mL and 0.8 mL prefilled syringes; *Neupogen®*; biosimilar;(Rx). FDA-approved biosimilar products are available but not considered interchangeable. Please refer to the FDA's Purple Book for more information about FDA-licensed biologics, including biosimilar and interchangeable products.

References
For the complete list of references, see **wiley.com/go/budde/plumb**

Finasteride
(fi-***nass***-ter-ide) *Proscar®, Propecia®*
5-Alpha-Reductase Inhibitor

Prescriber Highlights
- ► Potentially useful for dogs with benign prostatic hypertrophy and in ferrets with adrenal disease
- ► Can be used in breeding males without requiring castration and without affecting libido or spermatogenesis
- ► Contraindications include hypersensitivity to finasteride, sexually developing animals, and sexually mature females.
- ► Use with caution in patients with significant hepatic impairment
- ► Adverse effects include GI and possible minor sexual adverse effects.

Uses/Indications
Finasteride may be useful in treating benign prostatic hypertrophy in canine patients, particularly those used for breeding, as it allows successful treatment without castration and does not affect libido or spermatogenesis.[1] Because of the long duration of therapy required for response (up to 8 weeks), its usefulness may be limited in veterinary medicine.[2,3]

It may also be useful in the adjunctive treatment of adrenal disease in ferrets.[4]

Pharmacology/Actions
Finasteride competitively inhibits 5-alpha-reductase, the enzyme responsible for metabolizing testosterone to dihydrotestosterone (DHT) in the prostate, liver, and skin. DHT is a potent androgen and the primary hormone responsible for the development of the prostate. In dogs with BPH, clinical effects may be noted in as little as one week, but full efficacy may require up to 8 weeks of treatment.

Pharmacokinetics
In humans, finasteride exhibits 65% bioavailability following oral administration, reaches peak plasma concentration in 1 to 2 hours, and is approximately 90% protein bound. The presence of food does not affect absorption. It is distributed across the blood-brain barrier and is found in seminal fluid. Finasteride is extensively metabolized in the liver. Elimination half-life is 5 to 6 hours, and its metabolites are excreted in the urine and feces. In humans, a single daily dose suppresses DHT concentrations for 24 hours.

Contraindications/Precautions/Warnings
Finasteride is contraindicated in sexually developing animals, sexually mature females, and in patients with a history of hypersensitivity to the drug. It should be used with caution in patients with significant hepatic impairment as metabolism of the drug may be reduced.

Finasteride-induced reduction in prostate size is maintained only while the drug is being administered; prostate volume can be expected to increase after finasteride is discontinued.[5]

The National Institute for Occupational Safety and Health (NIOSH) classifies finasteride as a hazardous drug. Personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure. Cutting, crushing or otherwise manipulating tablets will increase risk of exposure.[2] Because finasteride can be absorbed through the skin, women should avoid contact with crushed or broken tablets.[6]

Adverse Effects
One study in dogs reported no adverse effects after treating for 21 weeks at 1 mg/kg.[5] Finasteride may reduce semen volume while maintaining semen quality in breeding dogs.[1,5] Reduced clinical benefit is seen one week after therapy discontinuation.

Adverse effects reported in humans have been very limited, mild, and transient; decreased libido, decreased ejaculate volume, and impotence have been reported.

Reproductive/Nursing Safety
Finasteride is not indicated for use in female patients, and it is unknown whether finasteride is excreted in milk. Breeding males retain fertility while taking finasteride, but ejaculate volume may be decreased.[5]

Overdose/Acute Toxicity
The reported LD_{50} in dogs following oral administration is greater than 1 g/kg and resulted in GI effects including nausea or vomiting. Recommended treatment is supportive as there is no known antidote and it is unlikely to be removed via dialysis.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control

center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving finasteride and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Anticholinergic Drugs**: May precipitate or aggravate urinary retention.

Dosages

DOGS:

Benign prostatic hypertrophy (BPH) (extra-label): Finasteride 0.1 – 0.5 mg/kg PO once daily has shown benefit.[1,7] Because of commercially available dosage forms, dosages are often rounded to the nearest full or half tablet; 5 mg is generally the maximum dose. Anecdotally, dose frequency may be able to be decreased to every other day after 3 to 4 months of therapy. Because finasteride's effects on prostate size are reversible, treatment is often continued for the life of the dog. To increase ejaculate volume, intact males used for breeding purposes should have finasteride discontinued several days in advance of breeding; the drug is resumed afterward.

FERRETS:

Adjunctive treatment of adrenal disease (extra-label): 5 mg/ferret (NOT mg/kg) PO once daily[4]

Monitoring

- Prostate examination in dogs and monitor for relief from clinical signs (eg, improved urine and fecal elimination)
- Prostatic ultrasound before starting therapy to obtain baseline measurements of the prostate; recheck prostatic ultrasound 6 to 8 weeks after starting therapy to monitor for decrease in prostate size.

Laboratory Considerations

- None

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after receiving finasteride on an empty stomach, give it with food or small treats. If vomiting continues, contact your veterinarian.
- This medicine may take several weeks to determine if it is working. Do not skip doses.
- Pregnant or women of childbearing potential should use caution when handling this medication. This medicine is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Finasteride is a 4-azasteroid synthetic drug that inhibits 5-alpha-dihydroreductase (DH) and has a molecular weight of 372.55.

Finasteride may also be known as: finasteridum, MK-0906, and MK-906; many trade names are available.

Storage/Stability

Store tablets below 30°C (86°F) in tight containers and protected from light.

Compatibility/Compounding Considerations

No specific information noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Finasteride Oral Tablets: 1 mg and 5 mg; *Proscar®*, *Propecia®*, generic; (Rx)

Firocoxib

(feer-oh-***koks***-ib) *Previcox®, Equioxx®*

Nonsteroidal Anti-Inflammatory Drug (NSAID), COX-2 Selective

Prescriber Highlights

- ► FDA-approved for use in dogs and horses for the control of pain and inflammation associated with osteoarthritis and in dogs for the control of pain and inflammation following orthopedic and soft-tissue surgery
- ► GI effects (eg, vomiting, anorexia) are the most likely adverse effects in dogs; renal and hepatic adverse effects are also possible.
- ► Adverse effects in horses include mouth ulcers, facial skin lesions, and excitation (rare).
- ► Appears to cause predominantly COX-2 inhibition at therapeutic doses
- ► Extra-label use in cats is not recommended, as the large tablet size makes safe administration difficult.

Uses/Indications

Firocoxib is indicated in dogs and horses for the control of pain and inflammation associated with osteoarthritis and in dogs for the control of postoperative pain and inflammation associated with orthopedic surgery. Like other NSAIDs, firocoxib can be useful for treatment of pyrexia, pain, and/or inflammation associated with other conditions.

In dogs with transitional cell carcinoma, firocoxib had antitumor effects and significantly enhanced the antitumor activity of cisplatin. Firocoxib could potentially be useful as a palliative treatment.[1]

Firocoxib may also be useful in other species, but information is limited regarding its safety and efficacy. One study[2] in cats evaluated firocoxib in treatment of experimentally induced pyrexia and demonstrated that the a single oral dose was effective in preventing or attenuating pyrexia. The drug also controlled postoperative pain in cats undergoing ovariohysterectomy.[3]

Pharmacology/Actions

Firocoxib is a coxib-class NSAID. It is believed to predominantly inhibit cyclooxygenase-2 (COX-2) and spare COX-1 at therapeutic dosages. This effect would theoretically inhibit production of the prostaglandins that contribute to pain and inflammation (COX-2) and spare those that maintain normal GI, platelet, and renal function (COX-1).[4,5] However, COX-1 and COX-2 inhibition studies are done in vitro and do not necessarily correlate perfectly with clinical effects seen in vivo.

Pharmacokinetics

In dogs, firocoxib absorption after oral administration varies individually. Oral bioavailability with the chewable tablets is ≈38% on average. Food will delay, but not affect the amount absorbed. Peak concentrations occur ≈1 hour after administration if the dog is fasted and 5 hours if the dog is fed. Volume of distribution at steady state is ≈3 L/kg; it is 96% bound to plasma proteins. Biotransformation occurs predominantly via dealkylation and glucuronidation in

the liver; elimination is principally in the bile and feces. Elimination half-life in dogs is ≈6 to 8 hours.

In horses, oral availability after receiving the paste is ≈79%. The equine chewable tablet provides a similar peak concentration and AUC as the paste formulation. Peak concentrations occur 4 to 12 hours after administration. Volume of distribution at steady state is ≈1.7 to 2.3 L/kg and it is 98% bound to plasma proteins. Biotransformation in horses occurs primarily via decyclopropylmethylation and then glucuronidation. Metabolites are primarily excreted in the urine. Elimination half-life is ≈30 to 40 hours. In neonatal foals, firocoxib 0.1 mg/kg PO every 24 hours for 9 consecutive days was rapidly absorbed and a maximum plasma concentration was reached 30 minutes after the first dose. Estimated terminal elimination half-life was ≈11 hours after the last dose.[6] One study reported significantly lower maximum plasma concentrations in ponies during late pregnancy as compared with early postpartum mares.[7]

Pharmacokinetics of firocoxib have only been reported in 2 cats.[2] Oral bioavailability after administering an oral suspension was ≈60% and the volume of distribution was 2 to 3 L/kg. Elimination half-life averaged ≈10 hours.

Contraindications/Precautions/Warnings

Firocoxib should not be used in animals hypersensitive to it or other NSAIDs. The drug should be used with caution and enhanced monitoring performed in patients with pre-existing renal, hepatic, or cardiovascular dysfunction and in those that are dehydrated, hypovolemic, hypotensive, or on concomitant diuretic therapy. Because many geriatric patients have reduced renal function and firocoxib is often used for treatment of osteoarthritis in these patients, ongoing monitoring for adverse effects is strongly recommended.

Because all NSAIDs can potentially cause GI toxicity, firocoxib is relatively contraindicated in dogs with active GI ulcerative conditions.

A chronic dosing study (ie, 5 mg/kg for 6 months) performed in puppies 10 to 13 weeks of age showed subclinical periportal hepatic fatty changes in half the puppies. Higher doses (ie, 15 – 25 mg/kg, which is 3-5 times the label recommendation) in this age range caused increased rates of hepatic fatty changes; some puppies died or were euthanized due to moribund conditions. The manufacturer package insert states, *Use of this product at doses above the recommended 5 mg/kg in puppies less than 7 months of age has been associated with serious adverse reactions, including death* and … *Due to tablet sizes and scoring, dogs weighing less than 12.5 lb (5.7 kg) cannot be accurately dosed*.[8] The UK label states the drug should not be used in dogs younger than 10 weeks of age.[9]

If changing NSAIDs due to lack of efficacy, consider a washout period between agents.

In horses, the manufacturer's label states that the safety of firocoxib in horses younger than 1 year of age, horses used for breeding, and pregnant or lactating mares has not been established, and treatment should be discontinued if signs such as inappetence, colic, abnormal feces, or lethargy are observed. Firocoxib's long half-life should be considered when switching from firocoxib to another NSAID and may necessitate a longer drug withdrawal for horses that are subject to drug testing (eg, race or performance horses).

Adverse Effects

In pre-approval studies in which 128 dogs were treated, vomiting and decreased appetite/anorexia were the most common adverse effects with an approximate incidence rate of 4% and 2%, respectively. Adverse effects reported postapproval included GI effects (eg, diarrhea, GI ulceration, hematemesis, hematochezia), renal effects (eg, azotemia, proteinuria, urinary incontinence, kidney failure), lethargy/depression, elevated liver enzymes (ALP, ALT) and bilirubin, anemia, tachycardia, pruritus, and dermatitis. It should be noted that the postapproval data reflect voluntary reporting to the FDA and do not reflect actual incidence rates nor is causation necessarily proven. Of note, one study in dogs did not show any changes in platelet aggregation.[10]

In pre-approval studies in horses treated for 14 days, diarrhea and loose stools were seen in ≈2% of horses; excitation was rarely detected (ie, less than 1%). In safety studies, oral lesions/ulcers were seen in some horses after receiving 1 to 5 times the recommended label dose.[11]

In a small study in cats (n = 8), 1 cat experienced vomiting and 2 cats developed reversible azotemia with significant increases in BUN and creatinine.[3]

Reproductive/Nursing Safety

Information on the safety of firocoxib in breeding, pregnant, or lactating dogs and horses is not available. Studies performed in pregnant rabbits given doses approximating those given to dogs demonstrated maternotoxic and fetotoxic effects.

Overdose/Acute Toxicity

Limited information is available for acute overdose in animals. The reported oral LD_{50} for rats is greater than 2 g/kg. Use of gastric decontamination protocols and supportive treatment (eg, IV fluids, oral sucralfate) may be useful.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center that specializes in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving firocoxib and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors** (eg, **benazepril, enalapril**): Some NSAIDs can reduce effects on blood pressure.
- **Aspirin**: May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea)
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea)
- **Digoxin**: NSAIDS may increase serum levels.
- **Fluconazole**: Administration has increased plasma levels of celecoxib in humans and could potentially also affect firocoxib levels in dogs.
- **Furosemide**: NSAIDs may reduce the saluretic and diuretic effects.
- **Highly Protein Bound Drugs** (eg, **oral anticoagulants, phenytoin, salicylates, sulfonamides**, **sulfonylurea antidiabetic agents, valproic acid**): Because firocoxib is highly bound to plasma proteins (greater than 95%), it could theoretically displace other highly bound drugs; a temporary increase in serum levels may occur. These interactions have not been shown to be of clinical concern.
- **Methotrexate**: Serious toxicity has occurred when NSAIDs have been used concomitantly with methotrexate; use together with extreme caution.
- **Nephrotoxic Drugs** (eg, **aminoglycosides**, **amphotericin B, furosemide**): May enhance the risk for nephrotoxicity development
- **Nonsteroidal Anti-inflammatory Drugs (NSAIDs;** eg, **carprofen, meloxicam, phenylbutazone**): May increase the risk for GI toxicity (eg, ulceration, bleeding, vomiting, diarrhea)

Laboratory Considerations

- No specific laboratory concerns

Dosages

DOGS:

Control of pain and inflammation associated with osteoarthritis and control of postoperative pain and inflammation associated with soft-tissue and orthopedic surgery in dogs (labeled dosage; FDA-approved): 5 mg/kg (2.27 mg/lb) PO once daily as needed for osteoarthritis and for 3 days as needed for postoperative pain and inflammation associated with soft-tissue and orthopedic surgery. Firocoxib tablets may be administered ≈2 hours prior to surgery. Dose should be calculated in half-tablet increments and can be administered with or without food. Use the lowest effective dose for the shortest duration consistent with individual response.[8,12,13]

Adjunctive treatment for transitional cell carcinoma of the urinary bladder (extra-label): Firocoxib 5 mg/kg PO every 24 hours used alone and in combination with cisplatin (60 mg/m^2 IV every 21 days)[1]

Adjunctive treatment for inflammatory colorectal polyps (extra-label): From a case series of miniature dachshunds, firocoxib 5 mg/kg PO once daily with chlorambucil 1.5 – 3.1 mg/m^2 (not mg/kg) PO daily. Median doses were 6.1 mg/kg/day and 1.8 mg/m^2/day respectively.[14]

HORSES:

Control of pain and inflammation associated with osteoarthritis (labeled dosage; FDA-approved):

Oral (Paste): 0.1 mg/kg (0.045 mg/lb) PO with or without food daily for up to 14 days[15]

Oral (Tablets): For horses weighing 364 to 591 kg (800-1300 lb): one 57 mg tablet (total dose; NOT mg/kg) PO once daily for up to 14 days; may be given with or without food[15]

Parenteral: 0.09 mg/kg (0.04 mg/lb) IV once daily for up to 5 days. If further treatment is needed, the oral paste can be used at 0.1 mg/kg PO once daily for an additional 9 days. Overall duration of treatment with injection and oral paste will be dependent on the response observed, but should not exceed 14 days.[15]

Monitoring

- Clinical efficacy
- Adverse effects
- Baseline and periodic physical examination
- Baseline and periodic: CBC, serum chemistry panel with electrolytes, and urinalysis.

Client Information

NOTE: The manufacturer provides a client handout that is recommended to be distributed each time the drug is dispensed.

- For dogs: This medicine is used for pain and inflammation associated with arthritis and surgery. It can be given with or without food, but food may reduce the chances for stomach problems (eg, poor appetite, nausea, vomiting). If your dog vomits or acts sick after receiving this medication on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Most dogs tolerate firocoxib well, but some dogs rarely develop stomach ulcers or serious kidney and liver problems. Stop giving this medicine and contact your veterinarian immediately if your animal has decreased appetite (ie, eating less than normal), persistent vomiting, diarrhea, changes in behavior or activity levels (ie, more or less active than normal), changes in drinking and urinating habits (ie, frequency, amount consumed), or yellowing of gums, skin, or whites of the eyes (ie, jaundice).
- Store chewable tablets well out of reach of animals and children.
- Keep water readily accessible during treatment and avoid dehydration.
- For dogs: Periodic laboratory tests are needed to check for liver and kidney side effects. Do not miss these important follow-up visits.
- For horses, contact your veterinarian if your horse develops ulcers or sores on the tongue or in the mouth, sores on facial skin or lips, diarrhea/loose stools, changes in behavior/activity, changes in feed or water consumption, or yellowing of the whites of the eyes or gums (ie, jaundice).
- Other medicines for pain or inflammation should not be used with this medication without the approval of your veterinarian.
- When using the equine paste, ensure the lock ring is secured to the nearest appropriate 50 lb weight notch.
- Do not increase or alter the dose without approval from your veterinarian.

Chemistry/Synonyms

Firocoxib occurs a white crystalline powder. The commercially available injection occurs as a colorless to pale-yellow solution.

Firocoxib may also be known as 3-(cyclopropylmethoxy)-5,5-dimethyl-4-(4-methylsulfonyl) phenylfuran-2(5H)-on; ML-1,785,713; *Equioxx*®; and *Previcox*®.

Storage/Stability

Commercially available tablets and oral paste should be stored at room temperature (15°C-30°C [59°F-86°F]); brief excursions are permitted up to 40°C (104°F). The injection should be stored at 20°C to 25°C (68°F-77°F), with excursions between 15°C to 30°C (59°F-86°F) permitted.

Compatibility/Compounding Considerations

The injection is a nonaqueous solution and should not be mixed with aqueous solutions. Do not flush through IV lines using aqueous flush solutions.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Firocoxib Chewable Tablets (scored): 57 mg and 227 mg; *Previcox*®; (Rx). FDA-approved for use in dogs; NADA #141-230

Firocoxib Oral Paste: 0.82% w/w (8.2 mg firocoxib per gram of paste) in a 6.93 g oral syringe (total of 56.8 mg of firocoxib per syringe); *Equioxx Oral Paste*®; (Rx). FDA approved for use in horses; NADA #141-253.

Firocoxib Chewable Tablets (scored): 57 mg; *Equioxx*® Tablets; (Rx). FDA-approved for use in horses; NADA #141-458. Not to be used in horses intended for food.

Firocoxib Injection: 20 mg/mL in 25 mL vials; *Equioxx*® Injection; (Rx). FDA-approved for use in horses; NADA #141-313. Do not use in horses intended for human consumption.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS: NONE

Florfenicol

(flor-***fen***-i-col) *NuFlor®*

Antibiotic

For topical formulations containing florfenicol, please see ***Corticosteroid/Antimicrobial Preparations.***

Prescriber Highlights

- ► Broad-spectrum antibiotic FDA-approved for use in cattle, swine, and fish
- ► Do **NOT** give IV. Not for use in veal calves or cattle of breeding age
- ► Adverse effects in cattle include anorexia, decreased water consumption, diarrhea, and injection site reactions, which may result in trim loss. IM injection may be painful in small animal species. Florfenicol does not appear to have the same risk for aplastic anemia as chloramphenicol.
- ► Slaughter withdrawals in cattle depend on route of administration (eg, IM shorter than SC).

Uses/Indications

In cattle, injectable florfenicol is FDA-approved for the treatment and control of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica*, *Pasteurella multocida*, and *Histophilus somni* and for the treatment of bovine interdigital phlegmon (eg, foot rot, acute interdigital necrobacillosis, infectious pododermatitis) associated with *Fusobacterium necrophorum* and *Bacteroides melaninogenicus*.[1]

An oral solution is FDA-approved for the treatment of swine respiratory disease (SRD) associated with *Actinobacillus pleuropneumoniae, Pasteurella multocida, Salmonella choleraesuis,* and *Streptococcus suis*. An injectable solution is also FDA-approved in swine for the same indications with an increased spectrum that also includes *Bordetella bronchiseptica* and *Glaesserella (Haemophilus) parasuis*.

Because florfenicol has activity against a wide range of microorganisms, it may also be useful for extra-label treatment of other infections in cattle (or other species), but specific data are limited.

Anecdotally, the injectable formulation has been used orally in dogs, but efficacy data are lacking and a short half-life after oral absorption may limit clinical use. Dosing regimens are not established in dogs or cats.

The combination product containing florfenicol and flunixin is FDA-approved for SC use in beef and nonlactating dairy cattle (not veal calves) for treatment of BRD associated with *Mannheimia haemolytica*, *Pasteurella multocida*, *Histophilus somni, Mycoplasma bovis,* and to control BRD-associated pyrexia.[2]

The World Health Organization (WHO) has designated florfenicol as a Highly Important antimicrobial for human medicine.[3] The Office International des Epizooties (OIE) has designated florfenicol as a Veterinary Critically Important Antimicrobial (VCIA) Agent in avian, bovine, caprine, equine, lagomorph, ovine, and swine species.[4]

Pharmacology/Actions

Like chloramphenicol, florfenicol is a time-dependent, broad-spectrum antibiotic that has activity against many aerobic and anaerobic gram-negative and gram-positive bacteria. Florfenicol acts by binding to the 50S ribosome, thereby inhibiting bacterial protein synthesis. Florfenicol is primarily bacteriostatic but is bactericidal against certain bacteria.

Pharmacokinetics

After IM injection in feeder calves, ≈79% of the dose is bioavailable.[1,5] The drug appears to be well-distributed throughout the body, including therapeutic levels in the CSF. In cattle, the volume of distribution is ≈0.7 L/kg, and only ≈13% is bound to serum proteins. Mean serum half-life is 18 hours, but wide interpatient variation exists. When administered at 40 mg/kg IM, serum concentrations are above the MIC_{90} (1 µg/mL) for *Mannheimia haemolytica* for 72 hours and above the MIC_{90} (0.5 µg/mL) for *Pasteurella multocida* and *Histophilus somni* for 96 hours.

Oral absorption is variable (24% to 97%) after gavage dosing in swine. Volume of distribution is ≈1 L/kg, and half-life is 2.2 hours.[6]

In dogs, florfenicol is absorbed poorly after SC injection and has an elimination half-life of less than 5 hours. After IV administration, total body clearance is ≈1 L/kg/hour. PO administration results in good bioavailability (ie, 95%), but the drug is eliminated rapidly (elimination half-life, 1.25 hours).[7]

Cats have high absorption of a 100 mg/mL solution administered IM or PO and an elimination half-life of less than 5 hours. In cats, time duration above an MIC of 2 mg/mL is 12 hours (IM) and 18 hours (PO); time duration above an MIC of 8 mg/mL is 10 hours (IM) and 6 hours (PO), respectively.

In sheep, florfenicol elimination half-life is ≈9 hours and has a mean residence time of ≈20 hours for its major metabolite (ie, FFC-a). Based on these values, a calculated withdrawal time of 42 days was determined.[8,9]

Contraindications/Precautions/Warnings

Do **NOT** give this drug IV. Florfenicol is contraindicated in animals hypersensitive to it and is not for use in animals intended for breeding. The effects of florfenicol on bovine reproductive performance, pregnancy, and lactation have not been determined. See residue warnings in ***Dosage Forms/Regulatory Status***.

Do not use this drug in female dairy cattle 20 months of age or older or in calves to be processed for veal.

Do not use in nursing piglets and swine of reproductive age intended for breeding.

Florfenicol is not recommended for use in equines, as administration resulted in loose stools and elevated bilirubin regardless of route (PO, IV, or IM).[10]

Florfenicol formulations contain an inactive ingredient that has been shown to cause reproductive and developmental toxicities in laboratory animals following high, repeated exposures; those who are pregnant should wear gloves when handling or avoid handling when possible.[11]

Adverse Effects

Noted transient adverse effects in cattle include anorexia, decreased water consumption, and diarrhea.[1] Injection site reactions after IM administration may persist for longer than 28 days and may result in trim loss. Reactions may be more severe if injected at sites other than the neck. Anaphylaxis and collapse have been reported in cattle.

GI effects, including severe diarrhea, are possible when this drug is used in other mammalian species.

Reproductive/Nursing Safety

Testicular degeneration and atrophy associated with florfenicol use has been observed in dogs, mice, and rats.[1] Safety or adverse effects of using this drug in breeding cattle or swine, during pregnancy, or during lactation are unknown; the manufacturer states florfenicol is not for use in cattle of breeding age or swine intended for breeding.[1,6]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In dogs administered florfenicol 30 or 100 mg/kg/day orally over 13 weeks, CNS vacuolation, hematopoietic toxicity, and renal tubule dilation were seen.[12]

In toxicology studies in which feeder calves were injected with up to 10 times the recommended dosage, increased serum liver and muscle enzymes (lactate dehydrogenase [LDH], gamma-glutamyl

transferase [GGT], ALT, AST) and anorexia, decreased water consumption, weight loss, and diarrhea were seen—these effects were generally transient in nature.[12] Long-term (ie, 43 days) standard dosage studies showed a transient decrease in feed consumption, but no long-term negative effects were noted.[12]

In swine receiving up to 10 times the recommended dosage, constipation and anal swelling, reduced feed and water intake, decreased body weight, and increased urine specific gravity were noted.[13]

A case report documented severe bone marrow suppression resulting in death in a gazelle that was administered 2 doses that were 10 times higher than intended.[14]

Because of the potential for serious bone marrow toxicity noted in some species, overdoses of oral florfenicol should be handled with gastric decontamination using standard protocols.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

No specific drug interactions for florfenicol were located, but florfenicol may behave similarly to chloramphenicol. If so, florfenicol could antagonize the bactericidal activity of **penicillins** or **aminoglycosides**. This antagonism has not been demonstrated in vivo, and these drug combinations have been used successfully many times clinically. Other antibiotics that bind to the 50S ribosomal subunit of susceptible bacteria (eg, **erythromycin, clindamycin, lincomycin, tylosin**) may potentially antagonize the activity of chloramphenicol or vice versa, but the clinical significance of this potential interaction has not been determined. For other drug interactions that florfenicol may share with chloramphenicol, see ***Chloramphenicol.***

In studies done in chickens[15] and rabbits,[16] CYP3A and p-glycoproteins are involved in the pharmacokinetics of florfenicol and may result in drug interactions with substrates, inducers, or inhibitors of CYP3A and p-glycoproteins.

Dosages

CATTLE:

Treatment of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica*, *Pasteurella multocida*, and *Histophilus somni* or bovine interdigital phlegmon (ie, foot rot) associated with *Fusobacterium necrophorum* and *Bacteroides melaninogenicus* (label dosage; FDA-approved): 20 mg/kg IM (in neck muscle only); repeat after 48 hours.[1] Alternatively, a single 40 mg/kg SC dose (in neck) may be used. **NOTE**: 20 mg/kg equates to 3 mL of the injection per 45.4 kg (100 lb) body weight. Do not exceed 10 mL per injection site.

Control of respiratory disease in cattle at high risk for developing BRD associated with *Mannheimia haemolytica*, *Pasteurella multocida*, and *Histophilus somni* (label dosage; FDA-approved): 40 mg/kg SC once.[1] Do not administer more than 10 mL at each site. Injection should be given only in the neck.

Florfenicol in combination with flunixin for treatment of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica*, *Pasteurella multocida,* and *Histophilus somni*, and control of BRD-associated pyrexia in beef and nonlactating dairy cattle (label dosage; FDA-approved): flunixin 2.2 mg/kg with florfenicol 40 mg/kg (6 mL/100 lb where each mL contains flunixin 16.5 mg with florfenicol 300 mg) SC once.[2] Do not administer more than 10 mL at each site. The injection should be administered only in the neck. Injection sites other than the neck have not been evaluated.

Infectious bovine keratoconjunctivitis (**IBK**; extra-label): 20 mg/kg IM in neck, repeated after 48 hours, or 40 mg/kg SC in neck once[17]

SHEEP/GOATS:

Respiratory disease complex in kids (extra-label): 20 mg/kg IM once daily for 2 days[18,19]

SWINE:

Treatment of swine respiratory disease associated with *Actinobacillus pleuropneumoniae*, *Pasteurella multocida*, *Salmonella choleraesuis*, and *Streptococcus suis* (label dosage; FDA-approved): In water at a concentration of 400 mg/gallon (100 ppm)[20]; use as only source of drinking water for 5 days.[6] For bulk tank, add 1 gallon of concentrate to 128 gallons of water, with proportioner set to 1:128 (0.8%).

Treatment of swine respiratory disease associated with *Actinobacillus pleuropneumoniae*, *Pasteurella multocida*, *Salmonella choleraesuis*, *Streptococcus suis*, *Bordetella bronchiseptica*, and *Glaesserella* (*Haemophilus*) *parasuis* (label dosage; FDA-approved): 15 mg/kg IM[11]; administer a second dose 48 hours later

CAMELIDS:

Susceptible pathogens (extra-label): 20 mg/kg IM once daily[18,21]

Monitoring

- Clinical efficacy
- Injection site reactions

Client Information

- Florfenicol is administered by injection into the muscle (intramusclar, IM) or under the skin (subcutaneous, SC). Your veterinarian will instruct which route is appropriate to use for your animal(s). Do NOT inject into the vein (IV).
- Injections into the muscle may result in local tissue reaction that persists beyond 28 days; this may result in trim loss at slaughter. Tissue reaction at injection sites other than the neck is likely to be more severe.
- US residue warnings: When florfenicol is administered as labeled, slaughter withdrawal in cattle is 28 days postinjection if injecting into the muscle (IM), and 38 days postinjection if injecting under the skin (SC); and slaughter withdrawal in swine (in drinking water) is 16 days.
- This medicine should not be used in female dairy cattle 20 months of age or older
- A withdrawal period has not been established for this medicine in preruminating calves. Do not use this medicine in calves to be processed for veal.
- Those who are pregnant should wear gloves when handling this medicine or avoid handling when possible.

Chemistry/Synonyms

Florfenicol, a fluorinated analogue of thiamphenicol, is commercially available as a light-yellow to straw-colored injectable solution that also contains n-ethyl-2-pyrolidone, propylene glycol, and polyethylene glycol. The commercially available products range from a bright yellow to straw color. Color does not affect potency.

Florfenicol may also be known as Sch-25298, *Aquaflor®*, *Florcon®*, *Florvio®*, *Longcor®*, *Norfenicol®*, *NuFlor®*, and *NuFlor-S®*.

Storage/Stability

Florfenicol injection storage requirements vary by manufacturer, but vials generally should be stored between 2°C to 30°C (36°F-86°F). Discard dates after first use range from 30 days to 6 months, and some products list a maximum number of times the vial may be punctured. Refer to individual product label for specific information.

The oral solution (swine) should be stored between 2°C to 26°C (36°F-77°F).

The combination product with flunixin should not be stored above 30°C (86°F) and should be used within 28 days. The 500 mL vial should not be punctured more than 20 times.

Compatibility/Compounding Considerations

No specific information has been noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Florfenicol Injection: 300 mg/mL in 100 mL, 250 mL, and 500 mL multi-dose vials; *NuFlor®*; (Rx). FDA-approved for use in cattle. Slaughter withdrawal (at label dosages) is 28 days (IM) and 38 days (SC). Do not use in female dairy cattle 20 months of age or older. A withdrawal period has not been established in preruminating calves. Do not use in calves to be processed for veal.

Florfenicol Injection: 300 mg/mL in multi-dose vials; *NuFlor®-S*; (Rx). FDA-approved for swine. Slaughter withdrawal (at label dosages) is 11 days (IM). Do not use in nursing piglets and swine of reproductive age intended for breeding.

Florfenicol Injection: 300 mg/mL (also contains 2-pyrrolidone 300 mg and triacetin qs) in 100 mL, 250 mL, and 500 mL vials; *Nuflor Gold®*; (Rx). FDA-approved for use in beef and nonlactating dairy cattle; NADA #141-265. Do not slaughter within 44 days of last treatment. Do not use in female dairy cattle 20 months of age or older. Use may cause milk residues. A withdrawal period has not been established in preruminating calves. Although this product is listed in the FDA Green Book, its marketing status is uncertain.

Florfenicol 2.3% (23 mg/mL) Concentrate Solution in 2.2 L bottles; *NuFlor® Concentrate Solution*, *Florcon®*, *Florvio®*; (Rx). FDA-approved for use in swine. Slaughter withdrawal (at label dosages) is 16 days.

There are florfenicol products for addition to catfish or salmonid feeds (*Aquaflor®*); (VFD) and swine feed additives (*Nuflor® Type A Medicated Article*); (VFD)

Florfenicol 300 mg/mL with Flunixin 16.5 mg/mL Injection in 100 mL, 250 mL, and 500 mL vials; *Resflor Gold®*; (Rx). FDA-approved for use in beef and nonlactating dairy cattle; NADA #141-299. Do not slaughter within 38 days of last treatment. Not for use in female dairy cattle 20 months of age or older or in calves to be processed for veal. Use may cause milk residues. A withdrawal period has not been established in preruminating calves.

For topical formulations containing florfenicol, please see ***Corticosteroid/Antimicrobial Preparations***.

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Fluconazole

(floo-***kon***-a-zole) *Diflucan®*

Antifungal, Azole

Prescriber Highlights

- ► Oral or parenteral antifungal particularly useful for CNS infections. Systemic mycoses may require treatment over several months.
- ► Similar efficacy as itraconazole; however, fluconazole does not require an acidic environment for PO absorption. Can be given with or without food
- ► Caution is advised in patients with chronic kidney disease, pregnancy, and hepatic failure.
- ► Adverse effects include occasional GI effects (eg, inappetence, vomiting, diarrhea) in cats and dogs; increased liver enzyme activity; and, rarely, severe hepatotoxicity.
- ► Many drug interactions are possible.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies fluconazole as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Fluconazole is used in the treatment of systemic mycoses, including cryptococcal meningitis, blastomycosis, histoplasmosis, and coccidioidomycosis. Because of the drug's unique pharmacokinetic qualities, it is likely more useful for treating CNS or urinary tract fungal infections than other azole derivatives. Unlike ketoconazole, fluconazole does not have appreciable effects on steroid hormone synthesis and may have fewer adverse effects in small animal species. Similarly, fluconazole impairs hepatic drug metabolism to a lesser extent than ketoconazole.

A retrospective study in dogs with blastomycosis found there was no significant difference in efficacy between fluconazole and itraconazole,[1] and although treatment with fluconazole was longer than with itraconazole (ie, median of 183 vs 138 days), fluconazole treatment costs were ≈⅓ less than itraconazole. Similarly, another retrospective study found no difference in efficacy between fluconazole and itraconazole in dogs with histoplasmosis.[2]

In dogs, fluconazole is effective for the treatment of *Malassezia* spp dermatitis,[3] but ketoconazole or itraconazole are preferred.[4]

Pharmacology/Actions

Fluconazole is a fungistatic triazole compound that inhibits a fungal CYP450-dependent demethylation enzyme that produces ergosterol in the fungal cell membrane. The resultant intracellular accumulation of methylated sterols weakens the cellular membranes of susceptible fungi, thereby increasing membrane permeability and allowing leakage of cellular contents and impairing uptake of purine and pyrimidine precursors. Fluconazole has efficacy against a variety of pathogenic fungi including yeasts and dermatophytes, although fluconazole's MIC against *Malassezia pachydermatis* is significantly higher than other azole antifungals.[4] In vivo studies using laboratory models have shown that fluconazole has fungistatic activity against some strains of *Candida* spp, *Coccidioides* spp, *Cryptococcus* spp, *Histoplasma* spp, and *Blastomyces* spp. Results from in vivo studies of efficacy against *Aspergillus* spp have been conflicting, and fluconazole is not considered a first-choice agent for these infections. Fluconazole and terbinafine combination treatment may have synergistic antifungal effects against *Candida albicans*.

Fluconazole resistance in *Candida* spp may be caused by overexpression of the target enzyme, reduced target enzyme affinity for fluconazole, or overexpression of efflux pumps.

In addition to its antifungal effects, fluconazole (similarly to other azoles) has been shown to have anti-inflammatory properties by re-

ducing IL-4 production, increasing production of interferon-gamma in *Candida albicans*-infected mice, and inhibiting the production of leukotriene B4 in vitro.[3] Fluconazole also inhibited neurogenic inflammation in mouse models, suggesting an additional antipruritic activity.[3]

Pharmacokinetics

In dogs, fluconazole oral bioavailability was 100%, and peak plasma concentration was reached 4 hours after oral administration. Volume of distribution was 0.7 to 0.8 L/kg, and plasma protein binding was low (11%). Elimination half-life was 13 to 15 hours. Plasma clearance was ≈0.65 mL/kg/minute. Approximately 70% of the fluconazole dose was excreted unchanged in urine.[5]

In cats, fluconazole was completely absorbed, with peak concentration reached 2.6 hours after oral administration. Volume of distribution was 1 L/kg. Mean ratios of fluid:serum fluconazole concentrations were 0.88 and 0.79 for CSF and aqueous humor, respectively, and 1.2 for epithelial lining fluid. Clearance was 0.6 to 0.9 mL/kg/minute and elimination half-life was ≈13 to 25 hours.[6,7]

In horses, fluconazole was completely absorbed after oral administration, with peak concentration reached after 2 hours. Volume of distribution was 1.2 L/kg, and the drug was found in CSF, synovial fluid, and aqueous humor at concentrations 35% to 50% that of plasma; urine concentration was almost twice that of plasma. Clearance was 0.02 L/kg/minute and elimination half-life was ≈38 to 42 hours.[8]

In cockatiels receiving fluconazole orally, peak concentration was reached ≈5 hours after oral administration, and elimination half-life was 19 hours. Pharmacokinetic data were similar when fluconazole was administered in drinking water.[9]

In humans, fluconazole is rapidly and nearly completely absorbed (ie, 90%) after oral administration.[10] Gastric pH or the presence of food does not appreciably alter fluconazole's oral bioavailability. It has low protein binding and is widely distributed throughout the body; however, protein binding may be altered in renal disease states associated with increased alpha-1-acid glycoprotein (AAG) concentrations.[11] The drug readily penetrates into bodily fluids, including into the CSF, eye, and peritoneal fluid. Fluconazole is eliminated primarily via the kidneys as unchanged drug and achieves high concentrations in the urine. Fluconazole's serum half-life is ≈30 hours in patients with normal renal function. Patients with impaired renal function may have significantly extended half-lives and dosage adjustments may be required. Because of its long half-life, fluconazole does not reach steady-state plasma concentrations for 6 to 14 days after beginning therapy, unless loading doses are given. Administration of a loading dose (2 times the labeled daily dose) on the first day of treatment results in plasma concentrations close to steady-state by the second day.[10]

Contraindications/Precautions/Warnings

Fluconazole should not be used in patients that are hypersensitive to it or other azole antifungal agents. As fluconazole may cause hepatotoxicity (rarely, and less than itraconazole or ketoconazole), this drug should only be used in patients with hepatic impairment when the potential benefits outweigh the risks. Because fluconazole is eliminated primarily by the kidneys, dosages may need to be adjusted in patients with renal impairment.

Fluconazole has been associated with prolongation of the QT interval and should be used with caution in patients at increased risk for arrhythmias (eg, structural heart disease, heart failure, electrolyte imbalance). In humans, fluconazole is contraindicated in patients receiving drugs that both prolong the QTc interval and are metabolized by cytochrome P450 3A4; significance in animals is unknown. See ***Drug Interactions.***

Fluconazole is reportedly both ineffective and highly toxic to budgerigars at typical doses.[12]

The National Institute for Occupational Safety and Health (NIOSH) classifies fluconazole as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Do not confuse fluconazole with flecaine, fluoxetine, or furosemide.

Adverse Effects

Fluconazole is well tolerated in the majority of dogs and cats. Inappetence, vomiting, soft stools, and diarrhea have occasionally been reported, but these may be mild and transient and not require cessation of therapy. Other adverse effects reported include focal alopecia, hypoadrenocorticism, ocular discharge, dry skin, and malaise.[14] Hepatotoxicity is possible and ≈15% to 20% of dogs receiving long-term treatment may have increased ALT activity; with continued monitoring of liver enzymes, most dogs were able to complete treatment without dose reduction or discontinuation of therapy.[1,2] There can also be an increase in ALT in cats.[14]

In humans, adverse effects have been generally limited to occasional GI effects (eg, vomiting, diarrhea, anorexia, nausea) and headaches.[10] Increased liver enzymes and hepatotoxicity, adrenal insufficiency, exfoliative skin disorders, and thrombocytopenia have been reported in humans (rarely). Humans receiving fluconazole for 28 days for treatment of coccidioidomycosis experienced adverse effects (eg, dry skin, alopecia, fatigue, and nausea and vomiting), with ≈⅔ requiring therapy changes.[15]

Reproductive/Nursing Safety

Fluconazole did not affect fertility in rats.[10] High-dose fluconazole resulted in congenital abnormalities in laboratory animals and women receiving fluconazole during pregnancy. In humans, it is recommended to avoid use of prolonged or high-dose therapy during pregnancy, except in patients with severe or life-threatening fungal infections in which the benefits to the mother outweigh potential risk to the fetus.[16,17]

Fluconazole is excreted into maternal milk at concentrations similar to plasma. Use with caution in lactating animals; consider milk replacer.

Overdose/Acute Toxicity

There is limited information available on the acute toxicity of fluconazole. Rats and mice survived doses of 1 g/kg but died within several days after receiving 1 – 2 g/kg.[18] Rats and mice receiving higher dosages demonstrated respiratory depression, salivation, lacrimation, urinary incontinence, and cyanosis. If a massive overdose occurs, consider gastric decontamination and give supportive therapy as required. Fluconazole may be removed by hemodialysis or peritoneal dialysis. In humans, a 3-hour hemodialysis decreases fluconazole plasma concentrations by ≈50%.[10]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

In humans, fluconazole is a potent CYP2C and moderate CYP3A inhibitor. The following drug interactions have either been reported or are theoretical in humans or animals receiving fluconazole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Laboratory animal studies have shown that fluconazole used concomitantly with amphotericin B may be antagonistic against *Aspergillus* spp or *Candida* spp; the clinical im-

portance of these findings is unclear.

- **Benzodiazepines** (eg, **alprazolam, diazepam, midazolam**): Increased benzodiazepine concentrations and subsequent adverse effects (eg, sedation) are possible. Fluconazole decreased midazolam clearance by 50% in dogs,[19] and prolonged clinical effects (eg, time to standing, heart rate) and recovery times have been noted in horses.[20]
- **Buspirone**: Plasma buspirone concentrations may be elevated.
- **Calcium Channel Blocking Agents** (eg, **amlodipine, diltiazem**): Fluconazole may increase exposure of calcium channel blockers.
- **Cannabidiol**: May increase cannabidiol concentration
- **Cimetidine**: May reduce fluconazole concentrations
- **Cisapride**: In humans, concomitant use is contraindicated, as it may increase cisapride plasma concentration and the risk for QT prolongation; significance in animals is unknown.
- **Colchicine**: Increased colchicine concentrations and adverse effects are possible. Contraindicated in humans with hepatic or renal impairment
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Fluconazole may inhibit the metabolism of corticosteroids; potential for increased adverse effects
- **Cyclophosphamide**: Fluconazole may inhibit the metabolism of cyclophosphamide and its metabolites; potential for increased toxicity
- **Cyclosporine**: Fluconazole increases cyclosporine concentrations without changing half-life. In healthy dogs, fluconazole 5 mg/kg PO once daily decreased cyclosporine dosages by ≈50% to achieve similar therapeutic trough concentrations.[21,22] In renal transplant dogs (also on mycophenolate), fluconazole decreased cyclosporine dose requirements by 33% on average.[23]
- **Diuretics, Thiazides** (eg, **hydrochlorothiazide**): Increased fluconazole concentrations are possible.
- **Fentanyl/Alfentanil**: Fluconazole may increase fentanyl concentrations.
- **Ketamine**: Fluconazole decreased ketamine clearance by 50% and prolonged clinical effects (eg, time to standing, heart rate) in dogs.[19] Prolonged recovery was noted in horses.[20]
- **Losartan**: Increased losartan effects are possible; increased monitoring of blood pressure is recommended.
- **Macrolide Antibiotics** (eg, **clarithromycin, erythromycin**): Concomitant use may increase the risk for QT prolongation; concurrent therapy is contraindicated in humans. Interaction may not apply to azithromycin.
- **Methadone**: Fluconazole significantly increases methadone exposure in dogs.[24] In humans, concomitant use is contraindicated, as it may also increase the risk for QT prolongation; significance in animals is unknown.
- **Nonsteroidal anti-inflammatory drugs (NSAIDs;** eg, **carprofen, flunixin, meloxicam, phenylbutazone, robenacoxib**): Fluconazole may increase plasma concentrations of some agents; increased risk for adverse effects
- **Quinidine**: May reduce quinidine metabolism, increasing the risk for cardiotoxicity. Concurrent therapy is contraindicated in humans.
- **QT prolonging Agents** (eg **amiodarone, disopyramide, ondansetron, procainamide, sotalol**): Increased risk for arrhythmias
- **Rifampin**: May decrease fluconazole exposure and efficacy; fluconazole may increase rifampin concentrations
- **Sildenafil**: Increased sildenafil exposure
- **Sulfonylurea Antidiabetic Agents** (eg, **glipizide, glyburide**): Fluconazole may increase concentrations; hypoglycemia is possible.
- **Theophylline/Aminophylline**: Increased theophylline concentrations are possible.
- **Tramadol**: In dogs, fluconazole increased tramadol and its M1 metabolite by 31 and 39 times, respectively.[25]
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): Fluconazole may exacerbate the effects of tricyclic antidepressants.
- **Vincristine/Vinblastine**: Fluconazole may inhibit vinca alkaloid metabolism.
- **Warfarin**: Fluconazole may cause increased prothrombin times in patients receiving warfarin or other coumarin anticoagulants.
- **Zidovudine**: Increased zidovudine concentration and exposure

Laboratory Considerations

None were noted.

Dosages

DOGS:

Systemic mycosis for fluconazole-sensitive organisms (potentially cryptococcosis,[26] blastomycosis,[1] histoplasmosis[2]) (extra-label): 5 – 10 mg/kg PO, IV every 12 to 24 hours. Infections involving the CNS and eyes may require dosages up to 15 mg/kg twice daily. IV doses should be administered over 1 to 2 hours. Treatment may be required for 4 to 8 months and should continue for 2 months after resolution of clinical signs with accompanying decline in antigen titers.

Urinary candidiasis (extra-label): 5 – 10 mg/kg PO every 24 hours for 3 to 5 weeks

***Coccidioides* osteomyelitis** (extra-label): Average initial dosage was 18 mg/kg/day PO; clinical signs improved rapidly, but long-term treatment was required.[27]

Systemic treatment for *Malassezia* dermatitis, dermatophytosis, onychomycosis (extra-label): 2.5 – 5 mg/kg PO every 24 hours. Continue treatment for at least 1 week after complete resolution of clinical signs (for *Malassezia* dermatitis) or until 2 negative skin cultures (taken 2 weeks apart) are obtained (for dermatophytosis and onychomycosis).[28,29] Ketoconazole or itraconazole are preferred.[4]

CATS:

Systemic mycosis for fluconazole-sensitive organisms (potentially cryptococcosis,[30,31] blastomycosis,[32,33] histoplasmosis,[34] coccidioidomycosis[35]) (extra-label): 10 mg/kg PO every 12 hours,[7] practically administered as one 50 mg tablet/cat (NOT mg/kg) PO every 12 hours. Rapidly progressing or severely disseminated infections may require 100 mg/cat (NOT mg/kg) PO every 12 hours. Tablets may be crushed. Treatment is usually required for several months and should continue for 1 to 3 months after resolution of clinical signs or negative antigen test results on serum and CSF.

Anterior uveitis due to cryptococcosis (extra-label): 10 – 15 mg/kg PO every 24 hours, continuing for 2 months after resolution of clinical signs with accompanying decline in antigen titers[26]

Systemic treatment for *Malassezia* dermatitis, dermatophytosis, onychomycosis (extra-label): 5 mg/kg PO every 12 hours. Continue treatment for at least 1 week after complete resolution of signs (for *Malassezia* dermatitis) or until 2 negative skin cultures (taken 2 weeks apart) are obtained (for dermatophytosis and onychomycosis).[36] Itraconazole is preferred.[4]

HORSES:

Susceptible fungal infections (extra-label): Loading dose of 14 mg/kg PO followed by 5 mg/kg PO once daily.[8] This dosage is supported by several case reports for a variety of topical[37–39] and systemic[40–42] fungal infections.

Cutaneous pythiosis: 10 mg/kg PO once as a loading dose followed by 5 mg/kg PO once daily[43]

***Coccidioides immitis* infection or *Candida* spp bacteremia** (extra-label): Loading dose of 14 mg/kg PO followed by 5 mg/kg PO once daily. There have been anecdotal reports of successful treatment of fungal keratitis using fluconazole 1 mg/kg PO every 24 hours.[44]

Infectious endometritis caused by susceptible fungal organisms of *Candida* spp (extra-label): Based on plasma and endometrial tissue concentrations, giving a 14 mg/kg PO loading dose and a maintenance dose of 5 mg/kg PO every 24 hours will result in endometrial tissue concentrations near the accepted MIC values for most *Candida* spp and surpass the MIC for *Candida albicans* in the reproductive tract of mares.[45]

BIRDS:

Candidiasis (extra-label): Fluconazole pharmacokinetics were determined in Goffin's cockatoos. Timneh African grey parrots and orange-winged Amazon parrots showed fluconazole 20 mg/kg PO every 24 to 48 hours or 10 mg/kg PO every 24 hours would likely be effective for treatment of *C albicans*.[46,47] This dose may be too low for treatment of *Candida glabrata* and *Candida parapsilosis*.

Candidiasis in cockatiels (extra-label): 10 mg/kg PO suspension and 100 mg/mL fluconazole-treated drinking water both maintained plasma concentrations above the MIC for most strains of *C albicans*. Computer modeling predicted 5 mg/kg PO once daily or 10 mg/kg PO every other day would also maintain plasma concentration above MIC or AUC:MIC ratio.[48]

Alternative treatment of aspergillosis (extra-label): 5 – 10 mg/kg PO once daily for up to 6 weeks, with or after amphotericin B treatment and/or surgical debridement[49,50]

RABBITS/RODENTS/SMALL MAMMALS:

Rabbits (extra-label): 25 – 43 mg/kg IV slowly every 12 hours[51]

REPTILES:

Dermatophytosis in iguanas (extra-label): 5 mg/kg PO once daily

Monitoring

- Clinical efficacy
- GI adverse effects
- Fungal antigen testing and/or fungal cultures when indicated
- Baseline and periodic chemistry panel (eg, ALT, ALP) are recommended with long-term therapy.

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after receiving fluconazole on an empty stomach, give with food or a small treat. If vomiting continues, contact your veterinarian.
- The most likely side effects are gastrointestinal (eg, lack of appetite, vomiting, diarrhea). Liver toxicity is possible but is very rare.
- Do not skip doses.

Chemistry/Synonyms

Fluconazole, a synthetic triazole antifungal agent, occurs as a white crystalline powder. It is slightly soluble in water. Solutions for injection have a pH of 4 to 8.

Fluconazole may also be known as fluconazolum, flukonatsoli, or UK-49858; many trade names are available, including *Diflucan*®.

Storage/Stability

Fluconazole tablets and the powder for oral suspension should be stored at temperatures less than 30°C (86°F) in tight containers. Fluconazole injection should be stored at temperatures of 5°C to 30°C (41°F-86°F); varies by manufacturer, refer to product label); avoid freezing. After reconstitution, fluconazole oral suspension should be stored at temperatures of 5°C to 30°C (41°F-86°F); avoid freezing. Discard unused portions of reconstituted oral suspension after 2 weeks.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Do not add additives to the injection. The following drugs have been reported to be **Y-site compatible** with fluconazole: amikacin, azithromycin, buprenorphine, butorphanol, cefazolin, dexamethasone sodium phosphate, dexmedetomidine, diltiazem, diphenhydramine, dobutamine, famotidine, fentanyl, gentamicin, heparin, hydrocortisone sodium succinate, insulin (regular), lactated Ringer's solution, lidocaine, magnesium sulfate, meropenem, metoclopramide, metronidazole, midazolam, morphine, nitroprusside, ondansetron, penicillin G, piperacillin/tazobactam, potassium chloride, and sodium bicarbonate.

The following drugs have been reported to be completely or variably **incompatible** with fluconazole: ampicillin, amphotericin B (all formulations), ceftazidime, clindamycin, dantrolene, diazepam, furosemide, hydroxyzine, pantoprazole, and sulfa-/trimethoprim.

