DEDICATION

A Tribute to Oscar Schalm

Oscar W. Schalm was born in 1909 and reared in Sturgis, Michigan. Upon graduation from Michigan State University, he entered the College of Veterinary Medicine at the urging of fellow students. He married Dorothy Burns, also of Sturgis, in 1930 and after attaining his DVM degree in 1932, he joined the Department of Veterinary Science at Berkeley, California as a research associate. He remained on the Berkeley campus until 1948, earning an M.S. in 1933 and Ph.D. in 1935. In 1948, he relocated to Davis, California, as the Department of Veterinary Medicine became the new School of Veterinary Medicine at the Davis campus.

Early in his career, Oscar established himself as a leader in bovine mastitis research, a subject he continued at Davis. At the founding of the School of Veterinary Medicine, Oscar was assigned the responsibility for clinical pathology, a most fortuitous choice for the field and generations of veterinary students. Oscar focused on the fledgling field of veterinary hematology. With his characteristic energy and productivity, within ten years he had written the first edition of the now classic *Veterinary Hematology*. The original and subsequent early editions represented compilations of materials that he had painstakingly collected and analyzed.

He became an authority in veterinary clinical hematology, and spread the gospel by a prodigious record of publications, national and international seminars, and through his classes at Davis to over 1500 veterinary students. He exemplified the teacher-researcher who can successfully share their expertise and motivate students. As evidence of his dedication to teaching and his students, he was selected three times to receive the School of Veterinary Medicine's Outstanding Teacher Award. He was listed in Educators of America in 1971 and 1973, and in 1973, he received the Davis Division of the Academic Senate's Outstanding Teaching Award.

Oscar's honors, awards, and prizes were many; some among them are the Borden Award in Veterinary Medicine (1964), the Gaines Award for Veterinarian of the Year (1965 and 1972), Alumni Award of Michigan State University (1969), and the Alumni Achievement Award of the School of Veterinary Medicine, University of California, Davis (1980). He was a Fulbright Scholar at the University of Munich in 1959, a visiting scholar and consultant to Israel in 1967, and was named Honorary Life Member of the Israeli Veterinary Medical Association in 1968.

Oscar Schalm retired in 1976, after 44 years of service to the university. He remained an active scholar, speaker, consultant, and contributor to prestigious journals throughout his retirement. At the time of his death, on September 15, 1982, a fourth edition of Schalm's Veterinary Hematology was in preparation. In recognition of Dr. Schalm's fundamental contributions to the field, all subsequent editions of this authoritative textbook have included his name in the title.

CONTENTS

Dedication v

Contributors xv

Preface xxv

Acknowledgments xxvii

SECTION I

Hemolymphatic Tissue 1

CHAPTER 1
Embryonic and Fetal Hematopoiesis 3
KELLI L. BOYD and BRAD BOLON

CHAPTER 2
Stem Cell Biology 9
DORI L. BORJESSON and JED A. OVERMANN

CHAPTER 3
Structure of the Bone Marrow 18
NICOLE I. STACY and JOHN W. HARVEY

CHAPTER 4
The Hematopoietic System 27
BRUCE D. CAR and DAVIS M. SEELIG

CHAPTER 5
Vasculogenesis and Endothelial Cell Production 37
JONG HYUK KIM

CHAPTER 6
Cluster of Differentiation (CD) Antigens 41
MELINDA J. WILKERSON and NORA L. SPRINGER

CHAPTER 7
Major Histocompatibility Complex Antigens 48
PAUL R. HESS

CHAPTER 8
Lymphocyte Biology and Functions 63
IAN TIZARD

CHAPTER 9
Structure and Function of Primary and Secondary Lymphoid Tissue 74
CLEVERSON D. SOUZA, MEREDETH McENTIRE, V.E. TED VALLI, and ROBERT M. JACOBS

SECTION II

Hematotoxicity 85

CHAPTER 10
Design and Methods of Nonclinical Hematotoxicity Studies 87
WILLIAM J. REAGAN and ARMANDO R. IRIZARRY ROVIRA

CHAPTER 11
Interpretation of Hematologic Data in Nonclinical Studies 93
JEFFREY McCARTNEY

CHAPTER 12
Nonclinical Evaluation of Compound-Related Cytopenias 100
LAURIE G. O'ROURKE

CHAPTER 13
Nonclinical Evaluation of Compound-Related Alterations in Hemostasis 108
F. POITOUT-BELISSENT

CHAPTER 14
Preclinical Evaluation of Immunotoxicity 116
KRISTIN L. HENSON

CHAPTER 15
Blood and Bone Marrow Toxicity Induced by Drugs, Heavy Metals, Chemicals, and Toxic Plants 122
DOUGLAS J. WEISS

CHAPTER 16
Acute Myelotoxicity and Myelitis in Domestic and Laboratory Animals 133
ADAM D. AULBACH and DOUGLAS J. WEISS

CHAPTER 17
Chronic Inflammation and Secondary Myelofibrosis in Domestic and Laboratory Animals 138
ADAM D. AULBACH and DOUGLAS J. WEISS

CHAPTER 18
Infectious Injury to Bone Marrow 144
K. JANE WARDROP

SECTION III
Erythrocytes 149

CHAPTER 19
Erythropoiesis 151
CHRISTINE SWARDSON OLVER

CHAPTER 20
Erythrocyte Structure and Function 158
CHRISTINE SWARDSON OLVER

CHAPTER 21
Erythrocyte Biochemistry 166
JOHN W. HARVEY

CHAPTER 22
Erythrokinetics and Erythrocyte Destruction 172
ANDREA PIRES DOS SANTOS, and JOHN A. CHRISTIAN

CHAPTER 23
Reticulocyte and Heinz Body Staining and Enumeration 181
HAROLD TVEDTEN and ANDREAS MORITZ

CHAPTER 24
Erythrocyte Morphology 188
ANNE M. BARGER

CHAPTER 25
Classification and Laboratory Evaluation of Anemia 198
HAROLD TVEDTEN

CHAPTER 26
Erythrocytosis 209
JOHN F. RANDOLPH, MARK E. PETERSON, and ERICA BEHLING-KELLY

CHAPTER 27
Iron and Copper Deficiencies, and Disorders of Iron Metabolism 215
LAUREN B. RADAKOVICH and CHRISTINE SWARDSON OLVER

CHAPTER 28
The Porphyrias—Disorders of Defective Heme Synthesis 221
ANDREA A. BOHN

CHAPTER 29
Hereditary Erythroenzymopathies 229
URS GIGER

CHAPTER 30
Erythrocyte Membrane Defects 238
MUTSUMI INABA and JOANNE B. MESSICK

CHAPTER 31
Congenital Dyserythropoiesis 248
DOUGLAS J. WEISS

CHAPTER 32
Anemia Associated with Oxidative Injury 252
ERICA BEHLING-KELLY and ASHLEIGH NEWMAN

CHAPTER 33
Anemia Caused by Rickettsia, Mycoplasma, and Protozoa 260
SUSAN FIELDER, ROBIN W. ALLISON, and JAMES H. MEINKOTH

CHAPTER 34
Anemia Associated with Bacterial and Viral Infections 273
GEORGE M. BARRINGTON and DEBRA C. SELLON

CHAPTER 35
Immune-Mediated Anemia in the Dog 278
JILLIAN M. HAINES, ANDREW MACKIN, and MICHAEL J. DAY

CHAPTER 36
Immune-Mediated Anemia in the Cat 292
ASHLEIGH NEWMAN and TRACY STOKOL

CHAPTER 37
Immune-Mediated Anemia in Ruminants and Horses 300
JENIFER R. GOLD

CHAPTER 38
Precursor-Targeted Immune-Mediated Anemia and Pure Red Cell Aplasia in Dogs and Cats 307
CYNTHIA A. LUCIDI

CHAPTER 39
Anemia of Inflammatory, Neoplastic, Renal, and Endocrine Diseases 313
AGATA K. GRZELAK and MICHAEL M. FRY

CHAPTER 40
Aplastic Anemia 318
JENNIFER L. BRAZZELL and DOUGLAS J. WEISS

SECTION IV
Leukocytes 323

CHAPTER 41
Granulopoiesis 325
M. JUDITH RADIN and MAXEY L. WELLMAN

CHAPTER 42
Neutrophil Structure and Biochemistry 333
CLAIRE B. ANDREASEN

CHAPTER 43
Neutrophil Function and Response 339
DANA N. LEVINE and CLAIRE B. ANDREASEN

CHAPTER 44
Neutrophil Function Disorders 347
STEFANO COMAZZI, LUCA ARESU, and DOUGLAS J. WEISS

CHAPTER 45
Clinical Evaluation of Neutrophil Function 354
STEFANO COMAZZI

CHAPTER 46
Eosinophils and Their Disorders 363
KAREN M. YOUNG and ELIZABETH A. LAYNE

CHAPTER 47
Basophils, Mast Cells, and Their Disorders 373
BRANDY C. KASTL and LISA M. POHLMAN

CHAPTER 48
Monocytes, Macrophages, and Dendritic Cell Production 381
CLEVERSON D. SOUZA and DOUGLAS J. WEISS

CHAPTER 49
Monocytes and Macrophages and Their Disorders 386
CLEVERSON D. SOUZA and MEAGHAN V. EREN

CHAPTER 50
Lymphocyte Ontogeny and Lymphopoiesis 395
AMY L. WARREN and ROBIN M. YATES

CHAPTER 51
Structure, Function, and Disorders of Lymphoid Tissue 402
AMY L. WARREN and ROBIN M. YATES

CHAPTER 52
Systemic Lupus Erythematosus 414
LUC CHABANNE

CHAPTER 53
Feline Immunodeficiency Virus 424
MARGARET J. HOSIE and HANS LUTZ

CHAPTER 54
T Cell, Immunoglobulin, and Complement Immunodeficiency Disorders 431
PETER J. FELSBURG

CHAPTER 55
Severe Combined Immunodeficiencies 436
STEVEN E. SUTER

CHAPTER 56
Lymphadenopathy Not Caused by Lymphoma 442
HAROLD TVEDTEN

SECTION V
Hematologic Neoplasia.....449

CHAPTER 57
Cell-Cycle Control in Hematopoietic Cells 451
JAIME F. MODIANO and CATHERINE A. ST. HILL

CHAPTER 58
Epidemiology of Hematopoietic Neoplasia 457
MICHELLE G. RITT

CHAPTER 59
Genetics of Hematopoietic Neoplasia 463
DIANA GIANNUZZI, JAIME F. MODIANO, and MATTHEW BREEN

CHAPTER 60
Transforming Retroviruses 471
MARY JO BURKHARD

CHAPTER 61
Cytochemical Staining and Immunocytochemistry 478
ROSE E. RASKIN, KELLY SANTANGELO, and KLAUDIA POLAK

CHAPTER 62
Determination of Clonality 500
YUKO GOTO-KOSHINO and HAJIME TSUJIMOTO

CHAPTER 63
Immunophenotyping 508
AUSTIN K. VIALL

CHAPTER 64
Flow Cytometry in Hematologic Neoplasia 515
JAIME L. TARIGO, DAVIS M. SEELIG, and ANNE C. AVERY

CHAPTER 65
Classification and General Features of Lymphoma and Leukemia 528
BARBARA C. RÜTGEN and JENNIFER BOUSCHOR

CHAPTER 66
Myeloproliferative Neoplasms 538
ERIC J. FISH

CHAPTER 67
Myelodysplastic Syndromes 548
DOUGLAS J. WEISS and RANCE K. SELLON

CHAPTER 68
Acute Myeloid Leukemia 557
TRACY STOKOL

CHAPTER 69
B-Cell Tumors 570
LUCA ARESU, STEFANO COMAZZI, LAURA MARCONATO, and FRANCESCO BERTONI

CHAPTER 70
Plasma Cell Tumors 588
ANTONELLA BORGATTI

CHAPTER 71
Hodgkin and Hodgkin-Like Lymphoma 599
DANIEL A. HEINRICH and ERIN N. BURTON

CHAPTER 72
T-Cell Tumors 605
NARIMAN DERAVI, STEFAN KELLER, and DOROTHEE BIENZLE

CHAPTER 73
Mast Cell Neoplasia 626
MELINDA S. CAMUS

CHAPTER 74
Histiocytic Proliferative Diseases of Dogs and Cats 633
PETER F. MOORE

SECTION VI
Platelets 649

CHAPTER 75
Thrombopoiesis 651
MARY K. BOUDREAUX and PETE W. CHRISTOPHERSON

CHAPTER 76
Platelet Structure 658
MARY K. BOUDREAUX and PETE W. CHRISTOPHERSON

CHAPTER 77
Platelet Signal Transduction and Activation Response 667
PETE W. CHRISTOPHERSON and MARY K. BOUDREAUX

CHAPTER 78
Platelet Kinetics and Laboratory Evaluation of Thrombocytopenia 675
ADI WASSERKRUG-NAOR

CHAPTER 79
Evaluation of Platelet Function 686
PETE W. CHRISTOPHERSON and MARJORY B. BROOKS

CHAPTER 80
Immune Thrombocytopenia 696
DANA N. LeVINE and MARJORY B. BROOKS

CHAPTER 81
Nonimmune-Mediated Thrombocytopenia 709
JULIE ALLEN

CHAPTER 82
Thrombocytosis and Essential Thrombocythemia 721
JULIE ALLEN and TRACY STOKOL

CHAPTER 83
von Willebrand Disease 731
MARJORY B. BROOKS and JAMES L. CATALFAMO

CHAPTER 84
Inherited Platelet Disorders 739
MARY K. BOUDREAUX and PETE W. CHRISTOPHERSON

CHAPTER 85
Acquired Platelet Dysfunction 747
BENJAMIN M. BRAINARD

CHAPTER 86
Treatment of Disorders of Platelet Number and Function 755
MARY BETH CALLAN

SECTION VII
Hemostasis 763

CHAPTER 87
Overview of Hemostasis 765
MAUREEN A. McMICHAEL

CHAPTER 88
Laboratory Testing of Coagulation Disorders 787
MARJORY B. BROOKS

CHAPTER 89
Acquired Coagulopathies 804
MARJORY B. BROOKS and ARMELLE DE LAFORCADE

CHAPTER 90
Hereditary Coagulopathies 812
MARJORY B. BROOKS

CHAPTER 91
Thrombotic Disorders 821
ERICA BEHLING-KELLY and ROBERT GOGGS

CHAPTER 92
Disseminated Intravascular Coagulation 837
TRACY STOKOL

CHAPTER 93
Vascular Diseases 848
SEAN P. McDONOUGH

CHAPTER 94
Treatment of Hemostatic Defects 855
ROBERT GOGGS and ALEX M. LYNCH

CHAPTER 95
Avian Hemostasis 865
KAREN E. RUSSELL and J. JILL HEATLEY

SECTION VIII
Transfusion Medicine 875

CHAPTER 96
Erythrocyte Antigens and Blood Groups 877
MARIE-CLAUDE BLAIS and MARIA CECILIA T. PENEDO

CHAPTER 97
Granulocyte and Platelet Antigens 891
JENNIFER S. THOMAS

CHAPTER 98
Principles of Canine and Feline Blood Collection, Processing, and Storage 898
ANTHONY C. G. ABRAMS-OGG and SHAUNA L. BLOIS

CHAPTER 99
Red Blood Cell Transfusion in the Dog and Cat 908
MARY BETH CALLAN

CHAPTER 100
Transfusion of Plasma Products 914
MARJORY B. BROOKS

CHAPTER 101
Platelet and Granulocyte Transfusion 921
ANTHONY C. G. ABRAMS-OGG, and SHAUNA L. BLOIS

CHAPTER 102
Blood Transfusion in Large Animals 927
MARGARET C. MUDGE

CHAPTER 103
Blood Transfusion in Exotic Species 933
ANNELIESE STRUNK and ANKE C. STÖHR

CHAPTER 104
Transfusion Reactions 940
NICOLE M. WEINSTEIN

CHAPTER 105
Cellular Therapy 948
STEVEN E. SUTER and STEVEN DOW

CHAPTER 106
Clinical Use of Hematopoietic Growth Factors 957
STEVEN E. SUTER

CHAPTER 107
Clinical Blood Typing and Crossmatching 964
K. JANE WARDROP

SECTION IX
Species-Specific Hematology 969

CHAPTER 108
Hematology of Dogs 971
MAGGIE R. McCOURT and THERESA E. RIZZI

CHAPTER 109
Hematology of Cats 983
DEANNA M. W. SCHAEFER

CHAPTER 110
Hematology of Equids 993
KATHLEEN P. FREEMAN, ALISON J. FARR, and ANNALISA BARRELET

CHAPTER 111
Hematology of Bovids 1004
R. DARREN WOOD

CHAPTER 112
Hematology of Sheep and Goats 1012
JASON STAYT

CHAPTER 113
Hematology of Pigs 1019
CATHERINE E. THORN, ANDREW S. BOWMAN, and DAVID ECKERSALL

CHAPTER 114
Hematology of Rodentia 1026
AMY L. MacNEILL

CHAPTER 115
Hematology of Mustelids 1034
STACY CLOTHIER and CATHY JOHNSON-DELANEY

CHAPTER 116
Hematology of Cavies 1043
SAMANTHA J. M. EVANS and KURT L. ZIMMERMAN

CHAPTER 117
Hematology of Lagomorphs 1050
FRANCISCO O. CONRADO

CHAPTER 118
Hematology of Laboratory Animals 1058
KARYN E. ENOS and DAVID M. MOORE

CHAPTER 119
Hematology of Camelids 1073
SUSAN J. TORNQUIST

CHAPTER 120
Hematology of Cervids 1079
BRIDGET C. GARNER

CHAPTER 121
Hematology of Paenungulata: Elephants, Sirenians, and Hyraxes 1090
EMMA H. HOOIJBERG

CHAPTER 122
Hematology of Marine Mammals 1104
NICOLE I. STACY and HENDRIK H. NOLLENS

CHAPTER 123
Hematology of Galliformes 1114
JULIE PICCIONE and JESSICA HOKAMP

CHAPTER 124
Hematology of Psittacines 1127
DIANA SCHWARTZ and HUGUES BEAUFRÈRE

CHAPTER 125
Hematology of Anseriformes 1140
JESSICA HOKAMP and JULIE PICCIONE

CHAPTER 126
Hematology of Raptors 1148
JENNIFER JOHNS

CHAPTER 127
Hematology of Ratites 1159
PHILLIP CLARK

CHAPTER 128
Hematology of Elasmobranchs 1166
JILL E. ARNOLD and ALEXA DELAUNE

CHAPTER 129
Hematology of Salmonids 1176
JERE STERN

CHAPTER 130
Hematology of Ictaluridae 1182
PATRICIA GAUNT

CHAPTER 131
Hematology of Cyprinidae 1188
ILZE K. BERZINS and ALEXANDER E. PRIMUS

CHAPTER 132
Hematology of Lizards, Crocodilians, and Tuatara 1197
CHARLOTTE HOLLINGER and JEAN A. PARÉ

CHAPTER 133
Hematology of Serpentes 1209
LAURA J. BLACK and MARJORIE BERCIER

CHAPTER 134
Hematology of Testudines 1219
JENNIFER D. STEINBERG and STEPHEN J. DIVERS

CHAPTER 135
Hematology of Amphibians 1228
PERRY BAIN and KENDAL E. HARR

CHAPTER 136
Hematology of Invertebrates 1233
JILL E. ARNOLD

SECTION X
Quality Management and Laboratory Techniques....1241

CHAPTER 137
Quality Management of Hematology Techniques 1243
MARTINA STIRN and KATHLEEN P. FREEMAN

CHAPTER 138
Total Error and Proficiency Testing 1255
STEN WESTGARD and KATHLEEN P. FREEMAN

CHAPTER 139
Quantitative Diagnostic Test Validation 1263
BENTE FLATLAND

CHAPTER 140
Reference Intervals and Decision Limits 1273
KRISTEN R. FRIEDRICHS, ASGER LUNDORFF JENSEN, and MADS KJELGAARD-HANSEN

CHAPTER 141
Bone Marrow Evaluation 1285
NATALI B. BAUER and KENDAL E. HARR

CHAPTER 142
Flow Cytometry 1295
UNITY JEFFERY

CHAPTER 143
Testing for Immune-Mediated Hematologic Disease 1311
K. JANE WARDROP, MELINDA J. WILKERSON, and CINZIA MASTRORILLI

CHAPTER 144
Electrophoresis and Acute-Phase Proteins 1320
ALESSIA GIORDANO

CHAPTER 145
Molecular Diagnostic Techniques 1331
ROBERT J. OSSIBOFF

CHAPTER 146
Genetic Evaluation of Inherited Hematologic Diseases 1337
NOA SAFRA and DANIKA BANNASCH

PREFACE

Veterinary clinical pathology has changed considerably since publication of the 6th edition of *Schalm's Veterinary Hematology*. No longer the practitioners of a discipline that deals primarily with the clinical evaluation of dog and cat samples, clinical pathologists are now called on to use their diagnostic skills for a broad variety of animal species. Current specialty areas encompass diverse fields such as pharmaceutical compound and device development and the management of zoo and free-range wildlife. Beyond nontraditional species, clinical pathologists have broadened the scope of their diagnostic expertise to incorporate genomics, proteomics, and metabolomics, and use novel assay platforms such as expression arrays, microfluidic devices, and multiplex immunoassays. Significant advances have also been made in more traditional techniques including flow cytometry, blood typing serology, and platelet function testing.

We have assembled a team of editors capable of covering this exceptional diversity in species and subject areas that now comprise the field of clinical pathology. Dr. Marjory Brooks' career has focused on comparative hemostasis and the development of translational biomarkers for preclinical and diagnostic applications. Dr. Kendal Harr provides expertise in nondomestic species and has devoted the past 15 years to making ASVCP's quality assurance guidelines more robust. Dr. Davis Seelig provides expertise in basic molecular biology, research techniques, and in hematopoietic neoplasia. Dr. Jane Wardrop has expertise in hematological disorders and transfusion medicine. Dr. Douglas Weiss has expertise in bone marrow disorders, infectious disease, and molecular biology.

Specific changes in this edition include a new section titled "Hemolymphatic Tissue" for detailed coverage of basic pathophysiology and disease mechanisms, expanded "Species-Specific Hematology" and "Hematotoxicity" sections, and more in-depth molecular and genetics content. Additionally, we have extensively revised and rearranged chapters to address emerging topics and to provide a more logical sequence for the material. With recognition of the hard work of our contributing authors, we are proud to provide the reader with a comprehensive, coherent, and state of the art presentation of topics in clinical pathology.

ACKNOWLEDGMENTS

To the teachers and mentors, who set me on the path of discovery, and to the students, clinicians, and colleagues, who continually bring new insights and challenges to the journey.

Marjory Brooks

I would like to express my gratitude to my whole family for their support and patience during the time it has taken to construct this tome. Especially my husband, Bob, who thankfully has fabulous cooking skills (among others) and my daughters, Lily and Maeve, who have, since the start of this work, matured to wonderful, fascinating adults. And, of course, my mom whose voice I still hear and provides guidance to this day. I also appreciate my co-editors, who have helped me become a better editor, reviewer, and author, especially Dr. K. Jane Wardrop.

Kendal E. Harr

To Catherine and Angela, who (in their own unique ways) provided much needed emotional support and relief. To my coworkers and resident trainees, who tolerated the many mornings and afternoons in which I was squirreled away in my office.

Davis Seelig

To my family for their continued support, and to my colleagues around the world, who contributed to the making of this edition. Your work inspires me to be a better author, researcher, teacher, and person.

K. Jane Wardrop

To my parents (Bud and Dorothy) for their strength, moral guidance, and work ethic, my family (Jane, Matthew, Kal) for their love and support, which was essential to my career as well as my well-being, and to Barb for partnering with me in undertaking a whole new vision of how to live in harmony with the earth and all living things.

Douglas J. Weiss (FF)

SECTION I
Hemolymphatic Tissue

CHAPTER 1

Embryonic and Fetal Hematopoiesis

KELLI L. BOYD and BRAD BOLON

Basic Principles of Hematopoietic Development
  Cell Structure and Function
Primitive Hematopoiesis
  Erythroid Cells
  Other Cells
Definitive Hematopoiesis
Hemoglobin Switching
Molecular Mechanisms Regulating Hematopoietic Development

Acronyms and Abbreviations

AGM, aorta-gonad-mesonephros; Bmp, bone morphogenetic protein; 2,3-DPG, 2,3-diphosphoglycerate; E#, day of embryonic development, where the number indicates age of the embryo in days after conception; EPO, erythropoietin; fL, femtoliter; Gata-1, -2, and -4, GATA-binding proteins 1, 2, and 4; HSC, hematopoietic stem cell; Ihh, Indian hedgehog; IL, interleukin; NK, natural killer; P#, day of postnatal development, where the number indicates age of the neonate in days after delivery; pg, picogram; PU.1, purine box-binding transcription factor 1; Scl/Tal-1, stem cell leukemia/T-cell acute leukemia factor 1.

The complexities of hematopoietic system development have been highly conserved throughout vertebrate evolution. Understanding the embryonic and fetal origins of hematopoiesis provides important insights regarding the function of the adult hematopoietic system. Hematopoiesis in embryonic and fetal animals has been studied intensively for several decades as a model for hematopoietic progression in humans. Recent technical advances have allowed researchers to characterize the spatial and temporal relationships as well as the cellular and molecular mechanisms of hematopoietic development.

This chapter reviews the basic biology of hematopoietic development in the mouse (*Mus musculus*). This appraisal will emphasize hematopoietic events during the embryonic and fetal stages of development, but also will cover selected features of neonatal hematopoiesis.

BASIC PRINCIPLES OF HEMATOPOIETIC DEVELOPMENT

Cell Structure and Function

Blood cells produced at different stages of development differ in morphology and function. Thus, primitive ("fetal") cells fabricated early in gestation have markedly different properties from their definitive ("adult") counterparts produced during late gestation and in postnatal life. This principle has been characterized most completely in erythroid lineage cells. Primitive erythrocytes (RBCs) are formed in the yolk sac, whereas definitive RBCs are produced by the liver and later spleen and bone marrow. Primitive RBCs are nucleated in circulation until approximately day 12.5 (E12.5) of gestation, after which nuclei gradually become condensed before being shed between E14.5 and E16.5.[35]

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

Enucleated primitive RBCs retain their large size and can remain in circulation until as late as postnatal day 5 (P5). Both primitive and definitive RBCs are released during most of the latter half of gestation (E10–E18), although the ratio shifts as time progresses from mainly primitive to mainly definitive RBCs.

Primitive and definitive RBCs can be distinguished by their size. The volume of primitive RBCs varies from 465 to 530 femtoliters (fL), which is approximately six times larger than that of definitive RBCs.[35] The hemoglobin content of primitive RBCs, 80–100 picograms (pg)/cell, also is nearly six times the amount found in definitive RBCs.[35] Both primitive and definitive RBCs have basophilic cytoplasm when first produced due to abundant rough endoplasmic reticulum, but basophilia recedes as maximal hemoglobin content is achieved.

Other hematopoietic lineages also differ in cell structure and function during the course of development. Primitive megakaryocytes from the yolk sac contain fewer nuclei of lower ploidy, are about half the size, and respond differently to cytokine stimulation relative to definitive megakaryocytes.[47] Primitive macrophages that originate in the yolk sac[42] lack certain enzyme activities, are capable of division, and survive for extended periods compared to definitive monocyte-derived macrophages. These functional differences are related to the roles that the two cell populations appear to play. Primitive macrophages are the source for many tissue macrophages in embryonic through juvenile stages of development, whereas definitive macrophages are the source for circulating monocytes and resident macrophages characteristic of the adult immune system.

PRIMITIVE HEMATOPOIESIS

The processes that drive primitive and definitive stages of hematopoiesis as well as the events that regulate transition between the two stages are mediated by a constellation of factors.[1,30,45,46] Cell adhesion factors, growth factors, and transcription factors that participate in this process often support differentiation of multiple hematopoietic cell types,[10,29,36] and the dependence of a given cell lineage on any particular molecule may differ between primitive and definitive hematopoiesis.

Erythroid Cells

Hematopoiesis occurs at multiple sites within the embryo and in extraembryonic tissues. The first phase of blood cell production, referred to as primitive hematopoiesis, is responsible for producing blood elements during the earliest stage of embryogenesis. Primitive hematopoiesis takes place in the visceral yolk sac beginning at approximately E7.[15,34] Thus, primitive hematopoietic cells are among the earliest distinct tissues to differentiate in the embryo. Formation of primitive cells declines rapidly after E11. The visceral yolk sac or extraembryonic splanchnopleure (the term for a structure in which mesoderm and endoderm are directly apposed) arises from the migration of extraembryonic mesoderm streaming from the caudal primitive streak along the inner surface of the visceral endoderm. The mesodermal cells committed to initiate and support hematopoiesis have been termed hemangioblasts because the contiguity of primitive hematopoiesis and vasculogenesis in both space and time suggests that primitive hematopoietic and endothelial cells in the yolk sac share a common ancestor.[1,9] Hemangioblasts arise as undifferentiated cells at the primitive-streak stage and commit to producing a particular cell lineage before blood island formation.[34,44] These pluripotent cells also can differentiate into other mesenchyme-derived tissues.

Between E7.5 and E9, hemangioblasts form multiple aggregates termed blood islands.[35] Each blood island contains a central core of unattached inner hemangioblasts (hematopoietic progenitors) surrounded by a rim of spindle-shaped outer hemangioblasts (endothelial progenitors).[15] Nucleated erythroid cells are first recognized in the cores of the blood islands at E8 and are evident circulating in the cardiovascular system starting at E8.25.[18] At this stage embryonic erythroblasts enter the circulation, where they continue to divide until approximately E13.

The majority of cells produced during primitive hematopoiesis are of the erythroid lineage. Committed erythroid colony-forming cells arrive in the yolk sac at approximately E7.25. These cells expand until E8 and then differentiate into primitive erythroblasts; all colony-forming cells have regressed completely by E9,[34] which corresponds approximately to the earliest phase of definitive erythropoiesis. Primitive erythroblasts serve as the sole source of RBCs in the early embryo from E8 to approximately E10.5[34] and remain an important source of RBCs until E13. Thus, embryos with a developmental age between E8 and E11 that are anemic suffer from a defect in primitive erythropoiesis.[26,38] Interestingly, seemingly profound defects in primitive hematopoiesis leading to persistent functional defects in adulthood may not elicit an aberrant hematologic profile in the embryo.

Other Cells

Recent studies suggest that other hematopoietic cell lineages also are generated in the yolk sac during this primitive stage of hematopoietic development. Primitive lymphoid precursors and even some adult stem cells evolve at E7.5 and subsequently seed other sites of hematopoiesis, including the aorta-gonad-mesonephros (AGM) region, umbilical vessels, and liver.[40] Primitive macrophages have been identified in the yolk sac by E8[4]–E9.[34] In vitro experiments have demonstrated that E7.5 yolk sac cells can give rise to functional megakaryocytic precursors by E10.5.[47] Many hemangioblasts actually serve as bipotent or oligopotent progenitors, including those capable of commitment to erythrocytic/myeloid,[4] erythrocytic/megakaryocytic,[27] granulocyte/macrophage,[34] and lymphoid (B cell and T cell)/myeloid

lineages. Stem cells for mast cells have also been reported to arise in the yolk sac during primitive hematopoiesis.[34]

DEFINITIVE HEMATOPOIESIS

The second stage of blood cell production, termed *definitive hematopoiesis*, is thought to arise primarily from the AGM.[3,27] The AGM is an amorphous band of intraembryonic splanchnopleure that encompasses the dorsomedial wall of the abdominal cavity. The AGM domain is the main source of mesenchyme-derived, definitive hematopoietic stem cells (HSCs) that will serve the developing animal during late gestation and postnatal life. Initiation of definitive hematopoiesis ranges between E8.5 and E9.25, with definitive HSCs evident in the AGM by no later than E10. Peak production of HSCs in the AGM occurs between E10.5 and E11.5, at which time they comprise almost 10% of all AGM cells. Although controversial, some AGM-independent HSCs may also arise from the allantois, chorion, definitive placenta, umbilical arteries, and yolk sac. The actual contribution of these secondary sites to the overall HSC population has yet to be defined. However, the placenta appears to serve a particularly important role. The yolk sac also appears to be an essential secondary site because it is a source of multiple progenitor cell lineages and remains for at least a day after the AGM has halted HSC production.[28]

Regardless of their original site of de novo synthesis, HSCs migrate to seed other locations that support definitive hematopoiesis: embryonic liver, followed by embryonic thymus, fetal spleen, and bone marrow (in that order). These latter destinations do not produce HSCs de novo, but rather contain niches suitable for expansion of newly arrived HSCs.[33] The suitability of such niches is controlled by specific characteristics of their stromal support cells.[33] The embryonic liver is colonized first, apparently because it shares many molecular and functional similarities with the yolk sac.[31] It provides the major locus for definitive hematopoiesis from E12 to E16.[39] The HSCs enter the embryonic liver in several succeeding waves between E9/E10 and E12.[12] The first HSCs to enter the liver are pluripotent and can form any type of hematopoietic cell. Their first step in intrahepatic maturation is to commit to a more limited range of lineage options, typically as either an erythromyeloid progenitor or a common myelolymphoid progenitor.[22] Definitive erythroid precursors mature and become enucleated within erythroid islands in the liver before entering the circulation.[27] Liver-derived myelolymphoid progenitors subsequently develop into bipotent cells (B cell and myeloid, or T cell and myeloid) before committing to produce a single-cell lineage.[22] Some T-cell progenitors have a bipotent commitment to natural killer (NK) cell lineage. T-cell precursors destined for transfer to the embryonic thymus are produced even in athymic mice, indicating that the fetal liver may play a role in promoting early T-cell differentiation.[20,21]

Embryonic thymus and fetal spleen are seeded either from the liver or AGM, or both, beginning about E13 for thymus and E15 for spleen. The thymus typically accepts only those HSCs that are committed to make T cells, whereas other multipotent myelolymphoid elements are directed to other sites.[20] The number of T-cell precursors in liver is abundant at E12, but decreases thereafter, whereas the population of intrahepatic B-cell progenitors exhibits a reverse trend.[19] Most types of definitive hematopoietic cells in the spleen arise from precursor cells that commit to a specific lineage before leaving the liver. Multipotent HSCs entering the spleen cease proliferating and differentiate into mature macrophages. These cells may regulate intrasplenic erythropoiesis.

The bone marrow first receives HSCs from hepatic depots at about E16.[39,45] Thereafter, the allocation of colony-forming hematopoietic precursors shifts from a primarily hepatocentric localization at E18 through a more dispersed distribution (bone marrow, liver, and spleen in approximately equal numbers) at P2 to a profile-favoring bone marrow and to a lesser-extent spleen at P4 and after.[49] Thus, the bone marrow, liver, and spleen function cooperatively to regulate definitive hematopoiesis. While cooperating, each organ supports a molecularly distinct subset of hematopoietic progenitors.

Committed hematopoietic progenitors necessary to foster all lineages observed in adult animals arise during definitive hematopoiesis. The AGM-derived HSCs contribute to all major hematopoietic cell lineages. The HSC population from the placenta reportedly supports the genesis of erythroid, lymphoid (both B-cell and T-cell lineages), and myeloid elements. By comparison, the lineages sustained by yolk-sac-derived HSCs are limited to lymphoid and myeloid cells.[40] Whether or not progenitors for a given definitive cell lineage arising from distinct HSC populations exhibit different functional and molecular properties during late fetal and/or postnatal life has yet to be determined.

Late-stage embryos (E13–E15), fetuses (E16 to birth), and neonates which present with anemia are afflicted with a defect in definitive erythropoiesis. Abnormalities associated with this presentation include the total absence of definitive hematopoiesis,[25,41] and an inability of progenitor cells to properly colonize intraembryonic sites of hematopoiesis. Multiple cell lineages may be affected; such a combined effect suggests that the hematopoietic defect occurs in a bipotent or multipotent stem cell rather than in one committed to forming a specific cell lineage.[43] Presentation with late-stage anemia also might result from a general delay in growth and development rather than a focused anomaly in the erythrocytic lineage.[7]

Young animals have circulating blood cell numbers that are different from that of adults.[39] RBC numbers are more than double between birth and young adulthood. Circulating leukocyte counts at birth are approximately 20% of adult levels before increasing to adult numbers by 6–7 weeks of age. Platelet counts in neonates are approximately one-third numbers.

HEMOGLOBIN SWITCHING

Primitive and definitive RBCs bear a battery of seven α- and β-globins, the mix of which varies with the developmental stage. The α-globins are encoded by three genes (ζ, α_1, and α_2), whereas β-globins are encoded by four main genes (εγ, βH1, β*min*, and β*maj*). The globins of a given type (e.g., α- or β-globins) typically exist as a series of closely linked homologous genes and related pseudogenes located on the same chromosome;[16,24] mouse globin genes are carried on chromosomes 7 (β-globins) and 11 (α-globins). All seven mouse globin genes are transcribed during erythroid development, but the production of three—ζ, εγ, and βH1—is limited to primitive RBCs.[23] A consequence of this limitation is that mouse β-globin genes, although closely related to human globins in most respects, do not follow the human pattern of upregulation in the sequence of their chromosomal arrangement.[23,24]

The extent of individual globin gene expression and the blend of globin genes that are expressed vary over time. For example, enucleated primitive RBCs contain relatively more β*min* than do definitive RBCs. At E11.5, β*min* constitutes approximately 80% of the β-globin in circulation. This level is reduced by approximately 60% at birth. Primitive RBCs express increasing levels of adult globins as gestation progresses, whereas definitive RBCs harbor only the adult protein variants. This evolution indicates that the pattern of globin expression switches as the primitive RBCs are replaced by definitive RBCs. Molecular mechanisms which regulate the switching process are complex.[17] The timing of this switch, between E10.5 and E12.5, coincides with the initial escalation in definitive erythropoiesis. Perturbed timing of this switch is a feature of some murine models of hematopoietic disease.[6]

Successful maintenance of the developing conceptus depends on preferential capture of oxygen in embryonic and fetal tissues. Therefore, primitive RBCs generally have a higher affinity for oxygen than do maternal RBCs, although domestic cats are an exception. This sequestration of oxygen is mediated by two primary mechanisms. The mechanism pertinent to the early embryonic period is the greater affinity of embryonic hemoglobin in primitive RBCs for oxygen relative to that of adult hemoglobin.[2] Alternatively, definitive RBCs in the late embryo and fetus possess a lower concentration of 2,3-diphosphoglycerate (2,3-DPG) than do maternal RBCs. Higher levels of 2,3-DPG facilitate oxygen release into tissues. After birth, levels 2,3-DPG content of RBCs rise to adult levels within 10–15 days.

MOLECULAR MECHANISMS REGULATING HEMATOPOIETIC DEVELOPMENT

A wide spectrum of growth factors, hormones, and transcription factors are required to specify the various stages of hematopoietic development in mammals. The entire meshwork responsible for directing any given event has not been completely characterized. Shifting levels of several transcription factors have been shown to modify blood cell production. Insufficiencies in many of these molecules act by forestalling primitive hematopoiesis in the yolk sac. For example, genesis of erythroid precursors is impacted by deficits in GATA-binding protein 1 (Gata-1),[13] shown in vivo to prevent erythroid maturation; Gata-2,[48] demonstrated in vivo to abort precursor expansion; and Gata-4,[5] for which an in vitro shortage thwarts hemangioblast-mediated specification of blood islands and their associated vessels. These effects occur because the GATA consensus elements are critical regulatory regions in many erythroid-specific genes. All cell lineages are affected by stem cell leukemia/T-cell acute leukemia factor 1 (Scl/Tal-1).[38] Abnormal levels of transcription factors can also act later in gestation to disrupt definitive hematopoiesis. For example, purine box-binding transcription factor 1 (PU.1) is required for production of definitive (monocyte-derived) macrophages, but not their primitive (yolk-sac-derived) counterparts. This disparity in response is intriguing in that PU.1 is highly expressed during early hematopoiesis, but fluctuates in various cell lineages as time progresses.[10] Normal genesis of many progenitor cells, including bipotent erythroid/megakaryocytic progenitors as well as B-cell and T-cell progenitors, requires that PU.1 levels be reduced, whereas production of myeloid progenitors necessitates an increase in PU.1.[10]

Secreted molecules also are important regulators of hematopoietic development during gestation. For example, erythropoietin (EPO) sustains both primitive and definitive erythropoiesis by stimulating proliferation and differentiation of immature primitive and definitive RBCs.[25] Reduction in EPO activity within the yolk sac greatly reduces the number of colony-forming cells and erythroblasts via excessive apoptosis. Thrombopoietin fulfills a similar function for megakaryocytes, although other cytokines (interleukin-3 [IL-3], IL-6) and growth factors (granulocyte-colony stimulating factor, stem cell factor) also are required.[47] Other ligand/receptor signaling pathways shown to affect hematopoietic development include the endoderm-derived molecule Indian hedgehog (Ihh)[8] and bone morphogenetic protein 4 (Bmp4),[11] both of which participate in blood island production and vasculogenesis in the yolk sac. In general, secreted molecules act via their interaction with a specific transcription factor.

Cell adhesion molecules of the integrin family are essential for the proper migration of hematopoietic precursors. For instance, β_1-integrins are essential if HSC are to reach the embryonic liver, and later the fetal spleen and bone marrow, at the appropriate developmental stages.[37] A loss of β_1-integrins prevents adhesive interactions between HSCs and endothelial cells, thereby stranding the HSCs within vessels.[32] Some integrins have functions in addition to their targeting role. For example, β_4-integrins are required not only for correct homing but also for expansion and differentiation of erythroid and B-cell precursors in liver, spleen, and bone marrow. As with secreted factors, the activities of some

integrins relate more to late gestation and neonatal stages rather than earlier stages of hematopoietic development. This chronology has been documented for β_4-integrin with respect to lymphoid and myeloid differentiation.[14]

Acronyms and Abbreviations

ABC transporter, ATP-binding cassette transporter; BMP, bone morphogenetic protein; CD, cluster of differentiation; EPC, endothelial precursor cell; EPO, erythropoietin; ERK, extracellular signal-related kinases; ESC, embryonic stem cell; FGF, fibroblast growth factor; GM-CSF, granulocyte/macrophage colony-stimulating factor; HSC, hematopoietic stem cell; IGF-2, insulin-like growth factor 2; IL, interleukin; iPSC, induced pluripotent stem cells; JAK/STAT, Janus kinase/signal transducers and activators of transcription; LIF, leukemia inhibitory factor; Lin⁻, lineage negative; miRNA, microribonucleic acid; MSC, mesenchymal stem cell; PE, phycoerythrin; PI3K, phosphoinositide 3-kinase; Sca-1, stem cell antigen-1; SCF, stem cell factor; SCID, severe combined immunodeficiency; SP, side population; Tie, tyrosine kinase with immunoglobulin-like and endothelial-growth-factor-like domains; TNK, T cell and natural killer cell progenitor; TPO, thrombopoietin.

DEFINING STEM CELLS

Characteristics

Stem cells are a population of unspecialized precursor cells that have capacity for self-renewal and the ability to differentiate, leading to formation of mature cells and tissues. Hematopoietic stem cells (HSCs) are the reservoir for replacement of blood cells and are present in a frequency of one in every 10,000–100,000 blood cells[3] (Figure 2.1; see Chapters 6–10). Two general functional characteristics are used in defining stem cells. The first of these is the ability of long-term self-renewal. Stem cells have the capability, through mitotic cell division, to maintain a population of undifferentiated cells within the stem cell pool for months to years, and over many cycles of cell division. As stem cells divide, on average, one daughter cell is a replica and remains in an

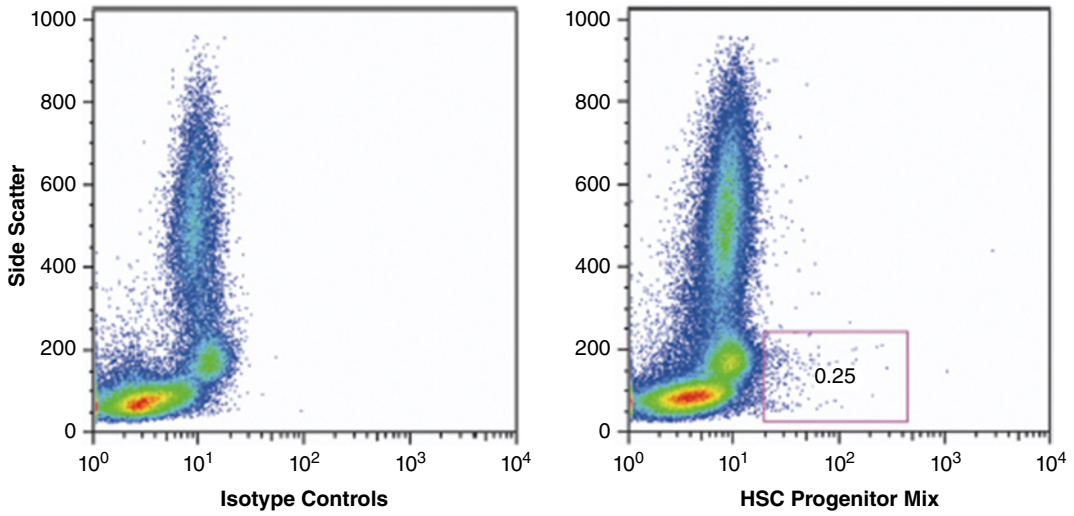

FIGURE 2.1 Hematopoietic progenitor cells in the peripheral circulation. Hematopoietic progenitor cells can be defined by expression of specific cell surface markers such as CD34, c-Kit, and CD133. In this case, such cells are detectable in blood from a normal dog using flow cytometry. Each panel shows a two-dimensional dot plot of FL2 (fluorescence channel-2 set to detect wavelength emission maxima at 575 ± 13 nm) versus right-angle side scatter. Cells were stained using routine protocols; dead cells were excluded using a vital dye. The left panel shows cells stained using an isotype control antibody. The right panel shows cells stained using a mix of antibodies against CD34, c-Kit, and CD133, each labeled with phycoerythrin (PE). In this healthy adult dog, approximately 0.25%, or ~2/1000 viable leukocytes expressed one or more of the progenitor markers. While the frequency is almost 20-fold greater than that seen in most healthy dogs, this case serves to illustrate the presence of hematopoietic progenitor cells in circulation with no associated pathology. (**Source**: Analysis and figure courtesy of Megan Duckett, Masonic Cancer Center, University of Minnesota.)

Magnification: 100× (**Source**: Figure courtesy of Dr. Amir Kol and Dr. Maria Questa, School of Veterinary Medicine, University of California, Davis); (b) Murine-bone-marrow-derived HSC colonies; each group of cells represents clonal expansion of a single progenitor cell; (c) Equine-bone-marrow-derived MSCs with typical fibroblast morphology.

undifferentiated state, while the second daughter cell is programed to differentiate. This production of two daughter cells with different properties is termed asymmetric cell division. The second characteristic of stem cells is the capacity to form differentiated or specialized cell types.

Types of Stem Cells

Potency is a term that is used to describe the degree or extent to which multiple functional cell lines can be formed. Based on potency, there are four types of stem cells. Totipotent stem cells are those cells that can form entire organisms, including extraembryonic tissues (e.g., placenta). This type of stem cell can be derived from the zygote or early blastomere. Pluripotent stem cells can form all cell types of the body. Embryonic stem cells (ESCs) are the canonical example of pluripotent stem cells (Figure 2.2a). These cells are derived from the inner cell mass of preimplantation blastocysts. ESCs can establish numerous different cells and tissues of the mature organism. Ethical issues surrounding the use of blastocysts for derivation of cell lines drove the development of a novel technique where transcription factors

related to pluripotency are incorporated into the genome of somatic cells to enable reprograming of these cells.[66] This technology enabled differentiated somatic cells to reverse their phenotype to an embryonic state, generating induced pluripotent stem cells (iPSCs, Figure 2.2a). Multipotent stem cells can generate all differentiated cells of a lineage. In the bone marrow (BM), HSCs are the classic example of a multipotent stem cell and much of this chapter will be focused on these cells (Figure 2.2b). HSCs are the reservoir for replacement of blood cells and are present in a frequency of one in every 10,000–100,000 blood cells[10] (Figure 2.1; see Chapters 6–10). Mesenchymal stem cells (MSC) meet the criteria of stem cells for all tissues that are found within bone including the bone tissue itself, cartilage, adipocytes, fibroblasts, and hematopoietic-supporting stroma (Figure 2.2c).[62] Small numbers of stem cells are retained throughout life as adult stem cells and are a reservoir for replacement of short-lived cells or regeneration of damaged tissues (for more information on tissue-resident stem cells, see reviews).[25,67] Finally, unipotent stem cells give rise to only a single-cell line (e.g., spermatogonial stem cells).[38]

Tests and Markers

Stem cells are best defined by functional assays to demonstrate their pluripotent or multipotent nature. For ESCs (and iPSCs), functional potency is demonstrated by the in vitro formation of embryoid bodies and the in vivo generation of teratomas in mice with severe combined immunodeficiency (SCID).[37,54,60] Functional potency for HSCs is demonstrated by repopulation of the hematopoietic system of lethally irradiated mice following transplantation of unpurified bone-marrow-derived cells.[69] Similar to HSCs, functional potency for MSCs was defined through in vivo transplantation assays where an isolated single MSC (skeletal stem cell) could generate a transplantable clonal progeny (ossicle) that included the stromal cells with phenotypes similar to the original explanted cell.[7,8,62]

For practical reasons, the identification and isolation of stem cells now rely largely on the use of a variety of markers such as surface molecules, transcription factors, and dye efflux. Numerous markers are available, and frequently are used in combination, to identify pluripotent and multipotent cells and stem cells within certain types of tissue. While some markers and tests are used more universally to recognize stem cells, special attention will be paid to those used in identifying bone-marrow-derived stem cells.

Cluster of Differentiation (CD)34

CD34 is a cell surface glycoprotein that has traditionally been used in identification and purification of HSCs and progenitor cells.[2] This marker appears to be highly conserved among mammalian species. Experimental evidence suggests that CD34 may be involved in cell adhesion of hematopoietic cells to stromal cells in the bone marrow microenvironment.[30] More recently, however, CD34-negative HSCs called side population (SP) cells were identified. SP cells are thought to be some of the most primitive HSCs because of their high proliferative potential and extreme efficiency at homing to sites of hematopoiesis when injected into recipient mice.[49] CD34 expression on HSCs may thus be related to the degree of activation of these cells, with CD34-negative cells being the most primitive and quiescent.[22]

Stem Cell Antigen

Stem cell antigen-1 (Sca-1) is a cell surface protein often used in identification of murine HSCs. This molecule may play a role in lineage determination.[12]

Dye Efflux

The ability of some primitive HSCs to efflux florescent dye allows for identification of this population, termed SP cells, by flow cytometry.[26,49] This ability appears to be due to increased number or activity of membrane pumps (e.g., ATP-binding cassette transporter [ABC transporter]), a hypothesis supported by the finding of blockage of dye efflux by the drug verapamil, a known inhibitor of these efflux pumps.[49] SP cells lack CD34 expression and have been described in multiple species.[27] As stated earlier, these CD34-negative cells have been proposed to be some of the most primitive HSCs.

c-Kit

c-Kit is a transmembrane tyrosine kinase receptor found on HSCs of multiple species. It binds the ligand stem cell factor (SCF, also called steel factor), and is important in the maintenance, proliferation, and differentiation of HSCs.[79]

Lin$^-$

As an adjunct to the presence of certain markers (e.g., CD34, c-Kit, Sca-1), the absence of markers present on differentiated cells has been used to isolate and purify HSCs. A lineage-negative (Lin$^-$) classification generally indicates that cells are negative for a combination of anywhere from 6 to 14 different lineage markers of mature blood cells.

Transcription Factors

Transcription factors that appear to be important in regulation of stem cell pluripotency and their undifferentiated state have been identified. Most notable are the transcription factors Oct-4, Nanog, and Sox-2, which have been used as markers of embryonic and adult stem cells.[15]

BONE-MARROW-DERIVED STEM CELLS

Within the bone marrow, there appear to be at least three different types of stem cell. HSCs are multipotent stem cells that give rise to the mature cellular elements of the blood (e.g., RBCs, neutrophils, monocytes, platelets,

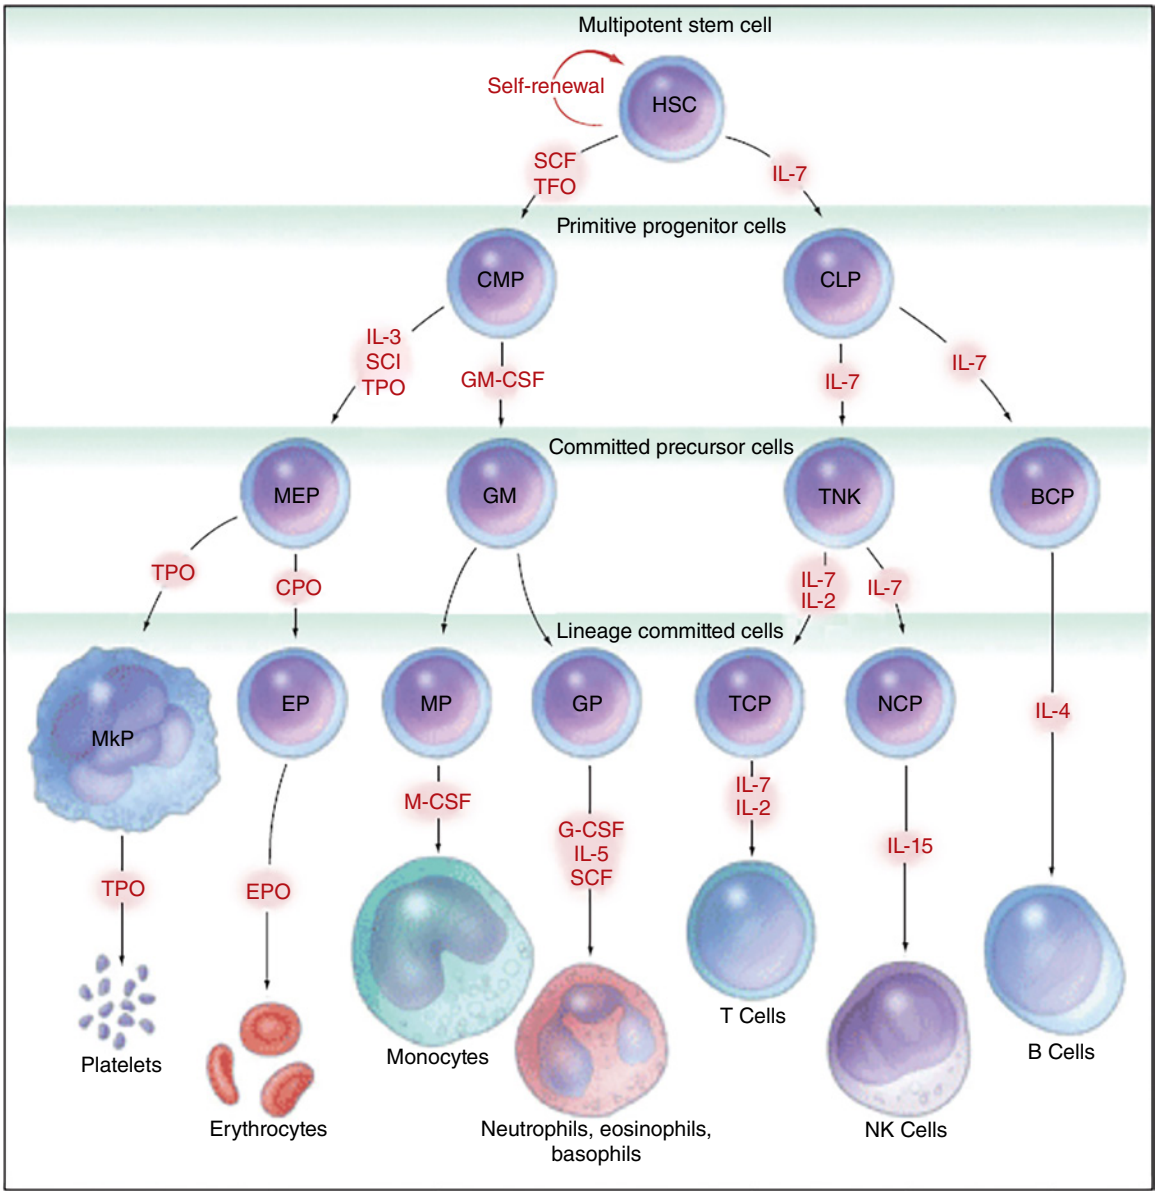

FIGURE 2.3 A general model of hematopoiesis. Blood cell development progresses from a HSC, which can undergo either self-renewal or differentiation into a multilineage committed progenitor cell: a common lymphoid progenitor (CLP) or a common myeloid progenitor (CMP). These cells then give rise to more differentiated progenitors, comprising those committed to two lineages that include T cells and natural killer cells (TNKs), granulocytes and macrophages (GMs), and megakaryocytes and erythroid cells (MEPs). Ultimately, these cells give rise to unilineage committed progenitors for B cells (BCPs), NK cells (NKPs), T cells (TCPs), granulocytes (GPs), monocytes (MPs), erythrocytes (EPs), and megakaryocytes (MkPs). Cytokines and growth factors that support the survival, proliferation, or differentiation of each type of cell are shown in red. For simplicity, the three types of granulocyte progenitor cells are not shown; in reality, distinct progenitors of neutrophils, eosinophils, and basophils or mast cells exist and are supported by distinct transcription factors and cytokines (e.g., interleukin-5 in the case of eosinophils, SCF in the case of basophils or mast cells, and granulocyte colony-stimulating factor (G-CSF) in the case of neutrophils). IL denotes interleukin, TPO thrombopoietin, M-CSF macrophage colony-stimulating factor, GM-CSF granulocyte/macrophage CSF, and EPO erythropoietin. (**Source**: Reprinted from Kaushansky[41], with permission. ©Massachusetts Medical Society 2006.)

etc.; Figure 2.3). The stromal components of bone marrow such as bone, cartilage, fat, and fibrous connective tissue are derived from MSCs, also termed marrow stromal cells. Finally, endothelial precursor cells (EPCs) are a population of bone-marrow-derived cells that function in angiogenesis. EPCs are mobilized from the bone marrow into the peripheral blood, where they home to sites of neovascularization such as those present in areas of inflammation, tumor vascularization, or wound repair (see Chapter 5).

STEM CELL BIOLOGY

Regulation of Survival and Pluripotency

Niche

The niche concept is important to the discussion of stem cell survival and differentiation. Niches are local tissue microenvironments that function to support, maintain, and regulate stem cells. Niches are largely based on the microanatomical organization and structural properties of tissues. These microenvironments are found in various tissues throughout the body; for example, the bulge region of the hair follicle, near the base of crypts in the gastrointestinal tract, and, in the case of HSCs, adjacent to endosteum and bone marrow sinusoids.[50,51,56] Regulation of stem cells by their niche occurs through physical contact and cell–cell interactions with adjacent cells, physical cues through the sympathetic nervous system, as well as elaboration of soluble factors.[50,51,56] Evidence also indicates that stem cells have the ability to influence the cellular elements of their niche. For example, HSCs from mice subjected to an acute hematopoietic stress have an increased ability to direct bone marrow MSCs toward osteoblastic differentiation as a result of HSC-derived bone morphogenetic proteins (BMPs).[40]

Molecular Mechanisms

What are the factors that cause stem cells to go down a pathway of self-renewal and remain undifferentiated versus progression toward lineage differentiation and mature cell phenotypes? The answer to this question is constantly evolving as specific molecular mechanisms are elucidated. Several factors important in the maintenance of stem cell survival, self-renewal, and pluripotency have been revealed in murine ESCs. These factors have been divided into extrinsic factors (e.g., cytokines) and intrinsic factors (e.g., transcription factors).