In one study, compounded fluconazole suspension concentration varied by 74% to 95% of the labeled concentration.[52]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Fluconazole Oral Tablets: 50 mg, 100 mg, 150 mg, and 200 mg; *Diflucan*®; generic; (Rx)

Fluconazole Powder for Oral Suspension: 10 mg/mL and 40 mg/mL (when reconstituted) in 35 mL; *Diflucan*®; generic; (Rx); orange flavored

Fluconazole in Sodium Chloride 0.9% Injection: 2 mg/mL in 100 mL and 200 mL bottles or bags; *Diflucan*®; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Flucytosine

(floo-***sye***-toe-seen) *Ancobon®*

Antifungal

Prescriber Highlights

- ► Antifungal used only in combination with other drugs for serious fungal infections. CNS penetration is excellent, and high urinary concentrations are attainable.
- ► Extreme caution is advised in patients with renal impairment, preexisting myelosuppression, hematologic diseases, or receiving other bone marrow suppressant drugs. Caution is advised in patients with hepatic disease.
- ► Not recommended for dogs, as they may develop severe cutaneous and/or mucocutaneous reactions
- ► Teratogenic in rats
- ► The most common adverse effects are GI effects (eg, inappetence, vomiting, diarrhea). Other potential effects include, dose-dependent myelosuppression, cutaneous eruption, oral ulceration, increased hepatic enzymes, and CNS effects (cats).

Uses/Indications

Flucytosine is active against *Cryptococcus* spp, *Candida* spp, and *Aspergillus* spp. It is used in combination with other antifungals (eg, azoles, amphotericin B). When flucytosine is used as a single agent, resistance can develop rapidly, particularly with *Cryptococcus* spp. Because it penetrates relatively well into the CNS, flucytosine has been used for the treatment of CNS cryptococcosis. Some cases of SC and systemic chromomycosis (chromoblastosis) may also respond to flucytosine.

Pharmacology/Actions

Flucytosine penetrates fungal cells where it is deaminated by cytosine deaminase to fluorouracil. Fungi lacking cytosine deaminase are not susceptible to flucytosine. Fluorouracil acts as an antimetabolite by competing with uracil, thereby interfering with pyrimidine metabolism and eventually RNA and protein synthesis. It is thought that fluorouracil is subsequently converted to fluorodeoxyuredylic acid that inhibits thymidylate synthesis and, ultimately, DNA synthesis.

In human cells, cytosine deaminase is apparently not present or only has minimal activity. Rats metabolize some of the drug to fluorouracil, which may explain the teratogenic effects seen in this species. It is unclear how much cytosine deaminase activity dog and cat cells possess. GI bacteria may deaminate small amounts of flucytosine to fluorouracil.

Flucytosine can have synergistic efficacy when used with amphotericin B.

Pharmacokinetics

Flucytosine is well absorbed after oral administration. The rate, but not extent, of absorption will be decreased if given with food.

Flucytosine is distributed widely throughout the body. CSF concentrations may be 60% to 100% of those found in the serum. In healthy humans, the volume of distribution is about 0.7 L/kg. Only about 2% to 4% of the drug is bound to plasma proteins. It is unknown if flucytosine is distributed into milk.

Flucytosine is excreted basically unchanged in the urine via glomerular filtration. The elimination half-life of flucytosine is ≈2.7 hours in dogs.[1] In humans, the half-life is about 3 to 6 hours in patients with normal renal function but may be significantly prolonged in patients with renal dysfunction.

Contraindications/Precautions/Warnings

Flucytosine is contraindicated in patients that are hypersensitive to it.

Flucytosine should be used with extreme caution in patients with renal impairment. Some clinicians recommend monitoring serum flucytosine concentrations in these patients and adjusting the dose (or dosing interval) to maintain peak serum concentration less than 100 µg/mL. One recommendation is to divide the flucytosine dose by the serum creatinine level if azotemia develops.[2]

Use flucytosine with extreme caution in dogs, as mucocutaneous or cutaneous drug eruptions can develop rapidly (within 10 to 20 days) but may occur as late as 6 weeks after beginning treatment.[1,3] Lesions may be localized to the nasal planum, lips, eyelids, and scrotum.

Use flucytosine with extreme caution in patients with preexisting myelosuppression, hematologic diseases, or in those receiving other bone marrow suppressant drugs. Flucytosine should also be used cautiously (with enhanced monitoring) in patients with hepatic disease.

Because resistance can develop rapidly when flucytosine is used alone, it should only be used in combination with other antifungal drugs.

Do not confuse flucytosine with fluorouracil.

Adverse Effects

The most common adverse effects seen with flucytosine are GI disturbances (eg, nausea, vomiting, diarrhea). Other potential adverse effects include a dose-dependent myelosuppression (eg, anemia, leukopenia, thrombocytopenia), oral ulceration, and increased liver enzymes. Dogs receiving flucytosine often develop a severe drug reaction (ie, mucocutaneous or cutaneous eruption with depigmentation, ulceration, exudation and crust formation, primarily seen on the scrotum and nasal planum) that typically appears within 10 to 20 days of initiating treatment.[1,3] Lesions should resolve within 2 to 3 weeks of stopping treatment and were less severe with immediate discontinuation of flucytosine.

Reports of aberrant behavior and seizures in a cat without concurrent CNS infection have been noted after flucytosine use. There are anecdotal reports of toxic epidermal necrolysis occurring in cats treated with flucytosine.

Reproductive/Nursing Safety

The effects of flucytosine on fertility and reproductive effects have not been well studied. Flucytosine crosses the placenta and has caused teratogenic effects in rats, but not in rabbits or mice.[4] It should be used in pregnant animals only when the benefits of therapy outweigh the risks.

It is not known whether flucytosine is excreted in milk. Because there are potential serious adverse reactions in nursing offspring, consider using milk replacer.

Overdose/Acute Toxicity

Limited information on the acute toxicity of flucytosine is available. It is suggested that a substantial overdose be handled with gut emptying, administration of activated charcoal, and a cathartic unless contraindicated. Flucytosine can be removed by dialysis.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving flucytosine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Antacids, Aluminum- or Magnesium-Containing**: May delay the absorption of flucytosine[5]

- **Amphotericin B**: When used with amphotericin B, synergism against *Cryptococcus* spp and *Candida* spp has been demonstrated in vitro. However, if amphotericin B induces renal dysfunction, the toxicity of flucytosine may be enhanced if it accumulates. If clinically significant renal toxicity develops, flucytosine dosage may need to be adjusted.
- **Cytarabine**: Impaired flucytosine activity may occur due to competition by cytarabine for fungal sites of action.
- **Myelosuppressive Drugs** (eg, **antineoplastics, azathioprine, chloramphenicol, methimazole**): Additive myelosuppression may occur.
- **Zidovudine**: Increased risk for neutropenia

Laboratory Considerations

- When determining **serum creatinine** using the ***Ektachem***® analyzer, false elevations in levels may be noted if patients are also taking flucytosine.

Dosages

DOGS:

NOTE: Because of potentially serious toxicity, flucytosine is usually **not recommended** for use in dogs.

Cryptococcosis (extra-label): 50 – 75 mg/kg PO every 8 hours; treatment requires 1 to 12 months. Flucytosine must be given with amphotericin B or azole antifungal agent.[6]

CATS:

Cryptococcosis (extra-label): Must be used with another antifungal (amphotericin B or an azole). 30 mg/kg PO every 6 hours or 50 mg/kg PO every 8 hours or 75 mg/kg PO every 12 hours, or 250 mg/cat (NOT mg/kg) every 6 to 8 hours. Treatment requires 1 to 9 months.[6]

Candidiasis (extra-label): 25 – 50 mg/kg PO every 6 hours or 50 – 65 mg/kg PO every 8 hours for 42 days. Flucytosine must be given with amphotericin B or azole antifungal agent.[7]

Monitoring

- Renal function (at least twice weekly if also receiving amphotericin B)
- CBC with platelets
- Hepatic enzymes at least monthly
- In humans, dosage adjustments should target peak flucytosine concentration of less than 100 µg/mL and trough flucytosine concentration of 20 – 40 µg/mL to minimize toxicity.[8]

Client Information

- Clients should report any clinical signs associated with hematologic toxicity (eg, abnormal bleeding, bruising).
- If vomiting occurs, give flucytosine with food or a small treat.
- Pregnant women should take precautions handling this medication. It has caused birth defects in laboratory animals.

Chemistry/Synonyms

Flucytosine, a fluorinated pyrimidine antifungal agent, occurs as a white to off-white, crystalline powder that is odorless or has a slight odor with pK_as of 2.9 and 10.71. Flucytosine has a molecular weight of 129.09. It is sparingly soluble in water and slightly soluble in alcohol. Flucytosine may also be known as 5-FC, 5-fluorocytosine, flucitozin, flucytosinum, Ro-2-9915, *Alcobon*®, and *Ancotil*®.

Storage/Stability

Store flucytosine capsules in tight, light-resistant containers at 25°C (77°F); excursions permitted to 15°C to 30°C (59°F-86°F).

Flucytosine may decompose to fluorouracil if stored at higher temperatures.

Compatibility/Compounding Considerations

Compounded preparation stability: Flucytosine oral suspension compounded from commercially available capsules has been published.[9] Triturating four (4) flucytosine 250 mg capsules with 50 mL of *Ora-Plus*® and *qs ad* to 100 mL with *Ora-Sweet*® (or *Ora-Sweet*® *SF*) yields a 10 mg/mL oral suspension that retains greater than 95% potency for 60 days stored at both 5°C (41°F) and 25°C (77°F).

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Flucytosine Oral Capsules: 250 mg and 500 mg; *Ancobon*®, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Fludrocortisone

(flue-droe-***kor***-ti-sone) *Florinef*®

Mineralocorticoid

Prescriber Highlights

- ► Oral mineralocorticoid alternative to DOCP for treating hypoadrenocorticism in small animal species
- ► Although fludrocortisone has some glucocorticoid activity that could cause adverse effects, some patients may require supplemental glucocorticoid therapy (eg, prednis[ol]one).
- ► Adverse effects are dose-related and include polyuria, polydipsia, GI upset, hypertension, edema, and hypokalemia.
- ► May be given without regard to food unless GI upset is noted

Uses/Indications

Fludrocortisone is used primarily for its mineralocorticoid effects in the treatment of hypoadrenocorticism (Addison's disease) in small animal species. One study assessing plasma renin activity of hypoadrenocorticism in dogs suggests that desoxycorticosterone pivalate (DOCP) may be more effective at suppressing renin activity (which is increased with hypoadrenocorticism due to decreased aldosterone production) than fludrocortisone.[1] Further studies are needed to understand the clinical significance of this difference, especially when measurement of renin activity is limited in veterinary patients.

In humans, fludrocortisone has also been used for severe postural hypotension and salt-losing, congenital adrenal hyperplasia.

Pharmacology/Actions

Fludrocortisone acetate is a potent corticosteroid that possesses both glucocorticoid and mineralocorticoid activity. It is ≈10 to 15 times as potent a glucocorticoid agent as hydrocortisone but is a much more potent mineralocorticoid (125 times that of hydrocortisone). It is only used clinically for its mineralocorticoid effects. Mineralocorticoids increase sodium reabsorption at the renal distal tubule and enhance potassium and hydrogen ion excretion in the collecting tubule.

The site of action of mineralocorticoids is at the renal distal tubule, where they increase the absorption of sodium and enhance urinary potassium and hydrogen ion excretion.

Pharmacokinetics

In humans, fludrocortisone is well-absorbed from the GI tract, with peak concentrations occurring in ≈1.7 hours. Plasma half-life is ≈3.5 hours, but biologic activity persists for 18 to 36 hours.[2]

Contraindications/Precautions/Warnings

Fludrocortisone is contraindicated in patients known to be hypersensitive to it and in patients with systemic fungal infections.

Some dogs or cats may require additional supplementation with a glucocorticoid agent on an ongoing basis. All animals with hypoadrenocorticism should receive additional glucocorticoids (at least 2 times basal) during periods of stress or acute illness. Because fludrocortisone has glucocorticoid properties, it should be withdrawn slowly if therapy is discontinued.

Long-term corticosteroid administration causes immunosuppression and increases risk for infection. The risk for glaucoma and cataract development may also be increased.

Use with caution in patients with cardiac or renal disease, as fludrocortisone causes fluid retention and may lead to electrolyte imbalances and hypertension. Use corticosteroids cautiously in patients with fresh intestinal anastomoses, active or latent peptic ulcer, osteoporosis, or myasthenia gravis.[2]

Adverse Effects

Adverse effects of fludrocortisone are generally a result of chronic, excessive dosage (see ***Overdose/Acute Toxicity***) or if withdrawal is too rapid. Because fludrocortisone also possesses glucocorticoid activity, it can cause the adverse effects associated with those compounds, such as polyuria/polydipsia, polyphagia, and panting. (See ***Glucocorticoid Agents, General Information***)

Reproductive/Nursing Safety

Specific information on fludrocortisone effects in pregnant or lactating animals is lacking. Corticosteroids have been shown to be teratogenic (eg, reduced fetal growth, cleft palate, deformed forelegs, phocomelia, anasarca).

Corticosteroids may be excreted in clinically significant quantities in milk. Puppies or kittens of mothers receiving fludrocortisone should receive milk replacer after colostrum is consumed.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdose may cause hypertension, edema, and hypokalemia. Electrolytes should be aggressively monitored, and potassium may need to be supplemented. The drug should be discontinued until clinical signs associated with overdose have resolved, then restarted at a lower dosage.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fludrocortisone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Concomitant administration may increase risk for hypokalemia.
- **Aspirin**: Concomitant administration may reduce salicylate levels and may also increase risk for GI adverse effects.
- **Calcitriol**: Concomitant administration may decrease the therapeutic effect of calcitriol.
- **Cholestyramine**: May decrease fludrocortisone bioavailability
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Concomitant administration may increase risk for corticosteroid side effects.
- **Cosyntropin**: Concomitant administration may decrease diagnostic effects of cosyntropin.
- **Desmopressin**: Concomitant administration may increase risk for hyponatremia from desmopressin.
- **Digoxin**: By lowering potassium, fludrocortisone may increase the risk for digoxin toxicity.
- **Diuretics, Potassium-Depleting** (eg, **thiazides**, **furosemide**): Concomitant administration may increase risk for hypokalemia. Diuretics also cause a loss of sodium and may counteract the effects of fludrocortisone.
- **Hypoglycemic Agents** (eg, **glipizide, insulin, metformin**): Fludrocortisone may increase blood glucose, reducing antidiabetic effect.
- **I^{131}**: Uptake of I^{131} by thyroid tissue may be decreased by glucocorticoids.
- **Immunosuppressive Agents** (eg, **leflunomide, mycophenolate, tacrolimus**): Concomitant administration may increase risk for immunosuppression and subsequent infection.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, meloxicam**): Concomitant administration may increase risk for GI adverse effects.
- **Phenobarbital**: Concomitant administration may result in decreased fludrocortisone efficacy.
- **Rifampin**: Concomitant administration may result in decreased fludrocortisone efficacy.
- **Vaccines**: Fludrocortisone may result in inadequate immunological response to the vaccine due to its immunosuppressive effects.

Laboratory Considerations

- Glucocorticoids may increase serum **cholesterol** and **urine glucose** levels.
- Glucocorticoids may decrease serum **potassium**.
- Glucocorticoids can suppress the release of thyroid stimulating hormone (TSH) and reduce **T_3** and **T_4** values. Thyroid gland atrophy has been reported after chronic glucocorticoid administration.
- Fludrocortisone suppressed serum **aldosterone** in healthy adult cats.[3]
- False-negative results of the **nitroblue tetrazolium test for systemic bacterial infections** may be induced by glucocorticoids.
- **Intradermal allergy testing (IDT)**: Suppression of IDT results may persist for 1 to 2 weeks after discontinuation of fludrocortisone. It is recommended that treatment be discontinued at least 2 weeks prior to testing.[4]

Dosages

DOGS:

Maintenance therapy for hypoadrenocorticism (extra-label): Initially, 0.01 – 0.02 mg/kg PO as either a single dose or divided and given twice daily. Dosages are adjusted in 0.05 – 0.1 mg increments (½ to one 0.1 mg tablet) every 5 days based on assessment of serum electrolyte concentrations. Once dose is stabilized, some dogs can be transitioned to once daily dosing. Most dogs will eventually require 0.02 – 0.03 mg/kg per day. Approximately 50% of dogs will require supplemental prednis(ol)one, and owners should have supplemental prednis(ol)one on hand and be instructed to use it when animal undergoes stress or illness (eg, veterinary visits, boarding). See ***Prednisolone/Prednisone***. In dogs that develop signs of hyperadrenocorticism (eg, polyuria, polydipsia) while being treated with fludrocortisone, first withdraw any additional glucocorticoid supplementation. If clinical signs persist, the signs may be due to the glucocorticoid activity of fludrocortisone. In dogs in which electrolyte concentrations cannot be effectively normalized with fludrocortisone, consider switch-

ing mineralocorticoid supplementation to desoxycorticosterone pivalate (DOCP).[5-9,10]

CATS:

Maintenance therapy for hypoadrenocorticism (extra-label): 0.05 – 0.1 mg/cat (NOT mg/kg) PO twice daily with prednisolone 2.5 – 5 mg/cat (NOT mg/kg) PO per day added as needed.[5] Taper prednisolone to the minimum dosage that controls clinical signs.

Possible diagnostic tool in the diagnosis of feline primary hyperaldosteronism (PHA)[11] (extra-label):

1. Urine aldosterone:creatinine ratio (UACR) is measured before and after administration of fludrocortisone 0.05 mg/kg PO every 12 hours for 4 days.[3,12]
2. Serum aldosterone:creatinine ratio is measured before and after administration of fludrocortisone 0.05 mg/kg PO every 12 hours for 3 doses.[3]

FERRETS:

Maintenance therapy for hypoadrenocorticism (extra-label): 0.05 – 0.1 mg/kg PO once daily (every 24 hours) or divided every 12 hours for animals that still exhibit signs of hypoadrenocorticism despite prednis(ol)one therapy[13]

Monitoring

- Prior to beginning treatment and following a dosage change, measure serum electrolyte concentrations, then measure again every 5 to 7 days until sodium and potassium concentrations have normalized.[14] Once dose is stabilized, recheck electrolytes every 3 to 6 months.
- Body weight, physical examination to check for edema (peripheral and pulmonary)
- Baseline and periodic blood pressure
- Signs of glucocorticoid excess (eg, polyuria, polydipsia)

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give medicine with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Side effects are unlikely, but if the dose is too high (long-term), your animal may develop changes in fur, abdominal swelling, hair loss. Contact your veterinarian as soon as possible if your animal shows signs of weakness, depression, lack of appetite, vomiting, and/or diarrhea, as these signs may mean the dose is too low.
- Surgery or stress (eg, trauma, illness) requires administration of additional glucocorticoids (eg, prednisolone). A supply of prednisolone should always be kept on hand.
- Do not stop this medicine suddenly or serious side effects could occur.

Chemistry/Synonyms

A synthetic glucocorticoid with significant mineralocorticoid activity, fludrocortisone acetate occurs as hygroscopic, fine, white to pale yellow powder or crystals. It is odorless or practically odorless. Fludrocortisone is insoluble in water and slightly soluble in alcohol.

Fludrocortisone acetate may also be known as fluohydrisone acetate, fluohydrocortisone acetate, 9alpha-fluorohydrocortisone acetate, fludrocortisoni acetas, 9alpha-fluorohydrocortisone 21-acetate, *Astonin®*, *Astonin H®*, *Florinef®*, *Florinefe®*, and *Lonikan®*.

Storage/Stability

Fludrocortisone acetate tablets should be stored at room temperature 20°C to 25°C (68°F-77°F) in well-closed containers; avoid excessive heat. The drug is relatively stable in light and air.

Compatibility/Compounding Considerations

No specific information noted

Flumazenil

(floo-***maz***-eh-nill) *Romazicon®*

Benzodiazepine Antagonist

Prescriber Highlights

- ► Used in a variety of species to reverse benzodiazepine overdose (OD) or adverse effects caused by intentional doses or when rapid recovery is required. May also have efficacy in ODs of non-benzodiazepine agonists of the benzodiazepine receptor (eg, zolpidem)
- ► Contraindications include known hypersensitivity, treatment with benzodiazepines for life-threatening conditions (eg, status epilepticus, increased intracranial pressure [ICP]), and tricyclic antidepressant OD treatment. Use extreme caution in mixed overdoses.
- ► Adverse effects in dogs occur primarily at higher dosages and include salivation, shivering, seizures, howling, hacking coughs, and opisthotonos. Injection-site reactions, vomiting, cutaneous vasodilatation, vertigo, and/or ataxia may also occur.

Uses/Indications

Flumazenil may be useful for reversal of the effects of benzodiazepines used in sedation or anesthetic protocols when adverse benzodiazepine effects arise or when rapid recovery is required. Flumazenil may also be used to reverse the anesthetic effects of tiletamine/zolazepam in dogs[1,2]; however, the effects of tiletamine (which are not reversible) may persist and be undesirable. Flumazenil also is used in the management of benzodiazepine overdoses and has shown benefit in the treatment of overdoses of nonbenzodiazepine agonists (eg, zolpidem[3]) of the benzodiazepine receptor.

In horses, flumazenil reversed the effect of midazolam/ketamine induction and midazolam CRI in two 2-hour total IV anesthesia protocols (ketamine/xylazine/midazolam and ketamine/dexmedetomidine/midazolam) with good to excellent recovery quality and improved respiratory function.[4,5]

Pharmacology/Actions

Flumazenil is a competitive neutral antagonist of benzodiazepines at benzodiazepine receptors on the $GABA_A$ receptor in the CNS. It antagonizes the sedative and amnestic qualities of benzodiazepines.

Pharmacokinetics

The therapeutic effect of flumazenil may occur within 1 to 2 minutes of IV administration.[6] It is rapidly distributed and almost completely metabolized in the liver. In humans, the average half-life is ≈1 hour. Half-life is prolonged in patients with liver dysfunction. This prolongs flumazenil effects but does not alter dosage requirements.

Contraindications/Precautions/Warnings

Flumazenil is contraindicated in patients hypersensitive to it or other benzodiazepines or in patients in which benzodiazepines are being used to treat a potentially life-threatening condition (eg, status epilepticus, increased intracranial pressure [ICP]).[6] Flumazenil should not be used, or should be used with extreme caution, in patients with mixed overdoses, particularly those receiving cyclic antidepressants (eg, clomipramine), as reversal of the benzodiazepine may lead to

seizures or other complications (eg, cardiac dysrhythmias) that may emerge once the benzodiazepine effects are removed.[6,7] Flumazenil should be used with caution in patients with head trauma, as it may precipitate seizures and alter cerebral blood flow.[6]

Although flumazenil has been investigated as treatment for overdoses of both baclofen and carisoprodol, it can cause worsening of clinical signs and thus may be contraindicated.[8]

In humans, flumazenil only antagonizes benzodiazepine effects without altering benzodiazepine pharmacokinetics.[6] Effects of long-acting benzodiazepines may recur after flumazenil's effects subside, and additional flumazenil doses may be needed.

Routine use of flumazenil as a benzodiazepine reversal agent is not advised as rare but serious adverse reactions, (including cardiac arrhythmias, seizures, and sudden death) have been reported in humans and experimental canine studies.

Adverse Effects

Adverse effects reported in dogs receiving higher doses (eg, 0.08 – 0.16 mg/kg) of flumazenil for the reversal of tiletamine/zolazepam include salivation, shivering, seizures, howling, hacking coughs, and opisthotonos. These effects are likely attributed to the effects of flumazenil on the CNS and the continued effects of tiletamine.[1] Muscle rigidity has been observed in miniature pigs.[9]

In humans, the risk for seizures is higher in patients with severe hepatic impairment and in patients receiving benzodiazepines chronically to control seizures.[6] Other adverse effects reported in humans include vomiting, cutaneous vasodilatation, arrhythmias, vertigo, agitation, increased muscle tone, ataxia, and blurred vision. Injection site reactions have occurred, and administration through a freely running infusion in a large vein is recommended. Deaths have been associated with flumazenil use in humans with serious underlying diseases.

Reproductive/Nursing Safety

Teratogenicity was not observed in rabbits or rats at oral doses up to 150 mg/kg, but embryocidal effects occurred in rabbits at doses exceeding 15 mg/kg IV.

It is unknown whether flumazenil is passed in milk.[6]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Large IV overdoses in the absence of a benzodiazepine have rarely caused symptoms in otherwise healthy humans. In humans, seizures, if precipitated, have been successfully managed with barbiturates, phenytoin, or benzodiazepines at high doses.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving flumazenil and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Cyclic** (tri-, tetra-) **Antidepressants** (eg, **clomipramine, amitriptyline**): Increased risk for seizures; use is contraindicated in patients experiencing a cyclic antidepressant overdose.[7]
- **Neuromuscular Blocking Agents**: Not recommended to use flumazenil until neuromuscular blockade has been fully reversed[6]

Laboratory Considerations

None noted

Dosages

DOGS/CATS:

Antagonist for benzodiazepine effects or toxicity (eg, respiratory depression) and for imidazopyridine sleep-aid drugs (eg, zolpidem) toxicity (extra-label): Most sources recommend an initial dose of 0.01 – 0.2mg/kg IV (or IO)[10]; start at the lower end of the dosage range (0.01 mg/kg) and repeat as needed to reverse sedation. If the high end of the dosage range does not elicit a reversal response, be sure to reverse any other drugs that were given and address other problems that could be contributing to the clinical situation (eg, hypothermia). Intratracheal administration has been suggested in an emergency situation when venous access is not possible. 0.04 – 0.06 mg/kg IV can be used to reverse tiletamine/zolazepam anesthesia.[1]

HORSES:

Reversal of benzodiazepine effects as part of multi-modal anesthesia (extra-label): 0.01 – 0.02 mg/kg IV over 10 minutes; administer 20 minutes after terminating TIVA.[5,11]

BIRDS

Reversal of intranasal midazolam sedation (extra-label): 0.05 mg/kg administered intranasally reversed the effects of intranasal midazolam within 10 minutes.[12]

REPTILES

Reversal of sedation protocols containing midazolam (extra-label)

1. **Snakes**: 0.08 mg/kg IM in the cranial third of the body. Re-sedation was observed in all snakes 3 hours after flumazenil administration.[13]
2. **Green iguanas**: 0.05 mg/kg IM[14]
3. **Leopard geckos**: 0.05 mg/kg SC craniodorsal to the contralateral thoracic limb where midazolam was administered[15]

Monitoring

- Efficacy at resolving respiratory depression and recovery from sedation
- Re-sedation may occur in patients that have received large doses of benzodiazepines, or multiple anesthetic agents and neuromuscular antagonists. Re-sedation may be more common in snakes.[13]
- Monitor for seizures in susceptible patients, particularly those with pre-existing hepatic dysfunction or neurologic disease.

Client information

- This drug is administered in a veterinary clinic to reverse the effects of certain sedating drugs.
- If your animal has received flumazenil, monitor for re-emergence of sedation.

Chemistry/Synonyms

A benzodiazepine antagonist, flumazenil is a 1,4-imidazobenzodiazepine derivative. It occurs as a white to off-white crystalline compound that is insoluble in water but slightly soluble in acidic aqueous solutions.

Flumazenil may also be known as: flumazenilum, flumazepil, Ro-15-1788, Ro-15-1788/000, *Anexate®*, *Fadaflumaz®*, *Flumage®*, *Flumanovag®*, *Flumazen®*, *Fluxifarm®*, *Lanexat®*, and *Romazicon®*.

Storage/Stability

Store flumazenil at 25°C (77°F). Excursions are permitted from 15°C to 30°C (59°F-86°F).[6] Once drawn into a syringe or mixed with the solutions listed below, discard after 24 hours.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration,

temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Flumazenil is physically **compatible** with lactated Ringer's, dextrose 5%, and normal saline solutions.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:
Flumazenil Injection: 0.1 mg/mL in 5 mL and 10 mL vials; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Flumethasone

(floo-***meth***-a-sone) *Flucort®*
Glucocorticoid

Prescriber Highlights

- ► Injectable and oral long-acting glucocorticoid. No longer commonly used in small animal species
- ► 15 times more potent than hydrocortisone; no appreciable mineralocorticoid activity
- ► Therapy goal is to use as much as is required and as little as possible for as short an amount of time as possible.
- ► Primary adverse effects are Cushingoid in nature with sustained use.
- ► Many potential drug and laboratory interactions

Uses/Indications

Flumethasone injection is available commercially as a free steroid alcohol solution. Although flumethasone does not work as rapidly as the corticosteroid phosphate and succinate esters (methylprednisolone sodium succinate, prednisolone sodium succinate, or dexamethasone sodium phosphate), it can be given either IM or IV and is useful for acute reactions, such as insect bite hypersensitivity or vaccine reactions.[1]

Flumethasone injection is labeled in horses as indicated for: 1) Musculoskeletal conditions due to inflammation, where permanent structural changes do not exist, such as bursitis, carpitis, osselets, and myositis. Following therapy, an appropriate period of rest should be instituted to allow a more normal return to function of the affected part. 2) Allergic states, such as urticaria (hives) and insect bites

Flumethasone injection is labeled in dogs as indicated for: 1) Musculoskeletal conditions due to inflammation of muscles or joints and accessory structures, where permanent structural changes do not exist, such as arthritis, osteoarthritis, intervertebral disc syndrome, and myositis. In septic arthritis, appropriate antibacterial therapy should be concurrently administered. 2) Certain acute and chronic dermatoses of varying etiology to help control the pruritus, irritation, and inflammation associated with these conditions. The drug has proven useful in otitis externa in conjunction with topical medication for similar reasons. 3) Allergic states, such as urticaria and insect bites.

Flumethasone injection is labeled in cats as indicated for certain acute and chronic dermatoses of varying etiology to help control the pruritus, irritation, and inflammation associated with these conditions.

Pharmacology/Actions

Flumethasone is considered a long-acting glucocorticoid agent with a duration of effect of 36 to 48 hours. Flumethasone is ≈15 times more potent than hydrocortisone; 1.3 mg of flumethasone is equivalent to ≈5 mg of prednisone. It does not have significant mineralocorticoid activity and is not suitable for every-other-day dosing. For more information, refer to the ***Glucocorticoid Agents, General Information*** monograph.

Pharmacokinetics

Following IV administration to exercised horses, the volume of distribution (steady state) was 5.9 L/kg, systemic clearance was 30.7 mL/kg/min, and elimination half-life was 4.8 hours.[2]

Contraindications/Precautions/Warnings

Flumethasone is contraindicated during the last trimester of pregnancy. Systemic use of glucocorticoids is generally considered contraindicated in systemic fungal infections (unless used for replacement therapy in patients with hypoadrenocorticism) when administered IM in patients with idiopathic thrombocytopenia and in those hypersensitive to a particular compound. Use of sustained-release, injectable glucocorticoids is contraindicated for chronic corticosteroid therapy of systemic diseases.

Animals that have received glucocorticoids systemically, other than with burst therapy, should be tapered off the drugs. Patients that have received the drugs chronically should be tapered off slowly as endogenous ACTH and corticosteroid function may return slowly. Should the animal undergo a stressor (eg, surgery, trauma, illness) during the tapering process or until normal adrenal and pituitary function resume, additional glucocorticoids should be administered.

Adverse Effects

Adverse effects are generally associated with long-term administration of these drugs, especially if given at high dosages or not on an alternate day regimen. Effects generally manifest as clinical signs of hyperadrenocorticism. When administered to young, growing animals, glucocorticoids can retard growth. Many of the potential effects, adverse and otherwise, are outlined in the ***Pharmacology*** section of the ***Glucocorticoid Agents, General Information*** monograph.

In dogs, GI effects (including GI ulceration) can occur with acute dosing. Polydipsia (PD), polyphagia (PP), and polyuria (PU) may be seen with short-term burst therapy. Adverse effects in dogs can include dull, dry haircoat, weight gain, panting, vomiting, diarrhea, increased liver enzymes, pancreatitis, GI ulceration, dyslipidemias, activation or worsening of diabetes mellitus, muscle wasting, and behavioral changes (depression, lethargy, viciousness). Discontinuation of the drug may be necessary; changing to an alternate-day steroid may also alleviate the problem. With the exception of PU/PD/PP, adverse effects associated with anti-inflammatory therapy are relatively uncommon. Adverse effects associated with immunosuppressive dosages are more common and potentially more severe.

Cats generally require higher dosages than dogs for clinical effect but tend to develop fewer adverse effects. Occasionally, polydipsia, polyuria, polyphagia with weight gain, diarrhea, or depression can be seen. However, long-term, high-dose therapy can lead to Cushingoid effects.

Reproductive/Nursing Safety

Corticosteroid therapy may induce parturition in large animal species during the latter stages of pregnancy. Corticosteroids administered orally or by injection to animals may induce the first stage of parturition if used during the last trimester of pregnancy and may precipitate premature parturition followed by dystocia, fetal death, retained placenta, and metritis.[3] In addition, corticosteroids administered to dogs, rabbits, and rodents during pregnancy have resulted in other congenital anomalies, including deformed forelegs, phocomelia, and anasarca

Caution is advised when using in nursing dams; glucocorticoids unbound to plasma proteins can enter milk. High doses or prolonged administration to nursing dams may potentially inhibit growth, interfere with endogenous corticosteroid production, or cause other unwanted effects in nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Glucocorticoids, when given short-term, are unlikely to cause harmful effects, even in massive doses. One incidence of a dog developing acute CNS effects after accidental ingestion of glucocorticoids has been reported. Should clinical signs occur, use supportive treatment if required.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving flumethasone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amphotericin B**: Concomitant administration with glucocorticoids may cause hypokalemia.
- **Anticholinesterase Agents** (eg, **pyridostigmine**, **neostigmine**): In patients with myasthenia gravis, concomitant glucocorticoid and anticholinesterase agent administration may lead to profound muscle weakness. If possible, discontinue anticholinesterase medication at least 24 hours prior to corticosteroid administration.
- **Aspirin**: Glucocorticoids may reduce salicylate blood concentration and increase the risk for GI ulceration/bleeding.
- **Azole Antifungals** (eg, **ketoconazole**): May decrease the metabolism of glucocorticoids and increase flumethasone blood concentration; ketoconazole may induce adrenal insufficiency when glucocorticoids are withdrawn by inhibiting adrenal corticosteroid synthesis.
- **Cyclophosphamide**: Glucocorticoids may inhibit the hepatic metabolism of cyclophosphamide; dosage adjustments may be required.
- **Cyclosporine**: Concomitant administration of glucocorticoids and cyclosporine may increase the blood concentration of each by mutually inhibiting the hepatic metabolism of the other; the clinical significance of this interaction is not clear.
- **Diazepam**: Flumethasone may decrease diazepam concentration.
- **Diuretics, Potassium-Depleting** (eg, **furosemide, thiazides**): Concomitant administration with glucocorticoids may cause hypokalemia.
- **Ephedrine**: May increase glucocorticoid metabolism, thereby reducing flumethasone blood concentration
- **Estrogens**: May potentiate the effects of glucocorticoids
- **Insulin**: Insulin requirements may increase in patients receiving glucocorticoids.
- **Macrolide Antibiotics** (eg, **erythromycin**, **clarithromycin**): May decrease the metabolism of glucocorticoids and increase flumethasone blood concentration
- **Mitotane**: May alter the metabolism of steroids; higher than usual doses of steroids may be necessary to treat mitotane-induced adrenal insufficiency.
- **Nonsteroidal Anti-Inflammatory Drugs** (**NSAIDs**; eg, **carprofen, flunixin, meloxicam, phenylbutazone**): Administration of ulcerogenic drugs with glucocorticoids may increase the risk for GI ulceration.
- **Rifampin**: May increase the metabolism of glucocorticoids and decrease flumethasone blood concentration
- **Phenobarbital, Primidone**: May increase the metabolism of glucocorticoids and decrease flumethasone blood concentration
- **Vaccines, Live Attenuated**: Patients receiving corticosteroids at immunosuppressive dosages should generally not receive live attenuated-virus vaccines as virus replication may be augmented; a diminished immune response may occur after the vaccine, toxoid, or bacterin administration in patients receiving glucocorticoids.

Laboratory Considerations

- Glucocorticoids may increase **serum cholesterol** and **urine glucose** concentration**.**
- Glucocorticoids may decrease **serum potassium.**
- Glucocorticoids can suppress the release of thyroid-stimulating hormone (TSH) and reduce $\mathbf{T_3}$ and $\mathbf{T_4}$ values. Thyroid gland atrophy has been reported after chronic glucocorticoid administration. The uptake of $\mathbf{I^{131}}$ by the thyroid may be decreased by glucocorticoids.
- Reactions to **intradermal skin tests** may be suppressed by glucocorticoids.
- False-negative results of the **nitroblue tetrazolium** test for systemic bacterial infections may be induced by glucocorticoids.
- Glucocorticoids may cause **neutrophilia** within 4 to 8 hours after dosing and return to baseline within 24 to 48 hours after drug discontinuation.
- Glucocorticoids can cause **lymphopenia**, which can persist for weeks after drug discontinuation in dogs.

Dosages

DOGS:

Musculoskeletal conditions due to inflammation; certain acute and chronic dermatoses when given orally, and also for allergic states or shock when given intravenously (label dosage; FDA-approved): Treat and adjust the dosage on an individual basis.

a) 0.0625 – 0.25 mg/dog (NOT mg/kg) PO daily in divided doses.[4] Dosage is dependent on the size of the animal, stage, and severity of the disease. **NOTE***: Tablets no longer marketed in the United States.*

b) Parenterally: 0.0625 – 0.25 mg/dog (NOT mg/kg) IV, IM, SC daily[5]; dose may be repeated

c) Intra-articularly: 0.166 – 1 mg/dog (NOT mg/kg) depending on the severity of the condition and the size of the involved joint[5]

d) Intra-lesionally: 0.125 – 1 mg/dog (NOT mg/kg) depending on the size and location of the lesion[5]

CATS:

Certain acute and chronic dermatoses to control associated pruritus, irritation, and inflammation (label dosage; FDA-approved): Treat and adjust the dosage on an individual basis:

a) 0.03125 – 0.125 mg/cat (NOT mg/kg) PO daily in divided doses.[4] **NOTE***: Tablets no longer marketed in the United States.*

b) Parenterally: 0.03125 – 0.125 mg/cat (NOT mg/kg) IV, IM, or SC[5]; dose may be repeated.

HORSES:

Musculoskeletal conditions due to inflammation, where permanent changes do not exist; also for allergic states, such as hives, urticaria, and insect bites (label dosage; FDA-approved): 1.25 – 2.5 mg/horse (NOT mg/kg) daily by IV, IM, or intra-articular injection[5]; dose may be repeated.

Monitoring

Monitoring of glucocorticoid therapy is dependent on its reason for use, dosage, the agent used (amount of mineralocorticoid activity),

dosage schedule (daily versus alternate day therapy), duration of therapy, and the animal's age and condition. The following list may not be appropriate or complete for all animals; use clinical assessment and judgment should adverse effects be noted:

- Weight, appetite, signs of edema
- Serum and/or urine electrolytes
- Total plasma proteins and albumin
- Blood glucose
- Urine culture
- Growth and development in young animals

Client Information

- Goal is to find the lowest dose possible and use for the shortest period of time. Carefully follow your veterinarian's instructions for how to give this medicine to your animal. Do not stop giving this medicine to your animal without talking to your veterinarian first, as serious side effects could occur.
- There might be side effects with this medicine. Contact your veterinarian should these effects become severe or progress. In dogs, stomach or intestinal ulcers, perforation, and/or bleeding can occur. Contact your veterinarian immediately if your dog stops eating or you notice a high fever, black tarry stools, or bloody vomit (will look like coffee grounds).
- This medicine may be given with (preferred) or without food. If your animal vomits or acts sick after receiving the medication on an empty stomach, give with food or small treat to see if this helps. If vomiting continues, contact your veterinarian.
- Be sure to tell your veterinarian about what other medications (including vitamins, supplements, or herbal therapies) you give your animal.

Chemistry/Synonyms

Flumethasone occurs as an odorless, white to creamy white, crystalline powder. Its chemical name is 6alpha, 9alpha-difluoro-16alpha methylprednisolone.

Flumethasone may also be known as flumetasone, glumetasoni pivalas, NSC-107680, *Anaprime®*, *Cerson®*, *Flucort®*, *Fluosmin®*, *Locacorten®*, *Locacortene®*, *Locorten®*, *Locortene®*, and *Lorinden®*.

Storage/Stability

Store flumethasone injection at room temperature; avoid freezing. Store flumethasone tablets at room temperature.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: Although this product is still listed in FDA's Green Book of approved animal drugs, it may no longer be commercially available in the United States.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations or contact local racing authorities for further guidance before entering in a competition while this medication is being administered. See ***Appendix*** for more information.

Flumethasone Injection: 0.5 mg/mL in 100 mL vials; *Flucort® Solution*; (Rx). FDA-approved for use in dogs, cats, and horses. NADA #030-414

Flumethasone Suspension: 2 mg/mL; *Anaprime®* Suspension; (Rx). FDA-approved for intra-articular use in horses. NADA #036-211

Flumethasone Tablets: 0.0625 mg; *Flucort®*; (Rx). FDA-approved for use in dogs and cats. NADA #030-415

Flumethasone Suspension: 2 mg/mL; *Fluosmin®* Suspension; (Rx). FDA-approved for use in dogs. (NADA #036-212)

HUMAN-LABELED PRODUCTS: NONE

Flunixin

(floo-***nix***-in) *Banamine®*

Nonsteroidal Anti-Inflammatory Agent

Prescriber Highlights

- ► Veterinary-only NSAID used primarily in large-animal species
- ► Use with caution in patients with pre-existing GI ulcers or renal, hepatic, or hematologic diseases; in horses with colic, flunixin may mask the behavior and cardiopulmonary signs associated with endotoxemia or intestinal devitalization.
- ► Use in small animal species has been largely supplanted by FDA-approved agents or those with better adverse effect profiles in target species.
- ► If first dose is ineffective for pain control, subsequent doses are unlikely to be of benefit.
- ► Adverse effects in horses and cattle: rare anaphylaxis (especially after rapid IV administration); IM injections (extra-label in food animals) may cause pain and swelling; myonecrosis reported in some horses

Uses/Indications

In the United States, flunixin is FDA-approved for use in horses, cattle, and swine; it is approved for use in dogs in other countries. FDA-approved indications for its use in horses include alleviation of inflammation and pain associated with musculoskeletal disorders and alleviation of visceral pain associated with colic. In cattle, the injectable form of flunixin is FDA-approved for the control of pyrexia associated with bovine respiratory disease (BRD), endotoxemia, and acute bovine mastitis and for the control of inflammation in endotoxemia. The transdermal flunixin formulation is FDA-approved to control pyrexia associated with BRD and control of pain associated with foot rot in steers, beef heifers, beef cows, beef bulls intended for slaughter, and replacement dairy heifers under 20 months of age. In swine, flunixin is FDA-approved for controlling pyrexia associated with swine respiratory disease. In ruminants, there is anecdotal evidence that flunixin is a better analgesic for visceral pain rather than for musculoskeletal pain.

Flunixin has also been suggested for many other indications in horses including foal diarrhea, shock, colitis, respiratory disease, postrace treatment, and pre- and postophthalmic and general surgery. In cattle, it may be used to treat acute respiratory disease, acute coliform mastitis with endotoxic shock, and pain (eg, downer cow); in swine, it may be used to treat agalactia/hypogalactia, lameness, and piglet diarrhea. In dogs and cats, flunixin has been used historically for analgesia and as an antipyretic, and in dogs undergoing ophthalmic surgery[1,2]; however, this therapy is no longer recommended with the availability of approved NSAIDs for these species. There may still be a limited use for flunixin in dogs undergoing ophthalmic surgery; use with caution.

The combination product containing florfenicol and flunixin is FDA-approved for SC use in beef and nonlactating dairy cattle (not veal calves) for treatment of BRD associated with *Mannheimia haemolytica*, *Pasteurella multocida*, *Histophilus somni, Mycoplasma bovis,* and to control BRD-associated pyrexia.[3]

The combination product containing oxytetracycline and flunixin is FDA-approved for SC or IM use in beef and nonlactating dairy cattle for the treatment of bacterial pneumonia associated with *Pasteurella* spp and for the control of associated pyrexia.[4]

Pharmacology/Actions

Flunixin is a potent inhibitor of cyclooxygenase and, like other NSAIDs, it exhibits analgesic, anti-inflammatory, and antipyretic activity. Flunixin does not appreciably alter GI motility in horses and may improve hemodynamics in animals with septic shock.

Pharmacokinetics

In the horse, flunixin is rapidly absorbed following oral administration, with an average bioavailability of 80% and peak serum levels in 30 minutes. Oral bioavailability is good when the injection is mixed with molasses and given orally. The onset of action is generally within 2 hours; peak response occurs between 12 to 16 hours, and the duration of action lasts up to 30 hours. Flunixin is highly bound to plasma proteins (ie, greater than 99% in cattle, 92% in dogs, 87% in horses). Volume of distribution ranges from ≈0.15 L/kg in horses to 0.78 L/kg in cattle, and flunixin persists in inflammatory tissue. Elimination in horses is primarily via hepatic routes by biliary excretion. Serum half-lives after IV administration have been determined as follows: dogs, ≈3.7 hours; horses, ≈1.6 to 4.2 hours; cattle, ≈3.1 to 8.1 hours; and swine, ≈6 to 8 hours. Flunixin is detectable in equine urine for at least 48 hours after a dose.

In cattle, absorption of flunixin transdermal solution is highly dependent on environmental temperature; higher temperatures can increase absorption, although dosage adjustments are not necessary.[5] The manufacturer states that treating cattle when the hide is wet or may get wet within 6 hours after dosing may affect absorption. Under experimental conditions with calves, rain was shown to reduce absorption of flunixin when administered within 30 minutes of light rain or within 4 hours of heavy rain.[6]

One study suggested that the pharmacokinetics and elimination of IV flunixin in milk differed between healthy cows and those with mastitis. The study also indicated that an extended withdrawal time may be needed in cows with mastitis.[7]

Flunixin transdermal solution in cattle has an average half-life of 8 hours in non-licking cattle compared to 9 hours in licking cattle.[5] Elimination of flunixin occurs through biliary excretion.

Contraindications/Precautions/Warnings

The only contraindication the manufacturer lists for flunixin use in horses is for patients with a history of hypersensitivity reactions to the drug. It is suggested, however, that flunixin be used cautiously in animals with renal, hepatic, or hematologic diseases, and in animals with suspected preexisting gastric erosions or ulcerations. When used to treat colic, flunixin may mask the behavioral and cardiopulmonary signs associated with endotoxemia or intestinal devitalization and must be used with caution.

Do not inject intra-arterially.

In horses with known or suspected equine gastric ulcer syndrome (EGUS), use should be avoided; single doses of flunixin will likely not result in catastrophic consequences, but repeated doses can exacerbate gastric ulcers.[8]

In cattle, the drug is contraindicated in animals that have shown hypersensitivity reactions. The IM route causes injection site muscle damage[9] and is extra-label in cattle; this route of administration has resulted in violative residues in the edible tissues of cattle sent to slaughter. Longer withdrawal times are required after IM use. Flunixin should not be used to move cattle to be shipped for slaughter. Cattle may lick the transdermal product; however, no dose adjustment is needed to account for this behavior. Do not treat cattle if hide is wet or may get wet within 6 hours after dosing.

Flunixin is not recommended in dogs and cats since safer, FDA-approved products are available.

Use of flunixin in birds is generally avoided as flunixin can have significant effects on renal function in some species.

Adverse Effects

When flunixin is used for pain, if the animal does not respond to an initial dose, additional doses will unlikely be effective and may increase the chance for toxicity. Following IM injection in horses, especially in the neck, localized swelling and tissue necrosis, induration, stiffness, and sweating have been reported; clinical signs are transient and generally do not require any treatment. Do not inject intra-arterially, as flunixin may cause CNS stimulation (hysteria), ataxia, hyperventilation, and muscle weakness. Flunixin appears to be a relatively safe agent for use in horses, but the potential exists for GI intolerance, hypoproteinemia, and hematologic abnormalities.

Horses have developed oral and gastric ulcers, anorexia, and depression when given high doses for prolonged periods (greater than 2 weeks). Although gastric ulceration is frequently observed in adult horses and foals, evidence of an association between this disease and administration of NSAIDs such as flunixin at recommended dosages is lacking. Giving prophylactic antiulcer medications to horses receiving therapeutic doses of NSAIDs is probably unnecessary in animals that are otherwise at low risk for gastric ulceration.[10]

In horses and cattle, rare anaphylactic-like reactions have been reported, primarily after rapid IV administration.[11] IM injections may rarely be associated with clostridial myonecrosis. Flunixin transdermal solution has been shown to irritate the skin and can potentially cause irreversible eye damage.

In swine, IM injection may result in local tissue damage,[12] which can persist for 28 days postinjection and result in trim loss at slaughter.

In dogs, GI distress is the most likely adverse reaction. Clinical signs may include vomiting, diarrhea, and ulceration with high doses or chronic use. There have been anecdotal reports of flunixin causing renal shutdown in dogs when used preoperatively at higher dosages.

In birds, flunixin has been shown to cause significant dose-related renal ischemia and nephrotoxicity.

Reproductive/Nursing Safety

Although reports of teratogenicity, effects on breeding performance, or gestation length have not been noted, flunixin should be used cautiously in pregnant animals.[11] Flunixin may delay parturition and prolong labor, increasing the risk of stillbirth. Flunixin use within 24 hours after parturition may lead to placental retention and metritis. Estrus may be delayed if flunixin is administered during the prostaglandin phase of the estrous cycle. Flunixin improved pregnancy rate in embryo-transfer beef cows without affecting return to estrus in nonpregnant cows.[13] While flunixin is not recommended for use in breeding bulls (lack of reproductive safety data), data in breeding stallions have shown no detrimental effect on spermatogenesis.

Flunixin is contraindicated within 48 hours of expected parturition, as it can delay parturition or increase the risk for stillbirth due to prolonged labor.

Overdose/Acute Toxicity

No clinical case reports of flunixin overdoses were discovered. Minimal toxicity was noted in horses or cattle at up to 5 times the labeled dosage. It is suggested that acute overdoses be handled using established protocols of GI decontamination (if oral ingestion and procedure is practical or possible) and treating the patient supportively.

Gastric ulceration is a distinct possibility in horses that have received overdoses of flunixin. Consider using antiulcer medications in overdosed horses.

Hematuria and occult fecal blood were observed in 6-month-old beef cattle receiving up to 5 times the label dose of the transdermal product for 3 consecutive days (3 times the label frequency).[5] These findings were also noted on occasion in cattle given 3 and 5 times the label injectable dose for 9 days.[11] Dose-related dermal and epidermal

necrosis occurred at topical application sites; abomasal erosions and ulceration were noted on pathology.[5]

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with one of the 24-hour poison consultation centers that specialize in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

Drug/drug interactions have not been appreciably studied for flunixin, and the label does not mention any drug interactions. However, the following drug interactions have either been reported or are theoretical in humans or animals receiving other NSAIDs and may be of significance in veterinary patients receiving flunixin.

- **ACE Inhibitors** (eg, **benazepril**, **enalapril**): Some NSAIDs can reduce effects on blood pressure.
- **Aspirin**: When aspirin is used concurrently with NSAIDs, plasma levels of the NSAID could decrease, and the likelihood of GI adverse effects (eg, blood loss) could increase.
- **Corticosteroids** (eg, **dexamethasone, prednis(ol)one**): Concurrent use may increase the risk for GI toxicity.
- **Cyclosporine**: NSAIDs may increase cyclosporine blood levels and increase the risk for nephrotoxicity.
- **Digoxin**: NSAIDs may increase serum levels of digoxin; use with caution in patients with severe cardiac failure.
- **Fluoroquinolones**: Enrofloxacin has been shown in dogs to increase the area under the curve (AUC) and elimination half-life of flunixin, and flunixin increases the AUC and elimination half-life of enrofloxacin.[14] Enrofloxacin and flunixin did not interact in rabbits.[15] Flunixin significantly increased moxifloxacin elimination half-life and total drug exposure (AUC). Applicability to other fluoroquinolones is unknown.[16]
- **Loop Diuretics** (eg, **furosemide**): NSAIDs may reduce the saluretic and diuretic effects of furosemide.
- **Methotrexate**: Serious toxicity has occurred when NSAIDs have been used concomitantly with methotrexate; use together with caution.
- **Nephrotoxic Agents** (eg, **aminoglycosides, amphotericin B**, **cisplatin**): Potential for increased risk for nephrotoxicity if used with NSAIDs
- **Oxytetracycline**: Flunixin increased clearance of oxytetracycline in dairy goats.[17]
- **Phenylbutazone**: Phenylbutazone administration 24 hours prior to flunixin increased flunixin clearance. Flunixin administration prior to phenylbutazone prolonged suppression of prostaglandin E2 and thromboxane B2.[18]
- **Probenecid**: May cause a significant increase in serum levels and half-life of some NSAIDs
- **Warfarin**: Use with NSAIDs may increase the risk for bleeding.