Leukemia Inhibitory Factor (LIF)

LIF is an interleukin (IL)-6-class cytokine that prevents differentiation of mouse ESCs in culture. Binding of LIF to its membrane receptor results in activation of multiple molecular signaling pathways such as Janus kinase/signal transducers and activators of transcription (JAK/STAT), phosphoinositide 3-kinase (PI3K), and extracellular signal-related kinases (ERK). Although these pathways are common downstream signals of many cytokines, in this context, their activation tends to promote maintenance of self-renewal and pluripotency. Activation of ERK in this example, however, appears to favor differentiation of mouse ESCs. Thus, LIF can activate signals that either promote or inhibit maintenance of an undifferentiated state, and it is the balance between these downstream effects (generally favoring self-renewal and pluripotency) that determines the outcome.[15]

Bone Morphogenetic Protein 4 (BMP4) and Basic Fibroblast Growth Factor (FGF)

BMP4 and basic FGF are additional examples of extrinsic factors that promote self-renewal and pluripotency in mouse ESCs. In the case of BMP4, it appears to work in a synergistic state with LIF.[15] Discovery of additional signaling pathways and factors is likely, as factors important for mouse ESCs are not universal when applied to human ESCs.

Wnt

Specific extrinsic factors involved in self-renewal of HSCs have been identified. The Wnt signaling pathway stimulates self-renewal of HSCs while concurrently inhibiting HSC differentiation. Inducing β-catenin activation, a downstream component of the Wnt signaling pathway, results in increased self-renewal of murine HSCs and limits differentiation of these cells. When inhibitors of the Wnt pathway are added to murine HSCs and growth factors, HSC proliferation is repressed.[61]

Tyrosine Kinase with Immunoglobulin-Like and Endothelial-Growth-Factor-Like Domains 2 (Tie2) and Angiopoietin-1

Tie2/angiopoietin-1 signaling has also been implicated in survival of HSCs. Tie2 is a receptor tyrosine kinase expressed on some HSCs. Angiopoietin-1 is the ligand for the Tie2 receptor and promotes quiescence and increased adhesion of murine HSCs to bone marrow stromal cells. Regulation of the quiescent state and maintenance within the HSC niche is thought to be important in HSC survival through a protective effect against myelosuppresive stresses.[3]

Other Cytokines

Other cytokines important in regulation of HSC survival include SCF, thrombopoietin (TPO), BMP, FGF, insulin-like growth factor 2 (IGF-2), and IL-10. SCF and TPO are common components of most cytokine combinations used in the culture and propagation of HSCs. Although TPO is the primary cytokine involved in megakaryocyte and platelet production, it also has been shown to have significant effects on HSCs. In vitro, TPO promotes survival and expansion of HSCs, and mice that have been genetically altered to lack TPO or its receptor have significantly fewer stem cells.[41,80]

Transcription Factors

The intrinsic factors governing the undifferentiated state of ESCs consist primarily of transcription factors. Most notable are Oct-4, Nanog, and Sox-2. These factors are found in pluripotent cell lines and, in general, downregulation results in differentiation of stem cells. Presence of Oct-4 and Sox-2 appears to be essential for pluripotency; however, the target genes for these transcription factors have not been completely characterized.[15] Several

transcription factors and cell cycle regulators governing self-renewal of HSCs also have been described.

Microribonucleic Acids (miRNAs)

miRNAs are an additional intrinsic molecular mechanism proposed to be involved in maintenance of pluripotent stem cells. miRNAs are short, single-stranded RNA molecules that regulate gene function by suppression of translation through annealing and sometimes degradation of mRNA. Novel miRNAs have been found that appear to be expressed preferentially in undifferentiated ESCs. In addition, evaluation of miRNA expression profiles from ESCs of varying degrees of differentiation as well as cells from mature tissues show repression or loss of specific miRNAs as cells progress to a more differentiated state.[36]

Regulation of Differentiation

Differentiation of stem cells into specific lineages is controlled or directed by factors including cytokines, niche interaction, and regulators of self-renewal and pluripotency. Cytokines influence and guide lineage determination of stem cells and many have been described in the context of HSCs and hematopoietic progenitor cell differentiation (Figure 2.3; see Chapters 6–11).

Stromal cells that constitute the stem cell niche influence differentiation and lineage determination through physical cell–cell interaction and elaboration of soluble or cell-bound factors (e.g., cytokines). Finally, as previously described, there are regulators that promote self-renewal and the pluripotent state of stem cells. For differentiation to occur, these regulators must be inhibited or suppressed. Mechanistically, there may be two general categories by which cells restrict lineage commitment.[68] The first of these involves the spectrum of surface receptors, adhesion proteins, and signaling pathways expressed by a given cell. For example, cytokines play an important role in lineage development. However, if a stem or progenitor cell lacks a cytokine receptor, then that cytokine would have little or no effect on its target. Gene silencing is a second mechanism by which lineage restriction may occur. For cells to differentiate, specific genes are activated or silenced, guiding cells toward a particular lineage. This may be accomplished through mechanisms such as DNA methylation and histone modification, which alter the transcriptional state of the chromatin.

STEM-CELL-ASSOCIATED DISEASES

Stem Cell Failure

The hematopoietic system offers a clear illustration of the effects of stem cell failure. HSCs are responsible for the constant replacement of all cellular components of blood, with HSC failure, cytopenias (e.g., anemia, leukopenia, thrombocytopenia), and their associated clinical manifestations (e.g., lethargy, infection, hemorrhage) ensue. HSC failure can be the result of a number of underlying pathologic processes, including toxic or drug-mediated damage, immune-mediated damage, infectious agents (e.g., parvovirus, feline leukemia virus, and *Ehrlichia* spp.), insufficient stimulation by cytokines and growth factors, and disruption of or damage to the stem cell niche (e.g., myelophthisis, ischemia, inflammation)[11,14,18,74,75] (see Section II).

Stem Cells and Proliferative Disorders

Just as adult stem cells are responsible for replacement of mature cells and tissues, there is strong evidence that cells with stem cell properties underlie the pathology of at least some types of cancer. The hypothesis of cancer stem cells is based on a few basic observations. The first of these is the observation of tumor heterogeneity. Many tumors comprise cells with different morphologies and phenotypes that in some cases loosely resemble the tissue of origin. This suggests a certain degree of differentiation within a population of tumor cells, leading to variability in structure and function. A more primitive precursor cell (i.e., cancer stem cell) could presumably give rise to the different phenotypes within a tumor. The second observation is that transplantation of a tumor required relatively large numbers of cancerous cells, an indication that only small numbers of cells in a given tumor have the ability to form a tumor. Cancer stem cells are present in small numbers within a tumor, and thus relatively large amounts of tissue would be needed to ensure the presence of these cells. Just like normal stem cells, cancer stem cells share the basic functional properties of self-renewal and the ability to differentiate.

In humans, evidence for cancer stem cells has been shown in hematopoietic, brain, breast, colon, prostate, bone, and ovarian cancers, and there is some evidence for the existence of cancer stem cells in animals.[39,43,48,78] Support for the existence of cancer stem cells in humans consists of identification of a subset of tumor cells that express stem cell markers and have exclusive or enhanced ability to form tumors in vitro or in vivo. Evidence exists that cancer stem cells may arise from normal stem cells and/or progenitor cells that have reacquired the ability of self-renewal. The origins of cancer stem cells continue to be explored.

The existence of cancer stem cells has clear implications for understanding cancer biology and treatment in at least certain types of cancers. For example, many chemotherapeutics target rapidly dividing cells. However, cancer stem cells are relatively slowly cycling, thus allowing them to persist with these conventional treatments. Newer therapeutic modalities directed at elimination of cancer stem cells will be important for effective treatment of these types of neoplasia.

STEM CELLS IN VETERINARY MEDICINE

Pluripotent stem cells, including ESCs and iPSCs, have only been variably derived and characterized in veterinary species. For many species, strict criteria for

functional potency have not been met (e.g., teratoma formation). Putative ESC lines have been derived from both companion and farm animals including the dog,[70] cat,[24] rabbit,[72] horse,[46] pig,[53,76] cow,[9,71] goat,[6] and sheep.[53] With most of these lines, there is a lack of appropriate species-specific markers to aid in stem cell identification and there is a loss of pluripotency, over a relatively short number of passages, in vitro and in vivo. Following advances in human and murine stem cell biology, a number of research groups have developed iPSC lines for companion and farm animals from a wide variety of tissue sources including adult and fetal fibroblasts.[20,29,35,47,52,63] New tools and resources, along with the ongoing advances being made in mouse and human stem cell biology focused on identifying factors critical to maintenance of pluripotency, provide promise for further identification and optimization of pluripotent stem cells for veterinary species.

STEM CELL UTILIZATION IN VETERINARY MEDICINE

Pluripotent stem cells are likely decades away from an FDA-approved veterinary product; however, iPSCs hold tremendous promise for the study of disease processes in vitro and the development of patient-specific cell-based regenerative therapies. In farm animals, the development of technologies surrounding ESCs and iPSCs opens the possibility for genomic selection, genome editing, and production of domestic ungulates with high genetic value.[65] These techniques can also be used to develop "tissue in a dish," 3D culture systems (including organoids) that permit novel, physiologically relevant in vitro systems to study cell function, host–pathogen interactions, novel therapeutics, and cell–cell interactions.[28,33,42,57,77] In zoo medicine, technologies are being harnessed to support wildlife conservation with novel resources including the Frozen Zoo® that maintains and stores irreplaceable living cell lines, gametes, and embryos to support conservation and assisted reproduction.[31]

HSCs are the only approved stem cell therapy in the United States. Dogs have been used as models for human hematopoietic cell (BM and HSC) transplantation for decades.[17,21,44] Recently, autologous HSC transplantation in dogs with lymphoma has developed as a viable treatment modality.[19] Dogs with B- and T-cell lymphoma are treated in a clinical setting with autologous peripheral blood progenitor cell transplants, using peripheral blood CD34+ progenitor cells harvested using an apheresis machine.[19,73]

A number of countries have approved human MSCs for a variety of clinical disorders, including graft versus host disease; however, there are no USA FDA-approved veterinary MSC products as of 2019. MSCs were largely viewed as powerful tools for orthopedic repair given their ability to differentiate into lineages including bone, cartilage, and fat. However, data now suggest that some of the most powerful MSC functions are their nonprogenitor functions including their ability to modulate angiogenesis and cells of the immune system.[13,23,45] MSCs also exert strong antimicrobial effects through indirect and direct mechanisms, partially mediated by the secretion of antimicrobial peptides and proteins.[1] Many of the immune modulatory and anti-inflammatory functions of MSC are mediated through a paracrine secretome including exosomes.[59] In veterinary medicine, MSCs have been widely used for a variety of diseases and disorders.[4,5,16,32,34,55,58,64] These clinical trials have largely proven the long-term safety of MSC administration; however, reported efficacy is highly variable. As with any stem-cell-based product, long-term, blinded, controlled prospective clinical trials will be needed to support product development based on strong biologic evidence of function.

Introduction
Supporting Structures
Vasculature and Sinus Architecture
Innervation
Cellular Organization
  Megakaryocytes and Thrombopoiesis
Erythroid Islands and Erythropoiesis
Granulocytes and Granulopoiesis, Monocytes/Macrophages (Monocytopoiesis), and Osteoclasts
Lymphoid Cells (Lymphopoiesis)
Stem Cell Niches

Acronyms and Abbreviations

AGM, aorta-gonad-mesonephros; CMP, common myeloid progenitor; DCP, dendritic cell progenitors; ECM, extracellular matrix; EPO, erythropoietin; FLT3L, (FMS)-like tyrosine kinase 3 ligand; GM-CSF, granulocyte–macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; HSC, hematopoietic stem cell; MDP, monocyte–dendritic cell progenitor; NK, natural killer; PTH, parathyroid hormone; PTHrP, parathyroid hormone related protein; RANK, receptor activator of nuclear factor kappa B; SCF, stem cell factor; TNF, tumor necrosis factor; TNFR, TNF receptor; TPO, thrombopoietin; VCAM, vascular cell adhesion molecule.

INTRODUCTION

Hematopoiesis first occurs during embryonic development in blood islands in the yolk sac, followed shortly thereafter within the aorta-gonad-mesonephros (AGM) region of the embryo in mammals.[26] Hematopoiesis subsequently shifts to liver, spleen, and eventually to the bone marrow during gestation.[17,40] The bone marrow develops in the embryo during the second trimester and becomes the major site of hematopoiesis at time of birth and continues in this function in adult mammals.[50] Bone marrow is a diffuse organ which constitutes approximately 3% of the body mass in rats, 2% in dogs, and 5% in humans.[51] Hematopoietic tissue is highly proliferative, producing billions of cells per kilogram of body weight every day.[17] Differences in locations of active bone marrow by species and changes due to aging need to be considered. Active marrow is mainly present in flat bones, vertebrae, and the proximal ends of the humeri and femurs in most adult mammals. Young mammals have red, active marrow with little fat throughout skeletal bones. Adipose tissue gradually accumulates in bone marrow as animals age to the extent that long bones primarily have yellow, fatty, inactive marrow.[17]

In nonmammalian species, major sites of hematopoiesis vary by taxon, and changes due to aging have not been described (to the authors' knowledge at the time of writing of this chapter). Invertebrates have stem cell niches within various hematopoietic organs that are structurally connected with the open vasculature.[22] Hematopoiesis in bony fish occurs mainly in the anterior kidney (referred to as the head kidney) and also in spleen, liver, intestines, and thymus.[18,20] In elasmobranchs, it is present in the epigonal organ (granulocytes, lymphocytes), spleen (lymphocytes, erythrocytes), organ of Leydig in the submucosa of the alimentary tract (granulocytes, lymphocytes), and thymus (lymphoid).[14,23] Hematopoiesis occurs in amphibians in the spleen and liver, and less frequently in kidney and bone marrow.[2,18] In reptiles, hematopoiesis occurs in bone marrow (e.g., proximal femur or tibia of legged reptiles), spleen, liver, and thymus.[12] In adult birds, hematopoiesis is mostly present in bone marrow (mainly erythropoiesis and thrombopoiesis, with granulopoiesis in

other tissues such as liver and spleen). While sampling of hematopoietic tissue in invertebrates, amphibians, and fish is performed during postmortem examinations, bone marrow sampling for cytological evaluation in bird patients can be achieved through the proximal tibiotarsus, keel, and most long bones except for pneumatic bones.[7,8] Bone marrow sampling is not recommended in live reptile patients, since it does not exfoliate well due to the fibrous nature of their bones that will even render postmortem tissue imprints of poor diagnostic quality. Therefore, histopathology is needed, but often also has limited diagnostic utility in the assessment of the actual status of hematopoiesis in reptiles, since extramedullary hematopoiesis can be prominent in liver, spleen, and thymus.[49]

Bone marrow consists of hematopoietic cells, vascular structures (including endothelial cells and myocytes), neural elements, supporting connective tissue cells (including adipocytes and reticular cells), extracellular matrix (ECM), and a myriad of soluble factors.[54] These elements are arranged in ways that create intravascular and extravascular spaces. These components create highly specialized environments with cellular communication through cytokines, growth factors, hormones, and interaction with ECM, which create specific niches for maintenance, proliferation, and differentiation of hematopoietic stem cells (HSCs) hematopoietic progenitors, and various progeny.

The complex vasculature and rich innervation of the marrow reflect the plethora of signals and mechanisms contributing to control and regulation of hematopoiesis. Bone marrow is a dynamic organ capable of structural and functional remodeling when responding to physiological changes (e.g., nutritional factors, endocrine signals, and age) or to diseases resulting in varying demands for production of RBCs, WBCs, and platelets. This chapter will review the structure of bone marrow with a brief conceptual framework for structural and functional relationships among the different components of bone marrow. For a more thorough discussion of the biochemical and molecular control of hematopoiesis and the hematopoietic microenvironment, the reader is referred to Chapters 1 and 4.

SUPPORTING STRUCTURES

Hematopoietic tissue is embedded within a rigid bony cortex, and is structurally supported by a meshwork of trabecular bone that serves as a partial scaffold for additional structural components that make up the stroma of the marrow including adipocytes, reticular cells, and ECM. In addition to providing physical support, each of these structural components contributes to the specialized microenvironment of hematopoietic tissue, either directly or via vascular connections. Hematopoiesis in mammals occurs in extravascular hematopoietic spaces which are located between venous sinuses that are composed of a luminal endothelial cell layer and an abluminal layer of adventitial reticular cells (fibroblast type) that provide a scaffold through cytoplasmic processes.[17]

Unlike other tissues that are arranged in stratified layers of developing cells, bone marrow is composed of a seemingly unstructured mixture of cells originating from different cell lineages and of various developmental stages, with unique niches that provide the necessary optimized microenvironment for hematopoiesis.[26] Bone within the marrow cavity is lined by a thin layer of elongated endosteal cells; this layer is punctuated with occasional osteoblasts and osteoclasts, and may be traversed by endosteal blood vessels connecting the hematopoietic space with bone in which osteocytes reside. Osteoblasts contribute to bone production and are derived from multipotent mesenchymal stem cells that also give rise to bone marrow endothelial cells, reticular cells, and adipocytes.[36] Osteoclasts are multinucleated cells derived from fused monocyte–macrophage precursors under the influence of numerous humoral signals, including those from osteoblasts.[36] Osteoblasts and osteoclasts remodel bone within the marrow space, while influencing the endosteal environment and presumably contributing to regulation of HSC proliferation and trafficking.[34] Osteoblasts and osteoclasts produce various cytokines, and interplay between bone and hematopoietic cells can influence bone turnover and remodeling.[36,41] Osteocytes, which originate from osteoblasts, are embedded in the bone matrix. Through their cellular connections with nearby osteocytes, osteoblasts, and cells lining the endosteal surface, they regulate hematopoietic stem cell and progenitor cell mobility and migration into the circulation.[3]

Fine, spindle- to stellate-shaped fibroblast-like reticular cells extend from endosteal regions into the parenchyma of hematopoietic tissue or form adventitial reticular cells supporting the endothelium of venous sinuses.[55] These cells derive from mesenchymal stem cells in the bone marrow, have extensively branched cytoplasmic processes, and form a supporting meshwork. Bone marrow reticular cells, with support from endothelial cells, produce structural fibrils such as collagen fibers, reticulin fibers, laminin, and fibronectin, and ground substance composed of water, salts, glycosaminoglycans (e.g., heparan sulfate, dermatan sulfate, hyaluronic acid), and glycoproteins, which, all together with basal laminae of endothelial cells, are referred to as the ECM.[26,44] Similar to other supporting cellular structures of the marrow, the ECM participates in both the structural and biochemical support of hematopoiesis through entrapping growth factors and through facilitation of cell-to-cell interactions between hematopoietic cells and stromal cell components.[35,42]

Bone marrow contains predominantly types I and III collagen, which take their final form after secretion into the extracellular space and undergoing enzymatic modification. Reticulin fibers are fine, argyrophilic fibers that are composed primarily of type III collagen fibrils surrounding a core of type I collagen embedded in a matrix of glycoproteins and glycosaminoglycans.[35] By contrast, coarse collagen fibers are predominantly type I collagen with less interfibrillar material than reticulin fibers. Although collagen and reticulin fibers are not prominent in routinely processed histology sections,

special stains can enhance their visualization. Coarse collagen fibers can be visualized with Mallory's or Masson's trichrome stains, whereas Gomori's silver stain highlights the presence of reticulin fibers. These stains can be useful in differentiating conditions resulting in reticulin fibrosis versus collagen fibrosis.[26,53]

Adipocytes are the most abundant stromal cells in bone marrow. In health, adipose tissue occupies approximately 25–75% of the bone marrow space, depending on the age of the animal.[26] Adipocytes are interspersed among hematopoietic cells and supporting structures, and present in various proportions depending on sites of active bone marrow in adult mammals. Although the relationships and communication between bone formation and adipose tissue are still not clearly understood, adipocytes and osteoblasts originate from mesenchymal stem cells within the bone marrow, with these compartments holding a reciprocal relationship and the potential for transdifferentiation between both cell types.[39,43] Given their origin from mesenchymal stem cells, adipocytes are believed to share common hematopoietic functions with reticular cells.[19]

Both brown and white adipose tissue are present in bone marrow; differences in biological function of these types of fat are not fully understood. Bone marrow adipose tissue tends to be relatively resistant to lipolysis during starvation compared with adipose tissue elsewhere in the body.[46] However, starvation resulting from many causes can lead to gelatinous transformation of bone marrow (serous atrophy of fat). This condition is characterized by loss of hematopoietic cells, peripheral cytopenias, atrophy of fat, and replacement of fat by acid mucopolysaccharides (mainly hyaluronic acid), which typically can be visualized with Alcian blue stain at pH 2.5.[26]

In addition to providing structural support, adipocytes reportedly participate in the hematopoietic microenvironment, notably as suppressive regulators as shown by lower frequencies of progenitor cells and relatively quiescent stem cells in adipocyte-rich bone marrow in mice.[38] However, cells derived from bone marrow adipose tissue are capable of supporting differentiation of hematopoietic progenitors in vitro.[10,13] Adipose tissue fulfills important endocrine and paracrine functions through production of hundreds of adipokines which are involved in numerous regulatory processes, including hematopoiesis, metabolism, and inflammation.[13,15]

VASCULATURE AND SINUS ARCHITECTURE

Several essential functions highlight the importance of the vasculature to the bone marrow microenvironment, including its contribution to structure, to regulation of movements of hematopoietic cells (e.g., extravascular, transendothelial), and, together with stromal cells, to production of ECM.[26] Bone marrow endothelial cells are specialized cells that support the long-term proliferation of hematopoietic progenitor cells of megakaryocytic and myeloid origin through cytokines, and with HSC trafficking and possibly proliferation through cell-to-cell contact.[30]

Nutrient arteries provide the major blood supply to the bone marrow (Figure 3.1). They enter the medullary cavity via one or more nutrient canals that also may contain one or two nutrient veins (e.g., two for long bones, several for flat bones).[51] Once the vessels have penetrated the cortex, ascending and descending branches bifurcate from the main vessels, coiling around the main venous bone marrow channel and central longitudinal vein. These branches form numerous arterioles and capillaries that penetrate the endosteal surface of the bone to communicate with cortical capillaries derived from arteries that supply surrounding muscle tissue. These interactions facilitate communication and reciprocal regulation between hematopoietic cells and bone.[36] Capillaries derived from the nutrient artery extend as far as the Haversian canals before coursing back to the bone marrow and opening into the venous sinuses. Periosteal arterioles penetrate cortical bone to form a second arterial system for the bone marrow. These vessels form branching networks of medullary venous sinuses that collect into the large central venous sinus; from there, blood enters the systemic circulation via the emissary vein, which exits through the nutrient foramen.[1]

Hematopoiesis occurs in extravascular spaces between venous sinuses in postnatal mammals, with

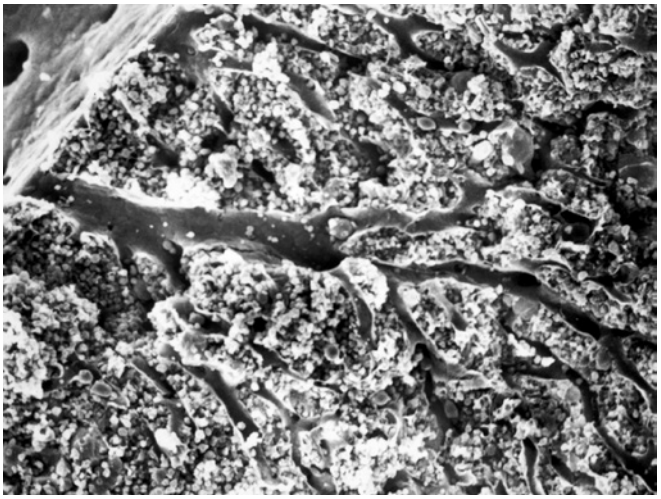

FIGURE 3.2 A scanning electron micrograph of the cut surface of bone marrow showing a system of vascular sinuses originating at the periphery of the marrow (right side of field) and draining into a large vein (upper left corner). The large vein has several apertures in its wall, representing tributary venous sinuses. Hematopoietic tissue lies between the vascular sinuses. (**Source:** From Weiss[54])

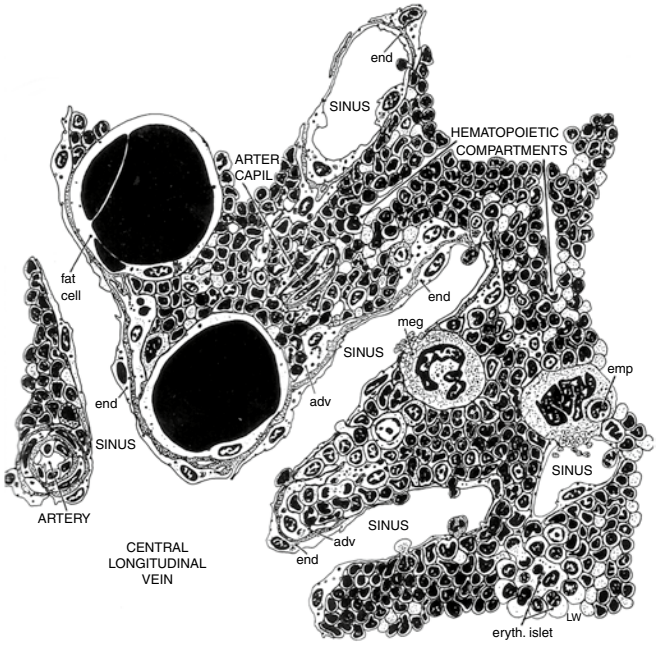

FIGURE 3.3 Schematic view of a cross-section of bone marrow near the central longitudinal vein. Hematopoietic cells lie in the hematopoietic compartment between the vascular sinuses that drain into the central vein. The sinus wall consists of endothelial cells (end), a basement membrane, and, in some areas, adventitial stromal cells (adv). Megakaryocytes (meg) lie against the outside of the vascular sinus wall and discharge proplatelets directly into the vascular lumen through apertures in the sinus wall. Erythroid cells are shown developing in an erythroid islet (eryth islet) around a central macrophage. Emperipolesis (emp), the entry of megakaryocyte cytoplasm by other cells, is occasionally observed. (**Source:** From Weiss[55])

close morphological and functional relationships of cells that line the venous sinuses (Figures 3.2 and 3.3). Reticular cells maintain close physical relationships with hematopoietic cells close to the sinus walls, frequently wrapping around or otherwise contacting hematopoietic precursors.

Sinus endothelial cells produce adhesion molecules, ECM components, and chemokines that not only promote hematopoiesis but also regulate translocation of cells and other substances between the extravascular space and the systemic circulation. Cell egress from the extravascular space into the vascular sinus occurs transcellularly through thin parajunctional zones of endothelial cell cytoplasm in vascular areas lacking basement membrane and adventitial reticular cells.[27]

Endothelial progenitor cells in the bone marrow can be recruited for angiogenesis and directed through surface receptors to healing tissues in adults. These endothelial progenitor cells also give rise to pluripotent angioblasts during fetal vasculogenesis, which can mature into endothelial cells of arteries, veins, or lymphatics, or into pericytes or myocytes surrounding blood vessels.[47]

INNERVATION

Primary innervation of the bone marrow is achieved via myelinated and more numerous nonmyelinated fibers. These fibers originate in spinal nerves entering through the nutrient foramen, although some innervation may originate from the epiphyseal and metaphyseal foramina.[6,51] Once inside the medullary cavity, the mixed myelinated and nonmyelinated nerve bundles, surrounded by a thin perineurium, divide to parallel the arterial vasculature of the bone marrow.[6] The main branches of the arterial vessels are surrounded by several nerve bundles, whereas arterioles and capillaries may be accompanied by only a single fiber, with nerve endings contacting vascular smooth muscle cells or periarterial reticular cells.[56] The sinusoidal system is less richly innervated than the arterial vasculature, with nerve endings frequently contacting the walls of sinusoids. Other nerve fibers appear to terminate within the hematopoietic parenchyma or along the endosteum.[6,16]

Autonomic innervation is mainly responsible for bone marrow regulation, homeostasis, stem cell proliferation and motility, and response to stressors. These effects result from direct interactions with progenitor and stem cells, or indirectly with other cells of the microenvironment via a plethora of receptors, neuropeptides, and neurotransmitters.[5,57] Even nerve-associated nonmyelinating Schwann cells are involved in maintenance of dormant HSCs.[57] Through a myriad of receptors and molecules, neural signaling is involved in hematopoiesis, inflammation, immune functions, and neoplasia.[3,24]

CELLULAR ORGANIZATION

The medullary cavity comprises an intricate three-dimensional complex of hematopoietic cells between vascular sinuses (Figure 3.3). Various cell lineages

localize to specific niches via adhesion molecules (e.g., integrins, lectins, other receptors) that interact with ligands, receptors, and/or ECM components. Lymphocytes, macrophages, and immature granulocytes are concentrated near the endosteum/bony trabeculae and arterioles, and megakaryocytes, erythroid cells, and mature granulocytes are located near venous sinuses.[1,37]

Hematopoietic cells originate from a common, self-renewing pluripotent HSC population which gives rise to committed lymphoid and myeloid progenitor cells.[17] Lymphoid progenitor cells generate lymphocytes, whereas the myeloid progenitor cells generate erythroid cells, megakaryocytes, basophils, eosinophils, and a common granulocyte–macrophage cell that produces neutrophils and macrophages. Hematopoietic cells continue to divide as they mature, resulting in progressively higher numbers (mitotic pool) and continue to mature after they stop dividing (postmitotic pool). The hematopoietic tissue is effectively controlled via local and systemic mechanisms, including numerous cytokines and growth factors, to maintain a steady state of blood cell kinetics in health and to respond rapidly to stimuli or disease.[17]

FIGURE 3.4 Elongated proplatelet processes (center and bottom left) are visible in a venous sinus within bone marrow from a dog. Regional constrictions along the length of the central proplatelet are consistent with platelet formation by fragmentation. (**Source:** From Handagama et al.[61])

Megakaryocytes and Thrombopoiesis

Megakaryocyte development begins with the megakaryoblast, progresses to promegakaryocytes and basophilic megakaryocytes, and results in formation of mature megakaryocytes. Thrombopoiesis is mainly regulated by thrombopoietin (TPO), which is produced primarily in the liver at a relatively constant rate and bound by platelets through their TPO receptor. Thus, in the face of thrombocytopenia, reduced numbers of platelets bind less TPO, which results in higher free TPO in plasma and thus in stimulation of thrombopoiesis.[17]

Megakaryocyte precursors are located near vascular sinuses. Sinus endothelial cells are an essential component of the megakaryocyte microenvironment, supporting megakaryocyte differentiation and maturation.[27] Megakaryocyte precursors progressively enlarge as they mature to become the largest cell in the bone marrow.[4] Their nuclei increase from a single nucleus to a large multilobulated nucleus through a process termed endomitosis (i.e., replication of DNA without cellular division), resulting in a polyploid cell (8–32N).[4,17] The cytoplasm of early megakaryocytic precursors is scant and, as cells continue to mature and increase in size up to 50–200 μm in diameter, it becomes deeply basophilic, more abundant, and then lightly basophilic to eosinophilic, and filled with abundant magenta-staining granules when visualized using Wright and/or Giemsa stains. The location of mature megakaryocytes adjacent to vascular sinuses enables cytoplasmic processes of megakaryocytes to extend through endothelial gaps and extend proplatelets directly into the lumen of vascular sinuses (Figure 3.4). Anucleate platelets are released from proplatelet processes into the peripheral circulation where their life span is about 6 days in dogs.[26] In contrast to mammals, thrombopoiesis of nonmammalian vertebrates begins with the thromboblast and results in production and release of nucleated thrombocytes.[8]

Erythroid Islands and Erythropoiesis

Stages of erythropoiesis include rubriblasts, prorubricytes, rubricytes, metarubricytes, reticulocytes, and non-nucleated mature erythrocytes in mammals (see Chapter 6). Erythropoiesis is regulated by the glycoprotein erythropoietin (EPO) in addition to other cytokines, including interleukin (IL)-3, granulocyte–macrophage colony-stimulating factor (GM-CSF), TPO, and stem cell factor (SCF).[26] Peritubular interstitial cells of kidneys produce EPO in response to hypoxia. EPO promotes proliferation and inhibits apoptosis of erythroid progenitors and early erythroid precursors. It also has a multitude of other effects on endothelial cells.[26] Iron metabolism is intricately linked to erythropoiesis, as it is an essential component of hemoglobin. Other nutrients including amino acids, copper, essential fatty acids, and vitamins are also necessary, and deficiencies can impair adequate erythropoiesis.[26]

As erythroid precursors mature and continue to divide, they become smaller, their nuclear to cytoplasmic ratio reduces, their cytoplasm becomes less basophilic and more polychromatophilic, and the nuclear chromatin becomes condensed. In mammals, the nucleus is extruded at the metarubricyte stage, resulting in formation of the reticulocyte. The reticulocyte retains ribosomes and mitochondria for hemoglobin synthesis, but these are ultimately lost when the cells mature to an erythrocyte.[26] In most mammals, except for horses and presumably closely related ungulates, reticulocytes are released from the bone marrow and continue to mature in the peripheral blood and the spleen. Horses do not

release reticulocytes into the circulation, similar to observations by the authors in some other ungulate species (e.g., rhinoceros, elephant). Nuclei are not extruded as erythrocytes develop in nonmammalian species. However, early nucleated erythroid precursors, with basophilic or polychromatophilic cytoplasm, as well as mitotic cells, may be present in the peripheral blood in response to anemia in these taxa.

Erythroid precursors develop in clusters around central macrophages that can be observed occasionally in bone marrow cytological samples (Figure 3.5). These have been referred to as erythroid (erythroblastic) islands. However, examination of three-dimensional histological sections indicates that most of these cellular aggregates may consist of elongated "erythroblastic cords" that are supported by stromal cells at their axial portion. These erythroblastic cords are reportedly closely connected with each other and interwoven with hematopoietic compartments and vascular sinuses, sometimes forming presumed perivascular structures. Segregated islands can be observed in close connection with sinuses.[37] Central macrophages are surrounded by erythrocyte precursors, whether in islands or cords.

Facilitated through adhesion molecules, including integrin α4β1 on erythroid precursors and vascular cell adhesion molecule 1 (VCAM1) on central macrophages, erythroid precursors proliferate and differentiate around a central macrophage that projects membranous processes in intimate contact with developing erythroid cells.[45] Central macrophages secrete soluble factors that promote proliferation, differentiation, and hemoglobinization of erythroid cells.[33] However, central macrophages can also produce inflammatory cytokines that inhibit erythropoiesis.[28] Central macrophages also phagocytize extruded nuclei that are enclosed in a thin layer of cytoplasm and plasma membrane, also known as pyrenocytes, and defective cells.[9] Maturing erythroid precursor cells are found in concentric circles surrounding the central macrophage with more immature forms closer to the macrophage.[1] The central macrophages are recruited from a subset of resident macrophages that originate from monocyte precursors. Erythroid islands are generally located near venous sinuses because they are capable of migration toward venous sinusoids as they mature.[9,58]

Granulocytes and Granulopoiesis, Monocytes/Macrophages (Monocytopoiesis), and Osteoclasts

Granulocytes and monocytes/macrophages share a common myeloid progenitor (CMP) that originates from an HSC. This CMP produces all nonlymphoid hematopoietic cell lines, including macrophages, dendritic cells, osteoclasts, and mast cells.[32] In granulopoiesis, the myeloblast is the earliest light microscopically recognizable precursor of granulocytes. Each myeloblast is capable of producing 16–32 progeny cells.[17] The mitotic pool is comprised of myeloblasts, promyelocytes, and myelocytes, whereas the postmitotic pool consists of metamyelocytes, bands, and segmented stages.[26] Neutrophils, eosinophils, and basophils develop in a parallel fashion from myeloblasts to mature cells. Granulocytes, similar to RBCs, decrease their cellular size and nuclear to cytoplasmic ratio as they mature. After primary reddish-purple granules lose their capacity to pick up routine cytologic stains (Wright and/or Giemsa), secondary specific granules become visible in the myelocyte stage and allow differentiation of the various granulocytic lineages. At the metamyelocyte stage, the round nucleus elongates and indents to form a bean-shaped nucleus before ultimately forming segmentations at full maturation.[26,46] Mature segmented neutrophils are stored in the bone marrow storage pool of which the size is species-dependent and which has implications for accurate leukogram interpretation.[26]

The monocyte–dendritic cell progenitor (MDP) that originates from the CMP produces monocytes and dendritic cell progenitors (DCP).[59] Monoblasts, the next

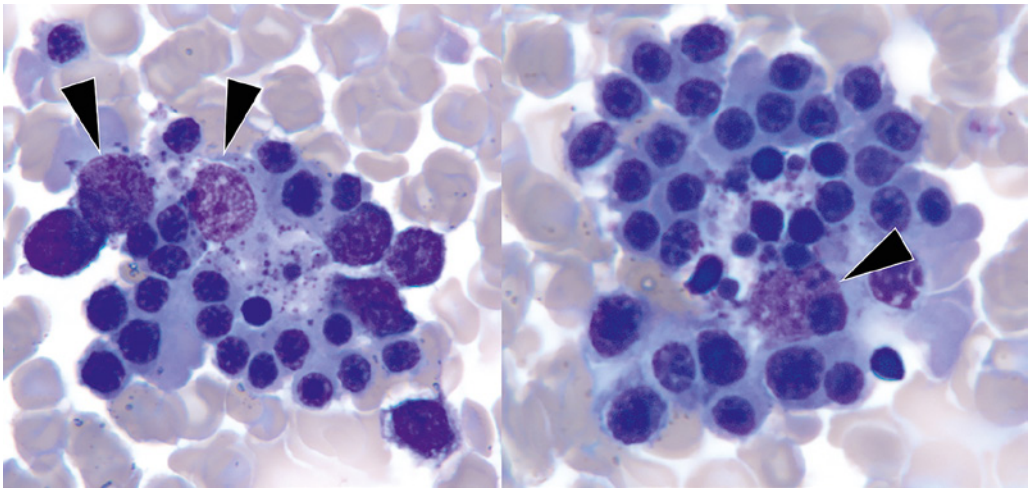

FIGURE 3.5 Erythroid islands in a bone marrow aspirate of a koala (*Phascolarctos cinereus*). Central macrophages (black arrowheads) with intracytoplasmic globular gray-basophilic pigment (presumptive hemosiderin) surrounded by developing erythroid precursors. 100×, Wright–Giemsa stain.

maturation stage after MDPs, are morphologically very similar to myeloblasts except for their nucleus, which is more irregular to convoluted. This morphological distinction can be useful in the cytological differentiation of acute myeloid leukemias.[26] developmental stages after the monoblast include promonocytes (which may be morphologically similar to neutrophilic myelocytes or metamyelocytes) and then finally monocytes.[26] Despite their uniform morphological features (e.g., round-, kidney-, or band-shaped nucleus, fine nuclear chromatin), several functional subsets develop from monocytes. This includes progenies that either leave the circulation and generate macrophages in tissues, or differentiate into inflammatory dendritic cells, depending upon effects of various cytokines in inflammatory or other conditions.[59] In addition, monocyte precursors fuse to produce osteoclasts under the regulation of macrophage-CSF, a family of biologically related tumor necrosis factor (TNF) and TNF receptor (TNFR) superfamilies that consist of receptor activator of nuclear factor kappa B (NF-κB) (RANK), its ligand RANKL, and osteoprotegerin (OPG).[48]

Granulopoiesis and monocytopoiesis are increased by various inflammatory mediators (e.g., interleukins and TNF-alpha) that stimulate fibroblasts, endothelial cells, and macrophages to produce granulocyte colony-stimulating factor (G-CSF) and GM-CSF. The location of granulocytic cells is dependent on their stage of maturity: immature forms are located near arterioles and bony trabeculae; as maturation proceeds, precursors migrate toward venous sinuses where they cross the endothelium and enter the peripheral circulation.[1,26]

Lymphoid Cells (Lymphopoiesis)

Early lymphoid progenitors are produced in the bone marrow under the influence of SCF and feline McDonough sarcoma (FMS)-like tyrosine kinase 3 ligand (FLT3L). These progenitors then give rise to B and T/natural killer (NK) progenitor cells. B lymphocytes develop further in the bone marrow and ileal Peyer's patches, after which they continue maturation in peripheral lymphoid tissues. T/NK precursors leave the bone marrow for further maturation in the thymus and other tissues and subsequently migrate to peripheral lymphoid tissues.[17] Trafficking of lymphocytes to and from these organs is accomplished through various chemokines and adhesion molecules, with recirculation involving both blood and lymphatic vessels. A majority of blood lymphocytes in normal mammals are T lymphocytes, with lesser numbers of B lymphocytes and even lower numbers of NK cells.

Immature lymphoid cells are located near the endosteum and arterioles, whereas mature lymphocytes are relatively uniformly distributed within the bone marrow parenchyma.[1,37] Morphological changes in lymphoid cells during maturation are less obvious than other blood cell lineages and include decreasing cell size, decreasing cytoplasmic basophilia (visualized with Wright and/or Giemsa stains), and increasing condensation of nuclear chromatin.[46]

In contrast to the significance of bone marrow tissue for lymphopoiesis in mammals, major lymphoid organs are thymus, spleen, and kidney in bony fish; epigonal organ, spleen, organ of Leydig, spiral valve, and thymus in elasmobranchs;[18,25] mainly spleen, and to a lesser extent, bone marrow, and kidney in amphibians;[11] thymus and spleen, with aggregates of lymphoid cells occurring in various tissues, e.g., gastrointestinal tract, lung, urinary bladder, kidney, and pancreas in reptiles;[49] and thymus, bone marrow, spleen, and bursa of Fabricius (B lymphocyte development) in birds.[21]

Stem Cell Niches

HSCs produce mammalian blood cells in extravascular spaces of the bone marrow starting mid-gestation and continuing throughout life. HSCs are defined by their long-term capacities for self-renewal and differentiation.[26] As their morphology is similar to small lymphocytes, they are indistinct and evaluation of surface proteins [e.g., cluster of differentiation antigen (CD)[34]] can be used to characterize these cells. HSCs give rise to common lymphoid and common myeloid progenitor cells, which can differentiate into all blood cell lines.

HSCs reside within stem cell niches within the bone marrow which provide an optimized microenvironment for their self-renewal, quiescence, and mobilization.[29,31] Two types of complex, heterogenous stem cell niches (endosteal and vascular) have been recognized. These niches share some common structures and factors, but differ in their function and response to stressors. HSCs in the endosteal niche are generally quiescent and concentrated around arterioles.[52] Osteoblasts have regulatory roles within this niche. HSCs in the vascular niche are located near vascular sinuses where endothelial cells and reticular cells have tropic effects on these cells.[29] These HSCs replicate more often and appear to be more actively involved in maintaining balanced cellular production in steady-state conditions. Factors involved in regulation of hematopoietic activity in niches include intrinsic and extrinsic factors (e.g., parathyroid hormone/parathyroid hormone related protein (PTH/PTHrP) signaling, Wnt/beta-catenin signaling, osteopontin, G-CSF, sympathetic nervous system). The complete difference and degree of interplay between these two niches poorly understood. Proposed theories include redundancy between both compartments, the role of the endosteal niche as a reservoir for the vascular niche in case of damage to central marrow, or that each niche fulfills unique functions that synergize during hematopoiesis.[29]

Acronyms and Abbreviations

AML, acute myeloid leukemia; Ang1, angiopoietin 1; BFU-E, erythroid burst-forming unit; CD, cluster of differentiation; CFC-S, splenic colony-forming cell; CFU-E, erythroid colony-forming unit; CFU-GEMM, colony-forming unit granulocyte, erythrocyte monocyte, megakaryocyte; CFU-GM, granulocyte–macrophage colony-forming unit; CHIP, clonal hematopoiesis of indeterminate potential; CLL, chronic lymphocytic leukemia; CLP, common lymphoid progenitor; CXCR4, CXC chemokine receptor 4; ECM, extracellular matrix; EDTA, ethylenediaminetetraacetic acid; EGF, epidermal growth factor; EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; GTPase, guanosine triphosphatase; HSC, hematopoietic stem cell; ICAM-4, intercellular adhesion molecule-4; IL, interleukin; JAK, Janus tyrosine kinase; JH, Janus homology; NK cell, natural killer cell; PI3K, phosphatidylinositol 3 kinase; PTH, parathyroid hormone; qPCR, quantitative polymerase chain reaction; Rac1 and Rac2, Ras-related C3 botulinum toxin substrate 1 and 2; SCF, stem cell factor; SCID, severe combined immunodeficiency; SDF-1, stromal-derived factor 1 (CXCL12); SH, src homology; SOCS, suppressor of cytokine signaling; STAT, signal transducer and activator of transcription; TGF-β, transforming growth factor-beta; Tie2, tyrosine kinase with immunoglobulin-like and EGF-like domains 2; TNFα, tumor necrosis factor-alpha; TPO, thrombopoietin; TRAIL, TNF-related apoptosis-inducing ligand; VCAM-1, vascular cellular adhesion molecule 1; VLA-4, very late antigen 4.

Current understanding of the hematopoietic system draws heavily from clinical observations and research in humans and mice. Numerous gene-deleted mice targeting transcription factors, hematopoietic cytokines and their receptors, and extracellular matrix (ECM) components and their receptors are central to our knowledge of hematopoiesis at the molecular level.[8] Recent studies have contributed information about the critical role of the bone marrow microenvironment. In domestic animals, research on spontaneous hematopoietic neoplasia, the roles of retroviruses and viral oncogenes that mimic hematopoietic tyrosine kinases, cyclic neutropenia of Gray Collies, and other species-specific hematopoietic diseases has added to our understanding of hematopoiesis, which is remarkably conserved across mammalian species.[40]

HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells (HSCs), which are considered to have lost their potential for mesenchymal differentiation, arise first in the embryonic yolk sac, then in fetal para-aortic splanchnopleura, from which liver and

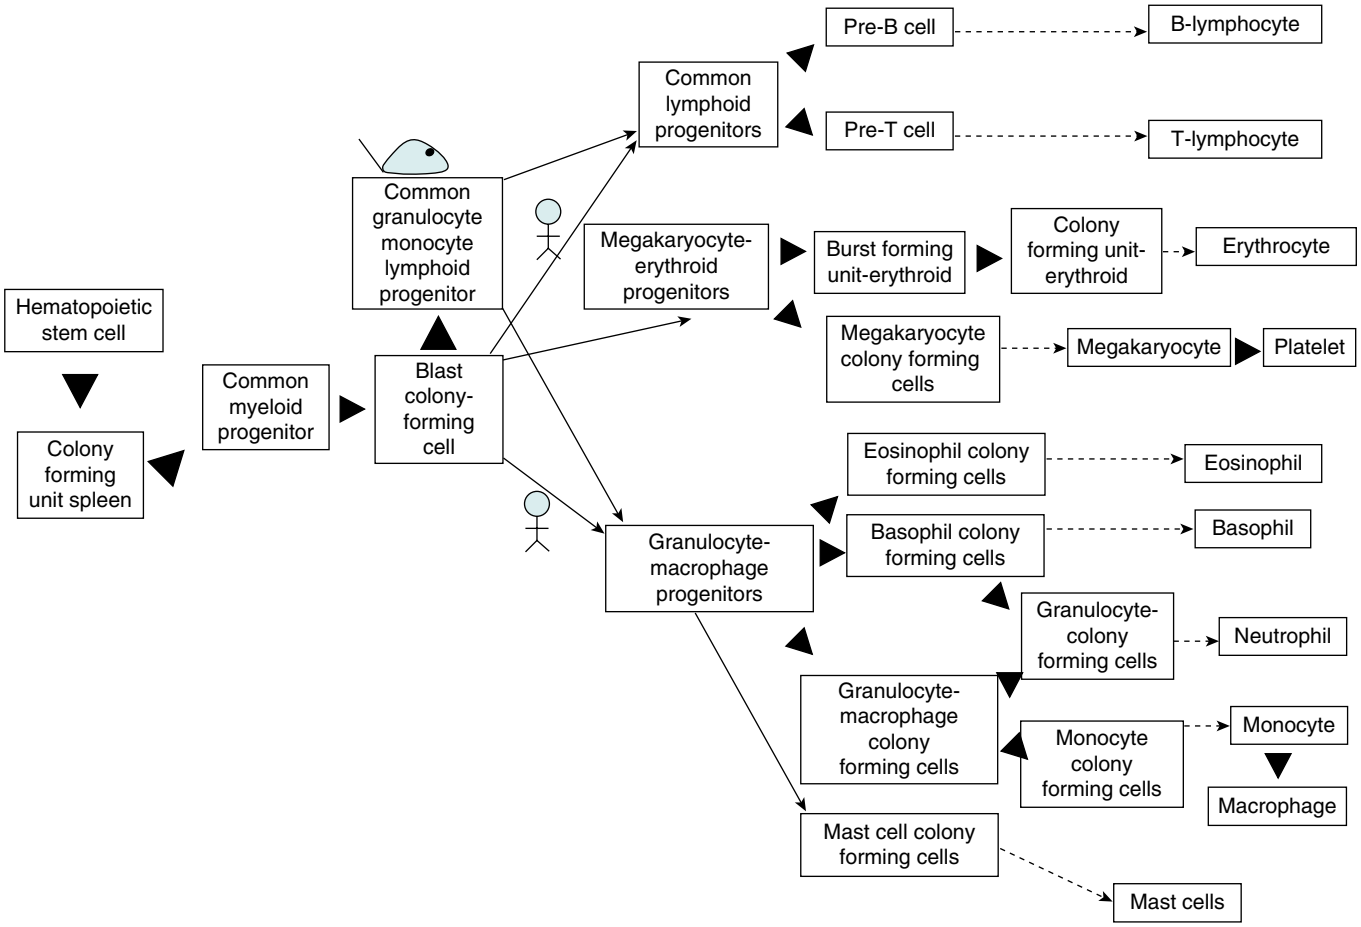

FIGURE 4.1 Hierarchical scheme of hematopoiesis. This figure depicts the conventional view of human and murine hematopoiesis. Larger block arrowheads indicate differentiation from pluripotent to oligopotent hematopoietic stem cells. Smaller block arrowheads indicate lineage commitment of oligopotent stem cells driven by cytokines and the JAK-STAT pathway. Dotted line arrows illustrate the multiple stages of differentiation that can be visually discriminated in Wright-Giemsa-stained bone marrow specimens. The figure has been modified from human and murine illustrations to indicate the mouse-specific GM-lymphoid precursors. (**Source:** Modified from Iwasaki H, Akashi K. Hematopoietic development pathways: on cellular basis. Oncogene 2007;26:6687–6696 and Metcalf D. Hematopoietic stem cells and tissue stem cells: current concepts and unanswered questions. Stem Cells 2007;25:2390–2395.)

finally bone marrow are seeded (see Chapter 1). In the conventional view of hematopoiesis, pluripotential HSCs with unlimited self-generative capacity progressively differentiate to multipotent or oligopotent stem cells with reduced self-replicative capacity, to lineage-committed progenitors with minimal ability to self-renew, to lineage-specific precursors with no self-regenerative ability, and finally to the mature cells of blood (Figure 4.1).[37] As shown in mice, hematopoiesis matures through a common granulocyte–monocyte–lymphoid oligopotent progenitor that has not been identified in higher species.[23] The strict division of common granulocyte–monocyte–erythroid–megakaryocytic progenitors and common natural killer (NK)/B and T-cell progenitors occurs for human hematopoiesis, and likely applies to hematopoiesis in domestic species.

Lineage commitment typically follows expression of lineage-restricted transcription factors (Table 4.1). Induction of these transcription factors occurs through a combination of specific cytokine receptor and ligand interactions, less-specific signal transduction pathways, and an overlay of highly specific, permissive microenvironmental influences from stromal cells, endothelial cells, adipocytes, osteoblasts, ECM proteins, adherent cytokines, and trabecular bone.

Because of the short life span of differentiated hematopoietic cells, mature blood cell production is an ongoing process; estimates suggest production of 1.5×10^6 cells/second in humans. It is unlikely that HSCs supply a continuous flux of cells from left to right as shown in Figure 4.1 because HSCs and multipotent cells are nondividing or very slowly dividing during normal hematopoiesis. Newer evidence suggests that information determined from experiments in lethally irradiated mice may not necessarily recapitulate normal or physiologically accelerated hematopoiesis and that there may be other homeostatic mechanisms that control hematopoiesis.[37]

A somewhat confusing nomenclature has evolved around early committed hematopoietic progenitors based on in vivo experiments in mice. Splenic colonies

TABLE 4.1 Hematopoietic Transcription Factors.[a]

Early hematopoietic development
- SCL (TAL 1) (stem cell leukemia, T-cell acute lymphocytic leukemia-1)
- GATA-2
- LMO2 (Rbtn-2) (Lim finger protein)
- AML-1 (acute myeloid leukemia 1 protein)
- Tel
- Notch 1

Erythropoiesis
- HIF-1 (Hypoxia-inducible factor-1)
- GATA-1
- EKLF-1 (erythroid kruppel-like factor 1)
- p45/NF-E2 (nuclear factor erythroid-2)
- STAT5a, STAT5b
- CBP/p300 (CREB binding protein/p300)
- SP1

Erythropoietic regulators
- FOG-1 (friend of GATA-1)
- TRAP220 (thyroid hormone receptor-associated protein 220)
- BRG1 (Brahma-related gene 1)
- CBP/p300 (CREB binding protein/p300)

Myelopoiesis
- Notch
- GATA-1
- C/EBP_{α} (CCAAT/enhancer binding protein $_{\alpha}$)
- STAT5a, STAT5b

Granulocytopoiesis
- RAR (Retinoic acid receptor)
- C/EBP_{α} and C/EBP_{ε}
- CBF (core binding factor)
- c-Myb
- STAT3
- NFκB (nuclear factor of kappa B) – late precursor
- AML1 – precursor

Monocytopoiesis
- EGR-1, EGR-2 (early growth response genes 1 and 2)
- Vitamin D receptor
- c-Fos, c-Fos
- PU.1
- RAR (retinoic acid receptor)
- C/EBP_{β} and C/EBP_{ε}
- MafB/c
- PU.1

Osteoclast differentation from monocyte precursor
- NFκB

Megakaryocytopoiesis
- Notch
- GATA-1
- PU.1
- Fli-1/NF-E2 (platelet production)
- FOG
- SCF (stem cell factor)
- STAT5a, STAT5b

Lymphoid
- PU.1
- Ikaros
- STAT3, STAT5a, STAT5b, STAT4, STAT6

B-cell
- E2A
- EBF (early B-cell factor)
- Pax 5
- NFκB (progenitors and late maturation)

T-cell
- HEB (TCF12 – T-cell factor 12)
- Notch/HES-1 (Hairy Enhancer of Split-1)
- NFAT (Nuclear Factor of Activated T cells) late maturation
- GATA-3
- TCF-1 (T cell factor 1)
- NFκB (progenitors and late maturation)

Mast cell
- $GATA\text{-}2^{+}$
- Elf-1
- MITF (microphthalmia-associated transcription factor)

Eosinophilopoiesis
- STAT1, STAT3, STAT5a, STAT5b
- GATA-1

[a]All transcription factors are involved in early lineage commitment and exert their effects on committed progenitors unless otherwise stated.

that appear in lethally irradiated mice reconstituted with HSCs are called splenic colony-forming cells (CFC-Ss), which have limited capacity for self-renewal. Whether similar cells occur in other species is unknown, because CFC-Ss are defined by specific experimental conditions in mice.

HEMATOPOIETIC PROGENITORS AND PRECURSORS

The term *progenitors* typically refers to cells whose presence is inferred from cytokine-driven differentiation of colonies in culture, such as granulocyte–macrophage colony-forming units (CFU-GMs) and erythroid colony-forming units (CFU-Es), whereas the term precursors refers to stages of hematopoietic differentiation recognized by cytologic evaluation. HSCs, oligopotent stem cells, and committed progenitors appear like small lymphocytes, although they can be separated by flow cytometry based on expression of surface proteins.

Toward the right of Figure 4.1, clonogenic cell types exist putatively without any capacity for self-generation. However, mature cell types such as macrophages and mast cells may have substantial self-generative properties. The initial model of hematopoiesis did not include the concept of plasticity.[37] In the current model, the concept of plasticity suggests that lineage fidelity

and progressive restriction of proliferative capacity in the traditional model are not absolute. Plasticity is recognized as a property of both proliferation and lineage commitment. How plasticity is regulated under physiologic and pathologic conditions is not well understood. It is clear though that neither HSC nor any of the oligopotent progenitors have the unlimited capacity for self-generation possessed by embryonic stem cells.

SPECIES SPECIFICITY OF HEMATOPOIESIS

In contrast to detailed information about murine hematopoiesis,[45] there are few detailed descriptions about the structure and function of the bone marrow in domestic species. Stem cell function, the biochemical nature of the bone marrow microenvironment, hematopoietic cytokines and their receptors, and lineage-specific and nonspecific transcription factors are assumed to apply to species other than mice or humans.[30,5] Studies have confirmed some common cytokines between domestic species and humans.[18,33–36,39,47,46] Research involving animal models of human diseases, toxicology, or other unique diseases such as cyclic hematopoiesis in dogs has provided additional information about hematopoiesis in domestic animals.[4,15,29,37] The gene sequences for many hematopoietic cytokines, receptors, and transcription factors for multiple species now are available in publicly accessible databases, so they can be assessed specifically by high-density microarray or more broadly by quantitative reverse transcription polymerase chain reaction (qPCR).[14,16,41]

Certain critical differences exist between human and murine hematopoiesis. Human HSCs express Flt3, the tyrosine kinase receptor for FLT3 ligand, whereas murine HSCs do not.[23] However, both murine and human common lymphoid progenitors (CLPs) express Flt3. Such differences are important because certain human acute myelogenous leukemias are associated with constitutive activation of Flt3.[9] Whether other species express similar mutations governs the potential utility of therapy with Flt3-kinase inhibiting drugs. Although the hierarchical relationships observed in murine hematopoiesis are generally preserved in other species (Figure 4.1), expression of a number of surface antigens at each developmental stage is different between mice and humans, and these and other differences may occur in other species. However, important similarities also have been recognized. Based on the recent molecular and genetic understanding of cyclic neutropenia in Gray Collie dogs and cyclic hematopoiesis in humans, some features of hematopoiesis appear similar. For example, allometric scaling correctly predicts granulopoietic cyclicity in mice (3 days), dogs (14 days), humans (19–21 days), and elephants (60 days).[4,37]

THE BONE MARROW MICROENVIRONMENT

The heterogeneous cellular elements in Figure 4.1 are intimately associated with adipocytes, macrophages, endothelial cells, nerves, osteoclasts, osteoblasts, ECM, sinusoids, and cytokines, collectively termed the bone marrow microenvironment. Cell–cell and cell–ECM interactions are important in the regulation of cell proliferation and differentiation of hematopoietic cells.[11] These interactions involve receptors and integrins, which are regulated by growth factors, cytokines, and transcription factors. The ultrastructure of the interactions between hematopoietic cells, stromal cells, and noncellular components of the bone marrow microenvironment was described in detail in 1978,[38] but the molecular mechanisms have more recently been characterized.

The best characterized integrin on HSC is very late antigen 4 (VLA-4 or α4 β1) which binds to fibronectin in the ECM as well as to vascular cellular adhesion molecule 1 (VCAM-1) on adjacent stromal cells. The binding of VLA-4 to fibronectin mediates adhesion of HSC and progenitors to the microenvironment, homing of circulating HSC and progenitors to specific areas within the bone marrow, and signal transduction. The Rho guanosine triphosphatases (GTPases), Ras-related C3 botulinum toxin substrate 1 (Rac1), and Rac2 also are key regulators of adhesion and migration of cells in the hematopoietic microenvironment.

The bone marrow microenvironment has highly specialized and integrated microanatomic functional units called niches. The two most clearly elucidated hematopoietic niches are the HSC niche (see Chapter 3) and the erythroblastic islands (Figures 4.2 and 4.3).[1]

The Hematopoietic Stem Cell Niche

Survival, proliferation, and differentiation of HSCs depend on their spatial and functional relationships with the cells and ECM of the microenvironment.[38] HSCs are enriched at sites adjacent to the endosteal surface of bone. A specialized subset of activated osteoblasts display ligands and receptors that facilitate homing and transient docking of HSC, and regulate slow cycling or rapid mobilization of HSCs as needed.[1] The interaction between stromal-derived factor 1 (SDF-1 or CXCL12) elaborated by osteoblasts and CXC chemokine receptor 4 (CXCR4), its cognate chemokine receptor on HSC, is central to this HSC niche. SDF-1 recruits quiescent progenitors, participates in their cycling and survival, and sensitizes them to further synergistic action of cytokines, thus contributing to hematopoietic homeostasis under both physiologic and stress conditions. HSC function also is regulated by osteoblasts through parathyroid hormone (PTH), the Notch signaling pathway, and interactions between angiopoietin 1 (Ang1) and its tyrosine kinase with immunoglobulin-like and EGF-like domains 2 (Tie2) receptor.[6] Disruption of this HSC niche may result in abnormal cell mobilization and contribute to extramedullary infiltration in leukemia.

The Erythropoietic Niche

Erythropoiesis occurs in distinct niches called erythroblastic islands that consist of a central macrophage surrounded by a ring of developing erythroblasts in

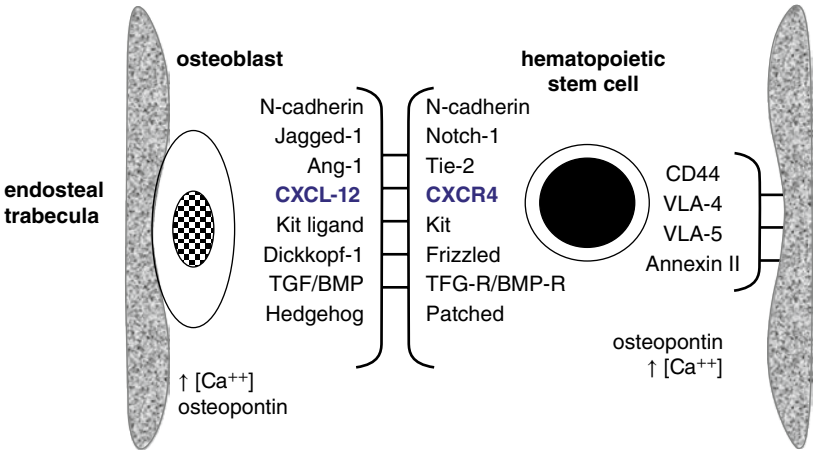

FIGURE 4.2 Hematopoietic stem cell niche (reciprocal molecular interactions). The relationship between a specialized subset of osteoblasts and the hematopoietic stem cell is shown, with reciprocal molecular interactions depicted between the two cell types, and between these cell types and endosteal bone.

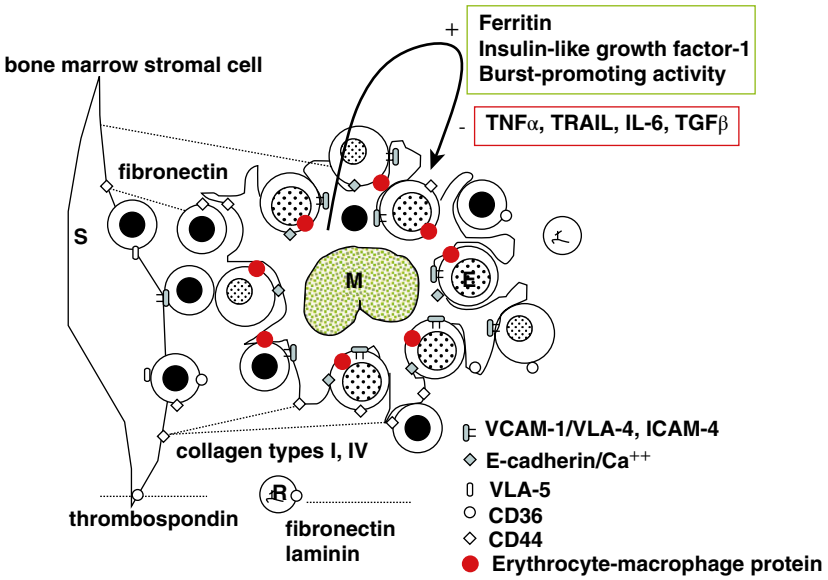

FIGURE 4.3 The erythropoietic niche. The erythroblastic island is illustrated with rubriblasts of graded levels of maturity surrounding macrophage (M) cytoplasm. Specific molecular interactions between macrophages and rubriblasts, between the erythroblastic island and marrow stromal cell(s), and of all these cellular elements with marrow stroma are shown. Autocrine cytokine loops involved in stimulation of erythropoiesis (green bordered box) and in the negative regulation of erythropoiesis (red bordered box) are shown. Dotted lines indicate extracellular matrix components. Arrow indicates factors elaborated by macrophages that influence growth and maturation of rubricytes.

bone marrow, fetal liver, and spleen, and even in long-term marrow cultures.[22] The macrophage contributes important signals to developing rubriblasts, phagocytoses-expelled metarubricyte nuclei, and transfers iron to developing rubriblasts. Unlike megakaryocytes that localize exclusively to marrow sinusoids, erythroblastic islands are located throughout the marrow.[11]

Adhesion molecules mediating important structural and functional interactions between developing erythroid cells and central macrophages include VCAM-1/VLA-4, α4β1/VLA-4, intercellular adhesion molecule-4 (ICAM-4)/αv, and E-cadherin. For example, ICAM-4 is postulated to enable reticulocytes to detach from central macrophages, allowing them to enter the circulation.[11] Laminin and fibronectin and their receptors expressed on late-stage rubriblasts also are key components in the differentiation of reticulocytes. VLA-4 and VLA-5 are involved in binding of erythroid burst-forming units (BFU-Es) to hematopoietic stromal cells. Expression of these adhesion molecules is highest on BFU-Es and CFU-Es, and is progressively lost during erythroid maturation. Hemonectin and collagen type I support binding of BFU-Es in vitro, and a role for tenascin-C has been inferred from knockout mice. Hemonectin is absent from anemic mice with Kit ligand or c-*kit* deficiency.

The surface antigen cluster differentiation 44 (CD44) is highly expressed on almost all hematopoietic cells in bone marrow and is responsible for interaction of these cells with collagen types I and IV, fibronectin, and hyaluronate.[53] Reticulocytes express only low levels of a few surface adhesion receptors, such a CD36 (thrombospondin receptor) and VLA-4. Thrombospondin serves as an adhesive ligand for committed progenitors including colony-forming units granulocyte, erythroid, monocyte, megakaryocyte (CFU-GEMM), and BFU-E. Adhesion molecule interactions of reticulocytes with bone marrow stromal cells and ECM may facilitate their egress into bone marrow sinuses. Mature RBCs do not express adhesion molecules under normal conditions.

CYTOKINES AND CYTOKINE SIGNALING IN HEMATOPOIESIS

Hematopoiesis is the cumulative result of intricately regulated signaling pathways mediated by soluble cytokines and their receptors (Table 4.2).[2] Evaluation of cytokine–receptor interactions in hematopoiesis has largely been achieved through creation of gene-deleted mice and conditional knockout mice, the phenotypes of which range from severe lethal embryonic, fetal, and neonatal defects to redundant null phenotypes.[8] These mice have provided much of our current insight into the regulation of physiologic and pathologic alterations in hematopoiesis.

Most hematopoietic cytokine receptors are multiple subunit complexes, except for those that signal through a single chain, such as erythropoietin (EPO), granulocyte–macrophage colony-stimulating factor (GM-CSF), and thrombopoietin (TPO). Hematopoietic cytokines are approximately 200 amino acids in length and carry a conserved sequence of tryptophan–serine–X–tryptophan–serine (W–S–X–W–S) in their extracellular domain, which functions as part of the ligand-binding domain.

Cytokine receptors contain docking regions for Janus tyrosine kinases (JAK1, JAK2, JAK3, TYK2) in their cytoplasmic termini that, when attached to the ligand-bound form of the cytokine receptor, recruit JAKs which then autophosphorylate. The JAK kinase then phosphorylates tyrosine residues on a specific signal transducer and activator of transcription (STAT) protein, which is STAT1, 3, or 5 for most hematopoietic cytokine receptors. JAKs contain a catalytic Janus homology (JH) 1 domain and a JH2 catalytic-like but inactive domain critical to the ability of JAKs to regulate themselves and to mediate cytokine-induced responses. Src kinase activation of STATs also is important for myeloid cell proliferation.

In unstimulated cells, STATs are present as cytoplasmic monomers in the unphosphorylated state. Phosphorylation by JAK kinases leads to dimerization through reciprocal interactions of SH2 domains with phosphotyrosine residues, and thereby activation of STAT, which then translocates to the nucleus.[20] STATs are transcription factors that prevent apoptosis or positively regulate prosurvival genes of late progenitor and early precursor cells.[20] Although there are numerous STAT responsive genes in many different cell types, STAT regulation of hematopoietic precursors occurs in a cell-type restricted manner.

Lineage-committed colony-forming cells respond to cytokines in a lineage-restricted fashion. The specificity of hematopoietic cytokines is determined by progenitor and precursor cell expression of their cognate receptors. For example, rubriblasts express EPO receptors but myeloblasts do not, which is different from the relatively promiscuous expression of JAK/STAT pathways. Given the importance of JAK-phosphorylation events in driving proliferation of hematopoietic precursors, it is not surprising that mutations leading to constitutively active JAK2 result in myeloproliferative disorders and leukemia. In addition to the prominent role of JAK–STAT interactions in hematopoiesis, the functional involvement of Ras and phosphoinositol 3 kinase (PI3K) pathways also has been shown following interleukin (IL)-3/IL-5 and GM-CSF stimulation of bone marrow cultures in vitro.[2]

TABLE 4.2 Hematopoietic Cytokines.[a]

Lineage/Function	Key Hematopoietic Cytokine
Early hematopoiesis	Stem Cell Factor (SCF) Interleukin 3 (IL-3) Wnt ligands (Jagged) and receptors Kit ligand SDF-1/FGF-4
Common myeloid progenitor/ myelopoiesis	Stem cell factor (SCF) Thrombopoietin (TPO)
Erythropoiesis	Erythropoietin (EPO)
Megakaryocytopoiesis	Thrombopoietin Interleukin-6 (IL-6)
Lymphocytopoiesis T cells NK cells B cells	IL-7 IL-7, IL-2 IL-7, IL-15 IL-4
Regulatory	Transforming growth factor-β (TGF-β) Bone morphogenetic protein (BMP) Activin

[a]Note that this table oversimplifies the actions of these cytokines. With further refined analyses of murine models it has become apparent that even lineage restricted cytokines such as EPO exert pleiotrophic effects within and external to the hematopoietic system.

Negative Regulation of JAK–STAT Signal Transduction

Suppressors of cytokine signaling (SOCSs) are a family of proteins that regulate the strength and duration of the hematopoietic cytokine-driven signaling cascade.[51] They are transcriptionally induced by JAK–STAT signaling. SOCS proteins contain src homology (SH) 2 domains and a SOCS-box which mediate binding to cytokine receptors and associated JAKs, and attenuate signal transduction directly. In addition to their transcriptional induction by hematopoietic cytokines and subsequent self-limiting stimulation of hematopoiesis, other cytokines including tumor necrosis factor-α (TNF-α), IL-1, and toll-like receptor ligands (e.g., lipopolysaccharide) also induce SOCS expression, providing negative regulation for granulocyte colony-stimulating factor (G-CSF) signaling. Another level of regulation is provided by phosphatases. The signaling and subsequent hematopoiesis induced by phosphorylated dimers of STAT proteins is terminated by removal of phosphates from STAT tyrosines by three specific protein tyrosine phosphatases.

Transforming growth factor-β (TGF-β) is perhaps the most potent endogenous negative regulator of hematopoiesis.[28] TGF-β suppresses expression of the stem cell factor (SCF) receptor, the response of progenitors to SCF,

and cell cycle progression of progenitors. The expression of receptors for TGF-β on primitive hematopoietic progenitors and subsequent stages of maturation suggests a broad role for this cytokine. Negative regulation of erythropoiesis by TNF-α, TNF-related apoptosis-inducing ligand (TRAIL), IL-6, and TGF-β occurs when chronic inflammatory disease increases systemic and local bone marrow concentrations of these cytokines (see Chapter 39).[11]

EVALUATION OF HEMATOPOIETIC FUNCTION

Hematopoiesis is studied to gain insight into mechanisms of cytopenias, leukemias, and other pathophysiologic responses. Evaluation of hematopoiesis begins with careful examination of peripheral blood and is complemented by cytologic or histologic assessment of bone marrow. Short- and long-term in vitro culture of bone-marrow-derived cells, genetically modified mice, animal models of retarded and accelerated hematopoiesis, syngeneic and xenogeneic hematopoietic stem cell transplantation, retroviral-mediated gene transfer, and gene therapy also have been used to study hematopoiesis.[52]

Gene-deleted and transgenic mice provide a special challenge to the hematologist because these mice frequently die during the embryonic, fetal, or early neonatal period. Peripheral blood examination may still provide valuable information. A 3 μL volume of heart blood obtained with a fine gauge needle is sufficient to prepare a blood smear; as little as 20 μL of heart blood may be diluted with 2 mg/mL EDTA in saline and analyzed with an electronic counter. Potential artifacts of dilution of small quantities can be overcome by comparing results from treated or genetically altered mice with similarly diluted volumes from control or wild-type mice.

Bone Marrow Evaluation in Mice

Direct examination of bone marrow complements information gained from assessment of blood. In fetal mice, which lack developed medullary hematopoiesis, cytologic examination of liver imprints for hematopoietic precursors is useful in assessing early hematopoietic function.

Evaluation of Hematopoiesis with Bone Marrow Culture

Hematopoietic interactions are best evaluated in vitro where culture systems permit evaluation of effects of individual cytokines, growth factors or their regulators, and combinations of factors. Target gene expression may be transiently induced by gene transfection or inhibited by transfection with antisense RNA. The significance of in vitro studies must be confirmed in vivo. For example, deficiency of hematopoietic cytokines or growth factors which would predictably have severe phenotypes based on in vitro work, such as IL-2 and GM-CSF, has much milder hematologic phenotypes than expected (i.e., failure to develop lymphopenia and neutropenia), underscoring the redundancy and pleiotropy which characterize many of these factors.

Bone marrow cells can be cultured from aspirates or core samples obtained from diseased or healthy animals. These cells are cultured in semisolid methylcellulose-based media with cocktails of cytokines, EPO, transferrin, bovine fetal serum, and albumin. Whereas EPO is active across species and has been cloned from a variety of species, other cytokines have more limited cross-species effects. When a species-specific cytokine is not available, conditioned spleen cell media obtained from phytohemagglutinin, endotoxin, or phorbol-ester-stimulated cells may serve as a useful source of cytokines. Conditions for culture of bone marrow progenitors from dogs, cats, sheep, cattle, horses, chickens, and other species have been described.[17,21,45,49] In general, methodologies applicable to murine and human culture systems apply to those of other species, when care is taken to ensure the quality of collected bone marrow specimens and species-specific reagents or appropriate substitutes are used. Short-term bone marrow cultures from mice, rats, and dogs are routinely performed to assess the potential toxicity of xenobiotics and define hematopoietic phenotypes of genetically altered animals.[45] These culture systems may be used to study hematopoiesis by the addition of individual cytokines, growth factors or their regulators, or combinations thereof. Alternatively, neutralizing antibodies to these components or small molecules (<1000 kDa) produced by medicinal chemistry can be used to dissect regulatory pathways. Similarly, hematopoietic progenitors from clinical cases can be studied in vitro by direct culture following aspiration biopsy. Plasma or plasma components from animals with bone marrow disorders may be added to bone marrow cells of clinically normal animals to study the nature of potential humoral myelosuppressive activities.

Long-term cultures of hematopoietic cells on established stromal cell layers (Dexter cultures) more closely recapitulate the hematopoietic microenvironment and allow long-term survival of pluripotent HSC. These culture systems were used to identify the stromal cell defect (defective SCF production) in Sl/Sl^{d} mouse (Steel anemia) and the complementary defect in W/W^{v} (white spotted) mouse (SCF receptor alternatively known as *c kit*). Long-term bone marrow cultures have been described for dogs[45,44] and sheep.[31]

Lethal Irradiation and Bone Marrow Transplantation

Lethally irradiated mice receiving bone marrow or hematopoietic cells with a capacity for partial or complete renewal of hematopoiesis develop large splenic foci of extramedullary hematopoiesis thought to be initiated by a single pluripotent stem cell. These colonies are grossly visible after 8–14 days, creating hemispherical distortions of the splenic contour which may be visually enumerated.[42] These CFU-S have since been found to represent a multipotent committed progenitor

cell rather than the pluripotent stem cell as originally hypothesized. Irradiation and stem cell transplantation methodologies are described in detail for dogs.[45]

Genetically Altered Mice

Through technology that permits homologous recombination of partially homologous, generally noncoding, genetic sequences in cultured murine stem cells, mice deficient in the protein product of specific target genes can be created. This technology has been extensively exploited to study the function of individual hematopoietic cytokines, growth factors, their cognate receptors, and hematopoietic transcription factors.[41] Without this technology, the study of transcription factors associated with primitive oligopotent progenitors (Tables 4.1 and 4.2) would not have been possible. The hematologic evaluation of mouse embryos or feti is a critical part of the phenotypic assessment of knockout mice. By rendering gene-deleted mice (−/−) transgenic (+/+) for a deficient gene under the control of an inducible or repressible tissue-specific promoter, the function(s) of a gene in adults, for which deletion otherwise results in nonviable feti, can be examined. Using the Cre–loxP system, genes may be removed or reactivated in a tissue-specific manner in the adult mouse.[32]

The development of methods to transplant human hematopoietic cells into severe combined immunodeficient (SCID) mice (SCID-hu) has provided an experimental tool with potential use in modeling leukemias, infectious diseases, autoimmune diseases, and a variety of primary nonneoplastic bone marrow disorders. Potential deficiencies of this model include incomplete cross-species functionality between murine cytokines and cytokine receptors and human receptors and ligands, since the absence of human bone marrow stroma in mice transplanted with human hematopoietic cells creates a chimeric hematopoietic microenvironment. Impaired passage of mature cells into and out of the bone marrow or circulation may occur when adhesion molecules and their receptors on leukocytes, platelets, and endothelial cells fail to recognize their respective murine or human counterparts.

Models of Accelerated Hematopoiesis

Several methods have been used to accelerate hematopoiesis. The intraperitoneal administration of a single 150 mg/kg dose of 5-fluorouracil or appropriate dosing regimen of cyclophosphamide completely depopulates murine bone marrow. Treatment with 5-fluorouracil spares the slowly cycling or noncycling stem cells.[55] Recovery of hematologic parameters is first detectable 5 days post-treatment, with complete recovery occurring after 15–20 days. This model has been used extensively to study accelerated hematopoiesis in gene-deleted mice with apparently normal basal hematopoiesis or in mice treated with agents that do not alter basal hematopoietic function. In this manner, the immunosuppressive rapamycin was shown, by virtue of its ability to inhibit signal transduction of a variety of proliferation-inducing cytokines, to have potential liability when administered in concert with cytotoxic agents.[43] Accelerated erythropoiesis is readily induced in rodents by a single 60 mg/kg intraperitoneal injection of phenylhydrazine. This regimen produces Heinz body hemolytic anemia with approximately 30% decrease in hematocrit after 2 days and a robust reticulocytosis by 5 days post-treatment.[50] Alternatively, a fixed volume of blood (up to 3% of body weight) can be removed from a rodent and replaced with intraperitoneal saline, stimulating erythropoiesis. To mobilize granulocytes and accelerate granulopoiesis, Bacto Tryptone (a potent chemotactic casein digest, 1 mL of a 10% solution) is administered intraperitoneally. A similar effect is achieved with intravenous G-CSF, which generally is species cross-reactive, at a dose of 5 μg/kg.[3]

Lessons learned from the evaluation of hematopoiesis in genetically altered rodents may be extended to the study of hematopoiesis in domestic species and provide a better understanding of dysregulation in primary diseases of bone marrow. The availability of specific reagents for domestic species and accessibility to bone marrow culture, flow cytometry, and PCR technologies permit increasingly sophisticated examination of bone marrow function, providing greater insight into abnormalities recognized by traditional hematologic methods.

Clonal Hematopoiesis

Hematologic malignancies are believed to result from the progressive and gradual accumulation of mutations within HSCs. The identification of common mutations in specific hematologic malignancies allowed for the large-scale genomic analysis of peripheral blood DNA from healthy individuals. These studies have identified age-related, leukemia-associated genetic mutations within healthy individuals, a phenomenon referred to as clonal hematopoiesis or clonal hematopoiesis of indeterminate potential (CHIP).[25]

Early clues to the existence of CHIP were provided by studies using X chromosome inactivation-based assays (see Chapter 62). These studies identified clonally skewed peripheral blood leukocytes (as evident by nonrandom X-allele inactivation) in 20–25% of healthy women greater than 60 years of age, which was much more frequent than younger women.[7,10] The identification of these cells contributed to the development of a stepwise model of leukemogenesis, which was subsequently supported through the identification of preleukemic HSCs (harboring initiating, but not late mutations) in humans with chronic lymphocytic leukemia (CLL) and acute myeloid leukemia (AML).[54,27,13,26,12,48] Subsequent genomic-mining studies have identified numerous mutations, including copy number alterations and deletions, in the peripheral blood of aged people. These mutations are rare in people under the age of 40 (<1%), but affect 10–20% of people in their eighties.[25] Moreover, clonal hematopoiesis is associated with an increased risk of developing a hematologic malignancy, as reflected by hazard ratios of 11.1 and 12.9 in two longitudinal studies of overly 14,000 people.[24,19]

The clinical implications of CHIP have yet to be fully defined. Beyond the gradually evolving risk of development of a hematologic malignancy (which is approximately 0.5–1% per year), patients in which clonal hematopoiesis was identified had an association with non-neoplastic diseases, including cardiovascular disease.[24] In one analysis of over 17,000 individuals, people with CHIP were at a higher risk of coronary heart disease and ischemic stroke.[24] Although the importance of CHIP in veterinary patients is uncertain, particularly given the comparatively shorter life of domestic animals, advances in the hematopoietic neoplasm diagnostic toolkit may open opportunities for comparative research.

Experimental Advances and Clinical Relevance

Acronyms and Abbreviations

Ang1, angiopoietin-1; BMP, bone morphogenetic protein; CD, cluster of differentiation; CXCR, CXC chemokine receptors; Dhh, desert hedgehog, EPCs, endothelial progenitor cells; FAK, focal adhesion kinase; FGF, fibroblast growth factor; G-CSF, granulocyte colony-stimulating factor; GDF, growth and differentiation factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; HGF, hepatocyte growth factor; Hh, hedgehog; HUVEC, human umbilical vein endothelial cell; Ihh, Indian hedgehog; iPSC, induced pluripotent stem cell; KDR, kinase insert domain receptor; MAPK, mitogen-activated protein kinase; PBMC, peripheral blood mononuclear cell; PI3K, phosphatidylinositol 3-kinase; PKB, protein kinase B; PKC, protein kinase C; PKD, protein kinase D; PlGF, placental growth factor; Sca1, stem cell antigen 1; SDF-1α, stromal-derived growth factor-1α; Shh, sonic hedgehog; TGF-β, transforming growth factor-β; TGFβR, transforming growth factor-β receptor; Tie-2, angiopoietin receptor-2; VEGF, vascular endothelial growth factor.

The vasculature is a specialized organ where a number of essential homeostatic functions, including the transport of oxygen and nutrients, are maintained throughout the body. Vasculogenesis is the de novo formation of vessels that establishes the vasculature. It specifically refers the production of new blood and lymphatic vessels via the recruitment of bone-marrow-derived progenitor cells that have an endothelial differentiation capacity (i.e., endothelial progenitor cells; EPCs). By contrast, angiogenesis is the generation of new vessels from endothelial cells through the sprouting of a pre-existing vascular network. Although vasculogenesis and angiogenesis are distinct, vessel formation may occur simultaneously through a combination of both processes. Vasculogenesis is the mechanism of vascular formation in the developmental stage of embryos and in adult tissues, and it is further characterized as prenatal or postnatal vasculogenesis. The first half of this chapter focuses on the roles of bone-marrow-derived EPCs in postnatal vasculogenesis and the remainder addresses the phenotypical identification of EPCs and their signaling pathways.

ENDOTHELIAL PROGENITOR CELLS

Phenotypic Determinants

EPCs are a unique population that is able to differentiate into endothelial cells and contribute to the formation of new vessels. Putative EPCs were first identified as circulating progenitor cells for endothelial lineage differentiation in adult human peripheral blood in the late nineties.[2] Since then, distinct EPC populations have been isolated and the phenotypical and functional characterization of this population has become clearer. EPCs give rise to functional endothelial cells; thus, those progenitor cells are expected to display an upregulation of endothelial cell surface markers and a downregulation of hematopoietic markers during differentiation. However, the definitive identification and characterization of EPCs still remain challenging due to a lack of definite surface markers. To overcome this limitation, a panel of surrogate markers is used to identify cells that show the vasculature-forming properties of EPCs.

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.

Putative circulating EPCs were first identified as such based upon their expression of cluster of differentiation (CD)34 (Flk-1 in the mouse) and kinase insert domain receptor (KDR) and their capacity to differentiate into cells expressing high levels of endothelial antigens, such as CD31, angiopoietin receptor-2 (Tie-2), and E-selectin.[2] Later, circulating EPCs were further defined as CD45– and CD34+ cells that express either CD133 or KDR.[19] In addition, EPCs appear to express a variety of cell surface markers similar to those that characterize vascular endothelial cells, such as CD31 and Tie-2.[13] Despite these findings, the identification of specific EPC markers has proven challenging because:[9,15] (1) hematopoietic cells and endothelial cells originate from a common progenitor (i.e., hemangioblast); (2) the two share a panel of antigens in both embryonic and adult stages; (3) marker validation is difficult, as in vitro EPC culture is not standardized; and (4) EPCs are dynamic and readily transit between endothelial and hematopoietic progenitors depending on their local niche. Hence, other sophisticated molecular approaches, such as global gene expression profiling, or a combination of in vitro and in vivo functional assays, are necessary for the clear identification of these populations.[26]

Murine EPCs are thought to originate from bone marrow, and the expression of a combination of multiple markers including stem cell antigen 1 (Sca1), cKit, Flk-1, CD31, Tie-2, CXCR4, CD133, and CD144 expression is used to enrich for these cells.[3,10] Circulating murine EPCs might present myeloid and pro-angiogenic properties, and resident EPCs have been isolated from rat lung tissue displaying neovasculogenic capacity. In domestic animals, putative EPCs have been suggested to be isolated from canine peripheral blood mononuclear cells (PBMCs).[14,25] Since there is a variety of antigenic determinants across animal species, determining a panel of specific markers that allows the identification and enrichment of species-specific EPCs remains a focus in the field.

Mobilization, Recruitment, and Homing

EPCs originate from the bone marrow, but can also be found circulating in peripheral blood.[2] EPCs are mobilized from bone marrow to sites where they play an important role in physiological and pathological production of new vessels. This includes vasculogenesis in ischemic tissues, during wound healing and during vascular repair, as well as disease-associated vascuologeneis as occurs in cancer, diabetic retinopathy, and retinopathy of prematurity. EPCs contribute to vasculogenesis through two fundamental mechanisms: they incorporate directly into damaged endothelium to form a functional vessel, and they secrete proangiogenic factors that have a paracrine effect on the residual endothelial cells to recover the vessel. The mobilization of EPCs that reside primarily in the bone marrow is initiated when tissue damage occurs. The affected tissue secretes pro-angiogenic factors, such as vascular endothelial growth factor (VEGF), angiopoietin-1 (Ang1), stromal-derived growth factor-1α (SDF-1α), and granulocyte–macrophage colony-stimulating factor (GM-CSF),[7] inducing the recruitment and homing of EPCs. Subsequently, EPCs may continue recruitment via their own release of VEGF, hepatocyte growth factor (HGF), granulocyte colony-stimulating factor (G-CSF), and GM-CSF.

GROWTH FACTORS AND SIGNALING PATHWAYS

Vasculogenesis is a complex process that is mediated by the orchestration of multiple cell types with growth factors and signaling pathways to sustain the vascular system. This section provides a brief introduction to the key signaling molecules that are essential for endothelial cell function and vasculogenesis.

Vascular Endothelial Growth Factors

VEGF is one of the main factors that contributes to vasculogenesis. The VEGF family is composed of a number of secreted polypeptides, including VEGF-A, -B, -C, -D, and placental growth factor (PlGF). The three main receptors that interact with VEGFs are VEGFR-1 (Flt-1), VEGFR-2 (KDR in humans and Flk-1 in mouse), and VEGFR-3 (Flt-4 in mouse). VEGF receptors are tyrosine kinase receptors and are composed of an extracellular domain responsible for VEGF binding and intracellular tyrosine kinase domain. Embryonic lethargy with vascular defects occurs in VEGF-, VEGFR-1-, and VEGFR-2-deficient mice,[6,17,22] confirming that these molecules are necessary for the initiation of vasculogenesis and embryonic development. VEGFR-3 appears to play a major role in lymphatic vessel development; however, its precise role in blood vessel formation is unclear. To activate intracellular signaling, VEGF ligands are required to bind to their respective tyrosine kinase receptors. This interaction induces homodimerization or heterodimerization of the receptors, kinase phosphorylation, and the induction of downstream signaling events that regulate the migration, differentiation, proliferation, and survival of endothelial cells. VEGF-induced signaling may trigger multiple pathways involving mitogen-activated protein kinase (MAPK), protein kinase B (PKB or AKT), protein kinase C (PKC), protein kinase D (PKD), phosphatidylinositol 3-kinase (PI3K), and focal adhesion kinase (FAK).[18] Neuropilin, which is a transmembrane glycoprotein, can also bind to the VEGFs as a coreceptor for the VEGFRs. The binding of VEGFs to neuropilin induces intracellular signal transduction, although it is unclear whether neuropilin is sufficient for independent signaling.[11] Neuropilins are expressed in endothelial cells and participate in vasculogenesis.

Transforming Growth Factor-β

The transforming growth factor-β (TGF-β) family is an enormous group of more than 30 structurally related proteins including TGF-β1, TGF-β2, TGF-β3, bone

morphogenetic protein (BMP), growth and differentiation factor (GDF), and activin. TGF-β receptors (TGFβRs) involved in signal transduction are classified as type I and type II receptors.[12,21] TGF-β signaling is dependent on Smad proteins and can be divided into four steps: (1) ligand binding to TGFβRII, (2) TGFβRI recruitment and formation of a heterotetrameric TGFβRI–TGFβRII complex, (3) phosphorylation of Smad proteins, and (4) translocation of the Smad complex to the nucleus. The TGF-β is expressed in endothelial cells, and TGF-β signaling plays a crucial role in the regulation of endothelial cell differentiation, the establishment of the vascular network, and the maintenance of vessel wall integrity.[20] The functional effects of TGF-β on endothelial cells vary due to the complexity of TGF-β signaling; thus, its precise roles in different contexts remain to be elucidated.

Fibroblast Growth Factors

Fibroblast growth factors (FGFs) are also key factors in vascular development and maintenance. The FGF family of ligands consists of 18 peptide members (FGF1–10 and FGF16–23), including five paracrine subfamilies and one endocrine subfamily. These 18 protein molecules activate FGF receptors (FGFRs) of tyrosine kinases,[4] whereas the FGF homologous factors previously known as FGF11–14 are unable to induce this signal transduction. The majority of FGFs and FGFRs are expressed in endothelial and vascular smooth muscle cells, where activation of FGF signaling stimulates growth and migration of the cells.[1] FGF signaling contributes to vascular homeostasis and vascular permeability by maintaining endothelial barrier function and integrity.[16]

Hedgehog Signaling

The hedgehog family includes sonic hedgehog (Shh), Indian hedgehog (Ihh), and desert hedgehog (Dhh). Hedgehog (Hh) signaling is essential for blood island formation during yolk sac vessel development[8] and for endothelial tube formation at various stages of development in avian and murine embryos.[24] Furthermore, Hh signaling contributes to the production of vascular growth factors by stimulating endothelial cells and cells supporting blood vessel.[5]

EXPERIMENTAL ADVANCES AND CLINICAL RELEVANCE

EPCs and endothelial cells have been isolated from peripheral blood; however, there are several limitations of such isolation. These limitations include the low yield, a low efficiency, difficulty in expansion, and source-dependent heterogeneity. Potential approaches to overcome these challenges include the reprograming of induced pluripotent stem cells (iPSCs). The use of iPSCs offers a powerful tool for multipurpose research and disease modeling, including cancers, immune diseases, and a variety of bone marrow disorders. Recent advances suggest that reprogramed iPSCs are able to differentiate substantial numbers of endothelial cells with consistent outcomes.[23] This approach also benefits from the easy access to source material, such as PBMCs and human umbilical vein endothelial cells (HUVECs). iPSC-derived endothelial cells have similar functional properties to natural endothelial cells and express endothelial markers, such as CD31 and CD144. A better understanding of the precise roles of EPCs and endothelial cells is necessary for the development of therapeutic interventions in vascular disorders. Since EPCs and circulating endothelial cells have been identified in pathological conditions, a better understanding of these cells is also important to define molecular mechanisms that regulate the mobilization, recruitment, and incorporation of EPCs, as well as to develop safe and efficient EPC therapies.

In the veterinary field, lessons learned from the differentiation of EPCs in vitro may be extended to studies on domestic and other species, providing a novel and better strategy to research vascular disorders, such as malignant vascular tumors (e.g., hemangiosarcoma) and cardiovascular diseases. Furthermore, the development of specific reagents for animal species and experimental applications could lead to a sophisticated assessment of the functions of EPCs.

CHAPTER 6

Cluster of Differentiation (CD) Antigens

MELINDA J. WILKERSON and NORA L. SPRINGER

Definition and History
Structure and Integration of Membrane Antigens
Transmembrane Proteins
  Single-Pass Type I Transmembrane Protein (I)
  Single-Pass Type II Transmembrane Protein (II)
  Multipass Transmembrane Protein (III)
  GPI Transmembrane Protein (V)
Tissue Distribution

Acronyms and Abbreviations

BCR, B cell receptor, CD, cluster differentiation; CLAW, Canine Leukocyte Antigen Workshop; ER, endoplasmic reticulum; FIV, feline immunodeficiency virus; GP, glycoprotein; GPI, glycosylphosphatidylinositol; Ig, immunoglobulin; IL, interleukin; LPS, lipopolysaccharide; MAb, monoclonal antibody; MDR-1, multidrug resistance transporter protein-1; MHC, major histocompatibility complex; NK, natural killer; TNFR, tumor necrosis factor receptor, VLA, very late antigen.

DEFINITION AND HISTORY

Cluster differentiation (CD) nomenclature was first introduced at an international conference in Paris (1982) during the boom in monoclonal antibody (MAb) technology.[2] This nomenclature was established to standardize the classification of cell surface antigens and to define the biological functions of molecules expressed by various hematopoietic lineages. Several international workshops have been held to exchange human and other species-specific MAbs and to compare their reactivity with cells and cell proteins from veterinary species.[8,16,19,24-26,29,30]

Based on these workshops, MAbs that have similar reactivity with tissues or cell types are assigned to a cluster group. Therefore, an antigen that is recognized by a cluster of MAbs is assigned a "cluster of differentiation" (CD) number. If MAbs defining a cluster of antigens are derived from the same laboratory, the suffix "w" is appended to the CD designation. Only eight CD antigens are internationally accepted as defined by the 1st Canine Leukocyte Antigen Workshop (CLAW) and include the following homologs to the human system: CD4, CD5, CD8, CD11a/18, CDw41, CD44, CD45, and CD45R.[8] The final meeting of the 8th Human Leukocyte Differentiation Antigen (HLDA) Workshop was held in December 2004, in Adelaide, Australia, and 376 MAbs from various companies, mainly directed against human leukocytes, were tested for their reactivity with cells from 17 different animal species. A special issue of the journal "Veterinary Immunology and Immunopathology" described these efforts.[24] Now, the efforts of the Human Cell Differentiation Molecules (HCDM) organization are focused on understanding the intracellular molecules involved in immune cell reactions with their environment (endothelial cells and stromal cells). Furthermore, the group is working toward aligning CD nomenclature to gene nomenclature. The HCDM website (http://www.hcdm.org/) includes a list of CD molecules and many useful links including new CD antigens defined in the 9th and 10th HLDA workshops.

Today, there are over 371 CD molecules defined (http://www.hcdm.org/index.php/molecule-information). This explosion in CD molecules is the result of the use of molecular biology techniques to identify new molecules. The purpose of this chapter is to provide the most current listing of CD antigens recognized by various antibodies in veterinary species. Table 6.1 summarizes the current knowledge of important veterinary CD antigens having MAb clones that react with dog, cat, horse, cattle, and pig CD antigens;

TABLE 6.1 Cluster differentiation antigens.

CD antigen	MAb reactivity	Topology	Cellular distribution	Physiology
CD1	Porcine[a] Canine[a] Feline[39]	I	Dendritic cells, macrophages, monocytes, and thymocytes	CD1 is a member of the immunoglobulin superfamily. Presents lipid antigens to T cells
CD2	Bovine[a] Equine[a]	I	T cells, NK cells	Enhances adhesion between T cells and antigen-presenting cells
CD3	Canine[a] Bovine[a] Porcine[a,b]	I	T cells	A family of proteins that forms a signal transduction complex for T-cell receptor when it binds antigen
CD4	Canine[a,b,c] Feline[a,b,c] Equine[a] Bovine[a,b] Porcine[a,b]	I	T cells, canine neutrophil	Receptor for MHC class II; facilitates recognition of peptide antigens
CD5	Canine[a] Feline[a,b] Equine[a,b] Porcine[a]	I	T cells	Receptor for CD72, facilitates signals transduced by T-cell receptor for antigen
CD8	Canine[a,b,c] Feline[a,c] Equine[b] Bovine[a,b] Porcine[a,b]	I	T cells	Receptor for MHC class I; facilitates recognition of peptide antigens
CD8 alpha	Canine[21] Feline[28] Equine[34] Bovine[a] Porcine[a]	I	Thymocytes, T cells	Forms a heterodimer with CD8β receptor for MHC class I; facilitates recognition of peptide antigens
CD8 beta	Canine[21] Feline[28] Equine[34] Porcine[a,b]	I	T cells	Forms a heterodimer with CD8α (see in the earlier text)
CD9	Feline[b] Equine[b] Bovine[b] Porcine[b]	III	Activated lymphocytes, monocytes, lymphocytes, granulocytes, platelets	Important for signal transduction, cell activation, adhesion, aggregation; coreceptor for FIV; associates with tetraspan superfamily (CD63, CD81, CD82)
CD11a	Canine[10] Equine[a] Porcine[a]	I	Monocytes, granulocytes, lymphocytes	Associates with CD18 to form a heterodimner receptor to facilitate adhesion
CD11b	Canine[a,c] Feline[b] Equine[c] Bovine[a]	I	Granulocytes, monocytes, lymphocyte subset	Associates with CD18 to form a heterodimer receptor to facilitate adhesion
CD11c	Canine[a]	I	Dendritic cells, granulocytes, macrophages, lymphocytes	Associates with CD18 to form a heterodimer receptor to facilitate adhesion
CD11d	Canine[a]	I	CD8+ T cells, γδ− T cells, macrophages in splenic red pulp	Associates with CD18 to form a heterodimner receptor to facilitate adhesion
CD13	Equine[a,b] Bovine[a]	II	Granulocytes and monocytes	Aminopeptidase N, a metalopeptidase in humans which removes NH_2 terminal amino acids from peptides
CD14	Canine[a] Feline[b] Equine[c] Bovine[a,b] Porcine[a,b,c]	V	Monocytes, myeloid cells	Receptor for lipopolysaccharide that transduces signals, leading to oxidative burst and proinflammatory cytokine synthesis
CD16	Feline[35] Equine[23] Porcine[a]	V	Granulocyte, monocyte, lymphocyte (natural killer cells)	A low-affinity receptor for the Fc region of aggregated IgG (FcγRIII)
CD18	Canine[a] Feline[a,b] Equine[a] Bovine[a] Porcine[a,b]	I	All leukocytes	Beta subunit of the integrin heterodimer and combines with the alpha subunit of either CD11a, CD11b, CD11c, or CD11d; plays a role in adhesion to endothelium

TABLE 6.1 (Continued)

CD antigen	MAb reactivity	Topology	Cellular distribution	Physiology
CD20	Canine[13] Feline[b]	III	B lymphocytes	Intracellular calcium signaling
CD21	Canine[a] Feline[a,b] Bovine[a,b] Porcine[a,b]	I	B cells, monocytes, follicular dendritic cells	Receptor for C3d fragment and CD23; enhances B cell antigen receptor signal transduction
CD25	Canine[a,c] Bovine[a] Porcine[a]	I	Mitogen stimulated T or B lymphocytes, regulatory T cells, lipopolysaccharide (LPS) stimulated monocytes	IL2-receptor-alpha subunit
CD26	Bovine[a]	II	T cells, dendritic cells	Dipeptidyl peptidase 4, activation molecule for T lymphocytes
CD27	Porcine[a,b]	I	monocytes	Ligand for CD70, costimulatory and proinflammatory
CD28	Canine[38] Bovine[a,b]	I	T cells, thymocytes, NK subset	Ligand for CD80 (B7-1) and CD86 (B7-2), and is a potent costimulator of T cells Signaling through CD28 augments IL-2 and IL-2 receptor expression, as well as cytotoxicity of CD3-activated T cells
CD31	Porcine[a,b,c]	I	Endothelial cells, platelets, leukocytes	Platelet–endothelial adhesion molecule
CD34	Canine[a,c] Porcine[c]	I	Lymphohematopoietic stem cells and progenitors, endothelial cells	Leukocyte–endothelial interactions through binding with CD62L and CD62E
CD40	Bovine[a]	Tumor necrosis factor receptor (TNFR)	B lymphocytes, subset of T lymphocytes	Differentiation of B lymphocytes into effector cells, and is also involved in interactions between T and B lymphocytes
CD41	Canine[a] Feline[a,b]	I	Platelets, megakaryocytes	Integrin αIIB CD41/CD61 complex, receptor for fibrinogen
CD42b	Canine[11] Feline[33]	I	Platelets	GPIb, vWF receptor, platelet activation
CD44	Canine[a,b,c] Feline[b] Equine[a,b,c] Bovine[a] Porcine[a,b,c]	I I	Most cell types including epithelial cells, activated T cells	Receptor for hyaluronate that facilitates lymphocytic binding to high endothelial venules
CD45	Canine[a,b] Bovine[a] Porcine[a]	I	Pan-leukocyte	Membrane-bound tyrosine phosphatase critical for antigen-receptor-mediated activation of leukocytes
CD45RA	Canine[7,8,36] Porcine[a,b]	I	Naïve T/B lymphocytes	Largest of the CD45 isoforms; predominant CD45 isoform expressed on B cells
CD45RB	Bovine[b]	I	Naïve T/B lymphocytes	Predominantly expressed on T cells
CD45RC	Porcine[a]	I	CD4 T cells, gamma delta thymocytes	
CD45RO	Bovine[b]	I	Memory T cells	
CD47	Canine[a] Porcine[a,b]	III	Lymphocytes, macrophages, granulocytes	Associates with CD61 integrins to form receptor for thrombospondin; role in chemotaxis and adhesive interactions with leukocytes and endothelial cells
CD49d	Feline[3,20] Canine Porcine[a]	I	Lymphocytes, macrophages, granulocytes	Very late antigen (VLA) binds with 39CD29; binds fibronectin and mucosal addressin
CD49f	Bovine[c] Porcine[a,b]	I	Macrophages, granulocytes	VLA antigen binds to CD29 and together is the fibronectin receptor and binds to RGD sequence of fibronectin
CD56	Canine[26] Feline[27]	I or V	Subset of lymphocytes	Homotypic adhesion and natural killer cell cytotoxicity
CD61	Canine[a] Feline[a,b] Porcine[a,b]	I	Platelets, megakaryocytes, monocytes	Associates with CD41 to form the GPIIb–IIIa heterodimer that facilitates platelet aggregation
CD62L	Canine[38] Bovine[c]	I	Leukocytes	Cell adhesion molecule L-selectin, homing of T cells to enter high endothelial venules (HEVs) in secondary lymphoid organs

(*Continued*)

TABLE 6.1 (Continued)

CD antigen	MAb reactivity	Topology	Cellular distribution	Physiology
CD62P	Canine[5,37] Feline[a] Equine[4] Porcine[a,b]	I	Activated platelets	Cell adhesion molecule P-selectin, stabilizes initial platelet aggregates in clot formation
CD68	Canine[a] Feline[b]	I	Monocytes, macrophages, and macrophage-derived cells such as osteoclasts	Binds to tissue- and organ-specific lectins or selectins, allowing for homing and migration
CD79a	Canine[a] Feline[b] Equine[b] Bovine[b] Porcine[a,b]	I	B lymphocytes	Cytoplasmic molecule associates with CD79b and heavy chain for surface B cell receptor (BCR) expression and BCR cell transduction
CD79b	Canine[a] Porcine[a]	I	B lymphocytes	Cytoplasmic molecule that associates with CD79a to form a heterodimer mediating B cell receptor signaling
CD80	Canine[b] Bovine[a] Porcine[b]	I	Dendritic cells, activated macrophages, activated B cells	Costimulatory molecule for T cell activation during primary immune response
CD81	Feline[b]	III	Germinal center B cells	Coreceptor for CR2 (CD21). CR2 intracellular domains dimerize with antigen cross-linked BCR to signal B cell activation
CD86	Bovine[a]	I	Dendritic cells, activated macrophages, activated B cells	Costimulatory molecule for T cell activation during primary immune response
CD90	Canine[a, c] Equine[3] Porcine[c]	V	Pro-thymocytes, T cells, monocytes; weak on granulocytes, renal tubular cells	May contribute to formation of neuron memory and to growth regulation of hematopoietic stem cells
CD94	Canine[c]	II	Lymphocyte subset (NK)	Binds to NKG2 and plays a role in recognition of MHC class I molecules by NK cells and some cytotoxic T cells; ligation of CD94 can inhibit or stimulate killing by NK cells
CD117	Canine[31,12] Porcine[a]	I	Hematopoietic stem cells, higher expression in common myeloid progenitor and lower expression in common lymphoid progenitor cells	Receptor tyrosine kinase type III that binds to stem cell factor and promotes cell survival, differentiation, and proliferation
CD133	Canine[b]	III	Hematopoietic stem cells	Function and ligand unknown
CD134	Feline[a]	I	CD4+ activated T cells	Tumor necrosis factor receptor superfamily; regulator of T-cell-dependent immune responses; receptor for FIV in conjunction with CXCR4
CD163	Porcine[a,b]	I	Monocytes, tissue macrophages	Scavenger receptor cysteine-rich family
CD172a	Bovine[a] Porcine[a]	I	Monocytes, granulocytes	Member of the signal regulatory protein family involved in negative regulation of receptor tyrosine-kinase-coupled signaling processes
CD204	Canine[14,15] Porcine[b]	II	Tissue macrophages	Class A scavenger receptor
CD282	Bovine[a]	I	Monocytes	Toll-like receptor (TLR) 2—cell surface pattern recognition receptor (PRR) that responds to a variety of bacterial cell wall components
CD335	Bovine[a] Porcine[a]	I	Natural killer cells	Also known as NKp46, functions as an activating receptor for NK cell activity

Column 1: CD designation of the antigen. Column 2: species of reactivity (letter superscripts are commercially available from [a]Bio-Rad, [b]ThermoFisher, and [c]R&D; number superscripts correspond to references). Column 3: integration of antigen to plasma membrane. Column 4: cell types and tissues known to express a CD. Column 5: proposed or known physiology of a CD antigen based on studies in animals or humans. The original clones and their original characterization can be found in the 6th edition of this chapter.

topology in the membrane; tissue distribution; and known physiology. Most CD antigens listed in Table 6.1 are commercially available; however, selected key references for CD antigens not known to be commercially available are included.

More in-depth information is available for the currently described CD molecules on several websites, including the taxonomic key program maintained by Washington State University, designed to provide information of the specificity of MAbs for intra- and cross-species of leukocyte differentiation molecules (https://apps.vetmed.wsu.edu/tkp/). Biocompare Antibodies is a search tool (https://www.biocompare.com/Antibodies/) where you can query the availability of commercially available

cross-reactive antibodies for a species of interest. Major suppliers of veterinary-specific MAbs are Bio-Rad (https://www.bio-rad-antibodies.com/veterinary-antibodies.html), Thermo Fisher (https://www.ThermoFisher.com/antibody), and R&D Systems (https://www.rndsystems.com/uniquemodels).

STRUCTURE AND INTEGRATION OF MEMBRANE ANTIGENS

CD antigens are principally membrane proteins defined by their location within or at the surface of the phospholipid bilayer. Membrane proteins are classified into three categories: integral, lipid-anchored, and peripheral, depending on the nature of membrane–protein interactions.[17] The CD antigens are grouped as integral membrane proteins or transmembrane proteins and consist of cytosolic, membrane spanning, and exoplasmic (luminal) domains. The cytosolic and exoplasmic domains have hydrophilic exterior surfaces with either C-terminus or N-terminus group endings. The membrane-spanning domains usually contain hydrophobic amino acids and consist of one or more alpha-helix or multiple beta strands.[17] Most integral membrane proteins fall into one of five classes, depending on how they anchor themselves in the membrane (Figure 6.1).[1] Type I and type II proteins have a single transmembrane region, whereas types III and IV have multiple transmembrane regions also referred to as tetraspanins. Type IV proteins (not shown in the figure) are distinguished from type III proteins by the presence of a water-filled transmembrane channel. Type V proteins attach to membranes via lipid. These lipids are either a glycosylphosphatidylinositol (GPI) anchor or lipid moieties such as myristoyl groups, which include cytoplasmic signaling proteins that will not be described in this chapter.[1,17] Each class pertinent to CD antigens used in veterinary medicine will be described briefly.

TRANSMEMBRANE PROTEINS

Single-Pass Type I Transmembrane Protein (I)

Types I and II transmembrane proteins have only one membrane-spanning α-helix containing 20–25 hydrophobic amino acids. Type I proteins have an N-terminal endoplasmic reticulum (ER) signal sequence that is cleaved after the molecule passes into the ER. This is the most common mode of membrane integration among the CD antigens (Figure 6.1). The protein is glycosylated in the Golgi apparatus if the protein has a glycosylation site and then is expressed on the cell surface. Type I proteins are anchored in the membrane with their hydrophilic N-terminal region on the exoplasmic face and their hydrophilic C-terminal region on the cytoplasmic face. These proteins commonly represent cell surface receptors and/or ligands (like CD4), of which many belong to the immunoglobulin (Ig) superfamily.[1]

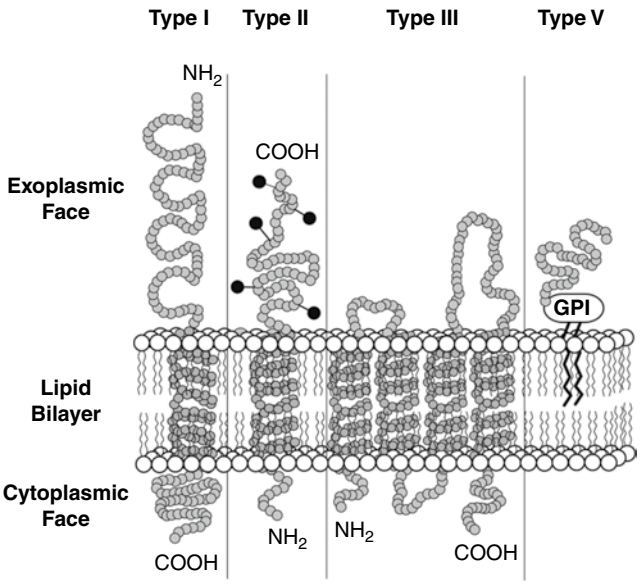

FIGURE 6.1 Major integral membrane proteins and their topology or interaction in the lipid bilayer. The types of membrane proteins are indicated at the top. CD4 is a type I transmembrane protein that passes through the membrane once, has four extracellular immunoglobulin domains, a carboxyl terminus on the cytoplasmic face of the bilayer, and N-terminus (NH_2) on the exoplasmic face. CD13 is a type II transmembrane protein with the N-terminus on the cytoplasmic face and the carboxyl terminus on the exoplasmic face. The extracellular domain of CD13 is heavily N-glycosylated (thin pegs extending from the polypeptide backbone). CD9 is a type III multipass membrane protein with four transmembrane regions, and N- and C-termini on the cytoplasmic face. CD14 is a type V glycosylphosphatidylinositol (GPI)-anchored protein. (**Source:** Courtesy of Mal Rooks Hoover, certified medical illustrator)

Single-Pass Type II Transmembrane Protein (II)

Type II transmembrane proteins lack a cleavable ER signal sequence and are oriented with their hydrophilic C-terminus on the exoplasmic face and the hydrophilic N-terminus on the cytoplasmic face. These proteins have an internal hydrophobic ER signal and membrane anchor sequence. Because these proteins can be released from the cell surface, they can act as plasma proteins with physiologic effect(s) on cells bearing the counter ligands.[1] For example, CD13, a zinc-binding metalloprotease, acts to facilitate antigen presentation by trimming the N-terminal amino acids from major histocompatibility complex (MHC)-class-II-bound peptides.[1]

Multipass Transmembrane Protein (III)

Type III transmembrane proteins cross the membrane multiple (2, 3, 4, 5, 7, or 12) times and are called tetraspanins. The most frequently found tetraspanins include those that span the membrane four and seven times. Structural studies indicate that the transmembrane regions are alpha-helices. If the type III protein has an even number of transmembrane alpha-helices, its N-terminus and C-terminus are oriented toward the

same side of the membrane. Many of these cell surface molecules function as receptors for soluble molecules such as prostaglandins and chemokines. Examples of seven transmembrane type III proteins are interleukin-8 (IL-8) receptor (CD128) and C5a receptor (CD88). CD9 is an example of a four-multipass transmembrane protein.[1] CD47 is an example of type III protein with five transmembrane sequences. The multidrug resistance transporter protein (MDR)-1 (CD243) has 12 transmembrane regions.[1]

GPI Transmembrane Protein (V)

Type V transmembrane proteins utilize GPI anchors attached to the C-terminus residue of the protein (Figure 6.1). GPI-anchored molecules have a secretion signal sequence at their N-terminus and C-terminus that is cleaved and replaced by the GPI anchor after synthesis of the molecule and entry into the ER.[18] CD14 is an example of a type V surface protein involved in the clearance of Gram-negative pathogens that bind to –LPS binding protein. Other examples of GPI-linked glycoproteins include CD56 and CD90.[1]

TISSUE DISTRIBUTION

Cell surface antigens commonly used in immunophenotyping of hematologic neoplasia initially were determined by studies of hematopoietic cell differentiation and maturation.[9,32] Lineage-associated markers can be broadly classified into groups that recognize B cell, T cell, natural killer (NK) cell, myeloid/monocytic, and erythroid, granulocytic, and platelet lineages. Noncommitted hematopoietic stem cells express CD34, a glycosylated surface glycoprotein. This marker is frequently used to differentiate acute immature leukemias of lymphoid or myeloid origin from chronic lymphocytic leukemia or leukemic stages of lymphoma.[36] See Chapter 63 for additional details on applied immunophenotyping. Although the last CLAW was in 1993, it was an important collaborative effort because anomalous expression of the CD4 antigen was identified on canine neutrophils in addition to its predicted expression on helper T cells.[21] Additional examples of CD antigen expression unique to domestic animals are high expression of the γδ T cell receptor in pig and ruminant lymphocytes[6,22] and co-expression of CD4 and CD8 on mature T cells in swine.[32]

Acronyms and Abbreviations

BCR, B-cell receptor; CD, cluster of differentiation; DLA, dog leukocyte antigen; DRB, DR beta, DRiP, defective ribosomal product; FLA, feline leukocyte antigen; GAD, glutamic acid decarboxylase; GVHD, graft-versus-host disease; HFE, high Fe; HLA, human leukocyte antigen; HSC, hematopoietic stem cell; IEDB, Immune Epitope Database; IR, immune response; KIR, killer cell immunoglobulin-like receptor; LIR, leukocyte immunoglobulin-like receptor; LMP, low-molecular-mass polypeptide; LT, lymphotoxin; MHC, major histocompatibility complex; MIC, MHC class I chain; NIH, National Institutes of Health; NK, natural killer; pMHC, peptide–MHC complex; TAP, transporters associated with antigen processing; TAPBP, tapasin; TCR, T-cell receptor; TNF, tumor necrosis factor.

INTRODUCTION

Self-/non-self-recognition is an important inherent characteristic of cellular life forms, and the basis of immunity: the process of clearing or compartmentalizing foreign materials and organisms to preserve homeostasis. For large, higher-order life forms, multifaceted, integrated immune systems have been selected to deal with such threats, primarily from much simpler microorganisms. Invasions by equally complex macroscopic

parasites also trigger patterns of immune defense that can protect the host from harm. For example, more than one-third of humans have been infected with *Toxoplasma gondii*, but most remain asymptomatic.[19] When immunity is impaired, however, such as with HIV/AIDS, then the devastating and sometimes lethal consequences of unrestrained parasitism can be observed.[64,73] Self-/nonself-recognition also occurs between conspecifics, at the level of tissue–tissue interactions, employing some of the same immune mechanisms used to fight off xenogeneic threats. For jawed vertebrates, the cornerstone of this recognition is the major histocompatibility complex, or MHC.

First discovered in the mouse,[25] the mammalian MHC comprises a very large and dense cluster of genes arrayed, generally, but not always, on a single chromosome. Many of the gene products are involved in immune sensing, antigen presentation, and adaptive and innate immune effector action. The MHCs of nonmammalian vertebrates are smaller and simpler, but contain similar elements and overall organization. Not surprisingly, the human MHC, a 4-million-plus base-pair stretch containing more than 220 genes, is the most extensively characterized since its formal identification in 1958,[15] and will serve as one of the standards that we reference in this chapter, to highlight the differences in the MHC of other species of veterinary interest.

MHC CLASS I AND CLASS II GENE DIVERSITIES ASSIST THE ADAPTIVE IMMUNE RESPONSE

Some 30–40% of MHC genes encode proteins related to immunity. The term MHC frequently is used colloquially to refer to two sets of genes within the cluster, class I and class II. More specifically, the reference is to so-called classical class I and class II genes in those regions that encode a number of surface glycoprotein receptors positioned directly at the interface between immune effector cell and foreign threat. Indeed, the rare absence of these classical MHC molecules results in severe immunodeficiency and loss of resistance to infectious agents, demonstrating the importance of the system to survival in an inimical world.[84] The classical genes are well-studied for other noteworthy features. Because MHC genes have and continue to evolve in an unceasing arms race, the tremendous diversity of pathogens (and individual pieces of those pathogens) to which an organism is exposed requires an equally robust level of diversity on the afferent (sensing) and efferent (effector) limbs of the immune system.

B- and T-Cell Responses Depend on MHC Diversity to Provide Robust Host Protection

The adaptive immune response of higher animals is an example of a strategy to counter this diversity problem. The collective business ends of an individual's adaptive effector cells, namely, the repertoires of B-cell receptors (BCR) and T-cell receptors (TCR), have diversity that is generated by switchable genetic recombination machinery operative during lymphocyte ontogeny. The extent of diversity is limited in practical terms only by the number of lymphocytes that the animal can physically hold. The MHC plays the afferent role, initiating, directing, and sustaining TCR-driven responses at a primary level, and BCR-driven responses, at a secondary level, via T-cell help. Diversity on the MHC side, which can range up to two orders of magnitude higher than the genomic average,[21] is maintained in part by extensive polymorphisms in the gene pool, which control the variety of pathogen pieces that are visible to T cells.[57] Not unexpectedly, specific classical MHC class I and class II allelic variants have been shown to correlate with differential resistance or susceptibility to infectious agents,[72,74,81] and in cases where the immune system inadvertently attacks self-tissue, with autoimmune disease risk.[2,22,40,41,97,96,98] As we will see in the following text, MHC polymorphisms also constitute the most significant structural basis for rejection of tissue allografts. Accordingly, the sum of all these features places the MHC at the "center of the immune universe."[91]

STRUCTURE OF THE MHC GENE CLUSTER

The genomic organization of the mouse and human MHCs began with gene mapping studies and was finalized by large-scale sequencing data. In other species, sequencing of orthologous individual MHC genes was the first work undertaken, but now, more complete pictures of their MHCs are emerging.