Dosages

HORSES:

Alleviation of inflammation and pain associated with musculoskeletal disorders and alleviation of visceral pain associated with colic (label dosage; FDA-approved):

a) Injectable: 1.1 mg/kg IV or IM once daily for up to 5 days.[11] For colic cases, use IV route; may re-dose when necessary.

b) Oral paste: 1.1 mg/kg PO (see markings on syringe—calibrated in 250 lb weight increments) once daily.[19] One syringe will treat a 453 kg (1000 lb) horse for 3 days. Do not exceed 5 days of consecutive therapy.

Decreasing pain, inflammation, and edema in laminitis (extra-label): 0.5 – 1.1 mg/kg IV or PO every 8 to 12 hours. A dose of 0.25 mg/kg can be administered IV every 8 hours to interrupt eicosanoid production associated with endotoxemia.[20]

Adjunctive treatment of uveitis in foals (extra-label): 0.5 – 1 mg/kg (route not noted) twice daily[21]

CATTLE:

Flunixin as a single agent (label dosage; FDA-approved):

a) **Control of pyrexia associated with respiratory disease, endotoxemia, and acute bovine mastitis and for the control of inflammation associated with endotoxemia (injectable)**: 1.1 – 2.2 mg/kg (0.5 – 1 mg/lb, 1 – 2 mL/100 lb) given slow IV either once a day as a single dose or divided into 2 doses every 12 hours for up to 3 days.[11] Avoid rapid IV administration.

b) **Control of pyrexia associated with bovine respiratory disease and the control of pain associated with foot rot (transdermal)**: Single application of 3.3 mg/kg (1.5 mg/lb, 3 mL/100 lb) topically in a narrow strip along the dorsal midline from withers to tailhead.[5] Round doses up to the nearest weight increment on dosing chamber located on the product.

Flunixin in combination with florfenicol for treatment of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica, Pasteurella multocida,* and *Histophilus somni*, and control of BRD-associated pyrexia in beef and nonlactating dairy cattle (label dosage; FDA-approved): flunixin 2.2 mg/kg with florfenicol 40 mg/kg (6 mL/100 lb where each mL contains flunixin 16.5 mg with florfenicol 300 mg) SC once.[3] Do not administer more than 10 mL at each site. The injection should be given only in the neck. Injection sites other than the neck have not been evaluated.

Flunixin in combination with oxytetracycline for treatment of bacterial pneumonia associated with *Pasteurella* spp and for the control of associated pyrexia in beef and nonlactating dairy cattle (label dosage; FDA-approved): 1 mL/10 kg (22 lb) equals flunixin 2 mg/kg (0.9 mg/lb) with oxytetracycline 30 mg/kg (13.6 mg/lb) IM or SC once.[4] Do not administer more than 10 L/injection site (1-2 mL/site in small calves). Drug combination recommended where re-treatment of calves and yearlings is impractical because of husbandry conditions, such as cattle on range, or where repeated restraint is inadvisable.

Analgesic using flunixin as a single agent (extra-label): 1.1 – 2.2 mg/kg IV every 6 to 12 hours; recommend 72-hour milk withdrawal at this dose rate.[22]

SHEEP, GOATS:

Analgesic (extra-label): 1 – 2 mg/kg IV once daily (every 24 hours); oral paste has also been used at 1 – 4 mg/kg PO once daily[23]

SWINE:

Controlling pyrexia associated with swine respiratory disease (label dosage; FDA-approved): 2.2 mg/kg IM once, only in the neck musculature with a maximum of 10 mL/site[12]

FERRETS:

Analgesic/anti-inflammatory (extra-label): 0.5 – 2 mg/kg PO or IM once daily[24]

RABBITS, RODENTS, & SMALL MAMMALS:

a) Rabbits: 1.1 mg/kg SC, IM, or IV every 12 to 24 hours[25]

b) Rabbits: 1.1 mg/kg SC or IM every 12 hours; Rodents: 2.5 mg/kg SC or IM every 12 hours[26]

c) Chinchillas: 1 – 3 mg/kg SC every 12 hours; Guinea pigs: 2.5 – 5 mg/kg SC every 12 hours; Gerbils, mice, rats, hamsters: 2.5 mg/kg SC every 12 to 24 hours[27]

Monitoring

- Analgesic/anti-inflammatory effects

- Body temperature
- GI effects in dogs
- Periodic CBC and fecal occult blood testing with chronic use in horses

Client Information

- If injecting IM, do not inject into neck muscles (except swine).
- The IM route is extra-label in cattle and has resulted in violative residues in the edible tissues of cattle sent to slaughter. Longer withdrawal times are required after IM use.
- Flunixin should not be used in cattle to be shipped for slaughter.
- Flunixin transdermal solution should not be used if hide is wet or may get wet in the 6 hours after dosing.
- Dosage adjustment of the transdermal solution for environmental temperatures is not necessary. Cattle may be permitted to lick the solution without compromising its effectiveness or increasing the risk for side effects.
- Flunixin transdermal solution may cause severe and potentially irreversible eye damage or skin irritation. Users should wear gloves and appropriate eye protection, as well as clothing that will prevent skin contact with the transdermal solution. In case of accidental eye contact, flush eyes immediately with water and seek medical attention. In case of accidental skin contact, wash skin thoroughly with soap and water. Wash hands after use.

Chemistry/Synonyms

Flunixin meglumine, a nonsteroidal anti-inflammatory agent, is a highly substituted derivative of nicotinic acid, and is unique structurally when compared to other NSAIDs. It occurs as a white to off-white powder that is soluble in water and alcohol. The chemical name for flunixin is 3-pyridine-carboxylic acid.

Flunixin may also be known as 3-pyridine-carboxylic acid, flunixin meglumine, Sch-14714, *Banamine®*, *Flumeglumine®*, *Finadyne®*, *Flu-Nix®D*, *Flunixamine®*, *Flunixiject®*, *Flunizine®*, *Prevail®*, *Suppressor®*, and *Vedagesic®*.

Storage/Stability

All flunixin products should be stored between 2°C and 30°C (36°F-86°F). Flunixin transdermal solution should be used within 6 months of first opening. Vials for injection should be used within 28 days of first puncture, punctured a maximum of 10 times.

The combination product with florfenicol (*Resflor Gold®*) should not be stored above 30°C (86°F). Once the vial is entered, it should be used within 28 days. The 500 mL vial should not be punctured more than 10 times.

Compatibility/Compounding Considerations

It has been recommended that flunixin meglumine injection not be mixed with other drugs because of unknown compatibilities.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: Individual products may be FDA-approved and labeled for different species, lactation status, different routes of administration (IV, IM). Refer to the specific product label for more information. The ARCI (Racing Commissioners International) has designated flunixin as a class 4 substance. See ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

Flunixin Meglumine for Injection: 50 mg/mL in 50 mL, 100 mL, and 250 mL vials; *Banamine®*, generic; (Rx). Products may be FDA-approved for use in horses (not for use in horses intended for food) and beef and dairy cattle (IV use only; not for use in dry dairy cows or veal calves). Depending on product, when used as labeled, withdrawal in cattle occurs as follows: Milk: 36 hours; Slaughter: 4 days (US).

Flunixin Meglumine Oral Paste: 1500 mg/syringe in 30 g syringes in boxes of 6; *Banamine® Paste*; (Rx). FDA-approved for use in horses

Flunixin Meglumine for Injection: 50 mg/mL in 100 mL vials; *Banamine®-S*; (Rx). FDA-approved for IM use in swine; slaughter withdrawal = 12 days

Flunixin Transdermal Solution: 50 mg/mL in 100 mL, 250 mL, and 1 L multiple-dose bottles; *Banamine® Transdermal;* (Rx). FDA-approved for topical use in cattle/steers, beef heifers, beef cows, beef bulls intended for slaughter, and replacement dairy heifers under 20 months of age. Do not slaughter within 8 days of last treatment. Not for use in female dairy cattle 20 months of age or older, including dry dairy cows. Use in these cattle may cause drug residues in milk and/or in calves born to these cows or heifers. Not for use in suckling beef calves, dairy calves, and veal calves. A withdrawal period has not been established in preruminating calves.

Combination Products:

Flunixin 16.5 mg/mL with Florfenicol 300 mg/mL injection in 100 mL, 250 mL, and 500 mL vials; *Resflor Gold®*; (Rx). FDA-approved for use in beef and nonlactating dairy cattle. Do not slaughter within 38 days of last treatment. Not for use in female dairy cattle 20 months of age or older or calves to be processed for veal. Use may cause milk residues. A withdrawal period has not been established in preruminating calves.

Flunixin 20 mg/mL (as flunixin meglumine) with oxytetracycline 300 mg/mL in 100 mL, 250 mL, and 500 mL vials; *Hexasol®*; (Rx). FDA-approved in beef and nonlactating dairy cattle. Do not slaughter within 21 days of last treatment. Not for use in female dairy cattle 20 months of age or older, including dry dairy cows. Use may cause milk residues. A withdrawal period has not been established for this product in preruminating calves.

Fluorouracil

(flure-oh-***yoor***-a-sill) *Adrucil®*

Antineoplastic Agent

For ophthalmic uses, refer to ***Ophthalmic***

Prescriber Highlights

- ► Used in dogs for susceptible tumors, including GI adenocarcinoma, anal sac adenocarcinoma, nasal adenocarcinoma, and sun-induced squamous cell carcinoma. This agent can also be given intralesionally or topically to horses with skin tumors.
- ► Contraindications: Do **NOT** use fluorouracil in any form with cats or in patients with known hypersensitivity, poor nutritional states, bone marrow suppression, or serious infections.
- ► Known teratogen
- ► Adverse effects include dose-dependent myelosuppression, GI toxicity, and neurotoxicity
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies fluorouracil as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Fluorouracil is a chemotherapeutic agent that has been used for canine mammary carcinoma (in combination with doxorubicin and

cyclophosphamide—AC or FAC protocol), dermal squamous cell carcinoma, and GI tract tumors. One study described the use of fluorouracil in combination with carboplatin in dogs for various carcinomas; the overall response rate was 43%.[1] It is also used topically and for intralesional injection with epinephrine for certain skin neoplasms (squamous cell carcinoma, melanoma, sarcoid) in horses. Use of fluorouracil in horses with cutaneous and nonperiocular SCC and sarcoids haves demonstrated efficacy with repeated intralesional injections and topical administration.[2–4]

Pharmacology/Actions

Fluorouracil is a pyrimidine analogue antimetabolite. The drug is converted via intracellular mechanisms to active monophosphate and triphosphate metabolites which interfere with DNA and RNA synthesis, inhibit cell growth, and promote cell death.[5]

Pharmacokinetics

Following IV administration, fluorouracil is rapidly removed from the systemic circulation (plasma half-life is about 15 minutes in humans) and primarily distributed into tumor cells, intestinal mucosa, liver, and bone marrow. The drug is predominantly metabolized by the liver and is excreted via the lungs and urine, while ≈15% of the dose is excreted unchanged into the urine.

Contraindications/Precautions/Warnings

Fluorouracil has a very narrow therapeutic index and should be used only by clinicians with experience using cancer chemotherapeutic agents. Fluorouracil is contraindicated in patients with known hypersensitivity, poor nutritional states, bone marrow suppression, or concurrent serious infections. It should be used with caution in patients with severe renal or hepatic impairment.

Cats develop a severe, potentially fatal neurotoxicity when given fluorouracil. Do **NOT** use in cats in any form. Severe, life-threatening toxicities have developed when pets have licked areas of topical application.

The National Institute for Occupational Safety and Health (NIOSH) classifies fluorouracil as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Do not confuse fluorouracil with flucytosine. Fluorouracil is considered a high alert medication (medication that requires special safeguards to reduce the risk for errors).[6] Consider instituting practices such as redundant drug dosage and volume checking and special alert labels.

Adverse Effects

In dogs, fluorouracil causes dose-dependent myelosuppression, GI toxicity (diarrhea, GI ulceration/sloughing, stomatitis), and neurotoxicity (seizures). Fluorouracil has a very narrow therapeutic index and should be used only by clinicians with experience using cancer chemotherapeutic agents. Additionally, cases of heart failure, severe mucositis/stomatitis/esophagopharyngitis, and hyperammonemic encephalopathy in the absence of liver disease have developed in humans following fluorouracil treatment.[7]

In humans, fluorouracil can increase cellular thiamine metabolism, inducing or exacerbating thiamine deficiency[8]; application to veterinary patients is unknown.

Reproductive/Nursing Safety

The drug is a known teratogen and has demonstrated fetal malformations (eg, cleft palate, skeletal defects) and embryolethality in laboratory animals. Its use during pregnancy should be weighed against any risks to offspring.

It is not known whether fluorouracil is excreted in milk. Because fluorouracil inhibits DNA, RNA, and protein synthesis, milk replacer should be considered if the dam requires fluorouracil.

Overdose/Acute Toxicity

Oral ingestions of topical products have occurred in dogs and cats. Toxic doses in dogs can be as little as 5 mg/kg, and doses greater than or equal to 40 mg/kg are reported to be uniformly fatal.[9] The LD_{50} in dogs following IV fluorouracil administration is 31.5 mg/kg. Signs at lower doses include mild GI irritation and vomiting. Seizures and death have been reported at doses as low as 10.3 mg/kg, and survival in dogs may be as low as 25%. The fatality rate in dogs was 65% following toxic exposure to fluorouracil.[10]

Very small ingestions can reportedly cause death in cats. Clinical signs may be seen within 30 minutes to 6 hours after ingestion; death has been reported in 7 hours. Clinical signs include acute nausea, vomiting, hemorrhagic diarrhea, abdominal pain, GI sloughing, ataxia, severe and non-responsive seizures, and severe dose-dependent myelosuppression affecting all cell lines. Severe metabolic acidosis and signs of multi-organ failure can also be seen.[11]

Should oral ingestion occur, aggressive GI decontamination with GI protection is recommended but may not be effective due to the rapid onset of toxicity. Treatment is primarily supportive and can include antiemetics, anticonvulsants, and fluid support. Seizure control with benzodiazepines, levetiracetam, or general anesthesia is often required.[12,13] Pain relief and body temperature control are important. Use broad-spectrum antibiotics to prevent secondary bacterial infections, and if bone marrow suppression develops, colony growth stimulating factors (eg, ***Filgrastim***) can be considered to stimulate stem cell proliferation in dogs. Complete blood counts should be routinely performed every 3 to 4 days for at least 18 days, as it may take up to 3 weeks before all cell lines return to normal.[11] Patients given an accidental parenteral overdose should undergo intensive hematologic monitoring for at least 4 weeks and be supported as required.

Uridine triacetate has been used as a successful antidote in humans, but it is not used in veterinary medicine due to the cost and administration requirements. Fluorouracil is dialyzable, but the rapid onset of toxicity limits its effectiveness.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fluorouracil and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **CYP2C9 Substrates** (eg, **diclofenac**): Fluorouracil may decrease the metabolism of CYP2C9 substrates.
- **Folic Acid/Leucovorin**: May increase the toxic effects of fluorouracil
- **Leflunomide**: Concurrent or sequential use of leflunomide without following a washout procedure may increase risk for myelosuppression and infections; avoid combination when possible.
- **Metronidazole**: May increase fluorouracil concentration and risk for toxicity
- **Myelosuppressive Agents** (eg, **antineoplastics**, **immunosuppressants**, **iron chelators**): Concurrent use with other bone marrow depressant medications may result in additive myelosuppression; avoid combination when possible.
- **Vaccines** (live and inactivated): Fluorouracil may diminish vaccine efficacy and enhance adverse effects of vaccines.

Laboratory Considerations

Fluorouracil may cause increases in **alkaline phosphatase**, **serum transaminase**, **serum bilirubin**, and **lactate dehydrogenase**.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and since chemotherapy indications, treatment protocols, and monitoring and safety guidelines often change, the following dosages should be used only as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[14–18] are strongly recommended. All doses are extra-label.

DOGS:

NOTE: Do not confuse mg/m^2 with mg/kg dosages.

Canine mammary carcinoma (in combination with cyclophosphamide and/or doxorubicin AC or FAC protocol), dermal squamous cell carcinoma, GI adenocarcinoma, anal sac adenocarcinoma, and nasal adenocarcinoma: 150 mg/m^2 IV weekly, or 5 – 10 mg/kg IV weekly[19–24]

Mesothelioma: Initially, 150 – 200 mg/m^2 IV weekly for 4 weeks, then 150 – 200 mg/m^2 IV every 2 weeks[25]

Canine soft tissue sarcoma; postsurgical, incisional injection: 150 mg/m^2 was injected along the surgical scar or in different parallel sites of the open wound to provide uniform distribution, using a 22-gauge needle attached to a 5-mL Luer lock syringe. Multiple injections may be needed to cover the treatment field.[26]

In combination with carboplatin to treat various carcinomas: Fluorouracil 150 mg/m^2 IV as a slow push followed by carboplatin 200 mg/m^2 IV over 10 minutes 1 hour after fluorouracil administration.[1]

HORSES:

Intralesional injection for squamous cell carcinoma (SCC), melanomas, sarcoids:

a) Fluorouracil can be injected intralesionally at doses of 1 – 3 mL per tumor site depending on the size of the tumor. Epinephrine is typically added to the injection at a ratio of 1 part epinephrine to 10 parts fluorouracil. It can also be mixed with sterile sesame seed oil (1:1) immediately prior to injection. Generally, this combination can be successful for the resolution of small sarcoids and SCC but is often ineffective for melanoma. The maximum systemic dosage is ≈750 mg (15 mL of 50 mg/mL fluorouracil injection) for an average horse.[27,28]

b) 50 mg/cm^3 injected intralesionally a single time[2] or every 2 weeks until resolution occurs[4]

Cutaneous neoplasia using a topical formulation (extra-label): Fluorouracil 5% cream administered topically to affected area once daily for 4 to 6 weeks[3]

Monitoring

- Baseline and periodic CBC with platelet counts (in humans, nadirs usually occur between days 9 and 14 with recovery by day 30)
- Baseline and periodic serum chemistry profiles
- GI and CNS adverse effects

Client Information

- Fluorouracil is a chemotherapy (anticancer) drug. The drug can be hazardous to other animals and people that come in contact with it. On the day your animal gets the drug and then for a few days afterward, handle all bodily waste (urine, feces, litter), blood, or vomit only while wearing disposable gloves. Seal the waste in a plastic bag and then place both the bag and gloves in with the regular trash.
- If applying fluorouracil to the skin of your animal, wear disposable gloves, and wash your hands immediately after each use. Take care to avoid contact with the administration site.
- Fluorouracil must NEVER be used in cats.
- Bone marrow depression can occur. The greatest effects on bone marrow usually occur within a few weeks after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal becomes tired easily, contact your veterinarian right away.
- Clients must understand the importance of immediately reporting any signs associated with toxicity (eg, abnormal bleeding, bruising, depression, infection, shortness of breath, changes in urination). Fluorouracil can be very toxic to the nervous system (seizures, convulsions) and to the gastrointestinal tract (vomiting and gastrointestinal upset).
- This medicine is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Fluorouracil (5-FU), a pyrimidine antagonist antineoplastic agent, occurs as a white, practically odorless, crystalline powder. It is sparingly soluble in water and slightly soluble in alcohol. The commercially available injection's pH is adjusted to 8.6 to 9.4 and may be colorless or slightly yellow in color.

Fluorouracil may also be known as 5-fluorouracil, fluorouracilo, fluorouracilum, 5-FU, NSC-19893, Ro-2-9757, and WR-69596; many trade names are available, including *Adrucil*®, *Carac*®, *Efudex*®, *Fluoroplex*®, *Tolak*®.

Storage/Stability

Store the injection between 20°C and 25°C (68°F and 77°F); avoid freezing and exposure to light.

Compatibility/Compounding Considerations

Slight color changes in the solution can occur during storage. If a precipitate forms, the solution can be gently heated to 60°C (140°F) to dissolve. Cool to body temperature before administering. If unsuccessful in dissolving the precipitate, discard. According to the manufacturer, vials should be used within 4 hours of initial entry, and solutions for infusion should be administered immediately. However, available data suggest that both undiluted and diluted solutions remain stable for longer periods.[29,30]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Fluorouracil Solution for Injection: 50 mg/mL in 10 mL, 20 mL, 50 mL, and 100 mL vials; *Adrucil*®; generic; (Rx).

Fluorouracil Cream: 0.5%, 1% and 5% in 30g and 40 g tubes; generic; (Rx)

Fluorouracil is also available in topical solutions.

Fluoxetine

(***floo-ox**-e-teen*) *Prozac®, Reconcile®*

Selective Serotonin Reuptake Inhibitor (SSRI)

Prescriber Highlights

- ► FDA-approved for use in dogs, and used extra-label in cats and horses for a variety of behavior disorders
- ► Contraindicated in animals with a known hypersensitivity to the drug and in those receiving monoamine oxidase inhibitors (MAOIs)
- ► Use with caution in animals with diabetes mellitus or seizure disorders; dose may need to be reduced for animals with severe hepatic impairment
- ► Most common adverse effects in dogs include anorexia, lethargy, GI effects, anxiety/restlessness, and vocalization. Seizures and aggressive behavior have been reported. Cats may show behavior changes (eg, anxiety, irritability, sleep disturbances, anorexia, changes in elimination patterns).
- ► Many potential drug interactions

Uses/Indications

Fluoxetine is a veterinary FDA-approved product labeled for treatment of canine separation anxiety in conjunction with a behavior modification plan.[1] Fluoxetine may be beneficial for treatment of canine (and feline) aggression,[2–4] stereotypic behaviors (and other compulsive behaviors),[5,6] and anxiety.[7–9] It also may be useful for treatment of inappropriate elimination in cats.[10–12]

Pharmacology/Actions

Fluoxetine is a highly selective inhibitor of the presynaptic reuptake of serotonin in the CNS with negligible effects on other neurotransmitters (eg, dopamine, norepinephrine). In dogs and cats, fluoxetine has anxiolytic and anticompulsive effects and may reduce aggressive behaviors by decreasing reactivity.

Pharmacokinetics

In dogs, fluoxetine is well absorbed after oral administration, and the bioavailability is 72% to 88%.[1,13] Fluoxetine chewable tablets caused 15% greater fluoxetine exposure (area under the curve [AUC]) as compared with fluoxetine-filled gelatin capsules.[1] The presence of food altered the rate, but not the extent, of absorption. Oral capsules and liquid are bioequivalent.

Fluoxetine and its principal metabolite, norfluoxetine (active), are distributed throughout the body, with the highest concentrations found in the lungs and liver. CNS concentrations can be detected within 1 hour of administration. Fluoxetine is primarily metabolized in the liver by CYP450 to a variety of metabolites, including norfluoxetine (active). Fluoxetine and norfluoxetine are eliminated slowly. In dogs, the average elimination half-life for fluoxetine and norfluoxetine is 6 to 18 hours and 49 hours, respectively.[1,13] Renal impairment does not significantly affect elimination rates, but liver impairment can decrease clearance rates.

In cats, the elimination half-life of fluoxetine and norfluoxetine is 47 and 52 hours, respectively, after oral administration.[14] When fluoxetine was applied transdermally (15% in a PLO gel) to cats, bioavailability was ≈10% of the oral route.[14] An alternative transdermal preparation (lipoderm base) produced significantly lower fluoxetine and norfluoxetine concentrations as compared with oral fluoxetine, and the authors theorized that the limited surface area on a cat's pinnae may limit the amount of drug that can be delivered by the transdermal route.[15]

In horses, the time to reach maximum concentration was 1.5 hours and half-life was 15.6 hours; norfluoxetine was not detected in any sample.[16]

In humans, fluoxetine is ≈95% bound to plasma proteins. The elimination half-life of fluoxetine and norfluoxetine is ≈2 to 3 days and ≈7 to 9 days, respectively.

Contraindications/Precautions/Warnings

The manufacturer states that fluoxetine should not be used in dogs with epilepsy or a history of seizures and should not be given in combination with drugs that lower the seizure threshold (eg, acepromazine, chlorpromazine). **NOTE**: No published evidence exists to support the claim that phenothiazines alone lower the seizure threshold.[17] It is not known if the use of fluoxetine in combination with this class of drugs may lower the seizure threshold, and SSRIs are recommended for treatment of anxiety and depression in humans with epilepsy.[18]

Fluoxetine is contraindicated in animals with a known hypersensitivity to it and in those receiving monoamine oxidase inhibitors (MAOIs; see ***Drug Interactions***). Although the veterinary label states that fluoxetine should not be used in the treatment of aggressive dogs, fluoxetine has safely and effectively reduced aggression in dogs.[2–4] Safe use has not been established in dogs younger than 6 months.

Fluoxetine should be used with caution in animals with diabetes mellitus because it may alter blood glucose concentrations.[1] Doses may need to be reduced in animals with severe hepatic impairment.

Because norfluoxetine has a long half-life, tapering the drug may only be necessary when an animal has been on the drug long term (ie, longer than 8 weeks)[19]; tapering the drug over a 3- to 5-week period has been recommended.[7] Because of its long half-life, the manufacturer recommends a 6-week washout after discontinuing fluoxetine and before starting medications that have significant interactions with fluoxetine or norfluoxetine.[1]

In humans, it is recommended to use a lower or less frequent dose in elderly patients due to risk for significant hyponatremia.[20]

Do not to confuse FLUoxetine with famotidine, FluVOXamine, or PARoxetine.

Adverse Effects

In multisite field trials in dogs, seizures were reported in some of the dogs treated with fluoxetine (0.4% to 2.5%); the absolute causality and incidence rate was not determined. Fluoxetine may cause lethargy (33%), vomiting (17%), diarrhea (10%), tremors (11%), restlessness (7%), and excessive vocalization (6%).[1] Anorexia (27%) and weight loss (30%) have occurred in dogs[1] but are usually transient and may be negated by starting the dog on a low dose and titrating up, which can temporarily increase the palatability of food. Some dogs have persistent anorexia that precludes further fluoxetine treatment. Aggressive behavior occurred in dogs at a rate similar to that in dogs that received a placebo.[1] Reducing the dose may eliminate or reduce the severity of adverse effects; returning to full dose may be tolerated following a dose reduction. Other reported adverse effects include mydriasis, panting, confusion, incoordination, and hypersalivation.

Cats may exhibit behavior changes (eg, anxiety, irritability, sleep disturbances), anorexia, and diarrhea or changes in elimination patterns. Skin irritation was noted with 2 different transdermal fluoxetine preparations.[14,15]

In humans, potential adverse effects are extensive and diverse, but those most commonly noted include anxiety, nervousness, insomnia, drowsiness, fatigue, dizziness, anorexia, nausea, rash, diarrhea, and sweating; seizures, hyponatremia, or hepatotoxicity are also possible. Epidemiology studies have noted an association between SSRI use and bleeding reactions, particularly when combined with other drugs (eg, NSAIDs, anticoagulants) that increase the risk for bleeding.[20] Approximately 15% of human patients discontinue treatment because of adverse effects.

Reproductive/Nursing Safety

Fluoxetine's safety during pregnancy has not been established. Studies to determine the effects of fluoxetine in breeding, pregnant, or lactating dogs or in animals younger than 6 months have not been conducted.[1] Fluoxetine crosses the placenta. Preliminary studies in rats demonstrated no overt teratogenic effects. In humans, SSRI use during the third trimester of pregnancy has been associated with neonatal complications.[20]

Fluoxetine is excreted in human milk (20% to 30% of plasma concentrations), and caution is advised in nursing patients. Clinical implications for nursing offspring are not clear.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The LD_{50} for rats is 452 mg/kg and for dogs is greater than 100 mg/kg, but a median dose of 15.9 mg/kg is reported to cause clinical signs of SSRI toxicosis in dogs.[21] In a study, 5 out of 6 dogs given an oral toxic dose developed seizures that immediately stopped after the dogs received diazepam IV. A retrospective study in cats found doses as low as 3.7 mg/kg caused clinical signs of toxicity.[22] In cats with SSRI toxicosis, only 24% exhibited clinical signs, including vomiting, diarrhea, agitation, and tremors. Approximately half the cats were hospitalized for a mean duration of 15 hours, and all cats survived.[22]

Common clinical signs associated with overdose include vomiting, hypersalivation, mydriasis, and vocalization.

Treatment for fluoxetine overdose consists of providing treatment based on clinical signs and supportive therapy. Gut-emptying techniques should be used when warranted and not contraindicated. Diazepam should be considered to treat seizures. Cyproheptadine can be used as a serotonin antagonist.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fluoxetine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Alprazolam**: Fluoxetine can increase alprazolam concentrations.
- **Anticoagulants** (eg, **clopidogrel, heparin, warfarin**): Concurrent use with fluoxetine has been associated with an increased risk for bleeding in humans.
- **Antiplatelet Agents** (eg, **aspirin, clopidogrel**): In humans, concurrent use with fluoxetine has been associated with an increased risk for bleeding.
- **Buspirone**: Increased risk for serotonin syndrome
- **Cyproheptadine**: May decrease or reverse the effects of SSRIs
- **Dextromethorphan**: Serotonin syndrome-like adverse effects are possible.
- **Diazepam**: Fluoxetine can prolong diazepam half-life.
- **Diuretics**: Increased risk for hyponatremia
- **Insulin**: May alter insulin requirements
- **Isoniazid (INH)**: Increased risk for serotonin syndrome
- **Monoamine Oxidase Inhibitors (MAOIs;** eg, **amitraz, linezolid,** and, potentially, **selegiline**): High risk for serotonin syndrome; concurrent use is contraindicated in dogs. A 6-week washout period is required after fluoxetine is discontinued, and a 2-week washout period is needed if the MAOI is first discontinued.[1]
- **Methadone**: In dogs, concurrent oral administration of fluoxetine may increase peak methadone concentration and exposure (AUC).[23]
- **Nonsteroidal Anti-Inflammatory Drugs (NSAIDs;** eg, **carprofen, meloxicam, robenacoxib**): SSRIs may increase the risk for GI ulceration and bleeding.
- **Pentazocine**: Serotonin syndrome-like adverse effects are possible.
- **Propranolol, Metoprolol**: Fluoxetine may increase the plasma concentration of these beta-blockers; atenolol may be safer to use if fluoxetine is required.
- **St. John's Wort**: Increased risk for serotonin syndrome
- **Tramadol**: SSRIs can inhibit the metabolism of tramadol to active metabolites, which may decrease its efficacy and increase the risk for toxicity (eg, serotonin syndrome, seizures).
- **Tricyclic Antidepressants (TCA**; eg, **clomipramine**, **amitriptyline**): Fluoxetine may increase TCA blood concentrations and the risk for serotonin syndrome.
- **Trazodone**: Increased plasma concentrations of trazodone are possible; increased risk for serotonin syndrome

Laboratory Considerations

None were noted.

Dosages

DOGS:

Treatment for canine separation anxiety in conjunction with a behavior modification plan (label dosage; FDA-approved): 1 – 2 mg/kg PO once daily in conjunction with a behavior modification plan[1]

Adjunctive treatment for behavior disorders (eg, noise aversion, compulsive disorder, stereotypic behaviors, aggression) (extra-label): 1 – 2 mg/kg PO every 24 hours; doses as high as 4 mg/kg every 24 hours have been noted. **NOTE**: It may take 4 to 8 weeks before efficacy can be fully assessed.

CATS:

Adjunctive treatment for behavior disorders (eg, urine marking, separation anxiety, aggression) (extra-label): Recommended dosage in cats is typically 0.5 – 1.3 mg/kg PO every 24 hours[11,24]; treatment may be required for up to 8 weeks before full determination of efficacy. When using fluoxetine to treat urine marking, after 8 to 12 weeks of successful treatment, dose may be reduced gradually (≈25%) per week. If urine marking returns, dose can be increased to the last effective dose.

HORSES:

Facilitating stall rest or treatment of behavior-related problems (extra-label): 0.25 mg/kg PO once daily was reported by owners to be successful in facilitating stall rest and for anxious or fractious behaviors. Daily doses ranged from 0.15 – 0.54 mg/kg.[25]

Monitoring

- Efficacy (eg, control of unwanted behaviors)
- Adverse effects, including appetite (weight)

Client Information

- This medication should be used along with a behavior modification plan. Some improvement may be seen in the first week, but it may take several weeks to reach full effect and determine if this medicine is working.
- This medicine may be given with or without food. If your ani-

mal vomits or acts sick after receiving this medicine on an empty stomach, give future doses with food or a small treat. If vomiting continues, contact your veterinarian.
- Do not suddenly stop giving this medicine to your animal without your veterinarian's guidance.
- The most common side effects are drowsiness or sleepiness and reduced appetite. Rare serious side effects can include seizures and aggression. Contact your veterinarian immediately if these are noted.
- Overdoses can be serious. Keep fluoxetine out of reach of other animals and children.
- Tell your veterinarian if your animal has worn a flea and tick collar in the past 2 weeks. Do not use a flea and tick collar on your animal while this medicine is being administered without first talking to your veterinarian.

Chemistry/Synonyms

Fluoxetine, part of the phenylpropylamine-derivative antidepressant group, differs structurally and pharmacologically from the tricyclic and monoamine oxidase inhibitor antidepressants. Commercial forms contain fluoxetine hydrochloride and potency is expressed in mg fluoxetine. Fluoxetine HCl occurs as a white to off-white crystalline solid. Approximately 50 mg are soluble in 1 mL of water.

Fluoxetine may also be known as fluoxetini hydrochloridum and/or LY-110140; many trade names are available.

Storage/Stability

Store capsules and tablets in well-closed containers at room temperature (20°C-25°C [68°F-77°F]); excursions are permitted between 15°C to 30°C (59°F-86°F). Do not remove desiccant from the chewable tablet bottle. The oral liquid should be stored in tight, light-resistant containers at room temperature.

Compatibility/Compounding Considerations

Fluoxetine has been compounded into transdermal formulations, but studies demonstrating efficacy and safety are lacking.[14,15]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Fluoxetine Chewable Tablets: 8 mg, 16 mg, 32 mg, and 64 mg; *Reconcile®*; (Rx). FDA-approved (NADA # 141-272) for use in dogs.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Fluoxetine HCl Oral Tablets: 10 mg and 20 mg; generic; (Rx)

Fluoxetine HCl Oral Capsules: 10 mg, 20 mg, and 40 mg; *Prozac®*, generic; (Rx)

Fluoxetine HCl Oral Delayed-release Capsules: 90 mg; generic; (Rx)

Fluoxetine HCl Oral Solution: 20 mg/5 mL (4 mg/mL; may contain alcohol, sucrose, benzoic acid) in 120 mL and 473 mL; *Prozac®*; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Fluralaner

(***floor***-ah-lan-er) *Bravecto®*

Isoxazoline Ectoparasiticide

Prescriber Highlights

- ► Insecticide and acaracide FDA-approved for use in dogs and cats
- ► Effective for 8 to 12 weeks against labeled parasites
- ► Chewable tablets should be administered with food.
- ► Adverse effects may include vomiting, diarrhea, inappetence, and lethargy.
- ► The FDA has warned that drugs in the isoxazoline class have the potential to cause neurologic adverse effects (eg, muscle tremors, ataxia, seizures) in dogs and cats. Use caution in animals with a history of seizures or other neurologic disorders.

Uses/Indications

For dogs and puppies 6 months of age and older weighing at least 2 kg (4.4 lb), fluralaner chewable tablets and topical solution (*Bravecto®*) are FDA-approved for the treatment and prevention of flea (*Ctenocephalides felis*) infestations; the treatment and control of tick infestations (*Ixodes scapularis* [black-legged tick], *Dermacentor variabilis* [American dog tick], and *Rhipicephalus sanguineus* [brown dog tick]) for 12 weeks; and for the treatment and control of *Amblyomma americanum* (Lone Star tick) infestations for 8 weeks.[1,2] Fluralaner chewable tablets that provide protection for 1 month (ie, *Bravecto®-1 Month*) for the same parasites and indications are FDA-approved for dogs and puppies weighing at least 2 kg (4.4 lb) and that are 8 weeks of age (6 months for *A americanum)* and older.[3] Fluralaner is effective as part of the treatment and control of flea allergy dermatitis in dogs.[4–6] Flea egg production is reduced by 100% within 48 hours of oral administration to dogs.[7] In other countries, fluralaner is also labeled for the treatment of flea (*C felis* and *Ctenocephalides canis*) and tick (*Ixodes ricinus, Rhipicephalus sanguineus,* and *Dermacentor reticulatus*) infestations in dogs.[8]

Fluralaner has been shown to be effective against generalized demodicosis in dogs, with studies showing no mites detectable at 56 and 84 days following a single oral dose[9] or following one or several doses for treatment of either adult- or juvenile-onset demodicosis.[8,10,11] Single oral or topical fluralaner treatment in dogs with naturally acquired *Sarcoptes scabiei* var *canis* infestation has resulted in a 100% reduction in mite counts 28 days posttreatment[12] and in clinical improvement within 14 to 21 days after a single oral dose.[8,11,13] Fluralaner has demonstrated efficacy in dogs against *Ixodes holocyclus*,[14] *Linognathus setosus*,[15] and *Otodectes cynotis*.[16] Fluralaner administered PO or topically has been shown to prevent transmission of *Babesia canis* from *D variabilis* ticks to dogs,[17,18] and *Ehrlichia canis* by *R sanguineus* ticks.[19]

A single dose of oral fluralaner killed greater than 99% of the insect *Triatoma infestans,* the vector of *Trypanosoma cruzi* (ie, Chagas disease, American trypanosomiasis), regardless of life stage, through 7 to 8 weeks posttreatment[20,21]; another study reported that 100% efficacy was demonstrated for up to 7 months.[22]

For cats and kittens 6 months of age and older weighing at least 1.2 kg (2.6 lb), fluralaner topical solution (*Bravecto®*) is FDA-approved for the treatment and prevention of flea infestations (*C felis*), for the treatment and control of *I scapularis* (black-legged tick) infestations for 12 weeks, and for the treatment and control of *D variabilis* (American dog tick) infestations for 8 weeks.[23] In other countries, fluralaner is also labeled for the treatment of *I ricinus* tick infestations in cats.[8] Fluralaner has also been used to treat *O cynotis*,[16] *Demodex gatoi*,[24] and *Demodex cati* [25] infestations in cats and maintained efficacy for 12 weeks (6 weeks for *Lynxacarus radovsky* infestations).[26]

Fluralaner in combination with moxidectin topical solution (*Bravecto® Plus*) is FDA-approved for cats and kittens 6 months of age and older weighing at least 1.2 kg (2.6 lb) for the prevention of heartworm disease caused by *Dirofilaria immitis, the* treatment of intestinal roundworms (*Toxocara cati*) and hookworms (*Ancylostoma tubaeforme), the* treatment and prevention of flea infestations (*C felis*), and the treatment and control of tick infestations (*I scapularis* [black-legged tick] and *D variabilis* [American dog tick]) for 2 months.[27]

Pharmacology/Actions

Fluralaner is an isoxazoline acaricide/insecticide that inhibits gamma-aminobutyric acid (GABA)- and glutamate-gated chloride channels with significant selectivity for insect neurons over mammalian neurons.[28] Inhibition induces uncontrolled neuronal activity with resultant paralysis and death of fleas and ticks. In dogs, onset of action is within 8 hours of fleas feeding[21,23] and within 12 hours of ticks feeding.[24–26] In cats, onset of action is within 12 hours of fleas feeding and within 48 hours of ticks feeding.[6]

Pharmacokinetics

The bioavailability of fluralaner following oral and topical administration is ≈25%[29]; giving chewable tablets with food increases bioavailability by ≈2 to 2.5 times.[30] Peak fluralaner concentrations are achieved between 7 and 42 days following topical administration in dogs, and the elimination half-life ranges between 14 and 29 days.[1,8] After oral administration in dogs, elimination half-life averages 9 to 16 days. The drug is not appreciably metabolized, and unchanged fluralaner is excreted in the feces.

Peak fluralaner concentrations are achieved between 7 and 21 days following topical administration in cats, and the elimination half-life ranges between 11 and 13 days. Fluralaner is highly bound to plasma proteins in cats. The drug is not appreciably metabolized, and the hepatic extraction ratio is estimated to be low (0.3%). Unchanged fluralaner is excreted in the feces.[1,8,31,32]

Contraindications/Precautions/Warnings

No contraindications have been listed for fluralaner and fluralaner combination products.[1–3,23,27] For topical applications, do not allow the animal to lick the site of application for 30 minutes after application; wait 3 days before bathing the animal.[33]

Use fluralaner and fluralaner combination products with caution in dogs and cats with a history of seizures or epilepsy. The FDA has warned that drugs in the isoxazoline class have the potential to cause neurologic adverse effects (eg, muscle tremors, ataxia, seizures) in dogs and cats.[34] These effects have also been noted in patients without a history of neurologic disorders.

No adverse effects were noted in a study after 3 times fluralaner labeled doses were administered to collies homozygous for the *MDR1* gene mutation (also known as *ABCB1-1delta*).[35]

Because ticks must feed on the host to become exposed to fluralaner, the risk of transmission of vector-borne diseases cannot be excluded.[36] This particularly applies to infections that have a shorter transmission time (eg, *Anaplasma phagocytophilum, Ehrlichia canis*); however, there is evidence that even in these cases fluralaner reduces this risk.[37]

For fluralaner/moxidectin combination products, use caution in cats with an unknown heartworm status or that are heartworm positive.

Adverse Effects

In preapproval field trials for dogs receiving fluralaner chewable tablets (*Bravecto®*), vomiting was the most common adverse effect reported; decreased appetite, hypersalivation, lethargy, and diarrhea were also reported.[1] Reported adverse effects in dogs receiving the fluralaner topical solution (*Bravecto®*) included vomiting, alopecia, diarrhea, and lethargy.[2] Adverse effects reported in dogs receiving the one-month fluralaner chewable tablets (*Bravecto® 1-Month*) included pruritus, vomiting, diarrhea and decreased appetite.[3]

Isoxazolines, including fluralaner, have been associated with neurologic adverse effects (eg, muscle tremors, ataxia, seizures) even in dogs with no known history of neurologic problems.[1–3,23,27]

Reported adverse effects in cats receiving the fluralaner topical solution (*Bravecto®*) included vomiting, pruritus, diarrhea, alopecia, decreased appetite, and lethargy; ataxia and tremors were also reported in field studies.[23] Adverse effects reported in preapproval field trials for cats receiving the fluralaner/moxidectin combination topical solution (*Bravecto® Plus*) included vomiting, alopecia, pruritus, diarrhea, lethargy, dry skin, elevated ALT (greater than twice the upper reference range of 100 IU/L in the absence of clinical signs).[27]

In both dogs and cats, adverse events were reported at a rate similar to control groups. Hypersalivation was noted in most dogs and cats that received topical fluralaner products orally at the maximum topical dose under experimental conditions.[1,23]

Reproductive/Nursing Safety

The United States product labels have no specific cautions regarding use in breeding, pregnant, or lactating dogs[1,3]; however, safe use in breeding and pregnant dogs has been established in other jurisdictions.[8,36] A reproductive safety study in beagles receiving the chewable tablet at doses up to 3 times the recommended dose found no clinically relevant effects on body weight, food consumption, reproductive performance, semen analysis, litter data, gross necropsy (in adult dogs), or histopathology findings (in adult dogs and puppies).[1] However, abnormalities were noted in 7 puppies from 2 of the 10 dams in the treated group: limb deformity (4 puppies), enlarged heart (2 puppies), enlarged spleen (3 puppies), and cleft palate (2 puppies).

The safety of fluralaner topical solutions for cats, either as a single agent or in combination with moxidectin, has not been evaluated in breeding, pregnant, and lactating cats.[8,23,27,38]

No information regarding fluralaner's distribution in maternal milk was located, but concentrations would be expected to be very low.

Because safety has not been firmly established, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Some puppies (8 to 9 weeks old) receiving up to 5 times the labeled dose of fluralaner tablets developed diarrhea with mucoid and bloody feces[1]; tremors were observed on the day of administration. No adverse reactions were noted in ≈12-week-old kittens that received up to 5 times the label dose topically at 8-week intervals.[8,23] If clinical signs occur after an overdose, treat supportively.

For patients that have experienced or are suspected to have experienced an overdose, it is strongly encouraged to consult with a 24-hour poison consultation center that specializes in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

In field trials, dogs and cats received concurrent vaccines, anthelmintics, antibiotics, and steroids without observed adverse reactions.[1–3,23] Fluralaner has been safely administered to dogs concurrent with milbemycin oxime/praziquantel[39] and deltamethrin collar.[40] In cats, concurrent use of fluralaner with emodepside/praziquantel combination has been determined to be safe.[41] The following drug interactions with fluralaner either have been reported or are theoretical in humans or animals and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks, and perform additional

monitoring when appropriate.

- **Highly Protein Bound Drugs** (eg, **maropitant, NSAIDs, warfarin**): Concurrent use of fluralaner with other highly protein bound drugs may cause a transient increase in serum concentrations of each drug. These interactions are unlikely to be of clinical concern because increased free drug concentrations will equilibrate through increased clearance.[8]

Dosages

DOGS:

Labeled indications (label dosage; FDA-approved): A minimum dose of 25 mg/kg (11.4 mg/lb) PO with food or topically every 12 weeks (8 weeks for *Amblyomma americanum* ticks).[1,2] Dosage forms deliver fluralaner 25 – 50 mg/kg. Dosed according to body weights listed in the table below.

Bravecto® chewable tablets and topical solution for dogs

Body weight in kg (lb)	Fluralaner (mg)	Number of tablets/ tubes to administer
2-4.5 (4.4-9.9)	112.5	1
More than 4.5-10 (9.9-22)	250	1
More than 10-20 (22-44)	500	1
More than 20-40 (44-88)	1000	1
More than 40-55.8 (88-123)	1400	1
More than 55.8 (123)	--	Appropriate combination of tablets/tubes

Labeled indications (label dosage; FDA-approved): A minimum dose of 10 mg/kg (4.5 mg/lb) PO with food every month.[3] Dosage form delivers fluralaner 10 – 22.5 mg/kg. Dosed according to body weights listed in the table below.

Bravecto® 1-Month chewable tablets for dogs

Body weight in kg (lb)	Fluralaner (mg)	Number of tablets to administer
2-4.5 (4.4-9.9)	45	1
More than 4.5-10 (9.9-22)	100	1
More than 10-20 (22-44)	200	1
More than 20-40 (44-88)	400	1
More than 40-55.8 (88-123)	560	1
More than 55.8 (123)	--	Appropriate combination of tablets

Demodicosis, generalized (extra-label): 25 mg/kg PO as a single dose.[9,42] Number of mites on skin scraping were reduced by greater than 99% by 28 days posttreatment.

Ixodes holocyclus (extra-label): 25 mg/kg PO as a single dose has prevented tick infestation for at least 115 days[14]

Linognathus setosus (extra-label): 25 mg/kg PO as a single dose has eliminated infestation within 28 days and led to complete dermatologic recovery[15]

Otodectes cynotis (extra-label): 25 mg/kg PO or topically as a single dose achieved clinical and parasitological cure within 14 to 28 days under experimental conditions[16]

***Sarcoptes scabiei* var *canis* infestation** (extra-label): 25 mg/kg PO or topically as a single dose.[12,13] Skin scrapings were negative for mites by 14 days posttreatment.[12]

Triatoma infestans* (vector of *Trypanosoma cruzi; extra-label): 25 mg/kg PO as a single dose[20–22]

CATS:

Labeled indications using fluralaner as a single agent (label dosage; FDA-approved): A minimum dose of 40 mg/kg (18.2 mg/lb) topically every 12 weeks (8 weeks for *Dermacentor variabilis* ticks).[23] Dosage forms deliver fluralaner 40 – 90 mg/kg. Dosed according to body weights listed in the table below.

Bravecto® topical solution for cats

Body weight in kg (lb)	Fluralaner (mg)	Number of tubes to administer
1.2-2.8 (2.6-6.2)	112.5	1
More than 2.8-6.3 (6.2-13.8)	250	1
More than 6.3-12.5 (13.8-27.5)	500	1

Demodex gatoi, Demodex cati (extra-label): 26 – 34 mg/kg PO (a single 112.5-mg tablet/cat) as a single dose[24,25]

Lynxacarus radovsky (extra-label): 25 – 50 mg/kg PO as a single dose eliminated 100% of mites within 28 days of administration, with clinical improvement noted by day 14[26]

Otodectes cynotis (extra-label): 40 mg/kg applied topically as a single dose achieved clinical and parasitological cure within 14 to 28 days under experimental conditions.[16]

Ixodes holocyclus (extra-label): 40 mg/kg applied topically as a single dose has been shown to kill 100% of ticks within 48 hours and maintain efficacy for 84 days[43]

Labeled indications using fluralaner/moxidectin combination product (label dosage; FDA-approved): A minimum dose of 40 mg/kg (18.2 mg/lb) of fluralaner and a minimum dose of 2 mg/kg (0.9 mg/lb) of moxidectin topically every 8 weeks.[27] Dosage forms deliver fluralaner 40 – 95 mg/kg and moxidectin 2 – 4.7 mg/kg. Dosed according to body weights listed in the table below.

Bravecto® Plus topical solution for cats

Body weight in kg (lb)	Fluralaner (mg)	Moxidectin (mg)	Number of tubes to administer
1.2-2.8 (2.6-6.2)	112.5	5.6	1
More than 2.8-6.3 (6.2-13.8)	250	12.5	1
More than 6.3-12.5 (13.8-27.5)	500	25	1

RABBITS:

Psoroptes cuniculi (extra-label): 25 mg/kg PO as a single dose yielded clinical and parasitological cure 12 days after administration and was maintained for the remainder of the 90-day study period[44]

HEDGEHOGS:

Caparinia tripilis (extra-label): 10 mg/kg PO as a single dose killed mites between 7 and 14 days after administration in an African pygmy hedgehog[45]

Monitoring

- Efficacy based on clinical signs and diagnostic testing (eg, fecal flotation, heartworm antigen testing [combination product only], external parasite elimination)
- For demodicosis, clinical signs and monthly skin scrapings;

continue treatment for 4 weeks beyond 2 negative monthly skin scrapings
- Adverse effects (eg, decreased appetite, vomiting, diarrhea)

Client Information
- Keep this medicine and all medicines out of the reach of other animals and children. Keep the product in the original packaging until use to prevent unintended exposure.
- Chewable tablets should be administered with a meal.
- For the topical dog product, avoid bathing or swimming for 3 days after application.
- Do not apply this medicine to irritated skin. Do not contact the application site or allow children to contact the application site until dry. Skin irritation has been reported in humans after close contact with the application site within 4 days of application. Contact a physician if there are any concerns. Be sure to have the product label available when calling.
- Do not eat, drink, or smoke while handling the topical products. The topical products are flammable. Keep away from heat, open flames, sparks, or other sources of ignition.
- Wash your hands thoroughly with soap and water immediately after use.
- Report any side effects, including adverse neurologic effects such as tremors, difficulty walking, or seizures, to your veterinarian.

Chemistry/Synonyms
Fluralaner is an isoxazoline-substituted benzamide derivative insecticide and acaracide. It has a molecular weight of 556.29 and an octanol/water partition coefficient of 5.35. The spot-on solution is colorless to yellow. ATCvet code is QP53BX, and trade name is *Bravecto®*.

Storage/Stability
Do not store fluralaner chewable tablets above 30°C (86°F) or topical solutions above 25°C (77°F). Store in the original packaging to protect from moisture. The topical solution is highly flammable. Keep away from heat, sparks, open flame, or other sources of ignition.

Compatibility/Compounding Considerations
No specific information noted

Dosage Forms/Regulatory Status
VETERINARY-LABELED PRODUCTS:

Fluralaner Chewable Tablets for Dogs: 112 mg, 250 mg, 500 mg, 1000 mg, and 1400 mg; *Bravecto®*; (Rx). FDA-approved. NADA #141-426

Fluralaner Chewable Tablets for Dogs: 45 mg, 100 mg, 200 mg, 400 mg, and 560 mg; *Bravecto® 1-Month*; (Rx). FDA-approved. NADA #141-532

Fluralaner 280 mg/ml Topical Solution for Dogs: 112 mg, 250 mg, 500 mg, 1000 mg, and 1400 mg; *Bravecto® topical solution for dogs*; (Rx). FDA-approved. NADA #141-459

Fluralaner 280 mg/ml Topical Solution for Cats: 112.5 mg, 250 mg, and 500 mg; *Bravecto® topical solution for cats*; (Rx). FDA-approved. NADA #141-459

Fluralaner 28% (280 mg/mL) and Moxidectin 1.4% (14 mg/mL) Topical Solution for Cats: 0.4 mL, 0.9 mL, and 1.8 mL tubes; *Bravecto® Plus* topical solution for cats; (Rx). FDA approved. NADA #141-518

HUMAN-LABELED PRODUCTS: NONE

For the complete list of references, see **wiley.com/go/budde/plumb**

Fluticasone
(floo-***ti***-ca-sone) *Flovent®*

Glucocorticoid, Inhaled

Prescriber Highlights
- ► Glucocorticoid used most commonly in veterinary medicine as an inhaled aerosol as local treatment of a condition while minimizing systemic adverse effects
- ► Has shown efficacy in the treatment of feline asthma, as well as chronic inflammatory airway disease in dogs and horses
- ► Adverse effects include possible suppression of HPA axis and secondary nasal demodicosis.
- ► Must be used with a species-appropriate delivery device
- ► Expense may be an issue.