The MHC Comprises Three Distinct Subregions

The human MHC, located on the short arm of chromosome 6, is divided into three distinct regions of similar function (Figure 7.1), running from centromere to telomere: class II (approximately 800 kb), class III (approximately 1100 kb), and class I (approximately 1800 kb). The class II region contains genes encoding both chains of the previously described classical molecules (called DP, DQ, and DR), nonclassical molecules (DM and DO), immune-related pseudogenes, and discordantly, genes related to processing of antigens destined for class I binding (the transporters associated with antigen processing [TAP]; the inducible proteasome subunits, low-molecular-mass polypeptide [LMP]; the chaperone, tapasin [TAPBP]). Class III is the most conserved, gene-dense region, with few pseudogenes, whose products (e.g., lymphotoxin [LT] and tumor necrosis factor [TNF]; complement factor C4) are related to innate immunity and inflammation, not adaptive responses. The class I region contains classical and nonclassical class I genes, such as human leukocyte antigen (HLA)-E, interspersed among nonimmune "framework" genes. The MHC arbitrarily ends with the last class I gene, but conceptually, the "extended MHC" is considered to run farther to the class-I-like gene high Fe (HFE), which is associated

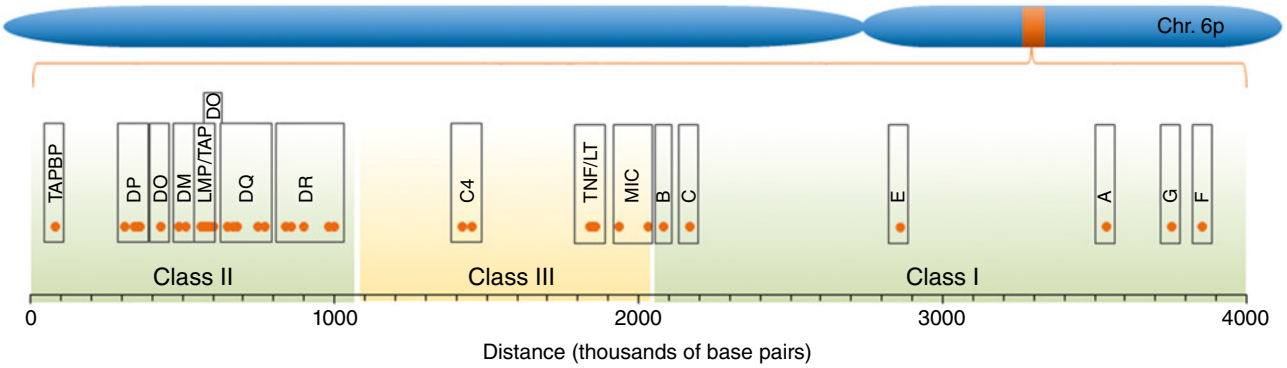

FIGURE 7.1 Overall genomic organization of HLA as a representative MHC. The depiction includes the extended class II (to tapasin [TAPBP]) region, but not extended class I. Boxes enclose a gene cluster; the individual genes are depicted by orange circles. The classical genes in class II are DP, DQ, and DR; nonclassical are DO and DM. The classical genes in class I are B, C, and A; nonclassical are E, G, and F. As described in the text, LMP and TAP are class-I-related antigen processing pathways, and C4, TNF/LT, and MHC class I chain related (MIC) are innate immune genes.

with an HLA-linked disease. It is important to point out that not all MHC haplotypes (i.e., haploid genotype—a particular constellation of MHC alleles) in humans or other animals have the exact same number of genes; this number can vary between individuals.[93] Also, the MHCs of other species are often not so neatly packaged on a single chromosome. Even when that is the case, however, multiple paralogs (i.e., genes that have been duplicated within the species) of many MHC genes can be identified on other chromosomes as well.[18,38] An example of such a paralog is the nonclassical canine MHC class I allele dog leukocyte antigen (DLA)-79.[12]

The Organization of the MHC Varies by Genome

The MHC of the shark, as a cartilaginous fish presumably closest in evolutionary terms to the common ancestor of jawed vertebrates that arose >500 million years ago, can serve as a representative of prototypical genomic organization.[68] Viewed through that lens, there are many differences in MHC organization that have evolved since divergence of particular orders from that ancestor, the most notable of which are listed in Table 7.1. For the interested reader, more detailed genomic information has now been published on the MHC of a number of species, including dogs, cats, rats, horses, pigs, cows, sheep, chickens, reptiles, and fish,[7,20,28,33,35,60,61,77,101,104,105] and broad reviews of comparative MHC structural features are also available.[18,39,45,46]

Comparing Classical Loci across Animal Species is Challenging

In humans, some nonhuman primates, mice, and rats, the classical loci found in the class II and class I regions have been functionally defined, by verifying their ability to direct T-cell responses. The same is not true in most other animals, where only a few have been similarly characterized. Instead, the designation (e.g., "classical class I locus" or "class II DRB") has been assigned by sequence homology. These genes contain the same promoters, exons, splice sites, and structurally important invariant amino acids (e.g., the two cysteine residues that form disulfide linkages between the beta-sheet and alpha-helix in class I molecules) to suggest that a properly folded, full-length, functional molecule will be expressed at the cell surface. That said, because the MHC is rapidly evolving, with genes being gained and lost in a continuous birth-and-death process, it is important to stress that there are limits when looking for orthologous genes between members of orders that are not closely related.[46,94] With the exception of bony fishes, classical class I genes are shorter-lived and more difficult to compare than class II genes, which have greater longevity, allowing orthologous loci to be identified between orders of mammals.[88] Classical class II genes are present in birds, reptiles, amphibians, and fish, but are different than their mammalian counterparts. The bottom line is that, while there are numerous regions of shared synteny that can be illuminating for comparative and evolutionary studies, different MHCs have different genes, order, size, organization, and chromosomal locations that also make the study of each a unique endeavor.

CLASSICAL MHC GENE PRODUCTS REGULATE T-CELL IMMUNITY

Despite these interspecies genetic differences in the MHC, the three-dimensional structures of MHC class I and class II molecules are well-conserved between species, reflecting a common gene ancestor[68] and similar functional demands. That function is to control T-cell activation during adaptive responses by providing (1) a confirmation of self when T cells interact with tissue cells; and (2) to display a fragment of pathogen materials, generally a short peptide (class I, 8–12 amino acids; class II, 13–17). The combination of self and non-self, known as altered self,[106] often, but not always (approximately 60% of the time[5]), has a corresponding TCR

TABLE 7.1 Selected differences in MHC genomic contents and organization.

Species	Chr.[a]	Distinguishing features
Mouse	17	Class II: Nonfunctional DP genes; DR genes functional in only one half of strains. Expanded class I genes in extended class II region. MHC-like MIC genes are absent.
Dog	12	Class II: Single functional DR beta (DRB) gene; inverted DRB gene; nonfunctional DP genes. Class I: split, with 500-kb portion moved to different chromosome (Chr. 35; no classical genes); regions corresponding to HLA-A and HLA-E are absent. "Divergent" class I gene on 3rd chromosome (chr. 18).
Cat	B2	Class II: Lack of DQ genes, nonfunctional DP genes, expansion of DR genes; inverted DRB gene. Class I: split/inversion, with centromere invasion; regions corresponding to HLA-A and HLA-E are absent.
Horse	20	Smaller MHC; nonfunctional DP genes. Five inverted DRB genes.
Cow, sheep	23, 20	Class II separated into two subregions by chromosomal inversion, causing loss of class II DP genes and gain of class II DI/DY genes; inverted DRB gene.
Pig	7	Class II separated from class I and class III by centromere; absence of DP genes.
Chicken	16	Compact MHC divided into two loci, B and Rfp-Y, on same mini-chromosome. Class II alpha chain outside of core MHC region. NK receptors LIR and KIR located within MHC; loss of LMP; only immune gene in class III is C4.
Tuatara	13	Low gene density; high content of repetitive elements. Multiple duplications of class II genes. Intermingling of class I and class II genes. Antigen-processing genes such as TAP and typical framework genes absent from MHC. Nonclassical class I genes (possible paralogs) on 2nd chromosome (chr. 4).
Frog	13[b]	Class I between class II and III regions; only one classical class I locus; some class-III-like genes moved to classical class I region. Duplicate MHC silenced in polyploidy.
Zebrafish	Multiple[c]	Separate chromosomal locations for classical class I (chr. 19) and class II (chr. 4, 8, and 18) genes. Nonclassical or paralogous class I genes on other chromosomes (chr. 1, 3, 8, 22, and 25). Lack of immune genes in class III region.

[a]Major chromosomal location.
[b]In *Xenopus laevis*: Courtet, M., Flajnik, M. & Du Pasquier, L. Major histocompatibility complex and immunoglobulin loci visualized by in situ hybridization on Xenopus chromosomes. Dev Comp Immunol 25, 149–157 (2001).

available in the animal's T-cell repertoire. When that is the case, and a sufficient number of serial MHC–TCR interactions occur, the T cell is triggered, leading to robust proliferation, followed by a coordinated program of downstream effector functions.

MHC Class I and Class II Gene Products Have Different Distributions and Functions

Well-established differences distinguish MHC class I and class II molecules. The former are found on virtually all cells, except erythrocytes, spermatozoa, and neurons, and regulate CD8+ T cells. The latter are, in most instances, expressed only on professional antigen-presenting cells, such as B cells, dendritic cells, and macrophages, and regulate CD4+ T cells. A depiction of these structures, and their interaction with T cells, is shown in Figure 7.2. Note that there appears to be no differences that distinguish TCRs that recognize MHC class I molecules from those that recognize class II. Instead, this conventional paradigm—class I/CD8; class II/CD4—is dictated by the binding of each coreceptor to conserved sites on their respective MHC molecules during T-cell development.[11,49,95] These simultaneous MHC–coreceptor interactions function to amplify peptide–MHC–TCR signaling.[4] It is possible to identify "rule-breaking" T cells, that is, CD4+ T cells regulated by class I,[10] and CD8+ T cells regulated by class II,[75] but these occur only at very low frequencies and under specific conditions.

MHC PROTEINS ARE ANTIGENS THAT DRIVE ALLOREACTIVITY

In an antigen-naïve animal, T cells corresponding to any given foreign peptide (p)-MHC class I or class II molecule combination are very rare, on the order of 1 in 100,000 T cells,[63,67] even discounting the inherent promiscuity of T-cell recognition.[99] What that rarity means is that observing a given T-cell response (e.g., specific for influenza hemagglutinin) against the enormous background (99.999%) of irrelevant T cells is not a trivial matter. Typically, an initial T-cell expansion in vivo is required (so-called priming, by infection or vaccination), followed 10–14 days later by a second round of antigen exposure ex vivo (restimulation, lasting 5–10 days). Only at that point are specific T cells present at a sufficiently high frequency to be measurable in a functional assay, or by flow cytometry.

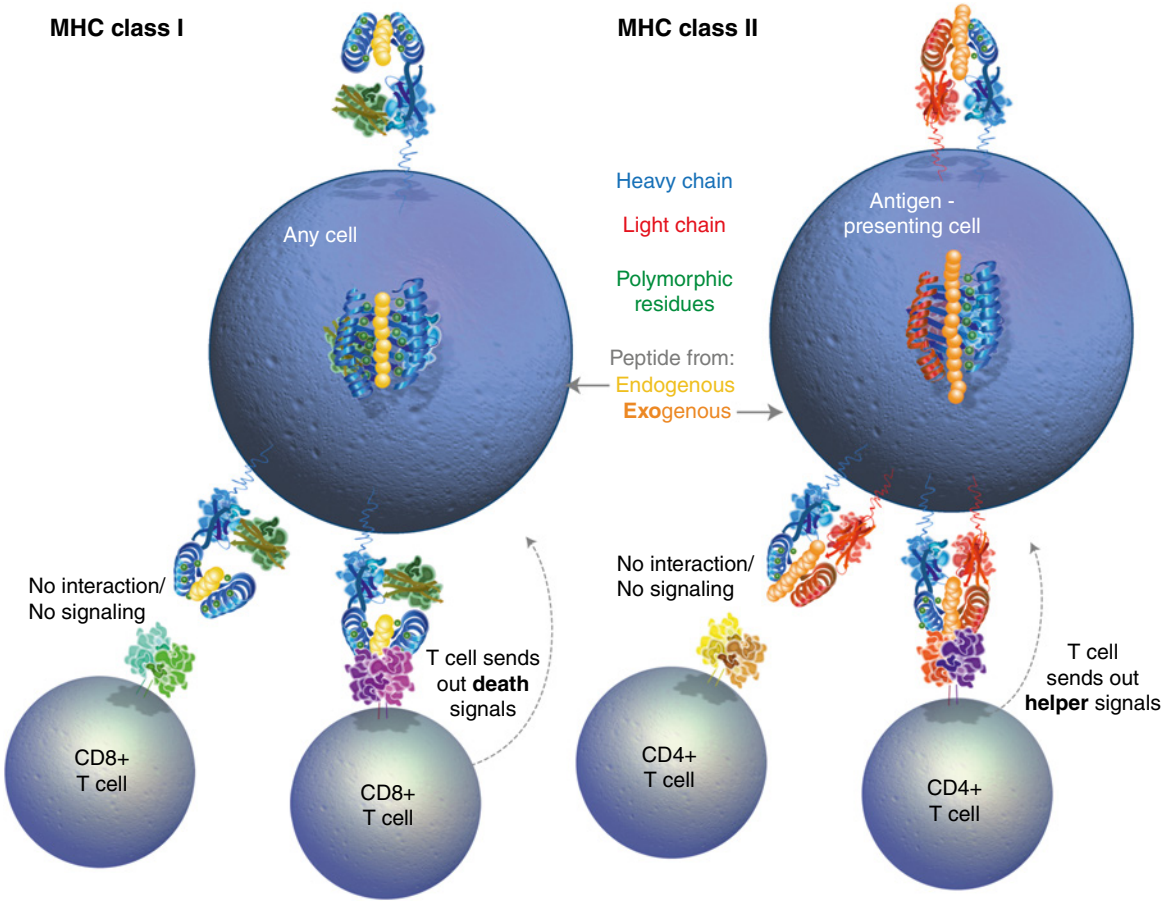

FIGURE 7.2 Left: Shown are three MHC class I molecules on the cell surface, one of which is interacting with the T-cell receptor (TCR) of a cytotoxic CD8+ T cell (bottom of figure). A short, 8–10 amino-acid-long peptide that matches the allomorph's binding preference (dictated by polymorphisms, shown as green circles) is held completely within the binding groove. Recognition by the corresponding ("cognate") TCR of the combination of self-MHC and non-self peptide leads to T-cell triggering and action—in this case, delivery of molecules that leads to death of the target cell. The non-MHC-encoded β2M light chain is shown as the olive/green ribbon structure. Right: Shown are three MHC class II molecules on the cell surface, one of which is interacting with the TCR of a helper CD4+ T cell (bottom of figure). A short, 12–15 amino-acid-long peptide that matches the allomorph's binding preference (dictated by polymorphisms, shown as green circles) is held within the binding groove, but extends beyond either end. Recognition by the cognate TCR of the combination of self-MHC and non-self peptide leads to T-cell triggering and action—in this case, delivery of cytokine and surface ligands that assist the immune function of the antigen-presenting cell ("T-cell help"). Illustration: AM Harvey.

T-Cell Responses to Non-Self-MHC Proteins are a Ubiquitous Phenomenon

Interestingly, T cells capable of recognizing the other form of non-self, that is, a foreign MHC allomorph (allomorph = allele-specific protein product), occur naturally at a high frequency, constituting up to 1 in 10 T cells. A hallmark of the phenomenon, known as alloreactivity, is that it is readily observed, without any need for prior sensitization or expansion. That property is shown by the classic mixed lymphocyte reaction, first described by Bach et al.: MHC-mismatched lymphocytes cultured together proliferate in response to non-self.[6] In fact, it was the observation of alloreactivity, rather than any demonstration of immune defense against microorganisms, that led pioneers such as Peter Gorer, George Snell, and Peter Medawar to the discovery of the MHC (hence the term histocompatibility in the name). Consequentially, polymorphic MHC class I and class II proteins have long been referred to as "antigens," because in early studies, they were detectable serologically, and recognized by T cells of other members of the species (and, of course, as self, they serve as "permissive" antigens, furnishing one half of the primary stimulatory signal for T cells). It is convention therefore to refer to the MHC class I and class II genes by the term "leukocyte antigens," preceded by the species name, such as HLA, or feline leukocyte antigen (FLA).

Anti-MHC Immune Responses Reflect Inherent Properties of T-Cell Populations

It is puzzling that T-cell responses against a rarely encountered foe, foreign tissue, are so much more easily demonstrated than responses against a virtually ubiquitous foe, infectious organisms. At first glance, the vigorous immune reaction against MHC allomorphs might

seem to be a quirk of the T-cell system. Indeed, as a way to explain alloreactivity, some studies have suggested that TCRs have a hardwired affinity for MHC molecules,[82] although others have failed to find support for this notion (reviewed in Felix et al.[17]). More importantly, though, mature T-cell populations have been substantially edited during thymic development, with those bearing TCRs with affinities for self peptide–MHC complex (pMHC) below positive or above negative selection thresholds being eliminated. Self-recognition by T cells is a dose-dependent phenomenon: like Goldilocks, neither too little nor too much is just right. Thus, allorecognition of non-self-MHC polymorphisms can be seen as a consequence of T cells having been chosen for overall increased MHC affinity, but without the restraints imposed by negative selection on too-vigorous binding to some pMHC combinations. In most natural settings, this phenomenon, however robust, might seem to be irrelevant, but there is one important exception: pregnancy. The fetus survives, despite the presence of hostile maternal T cells reactive against paternal MHC allomorphs, because these T cells are transiently rendered tolerant by several mechanisms.[65,87] That alloreactivity persists despite this cost suggests that a fitness advantage is conferred.

Why is Alloreactivity Tolerated?

One early explanation suggested that alloreactivity assisted with inbreeding avoidance.[37] A more recent and instructive model in this regard is provided by transmissible leukemias of mollusks, which lack an MHC system.[58,59] In the last decade or so, five separate lineages of parasitic tumors have been identified in clams, spread across hundreds of miles of coastline, in several far-flung locales, such as New England, northern Spain, and British Columbia. These transmissible tumors are passed horizontally, clam-to-clam, through seawater. In one bed, approximately 50% of clams were found to be afflicted. It seems plausible that MHC-based self-/non-self-recognition of conspecific tissues evolved as a defense against contagious cancers. These risks are evident in mammals, too, when T-cell allorecognition is disabled, as in well-known examples of group transmission of cancer clones in dogs and Tasmanian devils,[13,30] as well as in isolated human cases of vertical cancer spread.[34]

Alloreactivity Has Consequences for Clinical Medicine

Of course, alloreactivity against MHC antigens has taken on greater significance in humans since technological advances have made it possible to transfer solid and liquid (hematopoietic) tissues between species members. The consequences of HLA mismatch include graft rejection and graft-versus-host disease (GVHD). Newer molecular methods have facilitated histocompatibility typing, but, ironically, have also revealed far more HLA polymorphisms than recognized by older serologic-based methods, making exact matching difficult.[17] Nonetheless, recipients of mismatched and matched solid organ grafts can now enjoy similarly good outcomes, thanks to the development of powerful immunosuppressant agents capable of inhibiting alloreactive T cells. The same is not true for transplantation of hematopoietic stem cells (HSC), where matching remains critical to prevent the lethal consequences of GVHD. Presently, clinical allotransplantation is rare in veterinary patients, and, consequently, information on MHC typing and matching is limited. Appropriate protocols will likely need to be established and shared by individual investigators working in the field, on a per-species basis, so will not be reviewed here. Sequence-based typing of polymorphic DLA genes is available through the Fred Hutchinson Cancer Research Center, and is performed in preparation for allogeneic HSC transplantation following total body irradiation for treating lymphoid neoplasia.[53,85]

MHC PROTEINS PRESENT ANTIGENIC PEPTIDES TO T CELLS TO DIRECT IMMUNE RESPONSES

The demonstration that classical MHC gene function extended beyond transplanted tissue histocompatibility, and regulated immune responses to exogenous antigens, was not actually made until the late 1960s. Even then, the relationship between the two types of responses was unclear.[55,56] At that time, studies showed that some mouse strains carrying particular MHC genes made antibodies to weak synthetic polymeric antigens, while other strains were unable to do so. Now we understand that the differences in responsiveness were artifacts resulting from inbreeding and MHC homozygosity, which limited the diversity of the T-cell responses. More than a decade would then pass until Doherty and Zinkernagel showed that T-cell recognition of non-self viral antigens was dependent on the simultaneous presence of self-MHC polymorphisms. Hence, T-cell reactivity is said to be "MHC-restricted."[107] That the specific targets of T-cell recognition were peptide fragments of larger foreign proteins would emerge in the mid-1980s,[83,90] as did the structural basis of MHC class I presentation of those peptides.[8,9]

Classical MHC Molecules Bind Antigenic Peptides for T-Cell Recognition

What became clear from these and other studies is that antigenic peptides (also known as epitopes) bind to MHC class I and class II molecules via the interaction of amino acids at defined "anchor positions" in the peptide with certain residues contained in specific pockets of the peptide-binding groove. Most importantly, the amino acids in these peptide-binding pockets are encoded by gene regions where the extensive polymorphisms of classical MHC genes are concentrated (Figure 7.2, green circles). With different pocket chemistries, individual MHC allomorphs are seen to have

distinct and discernable preferences for peptides that vary at their anchor positions. These preferences constitute the binding motif, which can be worked out by sequencing large numbers of peptides eluted from the binding groove of a selected allomorph to form a consensus picture. For example, in the dog, the DLA-88 (dominant class I gene) allomorph *508:01 prefers 9- and 11-mer length peptides with hydrophobic residues at positions 2 and 3, and a basic residue at the C-terminus, while *034:01 prefers 9-mers with a basic residue at position 1, hydrophobic at position 2, an acidic at position 4, and a phenylalanine at the C-terminus.[66,79] The motif be quite constraining for MHC class I molecules, but less so for class II molecules, which are more accommodating of peptide variability. Catalogs of such peptides for a variety of species can be found at Immune Epitope Database (IEDB; see: https://www.iedb.org/home_v3.php), a resource funded by the National Institutes of Health (NIH). If the motif of a given class I or class II allomorph is established, then T-cell epitopes can also be predicted using online algorithms designed for this purpose.[50] Flow-cytometry-based binding assays using synthesized peptides can subsequently be used to confirm or refute such predictions for MHC class I molecules, as demonstrated for DLA.[80]

Diversity in Classical MHC Molecules Stems from Multiple Sources

Because of their binding fussiness, MHC molecules only present to T cells a very small percentage of possible peptides contained within a pathogen's proteome, estimated at just 2–3% for MHC class I molecules.[5] While this characteristic would seem to be a vulnerability in the host's armor, that is, pathogen mutants lacking motif-matching peptides would quickly be selected for, the MHC system has built-in countermeasures to reduce the likelihood of such immunoevasion. Most notably, at the population level, polymorphisms collectively increase the overall diversity of peptide coverage of a pathogen (e.g., different allomorphs = different motifs = different peptides). Thousands of MHC class I and class II alleles are found in humans (see the IPD-IMGT/HLA database at https://www.ebi.ac.uk/ipd/imgt/hla/ for the latest tally). In many species, the rich sequence diversity of the MHC appears to have arisen from multiple mechanisms, including single nucleotide mutations, insertions and deletions, and intralocus and interlocus gene conversion. Erosion of this genetic diversity is thought to be counterbalanced by parasite-mediated selection. There are two principal forces behind this process: negative frequency-dependent selection (rare alleles confer an advantage) and overdominant selection (heterozygosity confers an advantage).[3,14,32,44] Other mechanisms have also been postulated.[51] Moreover, there is evidence in multiple species that MHC-dependent sexual selection—selective fertilization or abortion, and disassortative matings—assists in maintaining polymorphisms.[23,48,52,78] Further, individual animals increase their MHC diversity by expressing both parental copies of multiple class I and class II genes (polygeny), for which they are typically heterozygous. Finally, some species use alternatives to allelic polymorphisms to achieve MHC diversity, such as the variable numbers and combinations of expressed class I genes, a strategy employed by rhesus macaques, for example.[69]

MHC-Presented Peptides are Generated by Several Cellular Mechanisms

The peptides presented to T cells by MHC class I and class II molecules have distinct origins. Classically, class I peptides come from degraded proteins, as well as defective ribosomal products (DRiPs), in the cytosol.[103] On the other hand, class II peptides are extracellular in origin, passing through the intracellular vesicular system of endosomes, phagolysosomes, endoplasmic reticulum, and Golgi apparatus on their way to the cell surface. The elegant cellular machinery for processing and loading peptides onto MHC molecules of either stripe has been well described in basic immunology texts, and will not be reviewed here. Many of these components responsible for antigen processing and presentation are encoded in the MHC, potentially to facilitate advantageous coevolution.[92] And, as we have seen before, classical pathways usually have alternatives in place to prevent pathogen evasion of immune mechanisms. Accordingly, extracellular antigens can be captured and "cross-presented" on MHC class I molecules by some dendritic cells, and, conversely, cytosolic antigens can be processed during autophagy for MHC class II presentation.[1,27,29,70]

SUBVERSION OF THE MHC TO EVADE T-CELL RECOGNITION

If the MHC protects from foreign invaders, then an obvious corollary is that such invaders, whether microorganism or transformed cell, should try to avoid this system to survive. A variety of examples of evasive activity can be seen in infectious diseases and cancer, particularly in the subversion of MHC class I, which constitutes the protection system that alerts patrolling cytotoxic CD8+ T cells to the presence of intracellular non-self antigens. For example, bovine herpes virus produces the immunoevasin UL49.5, which interferes with normal peptide loading, and hence stable surface expression, of class I molecules.[42,43] Similar phenomena are induced by herpes virus in other species, such as the cat, horse, and chicken.[36,54,62] Downregulation of class I expression is observed in canine and feline mammary gland tumors.[16,89] Naturally, a complementary surveillance system is in place to guard against this phenomenon of "missing self." Killer cell and leukocyte immunoglobulin-like receptors (KIRs and LIRs) expressed on natural killer (NK) cells normally bind MHC class I molecules, inhibiting cell activation. Should MHC I expression be reduced or absent, inhibition is removed and the NK cell lyses the immunoevasive

target cell. An additional self-sensor is provided by the nonclassical MHC class I gene product HLA-E, which presents peptides derived from conserved leader sequences of classical MHC class I molecules. This peptide–MHC complex signals the normal presence of self via interaction with an inhibitory NK cell receptor known as CD94/NKG2A.

BASIC UNDERSTANDING OF THE MHC: WHAT MATTERS, AND WHY?

Beyond the functional understanding of the role of the MHC in self-/non-self-recognition, and in the control of T cells, NK T cells, and NK cells, the study of highly polymorphic MHC class I and II genes has been useful in providing insights into the molecular evolution of vertebrates. But what should the reader interested in veterinary hematology know about MHC antigens, particularly in a comparative sense? Basic knowledge usually focuses on a handful of characteristics: (1) overall genomic organization; (2) identification and description of the classical loci; (3) catalog of known alleles of the classical loci, and their prevalence; or, if appropriate, other descriptors of diversity; (4) the peptide-binding motif of class I and class II allomorphs, and a catalog of immunologically significant peptides that they restrict; (5) associations of specific alleles or haplotypes with risks of particular diseases; and (6) information describing nonclassical loci and the types of lymphocytes, such as unconventional T cells and NK T cells, that they regulate. For those working outside the MHC field, it is only necessary to be conversant with general principles along those lines, as there are a lot of details and exceptions that vary with species and are not worthy of committing to memory, since they can be searched for when needed.

Systematic Naming Conventions are Necessary to Study the MHC

That said, it will be helpful for the reader to have some nodding acquaintance with the details of MHC nomenclature. Because polygeny and polymorphisms characterize MHC class I and class II genes, it became necessary to have a robust and easily expandable naming system in place to keep track of all the players as they are discovered. Some MHC names have arisen because of historical precedent and have been preserved in their now-idiosyncratic form. For example, the murine MHC is called H-2, named by Snell in honor of Gorer's discovery of histocompatibility antigen II in mice. But other vague, descriptive terms, such as the immune response (Ir)-1 locus, or overtly confusing terms, such as I-A, which designates a murine class II locus but sounds deceptively like a member of class I, have thankfully been jettisoned. The now-systematic naming convention began with the first International HLA Workshop meeting in Durham, North Carolina in 1964, with periodic issuing of Nomenclature Reports since then, the last in 2010, with additional sequence updates and corrections published on a monthly basis. The current convention is illustrated in Figure 7.3, using a cat MHC class I allele as an example. Of course, the reader is urged to consult the online IPD-HLA database for the most current naming guidelines. Allele numbers are usually assigned sequentially, in the order of discovery. As a note, shorter designations (Fields 1 and 2 only) are generally used in referencing an allele; that is, HLA-A*02:01 is preferred over HLA-A*02:01:01:01. This preference is because (1) the nucleotide substitutions specified in Fields 2 and 3 generally have no effect on peptide binding or TCR recognition, so the variants are functionally identical; (2) genotyping is often performed by partial-length sequencing of polymorphic regions, so information outside this area is unknown; and (3) expression status of

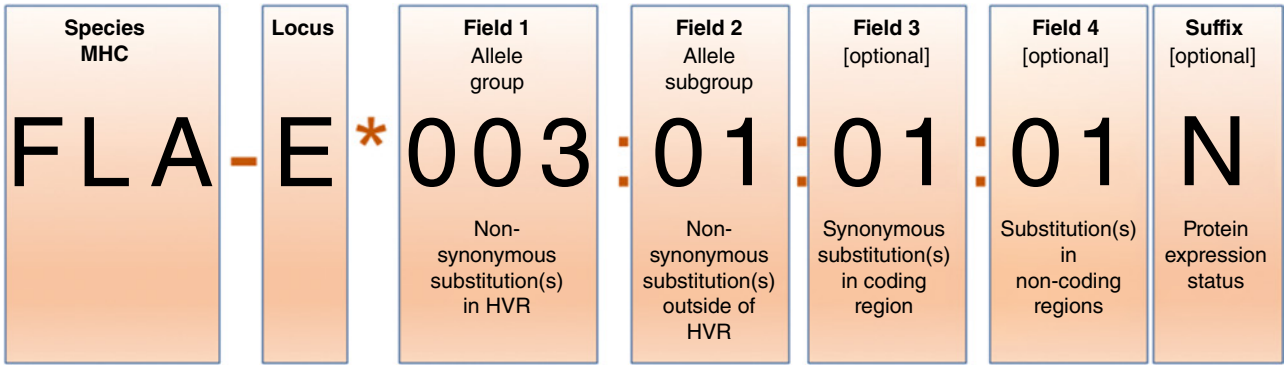

FIGURE 7.3 Nomenclature guidelines for classical MHC genes and their products, using feline leukocyte antigen (FLA) as an example. Separator marks are shown in dark orange. In Fields 1 and 2, the term HVR indicates the hypervariable regions in the exons that encode the functionally relevant peptide-binding residues in the class I and class II binding grooves that confer the allele group and subgroup name. Fields 3 and 4 are optional and often omitted, except for formal naming purposes. Letter suffixes can be appended to indicate protein expression status, if known; N: null; L: low; A: aberrant; Q: questionable; C: cytoplasm only; S: secreted. Note that other designations are sometimes used for a species' MHC (e.g., Feca, for *Felis catus*), as assigned by the Comparative MHC Nomenclature Committee of the International Society for Animal Genetics (ISAG); see: https://www.ebi.ac.uk/ipd/mhc/taxonomy/.

the allele (the letter designation) typically has not been formally investigated. In many cases, only names indicating the allele group (e.g., HLA-A*02) carried by the populations of individuals under study are used as shorthand. Finally, despite being surface antigens on leukocytes, MHC class I and class II molecules are not given cluster of differentiation (CD) antigen designations.

CHARACTERISTICS OF THE MHC IN SELECTED ANIMAL SPECIES

Table 7.1 summarized the distinctive genomic features of the MHC of various species. A brief description of some additional salient features of classical MHC genes is shown in Table 7.2. A catalog of MHC class I and class II genes and their products has also been compiled for some nonhuman animals, and is available at the IPD-MHC (https://www.ebi.ac.uk/ipd/mhc/), which was developed by the Anthony Nolan Research Institute, in collaboration with the European Bioinformatics Institute (EMBL-EBI), or the International Immunogenetics Information system (IMGT, www.imgt.org; mouse only).

HOW INVESTIGATING THE MHC AIDS THE STUDY OF T-CELL IMMUNITY

Precise information about the MHC has great significance to immunologists, because understanding T-cell immune responses depends on careful characterizations of the MHC genes and allomorphs controlling these responses. Despite the collective contributions of diversity inherent in the pathogen proteome, MHC polymorphisms, and the TCR repertoire, T-cell responses are surprisingly limited in number and predictable, with specific responses to specific pathogens or antigens shared across individuals that carry the same classical MHC allele. This phenomenon is known as immundominance.[102] Because of this restriction, which arises in part from the stringent binding preferences of MHC molecules, the study of T-cell responses in groups of individual animals is feasible and orderly.

Specific T-Cell Responses Can be Named by Their Cognate Peptide/MHC Molecule

Importantly, the particular peptide that a given T cell recognizes and the MHC allomorph that restricts the response can often be identified with some effort, and then be used to refer to that T-cell specificity. For example, HLA-A*02:01-carrying humans infected with influenza A virus frequently develop GILGFVFTL/HLA-A*02:01-specific T-cell responses against matrix protein (using single-letter code for the amino acids of the peptide).[26] Those with melanoma treated with immune checkpoint blockade may share newly primed QLSLLMWIT/HLA-A*02:01-specific T-cell responses against the cancer-testis antigen NY-ESO-1.[47] Those with type I diabetes mellitus may have in common HLVEALYLVT/HLA-A*02:01-specific T-cell responses against insulin B chain associated with rejection of their islet grafts.[71] One can be equally precise with CD4+ T cells. For example, type I diabetic patients can have autoimmune responses against glutamic acid decarboxylase (GAD)65 in the form of circulating NFIRMVISNPAAT/HLA-DRB1*04:01-specific T cells.[76] Defining T cells at this level allows the magnitude, kinetics, avidity, and other features of responses to be precisely studied, which is helpful in understanding immunity induced or modulated by infections, cancer, vaccination, transplantation, checkpoint blockade therapy, and in other settings.

Specific T-Cell Responses Can be Visualized by Their Cognate Peptide/MHC Molecule

There is another, more tangible benefit of achieving this level of specificity, too. It is possible to produce recombinant MHC class I and class II molecules, and mix them with synthetic copies of a peptide that they bind, to produce a correctly folded, soluble, functional pMHC complex. While the avidity of this pMHC complex for its corresponding TCR is too low to be of direct use, when these pMHC molecules are assembled into multimeric form (e.g., dimers, tetramers, pentamers, dextramers, and dodecamers[31]), and coupled to fluorescent or other functional molecules, they can be powerful tools for visualizing and manipulating epitope-specific T cells in polyclonal populations.[24,100] It is important to note that, for the most part, epitope-level T-cell responses are known in primates and rodents, and to a far lesser extent in other veterinary species, such as companion or food-source animals (Table 7.2). Reflecting that dearth, pMHC multimers are also rarely employed in T-cell studies in the latter populations, with scattered exceptions.[86]

CONCLUSION

The survival of complex animal life forms depends on preventing the invasion and colonization by parasitic agents, namely, prions, viruses, free-living microscopic and macroscopic organisms, and cancer cells. The key to this resistance is self-/non-self-recognition. One of the most important players in this defense network is the MHC, a large, dense cluster of genes involved in immune surveillance and regulation—most notably, the processing, transport, molecular loading, and presentation of self and foreign antigens. In order to counter almost any conceivable external threat, the MHC has evolved into a complex, diverse system, which varies in particulars across species, and even across individuals in these populations. However, there are many commonalities that unite MHC characteristics across these groups, too, reflecting the ancestry of the system, and common defense needs of animals in a hostile world.

TABLE 7.2 Features of classical MHC class I and II genes and their products in selected species of veterinary interest.

Species (MHC)	# of loci (class I) or subregions (class II)[a]	Locus name(s)	# of alleles reported[b]	Peptide-binding motif known?	Minimal peptide-reactive T cells?[c] Restricting element known?	MHC-disease susceptibility association?	Specifics for this species
Class I							
Mouse (H-2)	3	-D, -K, -L	46	Y—many	Y—many	Y—many	Inbred strains only; many null at L. Non-numerical allele naming scheme (b, d, etc.). # includes minor polymorphisms d2, k2, q2, and s2 listed at IMGT
Rabbit (RLA)	2–4	-A1,?	19	Y	N	Y—virus	Copy number variation may generate diversity
Guinea pig (GPLA)	2	-B, -S?	5	N	Y, but RE[d] unknown	N	Serologic and protein analyses only; classical status based on alloreactivity
Dog (DLA)	2	-88, -88L/-12	108	Y	Y, but RE not established	N	Two structural Hps: DLA-88/DLA-12 (80% freq.); DLA-88/DLA-88L (20% freq.) 22 of the 108 alleles at the DLA-12/DLA-88L locus. DLA-64 is nonclassical
Cat (FLA)	3	-E, -H, -K	206	Y	Y, but RE unknown	N	# includes unpublished data from Holmes & Hess
Ferret (Mufu)	?	-?	77	N	N	N	No named loci. # from two reports (48, 29 alleles) from same lab, but redundancy and/or originating loci unknown—probably mixture of classical & nonclassical
Horse (Eqca)	5–7	-1, -2, -3, -4, -16, -17?, -18?	30	Y	Y—several	N	Expression of loci varies with Hp. Peptide–MHC class I tetramers made
Cow (BoLA)	6	-1, -2, -3, -4, -5, -6	264	Y	Y—several	Y—virus, bacteria (mastitis), endoparasites, and ectoparasites	Expression of loci varies with Hp. Peptide–MHC class I tetramers made
Goat (Cahi)	1?	-N	1	N	N	N	Cahi-NC4 aligns with nonclassical BoLA class I, but status in goat is unknown
Pig (SLA)	3–4	-1, -2, -3, -12?	229	Y	Y	Y—diarrhea; endoparasite; melanoma (Hp-level only)	Expression of loci varies with Hp. Peptide–MHC class I tetramers made
Tuatara (Sppu)	2–3	-UA, -UB	49	N	N	N	Fewer expressed class I genes than other reptile orders. Subpopulations can have two or three genes
Chicken (Gaga)	2	-BF1, -BF2	50	Y	Y	Y—viruses, bacteria, protozoa, endoparasites, and ectoparasites (Hp-level only)	Only BF2 may have classical role in peptide presentation

(*Continued*)

TABLE 7.2 (Continued)

Species (MHC)	# of loci (class I) or subregions (class II)[a]	Locus name(s)	# of alleles reported[b]	Peptide-binding motif known?	Minimal peptide-reactive T cells?[c] Restricting element known?	MHC-disease susceptibility association?	Specifics for this species
Frog (Rana, Raja, etc.)	3?	-UA, -?	60	N	N	Y—fungus, virus, bacteria	# from three Rana species. Single locus in *R. temporaria* (129 alleles), Xenopus. Six other anuran species (three families) have been characterized. Susceptibility data from multiple species
Zebrafish (mhc1)	12	-uba to -uma	Few?	N	N	N	Predicted to bind β2M, CD8, and peptide; polymorphic. Genes vary with Hp. Expression consistent within, but varies across, Hps; also consistent across tissues in individual fish
Class II							
Mouse (H-2)	2	-A, -E	62	Y—many	Y—many	Y—many	Inbred strains only; many null at E. Non-numerical allele naming scheme (b, d, etc.). # includes minor polymorphisms d2, k2, q2, and s2 listed at IMGT. H2-Aa polymorphic but -Ea monomorphic
Rabbit (RLA)	3	-DP, -DQ, -DR	40	N	N	Y—virus, parasite	
Guinea pig (GPLA)	3	Ia group 1 (Ia1); Ia2; Ia3	9	N	Y, but RE unknown	Y—parasite	Serologic and protein analyses only; classical status based on alloreactivity
Dog (DLA)	2	-DQ, -DR	345	N	Y, but RE unknown	Y—protozoal, autoimmune, endocrine	Alleles can be grouped into functional DQB ($n = 9$) and DRB ($n = 5$) supertypes
Cat (FLA)	1	-DR	84	N	Y, but RE unknown	N	Expanded # of DR genes: DRA1, DRA2, DRA3 (all have different signal peptides); DRB1, DRB3, DRB4, and DRB5 (DRB2 is pseudogene)
Ferret (Mufu)	1	-DR	N/A	N	N	N	Serologic determination of DR only; SMRT sequencing of the ferret MHC reportedly completed (2018) but not yet available
Horse (Eqca)	2	-DQ, -DR	53	N	Y	Y—atopic dermatitis; sarcoid?	# from IPD-MHC database
Cow (BoLA)	2	-DQ, -DR	499	Y	Y	Y—virus, bacteria (mastitis), cancer	# from IPD-MHC database. T-cell responses against foot-and-mouth disease virus epitopes presented by DRB3 have been found
Goat (Cahi)	2	-DQ, -DR	71	N	N	Y—mycobacteria	Domestic goat, but includes other species (e.g., wild goat, *Capra aegagrus*) and strains
Pig (SLA)	2	-DQ, -DR	204	Y	Y, but RE unknown	Y—diarrheal disease; endoparasite; melanoma (Hp-level only)	# from IPD-MHC database

Tuatara (Sppu)	2?	-DA, -DB, -DC	6	N	N	N	DB may be nonclassical
Chicken (Gaga)	1	-BL	21	Y	N	Y—viruses, bacteria, protozoa, endoparasites, and ectoparasites (Hp-level only)	Two beta chain genes, BLB1 and BLB2. Allele assignment challenging. BLB1 expressed primarily in intestine. Monomorphic BLA gene outside B subregion
Frog (Rana, Raja, etc.)	2	-D1, -D2	82	N	N	Y—fungus	Other references call II or DA. # from multiple Rana sp. Fungal susceptibility in multiple non-Rana species
Zebrafish (mhc1)	1	-DA	N/A	N	N	N	Polymorphisms yet to be described

[a]For class II, subregion refers to specific cluster, e.g., DR, in which there are usually multiple loci/genes. For example, cats have three DRA and four DRB genes. Because the DQ subregion is lacking, and DPA and DPB are pseudogenes, the number of active class II subregions is counted as one (DR). For many of the species listed, class II gene-level details are not yet available.
[b]Allele numbers are provided to illustrate genetic diversity at the classical MHC loci in various animal species, and represent current (2020) estimates based on authors' claims in the literature; totals could thus include redundant alleles. These numbers are imprecise because, in most species, the number and identity of classical loci are ill-defined, sequence assignments are tentative. It should also be noted that different numbers of individuals have been studied, and that new alleles are constantly being reported.
[c]T cell recognizing a specific approximately 9-mer (class I) or approximately 15-mer (class II) peptide.
[d]Abbreviations: RE, restriction element; Hp, haplotype; N/A, not available.

Acronyms and Abbreviations

APC, antigen-presenting cell; BCR, B-cell antigen receptor; CpG, cytosine-phosphate-guanine; CR, complement receptor; CTLA, cytotoxic T-lymphocyte-associated protein; FcR, Fc (immunoglobulin) receptor; HEV, high endothelial venule; ICAM, intercellular cell adhesion molecule; IFN, interferon; IL, interleukin; ILC, innate lymphoid cell; MHC, major histocompatibility complex; NF-AT, nuclear factor of activated T cells; NF-κB, nuclear factor κB; NK cell, natural killer cell; NKT cell, natural killer T cell; SWC-1, swine workshop cluster-1; TCR, T-cell antigen receptor; Th1 cells, type 1 helper T cell; Th2 cells, type 2 helper T cell; TLR, toll-like receptors; TNF, tumor necrosis factor; WC1, workshop cluster 1.

Lymphocytes are the morphologically bland, small round leukocytes that predominate in the peripheral blood of herbivores and are a major leukocyte population in other mammals. They range in concentration from 4500–13,000 cells/μL in pigs to 1000–4800/μL in dogs. Their morphology is however no guide to their critical role in the defense of the body. There are three major populations of these cells; T cells, B cells, and innate lymphoid cells (ILCs).

All lymphocyte populations are engaged in the defense of the body. Given the diversity of potential microbial pathogens, it is unsurprising that lymphocytes also show considerable diversity. Immunologists classify the adaptive immune responses into two types. Type 1 immunity is mediated by type 1 helper (Th1) cells. Type 1 responses are responsible for immunity to bacteria, viruses, protozoa, and fungi. They generate some antibodies, cytotoxic T-cell responses and activate

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.

macrophages. Type 2 immunity in contrast is mediated by type 2 helper (Th2) cells. Type 2 immunity is primarily antibody-mediated. Type 2 responses are responsible for the destruction of extracellular bacteria and viruses, helminths, and arthropods, as well as for allergic responses. This functional division is directly related to the activities of different lymphocyte populations.

GENERAL PROPERTIES

Lymphocyte Structure

Lymphocytes are spherical cells with a round nucleus (that almost fills the cell), a thin rim of cytoplasm, and a smooth surface that may develop multiple villous projections when activated. Resting G1 lymphocytes are about 6–7 μm in diameter and contain a few mitochondria, vesicles, ribosomes, and a small Golgi (Figure 8.1). Natural killer (NK) cells, a cytotoxic population of innate lymphocytes, may be larger than the T or B cells, and may contain obvious magenta granules. Lymphocytes have historically been classified as either small or large; however, their size distribution is more heterogeneous. Since these cells are often dividing, a lymphocyte in M phase will be twice the size of its two progeny cells and can reach approximately 10–12 μm in diameter.

Lymphocyte Populations

Lymphocytes are found in peripheral blood, in lymphoid organs, and throughout many nonlymphoid tissues, especially the mucosa of the gastrointestinal tract.[24] As might be expected, changes in the circulating lymphocyte concentration reflect absolute alterations in population numbers or changes in distribution among tissue compartments, including the peripheral blood, lymphoid organs, and nonlymphoid tissues. Despite their morphologic overlap, lymphocytes represent cells that are functionally and phenotypically diverse. Their phenotype also includes the set of cell surface molecules, receptors, and secreted proteins that regulate their functions and reflect the activation and suppression of selected genes and their expressed products. Lymphocyte populations are characterized by their characteristic cell surface proteins and glycoproteins, especially their antigen-binding receptors (see Chapters 6 and 63 for more information of lymphocyte phenotyping). Further separation classifies B cells according to their location and function, divides T cells into helper (Th) or regulatory (Treg) cell types, and classifies ILCs as helper cells or NK cells (Table 8.1).

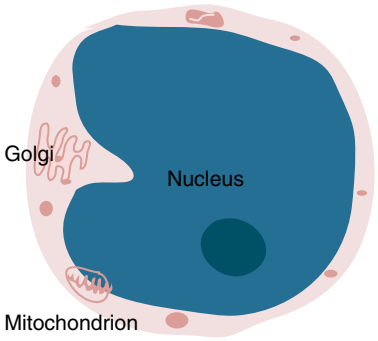

FIGURE 8.1 The structure of a lymphocyte. The nucleus is usually surrounded by a small amount of cytoplasm that contains the cellular organelles.

TABLE 8.1 Published peripheral blood lymphocyte percentages.

CELLS	DOG	CAT	BOVINE	SHEEP	PIG	HORSE

Lymphocyte Origins

Lymphocytes originate in the fetal omentum and yolk sac, then in the fetal liver, and finally in the bone marrow where they are derived from lymphoid stem cells. Some newly formed cells leave the bone marrow and migrate to the thymus. Following positive and negative selection, which eliminates many self-reactive T cells and may result in the loss of 75–95% of the entering cells, thymic lymphocytes exit as T cells and migrate to secondary lymphoid organs. It takes 4–5 days for these cells to pass through thymic processing before they emigrate as functional T cells. Although the thymus shrinks once it has succeeded in colonizing the secondary lymphoid organs, it remains functional throughout life.

In some mammals, most notably sheep, B-cell precursors migrate from the bone marrow to ileal Peyer's patches. These are sites of apoptosis for presumably faulty or self-reactive B cells and a site of microbiota-influenced B-cell maturation and diversification.[9,42] In other mammals, the bone marrow serves as both a primary lymphoid organ and the source of B-cell maturation.[43] Once they diversify and mature, B and T cells migrate to secondary lymphoid organs (e.g., lymph node and spleen) where they are optimally positioned to encounter invading organisms and foreign antigens.

Lymphocyte Circulation

Lymphocytes are highly mobile cells. They originate in the bone marrow, migrate to the thymus or Peyer's patches, move to secondary lymphoid organs, and readily traffic between these (and other) organs. However, their movement patterns vary according to phenotype. For example, effector ($CD8^+$) T cells survey the body, interrogate nucleated cells for abnormal or foreign proteins, and, if found, engage in cell killing. By contrast, B cells remain relatively static waiting for antigens to

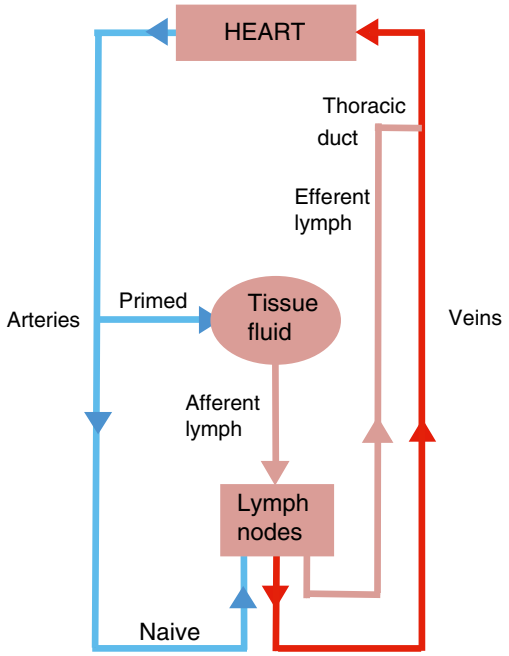

FIGURE 8.2 Lymphocyte circulation. Naïve lymphocytes enter lymph nodes from the bloodstream through high endothelial venules. Once primed they enter tissue fluid and are carried to lymph nodes through afferent lymph. They all return to the bloodstream by way of major lymphatic vessels such as the thoracic duct.

come to them. Additionally, lymphocyte circulation patterns differ between naïve and antigen primed cells. For example, naïve T cells leave the bloodstream and emigrate into the lymph node paracortex via specialized high endothelial venules (HEVs).[21] By contrast, memory T cells leave the bloodstream through conventional blood vessels and are carried to lymph nodes through afferent lymph. Both types of T cells leave lymph nodes through efferent lymphatics. Sheep afferent lymphatics contain approximately 85% T cells, 10% B cells, and 5% dendritic cells, whereas their efferent lymph contains approximately 75% T cells and 25% B cells. These T cells are continually patrolling the body, while the T cells migrate between lymphoid organs. Efferent lymphocytes pass through increasingly larger lymph vessels, including the thoracic duct, before eventually rejoining the bloodstream and, ultimately, circulating back to lymph nodes (Figure 8.2). Lymphocytes circulate differently in the pig.[5] In this species, lymphocytes enter and exit lymph nodes through HEVs. This results in a comparatively lower concentration of lymphocytes in the efferent lymph, but a correspondingly higher concentration of lymphocytes in the peripheral blood (i.e., 4500–13,000 cells/μL).

Lymphocyte Mitogens

To quantitate lymphocyte responsiveness or characterize chromosome structure and karyotype, lymphocytes can be stimulated to divide by exposure to lectins (proteins that bind to carbohydrate side chains on glycoproteins).[4] By measuring the magnitude of lymphocyte division in response to these mitogens, they can provide a quantitative measure of lymphocyte functionality. The most widely employed lectin is phytohemagglutinin, which is a plant protein that binds to cell surface glycoproteins and stimulates T-cell division. Additional, commonly used mitogens include the T-cell mitogen concanavalin A and the T- and B-cell mitogen, derived from the pokeweed plant.

LYMPHOCYTE SURFACE MOLECULES

All external cell surfaces are covered by a dense and diverse array of proteins.[37] These cell surface proteins are classified by the cluster of differentiation (CD) system. The CD system has primarily been established for mouse and human cells. While most of these proteins are homologous with those in domestic species, there are some distinctive and important molecules found only in domestic animals (see Chapters 6, 63, and 64 for more information).

Antigen Receptor Complexes

The most important lymphocyte surface molecules are the receptors for foreign antigens, namely, the B–cell antigen receptor (BCR) and the T–cell antigen receptor (TCR). Both receptors consist of glycoprotein complexes formed by multiple peptide chains, which for B cells consist of immunoglobulin molecules, whereas T cells use a specialized multipeptide antigen receptor (Figure 8.3).[50] Some of these chains form the antigen-binding site, while others play a role in signal transduction. Across T and B cells, there are subpopulations that utilize different peptide chains in their antigen receptors. B cells use five different immunoglobulin heavy chains (e.g., α, δ, γ, ε, and μ), whereas the TCR complex consists of either of the paired antigen-binding α/β or γ/δ chains plus a signal transduction complex collectively called CD3.[22] Notably, innate lymphoid cells do not possess specific antigen receptors, but rather they possess receptors that recognize surface molecules expressed on healthy normal cells (e.g., major histocompatibility complex [MHC] class I). When these lymphocytes encounter a cell lacking these surface molecules (a common feature of virus-infected cells), they will kill it.

T cells recognize and respond to two different kinds of antigens, namely, foreign antigens (bound to MHC class II molecules on the surface of antigen-processing cells [APCs]) or endogenous antigens (bound to MHC class I molecules). To bind to MHC class II, specialized T cells (helper cells) use a receptor called CD4. Alternately, endogenous antigens, which are generated in virus-infected cells, bind to MHC class I molecules. These MHC class I bind to CD8 on the T-cell surface. Thus, both CD8 and CD4 serve to bind the T cell tightly to the APC and so facilitate the exchange of signals and their activation. T-cell subsets in peripheral blood and tissues vary across species (e.g., in human blood, 65% of T cells are CD4+, whereas

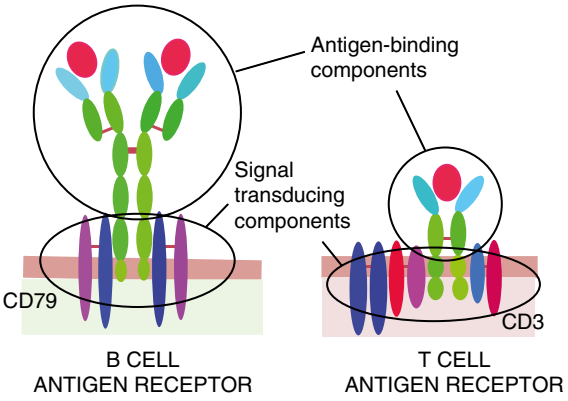

FIGURE 8.3 T and B cell antigen receptors. Both consist of an antigen-binding component and a signal transduction component. The signal transduction component of the TCR consists of six different peptide chains collectively called CD3. The signal transduction component of the BCR consists of two dimers called CD79.

30% are CD8+). In humans, these numerical relationships have significance, but their utility in animal species is largely unproven.

Regulatory Receptors

Regulatory proteins, including chemokines, cytokines, antibodies, and complement proteins and their corresponding receptors, regulate both B- and T-cell activation and function. For example, Th1 cells are regulated by specific receptors to interleukin (IL)-1, IL-12, and interferon (IFN)-γ Th2 cells are regulated by IL-4, IL-13, and IL-18; while Th17 cells are regulated by IL-23 (Figure 8.4).

Similarly, antibodies signal lymphocytes through specific receptors. Since these receptors bind to the Fc regions of immunoglobulins, they are called Fc receptors (FcR). One such receptor is CD32 (FcγR2), which is found on B cells. In the case of B cells, this receptor provides a negative feedback loop that regulates antibody production. Alternately, CD16 is a low-affinity IgG receptor (FcγRIII) found on NK cells. This receptor binds and allows the NK cell to destroy antibody-coated targets. In addition, complement proteins regulate lymphocyte activity through specific receptors. There are four of these, CR1–CR4. B cells express CR1 and CR2. NK cells express CR3 and CR4.

Adherence Molecules

Lymphocytes must interact with other lymphocytes, blood vessel walls, and APCs. As a result, they express intercellular adhesion molecules such as integrins and selectins. Integrins are heterodimeric glycoproteins that bind lymphocytes to extracellular matrix (e.g., laminin and fibronectin), to vascular endothelial cells, and to other lymphocytes. Selectins are also cell adherence molecules. For example, L-selectin is expressed on lymphocytes and binds them to high endothelial venules in the lymph node paracortex. Other adherence molecules include intercellular cell adhesion molecules (ICAM-1) (which is expressed on B cells and T cells, binds integrins, and is required for the emigration of circulating lymphocytes into tissues) and CD2 (which is expressed on T cells, binds to CD58 on antigen-processing macrophages and dendritic cells, and is essential for T-cell cytotoxicity).[40,41]

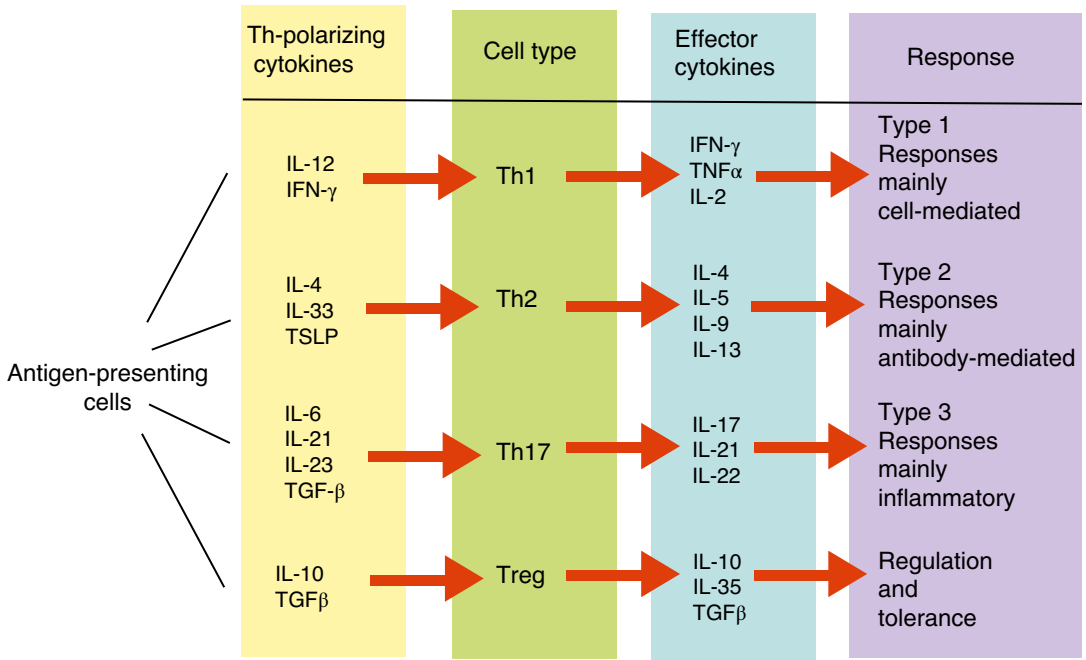

FIGURE 8.4 T-cell diversity. The development of specific T cell subpopulations is determined by the mixture of cytokines generated by antigen presenting cells and depends in large part on the properties of the initiating antigen. Once differentiated, each T cell subpopulation secretes its own unique mixture of cytokines. These in turn trigger specific types of immune response or tolerance.

WC1 Molecules

Workshop cluster 1 (WC1) molecules are a family of lymphocyte surface proteins found in many mammals.[26] WC1, while not found in humans, is a major cell surface protein on γ/δ T cells in cattle and sheep.[26,33,53] These WC1$^+$ cells are found in large numbers under the skin and mucus membranes. They have homologs in other domestic species, primarily herbivores.[49] The function of the WC1 family is unclear, but they likely bind T cells to macrophages and dendritic cells and are involved in T-cell activation.[25,54]

Changes in Phenotype

Lymphocytes do not present a stable phenotype.[56] As genes are turned on or off or epigenetic mechanisms come into play, their phenotype may change.[16,48] Thus, B cells switch the immunoglobulin class they produce and can turn into plasma cells and eventually into memory cells.[48] T cells also switch functions to become helper, regulatory, effector, or memory T cells.

Species Differences

There are notable, species-specific differences in circulating lymphocyte subsets. For example, B cells comprise 17–38% of total blood lymphocytes in the horse, 16–21% in cattle, 13–38% in pigs, and 7–30% in dogs. Similar differences in circulating T cells are seen, as they constitute 38–66% of blood lymphocytes in the horse, 45–53% in cattle, 45–57% in pigs, and 46–84% in dogs. In addition, individual species express unique lymphocyte subsets. For example, horse lymphocytes express two unique antigens of uncertain function, EqWC1 and EqWC2. EqWC1 is expressed on 70% of T cells and on 30% of B cells, whereas EqWC2 is found on most horse T cells. Cattle, sheep, and pigs are characterized by the presence of comparatively high levels of γ/δ T cells when compared to other veterinary species, humans, and laboratory rodents.[23] In adult cattle, γ/δ cells account for 10–15% of circulating T cells and up to 40% in young calves. These percentages are highly variable and are affected by stress and management. Most of these γ/δ T cells are also WC1-positive and, as a result, may be activated from signals from either the TCR or through WC1. When activated, they secrete a mixture of cytokines associated with type 1 immune responses. CD4$^+$ cells account for about 20–30% of T cells in calves. Double negative cells may account for 80% of lymphocytes in newborn calves, but this proportion drops significantly as they age, eventually stabilizing around 15–30%. These double negative cells are mainly γ/δ$^+$ WC1$^+$.

Sheep similarly demonstrate an age-dependent profile of γ/δ T-cell expression. In newborns, γ/δ cells constitute about 60% of circulating T cells, but this drops to 30% by 1 year and as low as 5% in aged sheep. They also express a unique antigen OvWC1 (T 19) that is structurally different in α/β T cells when compared to γ/δ cells.[52] Pigs also express proportionally high levels of γ/δ T cells.[6] Neonatal piglets have up to 66% circulating γ/δ-positive T cells, which drops to 25–50% of cells as they age. Pigs currently have nine unique WC molecules, although this number may drop if homologies with mice and humans are identified.[7] For example, swine workshop cluster-1 (SWC-1) is homologous to CD27 and occurs on T and NK cells. Notably, up to 60% of pig T cells are CD4/8 double positives, while the remainder are double negative.[15,31,38] In contrast to these species, less than 10% of their circulating T cells are γ/δ-positive.

B CELLS

The Response of B Cells to Antigen

Although B cells can be found circulating in peripheral blood, they predominantly reside in lymphoid organs, including the cortex and germinal centers of lymph nodes, Peyer's patches, bone marrow, and splenic white pulp, where they wait for antigens, both soluble and particulate, to be brought to them by lymph or blood flow. Each B cell possesses a unique antigen receptor that is, when activated, shed as an antibody molecule.

B-Cell Antigen Receptors

Each B cell is covered by up to 500,000 identical antigen receptor molecules. The BCR consists of two components, an immunoglobulin molecule that acts as an antigen-binding component and CD79, the signal-transducing component. Structurally, the antigen-binding component of the BCR consists of four immunoglobulin chains—two light chains and two heavy chains, bound by disulfide bonds. This immunoglobulin structure binds antigens through its Fab region, which is itself composed of regions of both the heavy and light chains. The signal-transducing CD79 is also composed of two chains, CD79-α and -β. The CD79-α chain differs according to the heavy chain class, while the CD79-β chain is homogeneous across all heavy chains. Functionally, when an antigen cross-links two BCRs, a signal is generated that activates transcription factors such as nuclear factor κB (NF-κB) and nuclear factor of activated T cells (NF-AT) leading to repeated cell division and gradual differentiation into a plasma cell. These resultant plasma cells are capable of secreting many thousands of immunoglobulin molecules every second into the bloodstream.

Antigen Presentation by B Cells

In addition to acting as antibody secretors, B cells can function as efficient antigen-presenting cells for CD4$^+$ helper T cells. In this pathway, activation of the B-cell receptor by antigen results in endocytosis and intracellular processing of that antigen and concludes with cell-surface expression of antigen bound to MHC class II molecules. That pathway only works in primed animals when these specific B cells have expanded their numbers.

Costimulation of B Cells

Binding of specific antigen to BCRs alone is usually insufficient to completely activate B cells and trigger an antibody response. B cells often require additional stimuli from T cells through cytokines, cell contact, complement, and toll-like receptors (TLR) ligands. Helper T cells serve as one such costimulant through the delivery of cytokines that not only activate B cells but also determine B-cell development and function. More specifically, Th2 T helper cells secrete IL-4, IL-5, IL-6, IL-13, and IL-21. Of these cytokines, IL-4 and IL-13 promote expression of Fc and MHC receptors, B-cell class switching, and the production of IgA and IgE. The other cytokines (IL-5 and IL-6) promote the differentiation of B cells into plasma cells, while IL-21 induces the differentiation of B cells into plasma cells and memory cells. The costimulatory effects of CD4 T cells on B cells are initiated by the binding CD154 (on T cells) to CD40 (on B cells). This binding triggers B-cell division and upregulation of B-cell cytokine receptors. Additional B-cell costimulants include the complement component C3d and pathogen-associated molecular patterns (PAMPs), provided by lipopolysaccharide, flagellin, or cytosine-phosphate-guanine (CpG) dinucleotides, that bind to B-cell toll-like receptors. These signals can partially replace T cell help and account for the activities of many vaccine adjuvants.[36]

B-Cell Responses

In newborn mammals, the earliest B cells express IgM and IgD BCRs. Once appropriately stimulated, B cells divide asymmetrically.[3] The side of the B cell that attaches to the helper cell receives a full dose of stimuli and progressively differentiates into a plasma cell, whereas the opposite pole receives less stimulus and differentiates into a memory B cell. The B cell destined to become a plasma cell develops an extensive endoplasmic reticulum as well as a large Golgi apparatus, both of which are needed for the synthesis and secretion of enormous quantities of immunoglobulins. Once differentiated, plasma cells switch from making IgM to another immunoglobulin class depending upon their signals they receive and their anatomic location. For example, B cells on the body surfaces primarily produce IgA or IgE, whereas those in the spleen primarily produce IgG. Simultaneous with division, B cells randomly change the genes encoding their immunoglobulin variable region. As a result, the B cell either increases or decreases its affinity for antigen. If the affinity decreases, the antigen provides less stimulus and the B cell dies. If the affinity increases, then that B cell is preferentially stimulated and that clone of cells expands. As a result, antibody affinity for antigen gradually increases over the course of an antibody response.

Plasma Cells

Plasma cells develop as B cells differentiate. They first appear in the B cell areas of secondary lymphoid organs and subsequently migrate to colonize all the secondary lymphoid organs. Plasma cells have a characteristic morphology and staining pattern that distinguishes them from other forms of lymphocyte. They are 10–12 µm diameter, ovoid cells that contain a round, paracentrally positioned nucleus with "clock-face" pattern chromatin and a prominent nucleolus. Because of the dense concentration of ribosomes, the cytoplasm is basophilic and pyroninophilic, but the very large Golgi is obvious as a pale area adjacent to the nucleus (Figure 8.5). Plasma cells are specialized immunoglobulin producers, and it is claimed that they can synthesize up to 10,000 immunoglobulin molecules/second.

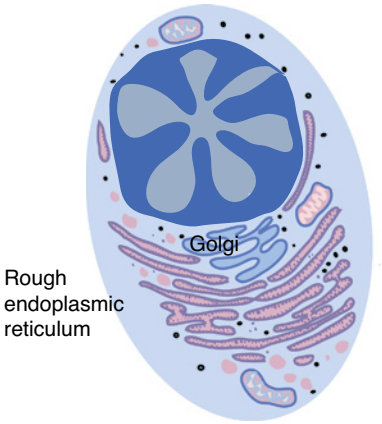

FIGURE 8.5 The structure of a plasma cell. A plasma cell is simply a B cell that has been activated so that it will produce an enormous quantity of antibody molecules. As a result, its cytoplasm expands to accommodate large quantities of rough endoplasmic reticulum and an enlarged Golgi apparatus.

Memory B Cells

As an antibody response progresses, short-lived plasma cells die but memory B cells survive. These are indistinguishable in morphology from other B cells. Their survival is, in part, mediated by helper T cells, which upregulate expression of the anti-apoptotic protein *Bcl*-2 in memory B cells. Although several different populations of memory B cells have been identified in humans and mice, a similar diversity has not been found in domestic species. This diversity is represented by long-lived lymphocytes that can be thought of as adult stem cells and will respond very rapidly when they next encounter antigen and long-lived plasma cells that continue to produce antibodies in response to persistent antigens. This latter population is the source of low levels of antibodies in older animals that have not been recently vaccinated.

B-Cell Subpopulations

Two distinct subpopulations of B cells have been identified in mice. One of the populations (B1 cells) originate early in fetal life and are phagocytic and can kill ingested bacteria. B1 cells have been further divided into B1a cells, which produce most "natural" IgM, and B1b cells, which are needed for antiparasitic immunity ("natural" antibodies are the low level of antibodies found in the

bloodstream of normal, unimmunized animals). B2 cells constitute the majority of B cells found in lymphoid organs and have slightly different phenotype.

HELPER T CELLS

The Response of Helper T Cells to Antigen

Foreign antigens trapped by APCs or expressed by virus-infected cells are bound to MHC molecules and presented to helper T cells. Upon receiving suitable costimulation, the helper T cells respond to the antigen by secreting a complex mixture of cytokines.[8] These cytokines then serve to determine the developmental pathway and magnitude of the subsequent immune response. Because of their central role in the immune system, helper T cells must be carefully regulated by cell–cell contact and cytokine exposure.

T-Cell Antigen Receptors

As noted in the earlier text, each T cell is covered with a large number (approximately 30,000 molecules) of identical antigen-binding TCRs. Analogous to the BCR, the TCR is structurally characterized by an antigen-binding component and a signal transduction component. The antigen-binding component consists of two disulfide-linked chains, the specifics of which vary according to species. In most nonruminants, α and β chains account for over 90% of the TCRs with the remaining containing γ and δ chains. These four antigen-binding chains all contain an N terminal variable domain, which is involved in antigen binding, and a set of C terminal constant domains, which links to the signal transduction component. Antigen peptides bind in the groove formed between the paired chains.

The signal transduction component of the TCR consists of six peptide chains in the form of three dimers. Collectively, this is called CD3 and its presence is a characteristic feature of T cells. Associated with the CD3 complex are two other peptide chains, CD4 and CD8. As described in the earlier text, T cells may have one, both, or neither. CD4 molecules bind T cells to MHC class II molecules and thus link the T cells to antigen-presenting cells. CD8, on the other hand, binds T cells to MHC class I molecules associated with abnormal cells of any type. This interaction between CD8 and MHC class I locks the cells together and facilitates cytotoxicity. As with B cells, the area of contact between the antigen-presenting cell and the T cell forms an immunological synapse. In the case of helper cells, the circular contact area has a target-like structure with the TCR complex at the center surrounded by a ring of costimulators and on the outside surrounded by a "gasket" of adherence molecules.[35]

Costimulation of T Cells

For a T cell to maximally respond to an antigen, it must receive multiple signals from the APC (Figure 8.6).

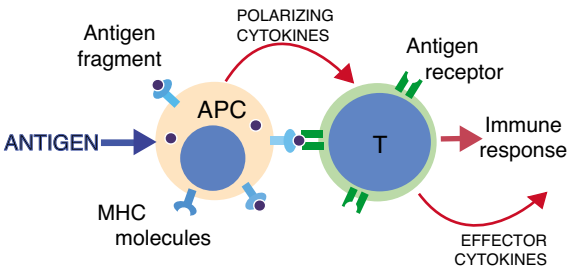

FIGURE 8.6 Development of an adaptive immune response. The key step in triggering an adaptive immune response is the presentation of processed antigen to T cells. The T cell antigen receptor will only recognize peptide fragments bound to MHC molecules on the surface of antigen-presenting cells such as dendritic cells.

This additional signaling is provided by costimulatory receptors, cytokines, and adherence molecules. Costimulatory receptor pairs include CD40 ([on] the APC) and CD154 (on the helper T cell), which, when bound to each other, induce the T cell to express CD28. CD28 then binds to CD80 on the APC and, as a result, the T cell becomes activated. A few days after being activated, the T cell turns on the genes encoding another T-cell receptor called cytotoxic T-lymphocyte-associated protein (CTLA)-4 (CD162). Binding to CTLA-4 suppresses T-cell cytotoxicity and its upregulation has been identified in many cancers. Monoclonal antibody-based blocking of CTLA-4 activity permits T-cell activation and antitumor immune activity. T-cell function is thus regulated by a balance between the suppressive effect of CTLA-4 and the stimulatory effect of CD28.

Helper T cells are also regulated by complex cytokine mixtures secreted by APCs.[55]

For example, IL-12, along with IFN-γ and IL-18, from dendritic cells causes undifferentiated T cells to become Th1 cells. In the absence of IL-12, and in the presence of cytokines such as IL-4, IL-13, IL-33, and IL-25, T cells differentiate into Th2 cells. Finally, T cell costimulation is provided by adherence [molecules], which bind the helper T cell to the APC so that signals can pass more freely between them. These cell adherence molecules include the CD11/CD18 integrin complex that is found on the surface of T cell and binds to CD54 on the APC.

Helper T-Cell Subpopulations

As $CD4^+$ T cells differentiate, they eventually form four discrete populations determined by their exposure to specific cytokine mixtures. These cytokine mixtures activate selected genes, which causes the T cells to secrete other cytokine mixtures that determine their biological activity and functions. Two of these cell populations, Th1 and Th2 cells, have been described in the earlier text. They are responsible for the generation of type 1 and type 2 immune responses, respectively (Figure 8.7).

Th1 cell differentiation is driven by interleukin-12 with the assistance of IFN-γ and IL-18. When

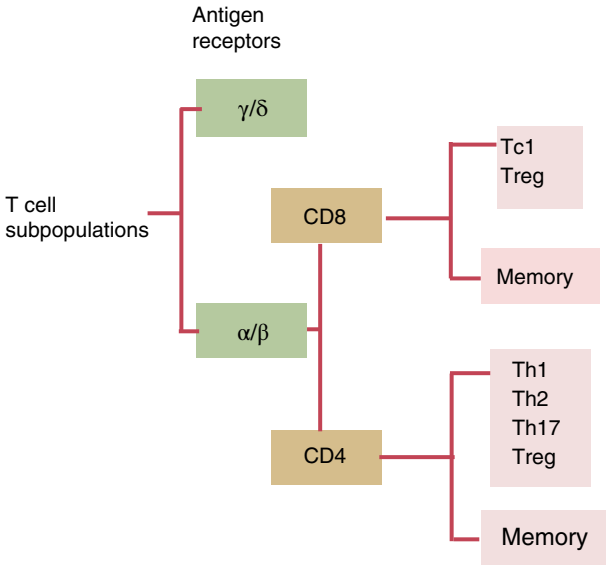

FIGURE 8.7 T-cell differentiation. As T cells develop, they turn genes on or off and eventually differentiate into multiple subpopulations. Some use alpha and beta chains in their TCTs, others use gamma and delta chains. The proportion of these two cell types differs between different domestic species.

they are activated, Th1 cells generate IL-2, IFN-γ, tumor necrosis factor (TNF)-α, and lymphotoxin (TNF-β). These cells promote type 1 responses that are primarily cell-mediated immune responses. Th2 cell differentiation is driven by IL-25 and IL-33. Once differentiated, they secrete IL-4, IL-5, IL-9, and IL-13. These cytokines stimulate B-cell proliferation and the production of immunoglobulins. While the B cells make predominantly IgG, under appropriate circumstances such as worm infestations, they may also promote the development of allergies by enhancing IgE synthesis. Th17 cells are a population of $CD4^+$ T cells that produce IL-17. This production is mainly stimulated by IL-23 with help from IL-1, IL-6, and IL-21. IL-17 and related molecules such as IL-21 and IL-22 promote inflammation. They play an important role in protection against extracellular bacteria. Treg cells are also $CD4^+$ cells that characteristically also express CD25. They produce immunosuppressive cytokines such as TGF-β and IL-10. Treg cells play an important role in controlling immune responses and preventing allergic and autoimmune disease.[18]

γ/δ T Cells

As described earlier, the relative proportion of γ/δ T cells to α/β T cells varies enormously between the different domestic animal species. Pigs and ruminants are γ/δ-high, while other mammals including the carnivores, rodents, and primates are γ/δ-low.[23] In γ/δ-low species, two subsets of γ/δ cells have been identified. One subset shows limited TCR diversity and probably functions as innate cells. These are mainly located in the genital tract and skin where they bind microbial products and lipids. They are activated by IL-23. The second γ/δ subset possesses highly variable TCRs and probably functions in adaptive immunity either as helper or effector cells. In γ/δ-high species, these cells predominantly are involved in adaptive immunity. They constitute the major T-cell population on surfaces such as the skin and mammary gland, the intestinal tract, and the genital tract. In ruminant blood, almost all are $WC1^+$ and are of the innate immunity type.[22] They may also have subpopulations that have both effector and regulatory functions. A similar situation applies to pigs where some γ/δ subsets have Th1 functions, while others have Th17-like activity.[45]

CYTOTOXIC T CELLS

When the body needs to rid itself of unwanted, damaged, or surplus cells, it may utilize apoptosis. Cytotoxic $CD8+$ T cells make use of this pathway to destroy virus-infected or otherwise abnormal cells. To affect this process, cytotoxic T cells bind to their target using a synapse that contains "two centers." One center consists of the molecules signaling *from* the target (i.e., antigen-MHC I signaling to the T cell), whereas the second consists of molecules signaling *to* the target (i.e., pro-apoptotic signaling).

The Response of Cytotoxic T Cells to Antigen

Cytotoxic $CD8^+$ T cells are activated and expanded by exposure to IL-12 from APCs together with IL-2 and IFN-γ from Th1 cells. Once activated, the T cells begin to divide. Their numbers increase very rapidly, as they can divide every 4–6 hours and do so up to 20 times. They reach maximal numbers 5–7 days after the onset of infection. These effector cells are however short-lived and die once the invaders are eliminated. Almost all undergo apoptosis within a few weeks.

Cytotoxic T-Cell Subpopulations

Mice have two subsets of cytotoxic T cells. Tc1 secrete IL-2 and IFN-γ, while Tc2 cells secrete IL-4 and IL-5. Many of these cells that do not even secrete cytokines are called Tc0 cells.

Memory T Cells

When a T-cell response occurs, there is a massive expansion of short-lived effector T cells that die once their job is done. However, about 5–10% of the responding cells evade apoptosis to become memory T cells. These are long-lived cells that accumulate over an animal's lifetime and, thus, the number of memory cells is much greater in older versus younger animals. Memory T cells, like memory B cells, are derived by asymmetric cell division.[12] These memory cells are $CD44^+$ and require IL-15 to survive. In mice, three types of memory T cells have been identified. Central memory T cells circulate with other lymphocytes and mount a very rapid

effector response upon re-encountering their original antigen. Effector memory T cells are attracted to sites of microbial invaders where they can immediately attack and destroy them. The third population, tissue-resident memory T cells, is located beneath body surfaces.[39] They do not recirculate but serve as a line of defense against invaders. All memory T cells express CD4 or CD8. They are in effect adult stem cells that slowly divide to replenish their numbers.

INNATE LYMPHOID CELLS

T and B cells express an enormous number of randomly generated antigen receptors that are derived from a limited number of germline genes through somatic mutation and gene recombination. Their recruitment and activation require a significant amount of time, and, thus, there is a lag before adaptive immunity develops. To partially fill this gap, there are populations of innate lymphocytes. These cells, which possess a limited array of germline-encoded receptors, circulate throughout the body and attack invading organisms as soon as they are recognized.[44] Innate lymphocytes include both innate helper cells and innate cytotoxic cells (i.e., NK cells) (Figure 8.8).[2,13]

Innate Helper Cells

There are three populations of ILCs: ILC1, ILC2, and ILC3 cells. ILC1 cells are the innate counterparts to Th1 cells and play an immediate role in the defense against invading bacteria, viruses, and parasites. They are mainly located under body surfaces and, like Th1 cells, can produce large amounts of IFN-γ and TNF-α in response to IL-12. ILC2 cells, by contrast, are found in many organs, including the lung, skin, and bone marrow. They are the innate counterparts of Th2 cells. They produce large amounts of IL-5 and IL-13 and are required for the early innate response to parasitic helminths.[32] They also play a major role in the development of allergies, since these cytokines control eosinophil production. ILC3 cells are located in the intestinal mucosa where they serve a function similar to Th17 cells. They produce IL-17 and IL-22 in response to IL-23. They are important in protecting mucosal surfaces against bacterial and fungal invasion and defend against intracellular bacteria. ILC3 cells are also essential for the development of lymphoid organs and in the generation of intestinal IgA-producing B cells.

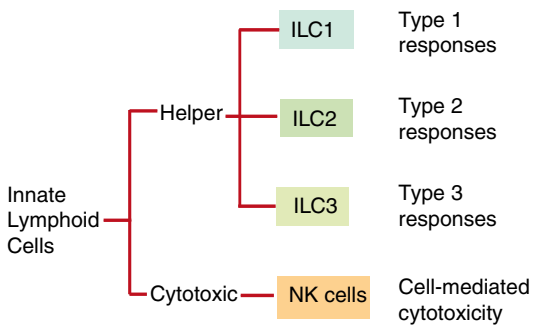

FIGURE 8.8 T-cell subpopulations. It is now recognized that there are several different innate lymphoid cell subpopulations that have equivalent functions to the T cell subpopulations. Thus ILC1 cells have similar functions to Th1 cells and produce cytokines that promote type 1 responses. The other innate populations also have T cell equivalents.

Innate Cytotoxic Cells

NK cells were first identified by their ability to kill abnormal cells, including tumor- and virus-infected cells, without previous priming. Morphologically, in most mammals, NK cells appear as large granular lymphocytes.[51] In cattle, they may be large lymphocytes without obvious granules, while in pigs there is a debate about their morphology with some asserting that they are small, lack granules, and thus indistinguishable from other lymphocytes.[20] NK cells are produced by bone marrow stem cells and are found throughout the secondary lymphoid organs. They may account for up to 15% of circulating lymphocytes in humans and 2–4% of circulating lymphocytes in cattle.[7] They have a characteristic phenotype of CD3−, CD56+, and NKp46+.[34]

Unlike T and B cells, NK cells do not possess an array of highly diverse antigen receptors. Instead, they have a small number of germline-encoded receptors that can detect one of two different signals, either: (1) the presence of MHC class I molecules on the target cell's surface or (2) the expression of stress-related molecules on cancer- or virus-infected cells. NK cells employ a "missing-self" strategy when evaluating cells for MHC class I expression. Recall that cytotoxic T cells rely upon the detection of antigen bound to MHC class I to identify and destroy a virus-infected cell. Thus, to evade destruction, a virus may downregulate cellular MHC I expression. To counter this, NK cells attack and destroy any cell *not* expressing MHC I. NK cells also possess receptors that detect the expression of "stress" proteins on cells which, when detected, send a positive signal stimulating NK cytotoxicity.

In different mammalian species, NK cells fall into three different types based on their critical receptors.[10] For example, in cattle and humans, the NK cells express killer cell immunoglobulin-like receptors (KIR), in rodents and horses, they express a C-type lectin called Ly49, whereas in rodents and primates, they express a receptor called NKG2D.[14,15,19,20,29,46,47] Each of these receptor types belongs to a family with both inhibitory and stimulatory members. NK cells also possess Fc receptors that allow them to bind and kill antibody-coated targets. Upon activation by contact with a target cell, NK cells kill their targets either by inducing their apoptosis through the CD95/95L pathway or by secreting toxic NK-lysins through the perforin pathway.[11] Unlike T and B cells that need to be activated before killing their targets, NK cells can immediately attack any virus-infected and tumor cells they encounter. Thus, they actively participate in the immune defense of the body.[30] NK cell numbers expand when needed and decline once the stimulus is removed. However, in a process termed

"trained immunity," small numbers of "memory" NK cells may persist to facilitate a more efficient response should the original stimulus be reencountered.[1]

NKT CELLS

Some [lymphocytes] express both T-cell and NK-cell markers and are accordingly called *NKT cells*.[17] There are two distinct subsets of these cells. Some, called *NKT1 cells*, use a TCR with an invariant α chain and a variable β chain. These cells recognize lipids and glycolipid antigens presented to them by cells with a specialized MHC molecule called *CD1*.[27] NKT1 cells are found in lymphoid tissues and the liver, and they constitute about 1% of human blood mononuclear cells. Type II NKT cells use a conventional TCR and also recognize lipids. They are likely primarily regulatory cells. Equine NKT cells may play a key role in recognizing the cell wall lipids of *Rhodococcus equi*. Cattle and other ruminants may not even possess classical NKT cells, but they have other cell types with similar functions.[28]

HEMATOPOIETIC SYSTEM CELLS AND ORGANS

The hematopoietic system consists of the cascade of cells produced by the bone marrow and their specialized conducting and supporting systems. These systems include vascular endothelium, the connective tissue cells of the marrow, lymph nodes, and spleen, and organ-specific specialized cell populations.[5,15,20,21,25]

The hematopoietic cells consist of all differentiated products of pluripotent stem cells, including monocyte–macrophage and granulocytic cells, as well as RBC, platelet, and lymphocyte precursors. The latter, which include the thymic- and bone-marrow-dependent arms of the lymphoid system, are respectively responsible for cellular and humoral immunity.[15]

The vascular endothelium of the hematopoietic system includes the regionally undifferentiated cells lining the lymphatics and regionally differentiated endothelial cells of the blood vascular system.[14]

The specialized circulating blood cells and their conducting and supporting structures are uniquely packaged in a series of separate organs—that is, the thymus, lymph nodes, and spleen—or are incorporated into other organs, as with the bone marrow. The interrelation and integration of the cells and organs of the vascular system have important consequences in health and disease.

FUNCTIONAL ANATOMY OF THE HEMATOPOIETIC SYSTEM

Thymus

The thymus is cytologically simple, but architecturally complex. Cytologically, the thymus contains lymphocytes and epithelial cells; architecturally, it consists of lobules differentiated into cortical and medullary areas (Figures 9.1 and 9.2).

Thymic epithelial cells are derived from the third and fourth pharyngeal pouches that, in the embryo, migrate in two streams to form paired thymic lobes within the anterior mediastinum. This migration occurs very early in embryological development and is immediately followed by seeding of the thymus with progenitor cells from the blood islands of the yolk sac.[15]

The first stream of epithelial migration forms the isolated reticular epithelial cells of the cortex and medulla. Early reticular epithelial cells form loose cuffs around

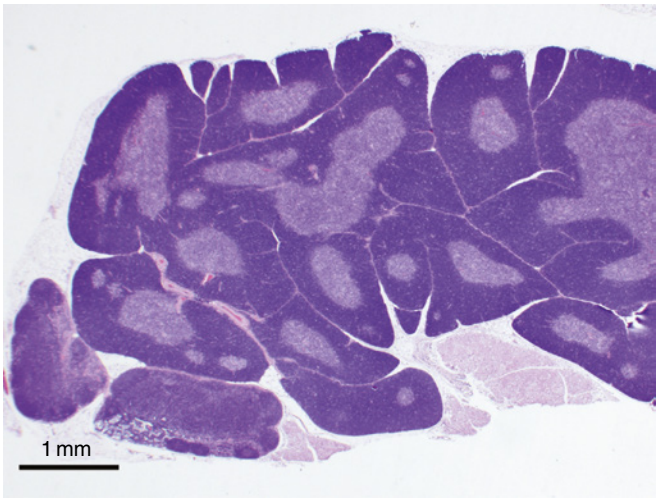

FIGURE 9.1 Thymus from a young adult male rat. The organ is composed of closely faceted lobules with a sharp distinction between the darker cortex and the lighter medullary areas of each lobule. H&E stain; bar = 1 mm.

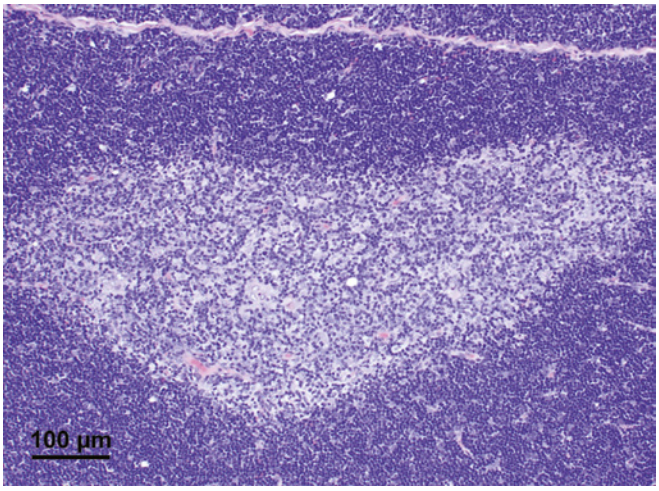

FIGURE 9.2 Mammalian thymus. In young healthy mammals, the medulla and cortex are sharply delineated; the width of the cortices and medulla equals approximately one-third the width of the entire lobe. H&E stain; bar = 100 µm.

small vessels that persist in adult life and become obvious in conditions of lymphoid atrophy. These epithelial cuffs of thymic vessels are a barrier to blood-borne antigens and the sole provider of immunologic training to naïve bone marrow lymphocytes.

The second epithelial migration forms the thymic duct epithelium and later the Hassall's corpuscles of the thymic medulla (Figure 9.3).[21] In early development, this ductular epithelium forms the branching system that communicates between the lobules of a single thymic lobe. The medullary epithelium produces trophic hormones that assist lymphocytic colonization and are the source of cysts lined by ciliated epithelium that frequently develop in adult life. The concentrically arranged, laminar squamous epithelial cells of the

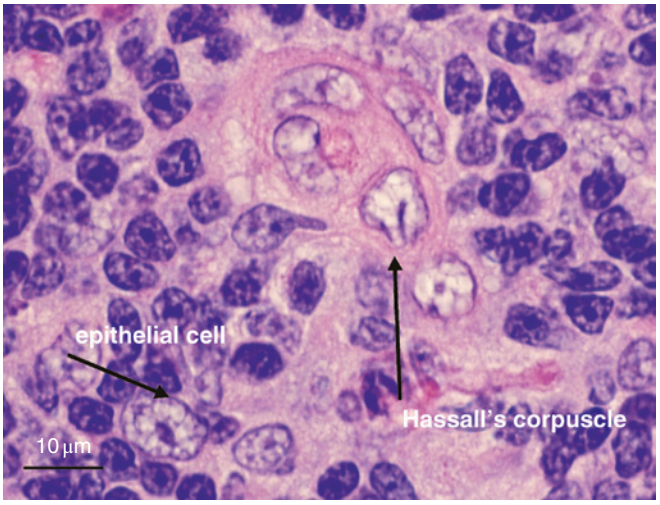

FIGURE 9.3 A Hassall's corpuscle in the thymic medulla consists of concentric laminations of squamous epithelial cells. The surrounding cells are a mix of small and medium lymphocytes and epithelial cells with large pale nuclei (arrow). These epithelial cells, with moderately abundant cytoplasm separating the nuclei, give the medulla a less-dense histologic appearance than the cortex. H&E stain; bar = 10 µm.

medullary Hassall's corpuscles are surrounded by myoid cells. These myoid cells are of uncertain histogenesis, but may have shared epitopes with thymic epithelial cells and are important in the pathogenesis of myasthenia gravis.[21]

The embryological relationship of these cells and structures is relevant in the diagnosis of adult thymic lesions. For example, a thymic lesion with loss of corticomedullary distinction that may be either medullary hyperplasia or a thymoma can be differentiated by the presence of reticular cuffs around the vessels, a finding that indicates thymoma.

The thymus is vital for the training and development of T cells. Uncommitted lymphocytes, originating in the bone marrow, have cell surface molecules to selectively home to thymic cortical vascular endothelium. Consequently, these uncommitted lymphocytes stream continuously into the thymic cortex. In the cortex, reticular epithelial cells form thin-walled pouches (caveolae) within which these lymphocytes undergo immunological selection for tolerance to self-antigens (see Chapter 51). These thymic cortical lymphocytes (thymocytes) have small, densely stained nuclei without apparent nucleoli, despite their intense cellular proliferation. The vast majority of these thymocyte progeny fail immunologic selection or successful T-cell receptor gene (TCR) rearrangement, die by apoptosis, and are removed by tingible body macrophages (Figure 9.4).[5] These macrophages become more prominent in conditions causing cortical lympholysis, such as certain viral infections, irradiation, or corticosteroid therapy.

Medullary lymphocytes are larger than cortical lymphocytes, with bigger, more vesicular nuclei and increased volumes of cytoplasm. As a consequence of this larger lymphocyte size, the thymic medulla is less

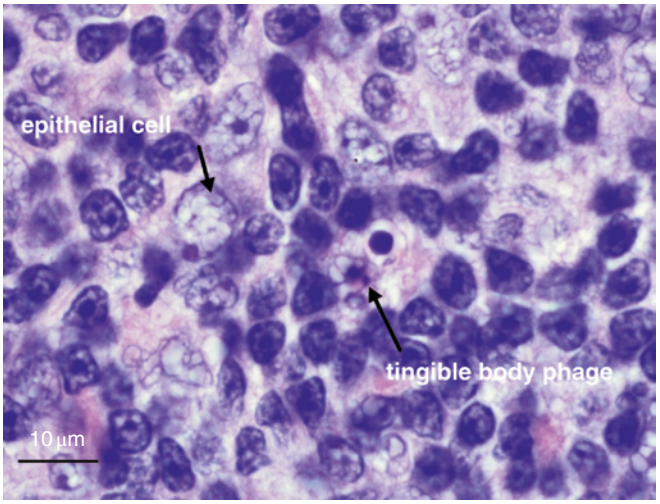

FIGURE 9.4 Thymic cortex composed of densely packed small lymphocytes (thymocytes). The cytoplasm of a tingible body macrophage (arrow) contains several pyknotic nuclear fragments (tingible bodies) of apoptotic thymocytes. The larger vesicular nuclei (arrow) are probably reticular epithelial cells involved in the immunologic training of developing T cells. H&E stain; bar = 10 µm.

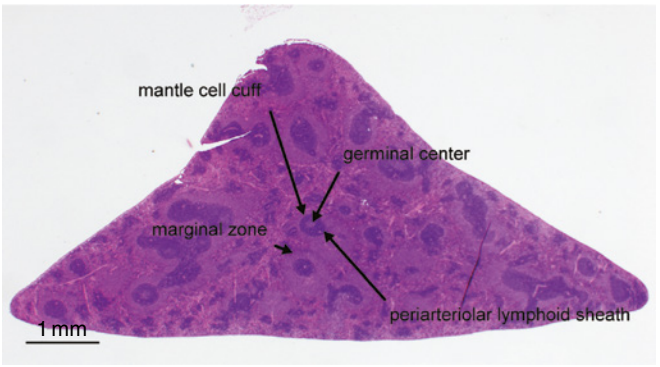

FIGURE 9.5 Cross-section of spleen from a young adult male rat. At the architectural level, the spleen is composed of multiple, dispersed round dark lymphoid nodules (white pulp) with the intervening lighter areas consisting of vascular sinuses (red pulp). The lymphoid areas may have a germinal center surrounded by a mantle cell cuff (arrows). The lighter mantle and marginal zones surrounded this mantle cell cuff. H&E stain; bar = 1 mm.

histologically dense. Within the medulla, some of the small fraction of mature T cells that survived both positive and negative selection undergo additional training that results in preferential homing to the intestinal mucosa and Peyer's patches.

Recent work suggests that terminal maturation of T cells may occur in the intestinal tract as well as in the thymus.[13] It would not be surprising if similar activity was found in both the lung and skin, which would provide a more comprehensive explanation for aberrant lymphoid reactions that can occur in benign and malignant states.

In addition to epithelial cells and lymphocytes, other cell types can be found within the thymus. In young rabbits, heterophils are frequently found in thymic tissue, particularly in lobular connective tissue. Eosinophils may occasionally be found in thymic connective tissues of other species. Mast cells are present in the thymic capsule of most species and are particularly frequent in rats.

In most species, the thymus reaches its maximal physiologic development about the time of puberty. An unusual antigenic stimulation during adolescence may cause benign thymic hyperplasia, which—in the calf—can result in an exaggerated chain of thymic lobules extending from the rami of the mandibles to the heart base. This thymic hyperplasia occurs largely through an increased number of lobules rather than increased lobule size. After adolescence, the thymus slowly decreases in size as a result of age-associated atrophy. Thymic atrophy, whether physiologic or pathologic, tends to result in a blurring of the corticomedullary distinction and fatty infiltration.

Thymic function—facilitating T-cell development and education—does not necessarily vary in relation to thymic size. Consequently, even a small thymic remnant may be responsible for persistent autoimmune disease in the adult. Unlike secondary lymphoid tissues (e.g., lymph nodes) that respond to antigenic stimulation, the thymus does not form lymphoid germinal centers. However, nonpathologic germinal centers can develop within the thymic vascular epithelial sheaths, as this unique location is immunologically "outside" the thymus.

Spleen

The spleen is cytologically and architecturally complex. It forms early in embryonic life and is a site of active erythropoiesis during the fetal period. Postnatally, it contains a wide variety of lymphoid and hematopoietic cells whose proportions vary in reactive and disease states. Diverse, dynamic regional anatomy is the result of a complex vascular system and expansile venous sinus system.

The spleen is composed of two primary tissues—red pulp and white pulp. The red pulp is comprised of many vascular sinusoids and serves as the spleen's filtering system to remove hematogenous antigens, microorganisms, and abnormal or effete blood cells. The white pulp is composed of lymphoid tissue and functions in lymphopoiesis and antibody production. These functional tissues are supported by internal trabeculae and an external capsule.

The spleen is unique in having efferent, but no afferent, lymphatics. Thus, all antigens enter the spleen through the blood vascular system. Both the major arterial supply and venous outflow enter through the spleen hilum and arborize together throughout its length. This interior arborization is relatively random in mammals, but reptiles have a major central venous sinus that is somewhat analogous to the bone marrow.

The white pulp consists of lymphoid tissue with unique histologic organization. At the level of small- and medium-sized arterioles, the blood vessels are sheathed in a cuff of small thymic-derived lymphocytes. These cuffs of lymphocytes are known as periarteriolar lymphoid sheaths (Figure 9.5). Very small branches from

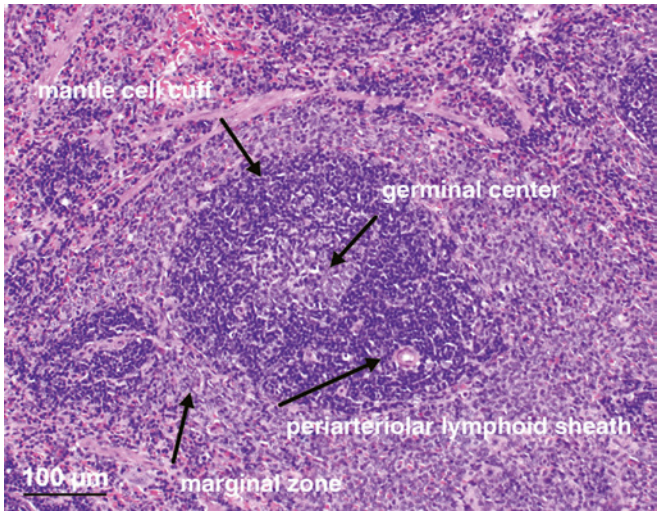

FIGURE 9.6 Details of Figure 9.5. Unlike larger mammals, rats tend to have less defined splenic germinal centers (shown). In the image center, a lighter zone constitutes the dendritic cell bed of a germinal center that abuts an eccentric small muscular arteriole (arrow). The germinal center is surrounded by cuffs of darker mantle lymphocytes and lighter marginal zone lymphocytes. The outermost marginal zone interfaces with the surrounding splenic red pulp. H&E stain; bar = 100 µm.

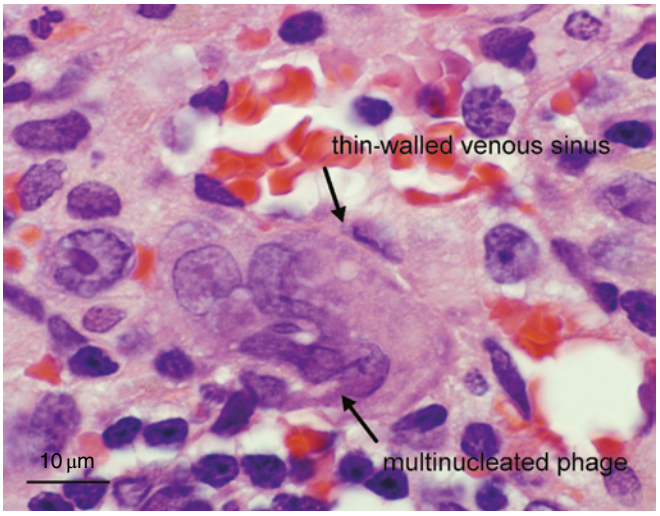

FIGURE 9.7 The interposition of macrophages, a multinucleated form in this field, and thin-walled vascular sinuses act as the filtering system of the spleen. H&E stain; bar = 10 µm.

these sheathed arteries give rise to germinal centers that are foci of B-cell proliferation. Surrounding the densely cellular periarteriolar lymphoid sheaths and germinal centers is a more loosely aggregated area of mixed T- and B-cell lymphocytes called the mantle cell layer. The rat and mouse have a clear stromal-appearing boundary around the mantle cells and germinal center that is not present in humans or domestic animals. Outside the mantle cells is a marginal zone of B cells (Figure 9.6). The marginal zone's width varies with immune activity and is itself surrounded by a trough or sinus area that receives blood passing through the germinal center. This trough or sinus area may appear redder in histological section and contains cells in the general circulation. In humans and the cat, this peripheral trough or sinus lies between the mantle cell cuff and the marginal zone layer.

While the cells of the periarteriolar sheath and germinal center are composed of resident cells whose movement occurs primarily through negative selection and replenishment, the lymphocytes of the mantle cell layer interchange with germinal center cells.

Small branches of the sheathed central arteriole may terminate in germinal centers, as described, or pass through the mantle and marginal zones to terminate in a penicillary array of small branches feeding directly into the sinusoids. These penicillary vessels are ensheathed by a few plump reticular cells that form a contractile ellipsoid. These ellipsoids are under neural and hormonal control to adjust the level of blood entering venous sinuses.

Under normal circumstances, 97% of the arteriolar blood entering the spleen exits directly via the penicillary vessels into a major sinus, which then quickly re-enters the central circulation. The remaining 3% undergoes filtration in the red pulp sinusoids. The walls of these sinusoids are unique. They consist of elongated endothelial cells arranged like the staves of a barrel, without junctions to their neighbors, which are maintained in alignment by a discontinuous encirclement of fine reticular fibers (Figure 9.7). Any filtered blood passes into the extrasinusoidal area—consisting of macrophages suspended in a loose reticular supporting framework—and then returns to central circulation by traversing between the sinusoidal endothelial cells. Reticulocytes, normal RBCs, and leukocytes easily pass between these endothelial cells to re-enter circulation, while senescent RBCs, those containing Howell–Jolly bodies, effete leukocytes, and foreign material cannot, so are phagocytosed by the extrasinusoidal macrophages. Cells that successfully re-enter the sinusoidal lumen exit to systemic circulation via the splenic vein. By this process, the entire blood volume is filtered by the spleen once each day.

Species with the genetic potential for sustained aerobic activity (i.e., humans, dogs, cats, and horses) have spleens with a contractile muscular capsule supported by equally contractile internal trabeculae. Contraction of these supporting structures permits maximal utilization of blood cells in systemic circulation. By contrast, species such as ruminants that group together for protection against their more agile predators tend to have spleens whose capsules are largely connective tissue with less capability for this contraction. In a muscular, contracted spleen, all of the blood passes directly from the arterial to venous system, thereby bypassing filtration. This "closed" circulation permits maximal utilization of blood cells. By contrast, any influence that causes a smooth muscle-rich splenic capsule to dilate (e.g., anesthesia, portal hypertension due to hepatic fibrosis, or marked increase in extrasinusoidal macrophages)

results in an expansion of the venous sinuses and a greater portion of blood passing through the extrasinusoidal filtering system.

The flow of blood through the red pulp is slow, thus cells are exposed to lower glucose and cholesterol concentrations and a lower pH than in systemic circulation. This biochemical environment is less hospitable to RBCs and platelets, so contributes to their premature aging and destruction. Thus, an enlarged spleen, regardless of cause, can decrease RBC and platelet life spans.[1]

A variety of changes occur in the spleen in response to systemic states such as toxicity, inflammation, starvation, immune-mediated disease, infarction, or neoplasia.

Acute toxic disease will result in lympholysis of the splenic germinal centers and replacement by residual proteinaceous debris. This process is referred to as follicular hyalinosis. While the nuclear debris resulting from acute lympholysis is cleared within 24 hours, the proteinaceous hyalin debris may remain for many months. In systemic amyloidosis, the germinal centers may become sites of amyloid deposition.

Atrophic changes due to starvation, aging, cancer, or chemotherapy may impact the thymic-dependent arteriolar sheaths and/or bone-marrow-dependent germinal center systems.

In chronic hemolytic anemias—particularly in old dogs—a marked increase in hemosiderin-bearing macrophages in sinus areas and iron deposition in the connective tissues can occur.

In dogs, hemorrhagic splenic infarction occurs in focal areas of hemangiosarcoma and can cause clinical anorexia or resistance to activity, even without hemorrhagic effusion. Ischemic infarction can be a consequence of myeloma-related blood hyperviscosity.

Painful splenic torsions, which are surprisingly compatible with life, occur primarily in dogs and humans. They also occur in adult pigs, but are rare.

Given the spleen's role in blood filtration, it is unsurprising that the major hazard to life after splenectomy appears to be septicemia.

Lymph Nodes

Lymph nodes are designed and strategically located to mount rapid and effective immune responses to foreign antigen.

The organization of lymph nodes and lymphatic vasculature is established during embryological development. During this early development, lymph nodes form at the confluence of an afferent lymphatic sprig and dilated sheath of blood vascular serosa. The blood vessel within the dilated serosal sheath produces a fine arborization of vessels that forms an architectural framework for future lymphocytic colonization.

Structurally, fully developed lymph nodes are composed of an outer cortex and inner medulla that are surrounded by a fibrous capsule and subcapsular sinus. The cortex consists primarily of B cells arranged as follicles, which may develop a germinal center upon antigen challenge. The deeper cortex, called the paracortex, is composed primarily of T cells. The medulla is composed of cords and sinuses. These medullary cords consist of plasma cells, macrophages, and B cells, while the medullary sinuses are vessel-like spaces between cords containing histiocytes and reticular cells.

The lymph node blood supply is highly organized with the arteriolar and venous branches arborizing through the medullary cords to form microcirculatory units. These circulatory units become the functional basis for germinal center formation. Specialized high endothelial venules form in the paracortical areas between–but never within–the germinal centers and present specific luminal adhesion molecules that regulate transmural lymphocyte traffic from the blood to the paracortex.[3]

The afferent lymphatics, peripheral capsule, and subcapsular sinus are the delivery system, whereby lymphatic fluid and antigens are delivered to the interior of the lymph node (Figure 9.8). The fibrous peripheral capsule will be thin and taut with a narrow subcapsular sinus when the lymph node has enlarged rapidly, while lymph node atrophy results in a thickened and wavy-appearing capsule with a wide subcapsular sinus. Chronic antigenic stimulation of a node, whether iatrogenic or pathologic, results in a thickened, sclerotic capsule with thick fibrous raphe that spans the cortex and terminates in a dense collagenous medullary fibrovascular network.[19] In cattle, and likely in other species, the lymph node capsule is contractile and under neural control, thus assisting lymph flow.[12]

Channels extend from the inner lining of the subcapsular sinus, through the cortex's lymphoid follicles and germinal centers, to the vascular microcirculatory units. These lymphoid follicles and germinal centers therefore act as the first order of antigenic filtration.

A fully developed germinal center is an organized structure consisting of a progression of cell types. The proliferative gradient created by this cellular progression provides the germinal center with an easily recognized polarity (Figures 9.9 and 9.10).[16] This polarity is largely due to an outer mantle cuff of small lymphocytes that is eccentrically thickened at the superficial or capsular pole, just beneath the inner lining of the subcapsular sinus, and thinned at the base or deep pole in the paracortex. Morphologically, the lymphocytes of the superficial pole have small dense nuclei with abundant lightly stained cytoplasm, while those in the deep pole have large nuclei with multiple prominent, usually peripheral, nucleoli and only a narrow rim of very basophilic cytoplasm. Antigen-presenting dendritic reticular cells and tingible body macrophages are located in the middle of the germinal center.

Dendritic reticular cells are derived from a variety of sources including myeloid or lymphoid precursors.[4,9,10,17] Consequently, dendritic cells at various anatomic sites have different phenotypic characteristics.[10] Ultrastructurally, dendritic cells are characterized by cytoplasmic tendrils that are joined between cells by tight junctions. In conditions of lymphoid depletion, these cells become exposed in germinal centers as an eosinophilic background of large pale cells.

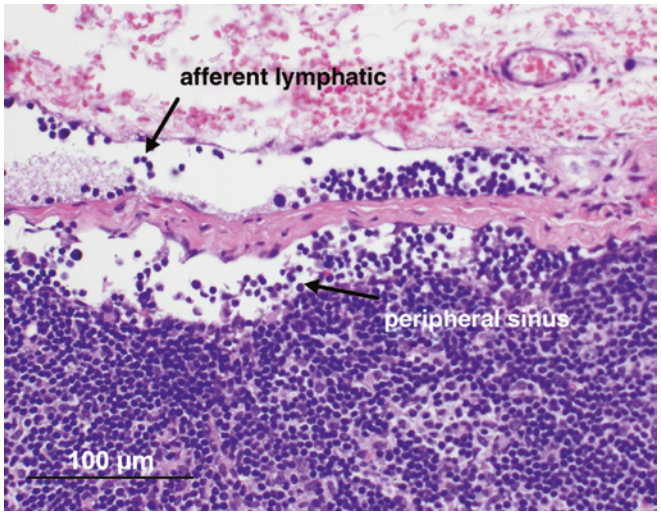

FIGURE 9.8 Lymph node outer cortex from a healthy dog. An afferent lymphatic (arrow) leads into the subcapsular sinus. The sinus is open and contains a few cells in transit on the left, but is compressed on the right by developing germinal centers. H&E stain; bar = 100 µm.

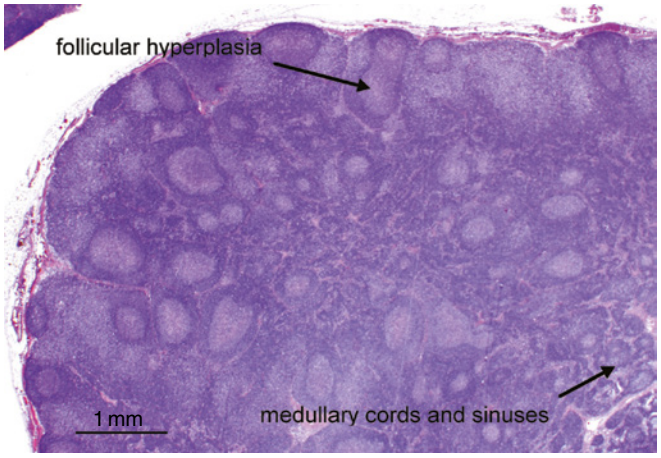

FIGURE 9.9 Architecture of the lymph node in Figure 9.8 showing follicular hyperplasia and densely cellular medullary cords and sinuses (arrows). H&E stain; bar = 1 mm.

One of the more difficult decisions when examining lymph nodes is the distinction between florid hyperplasia and lymphoma.[24] The neoplastic transformation of germinal centers to malignant disease is described in humans and it would appear that chronic lymphoid proliferation of any cause in animals can be a risk factor for lymphoma—examples include feline leukemia virus (FeLV) or bovine leukemia virus (BLV) infections and immunoproliferative small intestinal disease (e.g., inflammatory bowel disease).[6,14] The recognition of normal germinal center structure and orderly lymphoid proliferation is essential to distinguish benign and atypical follicular hyperplasia from follicular lymphoma. To this end, histiologic sections are made, so the germinal centers beneath the node capsule are in a plane that allows recognition of their antigen orientation, but those

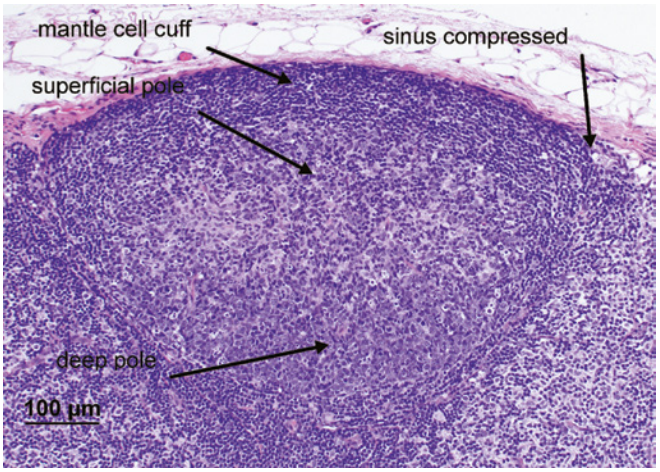

FIGURE 9.10 Lymph node cortex of Figure 9.9. The polarity of a subcapsular germinal center is directed toward the antigen being delivered from the subcapsular sinus into the superficial pole of small lymphocytes. The pale middle of the germinal center is composed of small and large lymphocytes with tingible body macrophages removing apoptotic lymphocyte nuclei. The deep pole area consists of lymphocytes with large nuclei and narrow rims of highly basophilic cytoplasm. H&E stain; bar = 100 µm.

in the medulla are oriented in a variety of planes, so all levels of the proliferative cellular progression can be viewed.[8] Follicular lymphomas, whether of small cleaved centrocytes, large centroblasts, or more often a mixture of both, can completely lack a mantle cell cuff and may instead be surrounded by a few residual small benign lymphocytes and aggregations of high endothelial venules. A particular type of follicular lymphoma that arises from the corona of cells surrounding the germinal center is known as mantle zone lymphoma. In this condition, coalescing nodular proliferations of moderate-sized lymphocytes surround fading germinal centers. Other distinguishing characteristics of follicular lymphoma include a conspicuous lack of cellular heterogeneity within the germinal center due to a clonal neoplastic expansion and a scarcity or absence of tingible body macrophages, since the tumor cells are not undergoing apoptosis.

Distinction between true benign or malignant follicular lesions and pseudofollicular lesions can be based on the location of the high endothelial venules. These specialized vessels are always between follicular proliferations and never within them, as may be seen with "pseudofollicular" lesions.

In the paracortex of some lymph nodes, particularly those in the mesentery of adult rats, there are semicircular or oval nodular structures distinct from germinal centers.[3,24] The main significance of these deep cortical nodules is to recognize their normalcy and not mistake them for a malignant lymphoid proliferation.[3] These deep cortical nodules, whose cellular input is from a distinct afferent lymphatic branch, form as a result of antigenic stimulation (Figure 9.11). They lie beneath the germinal centers of the outer cortex and are most easily visualized in lymph nodes with some degree of

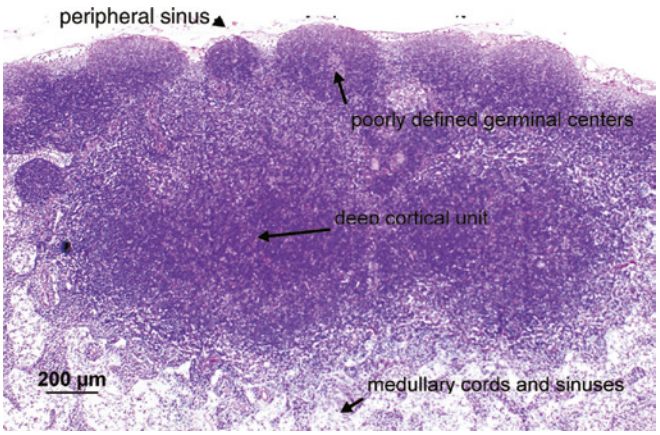

FIGURE 9.11 Cross-section of rat mesenteric lymph node. The superficial cortex is occupied by poorly defined germinal centers. The medullary cords and sinuses lie along the bottom of the image and abut a large, uniformly dense, oval deep cortical nodule. The deep cortical nodule is outlined by a paler rim of less-dense cells. H&E stain; bar = 200 µm.

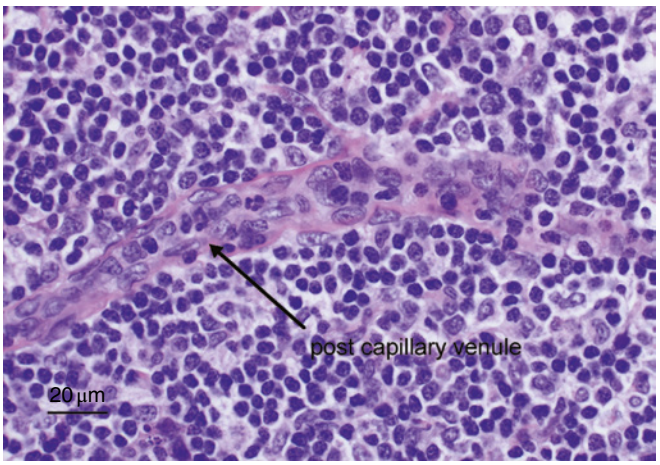

FIGURE 9.12 Paracortex of rat mesenteric lymph node. A high endothelial venule crosses this field (arrow). Several lymphocytes within the venule wall are in transmural transit—exiting the blood and entering the nodal cortex (near arrow). H&E stain; bar = 20 µm.

paracortical atrophy. The central area of these nodules is somewhat mottled due to varying proportions of large and small lymphocytes, some macrophages, and post-capillary venules (Figure 9.12). Edges of these deep cortical nodules gradually blend with the surrounding medullary cords and sinuses and are apparently the egress for cells entering the efferent lymphatic channels.[3]

The medullary cords and medullary sinuses are best considered together, as they form an interwoven matrix that waxes and wanes in unison or at the expense of one other (Figure 9.13). A medullary cord is composed of a branch of vascular structures—an artery, vein, and lymphatic—from the node hilum surrounded by a variable amount of connective tissue and covered by thin endothelium. The sinus area constitutes the space between the endothelial wall of the vascular structures and the similar endothelial wall of the medullary cords.