Uses/Indications
The inhaled aerosol formulation of fluticasone is used for treatment of canine chronic bronchitis, feline asthma and chronic bronchitis, and equine asthma. The optimal dosing of inhaled corticosteroids is unknown, and currently there are no studies specifically showing any advantages of inhaled corticosteroids over oral prednisolone in dogs and cats with naturally occurring airway disease.[1] In an 8-week study in cats (n = 9) with naturally occurring lower airway disease that compared oral prednisolone with fluticasone administered via inhalation twice daily, the authors concluded both treatments were effective in eliminating clinical signs and reducing airway eosinophilia; oral glucocorticoids were associated with more robust improvement in airway resistance and static compliance.[2]

The authors in one study[3] concluded that the benefits of using inhaled corticosteroids in the treatment of severe equine asthma (SEA) include a more rapid effect on lung function and airway smooth muscle remodeling as compared with antigen avoidance alone, without inducing detectable adverse effects with prolonged use. However, antigen avoidance leads to better control of inflammation and has additional beneficial effects on pulmonary function of inhaled corticosteroid-treated horses, even when clinical signs are apparently controlled by medication.

Pharmacology/Actions
Like other glucocorticoids, fluticasone has potent anti-inflammatory activity. Fluticasone has an affinity 18 times more than dexamethasone for human glucocorticoid receptors.[4] In a feline study, inhaled fluticasone significantly reduced airway eosinophilia.[5] For a more thorough discussion of glucocorticoid effects, refer to ***Glucocorticoid Agents, General Information***.

Pharmacokinetics
In humans administered inhaled fluticasone aerosol via the lungs, ≈30% is absorbed into systemic circulation; a dose of 880 µg showed peak plasma concentrations of 0.1 to 1 ng/mL. Volume of distribution averages 4.2 L/kg and is 91% bound to plasma proteins. Fluticasone is metabolized via CYP 3A4 isoenzymes to a metabolite with negligible pharmacologic activity. Following IV administration, terminal elimination half-life is ≈8 hours, with most of the drug excreted in the feces as parent drug and metabolites.

Medication administered via metered-dose inhalers was confirmed to deposit in the respiratory tract of dogs breathing tidally both with and without sedation; significantly more drug is deposited with nebulization.[6]

Contraindications/Precautions/Warnings
Fluticasone is contraindicated in patients hypersensitive to it, and is not indicated for treatment of acute bronchospasm (eg, status asthmaticus); cases of fluticasone-induced paradoxical bronchospasm have been reported in humans.[4]

When transitioning patients from systemic steroid therapy to inhaled steroids, wean slowly off systemic therapy to avoid acute adrenal insufficiency. During this transition period, patients should receive supplemental systemic steroid therapy during periods of acute stress or if severe asthma attacks occur during the withdrawal stage.

Adverse Effects

In humans, the most likely adverse effects are pharyngitis and upper respiratory infection. Although inhaled steroids generally cause significantly fewer adverse effects than injectable or oral therapy, suppression of the HPA axis can occur.

One study comparing ACTH-stimulated cortisol concentrations in healthy beagles, found that inhaled budesonide did not significantly affect cortisol concentrations, but oral prednisolone 1 mg/kg/day and inhaled fluticasone 250 µg twice daily did have a significant effect on cortisol concentrations after 35 days of treatment.[7] Evidence of pituitary-adrenal axis inhibition was identified in 2 dogs; 1 dog developed signs of iatrogenic hyperadrenocorticism (eg, weight gain, PU/PD, alopecia, skin thinning, abdominal distension, hepatomegaly, panting).[8]

A study in cats given different dosages of inhaled fluticasone did not show significant HPA axis suppression at 44 µg, 110 µg, or 220 µg every 12 hours.[5] Cats treated with inhaled corticosteroids may develop localized demodicosis on the muzzle/nasal planum.[9,10]

Another study in horses demonstrated that long-term inhaled fluticasone did not cause detectable effects on innate and adaptive (both humoral and cell-mediated) immune parameters studied.[11] Suppression of serum cortisol has been documented in horses treated long-term with inhaled fluticasone.[12]

Reproductive/Nursing Safety

Fluticasone given SC to laboratory animals caused a variety of teratogenic effects, including growth delays, cleft palate, omphalocele, and delayed cranial ossification.[4] See ***Glucocorticoid Agents, General Information.***

It is not known if the drug enters maternal milk; use with caution in nursing dams.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

An acute overdose of this medication is unlikely, but there have been reported cases of dogs puncturing canisters of albuterol and developing adverse effects. A similar occurrence with fluticasone would unlikely require treatment. Chronic overdoses could result in significant HPA axis suppression and adverse effects related to iatrogenic hyperadrenocorticism.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

Although the manufacturer states that due to the low systemic plasma concentrations associated with inhalational therapy clinically significant drug interactions are unlikely, use caution when fluticasone is used in conjunction with other drugs that can inhibit CYP3A4 isoenzymes (eg, **ketoconazole**); theoretically, fluticasone concentrations could be increased.

Laboratory Considerations

- **Intradermal skin testing** (IDST) for allergens: A related inhaled corticosteroid (ie, budesonide) in cats (for 1 month) eliminated skin reactivity in 3 out of 6 cats tested.[13] The authors suggested a 2-week withdrawal if using IDST, but withdrawal may not be necessary if using serum IgE testing for allergies. This same effect may apply to inhaled fluticasone.

Dosages

NOTES:

1. Optimal dosing of inhaled corticosteroids is unknown, and there have been no studies specifically demonstrating advantages of inhaled glucocorticoids over oral prednisone/prednisolone in patients with naturally occurring airway disease.
2. When using inhalant therapy, dogs and cats must take 7 to 10 breaths (3 to 5 breaths for horses) (with the appropriate delivery device [eg, *AeroDawg*, *AeroKat*, *AeroHippus*] still placed) after each time the metered dose inhaler (MDI) has been actuated to ensure the maximal dose is inhaled.

DOGS:

NOTE: Most commonly, when starting fluticasone, oral glucocorticoid therapy is continued for 10 to 14 days with a tapering overlap.[14]

Adjunctive treatment for chronic tracheobronchial disease (extra-label): Using 110 – 220 µg/puff MDI, administer 1 puff 2 to 4 times daily via an appropriate delivery device.[15-17] Adjust dose based on clinical response.

Eosinophilic bronchopneumopathy (extra-label): 100 – 250 µg/puff MDI twice daily[8,15]; dose can be adjusted based on clinical response.

CATS:

NOTE: Most commonly, when starting fluticasone, oral glucocorticoid therapy is continued for 10 to 14 days with a tapering overlap.[14]

Chronic bronchitis, feline asthma (extra-label):

1. Initially, 44 µg/puff or 110 µg/puff MDI, 1 puff every 12 hours[5]
2. 110 µg/puff MDI, 1 puff twice daily. Cats with more serious disease may require fluticasone 220 µg MDI.[18,19]
3. 250 µg MDI once daily[20] (**NOTE**: In the United States, the 250 microgram/puff concentration is labeled as 220 µg/puff; see ***Dosage Forms***)

Feline idiopathic chronic rhinitis; (extra-label): 220 µg/puff MDI, 2 puffs every 12 hours in combination with oral prednisolone. Once fluticasone therapy has been comfortably implemented, begin dose reductions of oral prednisolone (typically, 25% every 2 weeks) while monitoring clinical signs.[21,22]

HORSES:

Severe equine asthma (SEA; formerly known as recurrent airway obstruction [RAO], heaves; extra-label):

1. 2000 µg MDI every 12 hours for 1 month, then adjust dosages (2000 – 3000 µg every 12 to 24 hours) to control clinical signs[3,11]
2. 6000 µg MDI every 12 hours *prevented* acute exacerbations of SEA but did not treat acute SEA exacerbations as well as dexamethasone IV.[23]

Monitoring

- Efficacy: control of cough and/or other respiratory signs (eg, exercise intolerance, tachypnea, wheezing)
- Clinical signs of iatrogenic hyperadrenocorticism (eg, polyuria/polydipsia, polyphagia)

Client Information

- Shake the inhaler well before using. Do not puncture or incinerate the can. This product must be used with a spacer device appropriate for the species being treated.
- When using inhaled fluticasone with an appropriate spacer/facemask (eg, *AeroDawg, AeroKat*) in dogs and cats, the following tips

have been recommended[24]:

1. Allow the cat to get used to the device over several days, letting it investigate (eg, leaving the device by food bowl).
2. Reward (ie, praise, food, catnip, stroking) fearless approaches to the device, and start placing it near the cat's face.
3. Practice putting the mask over the cat's face without anything in the chamber.
4. Make sure the mask is placed snugly over the muzzle.
5. With the mask on, actuate the MDI and allow the animal to take 7 to 10 breaths before removing.
6. Container will last ≈2 months when used at 1 puff twice per day.

- When using inhaled fluticasone with an appropriate spacer/facemask (eg, *AeroHippus*) in horses, the following tips have been recommended:
  1. Slowly introduce the *AeroHippus* Chamber. Start with the mask only, getting your horse used to the feel of it.
  2. Reward your horse with treats before and/or after treatment.
  3. If your horse does not respond well to the sound of the inhaler, depress the inhaler behind your back before bringing the *AeroHippus* Chamber forward and placing mask over horse's nostril.
  4. With the mask over the nostril, allow the horse to take 3 to 5 breaths for each puff (actuation) from the MDI.

Chemistry/Synonyms

Fluticasone propionate, a trifluorinated glucocorticoid, occurs as a white to off-white powder that is practically insoluble in water and slightly soluble in ethanol.

Fluticasone may also be known as CCI-18781, fluticasoni propionas, *Advair Diskus®*, *Cutovate®*, *Flixotide®*, *Flixonase®*, *Flovent®*, and *Flutivate®*.

Storage/Stability

Fluticasone propionate aerosol for inhalation (*Flovent® HFA*) should be stored between 59°F to 86°F (15°C to 30°C); protect from freezing and direct sunlight, and do not store near heat or open flame. Store canister with the mouthpiece down.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

NOTE: The Association of Racing Commissioners International (ARCI) has designated fluticasone as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Fluticasone Propionate Aerosol for Inhalation: 44 µg/actuation, 110 µg/actuation, and 220 µg/actuation in 10.6-g and 12-g canisters with actuator. Each canister contains 120-metered inhalations; *Flovent® HFA*; (Rx). **NOTE**: In countries outside the United States, *Flovent® HFA* canister concentrations may be listed as 50 µg, 125 µg, and 250 µg per actuation; the difference in labeling relates to where the drug concentration is measured (eg, metering valve [eg, 50 µg] vs actuator nozzle [44 µg]). There are also breath-activated dry powder inhalers (ie, *Flovent® Diskus*, *Advair Diskus®* [with salmeterol]), but they are not suitable for veterinary use.

Fluticasone is also available commercially in combination as:

Fluticasone Propionate/Salmeterol Aerosol for Inhalation: fluticasone propionate 45 µg/salmeterol 21 µg/actuation; fluticasone propionate 115 µg/salmeterol 21 µg/actuation; and fluticasone propionate 230 µg/salmeterol 21 µg/actuation equivalent to salmeterol xinafoate 30.45 µg in 12-g pressurized canisters containing 120-metered inhalations.

Nasal solutions, topical creams, and ointments containing fluticasone are also available.

Fluvoxamine

(floo-***vox***-a-meen) *Luvox®*

Selective Serotonin Reuptake Inhibitor (SSRI)

Prescriber Highlights

- ► Uncommonly used selective serotonin reuptake inhibitor (SSRI) antidepressant similar to fluoxetine; can be used in dogs and cats for a variety of behavior disorders, but little information available to recommend its use in place of more commonly prescribed SSRIs
- ► Contraindications include patients with known hypersensitivity or who are receiving monoamine oxidase inhibitors (MAOIs).
- ► Use with caution in patients with severe cardiac, renal, or hepatic disease; dosages may need to be reduced in patients with severe renal or hepatic impairment.
- ► May take up to 8 weeks before efficacy can be fully assessed
- ► Adverse effect profile not well established. Possible adverse effects in dogs include anorexia, lethargy, GI effects, anxiety, irritability, insomnia, hyperactivity, or panting, as well as aggressive behavior in previously nonaggressive dogs. Cats may exhibit sedation, decreased appetite/anorexia, vomiting, diarrhea, behavior changes (eg, anxiety, irritability, sleep disturbances), and changes in elimination patterns.
- ► Many possible drug interactions. Coadministration of more than one serotonergic drug is not recommended due to the risk for the development of serotonin syndrome.

Uses/Indications

Fluvoxamine may be considered for use in treating a variety of behavior-related disorders in dogs and cats, including aggression and stereotypic behaviors (and other obsessive-compulsive behaviors). Because of a lack of published information documenting its safety and efficacy in animals, it is not commonly prescribed.

Pharmacology/Actions

Fluvoxamine is a highly selective inhibitor of the reuptake of serotonin in the CNS, thereby potentiating the pharmacologic activity of serotonin. Fluvoxamine has little effect on dopamine or norepinephrine and apparently no effect on other neurotransmitters.

Pharmacokinetics

There are limited data on the pharmacokinetics of fluvoxamine in domestic animals. In dogs, fluvoxamine appears to be completely absorbed; only about 10% of a dose is excreted unchanged in the urine.[1,2] The half-life appears to be similar to humans (15 hours).[1] No pharmacokinetic information for cats was located.

In humans, fluvoxamine is absorbed after oral administration, but bioavailability is only around 50%. Peak plasma concentrations occur between 3 and 8 hours postdose. Food does not appear to affect the absorptive characteristics of the drug. Fluvoxamine is widely distributed in the body and about 80% bound to plasma proteins. The drug is extensively metabolized in the liver to nonactive metabolites

and eliminated in the urine. The plasma half-life is about 15 hours.

Contraindications/Precautions/Warnings

Fluvoxamine is contraindicated in patients hypersensitive to it or any selective serotonin reuptake inhibitor (SSRI) or if the patient is receiving a monoamine oxidase inhibitor (MAOI) or cisapride. Consider using a lower dosage in patients with hepatic impairment or in geriatric patients.

Do not confuse FLUVoxamine with fluOXetine.

Adverse Effects

The adverse effect profile of fluvoxamine in dogs or cats has not been well established. In dogs, selective serotonin reuptake inhibitors (SSRIs) can cause lethargy, adverse GI effects, anxiety, irritability, insomnia/hyperactivity, or panting. Anorexia is a common adverse effect in dogs, which is usually transient and may be negated by temporarily increasing the palatability of food and/or hand feeding. Some dogs have persistent anorexia that precludes further treatment. Aggressive behavior in previously nonaggressive dogs has been reported. SSRIs in cats can cause sedation, decreased appetite/anorexia, vomiting, diarrhea, behavior changes (eg, anxiety, irritability, sleep disturbances), and changes in elimination patterns.

In humans, common adverse reactions (greater than 10%) include sexual adverse effects (eg, abnormal ejaculation, anorgasmia), agitation/nervousness, insomnia, nausea, dry mouth, constipation/diarrhea, dyspepsia, dizziness, headache, and somnolence. Hyponatremia and abnormal bleeding also have been noted.

Reproductive/Nursing Safety

In rats, fluvoxamine reportedly increased embryofetal death and pup mortality at birth and was associated with fetal abnormalities and decreased birth weights.[3]

Although fluvoxamine enters maternal milk, it is not expected to cause adverse effects to the offspring.[4]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited data exist for animals. Reportedly, any dose over 10 mg/kg can cause tremors and lethargy. A case of a dog developing clinical signs (CNS depression) after ingesting 1.5 mg/kg has been reported.[5] Other signs associated with overdoses may include nausea, salivation, vomiting, diarrhea, hypotension, heart rate and rhythm disturbances (bradycardia/tachycardia, ECG changes), hyperthermia, tremors, ataxia, muscle rigidity, somnolence/coma, and seizures.[6]

Fatalities have been reported in human overdoses; the highest reported dose where the patient survived was 10,000 mg. Treatment recommendations include standard protocols for drug adsorption and removal from the GI tract for potentially dangerous overdoses and supportive care based on clinical signs. Serotonin effects may be negated somewhat by administration of cyproheptadine. See ***Cyproheptadine***. Seizures or other neurologic signs may be treated with diazepam. See ***Diazepam***.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fluvoxamine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Benzodiazepines** (eg, **alprazolam, diazepam, midazolam**): May increase benzodiazepine concentrations
- **Buspirone**: May paradoxically decrease the clinical efficacy of buspirone and increase the risk for serotonin syndrome
- **Cisapride**: Fluvoxamine may increase plasma concentrations of cisapride, leading to toxicity.
- **Cyproheptadine**: May decrease or reverse the effects of selective serotonin reuptake inhibitors (SSRIs)
- **Diltiazem**: May increase the effects of diltiazem; bradycardia has been reported in humans taking this drug combination.
- **Fentanyl**: May increase the risk for serotonin syndrome
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid**, **selegiline**): High risk for serotonin syndrome; use together is contraindicated. In humans, a 5-week washout period is required after discontinuing fluvoxamine and a 2-week washout period if the MAOI is discontinued first.
- **Methadone**: May increase plasma concentrations of methadone, leading to toxicity; concurrent use may increase the risk for serotonin syndrome.
- **Metoclopramide**: May enhance adverse/toxic effects of SSRIs and increase the risk for serotonin syndrome
- **Mexiletine**: SSRIs may decrease the metabolism of mexiletine.
- **Propranolol, Metoprolol**: Fluvoxamine may increase these beta-blockers' plasma levels; atenolol may be safer to use if fluvoxamine is required.
- **Serotonergic Agents** (eg, **mirtazapine, ondansetron, trazodone**): Concurrent use may increase the risk for serotonin syndrome.
- **Theophylline, Aminophylline**: May increase plasma concentrations of theophylline
- **Tramadol**: SSRIs can inhibit the metabolism of tramadol to the active metabolites, thereby decreasing its efficacy and increasing the risk for toxicity (serotonin syndrome, seizures).
- **Tricyclic Antidepressants** (**TCAs**; eg, **amitriptyline, clomipramine**): May increase TCA blood concentrations and increase the risk for serotonin syndrome
- **Warfarin**: Fluvoxamine may increase the risk for bleeding.

Laboratory Considerations

- No fluvoxamine-related laboratory interactions were noted.

Dosages

NOTE: Fluvoxamine is available commercially as both regular tablets and extended-release capsules. Although the contents of the extended-release capsules could be compounded into smaller strengths for use in veterinary patients, there does not appear to be any information available to support this practice.

DOGS:

Adjunctive treatment of behavioral disorders (extra-label): 1 – 2 mg/kg PO once daily.[7] Treatment for 3 to 8 weeks may be required before assessing efficacy. If discontinuing therapy after this time, wean off over several weeks.

CATS:

Adjunctive treatment of behavioral disorders (extra-label): 0.25 – 0.5 mg/kg PO once daily.[7] Treatment for 3 to 8 weeks may be required before assessing efficacy. If discontinuing therapy after this time, wean off over several weeks. The smallest practical dosage available (without compounding) is ¼ of a 25 mg tablet (≈6 mg), which may be too high for the suggested dosage listed above.

Monitoring

- Efficacy
- Adverse effects (eg, hyporexia/anorexia, lethargy, and monitor for signs of serotonin syndrome [eg, nausea, vomiting, mydriasis, hy-

persalivation, and hyperthermia])

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give the medicine with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- This medication is most effective when used with a behavior modification program. It may take several days to weeks to determine if the medicine is working.
- Do not stop this medication abruptly without talking to your veterinarian first.
- The most common side effects of fluvoxamine are drowsiness/sleepiness and decreased appetite. Rarely, more serious side effects (eg, seizures, aggression) may occur. Contact your veterinarian immediately if these signs occur.
- Overdoses can be very serious. Keep this and all other medicines out of the reach of animals and children.
- If your animal has worn a flea and tick collar in the past two weeks, let your veterinarian know. Do not use one on your animal while it's getting this medicine without first talking to your veterinarian.

Chemistry/Synonyms

Fluvoxamine maleate is a selective serotonin reuptake inhibitor (SSRI) that occurs as a white to almost white crystalline powder. It is freely soluble in alcohol and sparingly soluble in water.

Fluvoxamine may also be known as DU-23000, desifluvoxamin, and *Luvox*®.

Storage/Stability

Store the commercially available tablets and extended-release capsules in tight, light-resistant containers at room temperatures 20°C to 25°C (68°F-77°F); excursions permitted to 15°C to 30°C (59°F-86°F); protect from high humidity.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 2 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering a competition while this medication is being administered. Contact local racing authorities for further guidance. See the ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Fluvoxamine Oral Tablets: 25 mg, 50 mg, and 100 mg; generic; (Rx)

Fluvoxamine Oral Extended-release (24-hour for humans) Capsules: 100 mg and 150 mg; *Luvox CR*®, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Folic Acid

Folate, Folacin, Vitamin B_9

(***foe***-lik ***ass***-id)

B Vitamin

Prescriber Highlights

- ► B vitamin necessary for nucleoprotein synthesis and normal erythropoiesis.
- ► Used for oral and parenteral treatment of folic acid (vitamin B_9) deficiency caused by small intestinal inflammatory disease, chronic administration of dihydrofolate reductase inhibitor drugs, or dietary deficiency.

Uses/Indications

Folic acid is used to treat folic acid deficiency in dogs, cats, horses, and other animal species, often due to small intestinal disease. GI malabsorption may lead to low serum folate concentrations, although hypocobalaminemia is more common than hypofolatemia in dogs and cats with chronic small intestinal disease or exocrine pancreatic insufficiency.[1,2] The incidence of clinically significant folic acid deficiency is unknown, although an association between hypofolatemia and hyperhomocysteinemia has been demonstrated in greyhounds.[3] Chronic administration of dihydrofolate reductase inhibiting drugs, such as pyrimethamine, ormetoprim, or trimethoprim, can lead to reduced activated folic acid (tetrahydrofolic acid); folic acid supplementation may be prescribed to prevent or treat hypofolatemia in these cases. Folic acid supplementation during pregnancy has been shown to reduce the occurrence of lip and/or palate cleft in pug and Chihuahua puppies,[4] but similar results were not observed in a colony of guide dogs.[5]

Pharmacology/Actions

Folic acid is required for several metabolic processes. It is reduced via dihydrofolate reductase in the body to tetrahydrofolate (5-methyltetrahydrofolate), which acts as a coenzyme in the synthesis of purine and pyrimidine nucleotides necessary for DNA synthesis. Folic acid is also required for the maintenance of normal erythropoiesis.

Pharmacokinetics

Folic acid is primarily absorbed in the proximal small intestine via carrier-mediated diffusion. In humans, synthetic folic acid is nearly completely absorbed after oral administration, while bioavailability of folate from dietary sources is about 50%. Peak concentrations are reached within 1 hour. Folic acid is converted to its active form, tetrahydrofolic acid, principally in the liver and plasma. Folate is distributed widely throughout the body and stored in the liver. Erythrocyte and CSF concentrations can be significantly higher than those found in serum. It can undergo enterohepatic recirculation and is excreted primarily in the urine either as metabolites or unchanged drug when administered in excess of body requirements.

Contraindications/Precautions/Warnings

Folic acid supplementation is contraindicated when known hypersensitivity to the drug is documented. In humans, cobalamin (B_{12}) levels may be reduced with megaloblastic anemias, and folic acid therapy may mask the signs associated with it. Folic acid supplementation should not be given until pernicious anemia (anemia associated with vitamin B_{12} deficiency) has been ruled out. As dogs may have increased, normal, or decreased folate levels associated with enteropathies, do not administer therapeutic doses until folate and cobalamin levels have been determined.

Parenteral products may contain aluminum and/or benzyl alcohol.

Adverse Effects

Folic acid has a wide safety margin and should not cause significant

adverse effects. Rarely in humans, folic acid tablets or injections have reportedly caused hypersensitivity reactions or GI effects. Very high oral doses in humans (15 mg/day) have occasionally caused CNS effects (eg, difficulty sleeping, excitement, confusion).

Reproductive/Nursing Safety

Folic acid is safe to use during pregnancy. In humans, it is routinely prescribed as part of prenatal vitamin supplementation as folate deficiency can increase the risk for fetal neural tube defects.

Folic acid is distributed into milk but is safe. Folic acid requirements may be increased in lactating animals.

Overdose/Acute Toxicity

Folic acid is relatively non-toxic, and no treatment should be required if an inadvertent overdose occurs. The excess drug is metabolized or rapidly excreted unchanged in the urine.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving folic acid and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Chloramphenicol**: May delay response to folic acid
- **Methotrexate, Trimethoprim, Ormetoprim, Pyrimethamine** (drugs that inhibit dihydrofolate reductase): May interfere with folic acid utilization
- **Phenobarbital**: May decrease phenobarbital serum levels; monitor therapy.
- **Primidone**: May increase risk for folate deficiency
- **Sulfasalazine, Primidone**: May increase risk for folate deficiency

Laboratory Considerations

- **Serum samples** to be analyzed for cobalamin and/or folate should be protected from bright light and excessive heat.
- **Hemolysis** can cause falsely elevated serum concentrations of folate.
- Decreased **serum cobalamin levels** (B_{12}) can occur in patients receiving prolonged folic acid supplementation.

Dosages

DOGS/CATS:

Folate deficiency associated with inflammatory bowel disease and pancreatic insufficiency (extra-label): Dosage recommendations vary, and there is little evidence to support any specific dosage recommendation. Suggested PO dosages for small animal species generally range from 400 µg to 1 mg/dog or cat (NOT mg/kg) once daily, although doses of 2 – 5 mg/dog (NOT mg/kg) PO once daily have been noted. When used for IBD, many recommend using with cobalamin (B_{12}).

Cats on long-term use of high dose sulfa-/trimethoprim (for treating *Nocardia* spp infections) (extra-label): 2 mg/cat (NOT mg/kg) PO once daily has been recommended.[6]

HORSES:

Prolonged therapy with antifolate medications (eg, trimethoprim, pyrimethamine); (extra-label): Some recommend folic acid at 20 – 40 mg/horse (NOT mg/kg) PO daily. Pregnant mares should routinely receive folic acid supplementation during treatment with antifolates.[7]

RABBITS:

Deep vein thrombosis (extra-label): Folic acid (vitamin B_9) 15 mg/rabbit (NOT mg/kg) in combination with cobalamin (vitamin B_{12}) 500 µg/rabbit (NOT µg/kg) PO once daily.[8] High levels of cobalamin (vitamin B_{12}) and folic acid (vitamin B_9) can improve plasma hyperhomocysteinemia, coagulation indexes, and some pathologic changes seen in deep vein thrombosis of the lower extremity.

Monitoring

- Small animal species: serum folate and cobalamin levels before, during, and after treatment
- Clinical signs associated with folate deficiency
- Baseline and periodic CBC

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after receiving the medication on an empty stomach, give with food or a small treat. If vomiting continues, contact your veterinarian.
- When used to treat folate deficiency associated with a small intestinal disease or pancreatic insufficiency, lifelong monitoring and periodic replacement therapy may be required. Do not miss important follow-up visits with your veterinarian.

Chemistry/Synonyms

Folic acid occurs as a yellow, yellow-brownish, or yellowish-orange, odorless crystalline powder. It is very slightly soluble in water and insoluble in alcohol. Commercially available folic acid is obtained synthetically.

Folic acid may also be known as folate, folacin, vitamin B_9, acidumfolicum, pteroylglutamic acid, pteroylmonoglutamic acid, *Folvite®*, and vitamin B_{11}.

Storage/Stability

Store folic acid tablets in well-closed containers between 20°C and 25°C (68°F and 77°F); protect from light and moisture. Store the injection protected from light between 20°C and 25°C (68°F and 77°F). Do not freeze.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

To compound a 1 mg/mL oral solution, bring 90 mL of purified water to near boiling. Dissolve methylparaben 200 mg and propylparaben 20 mg in the heated water. Allow it to cool to room temperature. Crush one hundred 1 mg tablets and dissolve in the solution. Using sodium hydroxide 10%, adjust pH to 8 to 8.5, *qs ad* to 100 mL with purified water, and mix well. The solution is stable for 30 days at room temperature.[9]

To compound a 0.05 mg/mL folic acid oral solution, mix 1 mL of injectable folic acid (5 mg/mL) with 90 mL of purified water. Using sodium hydroxide 10%, adjust pH to 8 to 8.5, *qs ad* to 100 mL with purified water, and mix well. The solution is stable for 30 days at room temperature.[10]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None, but there are many available products containing folic acid. If using one of these products, verify the folic acid content is enough to treat folate deficiency without overdosing fat-soluble vitamins (A, D, E, K).

HUMAN-LABELED PRODUCTS:

Folic Acid Tablets: 0.4 mg, 0.8 mg, and 1 mg; generic; (OTC); 1 mg; generic; (Rx).

Folic Acid Capsules: 0.8 mg, 5 mg, and 20 mg; generic; (OTC).

Folic Acid Injection: 5 mg/mL in 10 mL vials; generic; (Rx).

For the complete list of references, see **wiley.com/go/budde/plumb**

Fomepizole

4-Methylpyrazole (4-MP)

(foe-***me***-pi-zole) *Antizol-Vet®*

Antidote

Prescriber Highlights

- ► Synthetic alcohol dehydrogenase inhibitor used to treat dogs and cats with ethylene glycol toxicosis
- ► Has been shown to be efficacious in dogs if treated within 8 hours of ethylene glycol ingestion, and in cats at high dosages if given within 3 hours of ethylene glycol ingestion
- ► Monitor and treat acid/base, fluid, and electrolyte imbalances
- ► May inhibit or exacerbate elimination of ethanol
- ► Expensive and limited availability

Uses/Indications

Fomepizole (4-methylpyrazole; 4-MP) is used for the treatment of known or suspected ethylene glycol toxicosis in dogs if given within 8 hours of ingestion.[1] At high doses, it may be efficacious in treating recent ingestion (within 3 hours) of ethylene glycol in cats.[2,3] Ethanol treatment has previously been recommended as the drug of choice for ethylene glycol toxicosis in cats, but high-dose fomepizole was more effective.[3]

Pharmacology/Actions

Ethylene glycol is metabolized primarily by alcohol dehydrogenase into glycoaldehyde, which in turn forms glycolate, glyoxalic acid, and oxalic acid. The metabolic acidosis and renal tubular necrosis that result from these compounds can be fatal. Fomepizole is a competitive inhibitor of alcohol dehydrogenase, which allows ethylene glycol to be excreted, primarily unchanged, in the urine, decreasing the morbidity and mortality associated with ethylene glycol ingestion.

Pharmacokinetics

Fomepizole exhibits a dose-dependent accumulation over time due to saturable elimination; therefore, a reduction in subsequent doses can safely occur.

Contraindications/Precautions/Warnings

There are no labeled contraindications to fomepizole's use. In dogs, fomepizole treatment may be successful as late as 8 hours postingestion, but if azotemia is noted, treatment is less successful, and the prognosis is poor. Treatment should still be considered up to 36 hours postingestion, as fomepizole can potentially prevent further renal damage and some dogs may survive with dialysis and supportive therapy.[1]

Fomepizole has been shown to be effective in treating ethylene glycol toxicosis in cats, but a higher dose is required (6 times the dose in dogs or humans) and treatment should be started within 3 hours of ethylene glycol ingestion.[2,3]

Use of fomepizole alone without adequate monitoring and adjunctive supportive care (eg, correction of acid/base, fluid, and electrolyte imbalances) may lead to therapeutic failure; however, as fomepizole may increase serum bicarbonate (HCO_3), it has been recommended that correction of severe metabolic acidosis in cats, and presumably dogs, be treated with appropriate IV fluid therapy and fomepizole before consideration of HCO_3 administration.[4] If the animal is presented within 1 to 2 hours of ethylene glycol ingestion, consider inducing emesis and/or gastric lavage with activated charcoal to prevent further absorption.

Fomepizole does not prevent the CNS depression caused by unmetabolized ethylene glycol and could prolong it.

Adverse Effects

Fomepizole appears to be well tolerated. Cats receiving high-dose fomepizole may experience mild sedation.[3] Giving concentrated drug by rapid IV infusion may cause phlebitis and phlebosclerosis. Dilute as directed according to label instructions.

During clinical trials, one dog developed anaphylaxis.[1]

Cats may develop mild sedation, ataxia, and hypothermia when receiving fomepizole. Breath and urine may have the distinctive smell of fomepizole up to a week after dosing.[3]

Fomepizole may increase serum bicarbonate concentrations in dogs and cats. See ***Contraindications/Precautions/Warnings***.

Reproductive/Nursing Safety

Fomepizole's safe use during pregnancy, lactation, or in breeding animals has not been established; however, because of the morbidity and mortality associated with ethylene glycol toxicosis, the benefits of fomepizole generally outweigh its risks.

It is not known whether this drug is excreted in milk. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Overdoses may cause significant CNS depression. Monitor closely and treat supportively. Fomepizole is dialyzable.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fomepizole and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Ethanol**: Fomepizole inhibits alcohol dehydrogenase; ethanol metabolism is reduced significantly and alcohol poisoning (eg, CNS depression, coma, death) can occur. Use together is generally not recommended, but if both drugs are used, monitoring of ethanol blood concentration is mandatory.

Laboratory Considerations

Ethylene Glycol Testing Kits: Fomepizole may cause false readings on ethylene glycol screening tests. Refer to the product used for more information.

Dosages

NOTES:

1. A non-polycarbonate syringe must be used to withdraw fomepizole from the vial.
2. In humans, the drug should be diluted in at least 100 mL of 0.9% sodium chloride or 5% dextrose and infused over 30 minutes.[5] It is assumed these are relevant to veterinary patients.

DOGS:

Ethylene glycol toxicosis (extra-label): Initially, fomepizole 20 mg/kg IV; 12 hours after the initial dose, give 15 mg/kg IV; 24 hours after initial dose, give another 15 mg/kg IV; and 36 hours after initial dose, give 5 mg/kg IV; may give additional 5 mg/kg IV doses as necessary (eg, if animal has not recovered or has additional ethylene glycol in blood).[6]

CATS:

Ethylene glycol toxicosis (extra-label): Evidence from an experimental study and naturally occurring ethylene glycol intoxication (3 cats). Initially, 125 mg/kg slow IV; then at 12, 24, and 36 hours

after initial dose, give 31.25 mg/kg IV. In addition, treat supportively with supplemental IV fluids. Cats must be treated within 3 hours of ingestion. Cats that began treatment 4 hours after ethylene glycol ingestion had 100% mortality with either fomepizole or ethanol therapy.[3,4]

Monitoring

- Baseline ethylene glycol blood concentration to document diagnosis followed by intermittent testing to determine if therapy can be discontinued after 36 hours of treatment
- Hydration status
- Urine output
- Renal function tests (eg, BUN, serum creatinine, urinalysis)
- Blood gases and serum electrolytes
- Cats: body temperature

Client Information

- Clients should be informed that treatment of serious ethylene glycol toxicosis is an intensive care admission, and appropriate monitoring and therapy can be quite expensive, particularly when fomepizole is used in large dogs.
- Because time is critical, clients will need to make an informed decision rapidly. Dogs treated within 8 hours of ingestion have a significantly better prognosis than those treated after 10 to 12 hours. Cats must be treated within 3 hours of ingestion.

Chemistry/Synonyms

A synthetic alcohol dehydrogenase inhibitor, fomepizole is commonly called 4-methylpyrazole (4-MP). Its chemical name is 4-methyl-1H-pyrazole. It has a molecular weight of 81; it is soluble in water and highly soluble in ethanol.

Fomepizole may also be known as: 4-methylpyrazole, 4-MP, fomepisol, fomepizolum, and *Antizol®*.

Storage/Stability

Commercially available solutions should be stored at room temperature. The concentrate for injection may solidify at temperatures less than 25°C (77°F). Should this occur, resolubolize by running warm water over the vial. Solidification or resolubolization does not affect drug potency or stability.

Store reconstituted vials at room temperature and discard after 72 hours.

Compatibility/Compounding Considerations

Fomepizole diluted in 5% dextrose or 0.9% sodium chloride injection is stable for at least 24 hours when stored at room temperature or refrigerated.[5]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None. *Antizol-Vet®* was withdrawn from the US market in 2015.

HUMAN-LABELED PRODUCTS:

Fomepizole Injection Concentrate: 1 g/mL in 1.5 mL vials; *Antizol®*, generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Fosfomycin

(fos-foe-***my***-sin) *Monurol®*

Phosphonic Acid Antimicrobial

Prescriber Highlights

- ► Uncommonly used in dogs for treatment of multidrug-resistant bacterial UTIs; may be useful for systemic infections with some multidrug-resistant bacteria, but data supporting clinical use are lacking.
- ► Nephrotoxic in cats; do not use in this species.
- ► Adverse effects in dogs are primarily GI related (eg, diarrhea, anorexia).

Uses/Indications

Fosfomycin is an antibacterial agent that may be useful for treating multidrug-resistant UTIs in dogs; use should be limited to infections with documented resistance to other antibiotics and involving bacterial species typically susceptible to fosfomycin.[1] It may also be useful for other multidrug-resistant genitourinary infections (eg, prostatitis), although data and experience are limited.[1]

The World Health Organization (WHO) has designated fosfomycin as a Critically Important (High Priority) antimicrobial in human medicine.[2] The Office International des Epizooties (OIE) has designated fosfomycin as a Veterinary Highly Important Antimicrobial Agent in avian, bovine, and swine species.[3]

Pharmacology/Actions

Fosfomycin is a synthetic phosphonic acid derivative antibacterial agent. It irreversibly inhibits bacterial phosphoenolpyruvate transferase, an enzyme that catalyzes the formation of uridine diphosphate-N-acetylmuramic acid, which is the first step of microbial cell wall peptidoglycan synthesis. Additionally, it reduces adherence of bacteria to uroepithelial cells.[4]

Fosfomycin is a time-dependent antibacterial agent.[5] At therapeutic dosages, this antibiotic is rapidly bactericidal in urine. It has generally good activity against *Escherichia coli, Enterococcus faecalis,* and *Proteus* spp, typically including strains that are resistant to many other antimicrobials. It can also be effective against other bacteria such as staphylococci, *Enterococcus faecium, Klebsiella* spp, and *Enterobacter* spp.

Cross-resistance apparently does not occur with beta-lactams or aminoglycosides. Acquired (plasmid-mediated) resistance is currently uncommon in most areas[6,7] but has been identified in humans and companion animals, with potential transfer between humans and companion animals.[8-10]

Pharmacokinetics

Fosfomycin tromethamine is rapidly converted to the free acid fosfomycin after absorption.[11] Fosfomycin is distributed into the kidneys, bladder wall, and prostate, and crosses the placenta. The primary route of elimination is as unchanged drug in urine (38% of an oral dose in humans).

In dogs, following oral administration of fosfomycin disodium (compounded product) peak concentration occurs at ≈2 hours, bioavailability is ≈29%, and terminal half-life is ≈2 hours.[12] In the same study, following IV administration of fosfomycin disodium to dogs the volume of distribution (steady-state) is ≈0.7 L/kg with minimal protein binding, and clearance is ≈15 mL/kg/hour.[12]

The commercially available oral product is the tromethamine salt. Dogs receiving 80 mg/kg PO of this product showed high (≈100%) oral bioavailability when it was given with food. Fasted bioavailability was lower and averaged 66%. Elimination half-life was ≈2.5 hours. Serum concentrations exceeded the MIC_{90} reported for multidrug-resistant *Escherichia coli* (1.5 µg/mL) for 12 hours.[5,13] In healthy dogs

receiving 80 mg/kg fosfomycin tromethamine PO, fosfomycin half-life in the urine was 10 hours, and urinary concentrations were above 660 micrograms/mL for the entire 12-hour observation window.[14]

In horses, SC bioavailability of fosfomycin disodium is ≈85%. Peak concentrations occur ≈3.25 hours after SC dosing. Mean volume of distribution (steady-state) is 0.21 L/kg; clearance is 16 to 24 mL/kg/hour; and terminal half-life is ≈1.3 hours.[15]

Contraindications/Precautions/Warnings

Fosfomycin is contraindicated in patients with a known hypersensitivity to this antibiotic.

Because fosfomycin has been documented to be nephrotoxic in cats, it should also be considered contraindicated in this species.[16,17] In one study, cats were given fosfomycin (as the calcium or sodium salt) 20 mg/kg PO or IV twice daily for 3 days, and all cats (n = 25) that were given the drug had significant increases in serum creatinine.[17] Tubular necrosis, disappearance of tubular cells, and rearrangement of eosinophilic nonstructural material were observed in the kidneys of all the treated cats.

In humans, renal impairment can substantially increase half-life and dose reductions are recommended.[18] No data are available for specific recommendations when using fosfomycin in veterinary patients with impaired renal function.

Do not confuse fosfomycin with aminoglycoside antibacterials (eg, gentamicin).

Adverse Effects

There is little information available on this drug's adverse effect profile in animals. Mild to moderate diarrhea is the most common adverse effect seen in dogs treated with fosfomycin[13]; anecdotally, hyporexia and anorexia have also been reported.

In humans, the most common adverse effect is diarrhea (9%), with vaginitis (5%), nausea (4%), and headache (4%) also reported.[11]

Reproductive/Nursing Safety

Fosfomycin crosses the placental barrier in humans. Teratogenic effects were not observed in rats receiving up to 1000 mg/kg.[11]

It is unknown if fosfomycin is distributed into milk following oral administration[11]; following IM injection in pregnant sows, fosfomycin was found in to cross into milk.[19]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In most species, overdoses would most likely cause GI effects. In dogs, single oral overdoses up to 5 g/kg caused diarrhea and anorexia 2 to 3 days after administration.[11]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving fosfomycin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Prokinetic Gastrointestinal (GI) Agents** (eg, **metoclopramide**): Can decrease serum and urine concentrations of fosfomycin.[11] Although no interactions have been reported, drugs that can increase GI motility (eg, **bethanechol, cisapride, domperidone, metoclopramide, ranitidine, laxatives**) may have a similar effect. Separating administration may help minimize interaction.

Laboratory Considerations

- No specific concerns noted

Dosages

DOGS:

Bacterial cystitis caused by multidrug-resistant bacteria documented to be resistant to other antibiotics and involving bacterial species with confirmed susceptibility to fosfomycin (extra-label): 40 – 80 mg/kg PO (with food) every 12 hours.[1,14] Treatment for 3 to 5 days is likely to be sufficient for most infections, although longer treatment (eg, 7-14 days) may be needed for persistent or relapsing infections.[1]

Tissue-associated infections (eg, prostatitis, pyelonephritis; extra-label): 40 mg/kg PO (with food) every 8 hours[1]

Monitoring

- Clinical efficacy: resolution of clinical signs associated with UTI[1]
- Recheck urinalysis and aerobic bacterial urine culture 5 to 7 days after cessation of antimicrobials[1]
- Adverse effects: GI signs (eg, diarrhea, loss of appetite)

Client Information

- There is little clinical experience with this drug in animals; report any possible side effects to your veterinarian immediately. The most common side effects are diarrhea and loss of appetite.
- It is important to give this medication exactly as prescribed and to complete the full course of therapy, even if your animal seems better. Missing doses or stopping treatment early may result in the treatment not working.
- Give this medicine to your animal with food.
- After your animal finishes taking this medicine, it is important to return to your veterinarian for recheck testing 5 to 7 days after the last dose. Do not miss this important follow-up visit.
- This medicine should not be given to cats.

Chemistry/Synonyms

Fosfomycin is an antibacterial agent originally isolated from *Streptomyces fradiae*, now exclusively produced by chemical synthesis. It occurs as a white or almost white, hygroscopic powder that is very soluble in water, slightly soluble in alcohol or methyl alcohol, and practically insoluble in acetone. A 5% solution in water has a pH of 3.5 to 5.5.

Fosfomycin may also be known as MK-955, phosphomycin, phosphonomycin, fosfomicina, fosfomycine, fosfomycinum, or fosfomysiini. Its chemical name is cis-1, 2-epoxyphosphonic acid.

Storage/Stability

Fosfomycin tromethamine granules should be stored at room temperature (25°C [77°F]) with excursions permitted to 15°C to 30°C (59°F-86°F).[11]

Compatibility/Compounding Considerations

To reconstitute, pour the entire contents of a single-dose sachet of fosfomycin into 90 to 120 mL of water (½ cup) and stir to dissolve. Do not use hot water. Fosfomycin should be taken immediately after dissolving in water.[11]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Fosfomycin Tromethamine 3 g per packet (for dilution and oral use); *Monurol*®; (Rx)[11]

Fosfomycin sodium for injection may be available in countries outside the United States.

Frunevetmab

(froo-neh-***vet***-mab) *Solensia®*

Feline antinerve growth factor monoclonal antibody

Prescriber Highlights

- ► Feline-specific biologic agent approved for the control of pain associated with osteoarthritis in cats
- ► Contraindications include hypersensitivity to it, breeding cats, and pregnant or lactating queens. Product is not intended for use in any other species.
- ► Appears to be well-tolerated. Injection site pain, injection site reactions, and GI effects are possible.
- ► Pregnant or breastfeeding women, as well as those trying to conceive, should exercise extreme caution to avoid accidental self-injection; use appropriate precautions when handling.

Uses/Indications

Frunevetmab is approved for the control of pain associated with osteoarthritis in cats.[1,2] A single injection provided significant pain relief and increased activity for up to 6 weeks in cats with degenerative joint disease.[3] Up to 76% of cats that received 3 doses of frunevetmab were considered a treatment success based on objective owner assessments.[4] The analgesic effect of frunevetmab became apparent ≈2 to 3 weeks after administration.[3–5]

It is unknown whether frunevetmab is effective or safe for use in cats with immune-mediated arthropathies or with pain from other causes (eg, visceral pain, orthopedic surgery, fracture, metastatic cancer).

Pharmacology/Actions

Frunevetmab is a felinized immunoglobulin G (IgG) monoclonal antibody (mAb) that binds to nerve growth factor (NGF). NGF is essential for peripheral neuronal survival, particularly in early (prenatal and early postnatal) life, but in mature animals, NGF also modulates nociceptive neural activity.[6] NGF is one of many chemical mediators released in response to noxious stimuli and produces peripheral sensitization, neurogenic inflammation, and increased perception of pain. NGF is elevated in osteoarthritic joints. NGF receptors (tropomyosin receptor kinase A [TrkA] and $p75^{NTR}$) are found in many cell types (eg, immune and endothelial cells, synoviocytes, chondrocytes) as well as on peripheral nerves. Frunevetmab binds NGF, which subsequently inhibits the binding of NGF to its receptors and results in decreased release of other chemical mediators of pain and inflammation as well as reduced cellular signal transduction in cell types involved in pain.[6]

Frunevetmab does not bind to other neurotrophins (eg, feline neurotrophin-4, human neurotrophin -3 or -4, brain-derived neurotrophic factor).

Pharmacokinetics

Frunevetmab bioavailability following SC injection was 60% to 73% in cats with osteoarthritis (OA).[2,7] In healthy cats, peak frunevetmab concentration (C_{max}, ≈43 µg/mL) occurred 3.5 days after SC administration.[2] However, C_{max} was lower (26.1 µg/mL) and was reached later (3 to 7 days) in cats with OA.[7] Monoclonal antibodies have a volume of distribution roughly equal to the plasma volume and typically do not cross the blood–brain barrier.[8] Steady-state frunevetmab concentrations are reached after 2 doses.[2] Monoclonal antibodies undergo peptide degradation.[9] Frunevetmab half-life is ≈10 to 12 days.[2,7]

Contraindications/Precautions/Warnings

Frunvetmab is contraindicated in patients hypersensitive to it, in breeding cats, and in pregnant or lactating queens.[2] See ***Reproductive/Nursing Safety***. Hypersensitivity reactions, including delayed hypersensitivity, may occur with frunevetmab use and necessitates discontinuation. Frunevetmab is a feline-specific product; it has not been evaluated in cats less than 7 months old or 2.5 kg (5.5 lb) and should not be used in any other species.

Cats may form anti-frunevetmab antibodies, with resulting loss of effectiveness.[2]

Nerve growth factors play an important role in the normal development of the nervous system. The manufacturer cautions that women who are pregnant, trying to conceive, or breastfeeding should use extreme caution to avoid accidental self-injection. Use of personal protective equipment to minimize the risk for exposure is recommended.

Adverse Effects

In cats receiving frunevetmab, local reactions at the injection site (scabbing, dermatitis, alopecia, pruritus, swelling) were reported in ≈3% to 6% of cats and were reported more frequently with frunevetmab than placebo.[2] GI signs (vomiting, diarrhea, and anorexia) and injection site pain were reported in ≈7% to 14% of cats and occurred with similar/equivalent frequency in cats receiving frunevetmab and placebo. Worsening of existing renal insufficiency (6.6%), dehydration (4.4%), weight loss (3.3%), and gingival disorders (2.2%) also were reported in cats receiving frunevetmab.

Treatment-emergent immunogenicity was identified in 1.5% of cats treated with frunevetmab and in 2.3% of placebo-treated cats.[7]

The safety and immunogenicity of long-term (administered over many months or years) frunevetmab use are not yet known.

In humans, the use of antinerve growth factor monoclonal antibodies for knee or hip osteoarthritis pain has resulted in mild to moderate, dose-dependent peripheral or extremity pain and neurosensory symptoms (paresthesia, hypoesthesia, or hyperesthesia)[6]; these effects typically were transient and/or reversible.[10] Rapidly progressive osteoarthritis (RPOA) and osteonecrosis in nontarget joints were also observed; the incidence of RPOA was increased with concurrent NSAID use.[11,12] The significance of these findings for veterinary patients is uncertain.

Reproductive/Nursing Safety

Frunevetmab is contraindicated in breeding cats or in pregnant or lactating queens.[2] Fetal abnormalities, increased rates of stillbirths, and increased postpartum fetal mortality have been noted in rodents and primates receiving anti-NGF mAbs.

Overdosage/Acute Toxicity

Clinical signs in cats receiving up to 14 mg/kg every 28 days (5 times the maximum label dose) included GI (vomiting, diarrhea) and dermatologic (abrasions, alopecia, scabbing) signs.[2] Bilirubinuria was observed in 1 cat receiving 2.8 mg/kg, 1 cat receiving 8.4 mg/kg, and 1 receiving 14 mg/kg (3 cats total).

For patients that have experienced or are suspected of having experienced an overdose, it is strongly encouraged to contact a 24-hour poison consultation center that specializes in providing information specific for veterinary patients. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Laboratory Considerations

None noted

Drug Interactions

Frunevetmab has not been studied in combination with other medications, including NSAIDs. The following drug interactions have either been reported or are theoretical in humans or animals receiving similar medications and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Monoclonal Antibodies, Other** (eg, **lokivetmab**): Concur-

rent use of frunevetmab with other monoclonal antibodies has not been evaluated.[2]

- **Nonsteroidal Anti-Inflammatory Drugs (NSAIDs**; eg, **meloxicam, robenacoxib**): In humans, the incidence of rapidly progressing osteoarthritis (RPOA) is increased in patients that received a humanized antinerve growth factor concurrent with long-term NSAID use.[11,12] The significance of this finding for veterinary patients is uncertain, and RPOA has not been reported in cats.
- **Vaccines**: Administer vaccines at a different site than frunevetmab.[1]

Dosages

CATS:

Control of pain associated with osteoarthritis in cats (label dosage; FDA approved): Cats weighing 2.5 to 7 kg (5.5 to 15.4 lb): 1 vial (7 mg, 1 mL)/cat (NOT mg/kg) SC once per month; cats weighing 7.1 to 14 kg (15.5 to 30.8 lb): 2 vials (14 mg, 2 mL)/cat (NOT mg/kg) SC once monthly.[2] The entire contents of 1 or 2 vials is administered with a target dosage range of 1 – 2.8 mg/kg.

Body weight in kg (lb)	Monthly dose (mg)	Volume (mL)	Number of vials (entire contents)
2.5 to 7 kg (5.5 to 15.4 lb)	7	1	1
7.1 to 14 kg (15.5 to 30.8 lb)	14	2	2

Monitoring

- Clinical efficacy
- Pain scale or rating system
- Adverse effects, including injection site reactions

Client Information

- This medicine is given by injection under the skin once each month to relieve pain caused by osteoarthritis in cats.
- Frunevetmab should not be given to cats used for breeding, pregnant or lactating queens, or cats less than 7 months old.
- This medicine has not been studied in cats receiving other medications. Be sure to check with your veterinarian before giving your cat any other medication(s).
- Side effects are uncommon, but pain upon giving the injection, local skin reactions at the injection site, or vomiting are possible.
- Frunevetmab was developed specifically for cats. Do not use it in any other species (eg, dogs).
- This medicine is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH). Talk with your veterinarian or pharmacist about the use of personal protective equipment when handling this medicine.

Chemistry/Synonyms

Frunevetmab is a felinized immunoglobulin G monoclonal antibody. It is derived from murine antibodies in which mouse antibody regions have been replaced by feline counterparts except for the complementarity-determining regions and is manufactured through recombinant techniques in Chinese hamster ovary (CHO) cells.[13] The commercial solution is clear to slightly opalescent, has a pH of 6, and contains no preservatives.

Frunevetmab may also be known as anti-NGF mAb or *Solensia*®.

Storage/Stability

Protect frunevetmab from light and refrigerate at 2°C to 8°C (35°F-46°F); do not freeze. Store vials in an upright position; avoid shaking or foaming the solution. Use contents immediately once the vial is punctured.