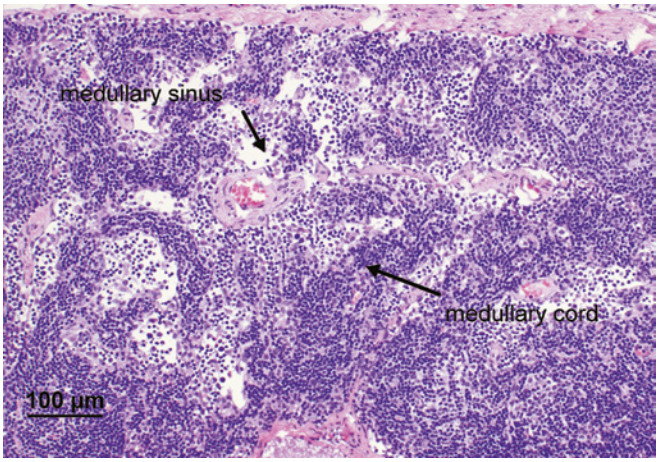

FIGURE 9.13 Medulla of a lymph node from a dog with normal cords and sinuses. The cords are densely cellular and surrounded by a thin endothelial membrane. The sinuses contain a few fixed macrophages, cells in transit, and lymphatic fluid. H&E stain; bar = 100 µm.

The medullary sinuses can extend all the way up to the subcapsular sinus in nodes with severe paracortical and follicular atrophy, such as the mesenteric nodes of cattle dying of acute bovine viral diarrhea virus infection. In this particular condition, massive B-cell lysis occurs and the sinuses tend to be filled with macrophages (sinus histiocytosis).

The cellularity and composition of the medullary sinuses vary widely. In diseases characterized by chronic immune stimulation, there are often high numbers of sinus macrophages suspended in a syncytial network. In nodes-draining areas of chronic dermatitis, the macrophages of the superficial cortex and medullary sinuses frequently contain abundant normal-appearing melanin granules.[18] Lymph-nodes-draining areas of hemorrhage have numerous hemosiderin-bearing medullary macrophages. Since the transit of RBCs to the lymph nodes and RBC intracellular degradation by medullary macrophages is rapid, the observation of erythrophagocytosis should be interpreted as a very recent event.

The medullary cords contain activated lymphocytes that encountered an antigen-presenting cell in the outer cortex expressing a major histocompatibility complex (MHC)/antigen to which they successfully bound. Antibody-producing plasma cells are typical of the medullary cords, but small or medium lymphocytes—rather than plasma cells—may predominate in reactions that have persisted for many weeks.

Nonlymphoid or nonmacrophagic cells can also be found in the medullary cords, as the fine reticular network forms a fertile microenvironment for extramedullary hematopoiesis. Malignant cells in myeloid leukemia can also colonize the medullary cords and may coexist with benign hematopoietic cells.

Naïve (nonactivated) lymphocytes circulate randomly in the blood and lymphatic fluid. However, their future migration becomes altered once activated by antigen recognition in the lymph node cortex. Activated B

cells migrate preferentially to mucosa-associated lymphoid tissues (MALT), while T cells migrate to peripheral lymph nodes.[5,7] This organ-specific lymphocyte homing occurs in both neoplastic and inflammatory conditions. The spread of malignant lymphocytes is therefore limited by their inherent capacity to migrate into various tissues. Thus, the spread of lymphoma to lymphoid structures is not a function of the tumor cells being able to enter the peripheral blood, but rather evidence of their successful binding to high endothelial venules and migration out of the blood and into additional lymphoid structures.[15] By this understanding, all lymphoid neoplasms circulate in the blood, but their degree of dissemination is limited by their binding capability. Therefore, differentiation between lymphoid leukemia and lymphoma is based simply on identification of the tissue with the greatest volume of tumor.

LYMPHOID SYSTEMS OF BODY SURFACES

Body surfaces that interface with the "outside world," including the skin, respiratory tract, and enteric system, have resident lymphoid populations and antigen-presenting cells vital in immune defense. Intraepithelial lymphocytes in these locations–those admixed within the epithelial layer–are cells in training, which return to deeper lymphoid structures following their specific sensitization to perform specific functions in differentiation and proliferation.

The skin's epidermis is 85% keratinocytes and 15% melanocytes, Langerhans cells, Merkel cells, and dendritic cells of uncertain type. The Langerhans cells arise from a variety of precursors and constitute the major antigen-presenting cells of the epidermis.[1] In the skin of humans and cattle, the Langerhans cells contain a typical cytoplasmic organelle visible on electron microscopy that is rod-shaped with a unipolar bulb called the Birbeck granule. The presence of Birbeck granules permits identification of Langerhans cells in the paracortex of lymph-nodes-draining skin. These cells phagocytose foreign molecules without degrading them, migrate to the local lymph nodes, and present these antigens in their specific MHC context to naïve lymphocytes. Both T and B cells are residents of the skin where their function is largely unknown, although a fairly consistent proportion of cutaneous lymphocytes are suppressor T cells that may be responsible for dampening cutaneous immune sensitization.[2]

The mucosa-associated lymphoid tissue of the respiratory and enteric systems is shared in the tonsillar and pharyngeal areas. In humans, these MALTs are collectively known as Waldeyer's ring. In the respiratory system, the epithelium of the nasal mucosa, larynx, trachea, and bronchi is infiltrated by variable numbers of lymphocytes with fewer neutrophils and macrophages. Mucosal lymphoid infiltration is more prominent above areas of submucosal lymphoid proliferation, such as the tonsil and bronchiolar-associated lymphoid tissues (BALT).[2] Lymphoid proliferation in the tonsil is usually characterized by prominent germinal center formation; while in the healthy lower lung, the BALT may be minimal and restricted to diffuse accumulations of cells between the bronchial epithelium and the supporting smooth muscle and cartilaginous plates (Figure 9.14).[20] In general, the degree of lymphoid reactivity in these areas is proportional to the level of antigenic stimulation. The impact of ambient air quality—reflected in the amount of dust and airborne infectious agents—is apparent in the lung histology of laboratory animals. Animals maintained in facilities with well-filtered air have minimal BALT and few intraepithelial lymphocytes. By contrast, animals exposed to poorer air quality have diffuse lymphoid proliferation in the proximal trachea and laryngeal areas with heavy, mixed cellular infiltration of the surface epithelium. In the lower lung, the reactive lymphoid proliferations may contain germinal centers, but are usually diffuse and may be of sufficient volume to partially occlude airways. The lymph nodes at the heart base and in the caudal mediastinum receive lymphatic fluid from the lung and consequently bear evidence of past environmental exposures, such as smoke or particulate inhalation.

The gut-associated lymphoid tissue forms a relatively continuous chain from the oral cavity to the anus with characteristic areas of proliferation. There are typically only a few lymphocytes in the epithelium and mucosa of the esophagus, whereas germinal center formation is relatively common, but not necessarily normal, beneath the gastric epithelium. In recent years, an association between *Helicobacter* sp. bacterial organisms and human gastric ulceration has been discovered. The gastric lymphoid tissue present in such cases appears antigen-dependent as it recedes with long-term antibiotic therapy targeting these organisms. Even more remarkably, the early stages of human gastric lymphoma appear antigen-dependent and the disease may regress with antibiotic treatment alone.

The amount of organized lymphoid tissue in the lower small intestine–including the Peyer's patches–is

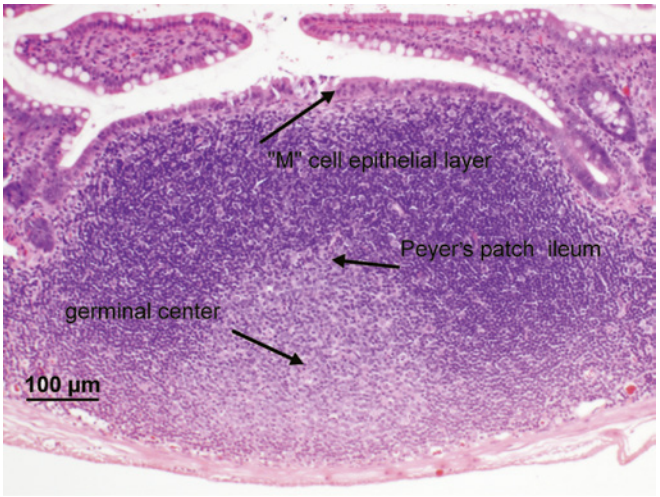

FIGURE 9.15 Lower small intestine of a normal rat. The epithelium overlying a focal, dome-shaped submucosal proliferation of lymphocytes lacks villi and is modified to facilitate antigen recognition and sorting. H&E stain; bar = 100 µm.

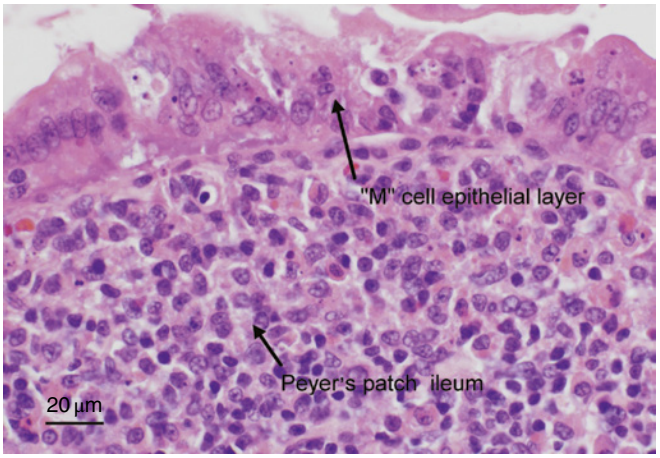

FIGURE 9.16 Details of Figure 9.15. The epithelium above the lymphoid follicle contains M cells with deeply folded cellular membranes. The M cells are capable of antigen uptake from the intestinal lumen and transport to secondary lymphoid tissues. H&E stain; bar = 20 µm.

roughly equivalent to the thymus gland in young animals (Figure 9.15). The intestinal epithelium overlying germinal centers is typically devoid of goblet cells or villi and has no glandular crypts (Figure 9.16). Instead, this distinctive epithelium has unique epithelial cells called microfold or M cells. These specialized cells, involved in the initiation of mucosal immunity responses, have complex apical membrane microfolding, hence their name.[23] M cells take up antigen from the intestinal lumen via selective endocytosis and deliver it to antigen-presenting dendritic cells or B cells in regional lymphoid tissues.

Much of the immunoglobulin (Ig) produced in BALT and MALT is IgA-type with luminal and mucosal concentrations significantly higher than in blood. The structure of immunoglobulin-A facilitates its crucial role in the immune function and protection of mucous membranes.

CBC, complete blood count; CBER, Center for Biologics Evaluation and Research; CDER, Center for Drug Evaluation and Research; CO_2, carbon dioxide; EDTA ethylenediaminetetraacetic acid; EMA, European Medicines Agency; FDA, Food and Drug Administration; HCT, hematocrit; HGB, hemoglobin concentration; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration; MHLW, Ministry of Health, Labor and Welfare; O_2, oxygen; PCV, packed cell volume; PLT, platelet count; PMDA, Pharmaceutical and Medical Devices Agency; RBC, red blood cell count; RDW, red cell distribution width; WBC, white blood cell count.

The CBC is the foundation of the evaluation of the hematopoietic system in nonclinical toxicology studies and clinical trials in humans. Microscopic evaluation of the bone marrow in nonclinical studies, together with concurrent evaluation of the CBC, provides a thorough evaluation of the health of the hematopoietic system and is often predictive of what will be seen in humans. The goal of this chapter is to briefly review the regulatory guidelines and best practices pertaining to the evaluation of the hematopoietic system in nonclinical toxicology studies, how and when to obtain samples, and the general approach to integration of the different hematologic tests.

REGULATORY GUIDELINES AND BEST PRACTICES

Governmental agencies responsible for ensuring the safety and efficacy of drug products, such as the United States Food and Drug Administration (FDA), European Medicines Agency (EMA), and Japan's Ministry of Health, Labor and Welfare (MHLW), have guidance documents for nonclinical toxicology studies that contain recommendations for hematologic testing, as well as bone marrow histologic and cytologic evaluation. The FDA has two main centers that are involved in human drug safety, including the Center for Drug Evaluation and Research (CDER) and the Center for Biologics Evaluation and Research (CBER). The Pharmaceutical and Medical Devices Agency (PMDA) partners with MHLW and has the responsibility for assessing human drug safety.

The types of toxicology studies that are needed for approval of new drugs consist of acute, subacute (or subchronic), chronic, and carcinogenicity toxicity studies. In stand-alone acute toxicity studies, the test article is administered once at different doses followed by an observation period of 14 days.[15] It is now recommended that the assessment of acute toxicity be done as part of other short-duration dose-range-finding studies that

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

will help to define the maximal tolerated dose.[14] Subacute and chronic toxicity studies are repeat-dose studies where the test article is administered multiple times at different doses for at least 2–4 weeks and for 6 or more months, respectively. Carcinogenicity studies are repeat-dose studies where the test article is administered for most of the lifetime of a rodent.

Hematologic testing is routinely performed in subchronic and chronic studies. The EMA gives very broad guidelines for clinical pathology testing.[12,13] Pharmaceuticals should be tested in two mammalian species, one of which must be a non-rodent, and both sexes should be evaluated in both species. Development of a pharmaceutical in a single mammalian species may be acceptable with appropriate justification. For rodents and non-rodents, historical control data should be available. Pre-study data should be generated in studies using non-rodents. The evaluation should be done at relevant time points to detect changes over time. Although EMA does not stipulate specific hematological parameters to evaluate, or timing of sampling, during the in-life and terminal phases of a study, it refers to the recommendations of the Joint Scientific Committee for International Harmonization of Clinical Pathology Testing for guidance.[32] EMA suggests that evaluation during the study should be done in all animals in studies with low numbers of animals. In rodent studies, specialized examinations may be performed in a subset of animals at all dose levels. Evaluations performed on animals to which test article is administered should also be performed on animals from the control group. Necropsy must be performed in all animals in the study. Blood smears are not specifically requested in the most recent guidance document.[13] Bone marrow smears and bone marrow for histopathologic evaluation (sternebrae, femur, or rib, depending on species) should be collected. Microscopic examination of bone marrow smears is to occur "if treatment-related changes are suspected in tissues/organs or in peripheral blood." If bone marrow smears are evaluated, EMA recommends a visual assessment of cellularity, distribution, morphology, and myeloid to erythroid ratio. However, the International Conference on Harmonization (ICH) S8 guideline, which the EMA adopted, is less definitive about when bone marrow smear evaluation is to occur, since it indicates that unexplained alterations in the peripheral blood or histology of the bone marrow "suggest" that microscopic evaluation of the bone marrow smears "would be appropriate."[12,20] The ICH S8 recommendation is more in line with the recommendations by the Bone Marrow Working Group of the American Society for Veterinary Clinical Pathology/Society of Toxicologic Pathology (ASVCP/STP), which indicated that bone marrow smears should be evaluated if characterization of the changes in the hematopoietic system were inadequate using hematology and histopathology results.[27] The EMA also recommends histopathologic evaluation of recommended tissues from all non-rodents, but in rodent studies histopathologic evaluation is performed first on animals in control and high-dose groups.[13] If microscopic changes are identified in the high-dose group, additional dose groups should be examined to clarify the dose relationship.

The MHLW guidelines for repeat-dose testing are very similar to EMA's guidelines.[33] They recommend blood samples be taken before necropsy in rodents, including interim sacrifice, and in non-rodents pretreatment samples should be evaluated. Although they recommend hematologic testing be done at the time of interim sacrifice of rodents, if these animals are in poor condition, many of the changes in the parameters may reflect secondary changes and thus may not be particularly useful in assessing the primary compound effect. In non-rodent studies of 1 month or longer duration, at least one interim blood sampling should be considered. If a 2-week exploratory study is done before the 1-month study, then hematologic evaluation at an interim time period may not be necessary. Hematological parameters to assess include RBC count, WBC count, WBC differential cell count, platelet (PLT) count, hemoglobin concentration (HGB), hematocrit (HCT), and reticulocyte count. Histopathology recommendations include bone marrow (sternum, femur). There is no mention of bone marrow cytologic examination.

CDER and CBER have not published their own recent guidelines for hematologic testing in repeated-dose toxicity studies. However, FDA had adopted ICH guidelines, some of which refer to, or provide general guidance about, the evaluation of the hematopoietic system.[16,20]

The guidelines governing the clinicopathologic evaluation of carcinogenicity studies vary between regulatory agencies. FDA and MHLW, both of which have adopted ICH guidelines for drugs intended for humans, do not explicitly indicate that hematological assessment is mandatory.[16,17,21,33] However, MHLW suggests that blood samples should be taken, if appropriate, to measure RBCs and WBCs, and to make blood smears in animals that are sacrificed before or at the end of the study. Blood smears may be useful to assess anemia or changes in lymph nodes, liver and spleen that may be present.[33] By contrast, the EMA suggests that monitoring hematologic parameters should be considered during the study and should be performed at study termination.[11] This recommendation is in contrast to the one made by the Joint Scientific Committee for International Harmonization of Clinical Pathology Testing that stated that blood smears at unscheduled and scheduled terminations should be made to help in the detection and differentiation of hematopoietic neoplasia, but other hematologic testing is not recommended because of the variability of the data.[32] Histopathologic evaluation of bone marrow is expected in carcinogenicity studies.[11,33]

There are now several new key position papers with recommendations of hematologic parameters to use in nonclinical toxicity testing.[27,29,34] The recommendations within these papers are very similar and overall align well with previous position papers as well as with most of the regulatory guidelines outlined in the preceding text. The most recent and comprehensive publication, "Best Practices for Veterinary Toxicologic Clinical Pathology, with Emphasis on the Pharmaceutical and Biotechnology Industries," was endorsed by the

Regulatory Affairs Committee of the ASVCP and STP and recommended these core parameters: RBC count, HGB and HCT, RBC indices (mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), mean corpuscular hemoglobin (MCH), red cell distribution width (RDW)), reticulocyte count, WBC count, absolute WBC differential counts, PLT count, and blood smear. Blood smears do not need to be reviewed routinely, but the criteria for review should be defined in standard operating procedures. Bone marrow cytology smears should also be prepared from each animal at termination in regulated studies, but only need to be reviewed on a case-by-case basis. This is typically done if the histologic and hematologic evaluation did not adequately characterize the bone marrow abnormality.[27] For carcinogenicity studies, the recent best practice paper recommends to follow the recommendations of the Carcinogenicity Study Working Group (STP/ASVCP).[34] Briefly, they recommend that blood smears be routinely collected from all animals that are euthanized (unscheduled and scheduled), since these slides may be useful in assessing hematologic neoplasia, but these should only be examined if necessary following histologic evaluation. They do not recommend routine hematology (or other standard testing) on these animals. Bone marrow smears should only be collected on a case-by-case basis.

PREANALYTICAL VARIABLES

General

Several preanalytical variables, including age, sex, source of the animals, fasting state, randomization and time of bleeding, anesthesia, diet, housing, and sample handling, should all be considered; controlling these variables will help ensure robust hematology data.[28] First, animals of similar age should be utilized, especially in rats, since hematologic parameters change with animal age.[18] Obtaining nonhuman primates of similar age can be more challenging, especially if wild-caught animals are used, or if sexual maturity is required. Animals should also be obtained from the same commercial and geographical source because this can affect hematological parameters. For example, cynomolgus monkeys (*Macaca fascicularis*) from Mauritius, the Philippines, or Indonesia have smaller RBCs than those from China or Vietnam.[19]

Randomization of the order of blood collection in toxicology studies also increases the uniformity of the data. This is especially true in rodents. If hematology sampling occurs on the same day as collection of a toxicokinetic sample, the hematology specimen should ideally be taken first to minimize the effect of changes in hematology parameters due to repeated phlebotomy.

Inconsistencies in how the animals are handled can have a major effect on hematologic parameters, especially for nonhuman primates where epinephrine-induced excitement responses readily occur (see Chapter 11). It has also been shown that transportation of mice within a facility to mimic what may be done prior to collection of blood can increase plasma corticosterone and lead to decreases in lymphocyte counts.[10] Therefore, it is important to treat all animals in the study in a similar manner to minimize stress. All these preanalytical variables will be minimized by a well-planned study that is carried out in a well-managed facility with appropriately trained personnel.

Fasted State

An important preanalytical variable to control is fasting.[32] The in-life samples typically are collected from rats and large laboratory animals with an overnight fast (15–16 hours). Collecting samples in the fasted state will help increase the homogeneity of the data as well as minimize chances of potentially inaccurate analysis due to postprandial lipemia. Thirty percent of non-fasted rat serum samples were found to be lipemic.[30] Fasting of rats can have significant effects on hematologic parameters, mainly caused by hemoconcentration resulting in increases in RBC count, HCT, HGB, and PLT count, but also decreases in WBC count and prolongation of prothrombin time and activated partial thromboplastin time.[1,24] In contrast to large laboratory animals and rats, mice should not be fasted overnight, as they tend to dehydrate rapidly; however, some facilities will use a three to five-hour fast.[18]

Timing of Blood Collection

The timing of sample acquisition from the peripheral blood is somewhat dependent on regulatory requirements, but also on the goal of the study, the animal species, the blood volume of the test animal, the number of additional samples needed to assess other parameters, the dosing time, and the results of previous studies. For repeat-dose studies in non-rodent species, hematologic testing is recommended at study termination and at least once at an earlier interval. For studies of 2–6 weeks' duration in non-rodent species, testing is also recommended within 7 days of dosing initiation, unless it compromises the health of the animals.[31] Additional sampling time points are included depending on the design of the study and should include the recovery period if present. In dogs and nonhuman primates, one or two prestudy baseline samples should always be taken. Due to the small number of animals per dose group and the variability of the hematological results, the baseline sampling is critical to accurately assess any changes that occur during the study. The comparison of the in-life and end of study hematologic results to the baseline sample(s) will allow for the most accurate assessment of the relevant changes in the hematologic parameters. Hematologic testing is necessary at study termination in rodent repeat-dose studies. Interim study testing may not be necessary in long-duration studies if it has been done in short-duration studies using similar dose levels.[32] Testing should be done at the end of the recovery period, if included.[32]

In rodent studies, baseline sampling is not typically done. This is in part due to less variability in the

hematological parameters of rats versus large animals. In addition, the number of rats used per dose group is greater (typically 10 rats per sex per group versus three or four per sex per group in large animal studies), which increases the confidence of the mean data in this species. The mean data of each dose group are then compared to the respective vehicle control, although individual animal data should also be evaluated. In addition, in longer-term studies, the hematologic parameters will change with age, which make comparison to pretreatment values difficult.

Method of Blood Collection

In dogs, interim in vivo samples are taken from the jugular vein with manual restraint of the animals. Other sites including the cephalic and saphenous veins could be used. In nonhuman primates, the animals are either manually restrained, typically with help of specialized chairs or cages, or anesthetized. The femoral vein is frequently used, but cephalic and saphenous veins can also be used. If chair restraint is used without anesthesia, it is critical to have a good acclimatization period for these animals before the start of the study to minimize the excitement of the animals during sampling.

Samples can be obtained terminally, under anesthesia, from large laboratory animals and are collected from the caudal vena cava, aorta, or cardiac puncture. There are differences in hematological parameters depending on which vessel is sampled, so having the site of sampling consistent throughout the study is ideal.

Sites of interim in vivo sampling in rats are the jugular vein, lateral tail vein, tail artery, and sublingual vein, and these procedures can be done with either manual restraint or with anesthesia.

In mice, limited amounts of blood can be obtained from the lateral tail vein or retro-orbital sinus. Some facilities are able to obtain a larger volume from the jugular vein with manual restraint or anesthesia. Terminal samples, under anesthesia, are taken at the time of necropsy from the caudal vena cava, aorta, or via cardiac puncture, and due to the greater volume these samples are easier to use for hematological analysis.

The use of anesthesia will have an effect on the hematologic results. Anesthesia is not typically used in dogs and may be used in nonhuman primates for in-life sampling. If anesthesia is utilized in nonhuman primates, ketamine is typically used and will decrease WBC counts, mainly due to decreased lymphocytes.[22] Historically, two of the more commonly used anesthetics for rats include isoflurane and CO_2/O_2.[8]

Amount of Blood Collected

The amount of blood that can be taken will be dictated by recommendations of the Animal Care and Use Committee at each facility. A good review on blood sampling has been published and makes recommendations on how much blood volume can be safely withdrawn.[9] The blood volume of a 10-kg dog is estimated to be 850 mL (85 mL/kg). Of this volume, 85 mL (10%) of the blood can be removed in a single sample or with multiple samplings over 24 hours if animals are allowed to recover for 2 weeks.[9] Blood volume is more of an issue in monkeys due to their small size. A 5-kg cynomolgus macaque would have 325 mL (65 mL/kg) of blood. Therefore, a total of 32 mL of blood (10%) can be removed in a single sample or with multiple samples over 24 hours if the animals are allowed to recover for 2 weeks.[9] Although these volumes are adequate for routine hematological assessment, multiple blood samples taken for other analyses such as toxicokinetic, cytokine, and immunophenotyping analyses frequently result in reaching maximal allowable amounts, and can lead to iatrogenic decreases in RBC mass.

Interim sampling can be done in rats, although the overall amount of blood and frequency of the bleeding will be limited. A 250-g rat has approximately 16 mL (64 mL/kg) of blood. Of this volume, a total of 1.6 mL (10%) can be safely removed in a single sample or with multiple samples over a 24-hour period if animals are allowed to recover for 2 weeks.[9]

Interim sampling in mice is infrequently done due the limited blood volume. A 25-g mouse has 1.8 mL (72 mL/kg) of blood. A total of 0.2 mL (10.0%) can be removed in a single sample or with multiple samples over 24 hours if the animals are allowed to recover for 2 weeks.[9]

HEMATOLOGIC ANALYSIS AND PARAMETERS

A few types of automated hematology analyzers work well for the laboratory animal samples used in nonclinical toxicity studies. These analyzers should have multispecies software to ensure proper analysis. It is recommended that the blood be analyzed within a few hours after collection in all species. In addition, blood smears from all animals should be made soon after collection for possible review. In dogs and nonhuman primates, making the blood smears within two hours after collection is sufficient for retention of good cellular morphology, although the sooner the slides are made after collection, the better. In some strains of rats, if blood smears are not made immediately after collection, there may be secondary artifacts of preparation, such as crenation of the RBCs.

Each laboratory needs proper review criteria in place to ensure good quality hematologic results from hematologic analyzers. Although not clearly defined in regulatory guidelines, it is the authors' opinion that blood smears should be reviewed in all good laboratory-practice-regulated studies. This review would include assessment of RBC, WBC, and PLT morphology, as well as identification of other rare cell types. At a minimum, blood smears should be made from all animals in a study for potential review, if warranted. Most laboratories that review blood smears will review all blood smears from the study. An alternative is to review blood smears from all large animals, and have a tiered response for rat studies where high-dose male and female rats as well as control samples are evaluated.

If there are significant changes in morphology, then additional dose groups are evaluated.

The hematologic parameters that should be measured are those recommended by the most recent best practices paper and include RBC count, HGB and HCT, RBC indices (MCV, MCHC, MCH, RDW), absolute reticulocyte count, WBC count, absolute differential WBC count, and PLT count.[29] Blood smears should be made for potential evaluation. Other parameters such as mean platelet volume may sometimes be useful to assess changes in PLTs, but was not recommended for routine use. The CBC should be evaluated in conjunction with the bone marrow histopathologic analysis.

BONE MARROW HISTOPATHOLOGY

Histopathologic evaluation of bone marrow is greatly dependent on prompt and proper preservation, collection, handling, processing, and staining.[27] In large animals, the sternebrae or ribs are the preferred sites for histologic analysis because these sites will be hematopoietically active relative to other sites. By contrast, sternebrae and long bones of rodents, such as the femur, are frequently used. An overall assessment of bone marrow cellularity can be obtained with histopathology (see Chapters 16 and 17). The cellularity of bone marrow is dependent on the species, the site of collection, and the age of the animal. In addition, food restriction, or treatment-induced decrements in food consumption, will affect bone marrow cellularity and blood cell counts.[23,25] Concurrent vehicle controls and historical knowledge of what is the normal range of cellularity of bone marrow for that age animal and species are necessary to make an accurate assessment. If there are changes in cellularity, one should try to differentiate the cell types that are changed. In large animals, relative changes in the myeloid population compared to the erythroid population should be assessed if possible, but in rodents, due to the high percentage of lymphoid cells, differentiation of erythroid changes from lymphoid changes is difficult.

BONE MARROW CYTOLOGY

Bone marrow cytologic examination should be considered if there are significant or unexplained changes in the CBC and/or in bone marrow histopathology results that need further clarification. Ideally, bone marrow smears should be made immediately or soon after euthanasia. Smears can be made by several techniques, including push smears, pull smears, and paintbrush technique (see Chapter 141). The slides made with any of the abovementioned techniques are air-dried and stained with a Romanowsky-type stain, such as Wright's or Wright–Giemsa stain.

Cytologic analysis may consist of qualitative evaluation of the marrow smears alone and/or enumeration of the relative percentages of cells, typically by doing a 500-cell differential cell count. Morphologic abnormalities should be noted during qualitative assessments or when enumerating cell types. Enumeration of hematopoietic cells can be done by detailed classification of the different cell types and stages of maturation or by classifying hematopoietic cells into the major categories of myeloid, erythroid, and lymphoid lineages. If the latter technique is used, a qualitative assessment can then be made of the maturation of the different lineages. Megakaryocytes should be noted as present or absent, but not enumerated. These cytological results will then be used in conjunction with the CBC and histopathologic results to make an accurate assessment of the effect of xenobiotics on the hematopoietic system.

FLOW CYTOMETRY

Bone marrow flow cytometric examination could be considered if there are significant or unexplained changes in the CBC and/or bone marrow histopathology results that need further clarification (see Chapter 142). This technique is an alternative to counting hematopoietic cells manually, although does not replace the cytologic morphologic assessment of the bone marrow.[2–7] Percentages of the different cell lineages, and with some techniques a subdivision into proliferating and nonproliferating populations, can be assessed.[3,5–7] In addition to these semi-quantitative assessments, a total nucleated cell count can be determined, and absolute counts of the different cell populations can be calculated. In contrast to only determining relative percentages of the different cell populations, absolute counts provide more definitive data to allow accurate assessment of which cell populations are truly affected. The results on any flow cytometric assessment need to be interpreted in conjunction with the CBC, cytomorphology, and histopathology of the bone marrow to determine which population is affected.

OTHER TECHNIQUES

Rarely, other techniques such as bone marrow clonogenic assays or electron microscopy may be useful during the development phase of a drug. Bone marrow clonogenic assays, also known as colony-forming-unit assays, are in vitro assays that are utilized to evaluate the potential effect of xenobiotics on the differentiation of bone marrow cells.[26] These assays use different mixtures of growth factors to drive differentiation of pluripotent cells into different hematopoietic lineages and thus allow an assessment of differential sensitivity of the various bone marrow precursors to the effects of xenobiotics. In vitro assays are most useful, and utilized, early in the drug discovery process to screen the evolving chemical space for potential hematotoxicity and help identify compounds that have less or no hematotoxicity. Electron microscopy, mainly transmission electron microscopy, is rarely used when additional morphologic characterization of in vivo findings, in blood or bone marrow, is needed.

Acronyms and Abbreviations

EPO, erythropoietin; GLP, good laboratory practice; HGB, hemoglobin; HCT, hematocrit; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MPV, mean platelet volume; N, number of individuals per group; M, male; NOAEL, no-observed-adverse-effect level; NOEL, no-observed-effect level; PLT, platelet; RBC, red blood cell; RETIC, reticulocyte count; RDW, range distribution width; SOP, standard operating procedures; SD, standard deviation; WBC, white blood cell.

Safety assessment toxicological studies are designed to determine the potential toxicity of novel pharmaceutical compounds and chemicals. Many synthesized compounds are screened each year through the drug development process, but very few reach the consumer market. Short-term studies with limited number of animals are initiated early in the drug development process to identify compounds to move forward for continued safety and efficacy investigation. Typically, only basic clinical pathology measurements are applied to these studies. Longer-term studies with new compounds are part of the development process and can identify findings of toxicity in all aspects of study design including clinical pathology, anatomic pathology, immunology, and other biomarkers. These studies typically involve one rodent species (mouse or rat) and one non-rodent species (e.g., dog, minipig, or nonhuman primate). They are regulated by government regulatory health agencies in various geographic locations (see Chapter 10).[22] Basic hematology, clinical chemistry, and coagulation measurements are also applied to these studies, and bone marrow histopathological evaluation is performed in at least one of these studies.[1,12,15,32,36] Further investigations, such as bone marrow cytology, are optional depending on the initial findings and evaluation of the hematology data.

Therefore, interpretation of hematological data is important at all stages of drug discovery and development. Final interpretation and conclusion should differentiate test-item-related effects and biological variations. These conclusions are part of an interpretative report, which is a subsection of the overall preclinical study data package. These are written in collaboration with pathologists and study toxicologists in order to provide not only the difference in the hematology parameters but also a scientific interpretation and the significance of the changes.[2,30]

DATA COLLECTION AND PRESENTATION

Recommendations for the core clinical pathology parameters in nonclinical toxicity studies have been published.[33,34] The standard panel for hematology includes white and red blood cell parameters with differential counts and blood and bone marrow smears prepared for each animal (see Chapter 10). The tabulation of the hematology data will typically involve both group mean and individual data for studies with adequate numbers of animals per group. For studies in rodents, the comparison of groups given the test item is with the control group typically given a reference item or drug vehicle. For studies involving larger animals, there are usually blood sampling time points prior to study start and comparison is done with both control and pre-study data.

Statistical Analysis

In nonclinical studies, there is typically a significant amount of laboratory data generated especially with larger numbers of animals or longer-term studies with multiple sampling time points. Statistical analysis of the data will frequently identify significant differences between control groups and groups to which a test item has been administered. These differences should be interpreted with caution, and not be used as a substitute for a complete evaluation of the data. A change may be statistically significant but have little biologic or toxicologic significance.[5] Conversely, compound-related changes that are not statistically significant may be considered biologically meaningful. Both parametric and nonparametric statistical models are used in nonclinical studies. Most parametric statistical models are suitable for data that are normally distributed and exhibit homogeneous variance. Nonparametric procedures are used when data are not normally distributed. The power of a statistical test is proportional to the number of animals per group. As the number of animals increase, differences of small magnitude become statistically significant, although they may not be toxicologically relevant. In studies with lower numbers of animals, there tend to be fewer statistically significant differences.

The group mean or average is another less sophisticated tool that is appropriate for normally distributed data. Standard deviation describes the variability around the mean and should be carefully evaluated as an indication of variability with that group of animals.

GOOD LABORATORY PRACTICE

Evaluation of hematology data should be done with knowledge of the inherent precision and variability of the assays used (see Chapters 137–139). Analytical data must be reliable, and the laboratory should validate all methods and operate internal and external control procedures. Agencies responsible for the investigation of the safety and efficacy of human health products regulate the conduct of nonclinical laboratory studies under good laboratory practice (GLP) regulations. GLP regulations must be applied to all nonclinical health and environmental safety studies required for registering or licensing pharmaceuticals for human use. Some countries may have additional GLP regulations, but differences in regulations are minor. There are memoranda of understanding with several countries that accept study data from different geographical locations.[6]

The GLP clinical laboratory must have written approved standard operating procedures (SOPs), record systems, and quality assurance for sample handling, analysis, and reporting. Quality assurance personnel audit the study protocol and perform in-process audits of study conduct, including generation of clinical pathology data and report.

REFERENCE RANGES

Reference ranges are also referred to as historical control data and are generally available from the laboratory generating the hematology data from the nonclinical study (see Chapter 140). Guidelines for generation of reference intervals in veterinary species are available.[11] Reference ranges can be calculated from naive control animals in toxicological studies. They are usually determined by the smallest and largest values if 20 or fewer animals are sampled, or by the 2.5th and 97.5th percentile range if more than 20 animals are sampled. Consequently, reference ranges display values observed in 95% of a healthy population. Values outside the reference range do not necessarily indicate an abnormal condition and, conversely, values within the reference range do not imply a normal condition.[21]

Reference ranges are influenced by many variables, including species, strain, sex, age, animal supplier, animal husbandry or handling practices, diet and fasting, anesthesia, sample matrix, instrumentation, and test methodology. It is important to use reference ranges produced by the laboratory performing the study rather than published reference ranges, which would be generated using animals and samples with different conditions than those used in a particular study. Therefore, there is no substitute for age- and sex-matched control animals from the same supplier undergoing the same procedures as the animals in a nonclinical study.[13,28] Reference ranges, however, are adequate to evaluate an individual animal, data prior to study start, data from controls, and to understand analyte variability. When referring to reference ranges in a nonclinical study report, the range is typically included as an appendix and will need to meet certain guidelines if the study is conducted under GLP conditions. Reference ranges should not be relied upon to determine potential test-item-related effects on hematology data, which in some scenarios are minimal and post-treatment values fall within the reference range. Comparison of hematologic data to the appropriate control group is best practice for data evaluation.

OVERVIEW OF DATA INTERPRETATION

Veterinary clinical pathologists evaluating clinical pathology data in nonclinical studies evaluate groups of animals and compare results with a vehicle-treated control group and/or pre-study values rather than evaluating individual animals. For most rodent toxicity studies, pretreatment testing is not done. In non-rodents studies (e.g., monkey and dog), one or two sets of pre-study values are usually collected. When comparing data to pre-study values, comparison to the second set of pretreatment data is usually preferred because these data are less likely to be influenced by stress, food intake, and other variables in the laboratory setting. In longer-term studies, comparison with a concurrent control group is also important.[35] For example, if multiple blood samplings are performed during a study, RBC parameters of treated groups might vary if they are compared to their pretreatment values, but differences in RBC values will not be observed if compared to control group values.

Biological variation is due to interanimal components (i.e., differences between individuals) and intraanimal components (i.e., changes within an individual over time).[5] Multiple physiological and procedural variables may influence hematology measurements, such as age, sex,[26] diet, fasting, restraint, circadian effects, blood sampling site,[8,24,27] collection technique, order of collection, transport time, and sample preparation (see Chapter 10).[14] Sources of preanalytical variations should be avoided, as these could potentially interfere with results and interpretation.

When evaluating nonclinical data, the overall objectives include determining if noted differences in the data are due to administration of the test item or related to analytical or biological variation or related to study procedures. If differences are test-item-related, then any relationship to dose response is also determined.[14] Identification of test-item-related effects in hematology data with subtle differences can be difficult and points to consider include: known class effects of the compound, presence of dose response, correlating findings in clinical pathology data and histopathology. Data interpretation should always include evaluation of both group mean and individual data. Individual data can identify outliers, which are values (low or high) widely divergent from the mean of a group of data. These values may be due to a technical error, or directly related to another cause or disease considered non-test-item-related.[18] For example, a rodent with inflammation in certain tissues, which is incidental, may have increases in white blood cell count and neutrophil count. In these situations, the group mean is affected and the standard deviation of the group will be increased.

Data interpretation has a subjective component.[18,20] If a difference is small, it is often interpreted as not important, and within pre-analytical or biological variability. As the change becomes larger, it is more likely to be relevant and compound-related. However, there is frequently a range of results that are difficult to classify, and not possible to clearly differentiate as compound-related effects or biological effects. Therefore, these changes may be reported as unknown significance to test item administration. Simplistic approaches to data interpretation such as statistics and comparison to reference ranges using a cutoff point decision method, with no consideration of a *gray zone*, may be a source of inappropriate decision-making in the drug development process.[4,9]

DIFFERENCES IN HEMATOLOGY PARAMETERS

Test-item-related differences in hematology parameters in nonclinical studies are typically described using the following qualitative terms: increased, higher, decreased, lower. Terminology typically used in clinical medicine (e.g., anemia, leukopenia, leukocytosis) is not used to describe differences in the data in an interpretative report. Typically, differences in hematology parameters are also reported with quantitative findings (fold or percent difference), and when several parameters are affected, a text table is used within the report to summarize the findings.

RED BLOOD CELLS

Lower red blood cell parameters (RBC count, HGB, HCT) can be observed in nonclinical studies. The reticulocyte count is considered a reliable and early indicator of RBC regeneration when sufficient time has elapsed in species with circulating reticulocytes.[3] Laboratory animals normally have low (dogs and nonhuman primates) to moderate (rodents) numbers of circulating reticulocytes. Decreases in RBC parameters with evidence of regeneration are either hemorrhagic or hemolytic, while decreases in RBC in the absence of regeneration indicate suppressed erythropoiesis. Slightly lower RBC parameters with no evidence of regeneration is not an uncommon observation and animals may exhibit mild reductions in body mass and food consumption. Decreased food intake may have a major impact on the hematopoietic system and has been shown to decrease white blood cell, platelet, and reticulocyte counts (see Chapter 12).[14,19,25] There are several compounds that impair erythropoiesis, either directly by injuring pluripotent hematopoietic stem cells, or their stromal microenvironment, or indirectly by inhibiting erythropoiesis (e.g., chronic inflammatory diseases).[16]

Higher red blood cell parameters are observed with subclinical or clinical dehydration in nonclinical studies, especially in animals with decreased food consumption or in rodents with prolonged fasting. Increases in RBC parameters (RBC, HGB, HCT) are often associated with increases in total protein levels or albumin and/or urea. Absolute erythrocytosis resulting from a persistent increase in RBC mass and associated expansion of blood volume is rarely observed in toxicity studies, but may be

seen when testing compounds with known pharmacologic activity of increasing erythropoiesis.

WHITE BLOOD CELLS

Increases in neutrophil and/or monocyte counts are observed with inflammation, excitement, steroid or stress response, or when testing pro-inflammatory compounds.[26] Physiological leukocytosis in response to excitement can increase counts in minutes. In laboratory primates, it is evenly distributed between neutrophils and lymphocytes. Increased neutrophil counts are most obvious in dogs, and increased lymphocyte counts are most evident in rats. Neutrophil counts increase in response to a variety of inflammatory conditions. Monocyte counts increase secondary to any condition with substantial tissue destruction, including inflammation or necrosis. Increases in lymphocyte counts may be observed with excitement in dogs and monkeys, and with chronic inflammatory lesions, especially in rodents, or with administration of antigenic compounds that elicit an immune response. Increases in eosinophil and/or basophil counts are not commonly observed in toxicological studies unless the test item specifically targets the production of these cell types. Leukemias involving any of the major white cell lineages can be observed in carcinogenicity studies using rodents.[14,31]

Leukocytes are frequently the first target of cytotoxic drugs because they have a shorter life span than platelets and red blood cells. In dogs and primates, marked acute inflammation and endotoxin-mediated pro-inflammatory cytokine release produce marked decreases in neutrophil counts, which are usually followed by a rebound neutrophilia. Recognition of decreased neutrophil counts is more difficult in mice and young rats that normally have low neutrophil counts. Immunotoxic drugs may trigger alterations in blood lymphocyte counts. Involution of the thymus is often interpreted as stress-related and correlates frequently with decreased lymphocyte counts. The significance of decreases in circulating monocytes, eosinophils, and basophils can be difficult to determine because these cells are normally present in low numbers and should not be overinterpreted. Decreases in eosinophils or monocytes may be observed with chemotherapeutic agents, which typically affect multiple white blood cell types, and decreases in eosinophils are sometimes observed with stress or steroid-related compounds.

Platelet Count

Lower platelet counts are frequently associated with difficult venipuncture resulting in platelet aggregation especially in dogs and rodents. Blood smear evaluation is important to confirm any low platelet counts and processes within the laboratory should be in place to trigger examination of the blood smear to confirm any decreased count. Compound-related decreases in platelet counts can also result from impaired production or accelerated destruction or utilization. Administration of a test item that reduces erythroid and myeloid cell lineage production can also inhibit platelet production. An example of hematology data interpretation from a nonclinical study is presented in Tables 11.1 and 11.2.

Physiologic increases in platelet counts are usually transient, and result from increased mobilization of platelets from storage pools during mild muscular activity or excitement. Healthy rodents have high platelet counts compared to other animal species. Compound-related increases in platelet counts may be associated with blood loss, iron deficiency, or inflammatory conditions. Test items occasionally induce platelet dysfunction, characterized by normal platelet count, increased bleeding time, and normal coagulation times (prothrombin time and activated partial thromboplastin time). When this profile is observed, platelet function testing is warranted.

TABLE 11.1 Group mean RBC parameters for a 13-week study with daily subcutaneous injection of human recombinant erythropoietin (EPO-R) in the Sprague–Dawley rat.[a]

Group	Summary information	RBC ($\times 10^6/\mu L$)	HGB (g/dL)	HCT (%)	MCV (fL)	MCH (pg)	MCHC (g/dL)	RDW (%)	PLT ($\times 10^3/\mu L$)	MPV (fL)	RETIC (%)	RETIC ($\times 10^9/\mu L$)

[a] Group 1 is the control group given vehicle control. Groups 2, 3, and 4 were given low, medium, and high doses of EPO-R, respectively. Interpretation of data: A treatment-related increase was observed in RBC, HGB, HCT, and reticulocytes (RETIC) in rats of Groups 2 and 3 compared to control group. A treatment-related increase was also observed in RBC, HGB, HCT, RETIC, and PLT in high-dose group (4) compared to control group. High standard deviations in Group 4 were indicative of large individual variations within the high-dose group (see Table 11.2).

TABLE 11.2 Individual RBC measurements from high-dose group Sprague–Dawley rats given human recombinant erythropoietin.[a]

Group/ sex	Animal number	RBC (×10⁶/μL)	HGB (g/dL)	HCT (%)	MCV (fL)	MCH (pg)	MCHC (g/dL)	RDW (%)	PLT (×10³/μL)	MPV (fL)	RETIC (%)	RETIC (×10⁹/μL)

[a] Large individual variations were observed in RBC, HGB, HCT, and RETIC. The majority of individuals had marked increases in RBC, HGB, HCT, and RETIC compared with control group, consistent with erythrocytosis and the pharmacological action of the compound. Some individuals (nos. 4002, 4003, and 4008) had a marked non-regenerative anemia due to anti-erythropoietin antibodies inducing an immune-mediated anemia in these individual animals.

Assessment of Recovery Studies

There are no specific study design recommendations available by the Food and Drug Administration to detail which comparisons should be made to evaluate the reversibility of findings in a nonclinical study. Best practice guidelines for the evaluation of clinical pathology data in the recovery phase of nonclinical studies have been established.[33,34] Standard clinical pathology parameters are commonly included in the recovery phase and the number of recovery groups may be similar to the dosing phase groups or limited to control and high-dose groups. In rodents, evaluation of different cohorts at the end of the dosing and recovery phases may be required preventing evaluation of recovery in the same individual animal. The number of animals in the recovery phase is typically smaller than in the dosing phase. Consultation with the clinical pathologist is important when determining the recovery phase strategy with respect to number of animals per group and length of the recovery phase.

Bone Marrow Evaluation

Bone marrow smears are typically collected from all animals in a nonclinical study as per best practice recommendations.[33,34] The decision to perform a bone marrow smear evaluation is based on interpretation of hematology data, histopathology findings, and all other study data to determine if cytologic evaluation is warranted.[29] Evaluation typically consists of both qualitative assessment of cell maturation and morphology or a quantitative evaluation (see Chapter 10). A quantitative approach involves a 500-cell differential count with classification of cells into the myeloid, erythroid, and lymphoid cell lineages and calculation of a myeloid:erythroid (M:E) ratio. Bone marrow cytologic and histopathologic assessment provides a complete evaluation of the hematopoietic system in a nonclinical study and an integrated report includes bone marrow cytologic observations and correlations with hematology data.

Correlation with Other Toxicology Study Data

Test-item-related hematology findings should be described with any association with other nonclinical study data including clinical signs, other clinical pathology data, organ weights, gross pathology and histopathologic findings, and toxicokinetic data.[10] The correlation of compound-related hematology differences and noteworthy pathology findings should be evaluated by an expert in veterinary hematology (veterinary clinical pathologist) and captured in the report. Decreases in red blood cell parameters should be correlated with histopathologic evidence of hemorrhage, extramedullary hematopoiesis, and bile pigment deposits and/or hemosiderin deposits in liver and/or spleen. Lymphoid decreases often correlate with histologic atrophy of lymphoid organs. Increases in leukocytes may be correlated with microscopic evidence of inflammation in tissues and bone marrow increased myeloid cellularity. Decreases in red blood cells should be correlated with any bone marrow histopathology observations such as decreased cellularity.

TOXICOKINETIC DATA

Toxicokinetics is a subdiscipline of pharmacokinetics concerning the absorption, distribution, metabolism, and elimination at doses higher than those expected to produce therapeutic effects.[7] Evaluations are determined directly from animals involved in nonclinical safety studies or from a designated toxicokinetic group of animals and determine systemic exposure, any dose–response relationship, and degree of interanimal variability.

When interpreting hematology data, the level of exposure to the test item must be considered. Knowledge of the bioavailability of a drug and the kinetics of absorption, distribution, and elimination are important to consider when interpreting hematology data.[17] In some studies, there may be unexpected differences in the level of drug exposure and this may influence the interpretation of the differences observed in the hematology data.

REPORT WRITING

An interpretative report is typically produced to capture all test-item-related findings in all clinical pathology data in the nonclinical study.[23] The test-item-related findings are evaluated in the context of other preclinical study data and are judged if considered adverse or non-adverse to help in determining the no-observed-effect level (NOEL) or no-observed-adverse-effect level (NOAEL). Some criteria to determine the adversity of observed differences can include adverse impact on function of life of the animal, magnitude and direction of change, and monitorability in nonclinical species and human patients.[33]

Data presentation can vary between companies, but as a general rule, data are tabulated to include group and individual values for each dose group. Group values include mean, standard deviation, and statistical analysis applied to each group. Group and individual values are generally presented in a conventional order: control group given vehicle followed by groups given increasing order of dosage (e.g., Table 11.1). When reporting the data, mean percentage differences or fold differences between treated and control groups can be used, and significance of the changes can be qualified by usage of modifiers: minimal, mild, moderate, or marked. When referring to fold difference, the method of comparison (e.g., pre-test values, second pre-test value, control group mean) should be stated. The US Food and Drug Association now requires all study data in nonclinical studies to be submitted in consistent harmonized format using the Standard for Exchange of Nonclinical Data (SEND). The data in this format are collected and presented in a standard and consistent format. The interpretative report should concisely report all relevant test-item-related findings, as this section is typically carried forward into an overall summary of the complete nonclinical study report and is often reviewed by nonpathologists in the entire drug development process.

CONCLUSION

Principles of hematologic interpretation used to clinical veterinary medicine apply in nonclinical toxicological studies. The main differences between these practices result from the evaluation of groups of animals rather than a single patient. Interpretation is based on comparison to values obtained prior to study or from animals given a nondrug vehicle, utilization of reference values and statistical analysis, correlation of hematology data with chemistry and urinalysis data, clinical observations, toxicokinetics, necropsy, and histopathological results. Clinical pathology data interpretation will help define the safety assessment profile for a new drug candidate moving through the drug development process.

Acronyms and Abbreviations

AIHA, autoimmune hemolytic anemia; AITP, autoimmune thrombocytopenia; BFU-E, burst-forming unit-erythroid; BM, bone marrow; CFU-E, colony-forming unit-erythroid; CFU-GM, colony-forming unit-granulocytic monocytic; DIA, drug-induced agranulocytosis; DIIMHA, drug-induced immune-mediated hemolytic anemia; DIMT, drug-induced immune-mediated thrombocytopenia; GP, glycoprotein; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; IgG, immunoglobulin G; IL, interleukin; PRCA, pure red cell aplasia; RBC, red blood cell; RDW, red cell distribution width; REDOX, reduction–oxidation reaction; TNF-α, tumor necrosis factor-alpha; TNFR, TNF-α receptor.

Exposure to xenobiotics (synthetic, pharmacologically active molecules, further defined as large or small molecular entities and biotherapeutics, which include monoclonal antibodies, recombinant proteins, cytokines, hormones, and nucleic acids) or their metabolites subjects the hematopoietic system to potential toxic insult. Bone marrow (BM) consists of a remarkably heterogeneous population of cells of mixed ontogenic origin capable of continuous replacement of circulating leukocytes, erythrocytes, and platelets and reserve ability to respond immediately to physiological and pathological demands. Rapid metabolism, high rate of proliferation, marked cross talk within and between BM niches and other organ systems make BM one of the most sensitive target organs evaluated in nonclinical toxicology studies. Unlike other target organs, the hematopoietic system can be easily and frequently biopsied via a blood sample before, during, and after exposure, making it one of the most critically evaluated organs of the risk assessment process.

COMPOUND-RELATED CYTOPENIAS IN NONCLINICAL STUDIES

Predicting Hematotoxicity

Toxicologic injury can occur via oxidative damage (see Chapter 32), nonoxidant mechanisms (see Chapters 15–17), immune-mediated damage (see Chapters 35–38, 40, and 80), and, very rarely, induced apoptosis. The intended purpose of the test molecule determines the acceptability of any impact on the hematopoietic system. For example, marketed antihypertensive drugs are safe and effective when used properly, but have been infrequently associated with adverse effects on the hematopoietic system.[27] A potential new antihypertensive must be less toxic and more efficacious than anything currently marketed to warrant development; therefore, any evidence of hematopoietic toxicity is unacceptable. However, the risk/benefit ratio associated with hematopoietic toxicity produced by a molecule being developed as a second-line anticancer drug might be acceptable. Highly targeted biotherapeutics that produce unexpected hematologic toxicity in nonclinical testing may offer therapeutic outcomes that warrant clinical use, with the caveat that monitoring, dose management, drug withdrawal, and/or therapeutic intervention become part of the drug protocol.

Knowledge of the bioavailability of a compound is helpful when evaluating compound-related effects.[14] In particular, distribution, binding properties, metabolism, and $t_{1/2}$ of parent or active metabolites can aid in predicting both nadir and recovery of circulating cell counts before initiation of safety studies.

Compound-related effects can be directly or indirectly induced by the parent molecule and/or its metabolites. Secondary effects are consequences of direct or indirect toxic effect, such as renal failure due to nephrotoxicity. Less well-understood or predictable are results termed as hyperpharmacology. This adverse effect is frequently observed with recombinant molecules that directly target key biochemical pathways, altering specific protein synthesis, secretion, or catabolism, blocking key receptors, or gene regulation, often producing unpredictable consequences associated with induction of endogenous signaling molecules. Adverse effects associated with biotherapeutic pharmaceuticals are most often hyperpharmacologic, immune-mediated, and/or idiosyncratic reactions.[15]

All cells that are found within the BM microenvironment are susceptible to compound-related effects. Chemists use in silico (computational) three-dimensional mock-ups to characterize common structural features of highly myelotoxic compounds for screening and modeling to design and modify molecules to eliminate offending portions while retaining the active moiety.[13,17,21] In vitro toxicity colony-forming unit-granulocytic monocytic (CFU-GM) assay testing, using fresh or cryopreserved primary target stem cells (hematopoietic and stromal/mesenchymal) from nonclinical test species and humans, has greatly expanded our ability to assess comparative myelotoxicity and evaluate compound toxicity relative to other known molecules by using maximum tolerated dose (MTD) and inhibitory concentration (IC).[26,33,40] In vivo mechanistic models, based on pharmacokinetic–pharmacodynamic data, are used to study the entire time course of myelosuppression and separate drug-specific parameters from system-related parameters, with the goal of optimizing dosing in clinical studies.[17] The complexity of cytokine and hormonal effects on BM, peripheral cell counts, and cell function are the most unpredictable.[3,16,49] Cytokines may directly or indirectly mediate cellular changes in hematopoietic and/or stromal/mesenchymal cells, by upregulation or downregulation. As changes are highly dynamic, sequential peripheral blood and BM collection relative to dosing become invaluable for interpretation and prognostication of toxicity and reversibility. In vitro and in vivo studies using transgenic test species may predict cytokine release and establish safety margins for clinical safety studies in healthy human cohorts.[3,33] While prescreening has greatly reduced hematopoietic toxicity, study data must be critically reviewed for effects that suggest toxicity related to the parent compound and/or metabolites, species specificity, hyperpharmacologic responses, immune-mediated effects, or idiosyncratic changes.[36]

Route of Exposure and Vehicles

Each route of exposure may introduce variables that can alter the effect of the compound on the hematopoietic system. Parenteral administration may prolong exposure. Intravascular administration introduces the molecule directly to circulating cells. Vehicles used may have no effect when tested separately, but may enhance or alter exposure to the test molecule. Such an event occurred in Europe when treatment with recombinant human erythropoietin was linked to an upsurge in the incidence of antibody-mediated pure red cell aplasia (PRCA) in dialysis patients. The increase in PRCA coincided with a change in formulation of erythropoietin in which serum albumin was replaced by glycine and polysorbate 80.[13,42] Variables that may have increased immunogenicity were investigated: (1) formation of epoetin-containing micelles, (2) interaction with leachates released from uncoated rubber stoppers of prefilled syringes, and (3) denaturation or aggregate formation due to improper storage and handling. The incidence of PRCA returned to very low levels following replacement of the uncoated rubber stoppers with coated stoppers.

Test Species

Mouse, rat, dog, marmoset, and macaque are used most extensively for toxicity studies; baboon and chimpanzee are used infrequently (use of nonhuman primates, in particular great apes, has been outlawed in some countries). Familiarity with the test species is important, as differences in response may occur between species (primates) and strains (rodents), and within species and strains based on vendor source.[39] Although dose-related

small-molecule-induced hematotoxicity may have a high concordance between in vitro and in vivo studies and between species, hematotoxicity findings in nonclinical safety studies that are low-incidence or idiosyncratic or that are high-incidence and species-specific are unpredictable across species.[15] Some strains of rodents are genetically prone to hematopoietic abnormalities or have increased sensitivity to certain compounds, particularly knockout and transgenic animals.

MECHANISTIC CLASSIFICATION OF DRUG-INDUCED CYTOPENIAS

Drug-Induced Immune-(Mediated) Cytopenias

Nonclinical observations are typically proprietary and rarely reported in the public domain; thus, no estimate is available for the incidence of drug-induced immune cytopenias identified at toxicological exposures. Only 6–10% of all adverse drug reactions identified in clinical trials or postmarketing are recognized as idiosyncratic.[17] Frequently, the mechanisms of these reactions are unknown, but the majority are believed to be immune-mediated. The incidence of reported drug-induced immune-mediated hemolytic anemia (DIIMHA) in the human population is estimated to be one per million individuals per year.[5] Drug-induced agranulocytosis (DIA), defined as $\leq 0.5 \times 10^9/L$, is estimated at an annual incidence of 2–15 per million people and the mechanism may be direct toxicity, immune-mediated, or both.[4] Drug-induced immune-mediated thrombocytopenia (DIMT), in contrast, is more frequent.[7,41] Immune-mediated reactions to xenobiotics may be classified as Type I (immediate, IgE-mediated), Type II (IgG- or IgM-mediated), Type III (IgG/IgM immune-complex-mediated), or Type IV (delayed or cell-mediated).[18,35] Nonimmune hypersensitivity arises from direct compliment activation. Adverse drug reactions identified in human subjects during clinical trials or postmarketing are reported as (1) Type A (more common; usually dose-dependent and predictable; readily reversible by dose reduction or drug withdrawal; result of primary or secondary pharmacology; may be problematic when a drug has a narrow therapeutic index); (2) Type B (unrelated to known pharmacologic actions of drug; often serious and associated with high mortality; thought to be of immunologic and pharmacogenetic mechanisms); (3) additional categories Type C (chronic), Type D (delayed), and Type E (end of use); and (4) drug interactions.[29]

Idiosyncratic reactions appear to arise from a combination of immune-mediated genetic predisposition and environmental factors in susceptible individuals, and are frequently non-dose-dependent and unpredictable. A minimum of four events have been suggested as necessary for the initiation of an idiosyncratic reaction:

1. Adequate amount of reactive metabolite(s).
2. Binding with a protein with high epitope density.
3. Upregulation of costimulatory signals on antigen-presenting cells to activate T cells.
4. Failure of immune system to downregulate a harmful immune response.[21]

Sites of reactive metabolite formation usually correlate with the target of idiosyncratic reactions.[23] For example, drugs oxidized by myeloperoxidase to reactive metabolites may induce immune-mediated agranulocytosis.[21] It has also been suggested that glucuronide conjugation of metabolites may increase immunogenicity.[11]

There are two types of drug-induced antibodies: drug-independent antibodies and drug-dependent antibodies.[5] No drug is required in the test system for the detection of drug-independent antibodies, which may be "true" autoantibodies or antibodies that react like autoantibodies in vitro and can be found in combination with drug-dependent antibodies. The mechanism of drug-independent antibody production is unknown, but is hypothesized to be the result of a direct effect by the drug or its metabolites on the immune system that induces an autoimmune disease. Reactions attributed to "true" autoantibodies are detectable by direct antiglobulin test (Coombs test). Well-documented cases of autoimmune hemolytic anemia (AIHA) have been induced by α-methyldopa and procaine amide.[6] Heavy metals are also incriminated, and depot injections of gold salts have frequently induced chronic autoimmune thrombocytopenia (AITP).[48] Drug-dependent antibodies require the presence of the drug in the test system for their detection and are frequently described as "hapten-type."[6] Hemolytic anemias induced by this type of antibody response are associated with a high IgG titer and extravascular RBC destruction. This mechanism may also be responsible for some types of drug-induced thrombocytopenia.[7] A second type of drug-dependent antibody, associated with complement activation and acute, severe intravascular hemolysis, is referred to as "immune complex type." A proposed mechanism is that drug and/or metabolites interact with the cell membrane (without covalent bonding) and lead to a polyclonal response to several epitopes. Antibodies that react with epitopes shared with the drug and cell membrane produce immune complexes that trigger the reaction.[5] The fibrinogen receptor, glycoprotein IIb/IIIa, von Willebrand factor receptor, or GPIb/IX may become selected epitopes, but the mechanism is not hapten-specific.[6] Immunoglobulins only react with these platelet membrane glycoproteins when drug or metabolite is present in soluble form.