Compatibility/Compounding Considerations

None noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Frunevetmab Injection: 7 mg/mL in 1 mL single-use vials supplied in cartons of 1, 2, or 6 vials; *Solensia*®; (Rx). NADA #141-546

Furazolidone

(fyoor-a-***zoe***-li-done) *Furoxone*®

Antibacterial/Antiprotozoal

Prescriber Highlights

- ► Antibacterial/antiprotozoal nitrofuran that has been used in dogs and cats; not available in the United States
- ► Contraindicated in animals with known hypersensitivity
- ► Adverse effects include GI effects (eg, anorexia, vomiting, cramping, diarrhea) and innocuous discoloration of urine to a dark yellow or brown color.
- ► Many potential drug Interactions
- ► Extra-label use is prohibited in food animals.

Uses/Indications

Furazolidone is usually a second-line choice for treatment of enteric infections in small animal species caused by susceptible bacteria and protozoa (see ***Pharmacology***). It is no longer commercially available in the United States.

Pharmacology/Actions

Furazolidone interferes with susceptible bacterial enzyme systems and is bactericidal. Its mechanism against susceptible protozoa is not well determined. Furazolidone has activity against *Giardia* spp, *Vibrio cholerae, Trichomonas* spp, *Coccidia* spp, and many strains of *Escherichia coli, Enterobacter* spp, *Campylobacter* spp, *Salmonella* spp, and *Shigella* spp. Not all strains are sensitive, but resistance is usually limited and develops slowly. Furazolidone metabolites inhibit monoamine oxidase.

Pharmacokinetics

Published information on the absorption characteristics of furazolidone is conflicting. Pigmented metabolites in the urine indicate that it is absorbed to some extent; however, because furazolidone is used to treat enteric infections, absorption only becomes important regarding the adverse effect profile and drug interactions. Reportedly, furazolidone distributes into the CSF. Absorbed furazolidone is rapidly metabolized in the liver, and the majority of the absorbed drug is eliminated in the urine.

Contraindications/Precautions/Warnings

Furazolidone is contraindicated in patients that are hypersensitive to it.

Because furazolidone also inhibits monoamine oxidase, it may potentially interact with several other drugs and foods (see ***Drug Interactions*** below). The clinical significance of these interactions remains unclear, especially in the presence of poor absorption.

Extra-label use of furazolidone in food animals is prohibited.

Adverse Effects

Adverse effects noted with furazolidone are usually minimal. An-

orexia, vomiting, cramping, and diarrhea may occasionally occur.

Hypersensitivity has been reported in some humans.

Reproductive/Nursing Safety

Although no teratogenic effects of furazolidone have been located, the safe use of furazolidone during pregnancy has not been established. One reference states that furazolidone should not be used in pregnant queens.[1] It is unknown if furazolidone enters maternal milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No information was located, but moderate overdoses are unlikely to cause significant toxicity. GI decontamination may be considered for large overdoses.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving furazolidone and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Ethanol**: Concomitant administration may cause a disulfiram-like reaction.

Because furazolidone inhibits monoamine oxidase, its use concurrently with the following drugs is not recommended because dangerous hypertension could occur:

- **Amitraz**
- **Buspirone**
- **Linezolid**
- **Methylene Blue**
- **Selegiline**
- **Serotonergic Agents** (eg, **cyproheptadine, fluoxetine, mirtazapine, sertraline, trazodone**)
- **Sympathomimetic amines** (eg, **phenylpropanolamine, ephedrine**)
- **Tricyclic antidepressants** (eg, **amitriptyline, clomipramine**)
- **Tyramine-Containing Foods** (eg, **fish, poultry, smoked meats, aged cheeses**)

Laboratory Considerations

- Furazolidone may cause a false-positive **urine glucose** determination when using the cupric sulfate solution test (eg, *Clinitest®*).

Dosages

CATS:

Giardiasis (extra-label): 4 mg/kg PO every 12 hours for 7 to 10 days; if re-treatment is required, higher doses or longer treatment duration may provide better results.[2,3]

Monitoring

- Efficacy (stool exams for parasitic infections)

Client Information

- Although this medicine may discolor your animal's urine to a dark yellow to brown color, it does not cause harm and will go away once the medicine is stopped.
- Contact your veterinarian if your animal has continued serious vomiting or diarrhea or loss of an appetite to your veterinarian.

Chemistry/Synonyms

Furazolidone, a synthetic nitrofuran-derivative antibacterial/antiprotozoal, occurs as a bitter-tasting, yellow, crystalline powder. It is practically insoluble in water.

Furazolidone may also be known as nifurazolidonum, *Enterolidon®*, *Exofur®*, *Furasian®*, *Furion®*, *Furoxona®*, *Fuxol®*, *Giarcid®*, *Giardil®*, *Giarlam®*, *Neo Furasil®*, *Nifuran®*, *Novafur®*, *Salmocide®*, and *Seforman®*.

Storage/Stability

Store this product protected from light in tight containers.

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

Extra-label use of furazolidone is prohibited in food-producing animals.

HUMAN-LABELED PRODUCTS:

None; the human product *Furoxone®* has been withdrawn from the United States market. Preparations may be available from compounding pharmacies.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Furosemide

(fur-***oh***-se-mide) *Disal®, Lasix®, Salix®*

Loop Diuretic

Prescriber Highlights

- ► A loop diuretic commonly used in many species for treatment of congestive heart failure, pulmonary edema, udder edema, hypercalcemia, and acute kidney injury. Used as adjunctive therapy in hyperkalemia and rarely as an antihypertensive agent. Used in racehorses to prevent/reduce exercise-induced pulmonary hemorrhage (EIPH)
- ► Contraindications include patients with anuria, hypersensitivity, dehydration, or serious electrolyte depletion.
- ► Use with caution in patients with preexisting electrolyte or water balance abnormalities, impaired hepatic function, progressive renal disease, and/or diabetes mellitus.
- ► Adverse effects include fluid and electrolyte (especially hyponatremia/hypochloremia) abnormalities, acid-base disturbances (metabolic alkalosis), ototoxicity, GI distress, hematologic effects, weakness, and restlessness. SC injection may cause ulcerative skin lesions in dogs and other species.
- ► Prerenal azotemia is possible if dehydration occurs.
- ► Normal food and water intake should be encouraged.

Uses/Indications

Furosemide is used for its diuretic activity in all species. It is used in small animals for the treatment of congestive heart failure (CHF), pulmonary edema, hypercalcemia, acute kidney injury, as adjunctive therapy in hyperkalemia, and, rarely, as an antihypertensive agent. It can be used to decrease the incidence of sterile hemorrhagic cystitis associated with cyclophosphamide administration in dogs.[1–4]

In cattle, furosemide is FDA-approved for the treatment of postparturient udder edema.[5]

Furosemide has also been used to help prevent or reduce the severity of epistaxis (ie, exercise-induced pulmonary hemorrhage; EIPH) in racehorses.[6,7] An American College of Veterinary Internal Medicine consensus statement declared that, based on the research

done on EIPH in horses, there is high-quality evidence that furosemide is effective in the prophylaxis of this disease.[8] The panel makes a weak recommendation for its use in management of racehorses with EIPH because of regulation of this issue by racing jurisdictions. The panel also found high-quality evidence that furosemide is associated with improved performance by thoroughbred and standardbred racehorses.

Pharmacology/Actions

Furosemide can reduce the absorption of electrolytes in the medullary portion of the thick ascending loop of Henle by impairing the activity of the NA^+-K^+-$2Cl^-$ cotransporter. It also decreases the reabsorption of both sodium and chloride, increases the excretion of potassium in the distal renal tubule, and directly affects electrolyte transport in the proximal tubule. It has no effect on carbonic anhydrase and does not antagonize aldosterone. In dogs and cats, furosemide is considered to have a potency of $1/10^{th}$ to $1/20^{th}$ that of torsemide, the other loop diuretic commonly used in veterinary medicine.[9–11]

Furosemide can increase renal excretion of water, sodium, potassium, chloride, calcium, magnesium, hydrogen, ammonium, and bicarbonate. In dogs, excretion of potassium is affected much less than sodium; hyponatremia may be more of a concern than hypokalemia and hypochloremia is common. Furosemide causes some renal vasodilation and transiently increases glomerular filtration rates (GFR). Renal blood flow is increased (so long as profound dehydration does not develop) and decreased peripheral vascular resistance may occur. Although furosemide increases renin secretion, because of its other effects on the nephron, increases in sodium and water retention do not occur.[12,13] Furosemide can cause hyperglycemia, but to a lesser extent than the thiazide diuretic agents.

Doses of 1 – 4 mg/kg IV or PO decreased, in a dose-proportional manner, left atrial pressure in dogs with experimentally induced mitral regurgitation.[14] It has been shown that in dogs, doses lower than 1 mg/kg can produce diuresis with only mild activation of the renin–angiotensin–aldosterone system.[15] In a study of healthy dogs, furosemide was diluted with 2.4% hypertonic saline and administered as a CRI for 5 hours. The results showed no intravascular volume expansion and a reduced activation of the renin–angiotensin–aldosterone system. The authors concluded that dilution of furosemide with hypertonic saline may be beneficial in dogs with heart failure.[16] At high doses (10 – 12 mg/kg), thoracic duct lymph flow is increased in dogs.[17] In horses, furosemide has some bronchodilatory effects.[18] Cats are reportedly more sensitive to the diuretic effects of furosemide as compared with other species.

In horses with recurrent obstructive pulmonary disease, furosemide administered by aerosol or IV at 1 mg/kg may significantly reduce pulmonary resistance and increase dynamic compliance.[18–20] This effect can persist for at least 5 hours, but it is abolished by flunixin meglumine.[20]

The efficacy of furosemide in reptiles, birds, and fish has been questioned because of these species' lack of a loop of Henle. However, furosemide seems to have other effects on the nephron and has been shown to reduce body weight and/or pulmonary blood volume, even when diuresis does not occur.[21]

Pharmacokinetics

In dogs, the oral bioavailability is ≈77%. It has a rapid onset of action of ≈5 minutes when administered IV, 30 minutes when administered IM, and 30 to 60 minutes when administered PO. The drug is highly (more than 90%) protein bound. Its duration of action is 3 to 6 hours, and the elimination half-life is ≈1 to 1.5 hours in dogs and cats, up to 2.7 hours in cattle,[22] and up to 3.2 hours in horses.[6] In healthy dogs, when administered IV, SC, and PO, the urine output peaked at 1 hour (IV), 1 hour (SC), and 2 hours (PO) and returned to baseline levels at 2, 4, and 6 hours, respectively. The total urine output was similar for all 3 routes of administration.[23]

The pharmacokinetics of furosemide were studies in healthy cats.[24] After oral administration, bioavailability was ≈50%, and half-life was ≈1.2 hours. After IV administration, the volume of distribution was 227 mL/kg, clearance was 149 mL/kg/hour, and elimination half-life was 2.25 hours.

In sheep, the time to peak concentration after IM and SC administration was 20 minutes and 25 minutes, respectively, with considerably different bioavailability of 97.9% after IM administration and 38% after SC, suggesting IM or IV as the preferred parenteral routes of administration in sheep. The elimination half-life was 0.8 hours by all routes of administration (IV, IM, SC) in sheep. The mean total clearance and volume of distribution at steady state following IV administration were 0.24 L/hour/kg and 0.17 L/kg, respectively.[25]

In humans, furosemide is 60% to 75% absorbed following oral administration. The diuretic effect takes place within 5 minutes after IV administration and within 1 hour after oral administration. Peak effects occur ≈30 minutes after IV administration and 1 to 2 hours after oral administration. The drug is ≈95% bound to plasma proteins in both azotemic and normal patients. The serum half-life is ≈2 hours but is prolonged in patients with chronic kidney disease, uremia, or CHF, and in neonates.

Contraindications/Precautions/Warnings

Furosemide is contraindicated in patients with anuria or hepatic coma and those that are hypersensitive to the drug. The manufacturer states that the drug should be discontinued in patients with progressive renal disease if increasing azotemia and oliguria occur during therapy.

Furosemide should be used with caution in patients with preexisting electrolyte or water balance abnormalities, impaired hepatic function (may precipitate hepatic coma), progressive renal disease, or diabetes mellitus. Patients with conditions that may lead to electrolyte or water balance abnormalities (eg, vomiting, diarrhea) should be monitored carefully. Patients hypersensitive to sulfonamides may also be hypersensitive to furosemide (not documented in veterinary species).

Furosemide should be used cautiously with other drugs that can cause renal toxicity or ototoxicity (eg, aminoglycoside antibiotics), as furosemide may potentiate these toxic effects.

Adverse Effects

Furosemide may induce fluid and electrolyte abnormalities. Patients should be monitored for hydration status and electrolyte imbalances (particularly potassium, sodium, and chloride, as well as calcium and magnesium). Prerenal azotemia may result if moderate to severe dehydration occurs. Hypochloremia is commonly encountered, and hyponatremia is likely the greatest concern, but hypocalcemia, hypokalemia, and hypomagnesemia may all occur. Animals with normal food and water intake are much less likely to develop water and electrolyte imbalances than those without.

Other potential adverse effects include ototoxicity, especially in cats receiving high-dose IV therapy.[26] Dogs reportedly require doses greater than 22 mg/kg IV to cause hearing loss.[27] Other effects include GI disturbances (eg, nausea, vomiting, diarrhea), weakness, and restlessness.

A case of a dermatologic reaction (ulcerative lesions) at the injection sites after SC administration of furosemide in a dog has been reported.[28] This dog had received injections from 2 separate formulations from different manufacturers. The product suspected of causation had a pH between 8.66 and 9.05, whereas the product that did not cause a reaction had a pH between 7.2 and 7.47 (although none of the tested lots were used in the patient). The authors concluded that veterinarians should exercise caution when prescribing

furosemide SC and consider the potential effects of the furosemide formulation (eg, pH) in their choice when prescribing this route.

Reproductive/Nursing Safety

Furosemide may cause fetal abnormalities and its use is contraindicated in pregnant animals and stallions used for breeding.[29,30] Unexplained maternal deaths and abortion occurred in the second trimester in rabbits receiving furosemide at 10 to 25 times the recommended average dose of 2 mg/kg for dogs, cats, horses, and cattle[5,31]; and fetal hydronephrosis has been noted in laboratory animals.[29,31] Although the United Kingdom product label states that furosemide can be used during pregnancy and lactation,[22] the United States product labels state that the drug is either not recommended during the second trimester of pregnancy[5,31] or that the drug is contraindicated in pregnant animals.[29,30] Clinicians should consider the risks versus benefits when using furosemide in a pregnant animal, as there is conflicting information between the United States and United Kingdom product labels.

Caution should be used in reproductively active hens, as furosemide has been shown to decrease eggshell thickness and inhibit calcium transport in the shell gland mucosa, which could lead to dystocia.[32]

Furosemide appears in milk; clinical significance to nursing offspring is unknown. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The LD_{50} in dogs is greater than 1000 mg/kg after oral administration and 300 mg/kg after IV injection.[31] Chronic overdosing at 10 mg/kg for 6 months in dogs has led to mild dehydration and development of calcification and scarring of the renal parenchyma.[31] Temporary deafness may occur, particularly after rapid IV administration of high doses. See ***Adverse Effects***.

Acute overdoses may cause electrolyte and water imbalances, neurologic effects (eg, lethargy, coma, seizures), and cardiovascular collapse.

Treatment consists of standard protocols to empty the gut after acute oral ingestion. Concomitant cathartics should not be used, as they may exacerbate fluid and electrolyte imbalances. Electrolyte and water balance abnormalities should be aggressively monitored and treated supportively. Respiratory, neurologic, and cardiovascular status should also be monitored and treated as clinically indicated.

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving furosemide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Angiotensin Converting Enzyme Inhibitors (ACEIs**; eg, **benazepril, enalapril**): Increased risk for hypotension, particularly in patients that are volume- or sodium-depleted secondary to diuretics
- **Aminoglycosides** (eg, **amikacin, gentamicin**): Increased risk for nephrotoxicity and ototoxicity (including complete deafness, even with use of typical drug dosages)
- **Amphotericin B**: Loop diuretics may increase the risk for nephrotoxicity and hypokalemia.
- **Cephalosporins** (eg, **cefazolin, cefovecin**): Increased risk for nephrotoxicity
- **Cisplatin**: Increased risk for nephrotoxicity and ototoxicity (including complete deafness, even with use of typical drug dosages)
- **Corticosteroids** (eg, **fludrocortisone, prednisone**): Increased risk for GI ulceration; hypokalemia
- **Cyclosporine**: Increased risk for hyperuricemia
- **Desmopressin**: Increased risk for hyponatremia
- **Digoxin**: Furosemide-induced hypokalemia may increase the potential for digoxin toxicity.
- **Insulin**: Furosemide may alter insulin requirements.
- **Nondepolarizing Muscle Relaxants** (eg, **atracurium, tubocurarine**): Furosemide may prolong neuromuscular blockade.
- **Nonsteroidal Anti-Inflammatory Drugs (NSAIDs**; eg, **carprofen, firocoxib, flunixin, meloxicam, phenylbutazone**): Increased risk for acute kidney injury
- **Oxytetracycline**: Increased risk for nephrotoxicity
- **Polymyxin B**: Increased risk for acute kidney injury
- **Probenecid**: Furosemide can reduce uricosuric effects.
- **Salicylates** (eg, **aspirin**): Loop diuretics can reduce excretion of salicylates.
- **Succinylcholine**: Furosemide may potentiate effects.
- **Theophylline/Aminophylline**: Pharmacologic effects of theophylline may be enhanced when used with furosemide.

Laboratory Considerations

- **Free thyroxine (fT_4)**: Furosemide can result in an increased fT_4 fraction; furosemide inhibits T_4 binding to canine serum in vitro.

Dosages

NOTE: Watch units closely when calculating doses. Do not confuse CRI dosages using mg/kg/hour with µg/kg/minute.

DOGS:

Label dosages (FDA-approved):

Treatment of edema (pulmonary congestion, ascites) associated with cardiac insufficiency and acute noninflammatory tissue edema:

- Injection: 2.75 – 5.5 mg/kg IV or IM once or twice daily after a 6- to 8-hour interval[5,29–31]
- PO: 2.2 – 5.5 mg/kg PO once or twice daily with a 6- to 8-hour interval between doses[30,31]

The dose should be adjusted to the individual animal's response.[5,31] In refractory or severe edematous cases, the dose may be doubled or increased by increments of 2.2 mg/kg of body weight to establish the effective dose. The established effective dose should be administered once or twice daily. The daily schedule can be timed for the convenience of the pet owner or veterinarian. Diuretic therapy should be discontinued after reduction of edema or, when necessary, maintained after determining a programmed dose schedule to prevent recurrence.

Extra-label dosages:

Acute cardiogenic or pulmonary edema (parenteral administration):

a) **Congestive heart failure from stage C myxomatous mitral valve disease**: Initial dose, furosemide 2 mg/kg IV (or IM), followed by 2 mg/kg IV or IM hourly until the patient's respiratory signs are substantially improved or a total of 8 mg/kg has been reached over 4 hours.[33] For life-threatening pulmonary edema, furosemide may also be administered as a CRI (see below).

b) Bolus dosing: Initially, 1 – 4 mg/kg IV, IM, or SC (use SC route with caution, see ***Adverse Effects***) is administered, then adjusted and repeated every 1 to 2 hours until respiratory rate and/or respiratory character improves. A maximum daily dose of 12 mg/kg has been noted.[33,34] **NOTE**: SC furosemide administration produced similar total urine output as compared with IV and PO doses.[23]

c) **CRI**: 0.66 – 1 mg/kg/hour IV CRI after the furosemide initial bolus[35,36] may produce greater diuresis, natriuresis, and less kaliuresis.[16,33,34,37] One study noted lower cumulative furosemide use when given by CRI (median dosage, 0.99 *mg/kg/hour*; range 0.025 – 3.73 mg/kg/hour) as compared with IV bolus (median, 1.19 mg/kg/hour; range 0.027 – 7.14 mg/kg/hour) with a trend toward longer hospitalization in the IV bolus group.[37] Another study found similar diuresis when furosemide was diluted to a final concentration of 2.2 mg/mL with 5% dextrose solution (1.5 mL/kg) or 2.4% hypertonic saline solution (1 mL/kg of 5% dextrose + 0.5 mL/kg of 7.2% sodium chloride).[16] Prolonged CRI administration (beyond 12 to 24 hours) should be performed cautiously as severe volume depletion may occur.

Adjunctive treatment of CHF (oral administration): Oral dosage recommendations can vary widely and are tailored for each patient. In general, the goal is to give the lowest effective dose of furosemide. Dogs with mild heart failure signs may initially be controlled with 1 mg/kg PO every 24 hours, whereas dogs with severe heart failure may require doses as high as 5 mg/kg PO every 8 hours. A common oral starting dosage in dogs with stage C myxomatous mitral valve disease when treating chronically at home is 2 mg/kg orally every 12 hours with the dose adjusted to effect to maintain patient comfort.[33]

Adjunctive treatment of dogs with glomerular disease and pulmonary edema or hyperkalemia: Furosemide may be administered at an initial dosage of 1 mg/kg every 6 to 12 hours IV or IM, with incremental increases of 0.5 – 1 mg/kg every 6 to 12 hours or conversion into 2 – 15 *µg/kg/minute* IV after an initial loading dose of 2 mg/kg IV in animals with insufficient response.[38]

Adjunctive treatment of moderate to severe hypercalcemia: Volume expansion is necessary before use of furosemide; 2 – 4 mg/kg every 8 to 12 hours, IV, SC, or PO.[39] Use SC route with caution, see ***Adverse Effects.***

Adjunctive therapy for systemic hypertension: 1 – 4 mg/kg PO every 8 to 24 hours. Loop diuretics can be considered as adjunctive treatment for systemic hypertension in dogs with edema that are not responding adequately to standard combination therapy (ie, amlodipine with ACE inhibitor or angiotensin receptor blocker).[40]

Oliguric acute kidney injury: Furosemide can increase urine output so that IV fluid therapy can correct acid-base and electrolyte imbalances, but it does not improve GFR or necessarily affect clinical outcome. Two basic dose protocols have been recommended:

a) 0.5 – 1 *mg/kg/hour* IV. If furosemide administration fails to increase urine production, osmotic diuresis (mannitol) can be attempted.
b) Initial bolus 1 – 2 mg/kg IV (up to 4 mg/kg in dogs if no response seen within 30 to 60 minutes), followed by 0.1 – 2 *mg/kg/hour* IV, adjusted depending on patient's response

Prevent sterile hemorrhagic cystitis (SHC) caused by cyclophosphamide treatment: 0.5 – 2.2 mg/kg PO and IV every 24 hours during the course of chemotherapy reduced the incidence of or prevented SHC.[1–3] 0.5 mg/kg PO every 12 hours is also effective.[4]

CATS:

Label Dosages (FDA-approved):

Treatment of edema (pulmonary congestion, ascites) associated with cardiac insufficiency and acute noninflammatory tissue edema:

- Injection: 2.75 – 5.5 mg/kg IV or IM once or twice daily with a 6- to 8-hour interval between doses[5]
- PO: 2.2 – 5.5 mg/kg PO once or twice daily with a 6- to 8-hour interval between doses[31]

The dose should be adjusted to the individual animal's response. In refractory or severe edematous cases, the dose may be doubled or increased by increments of 2.2 mg/kg to establish the effective dose. The established effective dose should be administered once or twice daily on an intermittent daily schedule. Diuretic therapy should be discontinued after reduction of edema or, when necessary, maintained after determining a programmed dose schedule to prevent recurrence.[5,31]

Extra-Label Dosages:

Severe acute cardiogenic or pulmonary edema (parenteral administration): 1 – 3 mg/kg IV, IM, or SC (use SC route with caution, see ***Adverse Effects***), then dose is adjusted and repeated every 1 to 2 hours until respiratory rate and/or respiratory character improves. In general, slightly lower doses of furosemide should be given to cats as compared to standard doses for dogs. Cats that can tolerate IV injection may benefit from a faster onset of action (5 minutes when given IV as compared with 30 minutes when given IM). The dose may be repeated within 1 to 2 hours. To avoid severe dehydration, dose must be reduced sharply once respiratory rate starts to decrease.[34]

Adjunctive treatment of CHF (oral administration): Oral dosage recommendations can vary widely in cats and are tailored for each patient. In general, the goal is to give the lowest effective dose of furosemide. Dosages tend to be slightly lower than that for dogs and range from 1 mg/kg PO every 2 to 3 days to 2 mg/kg PO every 8 to 12 hours for most patients. Dosages up to 7 mg/kg every 12 hours have been noted. Practically, many cats receive increments of 6.25 mg (½ of a 12.5 mg tablet).[41]

Oliguric acute kidney injury: Furosemide can increase urine output so that IV fluid therapy can correct acid-base and electrolyte imbalances, but it does not improve GFR or necessarily affect clinical outcome. Two basic dosing protocols have been recommended:

a) 0.25 – 1 mg/kg/hour IV. If furosemide administration fails to increase urine production, osmotic diuresis (mannitol) can be attempted.
b) Bolus of 1 – 2 mg/kg IV and, if an effect is seen, 0.25 to 1 *mg/kg/hour* IV CRI is started and adjusted based on patient's response.

HORSES:

Label Dosages (FDA-approved):

Edema (pulmonary congestion, ascites) associated with cardiac insufficiency and acute noninflammatory tissue edema: 250 – 500 mg/horse (NOT mg/kg) IM or IV once or twice daily at 6- to 8-hour intervals. Should not be used in horses intended for human consumption[5]

Acute noninflammatory tissue edema: 1 mg/kg IV or IM once or twice daily at 6- to 8-hour intervals or on an intermittent daily (eg, every other day) administration schedule[29]

Extra-Label Dosages:

Adjunctive therapy for CHF: Initially, 1 – 3 mg/kg IM or IV every 6 to 12 hours to control edema, which may be followed by a 0.12 *mg/kg/hour* IV CRI until improvement in clinical signs. Long-term therapy: 0.5 – 2 mg/kg PO or IM every 8 to 12 hours[42,43]

Adjunctive therapy of acute kidney injury:

a) 1 – 2 mg/kg IV every 2 hours up to 4 times[44]
b) 1 mg/kg IV every 8 hours[45]
c) Loading dose of furosemide 0.12 mg/kg IV followed by 0.12 *mg/kg/hour* IV CRI[45]

Epistaxis and to lessen the severity of exercise-induced pulmonary hemorrhage (EIPH; NOT racehorses): 0.5 – 1 mg/kg administered IV 4 hours before strenuous exercise has been shown to decrease the severity and incidence of EIPH. Consult applicable local, state, and/or federal rules prior to any competition (including performance horses).

Epistaxis and to lessen the severity of EIPH (racehorses): If the horse to be raced is on the furosemide list, the furosemide administered dose must be between 150 mg and 500 mg/horse (NOT mg/kg) given IV as a single injection. Administration must be given *not less than 4 hours prior to scheduled post time of the race for which a horse is entered to compete*. Consult applicable local, state, and/or federal rules prior to competition, as some United States tracks may have restrictions on the use of this drug in racing horses.

CATTLE:

Physiologic parturient edema of the mammary gland and associated structures (label dosage; FDA-approved): 500 mg/cow (NOT mg/kg) IM or IV once daily or 250 mg/cow (NOT mg/kg) IV or IM twice daily at 12-hour intervals; treatment should not exceed 48 hours postparturition.[5]

BIRDS:

Cardiopulmonary disorders (edema, pericardial effusion) (extra-label): Recommended dosages ranging from 0.15 – 2 mg/kg/day PO or IM.[46] **NOTE**: Lories are very sensitive to this agent and can be easily overdosed.[47]

Oliguria/anuria in patients with renal failure (extra-label): 1 mg/kg IM[48]

FERRETS:

Adjunctive therapy for fulminant congestive heart failure (extra-label): Initially 1 – 4 mg/kg IV or IM every 8 to 12 hours; repeated after 30 minutes if there is no improvement. Once the patient is stabilized, dosage is transitioned to 1 – 2 mg/kg PO every 12 hours.[46,49,50]

RABBITS, RODENTS, & SMALL MAMMALS:

NOTE: Dosages are primarily extrapolated from those recommended for dogs and cats with similar disease states. Use furosemide with caution when administering SC (see ***Adverse Effects***), as local tissue reactions can occur.

Rabbits (extra-label):

a) **CHF**: 2 – 5 mg/kg PO, SC, IM, or IV every 12 hours

b) **Pulmonary edema**: 1 – 4 mg/kg IV or IM every 4 to 6 hours[51]

Mice, rats, gerbils, hamsters, guinea pigs, chinchillas (extra-label): 5 – 10 mg/kg every 12 hours[52]

REPTILES:

Edema and pulmonary congestion (extra-label): 5 mg/kg PO, IM, IV every 12 to 24 hours[46]

FISH:

Edema and ascites (extra-label): 2 – 5 mg/kg IM every 12 to 72 hours[53]

Monitoring

- Serum electrolytes, acid-base balance (ie, venous blood gas), BUN, creatinine, glucose
- Hydration status (eg, serial body weight measurements, PCV/TP)
- Sleeping/resting respiratory rate
- Blood pressure and thoracic radiographs, if indicated by underlying disease
- Clinical signs of edema, (eg, increased resting respiratory rate, distal limb swelling, girth measurements)
- Evaluation of ototoxicity (hearing loss most common), particularly with prolonged treatment in cats

Client Information

- Furosemide may be given with or without food. If your animal vomits or acts sick after receiving this medicine on an empty stomach, try giving the next dose with food or a small treat. If vomiting continues, contact your veterinarian.
- Your animal will need to urinate more often than normal while taking this medication. Be sure that your animal always has ready access to fresh, clean water. Never withhold water to lessen the times your animal needs to urinate.
- Your veterinarian may ask you to keep a record of your animal's respiratory rate to help monitor for early signs of heart problems. Be sure to follow your veterinarian's instructions about how to measure your animal's respiratory rate and information about when to call your veterinarian.
- Your animal will need to be monitored closely by your veterinarian while it is taking this medicine. Do not miss these important follow-up visits.
- Contact your veterinarian immediately if you notice your animal has weakness, hearing loss, collapse, a head tilt, lack of urination, or a racing heartbeat.

Chemistry/Synonyms

Furosemide is an anthranilic acid derivative structurally related to the sulfonamides. It occurs as an odorless, practically tasteless, white to slightly yellow, fine crystalline powder. Furosemide has a melting point between 203°C and 205°C (397°F-401°F), with decomposition and a pK_a of 3.9. It is practically insoluble in water, sparingly soluble in alcohol, and freely soluble in alkaline solutions. The veterinary injectable products use either the diethanolamine or monoethanolamine salts of furosemide. Diethanolamine salts have a pH of 7 to 7.8 and monoethanolamine salts have a pH of 8 to 9.3; pH may be adjusted with NaOH or HCl.

Furosemide may also be known as frusemide, furosemidum, and LB-502; many trade names are available.

Storage/Stability

Store furosemide protected from light at room temperature up to 25°C (77°F). Furosemide tablets should be protected from moisture and stored in light-resistant, well-closed containers. Tablets may discolor with exposure to light, and discolored tablets should be discarded. The oral solution should be stored at room temperature and protected from light and freezing; discard opened bottles after 90 days.

Furosemide injection should be stored at room temperature. A precipitate may form if the injection is refrigerated, but it will resolubilize when warmed without alteration in potency. The human injection (10 mg/mL) should not be used if it has a yellow color. The veterinary injection (50 mg/mL) normally has a slight yellow color. Furosemide is unstable at an acid pH but is very stable under alkaline conditions. One manufacturer warns to discard the product after 32 vial punctures.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist can be consulted for more specific information.

Furosemide injection (10 mg/mL) is reportedly physically **compatible** with all commonly used IV solutions and with the following drugs (depending on concentration): amikacin sulfate, atropine sulfate, cefazolin, cyclosporine, dexamethasone sodium phosphate, dexmedetomidine, digoxin, epinephrine, heparin, lidocaine, mannitol, pamidronate, penicillin G, potassium chloride, ranitidine, sodium bicarbonate, sodium nitroprusside, tobramycin sulfate, vasopressin, verapamil, and zoledronic acid. Refer to a specialized reference or consult a hospital pharmacist for additional information.

Furosemide is reported to be physically **incompatible** with the following agents: ascorbic acid solutions, atracurium, butorphanol tartrate, ciprofloxacin, diazepam, diphenhydramine, dobutamine HCl, esmolol, gentamicin sulfate, glycopyrrolate, hydralazine, ketamine, metoclopramide, mycophenolate mofetil, ondansetron, pantoprazole, potassium phosphates, thiamine, and tetracyclines. It should generally not be mixed with antihistamines, local anesthetics, alkaloids, hypnotics, or opiates.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: Consult applicable local, state, and/or federal rules prior to competition, as some United States tracks may have restrictions on the use of this drug in racing animals.

Furosemide Tablets: 12.5 mg and 50 mg; *Salix®*, *Disal®*, generic; (Rx). Products may be FDA-approved for use in dogs and cats. Additional tablet strengths may be available in other countries.

Furosemide Oral Solution (Syrup): 10 mg/mL in 60 mL; generic; (Rx). FDA-approved for use in dogs

Furosemide for Injection: 50 mg/mL (5%) in 50 mL and 100 mL vials; *Disal® Injection*, *Salix® Injection*, generic; (Rx). Products may be FDA-approved for use in dogs, cats, horses, and cattle. Not for use in horses intended for human consumption. FDA milk/meat withdrawal periods in cattle are 48 hours; slaughter withdrawal for cattle is 28 days in the United Kingdom.

HUMAN-LABELED PRODUCTS:

Furosemide Oral Tablets: 20 mg, 40 mg, and 80 mg; *Lasix®*, generic; (Rx)

Furosemide Oral Solution: 10 mg/mL and 40 mg/5 mL (8 mg/mL); generic; (Rx)

Furosemide Injection: 10 mg/mL in 2 mL (20 mg), 4 mL (40 mg), and 10 mL (100 mg) single-dose vials or prefilled syringes; generic; (Rx)

Gabapentin

(gab-ah-***pen***-tin) *Neurontin®*

Anticonvulsant; Anxiolytic; Neuropathic Pain Analgesic

Prescriber Highlights

- ► May be useful in dogs and cats as adjunctive therapy for refractory or complex partial seizures and in many species for the treatment of chronic pain (especially neuropathic pain)
- ► Appears beneficial in cats for reducing fear responses associated with handling and examination, and in dogs for storm phobia
- ► Use of xylitol-containing oral liquid should be avoided in dogs.
- ► Sedation or ataxia are the most likely adverse effects in small animal species.
- ► Administration 3 times a day (ie, every 8 hours) in dogs or cats is likely the most effective regimen but may be problematic for pet owners.

Uses/Indications

Gabapentin may be useful as adjunctive therapy for refractory or complex partial seizures. As an analgesic, gabapentin has been demonstrated to be useful in treating chronic pain, particularly neuropathic pain, in small animals. Gabapentin has improved the quality of life in dogs[1] (but not in cats[2]) with chronic pain conditions. In the cat study, quality of life deteriorated in both the gabapentin and placebo group, leading the authors to state that the osteoarthritis in all cats was likely worsening.[2] Cats receiving gabapentin did have improved owner-identified impaired activities.

Gabapentin does not appear to be effective for treating acute pain, but it may be of benefit when given preemptively (eg, before surgery) for acute pain when it is used with other analgesics.[3] Research has shown that, when used preoperatively, gabapentin reduced the amount of opioids needed postoperatively in dogs undergoing mastectomy.[4] Gabapentin has been proposed for further study in horses to determine its efficacy as an adjunctive treatment for laminitis pain[5] and in cattle for treating neuropathic pain.[6]

Gabapentin has been used in cats to decrease fear responses and anxiety associated with transport and veterinary examinations[7–9] and in dogs for control of storm phobia.[10]

It appears that when used in combination with meloxicam, gabapentin can reduce the severity of lameness in calves.[11]

Pharmacology/Actions

Gabapentin has analgesic effects and can prevent allodynia (ie, sensation of pain resulting from a normally non-noxious stimulus) or hyperalgesia (ie, exaggerated response to painful stimuli). It also has anticonvulsant activity. The mechanism of action of gabapentin for either its anticonvulsant, analgesic, or anxiolytic actions is not fully understood, but it appears to bind to CaV alpha2delta, a subunit of the voltage-gated calcium channels. By decreasing calcium influx, the release of excitatory neurotransmitters (eg, substance P, glutamate, norepinephrine) is inhibited. Although gabapentin is structurally related to gamma-aminobutyric acid type A (GABA), it does not appear to alter GABA binding, reuptake, or degradation or to serve as a GABA agonist in vivo.

Pharmacokinetics

In dogs, oral bioavailability is ≈80% at a dose of 50 mg/kg. Peak plasma concentrations occur ≈1 to 2 hours after administration. Thirty-four percent of a gabapentin dose is metabolized to *N*-methyl-gabapentin; elimination is primarily via renal routes. Elimination half-life is ≈2 to 4 hours.[12–14]

In cats, gabapentin bioavailability was 90% to 95% after oral administration, with significant interpatient variation (50% to 120%) possible. Peak concentrations occurred 65 to 100 minutes after a single dose and at 45 minutes with repeated doses. Apparent volume of distribution at steady state was relatively low at 0.65 L/kg. Clearance was 2.7 to 3 mL/minute/kg, and the mean elimination half-life of 2.8 to 3.7 hours was similar to that of dogs.[15,16] Cats with IRIS stage 2 or 3 CKD had significantly higher serum gabapentin concentrations than healthy cats; gabapentin concentration correlated with serum creatinine and symmetric dimethylarginine.[17]

In 4 horses given single oral doses of 5 mg/kg, gabapentin was rapidly absorbed, with peak concentrations noted within 2 hours (mean, 1.4 hours). Plasma elimination half-life was ≈3.4 hours.[18] Another study in 6 horses showed that oral gabapentin had a low bioavailability (≈16%), and peak concentrations occurred ≈1 hour after administration. Elimination half-life was ≈7 to 8 hours. Gabapentin is cleared almost entirely by the kidneys.[19]

In ruminating calves, oral gabapentin (with or without meloxicam) at 10 or 15 mg/kg yielded plasma gabapentin concentrations of more than 2 µg/mL for up to 15 hours. The elimination half-life was ≈8 to 10 hours; the authors speculated that a decreased rate of oral absorption in ruminant calves prolonged half-life.[6]

One study in Hispaniolan Amazon parrots showed oral bioavailability of 80% to 89%.[20] IV half-life was 2.9 hours and oral half-life was 7.7 hours.[20]

In humans, gabapentin bioavailability decreases as dosage increases.[21] For example, at dosages of 900 mg/day, 60% of the dose is absorbed; however, at 4800 mg/day, only a minimum of 27% of the dose is absorbed. Limited data suggest that this effect may occur in dogs[14] and horses,[22] but it did not occur in Hispaniolan Amazon

parrots.[20] The presence of food only marginally alters absorption rate and extent of absorption.[21] Gabapentin is only minimally bound to plasma proteins; CSF concentrations are ≈20% of those in plasma. The drug is not significantly metabolized and is almost exclusively excreted unchanged in the urine. Elimination half-lives in humans are ≈5 to 7 hours.

An extended-release tablet formulation (gabapentin enacarbil) is available for humans, but no pharmacokinetic information for this product is noted for veterinary species.

Contraindications/Precautions/Warnings

Gabapentin is considered contraindicated in patients that are hypersensitive to it. Because gabapentin is eliminated via renal routes (practically 100% in humans), it should be used with caution in patients with renal insufficiency; if required, dosage adjustment should be considered. In dogs, the drug is also metabolized (30% to 40% of a dose), so dosage adjustment may not be required in dogs with mild to moderate renal dysfunction. However, one reference recommends that dosages be reduced and/or dose intervals increased in dogs and cats when serum creatinine clearance is 0.7 mL/kg/minute or less.[23]

In general, use of commercially available human oral solutions containing xylitol should be avoided in dogs. Because the threshold dose of xylitol that can cause hypoglycemia in dogs is ≈100 mg/kg, doses of gabapentin up to 15 mg/kg in dogs using the solution should be safe, but further data are needed to confirm this. In addition, xylitol may be hepatotoxic in dogs. Doses of 500 mg/kg of xylitol are currently thought to be the threshold for this toxicity, but there have been anecdotal reports of it occurring at much lower doses. In cats, at the dosages presently used for gabapentin oral solution, xylitol toxicity does not appear to be a problem, but the solution should be used with caution.[24]

Abrupt discontinuation of the drug after chronic use has led to withdrawal-precipitated seizures. In humans, it is recommended to wean off the drug when it is used for epilepsy treatment, and similar advice for animal patients seems prudent.

Adverse Effects

Sedation and ataxia are the most likely adverse effects seen in small animals. Starting the dose at the lower end of the range and increasing with time may alleviate these effects. One study in cats noted hypersalivation and vomiting, both of which resolved within 8 hours of administration.[8] In humans, the most common adverse effects associated with gabapentin therapy are dizziness, somnolence, and peripheral edema.[21]

Gabapentin was associated with an increased rate of pancreatic adenocarcinoma in male rats.[21] It is unknown if this effect occurs in other species.

Reproductive/Nursing Safety

At high doses (ie, at or above human maximum doses), gabapentin was associated with a variety of fetotoxic and teratogenic effects (eg, delayed ossification, hydronephrosis, fetal loss) in rats, mice, and rabbits.[21]

Gabapentin enters maternal milk. It has been calculated that a nursing human infant could be exposed to a maximum dosage of 1 mg/kg/day. This is 5% to 10% of the usual pediatric (older than 3 years) therapeutic dose. In veterinary patients, this appears unlikely to be of significant clinical concern.

Overdose/Acute Toxicity

In humans, doses up to 49 g have been reported without fatality. The most likely effects include ataxia, lethargy, somnolence, and diarrhea.[21] Common clinical signs associated with gabapentin overdose include ataxia, lethargy, and vomiting; cats may present with lethargy, sedation, and/or ataxia.

The commercially available oral solution contains xylitol 300 mg/mL; xylitol-containing gabapentin solution dosages of 0.33 mL/kg may cause hypoglycemia or liver toxicity in dogs.

Treatment is supportive, with general decontamination procedures including emesis, activated charcoal, and cathartics. Gabapentin can be removed with hemodialysis. If xylitol toxicity is suspected, secondary to the human-labeled liquid formulation, an animal poison control center should be contacted for further guidance. See ***Appendix***.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving gabapentin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks should be weighed and additional monitoring performed when appropriate.

- **Antacids (Aluminum-, Magnesium-, Calcium-Containing)**: Oral antacids given concurrently with gabapentin may decrease oral bioavailability by 20%; if antacids are required, administration should be separated from gabapentin administration by at least 2 hours. High doses of IV or epidural magnesium may increase the risk for sedation associated with gabapentin.
- **Cannabidiol**: May result in an increased risk for sedation
- **Hydroxyzine**: May result in an increased risk for sedation
- **Minocycline**: May result in an increased risk for sedation
- **Mirtazapine**: May result in an increased risk for sedation
- **Opioid Analgesics**: May result in an increased risk for sedation. Concurrent administration of gabapentin and hydrocodone may increase the area under the curve (AUC) of gabapentin and increase its efficacy and/or adverse effects. Gabapentin can reduce the AUC of hydrocodone, potentially reducing the drug's effectiveness. Morphine may increase gabapentin concentrations.

Laboratory Considerations

- There are reports of gabapentin causing false positive **urine protein** readings on *Ames N-Multistix® SG* dipstick tests in humans. Use of a sulfosalicylic acid precipitation test to determine presence of urine protein is recommended for patients receiving gabapentin.

Dosages

DOGS:

Ancillary therapy of refractory seizures (extra-label):

a) Evidence to support use is relatively weak; suggested dosages range from 10 – 20 mg/kg PO every 8 hours. Some clinicians recommend starting therapy at 10 mg/kg PO every 8 hours to reduce potential for oversedation; some clinicians suggest that dosages up to 30 mg/kg PO every 8 hours or administration every 6 hours may be required for efficacy.

b) A study in dogs with uncontrolled seizures (at least 2 per month and at least 6 over the past 3 months) when phenobarbital and potassium bromide concentrations were therapeutic or subtherapeutic but had unacceptable adverse effects. Dogs received gabapentin at ≈10 mg/kg PO every 8 hours for 3 months. Six of 11 dogs had a minimum of 50% reduction in seizures per week.[25]

Adjunctive analgesic (extra-label): Evidence to support use has strengthened in recent years, and the drug may be effective in some dogs, particularly for treatment of chronic pain conditions

with a neuropathic component. Dosage recommendations are 10 – 20 mg/kg PO every 12 hours, but similar doses as for seizures (10 – 20 mg/kg PO every 8 hours) may be considered. Based on pharmacokinetics, dosing every 8 hours is likely more effective than twice daily dosing.[26] A single oral dose of gabapentin 20 mg/kg 2 hours prior to isoflurane anesthesia produced a 20% MAC-sparing effect.[27]

Storm phobia (extra-label): 25 – 30 mg/kg PO administered 90 minutes before exposure reduced fear behavior.[10]

CATS:

Ancillary therapy of refractory seizures (extra-label): Evidence to support use is weak, but anecdotal initial dosages of 5 – 10 mg/kg PO every 8 to 12 hours have been noted. A recently published review article on epilepsy in cats lists an anecdotal dosage of 5 – 20 mg/kg PO every 6 to 12 hours.[28] Some clinicians have suggested initially giving the drug every 24 hours and then giving more often as necessary.

Adjunctive analgesic (extra-label): Evidence to support use is weak, but anecdotally it has been reported to be effective in some cats, particularly for chronic pain conditions with a neuropathic component. There is no strong evidence to support one dosage recommendation over another, and suggested initial dosages range from 3 mg/kg PO every 24 hours titrated up to 5 – 10 mg/kg PO every 12 hours (if required). Others start at 5 – 10 mg/kg PO every 8 to 12 hours. Based on pharmacokinetics, dosing every 8 hours is likely more effective than twice daily dosing.[26]

Transdermal analgesia (extra-label): 10 mg/kg transdermally to the pinna every 8 hours. Gabapentin was compounded in the proprietary base *Lipoderm*®; the drug was measurable in the serum, and lower pain scores were documented at some, but not all, study points.[29]

Postoperative analgesia following ovariohysterectomy (extra-label): 50 mg/cat (NOT mg/kg) PO 12 hours and 1 hour prior to surgery in addition to buprenorphine at the time of induction[3]

Osteoarthritis (extra-label): 10 mg/kg PO every 12 hours improved osteoarthritic cats overall as assessed by accelerometer and client questionnaire; quality of life was not changed as compared with placebo.[2]

Reduce fear responses and anxiety associated with veterinary examinations (extra label): 50 – 200 mg/cat (NOT mg/kg) PO (equating to 9 to ≈48 mg/kg) reduced fear responses in confined community cats without measurable sedation over 3 hours postadministration.[7–9] In cats with IRIS stage 2 or 3 CKD, 10 mg/kg PO resulted in improved compliance with handling 3 hours after administration.[17]

BIRDS:

Adjunctive analgesic for neuropathic pain in Hispaniolan Amazon parrots (extra-label): One study suggested 15 mg/kg PO every 8 hours as a reasonable starting point.[20]

Monitoring

NOTE: Gabapentin serum concentrations are usually not monitored; therapeutic concentrations are thought to be 4 – 16 µg/mL. When monitoring concentrations in dogs, samples should be taken when peak concentrations occur (≈2 hours postdose). Subsequent concentrations should be drawn at consistent times after administration.

- Clinical efficacy and adverse effects

Client Information

- This medicine may be given with or without food. If your animal vomits or acts sick after receiving the medicine on an empty stomach, give it with food or a small treat. If vomiting continues, contact your veterinarian.
- Drowsiness and loss of coordination are the most common side effects.
- The oral liquid made for humans should not be given to dogs as it contains xylitol, which is toxic to dogs.

Chemistry/Synonyms

Gabapentin occurs as a white to off-white crystalline solid that is freely soluble in water. It has a pK_{a1} of 3.7 and a pK_{a2} of 10.7. It is structurally related to GABA.

Gabapentin may also be known as CI-945, GOE-3450, *Aclonium*®, *Equipax*®, *Gantin*®, *Gabarone*®, *Neurontin*®, *Neurostil*®, and *Progresse*®.

Storage/Stability

The commercially available capsules and tablets should be stored at room temperature (25°C [77°F]); excursions are permitted between 15°C and 30°C (59°F-86°F). The oral liquid should be stored in the refrigerator between 2°C and 8°C (36°F-46°F).

Compatibility/Compounding Considerations

Compounded preparation stability: Commercially available gabapentin solutions contain xylitol, which may be toxic to canine patients. Gabapentin oral suspension compounded from commercially available tablets has been published.[30] Triturating 20 gabapentin 600 mg tablets with 60 mL of *Ora-Plus*® and qs ad to 120 mL with *Ora-Sweet*® (or *Ora-Sweet*® *SF*) yields a 100 mg/mL oral suspension that retains more than 90% potency for 56 days stored at both 4°C (39.2°F) and 25°C (77°F). Liquid formulations of gabapentin are most stable in the pH range of 5.5 to 6.5.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance. See ***Appendix*** for more information.

HUMAN-LABELED PRODUCTS:

Gabapentin Oral Capsules and Tablets: 100 mg, 300 mg, and 400 mg; 600 mg and 800 mg (film-coated); *Neurontin*®, generic; (Rx)

Gabapentin Oral Solution: 250 mg/5 mL (50 mg/mL) in 470 mL; *Neurontin*®, generic; (Rx). **NOTE**: May contain xylitol; label should be checked, and drug should be used cautiously in dogs.

Gabapentin Enacarbil Oral Extended-Release Tablets: 300 mg and 600 mg; *Horizant*®; (Rx). **NOTE**: No information on pharmacokinetics or clinical usage in dogs and cats is noted.

For the complete list of references, see **wiley.com/go/budde/plumb**

Gamithromycin

(gah-***mith***-roe-my-sin) *Zactran®*

Macrolide (Azalide) Antibiotic

Prescriber Highlights

- ► Injectable azalide-class macrolide antibiotic FDA-approved for treatment of BRD in beef and nonlactating dairy cattle; potentially useful in horses, foals, swine, and goats
- ► Not for use in female dairy cattle 20 months of age or older or in calves to be processed for veal
- ► Most common adverse effect is pain and swelling at injection site; colic and lameness have been reported in foals
- ► 35-day slaughter withdrawal (United States label)

Uses/Indications

Gamithromycin is FDA-approved for the treatment of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica, Pasteurella multocida, Histophilus somni,* and *Mycoplasma bovis* in beef and nonlactating dairy cattle.[1] It is also indicated for the control of respiratory disease in beef and nonlactating dairy cattle at high risk for developing BRD associated with *Mannheimia haemolytica* and *Pasteurella multocida*.

Gamithromycin could be useful in other species as well. One study in foals showed that IM doses of 6 mg/kg every 7 days would maintain pulmonary epithelial lining fluid (PELF) concentrations above the MIC_{90} for susceptible isolates of *Streptococcus equi* subsp *zooepidemicus* and phagocytic cell concentrations above the MIC_{90} for susceptible isolates of *Rhodococcus equi*.[2]

A single IM gamithromycin dose is effective for the treatment of swine respiratory disease (SRD) and infectious pododermatitis (foot rot) in sheep.[3]

The World Health Organization (WHO) has designated gamithromycin as a Critically Important, Highest Priority antimicrobial for human medicine.[4] The Office International des Epizooties (OIE) Antimicrobial Classification has designated gamithromycin as a Veterinary Critically Important antimicrobial for bovines.[5]

Pharmacology/Actions

Like other macrolides, gamithromycin penetrates bacterial cell membranes and binds to the 50s ribosomal subunit, thereby inhibiting protein synthesis. It inhibits the translocation process between 30S and 50s ribosomes, causing premature detachment of incomplete peptide chains.

The macrolide antimicrobials, as a class, are weak bases and as such, concentrate in some cells (such as pulmonary leukocytes). Prolonged exposure of extracellular pulmonary pathogens to macrolides appears to reflect the slow release of drug from its intracellular reservoir to the site of action, the pulmonary epithelial lining fluid (PELF). It is the drug concentration in the PELF that is relevant to the successful treatment and control of BRD. Gamithromycin is primarily bacteriostatic at therapeutic concentrations. Macrolides typically exhibit substantially higher concentrations in the alveolar macrophages and PELF as compared to concentrations observed in plasma.[1] Gamithromycin concentrations in the PELF and PELF cells exceed the concentrations observed in the plasma.