Drugs developed as ligand-mimetic GPIIb/IIIa inhibitors have produced acute and often severe thrombocytopenia in a subset of patients during clinical trials.[10,41] Naturally occurring antibodies present in otherwise normal patients recognize GPIIb/IIIa complexed with the drug on the surface of platelets and produce DIMT.

Drug-specific antibodies may be naturally occurring or induced. The cephalosporins are particularly prone to

producing this response, and the problem has become more frequently observed with newer generations of the drug. These DIIMHA can be very severe, with hemoglobinemia and hemoglobinuria. Differences in response to these drugs are found between age groups, with children often developing severe hemolysis within minutes after administration, while similar problems occur in adults only after several days.[5]

Drug-induced immune disease against granulocytes has been associated with:

1. no significant effect on circulating numbers of neutrophils,
2. moderate to severe neutropenia with normocellular to hypercellular BM, or
3. neutropenia with BM hypoplasia or maturation arrest.[12]

Identification of anti-neutrophil antibodies using various detection methods is difficult because they tend to be present in low titers and bind with low avidity. Autoantibodies that have been characterized in humans are directed against various membrane glycoproteins, including adhesion molecules. Anti-neutrophil antibodies can produce neutrophil dysfunction resulting in defects in adhesion, aggregation, chemotaxis, phagocytosis, or killing.

Aplastic anemia may be a predictable or idiosyncratic reaction that presents as pancytopenia (leukopenia and thrombocytopenia will be detected before anemia) due to BM failure (see Chapter 40). Most drug-related cases are believed to be immune-mediated.[9]

PRCA is an infrequent idiosyncratic drug reaction in which BM suppression is limited to the erythroid lineage. An immune-mediated process has been speculated as the mechanism behind PRCA.

Drug-Induced Marrow Suppression

In addition to direct cellular injury, hematopoiesis may be suppressed or enhanced by alterations in the cytokine network. For example, based on in vitro observation that interleukin-12 (IL-12) works synergistically with the c-kit ligand to promote hematopoietic stem cell proliferation, mice dosed with recombinant mouse IL-12 were expected to develop accelerated myelopoiesis.[46] Instead, treatment with IL-12 produced BM myelosuppression while enhancing splenic extramedullary hematopoiesis. The complex cross talk within the hematopoietic microenvironment is not restricted to compounds designed to impact hematopoiesis or regulate inflammation.[22] Cytokines, growth factors, and receptors in tissues outside the hematopoietic system that are seen as potential drug targets may impact BM as well. Blockade of neurokinin receptors has been pursued as a potential anti-anxiety target by allowing accumulation of substance P. However, the same receptors exist in the BM and play a critical regulatory role in hematopoiesis.[37] Depending on the receptor and the cross talk, substance P can either inhibit or stimulate hematopoiesis.

ANEMIA

Causes of anemia include decreased circulating lifespan, hemolysis, hemorrhage, decreased or ineffective production, or a combination of processes. The mechanism(s) of toxic effect(s) determines the type of anemia, time to onset, duration of effect, and whether persistence of the inciting agent is required for anemia to be maintained or progress.

Hypoproliferative Anemia

Mild normocytic normochromic anemia that is poorly regenerative and reverses when administration of the compound is discontinued is frequently seen in repeat-dose toxicity studies. Usually, histological and cytological BM evaluation from study animals is unremarkable and no impairment of leukocyte or platelet production is identified. Decreased erythropoiesis may be secondary to inanition associated with inappetence and other systemic toxicological effects of the administered compound.[25]

Compounds with toxic effects on proliferating BM cells or stromal cells may produce nonregenerative or hypoproliferative anemia. Examples include anti-neoplastic drugs that target DNA and drugs that interfere with hemoglobin synthesis.

Hypoproliferative anemia may occur secondary to decreased availability of iron, and may be induced by chronic administration of xenobiotics (e.g., recombinant cytokines or cytokine receptor inhibitors) that induce chronic inflammatory changes or renal toxicity (see Chapters 27 and 39).[20,28]

Hemorrhagic Anemia

Hemorrhagic anemia, caused by blood loss, may be a direct or indirect effect of a xenobiotic. Acute hemorrhagic anemia, occurring over 2–3 days, will present with a decrease in the erythron and no evidence of regeneration. Thereafter, a regenerative response (polychromasia, anisocytosis, increased red cell distribution width (RDW), reticulocytosis) is generally observed. More protracted hemorrhage may present as regenerative or nonregenerative, or with characteristics consistent with iron-deficiency anemia. Changes in platelet counts and plasma protein concentrations will vary depending upon cause, duration, severity, and whether blood loss is internal or external. Mechanisms of compound-related hemorrhage include enhanced fibrinolysis, impaired platelet function, single or multiple coagulation factor deficiencies, and/or coagulation factor inhibition.[28] Secondary or indirect compound-related hemorrhage may occur as a result of compound-related gastrointestinal lesions, impaired vitamin K absorption, or disseminated intravascular coagulopathy. Examples of compound classes that may be associated with hemorrhage include nonsteroidal anti-inflammatory drugs (secondary to gastrointestinal erosion, ulceration secondary to local irritation, inhibition of prostaglandin synthesis), vitamin K antagonists, platelet aggregation inhibitors, and gene therapy molecules.

Anemia Secondary to Induced Suicidal Erythrocyte Death

Wear and tear on RBCs expose them to osmotic shock, oxidative stress, and energy depletion until the erythrocyte, through the process of senescence, is no longer able to perform adequately and is removed from circulation by the mononuclear phagocyte system.[24] RBCs are also able to initiate programmed cell death, termed eryptosis, as it mimics apoptosis.[23] Hallmarks of eryptosis and the triggers that initiate it are similar to senescence, and include cell shrinkage, cell membrane blebbing, and translocation of phosphatidylserine to the extracellular face of the RBC membrane. Eryptosis contributes to decreased RBC life span and anemia found in a number of genetic and acquired disease conditions (e.g., sickle cell anemia, thalassemia, iron deficiency, renal failure, hepatic failure, malaria).[34,38] Eryptosis's complex regulation can be overridden by the presence of a foreign substance in the blood (i.e., a xenobiotic, which can produce oxidative stress, hyperosmolarity, and/or energy depletion in RBC) leading to activation of eryptosis mechanisms. Using flow cytometry and confocal microscopy, various endogenous molecules (e.g., ceramide, prostaglandin E2, platelet-activating factor) and xenobiotics (paclitaxel, azathioprine, amantadine, amiodarone, chlorpromazine, cyclosporine, methyldopa, retinoic acid, cisplatin, and zidovudine) tested in vitro have induced eryptosis activation mechanisms through Ca^{2+} ion entry, ceramide formation, or ATP depletion.[24,34] Finding that therapeutic concentrations of chlorpromazine caused eryptosis by triggering multiple mechanisms suggests that shifts in eryptosis probably occur in nonclinical studies, but are masked by the robust ability of the BM reserve to increase production.[38] Compound-induced eryptosis may occur simultaneously with other toxic effects and might be mechanistically responsible for minimal decreases in the erythron relative to baseline and concurrent controls or evidence of reduced RBC life span often seen in dosed animals. It may, therefore, be important to determine if a decrease in the erythron is a result of increased eryptosis rather than dismissing it as a secondary effect.

Hemolytic Anemia

Direct effects on circulating RBCs can produce acute or chronic hemolytic anemia. Hemolysis may be intravascular, extravascular, or both. Intravascular hemolysis may be accompanied by hemoglobinemia and hemoglobinuria. When damage is due to direct contact of a compound or its metabolite with the RBC, hemolysis is immediate and often severe. Examples of compounds capable of producing direct hemolysis include saponin, phenylhydrazine, arsine, or naphthalene.[43]

Drug-Induced Nonimmunologic Adsorption of Protein

Nonimmunologic protein adsorption onto the RBC membrane is a possible mechanism of hemolytic anemia.[5,6] Some drugs may be able to modify the RBC membrane, allowing adsorption of plasma proteins (e.g., immunoglobulins, albumin, complement, fibrinogen).[45] Unfortunately, diagnostic tests are not available to differentiate this mechanism from immune-mediated mechanisms.[5]

Oxidative Damage

Strong oxidants are able to overwhelm the capacity of RBCs to remain in a reduced state, resulting in production of methemoglobin and/or denatured hemoglobin (Heinz body formation) (see Chapters 15 and 32). Heinz body formation and altered ion transport lead to intravascular hemolysis and RBC removal by the mononuclear phagocyte system.[9,44] Many species form Heinz bodies when exposed to aniline, nitrobenzene, and related homologs. A blood film should be examined for evidence of Heinz bodies, eccentrocytes, and keratocytes whenever oxidative damage is suspected. Unless there is continual exposure, Heinz bodies may be difficult to detect in some species due to rapid removal by the mononuclear phagocyte system. The ability of a molecule to function as an oxidant depends upon the concentration of exposure, the reducing ability of RBCs, and the susceptibility of the hemoglobin molecule. Obtaining an accurate measurement of methemoglobin is difficult due to the constant reduction–oxidation reaction (REDOX) activity in the RBC, particularly in rodents. Some species are more susceptible to methemoglobin formation, while others produce more Heinz bodies. Human RBCs have a comparatively slow rate of methemoglobin reductase activity relative to laboratory species, and are particularly susceptible to Heinz body formation;[44] therefore, detection of either or both in a nonclinical study is a major toxicological finding that must be carefully weighed against potential benefits of the compound.

Leukopenia

Drug-induced leukopenias may be transient or persistent. Transient depressions in leukocyte counts that return to baseline or are comparable to concurrent control data despite continued exposure to the compound may represent various compensatory mechanisms. Leukocyte depressions that persist throughout the dosing period of the study but return to baseline at the end of the study represent reversible suppressions. Drug-induced neutropenia may be due to direct damage to BM progenitor cells, or damage to stromal cells that support granulopoiesis.[19] BM damage may be limited to granulopoiesis, or affect all cell lineages.[47] Time of evaluation can greatly influence interpretation. Neutropenia can occur after prolonged exposure, and may be due to decreased production secondary to hypoplastic BM.[29] Immune-mediated granulocytopenia may be directed against precursor cells and/or against circulating cells. Some drugs, such as clozapine, may interact with intracellular myeloperoxidase or NADPH oxidase to produce highly reactive products that are toxic to granulocytes.[30]

Criteria established to define idiosyncratic drug-induced agranulocytosis include:

1. neutropenia ($\leq 0.5 \times 10^9$/L);
2. onset during treatment or within 7 days of exposure with recovery within 1 month of discontinuation;
3. recurrence upon re-exposure.[4,8,43]

A recent review of nonchemotherapy drug-induced agranulocytosis found the median duration of exposure before onset ranged from 19 to 60 days, though one drug (dipyrone) had a median exposure of only 2 days.[2] Agranulocytosis caused by nonimmunological mechanisms appeared to have a later onset than when attributed to immune-mediated mechanism. Impaired granulopoiesis was responsible for 67% of the cases reviewed. This finding contrasts significantly with drug-induced thrombocytopenia or drug-induced hemolytic anemia, where circulating cells are the main target of the immune reaction.[5,7]

Thrombocytopenia

Thrombocytopenia in nonclinical studies is rarely associated with gross or microscopic hemorrhage unless there is concurrent platelet dysfunction. Thrombocytopenia is not a common finding in nonclinical studies evaluating toxicity of traditional chemical entities.[5,9,44] This may be a somewhat more common finding when the test article is a biotherapeutic.[15,16,41] Thrombocytopenia in nonclinical studies is always highly significant and requires full investigation. Compounds that indiscriminately attack actively dividing cells produce BM panhypoplasia. Selective megakaryocytic toxicity, either through toxicity or an immune-mediated mechanism, is associated with a paucity of BM megakaryocytes. Conversely, with platelet destruction or consumption, as happens with DIMT, BM will show a marked increase in megakaryocyte numbers. Because the majority of reported drug-related thrombocytopenias are idiosyncratic and occur postmarketing, nonclinical predictability remains underestimated. Any signal in the data from nonclinical studies that suggests that platelets are a target should be carefully and fully evaluated.

DISPARITY BETWEEN NONCLINICAL AND CLINICAL SAFETY DATA

Nonclinical studies may unfairly incriminate a compound or overestimate or underestimate the risk of exposure in humans receiving pharmacological doses. For example, during development of omalizumab (XOLAIR®), a recombinant humanized anti-IgE monoclonal antibody that neutralizes circulating IgE, thrombocytopenia was identified and reproduced in nonclinical safety studies in monkeys receiving the drug at 5–27 times the maximum clinical dose.[1] No petechiae, ecchymosis, or hemorrhage was identified in study animals. No effect on circulating platelet numbers was identified in clinical studies. After a temporary hold on development, the observation was determined likely to be species-specific and platelet counts in further clinical trials were intensely monitored. To date, this has not materialized as an adverse effect in humans.[50]

Conversely, nonclinical testing can fail to predict toxicity at intended exposure. A low incidence (<0.3%) of agranulocytosis was detected in the late phase of clinical trials with prinomide, a pyrroleprioprionitrile, nonsteroidal anti-inflammatory drug, resulting in immediate termination of further development of the drug.[24] No effect on hematopoiesis or circulating numbers of cells was evident in nonclinical studies (rodents, dogs, monkeys). The unique difference between the individuals enrolled in late phase studies who developed agranulocytosis was that they were experiencing active inflammatory conditions such as chronic arthritis. Mass spectroscopy revealed that one reactive metabolite, 1,4-benzoquinone, a compound implicated in myelotoxicity associated with benzene and produced under conditions of increased hydrogen peroxide (e.g., active inflammation), might explain the agranulocytosis identified in the late phase studies.[31,32]

Different abilities to detoxify, by conjugation or reductive properties between test species and humans, may not be identified until the first human studies are conducted. For example, a potential new drug administered to healthy adults unexpectedly produced methemoglobinemia during dose escalation studies, but had not produced similar effects in test species (L. G. O'Rourke, personal observation). Again, full review of all nonclinical data failed to predict this occurrence.

These examples are presented to first illustrate that classic animal models and nonclinical studies, despite their rigors, may fail to predict life-threatening adverse effects on the hematopoietic system in the intended species, or may overestimate risk of exposure. They also serve as reminders of the importance of understanding both differences and similarities between species. Clinical safety studies are a second line of defense, where discrepancies with nonclinical studies can usually be detected. However, when toxicity occurs only in certain individuals within the human population, it becomes difficult to determine if the responsible mechanism is due to a property of the drug or to the unique biology of that individual. The incidence of idiosyncrasy within the test population may be such that it is not detected in the premarketing phase of development. Many case reports present instances of drug-induced hematotoxicity that were either not predicted in nonclinical safety studies or were not identified until enough individuals were exposed postmarketing.

INVESTIGATIVE WORK

Cytopenia in individual or treatment group data needs to be addressed. All clinical observations, treatments, and handling must be reviewed to differentiate a direct compound-related effect from a secondary effect, such

as blood loss (e.g., excess phlebotomy; gastrointestinal bleeding) or illness. Actions that follow identification of a cytopenia in a safety study include:

- no change in protocol;
- temporary suspension of dosing;
- dose reduction;
- cessation of dosing and initiation of a monitoring period;
- humane termination;

or a combination of the abovementioned actions. If dosing is suspended and findings resolve only to return when dosing is reinstated, the compound or its metabolites are clearly implicated.

It is difficult to determine if an effect is idiosyncratic when the incidence of an adverse finding is extremely low and is only found in one species. However, a hematotoxicologic finding in a nonclinical study must be taken seriously and critically assessed. Depending on the gravity of the finding and mechanism(s) involved, molecular redesign or project termination may ensue. Conversely, findings limited to one species may be interpreted as species-specific. In these instances, further development of the compound may not be impacted, although all clinical trials should be carefully monitored.

CONCLUSIONS

Nonclinical safety studies in animals and clinical safety studies in humans are designed to rigorously test new chemical entities for evidence of toxicity based on their relative risk/benefit. Because the number of animals exposed is relatively small, any adverse effect on the hematopoietic system must be fully evaluated. When evidence of hematotoxicity occurs in human studies, either premarketing or postmarketing, both in vivo and in vitro studies specifically designed to define the mechanism(s) are indicated. Many of these mechanisms remain a mystery. As the tools of pharmacogenomics and pharmacogenetics are advanced, our abilities to examine and understand interspecies drug-, class-, and organ-specific pathways underlying toxicity, and to explore portions of the genome that may detect potential unanticipated impacts, will improve, further enhancing our ability to select useful new xenobiotics that are not associated with hematotoxicity or to address concerns detected through pharmacovigilance when potential adverse drug reactions targeting the hematopoietic system are identified.

Hemostasis is a normal physiological response and a protective mechanism preventing blood loss after alteration of the vascular system. It is comprised of the formation and stabilization of a blood clot after a vessel injury, and the dissolution of the blood clot after repair of the endothelium (see Chapter 87). Hemostasis is maintained by the equilibrium between coagulation and anticoagulant factors, and the presence and function of platelets.

Evaluation of compound-related alterations on hemostasis is done during nonclinical studies in laboratory animals, and is essential to avoid off-target hemostatic toxicity once the compound is administered to humans in clinical studies. Although the evaluation of hemostasis is common and well known in humans, multiple aspects remain difficult to evaluate in laboratory animals because of the lack of species-specific assays. In nonclinical studies, hemostasis testing focuses primarily

on the risk of bleeding, but the evaluation of the risk of thrombosis is particularly challenging and in constant development.[38] It is also difficult to anticipate whether the effects observed in laboratory animals will occur in humans. This chapter provides an overview of routine testing in nonclinical laboratories, reviews specific compound effects on hemostasis, and presents additional assays used in confirmatory investigational studies.

REGULATORY REQUIREMENTS

The agencies responsible for the investigation of safety and efficacy of human health products include the United States Food and Drug Administration (FDA), the European Medicines Agency (EMA), the Japan's Ministry of Health, Labour and Welfare (MHLW), and the Organization for Economic Cooperation and Development (OECD). These agencies provide regulatory guidelines and recommendations for testing during nonclinical toxicity evaluations, although these are often quite vague and infrequently updated. They include the evaluation of coagulation times—prothrombin time (PT) and activated partial thromboplastin time (APTT)—and platelet counts, in nonclinical studies with rodent (rat, mouse) and non-rodent (dog, nonhuman primate (NHP)) species. Treated animals and concurrent controls should be evaluated together at least once during chronic studies. In addition, fibrinogen is frequently measured as an acute phase protein.[17] Guidelines often refer to a previous publication recommending the minimum evaluation of PT, APTT, and platelet count, but also advocate for a flexible approach depending on the species, the observed or expected effects of a given substance, and states that additional testing should be considered if necessary for the investigation of toxic effects.[9,10,13,30,42] In this regard, the Regulatory Affairs Committee of the American Society for Veterinary Clinical Pathology (ASVCP) has recently recommended that PT, APTT, platelet count, and fibrinogen concentration be evaluated routinely, and has added more recommendations for the evaluation of additional hemostatic endpoints based on previous experience with the compound, or known class effects. These include the measurements of D-dimer, fibrinolytic factors, individual coagulation factors, platelet function and aggregation, thromboelastography, and flow cytometry assays, which should be included as part of a "fit-for-purpose" approach.[41]

EVALUATION OF COAGULATION TIMES: PT AND APTT

Laboratory Analyses and Species Consideration

Automated coagulation analyzers allow high throughput determination of PT and APTT for all laboratory species, using reagents approved for human diagnostic evaluation by regulatory agencies (see Chapter 88). In laboratory species (rat, mouse, rabbit, minipig, NHP, and dog), all coagulation factors, except for Ca^{++}, are synthesized in the liver, and all factors except for tissue factor (TF) are present in the circulation. However, their concentrations vary between species and strains, and even between sexes (see Table 13.1). Life spans of these coagulation factors vary from a few hours to 10 days.[11]

Coagulation times depend not only on the concentration of coagulation factors, but also on the reagents and method employed. Published reference ranges can only be used as a guide for method development and should not be used as a reference in nonclinical study evaluation (see Table 13.2). It is necessary to establish species-specific reference ranges for each laboratory and use a control group for each study.

PT time may be affected by the source and sensitivity of the commercially available thromboplastin reagents used for its determination, derived either from rabbit brain tissues or from human recombinant thromboplastin (see Chapter 88). In human medicine, the PT is measured and expressed as an international normalized ratio (INR). The international sensitivity index (ISI) value of the thromboplastin reagent refers to international reference plasma and is assigned by the manufacturer. ISI values vary among manufacturers between approximately 1.2 and 2.2. There is no validated reference material in animal hematology to determine the INR, but ISI values are important to understand the variability that can be observed in the PT assay within a given species. In rats, PT can vary by several seconds depending on PT reagents, whereas less variability is observed in dogs and humans (author's unpublished data).[7,14,27]

TABLE 13.1 Individual coagulation factor activity of laboratory animals compared to humans.

Species	Higher	Similar	Lower

In vitro APTT measurement evaluates the intrinsic coagulation pathway (see Chapter 87). Clotting is initiated by addition of a contact particle to citrate plasma: celite, kaolin, or ellagic acid with calcium and phospholipids, which can impact assay sensitivity (see Chapter 88).[14] Assays using synthetic phospholipids are highly reproducible, especially in NHPs, compared to assays using phospholipids extracted from rabbit brain (author's unpublished data).

Both PT and APTT assays lead to the generation of thrombin, which transforms fibrinogen into fibrin resulting in clot formation. Their sensitivity remains limited because the clot formation occurs when only 5% of the thrombin potentially present in plasma is produced.

In vitro thrombin time (TT) assesses the common pathway. Prolongation of TT is indicative of a deficiency of fibrinogen or an inhibition of thrombin.

Consideration of Blood Volumes for Laboratory Animals

Blood volume limitation is always of concern in laboratory animals, especially in rodents. In mice, coagulation times are rarely evaluated because of the small blood volume available in this species. In rat studies, as unexpected changes in coagulation times are quite unusual, assessment of coagulation is often deferred to the end of the studies. Small commercialized citrated tubes are preferred (0.5, 1, and 1.3 mL) and the 9:1 ratio of blood:citrate (3.2% or 3.8% sodium citrate) must be respected. It is possible to prepare smaller citrated tubes by adjusting the quantity of citrate, but these are prone to clotting and not recommended. Plasma should not be diluted for the evaluation of coagulation times, as these assays do not demonstrate linearity with dilution. The use of small non-automated coagulation analyzers can be advantageous because the whole plasma volume in the tubes can be utilized, and there is no dead volume remaining unlike with large automated analyzers.

Interpretation of Changes in PT and APTT

Preanalytical Changes

Preanalytical effects can cause either prolongation or shortening of PT and APTT. A difficult venipuncture may trigger the release of TF and collagen and the formation of small clots in the tube, increasing coagulation times. Overfilling citrate tubes increases the volume of plasma; hence, the sample concentrations of coagulation factors and calcium are increased and there is a deficient calcium–citrate binding, both coagulation times tend to decrease.[29] Likewise, underfilling of citrated tubes will result in increases of coagulation times.[1] In nonclinical studies, it is recommended not to analyze underfilled or overfilled tubes.

Selective Increases in PT or APTT

Increase in PT with no concurrent increase in APTT is an expected compound effect observed with administration of FVII inhibitors. Increases in APTT with no concurrent increase in PT are expected with administration of FVIII or FIX inhibitors. The first generation of antisense oligonucleotides has been reported to bind and inhibit coagulation factors VIIIa, IXa, X, and II and increase APTT.[26]

Combined Increases in PT and APTT

Combined increases in PT and APTT are more frequently observed and changes in APTT are most often of larger magnitude compared to PT. Increased red cell mass in dehydrated animals decreases the volume of plasma, consequently the proportion of coagulation

factors to citrate is decreased, and both coagulation times tend to increase.[29]

On a general basis in nonclinical studies, mild increases of group mean coagulation times (15–20%) are considered to be compound-related, but these criteria will change between laboratories based on assay variability. However, laboratory animals will not show clinical signs before APTT or PT increases by approximately 200%. Indeed, laboratory animals depleted of coagulation factors rarely form hematomas because they are maintained in cages and often isolated from their counterparts when considered at risk.

Compounds Affecting Vitamin K

Compound-related vitamin K deficiency can be suspected when PT and APTT are increased simultaneously with decreased availability of vitamin-K-dependent factors. Vitamin-K-dependent coagulation factors may be affected during nonclinical studies by anticoagulant compounds with coumarin moieties, such as warfarin, or by off-target compound effects.[40] Vitamin K is required for the synthesis of functional factors II, VII, IX, and X and proteins C and S. Unexpected vitamin K deficiencies can be observed in studies conducted in neonatal animals because of the immaturity of the liver, or with compounds causing gastrointestinal or pancreatic toxicity, which affects the absorption of fat-soluble vitamins.[7,11]

Vitamin Kconcentrations in liver, serum, or urine are measured by mass spectrometry and liquid chromatography, but measurement of vitamin-K-dependent factors remains an easier option.

Decreased activity in vitamin-K-dependent factors (II, VII, X, and X) without changes in factors that are vitamin-K-independent (VIII) is strongly supportive of vitamin K deficiency or antagonism.[7] PT is frequently increased before APTT because FVII has the shortest half-life of all factors, and animals may not show hemorrhages until FII (prothrombin) is deficient.[6] Changes in coagulation times may be different between male and female rats, because of a gender difference in the metabolism of vitamin K, and in activities of clotting factors.[23] Estrogens are reported to protect from vitamin K deficiency in rats, while testosterone is reported to aggravate it.[18,24,40] Compounds may have an impact of the hydroxylation of vitamin K by induction of hepatic cytochrome isozymes (CYP), and species differences in CYP induction could explain compound-related species differences observed in vitamin K deficiency.[8,40]

FIIa and FXa Inhibitors

Heparins and vitamin K antagonists have been used for many years for the treatment and prevention of thromboembolic disease, but pose a risk of bleeding. In recent years, a large number of direct thrombin and factor Xa inhibitors have been developed and accepted for clinical usage for the prophylaxis and treatment of venous thromboembolism and acute coronary syndromes. Direct thrombin inhibitors block both free and fibrin-bound thrombin in opposition to heparin that can form a bridge between thrombin and fibrin and enhance thrombin affinity for fibrin.[22] APTT and PT are both sensitive to the inhibition of FXa and thrombin, although this sensitivity varies between species. When evaluating heparins, APTT increases are proportional to the concentrations of heparins, but the PT assay remains unchanged because of the presence of a heparin inhibitor in the PT reagent.

Decreased production of coagulation factors secondary to compound-induced hepatic lesions are rarely encountered in nonclinical studies. Although the liver is often the target for compound-related toxicity, chronic hepatic lesions are rarely observed because of the short duration of nonclinical studies, and the animals suffering important hepatic lesions are not kept on studies for ethical reasons.

Decreases in Coagulation Times

Shortened APTT and/or PT are rarely encountered, and do not indicate hypercoagulability. These coagulation times are not very sensitive to procoagulant factors or the effects of fibrinolysis. Increased concentrations of fibrinogen up to 800 mg/dL do not impact APTT and PT but shorten TT in rats, and shorten APTT, PT, and TT in dogs.[20]

EVALUATION OF SPECIFIC COAGULATION OR ANTICOAGULANT FACTORS

Fibrinogen

Fibrinogen concentration is routinely evaluated during nonclinical studies. It is an acute-phase protein produced by the liver. Among all species, there is considerable similarity in the fibrinogen molecule.[14] Fibrinogen is most often determined by the modified thrombin time but an ELISA-based method can be used. Decreased fibrinogen concentration is commonly observed in poor-quality samples containing fibrin strands and in disseminated intravascular coagulation (DIC). Increased fibrinogen is a reliable biomarker of inflammation in all laboratory animal species.

Individual Coagulation Factors

Individual coagulation factors are infrequently measured, but may be evaluated to identify a mechanism of action for off-target effects.

Coagulation Factors Assay Using Human Deficient Plasma

Human-coagulation-factor-deficient plasmas are used for the quantification of specific coagulation factors. The assay is based on the ability of the tested plasma to correct the clotting time of the deficient plasma (see Chapter 88). In animal species, it is necessary to generate a standard curve for each species and reagent, using a pool of healthy nontreated animals, in order to

accommodate species differences. Coagulation factor activities vary with species, sex, age, and health status. In a rat model of diabetes, age-related changes consisted in increases in coagulation factor activities and decreases in fibrinolytic factors.[28]

Chromogenic Factor Assays

When absolute factor activities are required, chromogenic ELISA using a colorimetric detection can be adapted on automated coagulation analyzers (see Chapter 88). However, these quantitative immunoassays are designed with antibodies reacting specifically with human or mouse proteins and may be limited by the absence of cross-reactivity between species. Several chromogenic assays were successfully validated with laboratory animal samples. The FXa chromogenic assay was used to measure the efficacy of anti FXa inhibitors in rats and dogs, and the efficacy of heparins in rabbits.[2,7,32] Chromogenic FVIII and FIX assays were used for the evaluation of nonhuman primate models of hemophilia.[15]

FDP and D-dimers

Fibrin degradation products (FDP) result from the degradation of fibrinogen or fibrin fragments. Increased FDP is an indication of accelerated fibrinolysis, but is less specific than D-dimers concentration that is indicative of increased production of thrombin and activation of plasmin. D-dimers can be measured in NHPs and dogs using an immunoturbidimetric method (human reagent kit) adapted to an automated chemistry analyzer. Determination of D-dimers in rats was reported using an ELISA assay, although the variability of this assay was found to limit its reliability (author's unpublished data). D-dimers tend to vary in nonhuman primates and are elevated in prothrombotic conditions, and highly elevated with the formation of thrombi.

ATIII and TAT

There are several intrinsic coagulation inhibitors: antithrombin III (ATIII), protein C, protein S, heparin, heparin cofactor II, tissue factor pathway inhibitors, and annexin V. Antithrombin activity is most commonly evaluated in NHP and dogs, and is decreased in conditions of DIC. It is measured indirectly by its ability to inhibit thrombin and FXa using a chromogenic substrate or directly with an ELISA.[6,39]

Thrombin–antithrombin (TAT) complexes are also sensitive and specific indicators of thrombin activation. A high concentration of TAT indicates an earlier generation of thrombin and suggests hypercoagulability. In a rat model of inflammation, activation of coagulation by administration of lipopolysaccharide (LPS) resulted in an increase in TAT 3 hours postdose.[34] TAT complexes have also been determined in mice, rats, rabbits, dogs, pigs, and baboons using an ELISA kit for humans.[35]

GLOBAL COAGULATION ASSAYS

Thrombin Generation

Thrombin generation is a kinetic assay that is gaining interest in nonclinical studies, as it can be initiated on frozen plasma after analyses of first-tier markers and can detect both hypocoagulable and hypercoagulable conditions (see Chapter 88). Indeed, it is among the most interesting and sensitive assays that can detect an early compound-induced prothrombotic state. This assay can easily be validated in all species, as the processes of thrombin generation and fibrin clot formation are similar among all.

Thromboelastography

Whole blood viscoelastic assays, such as thromboelastography (TEG), are now used as investigative assays to provide a more comprehensive assessment of clot integrity (see Chapter 79). These assays should be considered in replacement of bleeding times and whole blood clotting times. A standard protocol should be used to ensure the reliability of viscoelastic assays.

In rodents, TEG is performed on citrate whole blood sampled from the femoral artery or abdominal aorta, stored 15–30 minutes before analysis, and measured within 2 hours of collection. Citrated blood is recalcified with calcium chloride to initiate the reaction. Addition of kaolin or TF is not necessary.[43]

Bleeding Time

Assessment of bleeding time is poorly reproducible because of large individual variability and lack of sensitivity (see Chapter 79). Hence, it is rarely performed, but is still considered advantageous to reflect the effects of anticoagulants or compounds affecting platelet function. In rats, the incision cut is made on the tail or pedal artery on anesthesized animals. In NHP, the incision is done on the forearm, and BT is typically less than 200 seconds.

Microparticles

Microparticles (MPs) have different hemostatic properties depending on their origin. The majority of circulating MPs are derived from platelets, and a lesser portion originates from endothelial cells and leukocytes. MPs generated after platelet activation have high pro-coagulant properties; leukocyte-derived MPs can inhibit coagulation, and calcium phosphate vesicles prevent coagulation. MPs, measured by flow cytometry, are infrequently evaluated in nonclinical studies.[3]

Whole Blood Clotting Assays

Whole blood clotting time consists of adding whole blood to glass tubes at 37 °C and measuring the time taken for the blood to clot. A contact activator is added in the activated clotting time (see Chapter 88). Such

assays offer a crude and limited assessment of the intrinsic system, and have limited interest, however they are mentioned in regulatory guidelines.[31]

EVALUATION OF PLATELETS

Platelets are the first line of defense against vascular bleeding and are major contributors to thrombosis and inflammation. Changes in platelet counts and/or platelet function are important findings in regulatory nonclinical studies. Although some drugs are developed specifically for their antiplatelet effects, others may affect platelet count or function as off-target effects, including effects that could lead to risks of thrombosis and increased bleeding.

Disseminated intravascular coagulation

DIC is a lethal syndrome characterized by multiorgan microvascular thrombosis (see Chapter 92). It represents an unbalanced response leading to the systemic release of proinflammatory cytokines. In toxicological studies, it may occur secondary to an inflammatory event or administration of an immunomodulator which increases cytokines, activates monocytes, and triggers activation of coagulation factors.[16] Overt DIC is recognized by clinical criteria of thrombocytopenia, prolonged clotting times, depletion of fibrinogen and antithrombin, and elevated D-dimers. By contrast, early subclinical or non-overt DIC has no specific predictive tests to differentiate patients who re-establish effective hemostatic balance from those who progress to overt DIC and death.[3] An endotoxin-induced inflammatory state was studied in rats. Rapid and transient increases in circulating concentrations of D-dimer, intercellular adhesion molecule-1 (sICAM-1), PAI-1, procoagulant extracellular vesicles and decreases in antithrombin III were observed within 4 hours, denoting early cellular activation and dysregulated coagulation and fibrinolysis that promote thrombus formation.[4] In a similar rat study, TAT were increased 3 hours postendotoxin injection, while thrombin generation was decreased, suggesting a rapid consumption of coagulation factors.[34]

Immune-Mediated Platelet Decreases

Compound-induced immune-mediated platelet decreases have been associated with several drug classes including sulfonamides, nonsteroidal anti-inflammatory drugs (NSAIDs), anticonvulsants, and diuretics (see Chapters 12 and 15). Small molecular compounds uncommonly generate immune responses. Alternatively, biologics such as monoclonal antibodies, growth factors, cytokines, enzymes, and peptides are more prone to induce immune reactions. [12,21,36,37]

Immunogenicity in animals is not considered predictive of immunogenicity in humans, therefore it is important to determine if findings observed in nonclinical studies are related to the pharmacology of the compound or to the immunogenicity. Possible assays for investigating immune-related toxicity include: measurement of circulating immune complexes (ICs), complement split products C3a and C5b9, and CH50 by ELISA.[21] Platelet aggregometry and platelet activation (by flow cytometry) may help to differentiate a direct effect on platelets or an anti-drug antibody-related effect.[33] Immunohistochemistry or electron microscopy can be used to visualize the presence of immune complexes in kidney, lungs, or other damaged organs.

Platelet Dysfunction

Altered platelet function should be suspected in nonclinical studies in animals with bruises, hematomas, or hemorrhages (often only observed histopathologically). Platelet dysfunction is typically assessed by platelet aggregation assays by adding aggregating agents or agonists to platelet-rich plasma or whole blood (see Chapter 79). There is a large variability of response to aggregating reagents and agonist concentration among animal species (Table 13.3).

Several drug classes, including antiplatelet agents, anticoagulants, and NSAIDs, interfere with platelet function disrupting distinct pathways of platelet function. Therefore, a new compound can be evaluated by combining it with drugs that are known to inhibit distinct pathways in order to assess potential synergistic or

TABLE 13.3 Platelet aggregation reactivity among species with different agonists (Chrono-log® reagents) (author's non published data). Aggregation was performed in whole blood using an impedance method or in PRP using an optical method.

Species	Platelet Aggregation
Dog	Whole blood: Large individual variability with collagen up to 10 µg/mL PRP: Large individual reactivity with collagen, ADP, arachidonic acid (AA), epinephrine, ristocetin. Many dogs do not show platelet reactivity, due in part to genetic variability in the response in thromboxane A2
NHP	Whole blood: Poor reactivity with ADP up to 20 µM, low reactivity with collagen 10 µg/mL and thrombin 0.2 µg/mL **PRP:** Good response with ADP 10 µM and collagen 2 µg/mL. Good reactivity with ristocetin ATP release is not detected with ADP, but with collagen
Guinea pig	PRP: Good responses with collagen, ADP, AA, and platelet-activating factor (PAF). Variable to poor reactivity with ristocetin
Rat	Whole blood: Poor reactivity PRP: Good response to ADP 1–5 µM, collagen 0.5–1 µg/mL. No response to AA in citrated PRP, and to PAF (lack of receptor). No reactivity with ristocetin
Mice	Whole blood: Poor reactivity PRP: Good response to ADP 10 µM
Human	PRP: Good reactivity with ADP, collagen, AA, thrombin receptor activating peptide (TRAP) and ristocetin

inhibitory effects on platelet function. Such assays are done first in vitro on human or nonhuman primate samples, and then in vivo.[5] For in vitro assay, the compound is spiked at various concentrations in whole blood or platelet-rich plasma, and platelet aggregation is evaluated after addition of an agonist. Platelet aggregation is generally measured using two agonists, ADP and collagen, because they use different membrane receptors and pathways for platelet activation.

Flow cytometric evaluation of platelet function is commonly used, often in parallel with platelet aggregation assays, in in vivo and ex vivo studies. Similarly, isolated platelets or anticoagulated whole blood are incubated with the compound and a platelet agonist (usually ADP). The evaluation of P-selectin and GIIb/IIIa is commonly performed in nonhuman primates and mice to detect activated platelets. These molecules are upregulated on the surface of activated platelets (see Chapter 79).

The PFA-100 instrument presents a different approach to platelet dysfunction: blood is aspirated at high shear through an aperture into a disposable cartridge coated with agonists and closure time is measured until a platelet plug is formed. In nonclinical studies the PFA is considered an interesting translational Nonclinical studies provide interesting translational markers from laboratory species to humans. from laboratory species to humans. It can be used in NHP and dogs, but does not function in rats because of the low reactivity of rat platelets in whole blood to the different agonists.

CONCLUSION

The evaluation of compound-related effects on hemostasis remains essential in nonclinical studies to determine their safety for administration to humans. In vitro assays of compound effects are gaining popularity because they limit the use of laboratory animals; however, evaluation of their predictive values can be challenging and comparison of newly developed compounds with already marketed compounds is sometimes necessary. The use of thrombosis or hemophilic models may be necessary to determine the doses for human administration. Due to the large species-specific variability in concentrations of coagulation factors, platelet numbers, and platelet function, the role of the veterinary clinical pathologist is essential to evaluate compound effects in regulatory nonclinical studies.

IMMUNOTOXICITY AND (BIO) PHARMACEUTICALS

Preclinical immunotoxicity evaluations in drug development are used to identify test-article-related changes to the innate and adaptive immune system, the mechanism of immunotoxic effects, and the consequences of these changes for normal immune function and homeostasis.[12] All investigational new drugs should be evaluated for immunotoxic potential through assessment of immune-relevant endpoints in standard toxicity studies (STS) or specialized immunotoxicity studies. Potential mechanisms of immunotoxicity include exaggerated or prolonged pharmacology on an immune system target, modulation of an immune target with multiple immune functions or a target expressed on other immune cells, or off-target cross-reactivity. Results of preclinical immunosafety assessment for compounds with immunotoxic potential inform first-in-human dosing and dose escalation, clinical trial inclusion and exclusion criteria, the clinical safety monitoring plan, and, ultimately, drug labeling for any identified toxicological effects on the immune system.

IMMUNOSUPPRESSION

Test-article-related effects on the immune system potentially resulting in immune suppression include depletion of circulating leukocytes and lymphoid tissues, decreased hematopoiesis, or alterations in immune function resulting in increased incidence of infections or

neoplasia. On-target or exaggerated immunopharmacology resulting in immunosuppression can be seen with (bio)pharmaceuticals intended for inflammatory and autoimmune diseases with effects mediated by binding to cell surface receptors resulting in cell depletion (rituximab), signaling pathway molecules (abatacept and belatacept), or inhibition of soluble mediators and cytokines (adalimumab).[29,31,36,42]

IMMUNOSTIMULATION

The safety implications of immune stimulation as a therapeutic target received much attention after administration of an anti-CD28 superagonist monoclonal antibody (TGN1412) to healthy volunteers resulting in life-threatening complications due to induction of cytokine storm.[39] Subsequently, intensive investigations and published reviews described potential mechanisms for the lack of predictivity for cytokine storm in nonhuman primate (NHP) preclinical toxicity testing, assays for improved assessment of potential for cytokine release syndrome (CRS), and strategies to mitigate the risk of immune stimulation in first-in-human studies and clinical trials. [15,19] Recently, immunotherapies, such as toll-like receptor agonists, immune cell checkpoint inhibitors, T-cell tumor antigen bispecific antibodies, and chimeric antigen receptor T-cell therapy, have demonstrated remarkable therapeutic benefit of targeted immune stimulation in cancer treatment. Safety considerations for cancer immunotherapies, including CRS and tissue inflammation, as well as the translatability of preclinical toxicity models to evaluate these safety findings have been reviewed.[11,22,23] Gene therapy is a rapidly progressing field with the preclinical safety assessment considerations for gene therapy products recently published.[1] Immunological considerations for gene therapy development include both the immune response to the therapeutic transgene and the viral vectors used to deliver the transgene, which may have pharmacokinetic, efficacy, and safety implications.[7]

HYPERSENSITIVITY AND AUTOIMMUNITY

Hypersensitivity

Adverse drug reactions (ADR) are unintended and undesired effects of drugs that occur during usual clinical use (see Chapters 12 and 15). Drug-induced hypersensitivity reactions are uncommon, unpredictable, dose-independent, and affect a small population (Type B ADR). Anaphylactoid or pseudoallergic drug reactions, due to complement or mast cell activation, may occur as an infusion reaction following the first dose.[43] Currently, no regulatory guidelines are in place identify the risk of drug-induced hypersensitivity in preclinical evaluations, and the complexity and unpredictability of the reactions make preclinical testing difficult. The in vivo local lymph node assay (LLNA), used for topical drugs, to screen for Type IV hypersensitivity risk has shown some promise for predictivity, especially if immunologically specific endpoints are included.[3] In vitro assays to assess drug-related T-cell and dendritic-cell activation also show promise for screening for hypersensitivity potential.[18] Currently, preclinical testing for drug-induced hypersensitivity should be considered on a case-by-case basis based upon pharmacology and results of preclinical testing and clinical findings.

Autoimmunity

Autoimmunity is the loss of immune tolerance to self-antigens with resulting immune-mediated destruction of cells and tissues. Potential drug-related causes for autoimmunity include molecular mimicry of the drug or metabolite to tissue antigens, binding of drug to cells or tissues resulting in a new antigenic target, and drug-related alterations in the immune system resulting in loss of tolerance, e.g., suppression of T regulatory cell function.[13] Due to the complexity of factors influencing autoimmune risk, preclinical assessment of the autoimmunity-inducing potential of a (bio)pharmaceutical is difficult. As immunoenhancement may increase risk of autoimmunity, methods to detect increased immune responses, including evaluation of tissue inflammation, T-cell populations involved in regulation of immune response, and immune function assessments (LLNA, delayed-type hypersensitivity (DTH), and antigen-specific immune challenge assays), may be considered for autoimmunity risk assessment. If there is clinical evidence of autoimmune risk or if the drug target or pathway raises concern for autoimmune potential, measurement of anti-DNA and anti-histone antibodies and screening for immune complex formation are additional screening methods with the recognition that these assays are not well validated in animal models for clinical translatability.[13]

REGULATORY GUIDELINES

The key guideline for (bio)pharmaceutical preclinical immunotoxicity assessment is the ICH (International Conference for Harmonisation) S8 guideline on immunotoxicity testing of human pharmaceuticals.[49] This guideline was the result of harmonization of immunotoxicity testing guidelines previously published by regulatory agencies (Table 14.1). For the purpose of the ICH S8 guideline, immunotoxicity is specified as unintended immunosuppression or enhancement with drug-induced hypersensitivity and autoimmunity excluded. The ICH S8 guidance recommends the evaluation of all new human pharmaceuticals for immunotoxic potential using a weight-of-evidence approach. Criteria for evaluating immunotoxicity include results of standard toxicity studies, pharmacological properties of the test compound, intended patient population, structural similarity to known immunomodulatory agents, disposition of the drug, and/or observations in clinical trials or clinical

use. If the potential for immunotoxicity is identified, then follow-up immunotoxicity testing using both morphological and functional assays should be conducted. The guideline provides recommendations on the duration, dosing, and types of immune testing to be included in the additional immunotoxicity studies.

Biotechnology-derived pharmaceuticals are considered out of scope for the ICH S8 guideline and reference is made to ICH S6 (R1) (preclinical safety evaluation of biotechnology-derived pharmaceuticals) published in 1997 and revised in 2011.[50] Regarding immunotoxic potential, ICH S6 (R1) notes that biotechnology-derived pharmaceuticals may induce either immunosuppression and immunoenhancement as well as immunogenicity, and testing strategies may require screening studies followed by mechanistic studies to clarify issues. However, routine tiered testing approaches or standard testing batteries are not recommended. For biosimilar therapeutic antibodies, the European Medicines Agency (EMA) guidance, while not specifically addressing immunotoxicity screening, recommends that Fc-receptor-mediated effects of the biosimilar monoclonal antibodies are similar to the reference product through use of in vitro assays evaluating antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), and complement activation.[45]

IMMUNOLOGICAL ENDPOINTS IN PRECLINICAL TOXICITY STUDIES

Based upon the weight-of-evidence approach described in ICH S8, a tiered testing strategy comprising immune-relevant endpoints in STS (tier 1), specialized structural and/or functional immune parameters (tier 2), and host resistance studies (tier 3) are utilized for the preclinical immunosafety assessment of (bio)pharmaceuticals.

Tier 1 Assessments

The immune-relevant endpoints in STS (tier 1) include hematology, serum globulin concentrations, lymphoid organ weights, and histopathology of lymphoid tissues and bone marrow. The observation of increased infections or tumor incidence is also a tier 1 immunological assessment and may be the only indicator of an immunotoxic effect if the function of a single cell type is affected, such as neutrophil or macrophage phagocytosis.[37]

Hematology

The preclinical evaluation of hematology parameters is discussed in Chapters 11 and 12. From an immunotoxicity perspective, increases in peripheral leukocyte absolute counts may indicate test-article-related immunostimulation/enhancement or infection secondary to immunosuppression. Decreases in circulating leukocyte numbers occur with bone marrow or lymphocyte cytotoxicity, alterations in leukocyte trafficking, targeted depletion of immune cells, or increased tissue utilization due to infection or inflammation.

Clinical Chemistry

Decreases in lymphocyte numbers or suppression of lymphocyte function may result in decreased immunoglobulin production with concomitant decrease in globulin concentrations as measured in the standard chemistry panel. Changes in serum globulins are interpreted in conjunction with renal and/or liver parameters and histopathology to rule out non-immune-related causes for the globulin change. If a test-article-related impact on globulin production is anticipated, inclusion of serum immunoglobulin subclass evaluations (IgM, IgG, IgA) in STS may be considered for additional characterization. As increases in acute phase proteins related to immunostimulation and/or inflammation are generally

not detectable on serum globulin assessment alone, evaluation of acute phase proteins may be added to STS if immune stimulation is anticipated or if evidence of inflammation is detected.[13]

Histopathology

Organ weight of lymphoid organs and histopathological evaluation of lymphoid tissue and bone marrow are important tier 1 immunotoxicity assessments. Increases in lymphoid organ weights suggest immunostimulation related to either infiltration of immune cells (inflammation or altered trafficking) or immune cell hyperplasia. Decreases in lymphoid (spleen, thymus) organ weights are suggestive of immune suppression related to lymphoid depletion, which may be an on-target effect, related to cytotoxicity, or secondary to stress. Age-related decreases in thymic weights due to thymic involution, most apparent in dogs and NHP, can make interpretation of a direct test-article-related effect on thymic lymphopoiesis difficult. Selection of tissues for appropriate tier 1 assessment of immunotoxic potential and considerations for reporting of findings have been reviewed.[21]

Stress and Immunotoxicity

Animal handling and test article doses at or near the maximum tolerated dose can result in changes to the immune system related to stress due to cortisol, corticosterone, or other mediators.[16] Differentiation of direct test-article-related effects on the immune system from stress-related immune suppression is a key component of the weight-of-evidence review for immunotoxic potential. The impacts of stress on immune cell populations and immune organs should be interpreted in conjunction with the overall degree of changes in the study.

Tier 2 Assessments

If results of STS and/or other considerations in the weight-of-evidence review suggest immunotoxic potential, tier 2 assessments consisting of morphological and functional tests should be implemented in either a standalone immunotoxicity study or repeated dose toxicity.[41]

Flow Cytometry

Flow cytometry is a frequently applied methodology within immunotoxicity evaluations to assess changes in immune cell populations (see Chapter 142). For immunotoxicity evaluations, flow cytometry is most commonly used for immunophenotyping lymphoid subsets in blood and lymphoid tissue (spleen, thymus, and, less frequently, lymph node).[2] Flow cytometry also can be used to evaluate test-article-related changes in neutrophil and monocyte populations, T regulatory (suppressor) cells, memory subsets, immune cell activation, proliferation potential, phagocytic function, production of intracellular cytokines, and evaluation of pharmacodynamic markers, such as target receptor occupancy. Due to intra-animal variability and changes in lymphocyte subset numbers related to excitement and handling, two predose samples for immunophenotyping are typically collected in large animals (dogs, NHP, minipig) for baseline comparisons. Application of immunophenotyping and flow cytometry assessments in laboratory animals (rodents, dogs, NHP, minipig) has been reviewed.[25,28,34,35]

T-Cell-Dependent Antibody Response

The T-cell-dependent antigen response (TDAR) is the most commonly applied immune function test in preclinical immunotoxicity assessments. The TDAR involves challenge with an antigen followed by evaluation of the primary and secondary antibody assessment.[17] A neoantigen to which the animal has not been previously exposed may be used to evaluate both primary (IgM) and secondary (IgG) responses and/or a recall antigen can be administered to evaluate recall (memory) antibody (IgG) response. As the TDAR involves antigen presentation, T-cell activation and regulation, antibody production, and immunoglobulin class switching, the assay is considered a broad functional assessment of immune function. In the pharmaceutical industry, the most frequently applied neo-antigen is keyhole limpet hemocyanin (KLH) with tetanus toxoid often used as a recall antigen.[20] Methodologies and considerations for TDAR in toxicological species have been described.[26–28,35] With increased interest in biomarkers of immune stimulation for immunotherapies, modifications of the TDAR in cynomolgus monkeys using doses of KLH to elicit sub-maximal antibody responses allowing for detection of increases anti-KLH IgM and IgG have been reported.[33] Although not commonly used, a T-cell-independent antibody response (TIAR) assay using T-cell-independent antigens (e.g., pneumococcal vaccine) can be used to evaluate potential effects on T-independent antibody responses, such as a targeted effect on the lymphoid marginal zone.[10]

Cell-Mediated Immunity

The effect of (bio)pharmaceuticals on innate immune cell and T-cell responses can be evaluated using both ex vivo and in vivo assays. Ex vivo assays to evaluate phagocytosis/oxidative burst, cell killing mediated by natural killer (NK) cells or cytotoxic T lymphocytes (CTL), basophil function, and T- and B-cell antigen-specific responses (activation, intracellular cytokine production, cytokine release) are described.[24,28,33,35] The DTH assay is an in vivo assay that evaluates T-cell-mediated responses (Type IV hypersensitivity) following an intradermal antigen challenge and is used as a screen for unintended suppression of cell-mediated immunity or as a pharmacodynamic marker for enhanced T-cell responses. [4,9,35]

Inflammatory Mediators

Cytokines and chemokines can be measured using ex vivo cytokine release assays (CRA) or serum or plasma samples from in vivo toxicity studies to evaluate the potential for immunostimulation. Methods for cytokine

and chemokine evaluation include ELISA or bead-based flow cytometric (Luminex®) or electrochemiluminescent (Meso Scale Discovery®) multiplex technologies. Considerations for cytokine detection in preclinical laboratory species and cytokine release assays have been described.[19,28,33,35,40] Cross-species reactivity should be confirmed for the method used for cytokine detection. Single cytokine or chemokine measurements using ELISA can be considered if the analyte is a known target or key component of the modulated immune pathway or is a pharmacodynamic marker. If multiplex assessments are available, evaluation of a panel of both inflammatory cytokines (IL-1β, IL-2, IL-5, IL-6, IL-12, interferon-λ, and TNF-α) and anti-inflammatory cytokines (IL-10, IL-1RA) is a useful screen for immune enhancement. Additional analytes may be included based on pharmacology of the compound. As cytokine/chemokine responses are time-dependent and often transient, samples are collected at predose and multiple times postdosing (0.5 hour, 4–6 hours, and 24 hours postdose). Excitement and animal handling may increase circulating levels of cytokines, such as IL-6.[40] Thus, two predose samples for baseline comparisons should be considered (when allowed by blood volume collection limits) with results interpreted in conjunction with sampling schedule and other markers of inflammation.

Evaluation of complement activity can be used to assess the risk for complement activation for compound classes with known activating potential, for compounds specifically targeting the complement system, or when complement activation is suspected based upon results of STS. Similar to cytokine evaluations, samples to evaluate complement activation should be collected predosing and shortly after dosing (15–30 minutes).[28,33]

Tier 3 Assessments

Host resistance studies involve the administration of an infectious agent (bacteria, virus, fungus, parasite) or tumor challenge to rodents in presence of test compound to assess the immunotoxic (suppressive) effect of the test compound.[6] These studies may be considered on a case-by-case basis for compounds that are broadly immunosuppressive, to investigate a clinical infection risk signal, or for compounds against targets with a known clinical infection risk. As these studies are performed only in specialized biohazard laboratories and the clinical translatability is uncertain, host resistance studies are infrequently conducted in the pharmaceutical industry.

IMMUNOGENICITY

Immunogenicity is the ability of a drug to elicit an immune response and is a particular consideration for large molecule biopharmaceuticals. While not considered predictive for development of immunogenicity in humans, the evaluation of anti-drug or anti-therapeutic antibodies (ADA or ATA) in preclinical toxicity studies is important for the accurate assessment of the toxicity study. ADA may impact preclinical study pharmacokinetics, pharmacodynamics, and safety via alterations in drug clearance, neutralization of target binding, or hypersensitivity responses (type I and type II). Regulatory guidelines for the assessment of ADA are listed in Table 14.1. The assessment and predictivity of ADA evaluations have been reviewed. [5,33]

DEVELOPMENTAL IMMUNOTOXICITY EVALUATIONS

If the drug target, immunopharmacology, or observations of adolescent or adult animals in STS suggest a cause for concern for immunotoxicity on the developing immune system, morphological and functional assays can be incorporated into reproductive toxicity studies. For low-molecular-weight (LMW) compounds or biotherapeutics that are cross-reactive in rodents, these assays are included into rodent prenatal and postnatal studies (PPND). For biotherapeutics that are only cross-reactive in NHP, immunosafety assessment can be included in the enhanced prenatal and postnatal development (ePPND) study recommended in ICH S6 (R1). Study designs for incorporation of immune endpoints in rodent and NHP developmental toxicity studies are described. [8,14,38,50]

ADR, adverse drug reaction; FDA, Food and Drug Administration; DDT, chlorophenothane; DNA, deoxyribonucleic acid; EDTA, ethylenediaminetetraacetic acid; ppm, parts per million, IMHA, immune-mediated hemolytic anemia; RBC, red blood cell; RNA, ribonucleic acid.

DRUG-INDUCED HEMATOLOGIC DISORDERS

A growing number of therapeutic drugs have been incriminated in adverse drug reactions (ADRs) associated with the hematologic system.[74,79] These drug toxicities have been categorized as dose-dependent or idiosyncratic (see Chapter 12 for more detailed discussion).[74] In dose-dependent reactions, toxicity increases with the dose and most members of a species are affected at higher doses. Idiosyncratic drug toxicities occur at therapeutic doses and only a small percentage of susceptible individuals in a population is affected.[74] Idiosyncratic drug toxicities frequently result from individual variation in the metabolism of drugs producing reactive metabolites that cause tissue injury in susceptible individuals. These reactive metabolites may cause oxidative injury or bind to cellular proteins forming haptens that trigger humoral or cellular immune responses.[74]

The site and mechanism by which a drug acts are important in determining the clinical syndrome and prognosis; however, some drugs act at multiple sites or

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

by several mechanisms making this determination difficult (Table 15.1).[75] Destruction of erythrocytes, leukocytes, or platelets in the peripheral blood results in rapid onset of cytopenias. The bone marrow can compensate by increasing production and cell numbers may return to normal despite continued administration of the drug. RBCs are particularly sensitive to oxidative injury. Oxidant drugs or those that are metabolized to oxidants tend to be dose-dependent because tissue injury is largely dependent on the degree of oxidative injury (see Chapter 32). Rapidly proliferating progenitor and proliferative cells in bone marrow are susceptible to chemotherapeutic agents. The development of cytopenias in the blood follows a predictable course.[17] Some drugs induce hematopoietic stem cell destruction or alter the hematopoietic microenvironment. The timing of development of cytopenias is more unpredictable and recovery is uncertain and delayed when it occurs. Endothelial cells of marrow capillaries and sinusoids also are vulnerable to toxic injury (see Chapter 16).

Evaluation of Suspected Adverse Drug Reactions

The mere temporal association of a drug treatment with a hematologic disorder does not in itself provide proof of an ADR. In each case, other potential causes of the hematologic condition should be eliminated by evaluation of the history, and clinicopathologic findings. When an ADR is suspected, the temporal relationship between onset of treatment and detection of the hematologic dyscrasia, previous exposure to the drug in question, and recovery from the hematologic dyscrasia after drug withdrawal should be documented.[42] This information not only documents the likelihood of a cause and effect relationship but may suggest a possible mechanism for the drug toxicity. When multiple drugs have been administered before detection of a hematologic dyscrasia, the Food and Drug Administration (FDA) database (http://www.fda.gov/cvm/adetoc.htm) can be reviewed or a literature search conducted to determine if other similar toxicities have been reported.[43] The FDA database can also be used to report suspected toxicities.