Significant increases in MIC can occur in *P multocida* and *M haemolytica* with the *msr*(E)-*mph*(E) gene.[6]

Pharmacokinetics

In cattle, after a 6 mg/kg SC (in neck) dose, gamithromycin absorption is complete and peak plasma concentrations occur in ≈1 hour. Volume of distribution is very high (≈25 L/kg) and only 26% of drug in plasma is bound to plasma proteins. Based on plasma and lung homogenate data, the terminal half-life ($T_{1/2}$) of gamithromycin is ≈3 days. Clearance is 712 mL/kg/hour and elimination half-life is ≈51 hours. The primary route of elimination is biliary excretion of unchanged drug. After a single (6 mg/kg) dose, gamithromycin concentrations in PELF, bronchiolar lavage fluid (BAL) cells, and lung tissue can persist above reported MIC_{90} for labeled organisms for 7 days (PELF) to 10 to 15+ days (BAL cells and lung tissue).[7–10]

In foals after a 6 mg/kg IM dose, peak plasma concentrations occur in ≈1 hour and elimination half-life is ≈39 hours. Gamithromycin concentrations in PELF were above the MIC_{90} for susceptible isolates of *S zooepidemicus* and phagocytic cell concentrations above the MIC_{90} for susceptible isolates of *R equi* for ≈7 days.[2]

Contraindications/Precautions/Warnings

Gamithromycin is contraindicated in animals that are hypersensitive to it. Potentially, animals hypersensitive to other azalide or macrolide antibiotics could also react to gamithromycin. Subcutaneous injection may cause a temporary local tissue reaction in some animals that may result in trim loss of edible tissues at slaughter.

Cross-resistance may occur with other macrolide/azalide antibiotics (eg, tulathromycin, tilmicosin).

Adverse Effects

Pain and swelling at the injections site are common. Swelling and local inflammation at injection site usually resolves within 3 to 14 days but has been reported to persist up to 35 days postinjection.[3]

In foals being treated for bronchopneumonia with IM gamithromycin, colic and hind limb lameness were observed in 45% and 40% of foals, respectively.[11]

Reproductive/Nursing Safety

Although gamithromycin is not labeled for use in pregnant animals, the product's material safety data sheet (MSDS) notes that none of the ingredients are considered to be a reproductive, teratogenic, or developmental toxin. The UK label reads: *Based on laboratory animal data, gamithromycin has not produced any evidence of selective developmental or reproductive effects. The safety of gamithromycin during pregnancy and lactation has not been evaluated in cattle. Use only according to the risk-benefit assessment by the responsible veterinarian.*[3]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Subcutaneous injections of gamithromycin 18 mg/kg and 30 mg/kg (3 times and 5 times the label dose, respectively) given every 5 days for 3 doses to 6-month-old beef cattle caused swelling and pain at the injection site (neck twisting, attempts to scratch or lick the injection site, and pawing at the ground).[12] Other clinically relevant treatment-related effects were not observed.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving gamithromycin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Rifampin:** Decreased gamithromycin clearance and increased gamithromycin exposure (AUC) in foals[13]

Laboratory Considerations

None noted

Dosages

HORSES:

Mild-moderate bronchopneumonia due to *Rhodococcus equi* (extra-label): 6 mg/kg bodyweight IM in the semimembranosus/semitendinosus muscles once a week for a minimum of 40 days; efficacy was similar to the combination of azithromycin with rifampin but had a much higher frequency of adverse effects.[14] Criteria for discontinuation of treatment were resolution of clinical signs and no evidence of consolidation upon thoracic ultrasonography for 2 consecutive weeks after a minimum of 40 days of treatment. The use of a diluted, IV administration of gamithromycin (6 mg/kg diluted with water to 50 mL final volume and injected IV over 2 to 3 minutes) has been reported.[15]

CATTLE:

Treatment of bovine respiratory disease (BRD) associated with *Mannheimia haemolytica, Pasteurella multocida, Histophilus somni,* and *Mycoplasma bovis* in beef and nonlactating dairy cattle; also indicated for the control of respiratory disease in beef and nonlactating dairy cattle at high risk for developing BRD associated with *Mannheimia haemolytica* and *Pasteurella multocida* (label dosage; FDA-approved): 6 mg/kg (2 mL/110 lb) bodyweight (BW) SC in the neck (in front of the shoulder) once.[1] If the total dose exceeds 10 mL, divide the dose so that no more than 10 mL is administered at each injection site. Animals should be appropriately restrained to achieve the proper route of administration.

SHEEP:

Elimination of footrot due to *Dichelobacter nodosus* (extra-label): 6 mg/kg SC administered cranial to the shoulder[3], or in the axilla[16]

GOATS:

Naturally occurring pneumonia in kids (extra-label): 6 mg/kg IM once[17]

SWINE:

Bacterial swine respiratory disease (extra-label): 6 mg/kg IM once in the neck[3,18,19]

***Bordetella bronchiseptica*-associated respiratory disease in piglets** (extra-label): 6 mg/kg IM once[20]

Monitoring

- Clinical response: In field trials, animals that responded to therapy did so within 24 hours of injection.

Client Information

- Understand and follow use restrictions and withdrawal times for food animals.
- Reactions (pain, swelling) at the administration site are common but usually resolve within a few days.
- Humans with a known drug allergy to macrolide antibiotics (eg, erythromycin, clarithromycin) should avoid contact with this medicine.
- In case of skin or eye exposure, wash and flush area with clean water. If accidental self-injection, seek medical advice immediately and show the product label to the physician.

Chemistry/Synonyms

Gamithromycin is a 7a-azalide macrolide antibiotic (CAS Registry: 145435-72-9). It differs structurally from other macrolides by having a 15-membered semisynthetic lactone ring with an alkylated nitrogen at the 7a-position. The commercially available injectable solution contains per mL: 150 mg of gamithromycin as the free base, 1 mg of monothioglycerol, and 40 mg of succinic acid in a glycerol formal vehicle.

Gamithromycin may also be known as ML-1,709,460 or UNII-ZE856183S0. A trade name is *Zactran*®.

Storage/Stability

The injection should be stored at or below 25°C (77°F) with excursions permitted between 15°C and 30°C (59°F-86°F). Use within 18 months of first puncture (United States label); once opened, use within 28 days (UK label). Viscosity of the injectable solution may increase at sub-freezing temperatures but should not affect syringability.[7]

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

No information was noted on the label (United States) or in other references, but the UK label states: Do not mix with any other veterinary medicinal product. In one study, gamithromycin injection was diluted with water to a final volume of 50 mL immediately prior to IV administration (over 2 to 3 minutes).[15]

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Solution for Injection: 150 mg/mL in 100 mL, 250 mL, and 500 mL bottles. *Zactran*®; (Rx). FDA-approved for use in beef and nonlactating dairy cattle. NADA #141-328

Withdrawal times/restrictions in the United States: Do not treat cattle within 35 days of slaughter. Do not use in female dairy cattle 20 months of age or older, or in calves to be processed for veal.

Withdrawal times/restrictions in the UK: Meat and offal withdrawal period: cattle, 64 days; sheep, 29 days; swine, 16 days. Not authorized for use in lactating animals producing milk for human consumption. In pregnant animals which are intended to produce milk for human consumption, do not use within 2 months (cows, heifers) or 1 month (sheep) of expected parturition.

HUMAN-LABELED PRODUCTS: NONE

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Gemcitabine

(jem-***site***-ah-ben) *Gemzar*®

Antineoplastic

Prescriber Highlights

- ► Antineoplastic agent potentially useful for treatment of several cancer types in dogs and cats as a single agent or part of chemotherapy protocol, or for tumors in which standard of care has not been definitively established
- ► Adverse effects: GI effects and myelosuppression (neutropenia) are most likely.
- ► The National Institute for Occupational Safety and Health (NIOSH) classifies gemcitabine as a hazardous drug; use appropriate precautions when handling.

Uses/Indications

Gemcitabine is an antineoplastic agent that has demonstrated limited clinical efficacy when used as a single agent in dogs with solid tumors.[1,2] However, no benefit was found when it was used in dogs with lymphoma[3] or nonresectable hepatocellular carcinoma,[4] or as an adjuvant to surgical removal of aggressive malignant mammary tumors.[5] The assessment of gemcitabine's additive or synergistic activities in combination have not been definitively confirmed. Simi-

larly, studies that assessed gemcitabine combination therapy in dogs have produced mixed results.[6–8]

A retrospective study in cats with exocrine pancreatic carcinoma showed that 82% of cats treated with gemcitabine (± carboplatin) had decreased clinical signs associated with their malignancies, but due to the retrospective nature of the study, any determination of actual improvement of quality of life was questionable.[9]

Gemcitabine has been used as a radiosensitizer for nonresectable tumors.[10] However, safe and effective dosing regimens have not been established and life-threatening toxicities have been reported with concurrent use in humans.[11] In one study, gemcitabine was given IV twice weekly as a radiosensitizing agent to 10 cats with oral squamous cell carcinoma and 15 dogs with nasal carcinoma undergoing radiotherapy.[12] The average dose was 50 mg/m^2 and 25 mg/m^2 in dogs and cats, respectively. Twelve of 15 dogs (80%) and 5 of 10 cats (50%) required chemotherapy dose reduction or postponement because of hematologic or normal tissue toxicity.

Based on documented significant toxicities, the use of gemcitabine at the studied dose and schedule is not recommended as a radiosensitizer.[12] In contrast, one small pilot study with 8 cats found that gemcitabine combined with palliative radiation was tolerable and produced exceptional response rates (75%) in cats with oral squamous cell carcinoma.[10]

In humans, gemcitabine, in combination with other chemotherapeutic agents, has shown efficacy in treating breast, pancreatic, small-cell lung, and ovarian cancers.

Pharmacology/Actions

Gemcitabine exhibits cell phase specificity, acting primarily on the S phase killing cells undergoing DNA synthesis and inhibiting cell progression through the G1/S-phase boundary.

Gemcitabine is metabolized intracellularly to diflurodeoxycytidine monophosphate (dFdCMP), which is then converted into diphosphate (dFdCDP) and triphosphate (dFdCTP) forms, the metabolites that give the drug its activity. The diphosphate inhibits ribonucleotide reductase. The triphosphate competes with deoxycytidine triphosphate (dTCP; the "normal nucleotide") for incorporation into DNA strands. DNA polymerase epsilon is unable to recognize the abnormal nucleotide (gemcitabine) and repair the DNA strand, which results in a prolonged intracellular half-life of gemcitabine compared with other nucleoside analogues.

Pharmacokinetics

In dogs, gemcitabine exhibits first-order elimination and has a terminal half-life of ≈1.5 to 3.2 hours. Volume of distribution (steady-state) is ≈1 L/kg. Approximately 80% of the drug is excreted in the urine within 24 hours of dosing, primarily as the uracil metabolite.[4]

In humans, gemcitabine pharmacokinetics were significantly influenced by gender and duration of infusion.[11] For infusions lasting less than 70 minutes versus longer infusions, volume of distribution was ≈50 L/m^2 and 370 L/m^2, respectively. Protein binding is negligible and less than 10% of the drug is excreted unchanged in the urine.

Contraindications/Precautions/Warnings

Gemcitabine is contraindicated in patients with a history of hypersensitivity to it and should be used with caution in patients with diminished renal or hepatic function.

In humans, infusions lasting longer than 60 minutes or administration more frequent than once weekly resulted in increased toxicities. Doses should be reduced or postponed in animals with severe myelosuppression.[11] Pulmonary toxicity has been reported in humans and can occur up to 2 weeks after the last dose; gemcitabine should be discontinued if unexplained new or worsening dyspnea or any other pulmonary symptoms occur. Life-threatening toxicities have occurred in humans receiving gemcitabine within 7 days of radiation therapy.

The National Institute for Occupational Safety and Health (NIOSH) classifies gemcitabine as a hazardous drug; personal protective equipment (PPE) should be used accordingly to minimize the risk for exposure.

Adverse Effects

Myelosuppression is usually the dose-limiting toxicity of gemcitabine and can include neutropenia, anemia, and thrombocytopenia, but neutrophils and platelets appear to be most affected. Neutrophil nadirs usually occur 3 to 7 days after treatment. GI effects have been reported but are usually mild to moderate.[2,8] Retinal hemorrhage could occur in animals receiving gemcitabine.[2]

In humans, the most common adverse effects are nausea and vomiting, anemia, hepatic transaminitis, neutropenia, increased alkaline phosphatase, proteinuria, fever, hematuria, rash, thrombocytopenia, dyspnea, and peripheral edema.[11]

Reproductive/Nursing Safety

Gemcitabine was teratogenic, embryotoxic, and fetotoxic in mice and rabbits.[11]

For sexually intact patients, verify pregnancy status prior to administration.

It is unknown whether gemcitabine is excreted in maternal milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

There is no known antidote to gemcitabine. In humans following a single dose of 5700 mg/m^2, myelosuppression, paresthesia, and severe rash were reported.[11] It is unknown if the drug is dialyzable, and the recommended treatment is supportive.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving gemcitabine and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Immunosuppressive Agents** (eg, **azathioprine, high-dose glucocorticoids, leflunomide, pyrimethamine**): Concurrent use may result in additive immunosuppression.
- **Myelosuppressive Agents** (eg, **antineoplastics**, **chloramphenicol**, **iron chelators**): Concurrent use with other bone marrow depressant medication may result in additive myelosuppression; avoid combination when possible.
- **Vaccines** (live and inactivated): Gemcitabine may diminish vaccine efficacy and enhance adverse effects of vaccines.

Laboratory Considerations

- None were noted.

Dosages

NOTE: Because of the potential toxicity of this drug to patients, veterinary personnel, and clients, and because chemotherapy indications, treatment protocols, monitoring and safety guidelines often change, the following dosages should only be used as a general guide. Consultation with a veterinary oncologist and referral to current veterinary oncology references[13–17] are strongly recommended.

DOGS/CATS:

Antineoplastic agent (extra-label): Relatively safe and effective dosages for gemcitabine in veterinary patients with potentially susceptible tumors are not known. Depending on the study, clinician, and protocol, dosages for dogs and cats have ranged widely from 45 mg/m^2 – 900 mg/m^2 (NOT mg/kg), usually given IV over 30 to 60 minutes every 7 to 14 days. Some studies combining gemcitabine with carboplatin in dogs and cats have used 2 mg/kg IV over 20 to 30 minutes no more than once every 7 days.

- 400 mg/m^2 (NOT mg/kg) weekly in dogs with lymphoma; dose reduction or treatment delay required due to significant decreases in neutrophils and platelets.[18]
- 675 mg/m^2 (NOT mg/kg) every 2 weeks in dogs; demonstrated minimal and acceptable toxicity[1]
- 800 – 950 mg/m^2 (NOT mg/kg) in dogs; efficacy was demonstrated at the maximum tolerated dose of 900 mg/m^2 (NOT mg/kg).[1]

Monitoring

- CBC before each treatment
- Fundic examination weekly while on therapy
- Prior to therapy, baseline renal and hepatic function and periodically thereafter

Client Information

- Gemcitabine is a chemotherapy (anticancer) drug. The drug can be hazardous to other animals and people that come in contact with it. On the day your animal gets the drug and then for a few days afterward, all bodily waste (eg, urine, feces, litter), blood, or vomit should only be handled while wearing disposable gloves. Seal the waste in a plastic bag, then place both the bag and gloves in the regular trash.
- This medication is considered to be a hazardous drug as defined by the National Institute for Occupational Safety and Health (NIOSH) because it may affect the reproductive ability of men or women actively trying to conceive, women who are pregnant or may become pregnant, and women who are breastfeeding. It is recommended that you wear gloves when administering this medication to your animal and wash your hands thoroughly afterwards. If you have questions about this medication's hazards, please speak with your veterinarian or pharmacist.
- Bone marrow suppression can occur. The greatest effects on bone marrow usually occur within a few weeks after treatment. Your veterinarian will do blood tests to watch for this, but if you see bleeding, bruising, fever (indicating an infection), or if your animal becomes tired easily, contact your veterinarian right away.
- Monitor for and immediately report any signs associated with toxicity (eg, abnormal bleeding, bruising, urination, depression, infection, shortness of breath).
- While your animal is taking this medication, it is important to return to your veterinarian for laboratory work. Do not miss these important follow-up visits.

Chemistry/Synonyms

A synthetic pyrimidine nucleoside cytarabine analogue antineoplastic agent, gemcitabine HCl occurs as white to off-white solid. It is soluble in water and practically insoluble in ethanol or polar organic solvents. Its chemical name is 2,2'-diflurodeoxycytidine.

Gemcitabine may also be known as: dFdC, LY-288022, *Abine®*, *Antoril®*, *Gemcite®*, or *Gemtrol®*, and *Gemzar®*.

Storage/Stability

Store gemcitabine solution refrigerated at (2°C-8°C [36°F-46°F]). Store unreconstituted gemcitabine lyophilized powder at controlled room temperature (20°C-25°C [68°F-77°F]). After reconstitution with 0.9% sodium chloride injection without preservatives, the resulting solution may be stored at room temperature for up to 24 hours.[11] Do not refrigerate, as crystallization may occur. Reconstituted solution concentration should not be greater than 40 mg/mL (at least 5 mL of diluent for 200 mg vial; 25 mL diluent for 1 gram vial). Additional diluent may be added to yield concentrations as low as 0.1 mg/mL. Discard all unused portions.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

Gemcitabine injection is reportedly physically **incompatible** with the following medications when used via Y-site injection: acyclovir, amphotericin B, cefoperazone, cefotaxime sodium, furosemide, imipenem, methotrexate, methylprednisolone sodium succinate, mitomycin, piperacillin, and prochlorperazine.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Gemcitabine HCl Lyophilized Powder for Injection: 200 mg, 1 g, and 2 g in single-use vials; generic; (Rx)

Gemcitabine Injection: 200 mg/5.26 mL, 1 g/26.3 mL, and 2 g/52.6 mL in single-use vials; generic; (Rx)

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Gemfibrozil

(jem-***fih***-broh-zil) *Lopid®*

Oral Antihyperlipidemic

Prescriber Highlights

- ► May be useful as adjunctive therapy, along with a low-fat diet, to treat hypertriglyceridemia in dogs and cats
- ► Limited experience in veterinary medicine and no published clinical studies in dogs or cats. Safety and efficacy are not established; dosages are anecdotal.
- ► Contraindications in dogs and cats are extrapolated from human data and include hypersensitivity to gemfibrozil, hepatic dysfunction, severe renal dysfunction, and pre-existing gallbladder disease.
- ► Adverse effects may include GI effects (eg, vomiting, diarrhea, abdominal pain, decreased appetite) and abnormal liver function tests.

Uses/Indications

Gemfibrozil may be useful in dogs and cats with hypertriglyceridemia to reduce serum triglycerides when diet modifications alone have been unsuccessful. The addition of drug therapy to maintain fasting serum triglyceride concentration below 400 mg/dL has been suggested.[1] Another recommendation is to add gemfibrozil to dietary therapy in dogs when dietary therapy alone fails to lower triglyceride levels below 5.65 mmol/L (500 mg/dL).[2] Some canine patients reportedly do not respond well to treatment with gemfibrozil.[3,4]

Pharmacology/Actions

Gemfibrozil inhibits lipoprotein lipase lipolysis in adipose tissue and reduces hepatic uptake of plasma-free fatty acids, causing reduced production of triglycerides and reduced serum triglyceride concentrations. Secondarily, gemfibrozil inhibits the synthesis of very-low-density lipoprotein (VLDL) carrier apolipoprotein B, which reduces VLDL production and incorporation of long-chain

fatty acids into triglycerides. Gemfibrozil increases high density lipoprotein (HDL) cholesterol but has only a modest effect on LDL or total cholesterol.[5]

Pharmacokinetics

No pharmacokinetic data for dogs or cats were found. In humans, gemfibrozil is rapidly and completely absorbed from the GI tract and undergoes enterohepatic recirculation. The rate and extent of absorption are greatest when administered 30 minutes before a meal. It is highly bound to plasma proteins, and the highest concentrations are found in the liver and kidneys. In the liver, 4 major metabolites are formed in humans, which are primarily excreted in the urine. The elimination half-life is ≈1.5 hours.[5] Reductions in plasma VDL concentrations are noted within 5 days; peak reductions occur about 4 weeks after starting therapy.

Contraindications/Precautions/Warnings

Gemfibrozil is contraindicated in dogs or cats that are hypersensitive to it. In humans, gemfibrozil is contraindicated in patients with hepatic dysfunction, severe renal dysfunction, or preexisting gallbladder disease.[5] Gemfibrozil is not recommended in humans with elevations of LDL only or with low HDL only.

Long-term studies done in rats that were administered at 1.7 times the labeled human dosage demonstrated increased rates of neoplasia (hepatic and testicular interstitial cell)[5]; gemfibrozil should only be used when the benefits outweigh the potential risks.

Use with caution in dogs and cats as very limited safety data are available for this medication.

Adverse Effects

Because no clinical studies have been published regarding gemfibrozil use in dogs and cats and clinical use has been quite limited, the accurate adverse effect profile is not known. Anecdotal reports indicate that gemfibrozil is well tolerated in the small population of patients that have received it. Reported adverse effects include abdominal pain, vomiting, diarrhea, and decreased appetite.[3,4]

In humans, the most common adverse effects reported are GI related (dyspepsia, nausea, vomiting, diarrhea) and CNS related (headache, paresthesias, somnolence, dizziness, fatigue). Other reported adverse effects include myositis, taste alterations, blurred vision, eczema, and decreased libido (impotence). Rarely, hypersensitivity reactions, myelosuppression, cholelithiasis, and increases in liver enzymes and function test values (AST, ALT, ALP, bilirubin) have been reported.[5]

Reproductive/Nursing Safety

Gemfibrozil administered to female rats prior to and during gestation at 0.6 to 2 times the human dose showed decreased fertility rates, and their offspring had an increased incidence of skeletal abnormalities. When given to pregnant rabbits at 1 to 3 times the human dose, litter sizes were decreased, and at the highest dose (3 times the labeled dose), parietal bone variations were noted.[5]

It is not known if gemfibrozil enters milk, and safe use during nursing cannot be assured. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available. One 7-year-old child ingested up to 9 g of gemfibrozil and recovered with supportive treatment.[5] The reported LD_{50} (oral) in rats is 3160 mg/kg. Consider GI decontamination protocols for acute, large oral ingestions and support as required. Monitor for dehydration and electrolyte imbalance if vomiting and/or diarrhea is severe or persists. Monitor liver enzymes and function tests.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving gemfibrozil and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Amiodarone**: May increase amiodarone exposure
- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, propranolol**): May increase triglyceride concentrations
- **Colchicine**: Increased risk for myopathy
- **Estrogens**: May increase triglyceride concentrations
- **Glipizide, Glyburide, and Glimeperide**: May result in hypoglycemia
- **Insulin**: May increase risk for hypoglycemia
- **Loperamide**: Concurrent use may result in increased loperamide plasma concentrations
- **Statins** (eg, **atorvastatin, simvastatin**): Increased risk for myopathy and rhabdomyolysis; concurrent use is contraindicated in humans
- **Thiazide Diuretics**: May increase triglyceride concentrations
- **Ursodiol**: May reduce the effectiveness of gemfibrozil
- **Warfarin**: Gemfibrozil may potentiate anticoagulant effects.

Laboratory Considerations

- No specific concerns associated with gemfibrozil; see ***Monitoring*** section below.

Dosages

DOGS/CATS:

Hypertriglyceridemia that has not been controlled with diet alone (extra-label): There is little information published on the safety and efficacy of this agent in dogs or cats. Anecdotal dosage recommendations for dogs are 10 mg/kg PO every 12 hours[1,4] or 150 – 300 mg/dog (NOT mg/kg) PO twice daily and for cats 7.5 – 10 mg/kg PO twice daily.[1] Based on human data, gemfibrozil should be given ≈30 minutes prior to meals.[5]

Monitoring

- Fasting plasma triglycerides; the realistic goal for therapy is 400 mg/dL or less.
- Baseline and periodic CBC
- Baseline and periodic serum liver enzymes and function tests
- Adverse effects (vomiting, diarrhea, appetite)
- If treatment is less effective than expected, ensure that clients have adhered to prescribed diet and dosing schedule before altering the dosage.

Client Information

- The use of this medicine in animals is investigational. Although it is FDA-approved for use in humans, there is little information about its use in dogs or cats.
- For this medicine to work, it is important to use gemfibrozil with the dietary recommendations made by your veterinarian.
- Give this medication 30 minutes before meals, as food can interfere with how well this medicine works.
- Report any significant side effects to your veterinarian, including changes in behavior, activity level, gastrointestinal effects (vomiting, diarrhea, lack of appetite), or yellowing of the eyes, skin, or gums (*jaundice*).

Chemistry/Synonyms

Gemfibrozil is a fibric acid derivative that occurs as a waxy, crystalline solid that is practically insoluble in water but soluble in alcohol.

Gemfibrozil may also be known as CI-719, gemfibrozilo, or gemfibrozilium; many international trade names are available.

Storage/Stability

Store gemfibrozil tablets or capsules below 30°C (86°F) in tight containers.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Gemfibrozil Oral Tablets: 600 mg; *Lopid*®, generic; (Rx). **NOTE**: 300 mg capsules are available in Canada.

Gentamicin, Systemic

(jen-ta-***mye***-sin) *Gentocin®, Garamycin®*

Aminoglycoside Antibiotic

See also ***Gentamicin Ophthalmic***

Prescriber Highlights

- ► Parenteral aminoglycoside antibiotic that is active against a variety of bacteria, predominantly gram-negative aerobic bacilli but also many staphylococci
- ► Intravitreal injection may be used to manage equine recurrent uveitis (ERU) and for management of uncontrolled elevated intraocular pressure (IOP) associated with end-stage glaucoma.
- ► Reserved for serious infections because of potential adverse effects (nephrotoxicity, ototoxicity, and neuromuscular blockade)
- ► Cats may be more sensitive to toxic effects, especially vestibular effects.
- ► Risk factors for nephrotoxicity include preexisting renal disease, age (both neonatal and geriatric), fever, treatment duration, hypokalemia, sepsis, hypotension, dehydration, and concurrent use with other potentially nephrotoxic drugs (eg, furosemide).

Uses/Indications

Although gentamicin is considered a first line agent in horses, the potential for toxicity of aminoglycosides limits their systemic (parenteral) use in other species to the treatment of serious infections when there is either a documented lack of susceptibility to other less toxic antibiotics or when the clinical situation dictates immediate treatment of a presumed gram-negative infection before culture and susceptibility results can be reported.

Various gentamicin products are FDA-approved for parenteral use in dogs, cats, swine, chickens, and turkeys, although the injectable products for small animal species are no longer marketed. Although routinely used parenterally in horses, gentamicin is only FDA-approved for intrauterine infusion in this species. Oral products are FDA-approved for GI infections in swine and turkeys.

Intravitreal injection of gentamicin may be beneficial for managing end-stage glaucoma[1] and equine recurrent uveitis (ERU).[2,3]

The World Health Organization has designated gentamicin as a Critically Important, High Priority antimicrobial for human medicine.[4] The Office International des Epizooties (OIE) has designated gentamicin as a Veterinary Critically Important Antimicrobial (VCIA) Agent in avian, bovine, camelid, caprine, equine, lagomorph, and ovine species.[5]

Pharmacology/Actions

Gentamicin has a mechanism of action and spectrum of activity (primarily gram-negative aerobes) similar to the other aminoglycosides covering *Escherichia coli, Klebsiella, Proteus, Pseudomonas, Salmonella, Enterobacter, Serratia, Shigella, Mycoplasma,* and *Staphylococcus*. Strains of *Pseudomonas aeruginosa*, *Proteus*, and *Serratia* that are resistant to gentamicin may still be susceptible to amikacin. Although gentamicin has in vitro activity against *Rhodococcus equi,* its water-soluble nature does not allow it to penetrate intracellularly, but liposomal forms show promise. Gentamicin acts on susceptible bacteria presumably by irreversibly binding to the 30S ribosomal subunit, thereby inhibiting protein synthesis. It is considered a bactericidal concentration-dependent antibiotic. A ratio of 10 or greater for peak plasma concentration to MIC is believed to be optimal for antibacterial efficacy.

Antimicrobial activity of the aminoglycosides is enhanced in an alkaline environment. The presence of pus, necrotic tissue, or cellular debris reduce aminoglycoside efficacy.

The aminoglycoside antibiotics are not active against fungi, viruses, and most anaerobic bacteria, although gentamicin has demonstrated in vitro activity against *Malassezia pachydermatis*.[6]

Intravitreal injection of gentamicin chemically ablates the ciliary body, thus reducing production of aqueous humor and lowering intraocular pressure (IOP).[1]

Pharmacokinetics

Gentamicin, like other aminoglycosides, is not appreciably absorbed after oral or intrauterine administration, but is absorbed from local administration (not skin or urinary bladder) when it is used in irrigations during surgical procedures, regional limb perfusion, or when impregnated into materials that are administered locally (eg, PMMA beads, collagen sponges, gels). Patients receiving oral aminoglycosides with hemorrhagic or necrotic enteritises may absorb appreciable quantities of the drug. After IM administration to dogs and cats, peak concentrations occur in 30 minutes to 1 hour. SC injection results in slightly delayed peak concentrations and more variability than after IM injection. Bioavailability from extravascular injection (IM or SC) is greater than 90%.

After absorption, aminoglycosides are distributed primarily in the extracellular fluid. They are found in ascitic, pleural, pericardial, peritoneal, synovial, and abscess fluids and high concentrations are found in sputum, bronchial secretions, and bile. Aminoglycosides are minimally protein bound (less than 20%) to plasma proteins. Aminoglycosides do not readily cross the blood-brain barrier or penetrate ocular tissue. CSF concentrations are unpredictable and range from 0% to 50% of those found in the serum. Therapeutic concentrations are found in the bone, heart, gallbladder, and lung tissues after parenteral dosing. Aminoglycosides tend to accumulate in certain tissues, such as the inner ear and kidneys, which may explain their toxicity. Volumes of distribution have been reported to be 0.15 to 0.3 L/kg in adult dogs and cats, and 0.26 – 0.58 L/kg in horses. Volumes of distribution may be significantly larger in neonates and juvenile animals due to their higher extracellular fluid fractions. Elimination of aminoglycosides after parenteral administration occurs almost entirely by glomerular filtration. The elimination half-lives for gentamicin have been reported to be 1.82 to 3.25 hours in horses, 2.2 to 2.7 hours in calves, 2.4 hours in sheep, 1.8 hours in cows, 1.9 hours in swine, 1 hour in rabbits, and 0.5 to 1.5 hours in dogs and cats. Patients with decreased renal function can have significantly prolonged half-lives. In humans with normal renal function, elimination rates can be highly variable with the aminoglycoside antibiotics.

Contraindications/Precautions/Warnings

Aminoglycosides are contraindicated in patients that are hypersensitive to them. Because these drugs are often the only effective agents

in severe gram-negative and staphylococcal infections, there are no other absolute contraindications to their use. However, they should be used with extreme caution in patients with preexisting renal disease, with concomitant monitoring and dosage interval adjustments made. Other risk factors for the development of toxicity include age (both neonatal and geriatric patients), fever, hypokalemia, treatment duration, sepsis, hypotension, and dehydration.

Monitor renal function prior to and during therapy. If signs of acute kidney injury (eg, renal casts in urine sediment, glucosuria, low urine-specific gravity, azotemia) are noted, therapy should be halted if possible, and alternative antibiotic therapy should be instituted.

Dosing adjustments (ie, prolonging dosing interval) can be used in situations where the risks for ongoing treatment outweigh renal concerns. Dosing is best based on measurement of peak and trough drug levels.

When administering gentamicin by intravitreal injection, it is recommended to use a preservative-free formulation.

Because aminoglycosides can cause irreversible ototoxicity, they should be used with caution in working or service dogs (eg, seeing-eye, herding, dogs for the hearing impaired) and should be avoided for treatment of otitis if an intact tympanic membrane is not known to be present. Gentamicin is considered more ototoxic than amikacin.[7]

Aminoglycosides should be used with caution in patients with neuromuscular disorders (eg, myasthenia gravis) because of their neuromuscular blocking activity. They should not be used in animals with botulism.

Sighthound dogs may require reduced dosages of aminoglycosides, as they have significantly smaller volumes of distribution.

Because aminoglycosides are eliminated primarily through renal mechanisms, they should be used cautiously, preferably with serum monitoring and dosage adjustment in neonatal or geriatric animals.

IM injections in horses have caused muscle irritation and IV injections are preferred. IV administration may be associated with allergic and anaphylactic reactions in horses. The injection should be pre-warmed and administered slowly. If clinical signs occur, corticosteroid treatment may be necessary. The risk for antibiotic-associated diarrhea/colitis in horses caused by gentamicin is thought to be low, but gentamicin may enhance beta-2 toxin production by *Clostridium perfringens* and may increase the severity of colitis.[8]

The American Association of Bovine Practitioners discourages extra-label aminoglycoside use in bovines.

Adverse Effects

Aminoglycosides' nephrotoxic and ototoxic effects are well known. The nephrotoxic (tubular necrosis) mechanisms of these drugs are not completely understood but are likely related to accumulation in the renal convoluted tubules, interfering with phospholipid metabolism in the lysosomes of proximal renal tubular cells, and resulting in leakage of proteolytic enzymes into the cytoplasm. Nephrotoxicity is usually recognized by azotemia and decreases in urine-specific gravity and creatinine clearance. Proteinuria and cells or casts may also be seen in the urine. Nephrotoxicity is usually reversible once the drug is discontinued, but development of oliguric acute kidney injury portends a poor prognosis. Although gentamicin may be more nephrotoxic than some other aminoglycosides, the risk for nephrotoxicity with all systemic aminoglycosides requires equal caution and monitoring. Strategies to reduce the potential for nephrotoxicity in animals with uncompromised renal function include once-daily administration, renal function monitoring, hydration and electrolyte balance, avoidance of other nephrotoxic drugs, and employment of therapeutic drug monitoring to adjust dosages and/or dosing intervals to maintain low trough concentrations (preferably less than 1 – 2 µg/mL). One study in rats showed that concurrent administration of ampicillin prevented nephrotoxicity, presumably by having a higher affinity than gentamicin for the renal tubule system.[9]

Aminoglycoside ototoxicity (eighth cranial nerve toxicity) can manifest by either auditory and/or vestibular clinical signs and may be irreversible. Vestibular clinical signs are more frequent with streptomycin, gentamicin, or tobramycin. Auditory clinical signs are more frequent with amikacin, neomycin, or kanamycin, but other forms can occur with any of the drugs.[7] Cats are apparently very sensitive to the vestibular effects of the aminoglycosides and can exhibit signs of vertigo, head tilt, ataxia, impaired righting reflex, and post-rotatory righting reflex.

Aminoglycosides can also cause neuromuscular blockade, facial edema, pain and inflammation at the injection site, peripheral neuropathy, and hypersensitivity reactions. Rarely, GI clinical signs, hematologic, and hepatic effects have been reported.

It has been anecdotally reported that some horses, after IV gentamicin administration, have colic-like symptoms including groaning, flehmen response, heavy sweating, pawing, tachypnea, tachycardia, laying down, rolling, shivering, and muscle tremors. These symptoms may indicate an allergic/anaphylactic reaction. In most cases, effects have been temporary, with full recovery occurring in a short time. Pre-warming the injection and injecting slowly may possibly prevent this reaction. Corticosteroid treatment may be necessary.

Although causation has not been proven, intravitreal gentamicin injections for ciliary body ablation may be linked to the development of intraocular tumors in dogs and cats.[10,11] Cataract formation and diffuse retinal degeneration have been reported in horses following intravitreal injection of low-dose gentamicin for management of equine recurrent uveitis (ERU).[3]

Reproductive/Nursing Safety

Aminoglycosides can cross the placenta and, although rare, may cause eighth cranial nerve toxicity or nephrotoxicity in fetuses. Because the drug should only be used in serious infections, the benefits of therapy may exceed the potential risks. One study showed no detectable levels in foals when gentamicin was administered to mares at term.[12] In other species, fetal concentrations range from 15% to 50% of those found in maternal serum.

Although small amounts of gentamicin may be excreted into milk, the risk to nursing offspring appears minimal.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No toxic effects were observed in cats receiving 10 mg/kg/day for 40 days,[13] but respiratory paralysis and neuromuscular blockade have been reported in cats receiving doses of 40 mg/kg.[14]

If an inadvertent overdose is given, dialysis can be used to reduce serum gentamicin concentrations. Hemodialysis effectively reduces serum gentamicin concentrations[14] but is not a viable option for most veterinary patients. Peritoneal dialysis also will reduce serum gentamicin concentrations but is much less effective.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving gentamicin and may be of concern in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Beta-Lactam Antibiotics** (eg, **penicillins**, **cephalosporins**): May have synergistic effects against some bacteria; there is some potential for inactivation of aminoglycosides when admixed or when administered together in patients with renal failure.
- **Cephalosporins**: The concurrent use of aminoglycosides with cephalosporins is somewhat controversial. Potentially, cephalosporins could cause additive nephrotoxicity when used with aminoglycosides, but this interaction has only been well documented with cephaloridine and cephalothin (both no longer marketed).
- **Diuretics, Loop** (eg, **furosemide**, **torsemide**): Concurrent use with loop diuretics may increase the nephrotoxic or ototoxic potential of the aminoglycosides.
- **Diuretics, Osmotic** (eg, **mannitol**): Concurrent use of osmotic diuretics may increase the nephrotoxic or ototoxic potential of the aminoglycosides.
- **Nephrotoxic Drugs, Other (eg, cisplatin, amphotericin B, cyclosporine, polymyxin B, vancomycin)**: Potential for increased risk for nephrotoxicity
- **Neuromuscular-Blocking Agents and Anesthetics, General**: Concomitant use with general anesthetics or neuromuscular-blocking agents could potentiate neuromuscular blockade.

Laboratory Considerations

- **Gentamicin serum concentrations** may be falsely decreased if the patient is also receiving beta-lactam antibiotics and the serum is stored prior to analysis. It is recommended that if assay is delayed, samples be frozen and, if possible, be drawn at times when the beta-lactam antibiotic is at a trough.

Dosages

NOTE: Most infectious disease clinicians agree that aminoglycosides should be dosed once a day in most patients (mammals) with uncompromised renal function. This dosing regimen yields higher peak levels with resultant greater bacterial kill, and as aminoglycosides exhibit a postantibiotic effect, surviving susceptible bacteria generally do not replicate as rapidly even when antibiotic concentrations are below MIC. Periods where levels are low may decrease the adaptive resistance (bacteria take up less drug in the presence of continuous exposure) that can occur. Once-daily dosing may also decrease the toxicity of aminoglycosides, as lower urinary concentrations may mean less uptake into renal tubular cells.

DOGS:

Susceptible infections (extra-label):

- Normal renal function: 9 – 14 mg/kg IV, IM, or SC once a day is reasonable for most breeds and infections. Use the higher end of dosing range for life-threatening infections, or in immunocompromised or neutropenic patients.
- Reduced renal function: If gentamicin use cannot be avoided, the following dosage modifications can be considered[15]:
  - ClCr 0.4 – 0.7 mL/kg/minute (serum creatinine ≈2.3 to 4 mg/dL): 9 – 14 mg/kg IV, IM, SC every 36 to 48 hours
  - ClCr 0.15 – 0.4 mL/kg/minute (serum creatinine ≈ 4.9 to 5.5 mg/dL): 9 – 14 mg/kg IV, IM, SC every 48 hours
  - ClCr less than 0.15 mg/kg/minute (serum creatinine ≈8.5 mg/dL or more): Use is not recommended
- Greyhounds, other sighthounds: 6 mg/kg IV once daily or 9 mg/kg SC/IM once daily[16]

Aerosolized treatment of *Bordetella bronchiseptica* (extra-label): 4 mg/kg nebulized over 10 minutes every 12 hours for 3 to 4 weeks[17]

Chemical ciliary body ablation (extra-label): 0.25 – 0.5 mL of gentamicin sulfate 100 mg/mL injection into the vitreous humor

CATS:

Susceptible infections (extra-label): 5 – 8 mg/kg IV, IM, or SC once daily

- Reduced renal function: If gentamicin use cannot be avoided, the following dosage modifications can be considered[15]:
  - ClCr 0.4 – 0.7 mL/kg/minute (serum creatinine ≈2.3 to 4 mg/dL): 5 – 8 mg/kg IV, IM, SC every 36 to 48 hours
  - ClCr 0.15 – 0.4 mL/kg/minute (serum creatinine ≈4.9 to 5.5 mg/dL): 5 – 8 mg/kg IV, IM, SC every 48 hours
  - ClCr less than 0.15 mg/kg/minute (serum creatinine ≈8.5 mg/dL or more): Use is not recommended

Chemical ciliary body ablation (extra-label): 0.25 – 0.5 mL of gentamicin sulfate 100 mg/mL injection into the vitreous humor

HORSES:

WARNING: IV administration may be associated with allergic and anaphylactic reactions in horses. The injection should be prewarmed and administered slowly. If clinical signs occur, corticosteroid treatment may be necessary.

Susceptible uterine infections via intrauterine infusion:

- Label Dosage (FDA-approved): 2 – 2.5 g (20 – 25 mL) diluted in 200 – 500 mL sterile normal saline and infused aseptically into uterus once daily for 3 to 5 days during estrus[13]
- Extra-label: Irrigate uterus for 2 to 3 days prior to antibiotic infusion to remove inflammatory debris. Gentamicin dosed at 1 – 2 g intrauterine infusion. Buffer with bicarbonate (equal volume of 7.5% bicarbonate and diluted in saline) or large volume (200 mL) of saline. Mares with bacterial endometritis should be treated with IU antibiotics once daily for 3 to 7 days. Treatment length is dependent on history, chronicity of infection, bacteria isolated, and mare's ability to clear uterine fluid.[18]

Susceptible infections (extra-label):

- Adults: 7.7 – 9.7 mg/kg IV once daily.[19] Historically, 6.6 mg/kg IV every 24 hours had been used and remains a viable option for ambulatory practices where isolate MICs may be lower.[20,21] IM administration may cause muscle irritation.
- Foals:
  - Less than 2 weeks old: 12 mg/kg IV every 36 hours
  - Greater than 2 weeks old: 6.6 mg/kg IV once daily (every 24 hours) should be adequate.[22]

Septic arthritis (extra-label): Direct intra-articular (IA) administration gentamicin 500 mg has been used, as well as IA continuous infusion of 0.17 mg/kg/hour using a CRI pump.[23] Regional intravenous limb perfusion (RILP) administration has also been used, under sedation in standing horses, using gentamicin 500 mg diluted in 40 mL 0.9% NaCl.[24]

Management of recurrent uveitis (extra-label): 4 or 6 mg/eye (total dose, NOT mg/kg) given as an intravitreal injection[2,3,25]

SWINE:

Susceptible infections (label dosage; FDA-approved):

- Colibacillosis in neonates: 5 mg/piglet (NOT mg/kg) PO or IM once[26,27]
- Weanlings and other swine[28]:
  - Colibacillosis: 1.1 mg/kg/day in drinking water (concentration of 25 mg/gallon) for 3 days
  - Swine dysentery (*Brachyspira hyodysenteriae*): 2.2 mg/kg per day in drinking water (concentration of 50 mg/gallon) for 3 days

BIRDS:

Susceptible infections (extra-label): 5 – 10 mg/kg IM every 12 hours[29,30]

FERRETS:

Susceptible infections (extra-label): 5 – 8 mg/kg IV, IM, or SC once daily

RABBITS/RODENTS/SMALL MAMMALS:

Rabbits (extra-label): 5 – 8 mg/kg daily dose (may divide into every 8 to 24 hours) SC, IM, or IV. Increased efficacy and decreased toxicity if given once daily. If given IV, dilute into 4 mL/kg of saline and give over 20 minutes.[31] Aminoglycosides adversely affect the GI flora balance in these animals; use with caution.

Chinchillas, gerbils, guinea pigs, hamsters, mice, rats (extra-label): 2 – 4 mg/kg SC or IM every 8 to 24 hours[32]

REPTILES:

Susceptible infections (extra-label):

Bacterial shell diseases in turtles: 5 – 10 mg/kg daily in water turtles, every other day in land turtles and tortoises for 7 to 10 days. Used commonly with a beta-lactam antibiotic. Recommend beginning therapy with 20 mL/kg fluid injection. Maintain hydration and monitor uric acid levels when possible.[33]

Monitoring

- Efficacy (cultures, clinical signs associated with infection)
- Renal toxicity; baseline urinalysis, serum creatinine/BUN. Casts in the urine are often the initial sign of impending nephrotoxicity. Decreasing urine-specific gravity is an earlier indicator than azotemia. Casts, urine-specific gravity, or increased serum creatinine may not be good markers in neonates. Frequency of monitoring during therapy is unclear. There is no contraindication to daily monitoring with urinalysis (cytological examination for casts and assessment of specific gravity) and serum creatinine but monitoring every 3 to 5 days at the start of treatment may be more practical in lower-risk cases (eg, adults, animals with no underlying renal disease or concerns about dehydration or hypotension).
- Gross monitoring for vestibular or auditory toxicity is recommended, especially in cats.
- Therapeutic drug monitoring (TDM) when possible in patients with uncompromised renal function; highly recommended for patients with risk factors for nephrotoxicity. Peak and trough levels are determined through samples collected 30 minutes after administration (peak) and immediately before administration of the next dose (trough). Generally, peak levels (≈30 to 60 minutes post IV dose) should be greater than 32 µg/mL and trough levels less than 1 – 2 µg/mL.[34] A clinical laboratory may be able to assist in sample-time determination and dosage amount and frequency adjustment.

Client Information

- To treat infections in the body, gentamicin must be injected; it is only given orally (by mouth) to reduce the amount of bacteria in animals' intestines before intestinal surgery.
- Gentamicin can be given once daily either in the vein (by your veterinarian), in a muscle, or under the skin (subcutaneously). If injecting at home, be sure you understand how to properly inject it.
- This drug can damage nerves, hearing, and kidneys. Cats may be more likely to have damage to their hearing.
- This drug can be used topically for ear, skin, or eye infections.

Chemistry/Synonyms

An aminoglycoside obtained from cultures of *Micromonospora purpurea*, gentamicin sulfate occurs as a white to buff powder that is soluble in water and insoluble in alcohol. The commercial product is a combination of gentamicin sulfate C_1, C_2, and C_3, but all these compounds apparently have similar antimicrobial activities. Commercially available injections have a pH from 3 to 5.5.

Gentamicin may also be known as gentamicin sulphate, gentamicini sulfas, NSC-82261, and Sch-9724; many trade names are available.

Storage/Stability

Gentamicin sulfate for injection and the oral solution should be stored at room temperature (15°C-30°C [59°F-86°F]); freezing or temperatures above 40°C (104°F) should be avoided. The soluble powder should be stored from 2°C to 30°C (46°F-86°F). Do not store or offer medicated drinking water in rusty containers or the drug may be destroyed.

Compatibility/Compounding Considerations

Although the manufacturer does not recommend that gentamicin be mixed with other drugs, it is reportedly physically **compatible** and stable in all commonly used IV solutions and with the following drugs: bleomycin sulfate, cefoxitin sodium, cimetidine HCl, clindamycin phosphate, metronidazole (with and without sodium bicarbonate), penicillin G sodium, and verapamil HCl.

The following drugs or solutions are reportedly physically **incompatible** or only compatible in specific situations with gentamicin: amphotericin B, ampicillin sodium, dopamine HCl, furosemide, and heparin sodium. In vitro inactivation of aminoglycoside antibiotics by beta-lactam antibiotics is well documented. Gentamicin is very susceptible to this effect, and it is recommended to avoid mixing with these compounds.

Compatibility is dependent upon factors such as pH, concentration, temperature, and diluent used; consult specialized references or a hospital pharmacist for more specific information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

The American Association of Bovine Practitioners and the American Veterinary Medical Association discourages extra-label aminoglycoside use in bovines.

Gentamicin Sulfate Solution (for intrauterine infusion): 100 mg/mL in 100 mL and 250 mL vials; multiple trade names, generic; (Rx); FDA-approved for horses

Gentamicin Sulfate Injection: 100 mg/mL (poultry only) in 100 mL vials; *Garasol® Injection*, *Gentapoult®*; (OTC). For use only in day-old chickens (slaughter withdrawal = 5 weeks) and 1- to 3-day-old turkeys (slaughter withdrawal = 9 weeks)

Gentamicin Sulfate Injection: 5 mg/mL in 250 mL vials; *Garacin® Piglet Injection*; (OTC). FDA-approved for use in piglets up to 3 days of age. Slaughter withdrawal (when used as labeled) = 40 days

Gentamicin Sulfate Oral Solution: 5 mg/mL in 118 mL bottles with pump applicator; generic; (Rx). FDA-approved for use in neonatal swine only. Slaughter withdrawal = 14 days

Gentamicin Soluble Powder: 333.33 mg/g in 360 g jars. FDA-approved for use in weanling swine. Slaughter withdrawal = 10 days. *Gen-Gard® Soluble Powder*; (OTC)

Gentamicin Sulfate Soluble Powder: 2 g gentamicin/30 g of powder in 360 g jar; *Garacin® Soluble Powder*; (OTC). FDA-approved for use in swine. Slaughter withdrawal (when used as labeled) = 10 days

Veterinary FDA-approved injections for chickens and turkeys plus a water additive for egg dipping may also be available. Ophthalmic, otic, and topical preparations are available with veterinary labeling.

HUMAN-APPROVED PRODUCTS:

Partial listing:

Gentamicin Sulfate Injection: 10 mg/mL and 40 mg/mL (as sulfate) in vials and cartridge-needle units and in various concentrations

(0.8 – 1.6 mg/mL) pre-mixed in saline in 50 mL and 100 mL single-dose containers; generic; (Rx)

Topical-, otic-, and ophthalmic-labeled products are also available.

Glipizide

(***glip***-i-zide) *Glucotrol®*

Sulfonylurea Antidiabetic Agent

Prescriber Highlights

- ► Human oral type II antidiabetic agent that may be useful in cats with nonketotic diabetes mellitus with mild to moderate signs and that are in good physical condition and able to be closely monitored.
- ► It may take 4 to 8 weeks before full effects are seen.
- ► Glipizide is NOT recommended in dogs.
- ► Contraindications include hypersensitivity, absolute insulin deficiency, and diabetic ketosis or ketoacidosis.
- ► Use with caution in patients with untreated adrenal or pituitary insufficiency, thyroid, renal, or hepatic function impairment, prolonged vomiting, high fever, malnourishment, other debilitating conditions, and patients with hypersensitivity to other sulfonamide derivatives.
- ► Adverse effects in cats include GI effects (eg, anorexia, vomiting), hypoglycemia, and liver toxicity.
- ► Do not confuse glipizide with glimepiride or glyburide.

Uses/Indications

Glipizide may be of benefit in treating cats with type II diabetes if there is existing pancreatic beta cell function. Glipizide has been reported to be beneficial in ≈30%[1] to 40%[2] of cats, but there is no way to predict which cats will benefit in advance of a trial. Glipizide should only be used in cats that have nonketotic diabetes mellitus with mild to moderate signs and that are in good physical condition and able to be closely monitored[1]; it should only be used in situations when owners refuse insulin therapy and only in combination with dietary therapy.[2] Insulin therapy is considered superior to glipizide therapy and should be the initial recommendation in newly diagnosed diabetic cats, as insulin therapy has an increased possibility for diabetic remission.[1,2]

A glipizide trial may also be appropriate when a cat appears to be relatively well controlled on small doses of insulin, and the owner would strongly prefer to no longer give insulin.[3]

Glipizide should not be used in dogs.[2] Although glipizide could theoretically be useful in treating canine patients with type II or III diabetes, dogs are typically absolutely or relatively insulinopenic by the time they present with hyperglycemia, and glipizide would therefore be ineffective.

Pharmacology/Actions

Glipizide is a second-generation sulfonylurea. Sulfonylureas lower blood glucose concentrations in both diabetic and non-diabetic patients. The exact mechanism of action is not known, but these agents are thought to exert the effect primarily by stimulating the beta cells in the pancreas to secrete additional endogenous insulin. Extrapancreatic effects include enhanced tissue sensitivity of circulating insulin. Ongoing use of the sulfonylureas appears to enhance peripheral sensitivity to insulin and reduce the production of hepatic basal glucose. The mechanisms causing these effects are yet to be fully explained.

Prolonged hyperglycemia may cause beta cell exhaustion with permanent damage, leading to cell death. It has been suggested that by treating all cats initially with insulin to rapidly reduce hyperglycemia, increases in beta cell sensitivity and insulin release may occur with time and potentially increase success using glipizide.[4]

Pharmacokinetics

Glipizide is rapidly and practically completely absorbed after oral administration. The absolute bioavailability reported in humans ranges from 80% to 100%. Food will alter the rate, but not the extent, of absorption. Transdermal administration on cats does not appear to be as adequately absorbed compared to oral administration but did lower blood glucose over time. Further studies are warranted to evaluate long-term use and topical effects of transdermal glipizide before it should be recommended for use.[5] Glipizide is highly bound to plasma proteins.[6] It is primarily biotransformed in the liver to inactive metabolites that are then excreted by the kidneys. In humans, the half-life is ≈2 to 4 hours.[6] Effects on insulin concentrations in cats tend to be short-lived. Effects peak in about 15 minutes and return to baseline after about 60 minutes.

Contraindications/Precautions/Warnings

Glipizide is contraindicated in patients hypersensitive to it. Glipizide is contraindicated in cats with an absolute insulin deficiency or that have diabetic ketosis or ketoacidosis. Glipizide should be used with caution in cats with untreated adrenal or pituitary insufficiency, thyroid, renal, or hepatic dysfunction, prolonged vomiting, high fever, malnourishment, or other debilitating conditions. Use with caution in cats that are allergic to other sulfonamide derivatives, as they may also develop an allergic reaction to glipizide.

Sulfonylureas have the potential to produce severe hypoglycemia. Although glipizide may initially be effective, it may become ineffective in weeks to months after starting therapy; insulin will then be required. Glipizide does not appear to be effective in cats demonstrating insulin resistance.

Some patients with type II or type III diabetes may have their disease complicated by the production of excessive amounts of cortisol or growth hormone, which may antagonize insulin's effects. These underlying causes should be ruled out before initiating oral antidiabetic therapy.

In humans, the use of oral antihyperglycemic medications has been reportedly associated with increased cardiovascular mortality compared to treatment with diet or diet plus insulin.[6]

Do not confuse glipiZIDE with glyBURIDE or gliMEPIRIDE. Consider writing part of the drug's name in uppercase letters (tallman designations) on prescriptions/orders to reduce the risk of errors.

Adverse Effects

GI adverse effects (eg, anorexia, vomiting) occur in ≈15% of cats receiving glipizide. Vomiting typically occurs shortly after dosing and subsides in 2 to 5 days. If persistent or severe, decrease dose or frequency; discontinue if necessary.

Some cats receiving glipizide have developed hypoglycemia, but severe hypoglycemia appears to be rare. If hypoglycemia occurs, discontinue glipizide and recheck blood glucose in one week; if hyperglycemia recurs, glipizide may be restarted at a lower dose or dosing frequency.

Increased amyloid deposit formation can occur with glipizide, which can potentially cause further destruction of functional beta cells.[7]

Hepatic adverse effects have been reported, and ≈8% of cats treated with glipizide may develop cholestatic jaundice with increased liver enzymes. Discontinue glipizide in cats with elevated enzymes if they develop lethargy, anorexia, vomiting, or if ALT exceeds 500 IU/L. If icterus occurs, discontinue glipizide and restart at a lower dose once icterus resolves; discontinue use if icterus reoccurs.

Other adverse effects reported in humans include allergic skin reactions and myelosuppression.[6]

Reproductive/Nursing Safety

Safe use during pregnancy has not been established. Glipizide was found to be mildly fetotoxic in rats when given at doses at 5 to 50 mg/kg; however, no other teratogenic effects were noted.[6] Use in pregnancy only when benefits outweigh potential risks.

It is unknown if glipizide enters milk. Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral LD_{50} values are greater than 4 g/kg in all animal species tested. Profound hypoglycemia is the greatest concern after an overdose. GI decontamination protocols should be employed when warranted. Because of its shorter half-life, prolonged hypoglycemia is less likely with glipizide, but blood glucose monitoring and treatment with parenteral glucose may be required for several days. Massive overdoses may also require additional monitoring (blood gases, serum electrolytes) and supportive therapy.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving glipizide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Azole Antifungals** (eg, **fluconazole, itraconazole, ketoconazole**): May increase plasma levels of glipizide
- **Beta-Adrenergic Receptor Antagonists** (eg, **atenolol, propranolol**): May potentiate the hypoglycemic effect
- **Chloramphenicol**: May displace glipizide from plasma proteins
- **Cimetidine**: May potentiate the hypoglycemic effect
- **Corticosteroids**: May reduce the efficacy of glipizide
- **Diuretics, Thiazide**: May reduce hypoglycemic efficacy
- **Ethanol**: A disulfiram-like reaction (anorexia, nausea, vomiting) has been reported in humans who have ingested alcohol within 48 to 72 hours of receiving glipizide.
- **Fluoroquinolones** (eg, **ciprofloxacin, enrofloxacin**): May increase risk for hypoglycemia or hyperglycemia
- **Isoniazid**: May reduce hypoglycemic efficacy
- **Monoamine Oxidase Inhibitors (MAOIs;** eg, **amitraz, linezolid, selegiline**): May potentiate the hypoglycemic effect
- **Niacin**: May reduce hypoglycemic efficacy
- **Phenothiazines** (eg, **acepromazine, chlorpromazine**): May reduce hypoglycemic efficacy
- **Probenecid**: May potentiate the hypoglycemic effect
- **Sulfonamides**: May displace glipizide from plasma proteins
- **Sympathomimetic Agents**: May reduce hypoglycemic efficacy
- **Thyroid Agents**: May reduce the hypoglycemic effect
- **Warfarin**: May displace glipizide from plasma proteins

Dosages

CATS:

NOTE: Glipizide is rarely recommended (see ***Uses/Indications***), and evidence to support any dosage regimen is low.

Diabetes mellitus (extra-label): Recommended initial dose is 2.5 mg/cat (NOT mg/kg) PO twice daily with food. The dose can be increased to 5 mg/cat (NOT mg/kg) PO twice daily with food if an inadequate response is seen after 2 weeks and no adverse effects are seen.[1,2] If no response is seen after 4 to 6 weeks, insulin therapy should be instituted. If the cat appears to be clinically responsive, the glipizide trial can continue for 12 weeks to assess response to therapy. If euglycemia or hypoglycemia develops, the dosage may be tapered down or discontinued. Re-evaluate blood glucose concentrations 1 week later to assess the need for the drug. If hyperglycemia recurs, increase or reinitiate glipizide at a lower maintenance dose.[8]

Monitoring

- Physical examinations and body weight weekly during the first month of treatment, then periodically
- Urine glucose and ketones weekly during the first month of treatment
- Blood glucose weekly during the first month of therapy, then periodically; some recommend blood glucose measurements every 3 to 4 hours for the first 12 to 18 hours of therapy to check for hypoglycemia. Blood glucose curves help to monitor therapeutic response.[6]
- Baseline and periodic CBC
- Regular serum chemistry profiles should be performed to screen for liver toxicity; every 1 to 2 weeks initially, then periodically[6]
- Adverse effects (eg, anorexia, vomiting, icterus)

Client Information

- Give this medicine with meals as directed by your veterinarian.
- About 15% of cats will throw up after starting this medicine, but this usually improves after a few days.
- This medicine can take 1 to 2 months to see if it is working properly.
- Rarely, glipizide can cause yellowing of the skin, gums, or eyes (*jaundice*) or cause blood sugar to be too low (*hypoglycemia*). Watch for signs of low blood sugar, such as seizures (convulsions), collapsing/fainting, rear leg weakness or paralysis, muscle twitching, unsteadiness, lack of energy, or depression.

Chemistry/Synonyms

Glipizide, a sulfonylurea antidiabetic agent, occurs as a whitish powder. It is practically insoluble in water and has a pK_a of 5.9.

Glipizide may also be known as CP-28720, glipizidum, glydiazinamide, or K-4024; many international trade names are available.

Storage/Stability

Store glipizide tablets in tight, light-resistant containers at controlled room temperature.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Glipizide Oral Tablets: 5 mg and 10 mg; generic (Rx).

Glipizide Oral Extended-Release Tablets: 2.5 mg, 5 mg, and 10 mg; *Glucotrol XL®*, generic; (Rx). **NOTE**: This product is generally not used in veterinary medicine.

Also available in fixed-dose combinations of glipizide with metformin.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Glucagon

(***gloo***-ka-gon) *GlucaGen®*

Hormonal Agent

Prescriber Highlights

- ► Hormone to increase blood glucose that may be useful for treating hypoglycemia in small animals and potentially fatty liver syndrome in transition dairy cows
- ► May be effective in treating beta-blocker or calcium channel blocker overdoses, or when patients being treated for anaphylaxis have received beta-blockers
- ► Use extreme caution in patients with pheochromocytoma; use caution in patients with cardiac disease.
- ► Not indicated for hypoglycemia due to starvation, adrenal insufficiency, or chronic hypoglycemia
- ► Must be parenterally administered
- ► When used as CRI, must be in a setting where blood glucose can be monitored.
- ► Possible adverse effects include sedation, nausea, vomiting, and diarrhea.

Uses/Indications

In small animals, the primary use for glucagon is to increase blood glucose in patients with excessive insulin levels, either endogenously produced (insulinoma) or exogenously administered (insulin overdose). There is significant interest in its potential SC use in emergency home treatment of hypoglycemia in small animals.[1]

In human medicine and potentially for veterinary patients, glucagon can be used in treating the cardiac manifestations of beta-blocker, calcium channel blocker, and tricyclic antidepressant overdoses. One study in dogs, however, demonstrated insulin to be superior to glucagon in treating experimental propranolol overdoses.[2] Glucagon can also be used in conjunction with epinephrine for treating anaphylaxis in patients that have received beta-blockers, and it has potential in the treatment of fatty liver syndrome in dairy cattle.

Glucagon is used to treat steakhouse syndrome (ie, food bolus lodged in the esophagus) in human patients by relaxing the esophagus so that food can pass into the stomach.

Pharmacology/Actions

Glucagon's main pharmacologic activities are to increase blood glucose and relax smooth muscles of the GI tract. It primarily increases blood glucose by stimulating hepatic glycogenolysis but can also increase glucose via hepatic gluconeogenesis from available amino acid substrates. Glucagon does not stimulate the reactive release of insulin or cause rebound hypoglycemia. In healthy dogs, glucagon can overcome the inhibitory activity of insulin on hepatic glucose production; IV (not SC) glucagon can also cause transient increases in ACTH and cortisol.[3]

During radiologic examinations, glucagon has been used to prevent GI motility and is thought to act by relaxing the smooth muscles of the stomach. At higher doses (greater than 1 mg in a human adult), contractility of the duodenum and jejunum can be seen, which is most likely attributable to nausea and diarrhea that can be caused by glucagon administration.[4] The exact mechanisms of action for its GI effects are not well understood.

Glucagon increases lipolysis and decreases lipid synthesis in cow hepatocytes.[5]

Pharmacokinetics

Glucagon must be administered parenterally; it is destroyed in the gut after oral dosing. In healthy beagles, 1 mg given SC caused plasma glucose to increase significantly within 10 minutes and peak at 20 minutes. Glucose levels were still ≈60% above baseline at 30 minutes. After IV injection, maximum glucose levels were attained ≈20 minutes later.[3]

Glucagon is degraded in the plasma, liver, and kidneys. In humans, hyperglycemic effects persist up to 90 minutes after dosing, and plasma half-life is around 10 minutes.

Contraindications/Precautions/Warnings

Glucagon should usually not be given to patients with pheochromocytoma, as catecholamines may be released, leading to hypertension. When glucagon is used for insulinoma, it must be in a setting where blood glucose can be closely monitored. Although glucagon may be useful for blood glucose elevation in insulinoma patients, its use for this indication in humans is cautioned, as it can stimulate insulin production, leading to greater hypoglycemia once the drug is discontinued.

Use with caution in patients with known cardiac disease, as glucagon increases myocardial oxygen demand. For glucagon treatment to reverse hypoglycemia, there must be adequate amounts of glycogen stored in the liver. Glucagon is of little or no help in states of starvation, adrenal insufficiency, or chronic hypoglycemia. Hypoglycemia in these conditions should be treated with glucose.[6]

Adverse Effects

Glucagon is usually well tolerated, but sedation and injection site reactions may occur. Potentially, nausea, vomiting, and diarrhea soon after administration are possible, which is increased if doses greater than 1 mg are administered.[4] Hypokalemia and hypersensitivity reactions (very rare) are unlikely but possible.

Reproductive/Nursing Safety

As an endogenously produced hormone, glucagon is unlikely to cause significant risk to offspring.

It is unknown if glucagon enters maternal milk, but it is unlikely to cause harm to nursing offspring.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Adverse effects seen with overdose include nausea, vomiting, diarrhea, gastric hypotonicity, and, possibly, hypokalemia. Because glucagon's elimination half-life is so short, treatment may not be necessary and would be symptomatic in nature. If the patient is also receiving beta-blockers, greater increases in blood pressure and heart rate may be seen.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving glucagon and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- ■ **Anticholinergic Agents** (eg, **amitriptyline, atropine, diphenhydramine, glycopyrrolate**): May enhance GI adverse effects of glucagon
- ■ **Beta-Blockers** (eg, **atenolol, propranolol**): Glucagon may transiently increase heart rate and blood pressure.
- ■ **Glucose-Lowering Agents** (eg, **exenatide**, **glipizide, metformin**): Glucagon may decrease efficacy of glucose-lowering agents.
- ■ **Indomethacin**: May diminish the effect of glucagon

- **Insulin**: Glucagon and insulin have opposing effects on blood glucose.
- **Warfarin**: Anticoagulant effect may be increased when glucagon is concurrently administered; this effect may be delayed. It is suggested to monitor for bleeding and prothrombin activity if glucagon is necessary.

Laboratory Considerations

- No glucagon-related laboratory interactions were noted.

Dosages

DOGS/CATS:

IV dosing for severe hypoglycemia (extra-label): There are 2 primary recommended dosing regimens; the available evidence does not support one over the other:

Regimen 1: Glucagon 1 mg (NOT mg/kg) is reconstituted per manufacturer directions and then added to 1000 mL of 0.9% sodium chloride; this results in a 1000 nanogram/mL solution. [**NOTE**: Some references state not to mix or dilute with saline solutions but use 5% dextrose only.] Initially, give a 50 nanogram/kg IV bolus and then administer at a CRI using a suitable pump at a rate of 10 – 15 nanograms/kg/minute. The rate may need to be increased up to 40 nanograms/kg/minute to maintain euglycemia.

Regimen 2: Prepare solution as above, but give as an IV CRI at an initial infusion rate of 5 – 10 nanograms/kg/minute and adjust as needed to maintain the blood glucose concentration between 60 and 100 mg/dL.[7] An average initial dosage of 11.8 nanograms/kg per minute also has been used.[8] When discontinuing glucagon therapy, the dose should be gradually decreased over 1 to 2 days, and the blood glucose concentration should be monitored for recurrence of severe hypoglycemia.

CATTLE:

Fatty liver in early lactation dairy cows older than 3.5 years (extra-label): Glucagon 5 mg (NOT mg/kg) in 60 mL of normal saline SC every 8 hours (15 mg/day) for 14 days[9]

Fatty liver in multiparous cows (extra-label): Glucagon 10 mg/cow/day (NOT mg/kg) diluted in 480 mL sodium chloride and given as continuous IV infusion at 20 mL/hour using a volumetric pump for 14 days[10]

Prevention of fatty liver development in postpartum dairy cows (extra-label): Glucagon 5 mg/cow (NOT mg/kg) diluted in 60 mL 0.9% sodium chloride and administered SC between the fifth and seventh intercostal space 3 times daily for 14 days. The dose is started on day 2 postpartum.[11]

FERRETS:

IV dosing for severe hypoglycemia (extra-label): Evidence is limited, but glucagon has been shown to be effective in a case study treating a ferret with hypoglycemia subsequent to insulinoma. The dose was as follows: Glucagon 1 mg (NOT mg/kg) reconstituted with 0.9% sodium chloride, diluted in 1000 mL 5% dextrose and administered at a rate of 15 nanograms/kg/minute IV CRI. If needed, the rate may be increased to 40 nanograms/kg/minute.[12]

Monitoring

- Blood glucose
- Serum potassium if used other than for acute treatment

Client Information

- Could potentially use glucagon for outpatient emergency initial treatment of hypoglycemia, but oral glucose is probably more appropriate (and cheaper) for use.

Chemistry/Synonyms

Glucagon is a hormone secreted by the alpha-2 cells of the pancreas. It is a straight-chain polypeptide that contains 29 amino acids whose sequence is consistent throughout mammalian species. It has a molecular weight of 3483. When in crystalline form, it is a white- to off-white powder that is relatively insoluble in water at physiologic pH but is soluble at a pH of less than 3 and greater than 9.5. Glucagon may be expressed in terms of international units (IU) or by weight. One IU is equivalent to one milligram of glucagon. Commercially available glucagon is now obtained via recombinant DNA sources.

Glucagon may also be known as glucagonum or HGF and *GlucaGen®*.

Storage/Stability

Store the commercially available powder for reconstitution at room temperature between 20°C and 25°C (68°F-77°F); avoid freezing and protect from light. Once reconstituted with the supplied diluent, ensure the solution is clear with a water-like consistency and use immediately; discard any unused portion. Discard the solution if it contains any gel formation or particles.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

To prepare for a CRI, dilute glucagon 1 mg with the supplied diluent or sterile water; gently roll until dissolved, and this may then be further diluted in 5% dextrose. It may be given through a Y-tube or 3-way stopcock if a dextrose solution is running.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Glucagon (human rDNA-origin) Powder for Injection: 1 mg (1 unit) with 1 mL diluent in vials and syringes; *GlucaGen Diagnostic®*, *GlucaGen HypoKit®*, *Glucagon Emergency Kit,* generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Glucosamine/Chondroitin Sulfate

(gloo-***kose***-a-meen/kon-***droy***-tin ***sul***-fayt) *Cosequin®*

Nutritional Supplement

Prescriber Highlights

- ► Dietary supplement (not an FDA-approved drug) that may be useful as an adjunctive treatment for osteoarthritis or other painful conditions in dogs, cats, and horses
- ► Well tolerated, but efficacy is uncertain
- ► Not a regulated drug; therefore, choose products carefully. There is a large variation in commercially available products.

Uses/Indications

Compounds containing glucosamine and/or chondroitin sulfate may be useful in treating osteoarthritis or other painful conditions in domestic animals, but large, well-designed controlled clinical studies proving efficacy were not located. Additionally, because there is no FDA approval process or oversight for these products, product quality and bioavailability are highly variable.

Studies have shown variable efficacy of glucosamine and/or chondroitin for improvement of osteoarthritis in veterinary patients. One study in dogs[1] showed some positive effect, but this study was not placebo-controlled and compared responses with carprofen. Other placebo-controlled, blinded studies in dogs failed to demonstrate statistically significant improvement after 60 days[2] and 90 days[3] of treatment. An article reviewing the quality of evidence supporting the use of glucosamine-based dietary supplements in equine joint

disease concluded that …*the quality of these studies is generally low*.[4] A systematic review of articles published from 2004 to 2014 dealing with dietary supplements and their efficacy in treatment of osteoarthritis in dogs came to the conclusion that the existing studies suffer from major limitations and/or bias.[5] Another review came to a similar conclusion that it is difficult to draw meaningful conclusions about efficacy because available trials used different products, salt forms, doses, and dosing regimens.[6] Based on available literature, the benefit of glucosamine/chondroitin for osteoarthritis is still questionable. However, studies have revealed that there are few adverse effects and therefore it can be administered long-term, even to dogs with comorbidities, unlike other treatments for osteoarthritis such as NSAIDs. Combining glucosamine/chondroitin with a veterinary NSAID appears beneficial.[7,8]

Glucosamine and chondroitin improved mobility and lameness scores in cats with osteoarthritis.[9] The potential benefit of N-acetyl-d-glucosamine has been tested in cats with feline lower urinary tract disease (FLUTD) but results have been conflicting.[10,11]

Glucosamine alone or with chondroitin has shown some benefit in horses with arthritis or reduced mobility.[12–14]

Pharmacology/Actions

Cartilage cells use glucosamine to produce glycosaminoglycans and hyaluronan, which form articular cartilage. Glucosamine supplementation is thought to provide the glycosaminoglycan building blocks required to strengthen existing cartilage. Glucosamine also regulates synthesis of collagen and proteoglycans in cartilage and has mild anti-inflammatory effects due to its inhibition of nuclear factor kappaB (NF-κB). Chondrocytes normally produce ample quantities of glucosamine from glucose and amino acids, but this ability may diminish with age, disease, or trauma. Exogenously administered glucosamine appears to be able to be used by chondrocytes. Glycosaminoglycans form part of the protective layer of the urinary tract.

Chondroitin sulfate possesses several pharmacologic effects. It appears to inhibit destructive enzymes in joint fluid and cartilage. In joint cartilage, chondroitin sulfate stimulates the production of glycosaminoglycans and proteoglycans and has a slight anti-inflammatory action. Thrombus formation in microvasculature may be reduced. It has been shown in vitro that glucosamine does not affect equine or canine platelet aggregation.[15]

Although in vitro evidence exists, there is no solid evidence that using these compounds together improves clinical effect over either alone, but in vivo studies are ongoing. Onset of any clinical efficacy may require 2 to 6 weeks of treatment.

Pharmacokinetics

The pharmacokinetics of these compounds are difficult to evaluate because of the different salts, lack of manufacturing or regulatory standards, and variability in product purity. Both glucosamine hydrochloride (HCl) and glucosamine sulfate can be absorbed in the gut after the salt is cleaved in the stomach, but bioavailability may be very low. One study in 6 mature horses that were fed diets with pure glucosamine and chondroitin top-dressed on their feed did not detect any absorption into plasma.[16] A study of oral absorption of tablet, chewable, and liquid formulations of glucosamine revealed there is a difference in pharmacokinetic parameters among these formulations; however, conclusions could not be drawn as to whether differences in these parameters impacted efficacy of the product.[17] Controversy exists as to whether one salt of glucosamine is superior to the other. Most clinical studies in veterinary species have been done with the HCl salt. Of the available OTC formulations, crystalline glucosamine sulfate has been shown to produce the highest plasma and synovial joint concentrations.[18] A study in rats and dogs concluded that addition of chitosan, a product derived from the shells of sea crustaceans, enhanced oral bioavailability of glucosamine.[19]

Contraindications/Precautions/Warnings

No absolute contraindications were located for these compounds. As hypersensitivity reactions are a theoretical possibility, animals demonstrating prior hypersensitivity reactions to these compounds should not receive them.

In humans, glucosamine may exacerbate symptoms associated with asthma. Although this has not yet been reported in veterinary patients, caution is advised in patients with bronchoconstrictive conditions.

Some glucosamine sulfate products contain significant amounts of potassium. Patients on a potassium-restricted diet should be given a glucosamine/chondroitin product that is low in potassium.

Adverse Effects

These products appear to be well tolerated in dogs, cats, and horses. Adverse effects could potentially include some minor GI effects (flatulence, stool softening). Because these products are often derived from natural sources including shellfish, hypersensitivity reactions could occur.

Reproductive/Nursing Safety

No studies on the safety of these compounds in pregnant or lactating animals have been performed.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Oral overdose is unlikely to cause significant problems. The LD_{50} for the combined compound in rats is greater than 5 g/kg.[20] GI effects may result. Changes in coagulation parameters could occur but have not been documented to date.

Products that contain manganese could lead to manganese toxicity if given in very high dosages (above label recommendations) chronically.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving glucosamine and/or chondroitin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Anticoagulants** (eg, **heparin, rivaroxaban, warfarin**): A high dose of chondroitin sulfate and/or glucosamine potentially could enhance the effects of drugs that affect coagulation.
- **Antidiabetic Agents** (eg, **glipizide, insulin, metformin**): Glucosamine may decrease the efficacy of hypoglycemic agents.
- **Doxorubicin**: Glucosamine may induce resistance by reducing inhibition of topoisomerase II.

Laboratory Considerations

- None noted

Dosages

NOTE: Because of the variability in products available, lack of controlled studies clearly documenting efficacy, or FDA approval, use of these products for controlling chronic pain conditions is controversial. If a therapy trial is undertaken, it is recommended to choose a product that has been tested in the species for which it is marketed. Consult the product's label for specific label information.

DOGS/CATS:

Adjunctive treatment of chronic pain conditions (extra-label): Anecdotal recommendations are to treat initially at 15 – 30 mg/kg (of the chondroitin component). After 4 to 6 weeks, if a positive response is seen, dosage may be halved or given every other day.

Feline idiopathic cystitis (extra-label): N-acetyl glucosamine 250 mg/cat (NOT mg/kg) PO once daily[21]

HORSES:

Adjunctive treatment of chronic pain conditions (extra-label): Glucosamine 9.96 g with chondroitin 2 g and methylsufonyl methane (MSM) 2.5 g/500 kg (1102 lb) body weight (NOT mg/kg) PO once daily[12]

Monitoring

- Clinical efficacy

Client Information

- This supplement may be given with or without food. If your animal vomits or acts sick after getting it on an empty stomach, give the medicine with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.
- It may take 2 to 6 weeks (or longer) of treatment to see if this supplement is helping.
- Do not switch brands from what is prescribed without first contacting your veterinarian.
- Side effects are unlikely, but mild gastrointestinal upset (eg, decreased appetite) has been reported.

Chemistry/Synonyms

Glucosamine is most often available as either glucosamine HCl or glucosamine sulfate. It is an amino sugar that is synthesized in vivo by animal cells from glucose and glutamine. Commercial preparations of glucosamine are primarily derived from crustaceans.[22]

Glucosamine (HCl or sulfate) may also be known as chitosamine, NSC-758, 2-amino-2-deoxy-beta-D-glucopyranose, G6SD-glucosamine, glucose-6-phosphate, or amino monosaccharide.

Chondroitin sulfate is an acid mucopolysaccharide/glycosaminoglycan that is found in most cartilaginous tissues. It is a long-chain compound that contains units of galactosamine and glucuronic acid.

Chondroitin sulfate may also be known as chondroitin 4-sulfate, chondroitin sulfate A, chondroitin sulfate B, chondroitin sulfate C, chondroitin sulfate sodium, CSA, sodium chondroitin sulfate, chondroitin polysulfate, CDA, CSCSC, GAG, or galactosaminoglucono-glycan sulfate.

Storage/Stability

Because of the multiple products and product formulations available, check label for storage and stability (expiration date) information. Chondroitin sulfate is an extremely hygroscopic compound and, generally, these products should be stored in tight containers at room temperature. Avoid storing in direct sunlight and keep away from moisture.

Compatibility/Compounding Considerations

No specific information was noted; refer to the product label for more information.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

None as pharmaceuticals. Supplements are available from a wide variety of sources, and dosage forms include tablets, capsules, and powder in a variety of concentrations. There are specific products marketed for use in animals, including *Cosequin®, Glycoflex®, NutriVet®, Next Level®, AniFlex®, Phycox®, Restor-A-Flex®, OsteO-3®, Arthri-Nu®, ProMotion®, Seraquin®, Oste-O-Guard®, Caniflex®, Equi-Phar Flex®*.

Glucosamine and chondroitin sulfate are considered dietary supplements by the FDA. No standards have been accepted for potency, purity, safety, or efficacy by regulatory bodies. Bioequivalence between products cannot be assumed and independent analysis has shown a wide variation in products.

HUMAN-LABELED PRODUCTS:

None as pharmaceuticals but a variety of OTC nutraceuticals are available.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Glyburide

(***glye***-byoor-ide) *DiaBeta®, Micronase®*

Sulfonylurea Antidiabetic Agent

Prescriber Highlights

- ► Oral antidiabetic agent that may be useful in cats with type 2-like diabetes
- ► Glipizide is used more often when oral hypoglycemics are tried; glyburide may be useful if glipizide is unavailable or if once-daily dosing is important.
- ► Contraindications include hypersensitivity, diabetic ketoacidosis, and insulin-dependent diabetes.
- ► Use caution with renal or hepatic insufficiency, elderly or malnourished patients, and adrenal or pituitary insufficiency.
- ► Adverse effects include vomiting, hypoglycemia, and liver toxicity.
- ► Do not confuse glyBURIDE with glipiZIDE or gliMEPERIDE.

Uses/Indications

Glyburide is an oral treatment for type 2-like diabetes mellitus in cats with mild diabetes, or for use as add-on therapy or when owners cannot or will not administer insulin.[1] Although there are more data supporting the use of glipizide, glyburide can be used if glipizide is unavailable or if twice-daily administration of glipizide is not tolerated (by cat or owner). Insulin therapy for cats with diabetes is generally preferred over oral treatments.

Pharmacology/Actions

Like glipizide and other oral sulfonylureas, glyburide lowers blood glucose concentrations in both diabetic and normal patients. Glyburide stimulates the release of insulin from the pancreas; therefore, functioning pancreatic beta cells are required for efficacy. Although the insulin secretory response generally declines over time, the blood glucose-lowering effect persists. The mechanism of blood glucose lowering with long-term administration is not precisely known but may be related to enhanced insulin activity at post-receptor sites and reduced basal hepatic glucose production.[2]

Pharmacokinetics

Glyburide appears to be well absorbed, but bioavailability data are lacking. Food apparently does not have an effect on the absorptive characteristics of the drug. Glyburide is distributed throughout the body, including into the brain and across the placenta. Glyburide is apparently completely metabolized, presumably in the liver. Metabolites are excreted in both the feces and urine. Although glyburide's elimination half-life in cats is not known, it is known to be a longer-acting sulfonylurea, so once-daily dosing appears to be effective in cats with noninsulin-dependent diabetic mellitus.[3]

Contraindications/Precautions/Warnings

Glyburide is contraindicated in patients that are hypersensitive to it, patients with diabetic ketoacidosis, or patients with insulin-dependent diabetes.[2] Animals that are allergic to other sulfonamide deriv-

atives may develop an allergic reaction to glyburide as well.

Renal or hepatic insufficiency may cause increased drug levels and increase the risk for severe hypoglycemia. Use glyburide with caution in elderly patients, malnourished patients, and patients with adrenal or pituitary insufficiency, as they may be more susceptible to hypoglycemia.

Glyburide tablets (eg, *DiaBeta®, Micronase®*) are not bioequivalent to glyburide micronized tablets (*Glynase®* generic equivalent). Monitor blood glucose if switching between forms.[2]

Glyburide requires functioning pancreatic beta cells for efficacy. Some patients with type 2 diabetes may have their disease complicated by the production of excessive amounts of cortisol or growth hormone that may antagonize insulin's effects. These causes should be ruled out before initiating oral antidiabetic therapy.

Do not confuse glyBURIDE with glipiZIDE or gliMEPIRIDE.

Adverse Effects

Experience with glyburide is limited in veterinary medicine. Hypoglycemia, vomiting, icterus, and increased ALT (SGPT) levels are all potentially possible. If adverse effects develop, a lower dose may be attempted after clinical signs resolve.

Other adverse effects reported in humans include allergic skin reactions (eg, pruritis, erythema, urticaria), other allergic reactions (eg, angioedema, arthralgia, myalgia, vasculitis), bone marrow suppression, cholestatic jaundice, liver function abnormalities, nausea, heartburn, photosensitivity, and blurred vision.

Glyburide may not be effective in cats demonstrating insulin resistance.

Reproductive/Nursing Safety

Studies in mice have shown that glyburide is a substrate of the BCRP transporter, which is expressed in placental tissue. BCRP plays an active role in preventing glyburide exposure to the fetus, which makes glyburide a possible therapeutic option in pregnancy. Caution needs to be taken when considering glyburide during pregnancy due to potential exposure to the fetus if BCRP inhibitors are present or if a genetic mutation exists where BCRP is not expressed in the animal.[4] Prolonged and severe hypoglycemia has occurred in human infants born of mothers receiving a sulfonylurea at the time of birth, and discontinuing glyburide 2 weeks prior to expected delivery date is recommended.[2]

In humans, glyburide was found to be excreted in breast milk after large doses (85 mg/day) of glyburide were given.[5] It is unknown the extent of glyburide that appears in breast milk after normal doses. There are still conflicting data as to whether or not glyburide should be used during lactation.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Profound hypoglycemia is the greatest concern after an overdose. In humans, severe hypoglycemia has occurred at relatively low dosages. GI decontamination protocols should be employed when warranted. Because its half-life is longer than glipizide, prolonged hypoglycemia may occur, and blood glucose monitoring and treatment with parenteral glucose may be required for several days. Massive overdoses may also require additional monitoring (eg, blood gases, serum electrolytes) and supportive therapy.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving glyburide and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **ACE Inhibitors**: May increase the risk for hypoglycemia
- **Alcohol**: A disulfiram-like reaction (eg, anorexia, nausea, vomiting) is possible.
- **Antifungals, Azole** (eg, **ketoconazole, itraconazole, fluconazole**): May increase plasma levels of glyburide
- **Beta-Blockers**: May potentiate the hypoglycemic effect
- **Chloramphenicol**: May displace glyburide from plasma proteins
- **Cimetidine**: May potentiate the hypoglycemic effect
- **Ciprofloxacin** (and potentially **other quinolones**): May potentiate the hypoglycemic effect of glyburide
- **Corticosteroids** (eg, **dexamethasone, fludrocortisone, predniso(lo)ne**): May reduce glyburide efficacy
- **Diuretics, Thiazide** (eg, **hydrochlorothiazide**): May reduce hypoglycemic efficacy
- **Fluoxetine**: May potentiate the hypoglycemic effect
- **Isoniazid**: May reduce hypoglycemic efficacy
- **Monoamine oxidase Inhibitors (MAOIs)**: May potentiate the hypoglycemic effect
- **Niacin**: May reduce hypoglycemic efficacy
- **nonsteroidal anti-inflammatory drugs (NSAIDs**; eg, **meloxicam, robenacoxib**): Highly protein-bound; may displace glyburide and potentiate hypoglycemic effect
- **Phenothiazines**: May reduce hypoglycemic efficacy
- **Probenecid**: May potentiate the hypoglycemic effect
- **Rifampin**: May reduce hypoglycemic efficacy by increasing glyburide metabolism
- **Sulfonamides**: May displace glyburide from plasma proteins
- **Sympathomimetic agents** (eg, **epinephrine**): May reduce hypoglycemic efficacy
- **Thyroid Agents**: May reduce the hypoglycemic effect
- **Warfarin**: May displace each other from plasma proteins; closely monitor both PT and blood glucose

Dosages

CATS:

Noninsulin-dependent diabetes mellitus (extra-label): There is little information published on using this medication in cats, and evidence to support clinical use is very weak. Using regular (ie, not micronized) glyburide tablets, 2 anecdotal dosage suggestions have been noted:

a) Initial dose at 0.625 mg/cat (NOT mg/kg) PO twice daily; may increase to 1.25 mg/cat (NOT mg/kg) twice daily. Once-daily administration may be suitable for some cats.[1,6]

b) 2.5 mg/cat (NOT mg/kg) PO twice a day for cats that are generally well, not ketoacidotic, and do not have peripheral neuropathy[7]

Monitoring

- Weekly examinations during the first month of therapy, including PE, body weight, urine glucose/ketones, and several types of blood glucose examinations
- Adverse effects (eg, vomiting, icterus) and occasional liver enzymes and CBC

Client Information

- May be useful for treating diabetes in cats; limited experience in veterinary medicine

- Give medicine with food around the same time each day. If severe or persistent vomiting occurs, contact your veterinarian.
- Watch for signs of blood sugar that is too low (ie, hypoglycemia; uncommon), seizures (ie, convulsions), collapsing/fainting, rear leg weakness or paralysis, muscle twitching, unsteadiness, lack of energy, or depression. If you see any of these signs, contact your veterinarian right away.
- This medicine has not been in use in many cats, so other side effects could occur. Report anything unusual to your veterinarian.
- While your animal is taking this medication, it is important to return to your veterinarian for examinations and bloodwork. Do not miss these important follow-up visits.

Chemistry/Synonyms

Glyburide is an oral sulfonylurea antidiabetic agent that occurs as a white or nearly white, odorless or almost odorless, crystalline powder. As pH increases, solubility increases. At a pH of 4, solubility in water is about 4 µg/mL, and at a pH of 9, solubility is 600 µg/mL. Glyburide has a pK_a of 6.8.

Glyburide may also be known as glibenclamide, glibenclamidum, glybenclamide, glybenzcyclamide, HB-419, and U-26452; many trade names are available, including *DiaBeta®*, *Glynase®*, and *Micronase®*.

Storage/Stability

Store glyburide oral tablets in well-closed containers at room temperature 20°C to 25°C (68°F-77°F).

Compatibility/Compounding Considerations

No specific information was noted.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Glyburide Oral Tablets: 1.25 mg, 2.5 mg, and 5 mg; micronized tablets: 1.5 mg, 3 mg, 4.5 mg, and 6 mg; *Glynase® PresTab*, *DiaBeta®*; generic; (Rx)

Glyburide/metformin tablets: 1.25 mg glyburide/250 mg metformin, 2.5 mg glyburide/500 mg metformin, and 5 mg glyburide/500 mg metformin; *Glucovance®*; generic; (Rx). **NOTE**: This product is unlikely to be of benefit to veterinary patients.

For the complete list of references, see **wiley.com/go/budde/plumb**

Glycerin, Oral

(***gli***-ser-in) *Glycerol, Osmoglyn®*

Osmotic Agent

Prescriber Highlights

- ► Oral osmotic agent that reduces intraocular and CSF pressures
- ► Contraindicated in patients with known hypersensitivity, well-established anuria, severe dehydration, severe cardiac decompensation, acute pulmonary edema
- ► Use caution in patients with compromised blood–aqueous barrier, hypovolemia, cardiac disease, or diabetes.
- ► Most common adverse effect is vomiting

Uses/Indications

Oral glycerin is used primarily for the short-term (up to 12 hours) reduction of intraocular pressure (IOP) in small animals with acute glaucoma. It may also be considered to reduce increased CSF pressure.

The IOP-lowering effect of glycerin may be more variable than with mannitol, but because glycerin may be given orally, it may be more advantageous to use in certain cases.

Pharmacology/Actions

Glycerin, in therapeutic oral doses, increases the osmotic pressure of plasma so that water from extracellular spaces is drawn into the blood to decrease intraocular pressure (IOP). The amount of decrease in IOP is dependent on the dose of glycerin, and the cause and extent of increased IOP. Glycerin also decreases extracellular water content from other tissues and can cause dehydration and decreased CSF pressure.

Pharmacokinetics

Glycerin is rapidly absorbed from the GI tract and decreases in intraocular pressure (IOP) can be seen within 30 minutes; peak serum concentrations generally occur within 90 minutes and maximum decreases in IOP usually occur within an hour of dosing and persist for 5 to 12 hours. Glycerin is distributed throughout the blood and is primarily metabolized by the liver. Approximately 10% of the drug is excreted unchanged in the urine. Serum half-life in humans is ≈30 to 45 minutes.

Contraindications/Precautions/Warnings

Glycerin is contraindicated in patients hypersensitive to it. It is also contraindicated in patients with well-established anuria, severe dehydration, severe cardiac decompensation, or with acute pulmonary edema. Glycerin may increase blood glucose,[1] and should be used with caution in dogs with diabetes mellitus.

Glycerin should be used with caution in animals when the blood–ocular barrier is not intact (hyphema, uveitis), and in those patients with hypovolemia, cardiac disease, or diabetes.[2] Another reference considers heart failure a contraindication and its use should be avoided in patients with chronic renal failure or compromised renal function.[3]

Adverse Effects

Vomiting after dosing is the most common adverse effect seen with glycerin use in animals. In humans, headache, nausea, thirst, and diarrhea have also been reported.

Reproductive/Nursing Safety

The safety of this drug in pregnant or lactating animals is unknown.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No specific information was located, but cardiac arrhythmias, nonketotic hyperosmolar coma, and severe dehydration have been reported with the drug.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving glycerin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Carbonic Anhydrase Inhibitors** (eg, **acetazolamide**, **dichlorphenamide**): Concomitant administration of carbonic anhydrase inhibitors may prolong the intraocular pressure (IOP)-reducing effects of glycerin.
- **Miotic Agents, Topical**: Concomitant administration of topical miotic agents may prolong the IOP-reducing effects of glycerin.

Dosages

DOGS & CATS:

Acute glaucoma as an emergency drug in place of aqueous centesis to rapidly reduce intraocular pressure (IOP) (extra-label): Most recommend using 1 – 2 g/kg PO. This would be ≈1.1 – 2.2 mL/kg of the 90% solution. To reduce the risk for vomiting, glycerin is recommended to be diluted to a 45% to 50% concentration with water, milk, or ice cream. In patients where it would not be contraindicated, withholding water or fluids for 3 to 4 hours after administering can increase efficacy.[2–5]

Monitoring

- Intraocular pressure (IOP)
- Urine output
- Hydration status

Chemistry/Synonyms

A trihydric alcohol, glycerin occurs as a clear, sweet, syrupy, hygroscopic liquid that has a characteristic odor. It is miscible with water and alcohol, but not miscible in oils. Glycerin solutions are neutral to litmus.

Glycerin may also be known as E422, glycerol, glicerol, glycerine, and glycerolum; many trade names are available.

Storage/Stability

Glycerin oral solution should be stored in tight containers at room temperature; protect from freezing.

Compatibility/Compounding Considerations

90% glycerin USP can be mixed into water, milk, or ice cream to reduce the potential for vomiting and improve palatability. To convert 90% glycerin to a 50% concentration, 1 mL of 90% glycerin can be diluted to a 50% concentration by the addition of 0.8 mL of diluent.

Practically, many clinicians will dilute with equal parts of diluent to obtain a 45% concentration.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS: NONE FOR SYSTEMIC USE

USP glycerin 90% could be used for oral use in small animals (see ***Compatibility/Compounding Considerations***).

Glycerin is also available in a topical ophthalmic solution and as suppositories or liquid for rectal laxative use.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Glycopyrrolate

(glye-koe-***pye***-roe-late) *Robinul®*

Anticholinergic (Antimuscarinic)

Prescriber Highlights

- ► Synthetic antimuscarinic agent similar to atropine and available both orally and parenterally; used for a variety of indications including bradycardia and as an antidote
- ► Contraindicated in conditions where anticholinergic effects would be detrimental (eg, narrow-angle glaucoma, tachycardia, ileus, urinary obstruction). Not recommended for use in treating bradycardia secondary to dexmedetomidine
- ► Adverse effects are dose related and anticholinergic in nature, including dry secretions; initial bradycardia, then tachycardia; slowing of gut and urinary tract motility; and mydriasis and cycloplegia.
- ► Many potential drug interactions

Uses/Indications

Glycopyrrolate injection is FDA-approved for use in dogs and cats as a preanesthetic anticholinergic agent. Glycopyrrolate may be of benefit in neonatal animals when cardiac output is dependent on heart rate or when potent opioids are used. The drug is also used in an extra-label manner to prevent perioperative bradycardia, treat sinus bradycardia, sinoatrial arrest, second-degree AV block, and when anticholinergic therapy may be beneficial. When cholinergic agents such as neostigmine or pyridostigmine are used to reverse neuromuscular blockade due to non-depolarizing muscle relaxants, glycopyrrolate may be administered immediately prior to the reversal to prevent the peripheral muscarinic effects of the cholinergic agent.

Pharmacology/Actions

Glycopyrrolate is an antimuscarinic with similar actions as atropine. It is a quaternary ammonium compound, and unlike atropine, glycopyrrolate does not appreciably cross the blood-brain and blood-placenta barriers. Therefore, CNS adverse effects and clinical effects in the fetus/newborn should not be exhibited. Antimuscarinic agents competitively inhibit acetylcholine or other cholinergic stimulants at postganglionic parasympathetic neuroeffector sites. High doses may block nicotinic receptors at the autonomic ganglia and at the neuromuscular junction. Pharmacologic effects are dose related. At low doses, salivation, bronchial secretions, and sweating (not in horses) are inhibited. At moderate systemic doses, glycopyrrolate increases heart rate. High doses decrease GI and urinary tract motility. Very high doses can inhibit gastric acid secretion.

Pharmacokinetics

In dogs, following IV administration, the onset of action is generally within a few minutes (ie, slower than atropine). After IM or SC administration, peak effects occur ≈30 to 45 minutes postinjection, and after IM administration they last for ≈1 hour.[1] The vagolytic effects persist for 2 to 3 hours, and the antisialagogue (reduced salivation) effects persist for up to 7 hours. Quaternary anticholinergic agents are incompletely absorbed after oral administration, but quantitative data reporting the rate and extent of absorption of glycopyrrolate are not available. After oral administration, the anticholinergic effects of glycopyrrolate may persist for 8 to 12 hours.

Little information is available regarding glycopyrrolate's distribution characteristics. Being a quaternary ammonium compound, it is completely ionized and therefore has poor lipid solubility and does not readily penetrate into the CNS or eye. Glycopyrrolate crosses the placenta only marginally; it is unknown if it is excreted into milk.

For horses, the pharmacokinetics of IV glycopyrrolate have been described. After 1 mg (1.72 – 1.93 μg/kg) was given IV, the following median values were reported: volume of distribution (SS), 1.43 L/kg; clearance, 14.2 mL/kg/minute; and terminal half-life, 7.4 hours. Plasma clearance of the drug in horses appears to be similar to hepatic blood flow.[2]

In humans, glycopyrrolate is eliminated rapidly from the serum after IV administration and virtually no drug remains in the serum 30 minutes to 3 hours after dosing. Only a small amount is metabolized; the majority is eliminated unchanged in the feces and urine.

Contraindications/Precautions/Warnings

Glycopyrrolate is contraindicated in patients that are hypersensitive to it.

Antimuscarinic agents should be used with extreme caution in patients with known or suspected GI obstruction or infections. Glycopyrrolate and other antimuscarinic agents decrease GI motility and prolong retention of the causative agent(s) or toxin(s), resulting in prolonged clinical signs.[3,4] Antimuscarinic agents must also be used with extreme caution in patients with autonomic neuropathy. Anticholinergic agents such as atropine or glycopyrrolate are not recommended to treat bradycardias secondary to dexmedetomidine;

the reversal agent atipamezole is preferred.

Antimuscarinic agents should be used with caution in geriatric patients and in patients with hepatic or renal disease, hyperthyroidism, hypertension, hypertrophic cardiomyopathy, congestive heart failure, tachyarrhythmias, prostatic hypertrophy, or esophageal reflux. These drugs can produce sinus tachycardia and predispose hypotensive patients to cardiac arrhythmias (including ventricular fibrillation).

Alpha-2 agonist-mediated bradycardia is primarily a reflex secondary to alpha-2-mediated vasoconstriction with a resultant increase in blood pressure. Administration of anticholinergic agents in dogs or cats at the same time or after alpha-2 agonists leads to adverse cardiovascular effects (secondary tachycardia, prolonged hypertension, and cardiac arrhythmias).[5–7] The routine use of anticholinergics simultaneously with, or after, dexmedetomidine in dogs or cats is neither recommended nor necessary because blood pressure is generally normal to high. During anesthesia, if both the heart rate AND the blood pressure are low, an anticholinergic drug (atropine or glycopyrrolate) can be used as part of blood pressure support.[8] Another treatment option is reversal of the alpha-2 agonist (see ***Atipamezole***).

Antimuscarinics (eg, atropine, glycopyrrolate) are not routinely administered to reptiles, as they can cause increased viscosity of respiratory tract secretions with resultant risks for airway obstruction or endotracheal tube occlusion.

Adverse Effects

With the exceptions of rare CNS adverse effects and being slightly less arrhythmogenic, glycopyrrolate can be expected to have a similar adverse effect profile as atropine, which generally includes dose-related extensions of the drug's pharmacologic effects. At usual doses, adverse effects tend to be mild in relatively healthy patients. The more severe effects listed tend to occur with high or toxic doses. GI effects include dry mouth (xerostomia), increased viscosity of secretions, dysphagia, constipation, vomiting, and thirst. Genitourinary effects include urinary retention or hesitancy. Ocular effects, including blurred vision, pupil dilation, cycloplegia, and photophobia, are possible but less likely than with atropine. In dogs, glycopyrrolate 0.01 mg/kg IM decreased tear production but did not have any effects on intraocular pressure or pupil diameter.[9] Cardiovascular effects include sinus tachycardia (at higher doses), increased myocardial work and oxygen consumption, bradycardia (initially, or at very low doses), hypertension, hypotension, arrhythmias (ectopic complexes), and circulatory failure.

The veterinary drug label only lists mydriasis, tachycardia, and xerostomia as adverse effects in dogs and cats at labeled doses.

Reproductive/Nursing Safety

Glycopyrrolate only marginally crosses the placenta, and teratogenicity was not observed in rabbits that received IM glycopyrrolate.[10]

No specific lactation safety information was found; however, it is unlikely to be excreted into milk in substantial quantities because of its quaternary structure.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Signs of glycopyrrolate toxicity are an extension of its pharmacologic activity. GI effects can include dry mouth (ie, xerostomia), increased viscosity of secretions, dysphagia, constipation, and vomiting. Genitourinary effects may include urinary retention. CNS effects may include stimulation, drowsiness, ataxia, seizures, and respiratory depression; however, because of its quaternary structure, it would be expected that minimal CNS effects would occur after an overdose of glycopyrrolate when compared with atropine. Ophthalmic effects include mydriasis, cycloplegia, photophobia, and an increase in intraocular pressure. Cardiovascular effects include sinus tachycardia (at higher doses), increased myocardial oxygen consumption, bradycardia (initially, or at very low doses), hypertension, hypotension, tachyarrhythmia (eg, premature ventricular complexes [PVCs], ventricular tachycardia), and circulatory failure. In dogs, the LD_{50} for glycopyrrolate is reported to be 25 mg/kg IV. Glycopyrrolate doses of 2 mg/kg IV daily for 5 days per week for 4 weeks demonstrated no signs of toxicity. In cats, the LD_{50} after IM injection is 283 mg/kg.[11]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix***.

Drug Interactions

Glycopyrrolate would be expected to have a similar drug interaction profile as atropine. The following drug interactions either have been reported or are theoretical in humans or animals receiving atropine or glycopyrrolate and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Acetylcholinesterase Inhibitors** (**AChI**, eg, **neostigmine**): May reduce glycopyrrolate effects. Glycopyrrolate may intentionally be administered immediately prior to AChI to prevent peripheral muscarinic effects.
- **Alpha-2 Agonists** (eg, **dexmedetomidine, medetomidine, xylazine**): Use of glycopyrrolate with alpha-2 agonists may significantly increase arterial blood pressure, heart rate, and the incidence of arrhythmia.[12,13] Clinical use of atropine or glycopyrrolate to prevent or treat bradycardia caused by alpha-2 agonists is controversial and use together is discouraged; this may be particularly important when using higher doses of the alpha-2 agonist. See ***Contraindications/Precautions/Warnings***.
- **Amitraz**: Glycopyrrolate may aggravate some signs seen with amitraz toxicity, leading to hypertension and further inhibition of peristalsis.
- **Antacids (Aluminum-, Magnesium-, Calcium-Containing)**: May decrease oral glycopyrrolate absorption; give oral glycopyrrolate at least 1 hour prior to oral antacids.
- **Beta-Blockers** (eg, **atenolol, propranolol**): Glycopyrrolate may increase oral bioavailability.
- **Bethanechol**: Concurrent use of cholinergic agonists and antagonists should be avoided.
- **Digoxin** (**tablets**): Glycopyrrolate may increase serum digoxin concentrations; use oral liquid.
- **Domperidone**: Glycopyrrolate may reduce domperidone efficacy.
- **Potassium Chloride, Oral (solid dosage forms)**: Concurrent use with glycopyrrolate may significantly increase the amount of potassium absorbed. This combination may also increase risk for GI lesions and is contraindicated in humans.
- **Promotility Agents** (eg, **cisapride, metoclopramide**): Concurrent use with glycopyrrolate may antagonize promotility effects.

The following drugs may enhance the activity or toxicity of glycopyrrolate:

- **Amantadine**
- **Anticholinergic Agents (Other)** (eg, **atropine, hyoscyamine**)
- **Anticholinergic Muscle Relaxants** (eg, **dantrolene, methocarbamol**)

- **Antihistamines** (eg, **diphenhydramine**)
- **Opioids** (eg, **fentanyl, morphine, oxymorphone**)
- **Phenothiazines** (eg, **acepromazine**)
- **Procainamide**
- **Primidone**
- **Tricyclic Antidepressants** (eg, **amitriptyline, clomipramine**)

Dosages

DOGS/CATS:

Adjunct to anesthesia:

a) Label dosage (FDA-approved): 0.011 mg/kg IV, IM, or SC[14]

b) Extra-label dosage: Not routinely used but may be of benefit in pediatric patients or when using potent opioids. When used, it is usually as part of a premedication dosed at 0.005 – 0.01 mg/kg IV, IM, or SC, but doses as low as 0.003 mg/kg have been noted.

Vagolytic agent for bradyarrhythmias (extra-label):

a) To determine if increased vagal tone is contributing to a bradyarrhythmia: 0.01 mg/kg IV

b) To treat vagally induced bradyarrhythmias, glycopyrrolate is usually dosed at 0.005 – 0.01 mg/kg IV. If given IM or SC, slightly higher dosages (up to 0.02 mg/kg) may be considered.

Adjunctive treatment of muscarinic signs associated with carbamate or organophosphate intoxication (extra-label): 0.01 – 0.02 mg/kg IV; repeat as necessary

HORSES:

Treatment of bradyarrhythmias (extra-label): 0.00175 – 0.0025 mg/kg (1.7 – 2.5 µg/kg) IV[2,15–19]

Controlling muscarinic adverse effects associated with imidocarb therapy (extra-label): 0.0025 mg/kg IV[16]

RUMINANTS:

Bradycardia, reduce salivary secretions (extra-label): 0.005 – 0.001 mg/kg IM, or 0.002 – 0.005 mg/kg IV[20]

FERRETS:

Premedication (extra-label): 0.01 – 0.02 mg/kg IM, SC, or IV

RABBITS/RODENTS/SMALL MAMMALS:

Preanesthetic (extra-label): **Rodents**: 0.01 – 0.02 mg/kg SC or IM. **Rabbits**: 0.01 – 0.1 mg/kg IM or SC. As part of an injectable anesthesia protocol in rabbits: acepromazine (0.2 mg/kg) with oxymorphone (0.1 mg/kg) and glycopyrrolate (0.01 mg/kg) IM[21]

Adjunctive drug for CPR in rabbits (extra-label): A retrospective study found the median dose used was 0.01 mg/kg IV.[22]

REPTILES:

Treatment of bradycardia (prolonged or profound) associated with anesthesia (extra-label): 0.01 mg/kg IM, IV, or IC (intracoelemic)[23]

Monitoring

Dependent on dose and indication:

- Heart rate and rhythm
- Blood pressure
- GI motility (via auscultation) in horses and potentially in ruminants
- Urination, defecation capability
- Hydration; dry mouth and secretions (eg, respiratory)

Client Information

- Injectable glycopyrrolate administration is best performed by professional staff at a veterinary clinic where adequate cardiac monitoring is available.
- If your animal is receiving glycopyrrolate tablets, provide access to water, and encourage drinking if dry mouth is a problem. The medicine can be given with or without food. If your animal vomits or acts sick after receiving it on an empty stomach, give the medicine with food or a small treat to see if this helps. If vomiting continues, contact your veterinarian.

Chemistry/Synonyms

A synthetic quaternary ammonium antimuscarinic agent, glycopyrrolate occurs as a bitter-tasting, practically odorless, white, crystalline powder with a melting range of 193 °C to 198°C (379°F-388 °F). One gram is soluble in 20 mL of water; 30 mL of alcohol. The commercially available injection is adjusted to a pH of 2 to 3 and contains 0.9% benzyl alcohol as a preservative.

Glycopyrrolate may also be known as glycopyrronium bromide, AHR-504, *Acpan*®, *Gastrodyn*®, *Glycostigmin*®, and *Robinul*®.

Storage/Stability

Glycopyrrolate tablets should be stored in tight containers and both the injection and tablets should be stored at room temperature (15°C -30°C [59°F-86°F]).

Glycopyrrolate is stable under ordinary conditions of light and temperature. It is most stable in solution at an acidic pH and undergoes ester hydrolysis at pH above 6.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; consult specialized references or a veterinary hospital pharmacist for more specific information. Although stability information was not located, glycopyrrolate injection has been mixed in syringes with acepromazine, buprenorphine, morphine, and ketamine.

Glycopyrrolate injection is physically **stable** in the following IV solutions: D_5W, D_5/half normal saline, Ringer's injection, and normal saline. Glycopyrrolate may be administered via the tubing of an IV running lactated Ringer's, but rapid hydrolysis will occur if it is added to an IV bag of LRS. The following drugs are reportedly physically **compatible** with glycopyrrolate: atropine sulfate, chlorpromazine HCl, codeine phosphate, diphenhydramine HCl, hydromorphone, hydroxyzine HCl, lidocaine HCl, meperidine HCl, morphine sulfate, neostigmine methylsulfate, oxymorphone HCl, procaine HCl, prochlorperazine HCl, promazine HCl, promethazine HCl, pyridostigmine Br, and scopolamine HBr.

The following drugs are reportedly physically **incompatible** with glycopyrrolate: chloramphenicol sodium succinate, dexamethasone sodium phosphate, diazepam, dimenhydrinate, methohexital sodium, methylprednisolone sodium succinate, pentazocine lactate, pentobarbital sodium, sodium bicarbonate, and thiopental sodium. Other alkaline drugs (eg, thiamylal) would also be **expected to be incompatible** with glycopyrrolate.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Glycopyrrolate for Injection: 0.2 mg/mL; (Rx). Although approved products for dogs and cats are still listed in the FDA Green Book, they may not be commercially marketed.

The Association of Racing Commissioners International (ARCI) has designated this drug as a class 4 substance. See the ***Appendix*** for more information. Use of this drug may not be allowed in certain animal competitions. Check rules and regulations before entering in a competition while this medication is being administered. Contact local racing authorities for further guidance.

HUMAN-LABELED PRODUCTS:

Glycopyrrolate Tablets: 1 mg and 2 mg; *Robinul*® and *Robinul Forte*®, generic; (Rx)

Glycopyrrolate Oral Solution: 1 mg/5 ml (0.2 mg/mL); *Cuvposa*®; (Rx)

Glycopyrrolate Injection: 0.2 mg/mL in 1 mL, 2 mL, 5 mL, and 20 mL vials; *Robinul*®, generic; (Rx)

For the complete list of references, see **wiley.com/go/budde/plumb**

Gonadorelin

GnRH

(goe-***nad***-oe-rell-in)

Hormonal Agent

Prescriber Highlights

- ► Hypothalamic hormone used to treat ovarian cysts and other reproductive disorders in a variety of species. In cattle, FDA restricts use for fixed time artificial insemination (FTAI) in combination with prostaglandins to specific approved products.
- ► Duration of action is very short (minutes).
- ► No contraindications and adverse effects have been reported.
- ► No slaughter or milk withdrawal when used as labeled

Uses/Indications

Gonadorelin (GnRH) is indicated (FDA-approved) for the treatment of ovarian follicular cysts in cattle, which reduces the number of days to first estrus. It also is approved for use with cloprostenol or dinoprost to synchronize estrous cycles to allow for fixed time artificial insemination (FTAI) in cattle. In manufacturer field studies, pregnancy rates were approximately doubled with use of gonadorelin compared to the prostaglandin only. One study comparing two different GnRH products (gonadorelin hydrochloride and gonadorelin diacetate tetrahydrate) demonstrated equivalent pregnancy rates.[1]

Additionally, gonadorelin has been used in cattle to reduce the time interval from calving to first ovulation and to increase the number of ovulations within the first 3 months after calving. This may be particularly important in increasing fertility in cows with retained placenta.

In dogs, gonadorelin has been used experimentally to help diagnose reproductive disorders or to identify intact animals versus castrated ones by maximally stimulating FSH and LH production. It has also been used experimentally in dogs to induce estrus through pulsatile dosing. Although apparently effective, specialized administration equipment is required for this method. Other uses in dogs may include enhancement of libido and treatment of oligospermia in male dogs and induction of ovulation or treatment of ovarian cysts in bitches.

Gonadorelin has been used as an alternate therapy to FSH or hCG to induce estrus or ovulation in cats with prolonged anestrus.

In other species, gonadorelin has been used to enhance sexual behavior in breeding stallions, for estrus synchronization in sheep and goats, and to induce ovulation in alpacas.

In human medicine, gonadorelin has been used for the diagnosis of hypothalamic-pituitary dysfunction, cryptorchidism, and depression secondary to prolonged severe stress.

Pharmacology/Actions

Gonadorelin is a synthetic form of GnRH and it stimulates the production and release of FSH and LH from the anterior pituitary. Secretion of endogenous GnRH from the hypothalamus is thought to be controlled by several factors, including circulating sex hormones. Synthetic gonadorelin administered IV or IM also causes the release of endogenous LH or FSH from the anterior pituitary.[2] Synthetic gonadorelin is physiologically and chemically identical to the endogenous bovine hypothalamic releasing factor.

Gonadorelin causes a surge of FSH and LH after a single injection. In cows and ewes, this can induce ovulation, but not in estrus mares. A constant infusion of gonadorelin will initially stimulate LH and FSH release, but after a period of time, LH and FSH concentrations will return to baseline.

Pharmacokinetics

After IV injection in pigs, gonadorelin is rapidly distributed to extracellular fluid, with a distribution half-life of ≈2 minutes. The elimination half-life of gonadorelin is ≈13 minutes in the pig.

After IV injection in humans, gonadorelin has a plasma half-life of 10 to 40 minutes. Within one hour, approximately ½ the dose is excreted in the urine as metabolites. It is not absorbed after oral administration.

Contraindications/Precautions/Warnings

None are noted on the label.

Adverse Effects

Adverse effects, including injection site reactions, were reported at the same rate as placebo in manufacturer field studies. Synthetically prepared gonadorelin should not cause any hypersensitivity reactions. This may not be the case with pituitary-obtained LH preparations or hCG.

Reproductive/Nursing Safety

Administration of 60 µg/kg/day of gonadorelin diacetate tetrahydrate to pregnant rats and rabbits during organogenesis did not cause embryotoxic or teratogenic effects.[3]

No specific lactation safety information was listed for this drug.

Overdose/Acute Toxicity

In doses up to 120 µg/kg, no adverse effects were noted in several species of test animals.[3] The LD_{50} in rats and dogs is 60 mg/kg and 600 µg/kg, respectively. Gonadorelin is unlikely to cause significant adverse effects after inadvertent overdosage.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

None noted

Dosages

DOGS:

GnRH stimulation test to differentiate castration from cryptorchidism (extra-label): Take preinjection blood sample, administer 50 µg/dog (NOT µg/kg) IM, 2 to 3 hours later take postinjection blood sample. Neutered dogs have testosterone concentrations less than 0.1 ng/mL; GnRH does not stimulate testosterone production.[4]

Increasing libido in male dogs (extra-label): 50 µg IM weekly for 4 to 6 weeks may improve libido.[5]

Improvement in semen quality (extra-label): 1 – 3 µg/kg IM once, or once weekly[6]

Cystic ovarian disease (extra-label): 3.3 µg/kg IM once daily for 3 days. An elevated progesterone concentration (more than 2 ng/mL) measured 1 to 2 weeks posttreatment verifies success.[7]

CATS:

Infertility, reduced libido, testis descent in male cats (extra-label): 1 µg/kg every 2 to 3 days[8]

Detection of ovarian remnants after ovariohysterectomy (extra-label): 25 µg/cat (NOT µg/kg). A progesterone concentration more than 1 ng/mL measured 1 to 2 weeks posttreatment verifies presence of ovarian tissue in the abdomen.[7]

CATTLE:

Treatment of ovarian cysts (label dosage; FDA-approved): 86 or 100 µg gonadorelin *base* (depends on product)/cow (NOT µg/kg) IM or IV. **NOTE**: *Factrel®* is labeled for IM use only.

Using with dinoprost tromethamine to synchronize estrous cycles to allow fixed-time artificial insemination (FTAI) in lactating dairy cows (label dosage; FDA approved): 100 – 200 µg/cow (NOT µg/kg) IM at Day 0. Administer dinoprost 25 mg/cow (NOT mg/kg) (as dinoprost tromethamine) IM 6 to 8 days after the first dose of gonadorelin. Administer a second dose of gonadorelin 30 to 72 hours after dinoprost. Perform fixed-time artificial insemination (FTAI) 0 to 24 hours after the second dose of gonadorelin or inseminate cows on detected estrus using standard herd practices.[9]

Using with cloprostenol sodium to synchronize estrous cycles to allow fixed-time artificial insemination (FTAI) in beef and/or lactating dairy cows (label dosage for *Cystorelin®*, *GONABreed®*, *OvaCyst®* and *Fertagyl®*; FDA-approved): Administer 86 µg/cow (NOT µg/kg) IM (2 mL; *Fertagyl®* or *Cystorelin®*) or 100 µg/cow (NOT µg/kg) IM (1 mL; *GONABreed®*) at Day 0. Administer cloprostenol (as cloprostenol sodium) 500 µg/cow (NOT µg/kg) IM 6 to 8 days after the first gonadorelin dose. Administer a second gonadorelin dose (*Fertagyl®* or *Cystorelin®* 2 mL OR *GONABreed®* 1 mL) 30 to 72 hours after cloprostenol. Perform FTAI 0 to 24 hours after the second gonadorelin dose or inseminate cows on detected estrus using standard herd practices. See table below. (Adapted from labels; *Cystorelin®*, *Fertagyl®*, *GONABreed®*, *OvaCyst®*)

Gonadorelin product	First Gonadorelin dose at Day 0 of cycle	Cloprostenol dose (day of cycle)	Second Gonadorelin dose 30 to 72 hours after Cloprostenol	FTAI timing
Fertagyl®	86 µg/cow (NOT µg/kg) (2 mL) IM	500 µg/cow (NOT µg/kg) IM (Day 6 to 8)	86 µg/cow (NOT µg/kg) (2 mL) IM	0 to 24 hours after the second gonadorelin dose for beef cattle, 8 to 24 hours for lactating dairy cattle or on detected estrus using standard herd practices
Cystorelin®, *OvaCyst®*	86 µg/cow (NOT µg/kg) (2 mL) IM	500 µg/cow (NOT µg/kg) IM (Day 6 to 8)	86 µg/cow (NOT µg/kg) (2 mL) IM	0 to 24 hours after the second gonadorelin dose or on detected estrus using standard herd practices
GONABreed®	100 µg/cow (NOT µg/kg) (1 mL) IM	500 µg/cow (NOT µg/kg) IM (Day 6 to 8)	100 µg/cow (NOT µg/kg) (1 mL) IM	0 to 24 hours after the second gonadorelin dose or on detected estrus using standard herd practices

Monitoring

- Dependent on reason for use; efficacy

Client Information

- In small animals, gonadorelin is best administered by a veterinarian.

Chemistry/Synonyms

A hormone produced by the hypothalamus, gonadorelin is obtained from natural sources or is synthetically produced. It is a decapeptide that occurs as a white or faintly yellowish-white powder. One gram is soluble in 25 mL of water or in 50 mL of methyl alcohol. 50 µg of gonadorelin acetate is equivalent to ≈31 units.

Gonadorelin may also be known as follicle stimulating hormone-releasing factor, GnRH, gonadoliberin, gonadorelinum, gonadotrophin-releasing hormone, Hoe-471, LH/FSH-RF, LH/FSH-RH, LH-RF, LH-RH, luliberin, luteinising hormone-releasing factor, *Cystorelin®*, *Factrel®*, *Fertagyl®*, *GONABreed®*, and *OvaCyst®*.

Storage/Stability

Most gonadorelin products (*Factrel®*, *Fertagyl®*, and *GONABreed®*) should be refrigerated at 2°C to 8°C (36°F to 46°F) for long-term storage. One product (*Cystorelin®*) should be stored at or below 25°C (77°F), with brief excursions to 30°C (86°F) permitted. Discard dates for in-use vials vary by manufacturer:

- *Cystorelin®*: discard after 6 months
- *Factrel®*: 1 month after first puncture
- *Fertagyl®*: within 28 days of first use, but the 100 mL vial should not be punctured more than 10 times; see product label for further details
- *GONABreed®*: 180 days after first use, and in-use vials may be stored at temperatures up to 25°C (77°F)
- *OvaCyst®*: 3 months after first use

There is very little information available on the stability of gonadorelin.

Compatibility/Compounding Considerations

There is very little information available on the compatibility of gonadorelin.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

NOTE: Because the FDA does not consider estrous control and synchrony a "therapeutic purpose" under the requirements of extra-label drug use in food-producing animals, using a drug in an extra-label manner for estrous control in cattle is not permissible.[10]

Gonadorelin (diacetate tetrahydrate) for Injection: 43 µg/mL gonadorelin (equivalent to 50 µ/mL gonadorelin diacetate tetrahydrate suitable for IM or IV administration according to the indication) in 10 mL, 30 mL, 50 mL, and 100 mL multidose vials; *Cystorelin®*; (Rx). FDA-approved for the IV or IM treatment of ovarian follicular cysts in dairy cattle, and IM with cloprostenol sodium to synchronize estrous cycles to allow for fixed time artificial insemination (FTAI) in lactating dairy cows and synchronize estrous cycles to allow for FTAI in beef cows. *Ovacyst®*; (Rx). FDA-approved for the IM treatment of ovarian follicular cysts in dairy cattle, in 36 mL multidose vials. There are no withdrawal times required for either milk or slaughter.

Gonadorelin (acetate) for Injection: 43 µg/mL (gonadorelin) available in 20 mL and 100 mL multidose vials; *Fertagyl®*; (Rx). FDA-approved IV or IM for the treatment of ovarian follicular cysts in dairy cattle, and IM with cloprostenol to synchronize estrous cycles to allow for FTAI in beef cows. There are no withdrawal times required for either milk or slaughter.

Gonadorelin (acetate) for Injection: 100 µg/mL (gonadorelin) in 20 mL and 100 mL multidose vials; *GONABreed®*; (Rx). FDA-

approved for the treatment of ovarian follicular cysts in dairy cattle (IM or IV) and in combination with cloprostenol sodium to synchronize estrous cycles to allow for FTAI in lactating dairy and beef cows (IM only). No withdrawal period required.

Gonadorelin HCl Solution for Injection: 50 µg/mL (gonadorelin) 20 and 50 mL multidose vials; *Factrel*®; (Rx). FDA-approved for the IM treatment of ovarian follicular cysts in in lactating dairy cows, beef cows, and replacement dairy and beef heifers and in combination with dinoprost tromethamine to synchronize estrous cycles to allow FTAI in lactating dairy cows. No withdrawal period required.

HUMAN-LABELED PRODUCTS: NONE

Granisetron

(gran-***iss***-eh-tron) *Kytril*®

5-HT_3 Antagonist Antiemetic

Prescriber Highlights

- ► Used for the treatment of severe vomiting or emesis prophylaxis before chemotherapy.
- ► It appears safe, but it is not commonly used in veterinary medicine.

Uses/Indications

Granisetron is an alternative to other 5-HT_3 receptor antagonists (eg, ondansetron or dolasetron) for the treatment of severe vomiting or prophylaxis before administering antineoplastic drugs, such as cisplatin, that can cause severe vomiting.

Pharmacology/Actions

Granisetron, like ondansetron or dolasetron, exerts its antinausea and antiemetic actions by selectively antagonizing 5-hydroxytryptamine$_3$ (5-HT_3; serotonin$_3$) receptors. These receptors are found primarily in the CNS chemoreceptor trigger zone, on vagal nerve terminals, and enteric neurons in the GI tract. Chemotherapy-associated vomiting in cats is believed primarily due to activation of 5-HT_3 receptors in the chemoreceptor trigger zone (CTZ), but in dogs, enteric and vagal receptors may be more important. Granisetron did not prevent apomorphine-induced vomiting in beagles.[1]

Pharmacokinetics

No pharmacokinetic data for dogs or cats were located. In humans, granisetron is rapidly absorbed after oral dosing, and peak concentrations occur in about 2 hours. Oral bioavailability is only 60% due to first-pass metabolism in the liver. The presence of food can decrease AUC by 5% but increase peak concentrations by 30%. Granisetron has a volume of distribution of about 3 L/kg, and plasma protein binding is ≈65%. The drug is metabolized in the liver, primarily via demethylation and oxidation and then conjugation. Less than 20% is excreted unchanged in the urine; the remainder is eliminated in the urine and feces as metabolites. Elimination half-life varies considerably, with reported values from about 1 to 30 hours. Cancer patients appear to have longer elimination half-lives compared to healthy adults.

Contraindications/Precautions/Warnings

There are no known contraindications to using this medication in dogs or cats. In humans, granisetron is contraindicated in patients hypersensitive to it, and it should not be used to treat vomiting associated with apomorphine (see ***Drug Interactions***).

No dosage adjustments are required in elderly patients or those with impaired renal or hepatic function. Granisetron may mask signs associated with progressive ileus and/or gastric distention; it should not replace required nasogastric suction.

Adverse Effects

Because of limited use in dogs and cats, a comprehensive adverse effect profile for granisetron is not known; however, it appears to be tolerated well.

In humans, the most common adverse effect reported is headache. Other adverse effects that may occur include abdominal pain, constipation or diarrhea, asthenia, or somnolence. Rarely, hypersensitivity reactions or cardiovascular effects (arrhythmias, chest pain, hypotension) have been reported.

Reproductive/Nursing Safety

Safety in pregnancy is not clearly established, but high-dose studies in rodents and rabbits did not demonstrate overt fetal toxicity or teratogenicity.

It is not known if granisetron enters milk.

Because safety of granisetron has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

Limited information is available. An overdose of 38.5 mg in a human caused only a slight headache. Observation and, if required, supportive treatment are suggested.

For patients that have experienced or are suspected of having experienced an overdose, consultation with a 24-hour poison consultation center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions have either been reported or are theoretical in humans or animals receiving granisetron and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Apomorphine**: Profound hypotension can occur.
- **Buprenorphine**: Concurrent use may increase the risk for serotonin syndrome.
- **Cisapride**: Concurrent use may result in increased risk for QT-interval prolongation. This combination is contraindicated in humans.
- **Fluconazole**: Concurrent use may result in increased risk for QT-interval prolongation. This combination is contraindicated in humans.
- **Fluoroquinolone Antibiotics** (eg, **enrofloxacin**): Concurrent use may increase the risk for QT interval prolongation.
- **Ketoconazole**: May inhibit the metabolism of granisetron and increase the risk for QT-interval prolongation
- **Macrolide Antibiotics** (eg, **clarithromycin**): Concurrent use may increase the risk for QT interval prolongation.
- **Metronidazole**: Concurrent use may increase the risk for QT interval prolongation.
- **Monoamine Oxidase Inhibitors** (**MAOIs**; eg, **amitraz, linezolid, selegiline**): Increased risk for serotonin syndrome
- **Phenobarbital**: Can induce the metabolism of granisetron
- **Serotonergic Agents, Other** (eg, **clomipramine, fentanyl, fluoxetine, mirtazapine, tramadol, trazodone**): Increased risk for serotonin syndrome

Laboratory Considerations

- No specific laboratory concerns are associated with granisetron.

Dosages

DOGS/CATS:

Antiemetic (extra-label): Little is published on the clinical use of

this drug in animals; single doses of 0.02 – 0.4 mg/kg IV have demonstrated efficacy in dogs,[2,3] and dosages of 0.1 – 0.5 mg/kg PO or IV every 12 hours to 24 hours have been suggested. IV administration may be more effective than PO. In cats, 1 mg/kg IM 3 times daily also has been reported.[4]

Monitoring

- Clinical efficacy

Client Information

- This drug is usually used on an inpatient basis or during outpatient visits for chemotherapy.
- If used orally on an outpatient basis, be sure to contact your veterinarian for further instructions in case of uncontrolled vomiting or if the dose is vomited up after administering.

Chemistry/Synonyms

Granisetron HCl occurs as a white or almost white powder that is freely soluble in water. Dosages are expressed in terms of the base; 1.12 mg of granisetron HCl is equivalent to 1 mg of granisetron base.

Granisetron may also be known as granistroni, granisetrono, or BRL-43694A, *Aludal®, Eumetic®, Granicip®, Granitron®, Kytril®, Kevatril®, Rigmoz®*, or *Setron®*.

Storage/Stability

Store granisetron products at room temperature (20°C to 25°C [68°F-77°F]) in tight containers and protected from light. Do not freeze the solution for injection. Upon penetration of the multi-dose vial, use it within 30 days.

Compatibility/Compounding Considerations

Compatibility is dependent on factors such as pH, concentration, temperature, and diluent used; specialized references or a hospital pharmacist should be consulted for more specific information.

The injectable solution is **compatible** with 0.9% sodium chloride, 5% dextrose in 0.45% or 0.9% sodium chloride, and 5% dextrose in water. It is **compatible** with many drugs at intravenous Y-sites, but it is **incompatible** with amphotericin B.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS: NONE

HUMAN-LABELED PRODUCTS:

Granisetron Oral Tablets: 1 mg (1.12 mg as HCl); generic; (Rx)

Granisetron Injection Solution: 0.1 mg/mL (0.112 mg/mL as HCl) preservative-free, may contain sodium chloride 9 mg in 1 mL single-use vials; 1 mg/mL (1.12 mg/mL as HCl), regular and preservative-free, in 1 mL single-dose and 4 mL multi-dose vials; generic; (Rx)

Granisetron transdermal patch and extended-release subcutaneous injection solution also are available, although there is no information about the use of these products in veterinary species.

References

For the complete list of references, see **wiley.com/go/budde/plumb**

Grapiprant

(**gra**-pi-prant) *Galliprant®*

Prostaglandin E_2 EP4-Receptor Antagonist

Prescriber Highlights

- ► Used for the treatment of osteoarthritis (OA) pain in dogs
- ► Contraindicated in dogs hypersensitive to it
- ► Adverse GI effects (eg, vomiting; loose, mucoid, watery, or bloody stool) are possible.
- ► Dogs homozygous for the MDR1 gene mutation (also known as *ABCB1*-1delta) likely require lower dosages.

Uses/Indications

Grapiprant is approved for the control of pain and inflammation associated with osteoarthritis (OA) in dogs.[1] In the UK and Europe, grapiprant is specifically indicated for use in dogs with mild to moderate OA.[2]

Grapiprant has demonstrated an antinociceptive effect in rabbits under experimental conditions[3]; further study is warranted before the drug is used clinically in this species.

Pharmacology/Actions

Grapiprant is a prostaglandin E_2 (PGE_2) EP4-receptor antagonist NSAID; it does not inhibit cyclooxygenase like other commonly prescribed NSAIDs.

EP4 receptors are found in a wide range of tissues (eg, hematopoietic tissues, GI tract, cardiovascular system, bones, kidneys) and are the most widely expressed PGE_2 receptors.[4] EP4 receptors impact GI homeostasis and renal function[4]; they have also been shown to be upregulated during arthritic states.[5] The EP4 receptor is the sole PGE_2-mediated receptor for stimulation of acid secretion in the stomach, bicarbonate secretion in the duodenum, and mucus secretion in the duodenum and large intestine.[1,4] The EP4 receptor can mediate the antinatriuretic effects of PGE_2 by stimulating release of renin in the kidney.[4,6] EP4 receptors are abundantly expressed in the hearts of dogs[1,7]; however, the clinical significance of this is not yet known.

By inhibiting the EP4 receptor, grapiprant decreases the inflammatory effects of PGE_2 and therefore lessens pain transmission at sensory neurons.[1,8] Grapiprant may also inhibit PGE_2-mediated small intestine motility and cytokine expression in the large intestine.[9]

EP4 receptors are not involved with causing pyrexia.

Pharmacokinetics

Grapiprant tablets are rapidly absorbed after oral administration, with peak concentrations (C_{MAX}) of up to 1600 ng/mL occurring ≈1 to 2 hours postadministration in fasted dogs.[10] The presence of food can significantly delay time to peak concentrations and reduce C_{MAX} (4-fold) and area under the curve (AUC; 2-fold).[1,11] AUC in fasted dogs was 2.8 micrograms*hour/mL following a single 2 mg/kg PO dose.[1] The US label does not recommend administering grapiprant in the fasted state,[1] whereas the UK label states to administer on an empty stomach and at least 1 hour prior to the next meal.[2] A plasma concentration of 164 ng/mL has been reported to be effective for analgesia.[12] Plasma protein-binding is ≈95%.[2,12] Elimination half-life can range from ≈4.5 to 6 hours.[1,12,13] Biotransformation and elimination processes have not been fully described, but hydroxylated and *N*-oxidated metabolites have been detected in urine and feces.[1,11,14] Excretion is predominantly fecal (≈65%) and renal (≈20%).[2]

In collies homozygous for the multidrug sensitivity gene (*MDR1* gene, also known as *ABCB1* gene) receiving the label dose, C_{MAX} was 4600 to 5200 ng/mL, AUC_{0-24} was 15.2 to 17.3 micrograms*hour/mL, and half-life was 4.3 hours.[15] While the reported half-life is similar to that of "normal" dogs, the values for C_{MAX} and

AUC are substantially higher.

In cats given 3 mg/kg PO once daily for 28 days, peak concentrations of ≈1100 ng/mL occurred 1.2 to 1.7 hours after administration.[16] Elimination half-life was 3.1 to 14.1 hours.[16] Following single 2 mg/kg doses given IV or PO, oral bioavailability was 40%, steady state volume of distribution was 0.9 L/kg, clearance was 173 mL/kg/hour, and half-life was 5.5 hours.[17]

In fasted, exercised thoroughbreds given a single 2 mg/kg PO dose, a peak serum concentration of 31.1 ng/mL was reached within 90 minutes of administration. Elimination half-life was 5.9 hours.[18] In fasted mixed-breed mares, the peak plasma concentrations ranged from 71 to 149 ng/mL (mean 106 ng/mL) reached 30 minutes after administration.[19]

Contraindications/Precautions/Warnings

Grapiprant is contraindicated in dogs that are hypersensitive to it or that are currently taking other NSAIDs or corticosteroids.

Safety has not been evaluated in dogs younger than 9 months or weighing less than 3.6 kg (8 lb). Grapiprant use in dogs with cardiac disease has not been studied.[1] The UK label states to *use with caution in dogs suffering from pre-existing liver, cardiovascular, or renal dysfunctions or from gastrointestinal disease*.[2]

Grapiprant is a methylbenzenesulfonamide, and it is not known if dogs with a history of hypersensitivity to sulfonamide drugs will react to grapiprant.[1]

Adverse Effects

Adverse effects in dogs include vomiting; diarrhea or soft stools; decreased appetite; lethargy; mucoid, watery, or bloody stool; increases in alkaline phosphatase and alanine aminotransferase; and decreases in serum albumin and total protein.[1] A preapproval efficacy study of 131 dogs given labeled doses also reported increased calcium concentrations.[14] These adverse effects were deemed mild and transient by the authors.[20] In collies homozygous for the multidrug sensitivity gene (*MDR1* gene, also known as *ABCB1* gene), 25% experienced vomiting, and one dog had slight decreases in serum albumin and total protein; CNS effects were not observed.[15]

In a study, grapiprant was tolerated in cats receiving up to 15 mg/kg/day orally for 28 days; no adverse effects or histopathologic changes were detected.[16]

Reproductive/Nursing Safety

Safe use has not been established in breeding, pregnant, or lactating dogs.[1]

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

In a preapproval safety study, grapiprant was administered at 50 mg/kg PO every 24 hours in a methylcellulose suspension to healthy 9-month-old beagles.[20] Because the bioavailability of the suspension is significantly less than that of the tablet's and feeding status can impact bioavailability, this dose equates to ≈5 to 10 times that of the labeled dose.[21] All (n = 12) dogs survived the study. GI signs included vomiting and loose, watery, bloody, and/or mucoid stools were observed in 67% to 100% of dogs. Mildly decreased albumin, total protein, and/or calcium concentrations were observed in some treated dogs.[20] Overdoses should be treated with supportive care based on presenting clinical signs.[2]

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

NOTE: The manufacturer warns that concomitant use of grapiprant with other anti-inflammatory drugs (eg, COX-inhibiting NSAIDs, corticosteroids) should be avoided, as concurrent use has not been studied. An appropriate washout period has been suggested when switching from corticosteroids or COX-inhibiting NSAIDs to grapiprant.[1]

Grapiprant does not inhibit metabolism pathways mediated by cytochrome P450 1A2 isozyme (CYP1A2), CYP2C9, CYP2C19, CYP2D6, or CYP3A4.[1] Grapiprant is a substrate of P-glycoprotein transport, but no clinically relevant drug interactions have been identified.

Although the following drug interactions have either been reported or are theoretical in humans or animals receiving NSAIDs, their significance in veterinary patients is unknown. Unless otherwise noted, use together is not necessarily contraindicated, but the potential risks must be weighed and additional monitoring performed when appropriate.

- **Angiotensin Converting Enzyme Inhibitors** (**ACEIs**; eg, **benazepril**, **enalapril**): NSAIDs may decrease effectiveness of ACE inhibitors by reducing renal vasodilatory prostaglandins. Interaction may apply to grapiprant.
- **Aspirin or Other NSAIDs** (eg, **carprofen, meloxicam**): Concurrent administration with grapiprant may increase the risk for toxicity (eg, GI ulceration).
- **Corticosteroids** (eg, **dexamethasone**, **fludrocortisone**, **prednis(ol)one**): Concomitant administration with grapiprant may increase the risk for GI adverse effects.
- **Highly Protein Bound Drugs** (eg, **oral anticoagulants**, **other anti-inflammatory agents, salicylates**, **sulfonamides**, **sulfonylurea antidiabetic agents**): Because grapiprant is highly bound to plasma proteins (95%), it could theoretically displace other highly bound drugs causing a transient increase in serum concentrations of each drug. These interactions are unlikely to be of clinical concern because increased free drug concentrations will equilibrate through increased clearance. Monitor for adverse effects of each drug when using this combination.
- **Loop Diuretics** (eg, **furosemide**): Concurrent use of NSAIDs and loop diuretics may increase the risk for renal damage secondary to decreased renal blood flow. Interaction may apply to grapiprant.

Laboratory Considerations

- Some dogs receiving grapiprant may develop **decreased serum albumin** and **total protein** concentrations. Laboratory test relevance, if any, is not known.
- Increased **alkaline phosphatase** and **alanine aminotransferase** have been reported.

Dosages

DOGS:

Control of pain and inflammation associated with osteoarthritis (labeled dosage; FDA-approved): 2 mg/kg (0.9 mg/lb.) PO every 24 hours.[1] Tablets are scored (except the 100 mg size), and the dose should be calculated in half-tablet increments (see table below). The lowest effective dose should be used for the shortest duration consistent with individual response. Dogs weighing less than 3.6 kg (8 lb) cannot be accurately dosed. The "Information for Dog Owners" sheet should be provided with the prescription. According to the UK label, the drug should be administered on an empty stomach at least 1 hour before the next meal, and if no clinical improvement is noted after 14 days, grapiprant should be discontinued and other treatment options explored.[2]

Patient weight in kg (lb)	Number of 20 mg tablets	Number of 60 mg tablets	Number of 100 mg tablets
3.6 - 6.8 (8 – 15)	0.5		
6.9 - 13.6 (15.1 – 30)	1		
13.7 - 20.4 (30.1 – 45)		0.5	
20.5 – 34 (45.1 – 75)		1	
34.1 – 68 (75.1 – 150)			1
Greater than 68(150)	Use a combination of half and full tablets to achieve the appropriate dose		

Control of pain and inflammation associated with osteoarthritis in dogs homozygous or heterozygous for the multidrug sensitivity gene (*MDR1* gene, also known as *ABCB1* gene) (extra-label): 1 mg/kg (50% dose reduction) PO once daily (homozygous) or 1.5 mg/kg (25% dose reduction) PO once daily (heterozygous) has been suggested.[15] The dose could then be increased as tolerated to the full 2 mg/kg/day dose. Alternatively, for dogs with more severe pain and inflammation, the full dose could be administered with close monitoring for adverse effects and recheck of plasma protein concentration 4 to 6 weeks after the first administration.

Monitoring

- Clinical efficacy
- Appetite; vomiting
- Stool characteristics (eg, presence of blood or mucus; changes in consistency)
- Although no mention is made on the product label, a baseline CBC, serum chemistry profile and urinalysis should be considered before prescribing. For dogs receiving this drug long term, monitoring these laboratory values at regular intervals may be helpful to detect development of problems. Frequency of monitoring is not known at this time. More frequent monitoring should be considered in patients with underlying problems or in patients with clinical signs; less frequent monitoring can be considered in healthy patients with no apparent adverse effects.

Client Information

- This medicine may be given with or without food. Try giving the medicine with food if vomiting occurs.
- Side effects can include vomiting, diarrhea, and decreased appetite. Contact your veterinarian if your animal's appetite decreases or if your animal vomits or develops abnormal stool (eg, watery, presence of blood or mucus).
- Store this medicine well out of reach of animals and children.

Chemistry/Synonyms

Grapiprant is a methylbenzenesulfonamide in the piprant class of NSAIDs. It has a molecular weight of 491.6 daltons. It appears as a white to off-white crystalline powder and is poorly soluble in water. The commercially available flavored tablets contain desiccated pork liver as a flavoring agent.

Grapiprant may also be known as AT-001, grapiprantrum, UNII-J9F5ZPH7NB, MR10A7, CJ-023423, RQ-00000007, 415903-37-6, or *Galliprant*®.

Storage/Stability

Store tablets at or below 30°C (86°F) and out of reach of other animals and children.

Compatibility/Compounding Considerations

No specific information noted

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Grapiprant Flavored Tablets (scored): 20 mg, 60 mg, and 100 mg; *Galliprant*®; (Rx). FDA-approved for use in dogs (NADA #141-455). The 20 mg and 60 mg tablets are scored; the 100 mg tablets are not scored and the manufacturer states that these tablets should not be broken in half, as the amount of drug in each half of the tablet cannot be guaranteed.[1]

HUMAN-LABELED PRODUCTS: NONE

Griseofulvin

(gri-see-oh-***ful***-vin) *Fulvicin®, Gris-PEG®*

Antifungal Agent

Prescriber Highlights

- ► Fungistatic antibiotic used to treat dermatophytosis; it has no effect on other fungi. Azole antifungal agents and terbinafine have largely supplanted griseofulvin use for treating small animal species.
- ► Contraindications include known hypersensitivity, hepatocellular failure, and pregnancy (known teratogen in cats).
- ► Use with caution in cats with FIV and in kittens, as they may be overly sensitive to the drug.
- ► Adverse effects include anorexia, vomiting, diarrhea, anemia, neutropenia, leukopenia, thrombocytopenia, depression, ataxia, hepatotoxicity, or dermatitis/photosensitivity.
- ► Only new hair and nail growth are resistant to dermatophytes after treating.
- ► Dosing is different for microsize and ultramicrosize forms.

Uses/Indications

Griseofulvin has been FDA-approved for use in dogs and cats to treat dermatophytic fungal infections of the skin, hair, and claws. In horses, griseofulvin is FDA-approved to treat dermatophyte infections caused by *Trichophyton equinum* and *Microsporum gypseum*.

The oral tablets (FDA-approved for dogs and cats) are no longer marketed in the United States, but human dosage forms are available. Due to the availability of more effective and less toxic drugs such as azole antifungals, griseofulvin is infrequently recommended today for use in small animal species, especially cats.[1]

In horses, griseofulvin has also been shown to be effective for dermatophyte isolates *T mentagrophytes* and *T verrucosum*.[2]

Griseofulvin has also been used to treat dermatophytic fungal infections in laboratory animals and ruminants.

Pharmacology/Actions

Griseofulvin acts on susceptible fungi by disrupting the structure of the cell's mitotic spindle, arresting the metaphase of cell division, and inhibiting nucleic acid synthesis. Griseofulvin has activity against species of *Trichophyton*, *Microsporum*, and *Epidermophyton*. Because griseofulvin is deposited only in new hair and nail growth, response time depends on rate of keratinization and time required to desquamate infected structures. It has no antibacterial activity and is not clinically useful against other pathogenic fungi, including *Malassezia* spp.

Pharmacokinetics

Griseofulvin is a weak water-soluble drug that is poorly absorbed in the GI tract.[3] The microsize formulations have variable absorption (25% to 70%); dietary fat will enhance absorption. The ultramicrosize form of the drug has the best absorption and is absorbed 1.5 times as well as the microsize form for a given patient.

Griseofulvin is concentrated in skin, hair, nails, fat, skeletal muscle, and the liver, and can be found in the stratum corneum within 4 hours of dosing.

Griseofulvin is metabolized by the liver via oxidative demethylation and glucuronidation to 6-desmethylgriseofulvin, which is not active.[3] In humans, the half-life is 9 to 24 hours. A serum half-life of 47 minutes has been reported for dogs. Less than 1% of the drug is excreted unchanged in the urine.

In humans, topically applied griseofulvin does not penetrate keratinized tissue.

Contraindications/Precautions/Warnings

Griseofulvin is contraindicated in patients that are hypersensitive to it or with hepatocellular failure.[3] The drug is considered contraindicated during pregnancy.

Because kittens may be overly sensitive to the adverse effects associated with griseofulvin, they should be monitored carefully if treatment is instituted. Cats should be tested for FIV before using griseofulvin because of the possible neutropenic or panleukopenic effects of the drug.

In humans, use of griseofulvin is not considered justified for minor infections that will respond to topical treatment.

Do not confuse griseofulvin microsize and ultramicrosize formulations, as dosages are not interchangeable.

Adverse Effects

Griseofulvin can cause anorexia, vomiting, diarrhea, anemia, neutropenia, leukopenia, thrombocytopenia, depression, ataxia, hepatotoxicity, dermatitis, photosensitivity, and toxic epidermal necrolysis. The drug has a disagreeable taste so dosing may be difficult. With the exception of GI clinical signs, adverse effects are uncommon in dogs at usual doses. Cats, particularly kittens, may be more susceptible to adverse effects (eg, bone marrow depression) than other species. Cats with FIV are at increased risk for neutropenia and bone marrow suppression associated with griseofulvin administration.[4] This effect could be due to this species' propensity to more slowly form glucuronide conjugates and thus metabolize the drug at a slower rate than either dogs or humans.

Reproductive/Nursing Safety

Griseofulvin is contraindicated during pregnancy.[3] For sexually intact females, verify pregnancy status before administration. It is a known teratogen in dogs,[3,5] cats, mice, and rats and likely horses as well. Dosages of 35 mg/kg given to cats during the first trimester caused cleft palate and other skeletal and brain malformations in kittens. Administration of griseofulvin to pregnant cats for treatment of dermatomycosis has resulted in anophthalmos or microphthalmos in their kittens.[6] Griseofulvin may also inhibit spermatogenesis and decrease sperm counts; however, in one study, therapeutic dosage of griseofulvin had no deleterious effect on the semen quality in dogs.[7] Griseofulvin has been used in mares during the later stages of pregnancy without noted ill effect.[8]

Safety during lactation has not been established.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

No specifics regarding griseofulvin overdosage or acute toxicity were located. It is suggested that significant overdoses be handled with GI decontamination, charcoal, and cathartic administration unless contraindicated.

Cats that received griseofulvin 110 – 145 mg/kg for 11 weeks did not have any changes in liver enzymes, bone marrow aspirates, or ACTH stimulation tests.[9]

Cats with FIV received 80 – 147 mg/kg developed fever, anorexia, diarrhea, and depression with increased risk for neutropenia.[4]

Horses have received 100 mg/kg PO for 20 days without apparent ill effect.

For patients that have experienced or are suspected to have experienced an overdose, consultation with a 24-hour poison control center specializing in providing veterinary-specific information is recommended. For general information related to overdose and toxin exposures, as well as contact information for poison control centers, refer to ***Appendix.***

Drug Interactions

The following drug interactions either have been reported or are theoretical in humans or animals receiving griseofulvin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- Alcohol (Ethanol): Griseofulvin may potentiate the effects of alcohol.
- Aspirin: Griseofulvin may decrease salicylate concentrations.
- Cyclosporine: Griseofulvin may decrease cyclosporine concentrations.
- Estrogens (eg, **estriol**): Griseofulvin may decrease estrogen concentrations.
- Phenobarbital: Decreased griseofulvin blood concentrations
- Progestins (eg, **medroxyprogesterone, megestrol**): Griseofulvin may decrease progestin concentrations.
- Theophylline, Aminophylline: In some patients, griseofulvin may decrease theophylline half-life and concentrations.
- Warfarin: Anticoagulant activity may be reduced.

Dosages

DOGS:

Dermatophytosis (label dosage; FDA-approved):

a) Daily dosing given as a single dose or divided[10]:
- For animals weighing up to 2.7 kg (6 lb): 62.5 mg
- For animals weighing 2.7 to 8.2 kg (6 to 18 lb): 125 mg
- For animals weighing 8.2 to 16.4 kg (18 to 36 lb): 250 mg
- For animals weighing 16.4 kg to 21.8 kg (36 to 48 lb): 375 mg
- For animals weighing 21.8 kg to 34.1 kg (48 to 75 lb): 500 mg

b) Weekly dose[10]: Dose is administered at intervals of 7 to 10 days; amount to be given at each interval is calculated as 10 mg/lb of body weight times the number of days between treatments. Adjust dose according to response. Administer additional dose after animal is free of infection.

Dermatophytosis (extra-label): Griseofulvin is not frequently recommended today and dosage forms suitable for dogs may be difficult to obtain. Dosage recommendations have usually been: *Microsize forms*: 50 mg/kg PO once daily or divided and given twice daily. *Ultramicrosize forms*: 5 – 10 mg/kg PO once daily. Both forms should be given with or immediately following a fatty meal. Treat for at least 2 weeks following clinical cure and 2 negative skin cultures taken at least 1 week apart. Treatment may be required for many months.

HORSES:

Dermatophytosis caused by *T equinum* and *M gypseum* (label dosage; FDA-approved): Using griseofulvin (microsize) powder sachets: adults, 1 packet (2.5 g griseofulvin) daily; yearlings, ½

to 1 packet (1.25 – 2.5 g) daily; foals, ½ packet (1.25 g) daily.[11] Treat for at least 10 days and continue until all affected areas are confirmed negative.

Dermatophytosis (extra-label): Using the microsize (not ultramicrosize) products: 5 mg/kg PO once daily. Smaller doses (1.25 g) should be used for foals or ponies. If using ultramicrosize (human) formulations, the dose should be reduced by 50%.[8]

RABBITS/RODENTS/SMALL MAMMALS:

Dermatophytosis in small exotic mammals (extra-label): 25 – 100 mg/kg/day PO divided into 2 to 3 doses for 2 to 4 weeks[12]

Monitoring

- Clinical efficacy; dermatophyte culture
- Adverse effects
- Baseline and periodic (every 1 to 3 weeks) CBC during therapy
- Baseline and periodic chemistry panel as indicated during therapy

Client Information

- Follow your veterinarian's instructions for how to clean up the animal's environment to minimize the risk for reinfection.
- This medicine should be given with fatty foods or oils (eg, cheese, cream, butter, corn oil).
- Contact your veterinarian if your animal has a lack of appetite (eating less or not at all), vomiting, and/or diarrhea.
- Pregnant women should not handle this medicine, as it has caused birth defects in animals and may do so in humans.
- Your veterinarian will need to monitor your animal while it is taking this medicine. Do not miss these important follow-up visits.

Chemistry/Synonyms

A fungistatic antibiotic produced by species of penicillium (primarily *P griseofulvum*), griseofulvin occurs as an odorless or nearly odorless, bitter tasting, white to creamy white powder. It is very slightly soluble in water and sparingly soluble in alcohol.

Two forms of the drug are available commercially. Microsize griseofulvin contains particles with a predominant size of 4 micrometers in diameter, while the ultramicrosize form particle size averages less than 1 micron in diameter.

Griseofulvin may also be known as curling factor, griseofulvina, and griseofulvinum; many trade names are available.

Storage/Stability

Griseofulvin products should be stored at 20° to 25°C (68°F-77°F).[3] Griseofulvin suspension should be stored in tight, light-resistant containers. Microsize tablets and capsules should be stored in tight containers; the ultramicrosize tablets should be stored in well-closed containers.

Compatibility/Compounding Considerations

If obtaining compounded dosage forms, understand which form (microsize or ultramicrosize) of griseofulvin is being supplied and adjust dosage accordingly.

Dosage Forms/Regulatory Status

VETERINARY-LABELED PRODUCTS:

Griseofulvin (Microsize) Powder: 2.5 g griseofulvin in 15 g sachets; generic; (Rx). FDA-approved for use in horses not intended for food. Marketing status is unknown.

The FDA's Green Book still lists several other veterinary FDA-approved griseofulvin products, but it does not appear they are presently being marketed.

HUMAN-LABELED PRODUCTS:

Griseofulvin Microsize Tablets: 250 mg and 500 mg; generic; (Rx)

Griseofulvin Ultramicrosize Tablets: 125 mg and 250 mg; generic; (Rx)

Griseofulvin Microsize Oral Suspension: 125 mg/5 mL (25 mg/mL) in 120 mL bottles; generic; (Rx)

Guaifenesin, Intravenous

(gwye-***fen***-e-sin) *GG, Guailaxin®*

Parenteral Muscle Relaxant

Prescriber Highlights

- ► Used as adjunctive therapy for anesthesia in horses, camelids, and small ruminants
- ► No contraindications noted. Must be used with caution in induction protocols.
- ► Adverse effects include a mild hypotensive effect and thrombophlebitis; concentration-dependent hemolysis is possible.
- ► Availability is an issue; must be obtained from a compounding pharmacy.

Uses/Indications

In veterinary medicine, guaifenesin is used to induce muscle relaxation and as an adjunct to anesthesia for short procedures (30 to 60 minutes) in horses, camelids, and small ruminants. There are oral products containing guaifenesin that treat respiratory conditions in horses.

Pharmacology/Actions

Although the exact mechanism of action for the muscle relaxant effect is not known, it is believed that guaifenesin acts centrally by depressing or blocking nerve impulse transmission at the internuncial neuron level of the subcortical areas of the brain, brainstem, and spinal cord. It relaxes both the laryngeal and pharyngeal muscles, thus allowing easier intubation. Guaifenesin produces muscle relaxation but has no clinically relevant intrinsic analgesic effects.

After adequate sedation, guaifenesin combined with ketamine causes an excitement-free induction and recovery from anesthesia in horses. It produces relaxation of the skeletal muscles but does not affect diaphragmatic function and has little, if any, effect on respiratory function at commonly used dosages. Possible effects on the cardiovascular system include transient mild decreases in blood pressure without changes in heart rate. GI motility may be increased, but generally no issues are seen with this effect.

Guaifenesin can potentiate the activity of preanesthetic and anesthetic agents.

Pharmacokinetics

The pharmacokinetics of guaifenesin have not been thoroughly studied in most species. After oral administration to horses, peak concentrations were reached at 15 minutes, and elimination half-life averaged 2.6 hours. In 3 horses, guaifenesin was detectable in serum longer than 48 hours after the last dose.[1] After IV administration (≈130 mg/kg in donkeys and 210 mg/kg in horses), the volume of distribution was 678 mL/kg and 794 mL/kg, and the clearance was 546 mL/kg/hour and 313 mL/kg/hour in donkeys and horses, respectively.[2]

When guaifenesin is administered alone to horses IV, recumbency usually occurs within 2 minutes, and light (not surgical level) restraint persists for about 6 minutes. Muscle relaxation reportedly persists for 10 to 20 minutes after a single dose.

Guaifenesin is conjugated in the liver and excreted into the urine. A gender difference in the elimination half-life of guaifenesin in ponies has been demonstrated, with a half-life of ≈85 minutes in male ponies and a half-life of about 60 minutes in female ponies.[3] Guai-

fenesin reportedly crosses the placenta, but adverse effects in newborns of mothers who received guaifenesin have not been described.

Contraindications/Precautions/Warnings

When guaifenesin is used as part of an induction protocol in horses, appropriate numbers of personnel and equipment (eg, induction swing-gate) should be available. Muscle relaxation and ataxia can occur dramatically, and timing of the administration of a drug like ketamine is critical. These concerns have led some clinicians to NOT use guaifenesin as part of induction for field anesthesia.[4] Although guaifenesin has some sedative effects, it must be used intraoperatively with other suitable anesthetic and analgesic agents.

Because guaifenesin can cause significant tissue damage if given perivascularly, it should always be administered through an IV catheter.

Adverse Effects

At usual doses, adverse effects with guaifenesin are transient and generally minor. A mild decrease in blood pressure can be seen. Thrombophlebitis has been reported after IV injection; perivascular administration may cause tissue reaction. Hemolysis may occur in solutions containing greater than a 5% concentration of guaifenesin, although some sources state this is insignificant at even a 15% concentration.[4,5] Hemolysis may be more of an issue in ruminants than in horses.[6]

Reproductive/Nursing Safety

Guaifenesin crosses the placenta, with neonatal plasma guaifenesin concentration ≈30% that of maternal plasma.[7] It is not known whether guaifenesin is excreted in milk.

Because safety has not been established in animals, this drug should only be used when the maternal benefits outweigh the potential risks to offspring.

Overdose/Acute Toxicity

The margin of safety with guaifenesin is reportedly 3 times the usual dose. Clinical signs associated with toxic levels of parenteral guaifenesin include opisthotonus, apneustic breathing, nystagmus, hypotension, and contradictory muscle rigidity. If any of these signs occur, it is recommended to stop the infusion and give supportive care as needed.

No specific antidote is available. It is suggested that treatment be supportive until the drug is cleared to sub-toxic levels.

Drug Interactions

Drug interactions with parenteral guaifenesin are not well studied. The following drug interactions either have been reported or are theoretical in animals receiving guaifenesin and may be of significance in veterinary patients. Unless otherwise noted, use together is not necessarily contraindicated, but weigh the potential risks and perform additional monitoring when appropriate.

- **Physostigmine**: The veterinary label states that physostigmine is contraindicated in horses receiving guaifenesin but does not elucidate on the actual interaction. It may be logical to assume that other anticholinesterase agents (eg, **neostigmine**, **pyridostigmine**, **edrophonium**) may also be contraindicated; however, anecdotal reports suggest that concurrent use appears to be tolerated.

Dosages

NOTE: Various protocols combining guaifenesin with other drugs are too numerous to list in this reference. The following listings are examples for horses, small ruminants, and new world camelids. Additional protocols for other drug combinations and species can be found in other anesthesia references. Referring to these references or consulting with a veterinary anesthesiologist is highly recommended when considering using this agent as an anesthetic adjunct.

HORSES:

Part of induction protocols (extra-label): **NOTE**: Use with caution; this protocol is not recommended for field anesthesia without an IV catheter in place. The following is one example using xylazine as the alpha-2 agonist in the protocols. There are numerous others that use different alpha-2 agonists (eg, detomidine, romifidine), butorphanol, and/or acepromazine. See equine anesthesia references for additional information.[8]

a) For normal healthy animals: Premedicate with xylazine 0.44 – 0.66 mg/kg IV (or 200 – 300 mg/450 kg [992 lb] horse [NOT mg/kg]). Wait for sedation and muscle relaxation to occur (≈5 minutes), then rapidly infuse guaifenesin 5% solution (50 mg/mL) IV using pressurization until marked sedation and muscle relaxation is achieved, generally a total dose of 30 – 50 mg/kg. Administer ketamine 2.2 mg/kg IV (or 1000 mg/450 kg [992 lb] horse [NOT mg/kg]) at a point that allows for slow onset to occur without the animal becoming excessively weak and collapsing from the effects of guaifenesin. Recumbency generally occurs ≈45 to 60 seconds following ketamine administration. The slow administration of guaifenesin (described below) can also be used in normal healthy animals in place of a supplemental dose of xylazine when the level of initial sedation is inadequate.