TABLE 15.1 Drugs suspected or confirmed to cause hematologic dyscrasias in animals.

Class and drug	Species	Suspected mechanism
Antineoplastics		
Class effect	All	Marrow suppression, dysmyelopoiesis
Endocrine		
Estrogen	Dog	Marrow suppression
Propylthiouracil	Cat	Immune-mediated
Methimazole	Cat	Immune-mediated
Anti-inflammatory		
Phenylbutazone	Dog, Cat	Marrow suppression, immune-mediated
Meclofenamic acid	Dog	Marrow suppression
Carprofen	Dog	Marrow suppression
Azathioprine	Dog, Cat	Marrow suppression
Naproxen	Dog	Blood loss
Antibacterial		
Chloramphenicol	Dog	Dysmyelopoiesis
Cephalosporin	Dog	Immune-mediated, marrow suppression, dysmyelopoiesis
Penicillin	Horse	Immune-mediated
Sulfonamides	Dog	Immune-mediated, marrow suppression
	Horse	Immune-mediated
Antifungal		
Griseofulvin	Cat	Marrow suppression
Antiviral		
Azidothymidine/Acyclovir	Cat	Marrow suppression
Anticonvulsants		
Phenobarbital/Primidone	Dog	Marrow suppression
Phenytoin	Dog	Marrow suppression
Antiparasitics		
Levamisole	Dog	Marrow suppression/immune-mediated
Albendazole	Dog, Cat	Marrow suppression

(*Continued*)

TABLE 15.1 (Continued)

Class and drug	Species	Suspected mechanism
Metronidazole	Dog	Marrow suppression
Fenbendazole	Dog	Marrow suppression
Amitraz	Dog	Unknown
Cardiovascular		
Amiodarone	Dog	Immune-mediated
Captopril	Dog	Marrow suppression
Quinidine gluconate	Dog	Unknown
Analgesics		
Acetaminophen	Dog, Cat	Oxidant
Aspirin	Dog, Cat	Oxidant
Phenacetin	Dog	Oxidant
Anesthetics		
Benzocaine	Dog, Cat	Oxidant
Cetacaine	Cat	Oxidant
Propofol	Cat	Oxidant
Urinary acidifiers/antiseptics

Human erythropoietin/Darbepoetin	Dog	Immune-mediated
Mitotane	Dog	Marrow suppression
Colchicine	Dog	Marrow suppression
Azidothymidine (AZT)	Cat	Marrow suppression
Phenothiazine	Horse	Oxidant
Dimethyl sulfoxide	Horse	Oxidant
Heparin	Horse	Hemolysis

TABLE 15.2 Myelosuppressive potential of chemotherapeutic drugs used in dogs and cats.

High	Moderate	Low to none
Cyclophosphamide	Methotrexate	Corticosteroids
Cytosine arabinoside	Chlorambucil	L-Asparaginase
Doxorubicin	6-Mercaptopurine	Bleomycin
Vinblastine	Melphalan	
Hydroxyurea	5-Fluorouracil vincristine	

Usually, this information combined with serial complete blood counts, tests for immune-mediated hematologic diseases, and bone marrow aspiration and core biopsy specimens is the only data available to link a drug to a clinical ADR. Other tests that can be considered include evaluation of the hemolytic effects of the drug and evaluation of the effects of the drug, patient serum, or patient lymphocytes on blood cell or bone marrow cytotoxicity or on in vitro bone marrow cell culture.[25,39,60]

Adverse Drug Reactions in Dogs

Antineoplastic Drugs

Chemotherapeutic agents cause dose-dependent ADR. Because of their high mitotic rate, progenitor and proliferative cells in bone marrow are predisposed to injury by chemotherapeutic drugs. The myelosuppressive potential of chemotherapeutic agents varies (Table 15.2).[17]

Cytopenias are the most frequent chemotherapeutic toxicity identified and often necessitate temporary or permanent discontinuation of treatment. Bone marrow suppression follows a predictable course based primarily on the half-life of cells in the blood. Neutropenia occurs 5–7 days after myelosuppression followed by thrombocytopenia 9–14 days after myelosuppression.[16] Anemia as a direct result of chemotherapy is usually not seen because of the comparatively long half-life of RBCs.[17] Neutrophil and platelet counts usually return to baseline values within 72–96 hours after discontinuing therapy.[17]

Beyond destruction of hematopoietic cells, chemotherapeutic drugs have few adverse effects on the hematopoietic system. Multifocal areas of coagulation-type necrosis have been reported in association with administration of cyclophosphamide and vincristine.[78] An increase in dysplastic hematopoietic cells and atypical mitotic figures (i.e., secondary dysmyelopoiesis) is a frequent finding and should not be confused with a myelodysplastic syndrome (see Chapter 67).[1,81] Doxorubicin administration to dogs has been associated with poikilocytosis including the presence of ovalocytes, echinocytes, schistocytes, and keratocytes.[5] Doxorubicin is thought to bind to spectrin, a major cell membrane structural protein.[5]

Estrogen

Dog and ferret bone marrow is highly susceptible to estrogen-induced myelosuppression, and both dose-dependent and idiosyncratic reactions have been documented in dogs (aplastic anemia is discussed in Chapter 40).[44,67,82] In dogs, a single large dose of estradiol, therapeutic doses of estradiol, and therapeutic doses of diethylstilbestrol have been documented to result in hematologic dyscrasias. Therapeutic doses of estradiol or diethylstilbestrol, used in treatment of mammary tumors or prostatic hyperplasia, consistently cause a transient decrease in platelet count and neutrophilia 10–20 days after administration.[21] Administration of a single large dose of estradiol to dogs consistently results in leukocytosis, thrombocytopenia, and mild but progressive nonregenerative anemia in the first 3 weeks after injection of 1–3 mg/kg body mass of estradiol. Pancytopenia with bone marrow aplasia develops between 3 and 4 weeks after injection and most dogs begin to recover after 4 weeks. Although the mechanism is complex and poorly understood, serum inhibitors of hematopoiesis produced by T cells have been identified.[23] Myelofibrosis, bone marrow necrosis, and dysmyelopoiesis have been observed in dogs given therapeutic doses of estradiol propionate.[82]

Individual dogs appear to be uniquely sensitive to the effects of estrogen and develop severe aplastic anemia. Dogs given repeated therapeutic doses of estradiol or dogs having elevated endogenous estrogen levels resulting from cystic ovarian follicles, ovarian granulosa cell tumors, or Sertoli cell tumors may develop hematologic dyscrasias.[21] Dogs with endogenous estrogen toxicity typically are pancytopenic, but some are bicytopenic.[44,67,82] The bone marrow is typically aplastic.[23,82] This appears to be the result of hematopoietic stem cell destruction. The prognosis for these dogs is poor, but recovery after weeks to months of supportive care has been documented.[82] However, recent studies have reported recovery after removal of Sertoli cell tumors.[44,64]

Anti-Inflammatory Drugs

Phenylbutazone/Meclofenamic Acid Many cases of phenylbutazone-associated hematologic dyscrasias have been reported and one case of meclofenamic-acid-associated aplastic anemia has been reported.[38] Several types of idiosyncratic phenylbutazone-associated hematologic dyscrasias have been observed in dogs.[66] One type is a transient agranulocytosis that typically occurs within 2 weeks after starting treatment. Affected dogs frequently recover promptly when the drug is discontinued. This condition is most probably immune-mediated, but inhibition of bone marrow cell division or DNA synthesis is also a possible explanation. In another type of hematologic dyscrasia, dogs develop aplastic anemia months or years after initiation of treatment, presumably as a result of bone marrow toxicity.[77,82] In the experience of the author, the prognosis for recovery is poor. Additionally, phenylbutazone therapy has been associated with myelonecrosis and myelofibrosis.[77,82]

Carprofen Coagulation-type myelonecrosis has been reported in bone marrow from several dogs treated with therapeutic doses of carprofen.[78] Another dog was reported to have a neutrophilic dermatitis, vasculitis, immune-mediated hemolytic anemia (IMHA), and thrombocytopenia associated with carprofen adminstration.[45]

Azathioprine Neutropenia and thrombocytopenia or pancytopenia have been observed in dogs one to several months after initiation of treatment with immunosuppressive doses of azathioprine.[62] Bone marrow is aplastic, and some dogs have mild myelofibrosis. Peripheral blood cell numbers slowly return to normal once the drug is discontinued, but complete recovery may be delayed.

Naproxen Naproxen administration has been associated with blood loss anemia in dogs.[20,28] Gastrointestinal erosions or ulcerations are suspected to be the cause of the blood loss. This may result from local irritation or inhibition of prostaglandin synthesis.

Antibacterial Drugs

Sulfonamides Adverse drug events have been reported for sulfadiazine, sulfamethoxazole, and sulfadimethoxine.[27,82] These drugs induce an idiosyncratic syndrome that includes neutropenia, thrombocytopenia, hemolytic anemia, fever, polyarthropathy, or hepatocellular necrosis.[27,74] Doberman Pinschers may be at increased risk of sulfonamide hypersensitivity.[26] Others have reported sulfadiazine-associated aplastic anemia

(Figure 15.1).[69] The mechanism appears to be immune-mediated and does not appear to be related to folate deficiency.[27] Evidence of an immune-mediated etiology includes demonstration of drug-dependent antiplatelet antibodies and a positive direct Coombs test.[26] This immune response appears to be caused by an oxidized hydroxylamine metabolite that acts as a hapten when bound to proteins. Drug-specific T cells have been identified in humans and antidrug antibodies have been identified in dogs with sulfonamide hypersensitivity.[41,61] In dogs that are thrombocytopenic, antibodies recognize drug–platelet complexes.[42]

In dogs with sulfadiazine-induced aplastic anemia, pancytopenia usually occurs 10–14 days after initiation of treatment. The bone marrow is typically aplastic with the hematopoietic space replaced by adipose tissue.[80] The hematologic dyscrasia frequently resolves within 2 weeks after discontinuing treatment.

Chloramphenicol Severe aplastic anemia has been reported as an idiosyncratic reaction in humans treated with chloramphenicol, but has not been reported in dogs given therapeutic doses. One apparent idiosyncratic reaction was reported.[32] This dog had a moderate nonregenerative anemia with large numbers of siderocytes and ringed sideroblasts. This response suggests a reversible dysmyelopoiesis, perhaps secondary to drug-induced mitochondrial damage.

Cephalosporins Certain cephalosporins have been associated with several types of hematologic dyscrasias in dogs.[10,18] High dose or prolonged administration of cephalosporins can induce agranulocytosis, thrombocytosis, and a positive direct Coombs test.[15] Approximately half of dogs given high doses of cefonicid or cefazedone intravenously developed pancytopenia within 6–10 weeks after initiation of treatment.[10,18] The mechanism appears to be complex. In one study, the presence of anti-RBC, antineutrophil, and antiplatelet antibodies was consistent with immune-mediated destruction.[10] Cephalosporins also induce alteration in the bone marrow. Granulocytic and erythroid maturation arrest has been reported in dogs treated with cephalosporins.[18] The most prominent ultrastructural change in bone marrow was mitochondrial damage to hematopoietic and nonhematopoietic cells.[18] The hematologic dyscrasia resolved rapidly after discontinuing the drug. Aplastic anemia associated with persistent suppression of hematopoietic stem cell activity also has been reported when dogs were administered high doses of cefazedone.[15] Further, cefoperazone, cefamandole, and moxalactam inhibit synthesis of vitamin-K-dependent clotting factors and can lead to hypoprothrombinemia and a resultant coagulopathy.[15]

Anticonvulsant Drugs

Phenobarbital/Primidone Phenobarbital and primidone therapy has been associated with several types of hematologic dyscrasias in dogs. Because primidone is metabolized to phenobarbital, the mechanism of toxicity may be similar for both drugs. The mildest hematologic disorders are neutropenia and thrombocytopenia.[37,78] The presence of granulocyte hyperplasia in bone marrow indicates that the neutropenia is due to destruction of mature granulocytes. A more frequent ADR is myelonecrosis or myelofibrosis (Figure 15.2).[78,83] Dogs with myelonecrosis are frequently bicytopenic or pancytopenic. Bone marrow is characterized by multifocal areas of coagulation-type necrosis with variable degrees of myelofibrosis present.[83] Dogs with myelofibrosis, without concurrent necrosis, frequently have a severe nonregenerative anemia. The myelofibrosis appears to represent the chronic stage of myelonecrosis.

In a retrospective study of 37 dogs treated for 1 month or more with phenobarbital 8 (22%) had hematologic

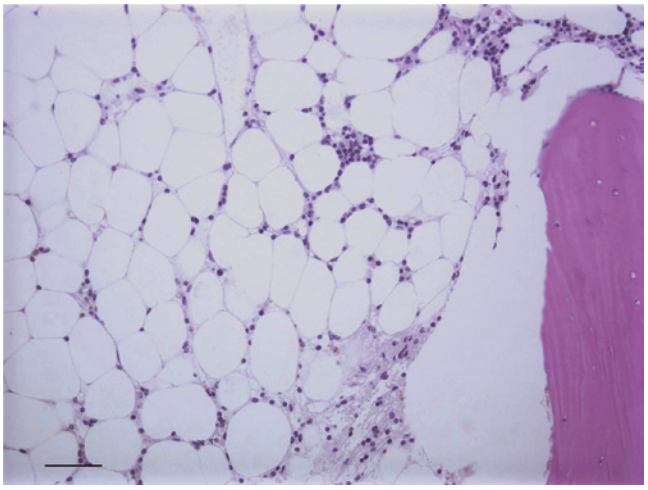

FIGURE 15.1 Bone marrow core biopsy from a dog treated with trimethoprim–sulfadiazine for 15 days. Note the presence of marrow aplasia. Cells present are mostly small lymphocytes. H&E stain; bar, 200 μm.

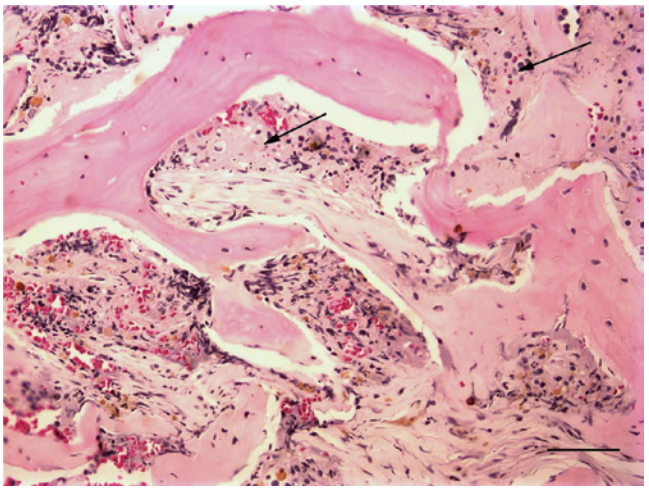

FIGURE 15.2 Bone marrow core biopsy from a dog treated with therapeutic doses of phenobarbital. Note the presence of coagulation-type necrosis (arrows) and myelofibrosis. H&E stain; bar, 200 μm.

changes.[29] Hematologic alterations varied from mild anemia to severe pancytopenia.

Both phenobarbital and primidone induce cytochrome P450 that may in part be responsible for their toxicity.[74] Alternatively, in human patients with anticonvulsant hypersensitivity syndrome, drug-specific T cells appear to elicit a secondary immune response.[74]

Phenytoin Long-term administration of phenytoin to dogs results in RBC macrocytosis, neutropenia, thrombocytopenia, and neutrophil hypersegmentation.[13] These changes were thought to be due to folate deficiency; however, folate deficiency does not appear to cause RBC macrocytosis in dogs.[13] Another dog undergoing long-term phenytoin therapy developed a severe normocytic nonregenerative anemia associated with severe myelofibrosis in bone marrow.[83]

Antiparasitic Drugs

Several antiparasitic drugs have been associated with idiosyncratic drug toxicities. Levamisole-induced thrombocytopenia and direct Coombs positive hemolytic anemia have been reported in several dogs.[3,4] All dogs had hyperplastic bone marrow and recovered after discontinuing levamisole treatment. Albendazole toxicity has been reported in one dog.[71] The dog had pancytopenia and an aplastic bone marrow, but recovered within 1 week after discontinuing treatment. Three dogs treated with metronidazole had coagulation-type myelonecrosis.[78] All dogs had pancytopenia but recovered after discontinuation of treatment. Fenbendazole administration has been associated with bone marrow coagulation-type necrosis.[78] One dog had pancytopenia after repeated weekly administration of the organic arsenical thiacetarsamide for treatment of demodectic mange.[76] The bone marrow was hypercellular and the dog recovered after discontinuation of treatment. However, the dog subsequently developed bone marrow RBC aplasia and died. Pancytopenia was reported in one dog given with amitraz for treatment for demodicosis.[52] The dog had a cellular bone marrow and peripheral blood cell counts recovered despite continued administration of the drug.

Cardiovascular Drugs

Several cardiovascular drugs have been associated with idiosyncratic drug toxicities. Amiodarone is an antiarrhythmic drug that has been associated with hemolytic anemias and hepatopathies in dogs.[14,35] Hematologic alterations were characterized by thrombocytopenia and positive direct Coombs test results with or without the presence of anemia. Affected dogs recover when treatment is discontinued. One dog developed pancytopenia and aplastic bone marrow after 18 months of continuous administration of captopril for treatment of a heart murmur.[35] Withdrawal of the drug and treatment of the dog with human granulocyte colony-stimulating factor and erythropoietin resulted in prompt hematologic recovery. In vitro studies using canine bone marrow cell cultures indicated that the toxic effects of captopril were dependent on a reactive thiol group.[30] This thiol group reacted with copper to generate hydrogen peroxide that was toxic to canine neutrophil progenitor cells. One dog developed neutropenia and anemia after prolonged administration of quinidine gluconate.[82] Three days after discontinuing the drug, the neutrophil count returned to normal and bone marrow cellularity was normal.

Adverse Drug Reactions in Cats

Antineoplastic Drugs

Neutropenia and thrombocytopenia are frequently dose-limiting factors in chemotherapy.[17] As in other species, rapidly proliferating progenitor and proliferative cells in bone marrow are susceptible to destruction by chemotherapeutic agents. Beyond cytopenias, dysplastic hematopoietic cells and atypical mitotic figures (i.e., secondary dysmyelopoiesis) are frequently found in bone marrow. Doxorubicin administration to cats has been associated with poikilocytosis including the presence of ovalocytes, echinocytes, schistocytes, and keratocytes.[51]

Azathioprine

Cats appear to be highly sensitive to azathioprine-induced bone marrow suppression. Of five cats given 2.2 mg/kg of azathioprine on alternate days, four developed multiple cytopenia.[8] Azathioprine-induced bone marrow suppression in humans has been associated with homozygosity for the gene for thiopurine methyltransferase.[8] This enzyme plays an important role in the catabolism of azathioprine.

Propylthiouracil/Methimazole

Severe idiosyncratic drug toxicities, consisting of agranulocytosis and severe thrombocytopenia, have been reported in 8.6% of hyperthyroid cats treated with propylthiouracil and 3.8% of cats treated with methimazole.[56,57] Similar types of reactions have been reported for carbimazole, which is a prodrug of methimazole.[74] In addition, mild hematologic alterations, including eosinophilia, lymphocytosis, and mild leukopenia, were reported in 4% of cats treated with methimazole.[57] Clinical signs develop within 1–2 months after initiation of treatment and include lethargy, weakness, anorexia, and platelet-related bleeding diathesis. Many affected cats had positive fluorescent antinuclear antibody and direct Coombs test results, indicating that the hematologic dyscrasia was immune-mediated.[74] These hematologic abnormalities resolved within 2 weeks after discontinuing methimazole treatment.

Griseofulvin

Griseofulvin is a fungistatic antibiotic used for treatment of mycotic diseases.[34] Neutropenia or panleukopenia

occurs as an idiosyncratic reaction to griseofulvin in cats.[34] In most cases, this occurs several weeks after initiation of griseofulvin treatment.[63] The bone marrow is typically hypoplastic.[63] The majority of cats recover after treatment is discontinued.

Albendazole

Albendazole toxicity has been reported in two cats.[71] Both cats were pancytopenic, but had hypercellular bone marrow. The cats had rapid hematologic recovery within 1 week after discontinuing treatment.

Antiviral Agents

Several antiviral agents have been shown to suppress feline bone marrow. Azidothymidine is a dideoxynucleoside derivative reverse transcriptase inhibitor used for treatment of feline immunodeficiency virus and feline leukemia virus infections. A transient or progressive nonregenerative anemia develops after several weeks of treatment.[33] The anemia is primarily the result of bone marrow erythroid hypoplasia, but Heinz body formation may also be a contributing factor. Acyclovir appears to be highly toxic to cats. Treatment of cats with 60 mg/kg body weight resulted in severe bone marrow suppression in addition to renal and hepatic necrosis.[49]

Adverse Drug Reactions in Horses

Mechanisms associated with ADRs in horses include immune-mediated hemolytic anemias (penicillin and trimethoprim–sulfamethoxazole), non-immune-mediated hemolysis (phenothiazine, L-tryptophan, indole, dimethyl sulfoxide), RBC agglutination (heparin), and bone marrow suppression (phenylbutazone).

Drug-Induced Immune-Mediated Hemolysis

Penicillin administration to horses has been associated with acute allergic reactions and with IMHA.[11,70] These allergic reactions consist of acute anaphylaxis, collapse, shaking, urticaria, fever, leukopenia, eosinophilia, thrombocytopenia, and anemia, and are thought to be an adverse response to procaine.[11] Penicillin and its metabolites bind firmly to RBC membranes and in most horses induce only low titers of IgM antipenicillin antibodies, which do not induce hemolysis.[11] Alternatively, some horses induce higher titers of IgG antipenicillin antibodies that induce hemolysis.[11]

One horse developed IMHA during treatment with trimethoprim–sulfamethoxazole.[73] Prompt recovery after withdrawal of drug treatment incriminated the drug in the causation of the anemia.

Drug-Induced Non-Immune-Mediated Hemolysis

Phenothiazine poisoning has been associated with hemolytic anemia in a horse.[6] Although this was thought to be an oxidant-induced hemolysis, few Heinz bodies were identified.

Oral or intravenous administration of L-tryptophan or indole to ponies results in acute hemolytic anemia and hemoglobinuria.[53,54] Indole is the major metabolite of L-tryptophan that induces hemolysis. Indole has lipophilic properties and interacts with RBC membranes, perhaps explaining its hemolytic properties. However, some ponies treated with indole had Heinz bodies in RBCs suggesting a possible Heinz body anemia.

Rapid intravenous administration of a 40% solution of dimethyl sulfoxide results in intravascular hemolysis in horses.[2] The hemolytic effects of dimethyl sulfoxide appear to be concentration-dependent and administration of a more dilute solution significantly reduced or eliminated the hemolysis.[2] The mechanism of dimethylsulfoxide-induced hemolysis is uncertain, but appears to involve potassium leakage from erythrocytes before hemolysis.

Heparin Unfractionated heparin has been reported to cause marked thrombocytopenia as an idiosyncratic reaction in human patients within 4–14 days after initiation of treatment.[31] Heparin appears to exert a direct effect on platelets causing platelet activation and aggregation, and also induces antiplatelet antibodies. In horses, the most frequent complication associated with heparin administration is anemia that is associated with RBC agglutination.[19,46] Heparin may bind to equine RBC and act as a hapten inducing agglutinating anti-RBC antibodies. Rapid increases in hematocrit occur after discontinuing heparin treatment. Because the increase in hematocrit exceeds the expected capacity of the bone marrow to replace erythrocytes, it is suspected that heparin causes in vivo agglutination of RBCs in the microvasculature.

HEAVY-METAL-INDUCED HEMATOPOIETIC INJURY

Several heavy metals, including lead, mercury, and arsenic, cause hematopoietic toxicity in addition to toxicity in other tissues. Zinc and copper toxicities cause oxidant-induced hemolysis and are discussed in Chapter 32.

Lead

Lead poisoning has been documented in dogs, cats, and cattle, as well as in waterfowl and some exotic species. The source of lead exposure varies by species. In dogs and cats, lead-containing paints; in cattle, discarded batteries and industrial contamination of pastures; and in waterfowl, lead shot are the major sources of exposure.[7,40,47] In dogs and cats, anemia can be associated with chronic lead poisoning. In dogs, basophilic stippling and metarubricytosis have been described as classical features. However, these changes appear to be infrequent findings. Collection of blood in EDTA may cause the stippling to disappear. The pathogenesis of the anemia in dogs involves a shortened RBC life span and

dyserythropoiesis. Lead may shorten RBC survival by inhibiting membrane ATPase. Dyserythropoiesis may result from lead interfering with several enzymes in the heme synthesis pathway and inhibiting pyrimidine 5′-nucleotidase that is involved in depolymerization of reticulocyte ribosomal RNA. Resultant retention of RNA in reticulocytes may be responsible for the basophilic stippling seen in some animals.

Mercury

Mercury has hematotoxic and immunotoxic effects.[69] Fish, waterfowl, and shore birds are at greatest risk of exposure to environmental mercury contaminants.[69] Exposure of egrets or ducks to low-dose methylmercury results in anemia with increased bone marrow cellularity.[69] This suggests a hemolytic anemia. Hemolysis may be due to the capacity of mercury to inhibit several RBC enzymes including glutathione reductase, glutathione-6-phosphate dehydrogenase, and acetylcholinesterase. Mercury also induces idiosyncratic immune-mediated hematologic disorders. Exposure of egrets to high-dose methylmercury results in bone marrow hypoplasia and depletion of lymphocytes in lymph nodes and thymus.[69] Mercury has been shown to be cytotoxic to hematopoietic cells and to cause dysmyelopoiesis in laboratory animals.[16]

Arsenic

Arsenic poisoning causes both hemolytic anemia and dyserythropoiesis, and has genotoxic effects. Arsenic in the form of arsine gas is a potent hemolytic agent; however, the main source of exposure is to humans in industrial settings. In the environment, arsenic exists in inorganic forms and the main source of exposure is through contaminated drinking water.[9] Severe poisoning in humans results in marked anemia, and in some cases neutropenia and thrombocytopenia.[24] Arsenic poisoning causes marked dyserythropoiesis characterized by karyorrhexis, megaloblastosis, and multinuclearity. This is thought to result from a direct toxic effect on DNA synthesis that results in altered nuclear division.[24] Results of several studies conclude that inorganic arsenic has genotoxic effects in a variety of laboratory animal species based on the presence of micronuclei and DNA strand breaks observed in bone marrow.[9]

CHEMICAL-INDUCED HEMATOPOIETIC INJURY

Benzene

Benzene and its metabolites are highly toxic to the hematopoietic system.[59] Benzene is widely used as a solvent in the manufacture of drugs, chemicals, dyes, and explosives. Benzene has both cytotoxic and genotoxic effects on the hematopoietic system. A variety of hematologic dyscrasias have been observed including hemolytic anemia, bone marrow hyperplasia, leukopenia, dysmyelopoiesis, aplastic anemia, myelodysplastic syndromes, leukemia, and lymphoma.[59] Concentrations as low as 100 parts per million (ppm) have been associated with leukopenias in approximately one-third of exposed workers.

Experimental inhalation or injection of benzene produces aplastic anemia in rabbits and mice.[59] The aplasia is preceded by dysmyelopoiesis. Despite the typical aplastic marrow and pancytopenia, stem cell numbers in marrow are normal suggesting that committed progenitor cells rather than stem cells are damaged by benzene. However, benzene-treated lethally irradiated marrow is not reconstituted by transplantation of normal marrow. This suggests that benzene damages the marrow microenvironment.

Chlorinated Hydrocarbons

A variety of chlorinated hydrocarbons are toxic to bone marrow and have the potential to cause clinical disease. These drugs include carbon tetrachloride, hexachlorophene, lindane, chlordane, chlorobenzene, chlorophenothane (DDT), chlorinated dioxins, pentachlorophenol, and trichloroethylene. Some of these compounds, including DDT, lindane (i.e., gamma-benzene hexachloride), and pentachlorophenol, are derivatives of benzene. Chlordane, DDT, lindane, and pentachlorophenol have been implicated as causes of aplastic anemia in humans and trichloroethylene has been implicated as a cause of aplastic anemia in cattle (see Chapter 40).[26,36,55] These compounds have multiple injurious effects on hematopoietic tissue. Chlorinated hydrocarbons appear to be toxic to primitive hematopoietic cells. Exposure of mice to various doses of lindane transiently reduced the number of pluripotent stem cells and progenitor cells.[36] In addition, residual long-term progenitor cell depletion has been demonstrated.[65] Dysmyelopoiesis is also a frequent finding associated with chlorinated hydrocarbon toxicity. Many chlorinated hydrocarbons also have genotoxic effects. The genotoxic potential of 1,1-dichloroethane has been evaluated in Swiss–Webster mice by evaluation of mitotic index, micronuclei, and chromosomal aberrations.[55] A dose-related increase in the number of chromosomal aberrations and micronuclei formation was observed.

Chlorinated dioxins cause anemia and progressive leukopenia in a variety of species including chickens, primates, and rats.[50] Chickens appear to be highly sensitive and develop clinical signs after ingestion of feeds containing fats industrially contaminated with dibenzo-*p*-dioxin. Administration of this material to chickens, primates, and rats resulted in hypoplasia of bone marrow and lymphoid tissue in all three species.[50]

Many fatal cases of aplastic anemia in cattle in Minnesota in the 1950s were traced to feeding of trichloroethylene-extracted soybean oil meal.[58] Although no longer used for this purpose, trichloroethylene is widely used as a solvent. In experimental studies, tetrachloroethylene-treated mice had a reduction in erythroid and granulocytic progenitor cells, but no decrease in pluripotent stem cells after inhalation exposure.[72]

Trichloroethylene also has been shown to inhibit delta-aminolevulinate dehydratase, an enzyme involved in heme synthesis, in rats and has genotoxic effects.[65]

PLANT-TOXIN-INDUCED HEMATOPOIETIC INJURY

Mycotoxins

A variety of mycotoxins produce aplastic anemia in animals. Mycotoxin exposure occurs with ingestion of food contaminated with fungal organisms. For animals, this is frequently the result of ingestion of grain that has been allowed to become damp during storage. Aplastic anemia has been documented in horses and cattle ingesting feed contaminated with *Stachybotrys alternans*. Many mycotoxins, including T-2 mycotoxin, trichothecene mycotoxin, trichothecene vomitoxin, ochratoxin, and zearalenone, produce toxicity in humans.[22] These toxins appear to be directly cytotoxic to a variety of cells including hematopoietic precursor cells and lymphocytes. As a result, many mycotoxins cause bone marrow hypoplasia/aplasia and lymphocyte depletion. Depletion of stem cells and granulocyte-macrophage progenitor cells was detected when mice were exposed to ochratoxin.[12] A marked increase in apoptotic hematopoietic cells was detected in bone marrow after injection of T-2 mycotoxin into mice.[68] The effect of mycotoxins on bone marrow and the immune system appears to be amplified by exposure to lipopolysaccharide. Genotoxic effects of some mycotoxins have also been documented in mouse studies.

Bracken Fern

Bracken fern (*Pteridium aquilinum*) is one of the most widely distributed plants on earth. Animals repeatedly ingesting bracken fern develop aplastic anemia (see Chapter 40). Cattle, horses, sheep, and pigs may be affected. The major toxin in bracken is ptaquiloside.[84] Ptaquiloside is a thiaminase.[84] After repeated exposure and thiamine depletion, cattle tend to develop aplastic anemia. This results in anemia, hemorrhage, and increased susceptibility to infection. Other species develop neurological signs due to polioencephalomalacia.

Chronic enzootic hematuria in cattle has also been linked to development of urinary bladder neoplasia after prolonged ingestion of bracken fern.[48] Metabolites of ptaquiloside are carcinogenic and induce bladder and intestinal carcinomas in cattle and other farm animals, as well as in laboratory animals.[48] Lymphocytic leukemia and pulmonary tumors have also been detected in mice exposed to ptaquiloside.

ACUTE MYELONECROSIS AND MYELITIS IN DOMESTIC ANIMALS

As a rapidly proliferating tissue, bone marrow is sensitive to toxic injury. Components most vulnerable to injury include progenitor and proliferating hematopoietic cells, and the microvasculature. Microvascular injury results in altered vascular permeability and manifests as edema, hemorrhage, inflammation, or ischemia.[23] Myelonecrosis occurs when ischemia is severe, and in the chronic stage, necrotic areas may become fibrotic.[7,15,20] If the initiating agent is eliminated and blood flow is reestablished, myelofibrosis is reversible and regeneration of the hematopoietic tissue is possible.

Hematopoietic cell injury can result in hematopoietic cell death (necrosis or apoptosis) at various stages of maturation and may result in maturation arrest with or without dysplastic changes.[17] Hematopoietic cell injury usually results in reduced hematopoietic marrow cellularity. In the acute stages of hematopoietic injury, myelotoxic changes are frequently observed in the cytoplasm of metamyelocytes and band neutrophils. Common morphologic abnormalities include foamy basophilic cytoplasm (RNA clumping) and/or the presence of Döhle bodies.[20] Some myelotoxic compounds also can induce distinct cytoplasmic vacuolation (Figure 16.1).[20] Toxic changes to the nucleus may consist of hyper and/or bizarre segmentation of neutrophils. Nuclear blebbing may be observed among late-stage erythroid precursors. Other morphologic features of hematopoietic toxicity include cells that stain poorly and/or have indistinct nuclear or cytoplasmic borders. Donut-shaped nuclei are a normal finding in rodents, but would be considered abnormal in domestic animals and primates. Donut-shaped nuclei have been reported in dogs in association with an acute inflammatory response.[16,19] Arrested maturation frequently is characterized by reduced cell counts in the blood, a cellular bone marrow with maturation arrest, and/or dysplastic changes in one or more cell lines. Dysplastic changes can be seen as nuclear or cytoplasmic maturation defects. Nuclear maturation defects result from interference with DNA synthesis and may include megaloblastosis, atypical mitotic figures, fragmented nuclei, nuclear blebbing, and bi/multinucleation. Dysplastic cytoplasmic changes are most frequently seen in erythroid precursor cells where hemoglobin production is inhibited.

Microvascular Injury

The bone marrow microvasculature also is susceptible to toxic injury.[6,18] This is supported by experimental studies in which mouse bone marrow was evaluated after injection of endotoxin and rabbit bone marrow was

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

evaluated after saponin injection.[8,26] Early ultrastructural lesions in bone marrow were characterized by degeneration of sinusoidal endothelial cells. Later lesions consisted of dilated sinusoids, interstitial edema, hemorrhage, and necrosis. Chronic lesions consisted of myelofibrosis.

Similar lesions have been described in humans and a variety of animal species.[1,4,9,14,18,25] Acute vascular injury is accompanied by dilated sinusoids, interstitial edema, and hemorrhage.[4,18] Acute inflammation is characterized by exudation of fibrin that may be accompanied by an infiltration of neutrophils.[4,25] Vascular injury also results in varying degrees of ischemia. When severe, ischemia induces ischemic necrosis.

Myelonecrosis

Myelonecrosis is usually associated with bone marrow ischemia, although it has also been associated with the administration of certain antineoplastic pharmaceutical agents (i.e., presumably direct cytotoxicity).[1,7,20] It is important to distinguish true degenerative changes from those associated with postmortem autolysis; prominent shrinkage and condensation of megakaryocytic nuclei are common features of the latter.[19]

In histopathologic sections, myelonecrosis can appear as multifocal areas of coagulation-type necrosis or as individual necrotic cells (Figure 16.1).[20] Coagulation-type necrosis appears as a central area of karyorrhexis and pyknotic cells enmeshed in an amorphous eosinophilic background material. Macrophages are frequently increased in number. Severe myelonecrosis may be accompanied by osteonecrosis (Figure 16.1). Osteonecrosis is characterized by loss of osteocytes, osteoblasts, and osteoclasts in bone as well as a homogeneous appearance of bone with loss of striations. In some cases, the surface of the bone may become irregular and moth-eaten in appearance (Figure 16.1). For dogs, severe myelonecrosis and osteonecrosis are frequently associated with leg pain and even reluctance to walk.

Coagulation-type necrosis occurs relatively frequently in dogs, but is rarely seen in cats.[21] Alternatively, in one study, individual cell necrosis was observed in 8% of cat clinical bone marrow specimens and is characterized by large numbers of degenerating, frequently anuclear, hematopoietic cells and increased pink amorphous background material (Figure 16.2).[21]

In the acute stage of either coagulation or individual myelonecrosis, necrosis is frequently accompanied by acute inflammation or hemorrhage, whereas in subacute myelonecrosis, necrosis is associated with phagocytic macrophages presumably removing the necrotic cells. In chronic myelonecrosis, reticulin or collagen myelofibrosis is frequently present.

Myelonecrosis is difficult to appreciate in bone marrow aspiration smears. The necrotic marrow smears unevenly, resulting in irregular elongated clumps of necrotic cells. Microscopically, slides often have a diffuse amorphous eosinophilic background and cells stain poorly. Many of the cells are lysed or have a morphologic appearance that makes definitive identification impossible. Differentiating these necrotic features from poor collection techniques is problematic.

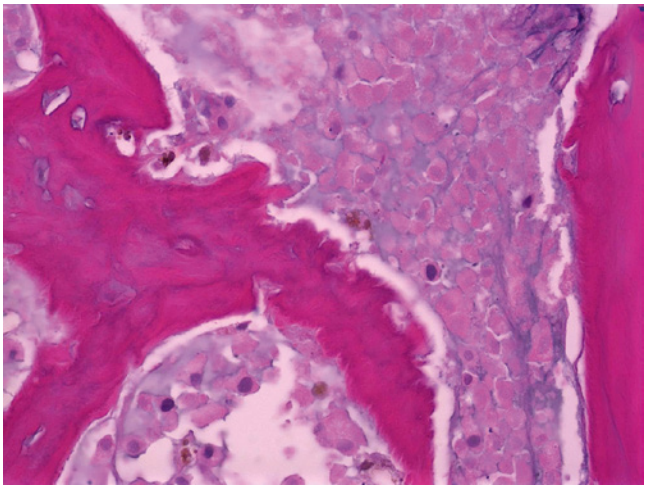

FIGURE 16.1 Diffuse coagulation necrosis with karyorrhexis and some pyknotic cells accompanied by osteonecrosis in a bone marrow biopsy section from a dog. Osteonecrosis is characterized by irregular border to trabeculae and loss of osteocytes, osteoblasts, and osteoclasts. H&E stain.

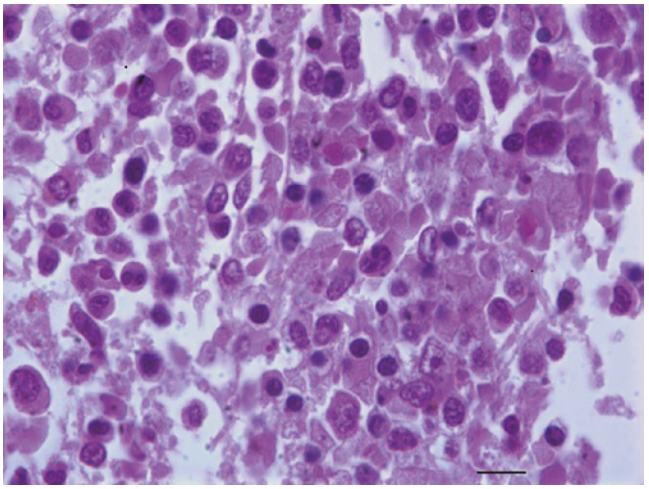

FIGURE 16.2 Individual cell necrosis in a core biopsy section from a cat with nonregenerative immune-mediated hemolytic anemia. Note the presence of many anuclear cells, cells with poorly staining nuclei, and cellular debris. H&E stain. (Douglas J. Weiss.)

Frequent causes of myelonecrosis in cats and dogs include immune-mediated hemolytic anemia (IMHA), sepsis, and leukemia/lymphoma. Less frequent causes identified in dogs include idiopathic causes, systemic lupus erythematosus, disseminated intravascular coagulopathy, and drug treatments.[20,22] Drugs associated with myelonecrosis include estradiol, phenobarbital, carprofen, mitotane, colchicine, metronidazole, fenbendazole, cephalosporins, and chemotherapeutic agents including cyclophosphamide and vincristine (see Chapter 15).

The mechanisms responsible for myelonecrosis have not been extensively investigated. In immune-mediated diseases and disseminated intravascular coagulopathy, thrombotic events may induce marrow ischemia. The necrosis associated with systemic lupus erythematosus in humans has been attributed to the presence of antiphospholipid antibodies. In sepsis, endotoxin or other bacterial toxins may induce sinusoidal injury as well as being toxic to hematopoietic precursor cells. Leukemic cells in bone marrow frequently outgrow their blood supply resulting in myelonecrosis.

Dogs and cats with myelonecrosis have various combinations of nonregenerative anemia, leukopenia, and thrombocytopenia.[20,22] In some instances, the cytopenias may be the result of myelonecrosis, whereas, in other animals, they are the result of a combination of the primary disease process and myelonecrosis. Treatment and prognosis for myelonecrosis should be based on the cause of the necrosis.[20,22] In general, if the primary condition can be successfully treated, the prognosis for recovery is good.[20]

Acute Myelitis

Acute myelitis, like myelonecrosis, is thought to be associated with acute injury to bone marrow sinusoids.[4] These changes are only visible in bone marrow histopathologic sections. In one study, acute myelitis was observed in approximately 3% of canine clinical bone marrow specimens.[23] Altered vascular permeability was the initial lesion identified in bone marrow. Histopathologic alterations include dilated or congested sinusoids, interstitial edema, and hemorrhage. Interstitial edema is seen as amorphous pink proteinaceous material between hematopoietic cells (Figure 16.3).[23,24] Pathologic hemorrhage must be differentiated from artifactual hemorrhage induced by the biopsy procedure. When the sample is obtained by needle biopsy, artifactual hemorrhage is frequently present on either end of the biopsy specimen and may be present on the edges of the specimen. Pathologic hemorrhage should be observed within the hematopoietic space away from the ends or edges of the specimen and should be accompanied by evidence of vascular alterations or interstitial edema. These alterations cannot be reliably evaluated in bone marrow specimens obtained post mortem because dilated sinusoids and altered permeability can occur as agonal changes or perhaps be induced by administration of euthanasia solution.

Acute microvascular injury also can result in exudation that is characterized by multifocal fibrin deposits or multifocal infiltrates of neutrophils (Figure 16.4).[23,24] Fibrin deposits are particularly prominent in cat bone marrow.[22,24] Fibrin appears as pink fibrillar material. The presence of fibrin can be confirmed by selective staining with Fraser–Lendrum stain.[25] Frequently, these fibrin deposits contain variable numbers of segmented neutrophils. In cases of sepsis, discrete microabscesses may be present in bone marrow.[23] These structures may represent septic thrombi.

Causes of acute myelitis in dog bone marrow include nonregenerative IMHA, systemic lupus erythematosus, and bacterial sepsis; in cat, they include IMHA and bacterial sepsis.[22–24]

In horses and cattle, acute myelitis has been associated with bacterial sepsis.[25] Acute myelitis has been identified in septicemic foals. Lesions are characterized by large multifocal infiltrates of neutrophils resembling microabscesses. Neutrophils in the lesions may appear degenerate and the centers of the microabscesses may be necrotic. Other lesions included dilated sinusoids, hemorrhage, and fibrin deposition. Bacteria are usually not seen in bone marrow sections, but can, in some cases, be cultured from bone marrow. Perivascular neutrophilic infiltrates in bone marrow were reported in a steer with chronic pneumonia caused by *Mannheimia haemolytica*.[24] Other cattle with a diagnosis of bacterial pneumonia and septicemia had fibrin deposits in bone marrow.

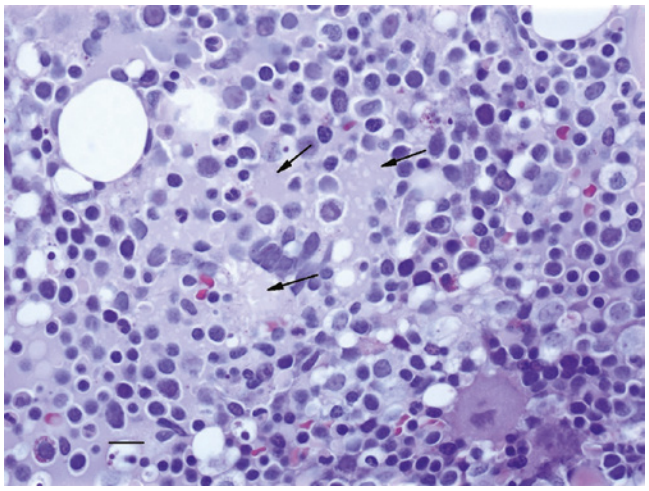

FIGURE 16.3 Interstitial edema in a bone marrow core biopsy section from a dog with immune-mediated hemolytic anemia. H&E stain. (Douglas J. Weiss.)

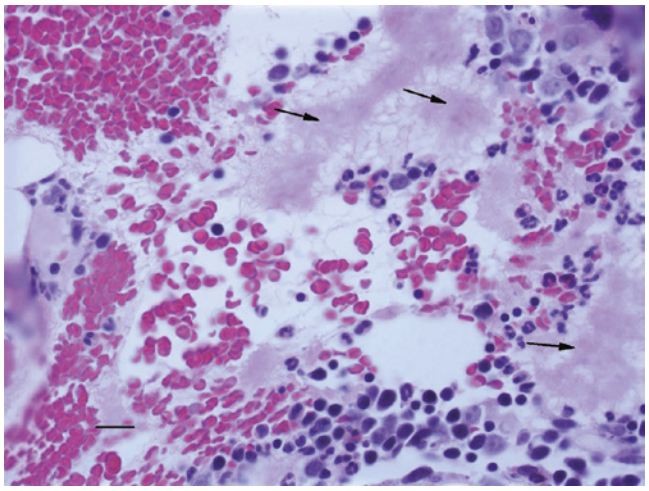

FIGURE 16.4 Fibrinous inflammation in a bone marrow core biopsy section from a dog with immune-mediated hemolytic anemia. Note the presence of fibrin and hemorrhage. H&E stain.

Eosinophilic inflammatory responses are less well-defined. A cow and a sheep with fibrinous inflammation and large numbers of eosinophils in bone marrow have been described.[24] The cow had bacterial enteritis and the sheep had a systemic vasculitis of unknown origin.

ACUTE MYELONECROSIS AND MYELITIS IN LABORATORY ANIMALS

Myelonecrosis

In laboratory animals, degeneration/necrosis of bone marrow tissues may be a direct consequence of test compound administration, but also can be a sequela of an infectious (e.g., bacterial sepsis) or neoplastic disease processes.[5,11,12,19] Similar to domestic animals, these lesions may be focal or multifocal and are characterized by karyorrhexis, karyolysis, cytoplasmic vacuolation, and/or nuclear pyknosis of hematopoietic cells. In early-stage lesions, findings may be limited to hematopoietic cells that poorly take up stain and/or have indistinct cell borders.[2] Varying degrees of associated inflammatory cells, hemorrhage, sinusoidal dilation, and edema may also be seen. Ischemic bone marrow injury resulting in necrosis does occur in laboratory animals and is most often the result of vascular pathology and/or infarction as related to disseminated intravascular coagulation, thrombosis, malignant neoplasia, or sepsis.[2] In almost all cases of bone marrow injury, associated decreases in circulating blood cells affecting one or more cell lines will be present. Peripheral cytopenias often precede or are a more sensitive indicator of marrow hypocellularity as observed histologically.

In rodents, prolonged and severe dietary restriction/anorexia (i.e., <25% of ad libitum food intake for 1–2 weeks) is associated with myelonecrosis involving hematopoietic and stromal bone marrow elements (Figure 16.5).[10,13] This phenomenon is relatively common in toxicology studies; however, it is often difficult to make a distinction between direct compound-related marrow injury and effects secondary to general moribundity/anorexia, hence, lesions solely related to decreased food intake are rarely encountered. In rats, peripheral blood reticulocyte counts are generally the most sensitive indicator of the myelodegenerative effects of severe anorexia/feed restriction (i.e., ≥25% reductions in food consumption), and often become evident before the appearance of histologic alterations.[10,13] Given sufficient time, reduced reticulocyte counts can result in overt decreases in circulating red cell mass; however, shorter fasting periods (48 hours or less) may actually cause an initial increase in red cell mass as a reflection of hemoconcentration.[13] Bone marrow degeneration/necrosis also has been described in cachectic animals, and as sequela of general moribundity in severely debilitated rats.[12]

Bone marrow necrosis, hypocellularity, and/or stromal proliferation have been described in several laboratory animal species in response to a variety of anticancer compounds.[3,11] Bone marrow lesions most often include decreases in hematopoietic cellularity with varying degrees of marrow necrosis, fibrin deposits, stromal or myelostromal proliferation, and/or new woven bone formation. Inflammation was not noted as a significant component of these lesions.

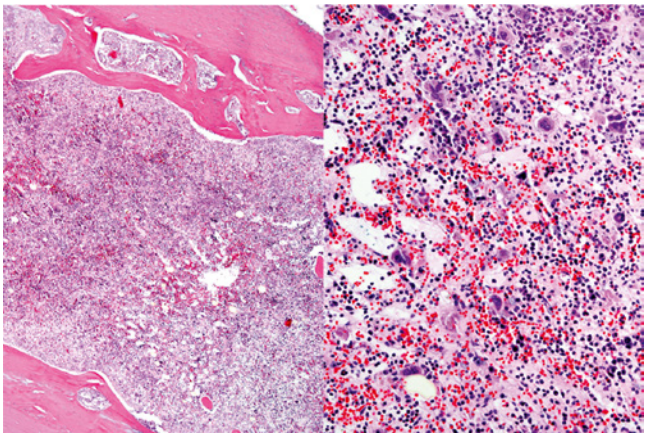

FIGURE 16.5 Myelonecrosis and hemorrhage in a rat. Note the paucity of myeloid and erythroid cells and the presence of karyorrhexis, karyolysis, and nuclear pyknosis of hematopoietic cells. Extravasation of erythrocytes and edema are also present. H&E stain (original magnification: Left 40× Right 200×) (Images courtesy of Michelle Cora, National Toxicology Program).

Acute Myelitis

Although it is widely recognized that bone marrow is exquisitely sensitive to a variety of drugs, test compounds, and toxins, acute myelitis is an uncommon finding in laboratory animals involved in nonclinical toxicology studies. The timing of tissue collections in toxicology studies likely contributes to this, as study designs and necropsy practices are not usually aimed at capturing the early stages of bone marrow effects. Acute inflammation of bone marrow in laboratory animals most often occurs secondary to systemic bacterial sepsis, which may be incidental, or secondary to experimentally induced immunosuppression.[2,12,19] Lesions are characterized by the presence of neutrophils (degenerate and/or nondegenerate), amorphous cell debris, edema, hemorrhage, and fibrin, with fewer numbers of macrophages, plasma cells, and/or small lymphocytes. Hematology findings are typically consistent with an acute inflammatory response as related to sepsis. Acute myelitis is generally not a significant component of the marrow response to myelotoxic effects of anticancer compounds.[3,11]

FeLV, feline leukemia virus; IMHA, immune-mediated hemolytic anemia; PRCA, pure red cell aplasia.

Chronic bone marrow injury can occur as a sequela of myelonecrosis or acute myelitis (see Chapter 16), be associated with chronic conditions, or result from prolonged or recurrent exposure to a toxic agent.[17,22,30] These chronic responses in bone marrow include chronic inflammatory responses (e.g., lymphocytosis, plasmacytosis, histiocytic proliferation, and granulomatous inflammation), secondary myelofibrosis, osteosclerosis, osteomyelitis, and serous atrophy of fat/gelatinous transformation.[2,10,32,42] As with acute bone marrow injury, many of these lesions are difficult or impossible to detect in bone marrow aspirates. Therefore, it is essential to evaluate both bone marrow aspirates and histopathologic sections to detect chronic bone marrow injury.

CHRONIC INFLAMMATION AND MYELOFIBROSIS IN DOMESTIC ANIMALS

Chronic Inflammation

Lymphocytosis

In general, domestic animals and avian species typically have less than 10% lymphocytes in cellular bone marrow specimens.[31] However, reference intervals reported for the percentage of lymphocytes in cat bone marrow vary with most indicating that up to 15% should be considered normal.[16,35] In healthy animals, most lymphocytes in bone marrow are small lymphocytes. Benign

lymphocytosis is the most frequent type of chronic inflammation in cats, but occurs infrequently in dogs.[36,37] In a retrospective study of 203 consecutive feline bone marrow specimens, lymphocytosis (defined as lymphocytes >15% of all nucleated cells) was observed in 15.6% of the specimens.[36] In some cats, lymphocyte numbers exceeded 50% of all nucleated cells in bone marrow.[35] Greater than 80% of cats with lymphocytosis had a diagnosis of nonregenerative immune-mediated hemolytic anemia (IMHA) or pure red cell aplasia (PRCA).[35,36] Differentiating benign lymphocytosis from chronic lymphocytic leukemia can be problematic, but lymphocyte distribution and phenotype may be helpful. Benign lymphocytes are frequently arranged in small multifocal aggregates in bone marrow, whereas, in chronic lymphocytic leukemia, they are diffusely distributed throughout the marrow.[35,43] Immunophenotyping of a few cases has revealed that most lymphocytes in reactive lymphocytosis are B cells, whereas malignant lymphocytes in chronic lymphocytic leukemia were T cells.[35,43]

Unlike cats, only 1% of canine clinical bone marrow specimens had lymphocytosis.[37] These cases were associated with immune-mediated diseases including IMHA and PRCA. Therefore, at least in the Northern USA, bone marrow lymphocytosis in both cats and dogs correlated with immune-mediated hematologic diseases.

Lymphoid Aggregates

In a review of 17 species of mammals, lymphoid aggregates were identified only in humans and cats.[11] Lymphoid aggregates are small clusters of mature small lymphocytes with no evidence of organized structure (Figure 17.1). However, results of large retrospective studies indicate that lymphoid aggregates occur in both cat and dog bone marrow core biopsy specimens.[37,38] When present, lymphoid aggregates correlate with the presence of immune-mediated hematologic diseases or other chronic systemic immunologic stimulation.[35,41]

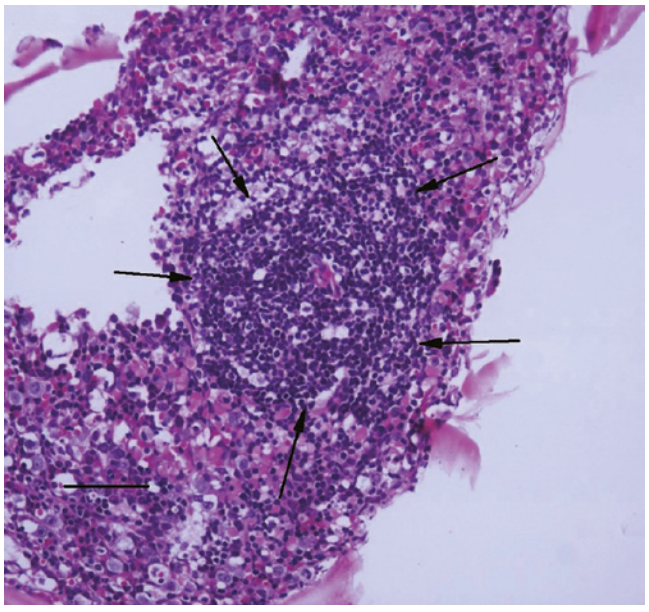

FIGURE 17.1 Lymphoid aggregate (arrows) in a bone marrow core biopsy section from a cat with nonregenerative immune-mediated hemolytic anemia. H&E stain; bar, 200 µm.

Plasmacytosis

Plasmacytosis is usually evaluated subjectively in bone marrow aspirates or core biopsy specimens because of their low numbers and uneven distribution. Plasmacytosis has been observed in approximately 10% of canine clinical bone marrow specimens and 6% of cat bone marrow specimens.[37,38] Plasmacytosis in cats has been associated with IMHA, PRCA, immune-mediated thrombocytopenia, and feline infectious peritonitis. Plasmacytosis is a consistent finding in bone marrow of dogs with immune-mediated diseases including IMHA, PRCA, and immune-mediated thrombocytopenia. Other causes of bone marrow plasmacytosis that should be considered include *Ehrlichia* spp. and *Leishmania* spp. infections.

Macrophage Proliferation

The presence of increased numbers of macrophages in bone marrow is associated with a variety of disorders. Macrophages can range from relatively immature cells with minimal phagocytosis to mature cells that have a foamy cytoplasm or contain phagocytic vacuoles. These phagocytic vacuoles may contain cells, cytoplasmic debris, hemosiderin, or organisms. Four general types of mononuclear phagocyte proliferations can be observed in bone marrow. Differentiating these types can be problematic and may require the use of flow cytometry or immunophenotyping.[34] The four types include reactive macrophage proliferation, reactive hemophagocytic syndrome[39] (see Chapter 49), lipid storage diseases (see Chapter 49), and malignant proliferations of monocytes (acute monocytic or myelomonocytic leukemia, chronic myelomonocytic leukemia; see Chapters 66 and 68) and dendritic cells (malignant histiocytosis, see Chapter 74). Reactive macrophage proliferations are macrophages responding to a need to remove necrotic debris or infectious agents. Increased necrotic debris is present in the subacute stages of myelonecrosis and in conditions of ineffective hematopoiesis.[36] Ineffective hematopoiesis is present in myelodysplastic syndromes, immune-mediated hematologic diseases, and in some leukemias.

A variety of infectious agents cause reactive macrophage proliferations in bone marrow. These vary with the species and geographic distribution of infectious organisms. In dogs, leishmaniasis, parvovirus infection, and deep fungal infections have been associated with macrophage proliferations (see Chapter 18).[4] In leishmaniasis and deep fungal infections, macrophages appear to be part of an inflammatory response in that organisms are found in the marrow in these conditions. Additionally, the presence of increased numbers of neutrophils is consistent with a diagnosis of a pyogranulomatous inflammation.

In parvovirus infection, macrophages may be reacting to the need to remove necrotic cells.

Granulomatous inflammation typically consists of a mixed infiltrate of macrophages, giant cells, small lymphocytes, and plasma cells, and may form distinct granulomas. Granulomas are distinct compact aggregates of inflammatory cells (Figure 17.2). These may contain epithelioid macrophages that have a large amount of pale cytoplasm and elongated nuclei with a dispersed chromatin pattern. Epithelioid cells may fuse to form giant cells. Other cells associated with the granuloma may include lymphocytes, plasma cells, and neutrophils. Discrete granulomas are infrequently seen in bone marrow of domestic animals.[36,37] Granulomatous inflammation has been associated with disseminated histoplasmosis in dogs and cats and *Mycobacterium avium* subsp. *avium* infection in dogs (see Chapter 18). A horse with an idiopathic systemic granulomatous disease was reported.[42] Lipid granulomas were observed in a cow with serous atrophy of fat.[42] Lipid granulomas consist of aggregates of lipid-laden macrophages. Other cells that may be present in lipid granulomas include lymphocytes, plasma cells, epithelioid cells, and giant cells. In humans, bone marrow granulomas have been associated with a variety of drug hypersensitivities. These drugs include phenytoin, procainamide, phenylbutazone, chlorpropamide, sulfasalazine, ibuprofen, indometacin, allopurinol, and carbamazepine.[2]

Myelofibrosis

Myelofibrosis is a bone marrow disorder characterized by proliferation of fibroblasts or collagen or reticulin fibers in the hematopoietic space (Figure 17.3).[1,2] Secondary myelofibrosis must be differentiated from primary idiopathic myelofibrosis. Primary idiopathic myelofibrosis is a relatively rare chronic myeloproliferative disease characterized by trilineage extramedullary hematopoiesis throughout the body and myelofibrosis.[13,14,21] In human primary idiopathic myelofibrosis, the myelofibrosis appears to occur secondary to the myeloproliferative disease and may be induced by secretion of platelet-derived growth factor, transforming growth factor-beta, and/or platelet factor-4 by megakaryocytes.

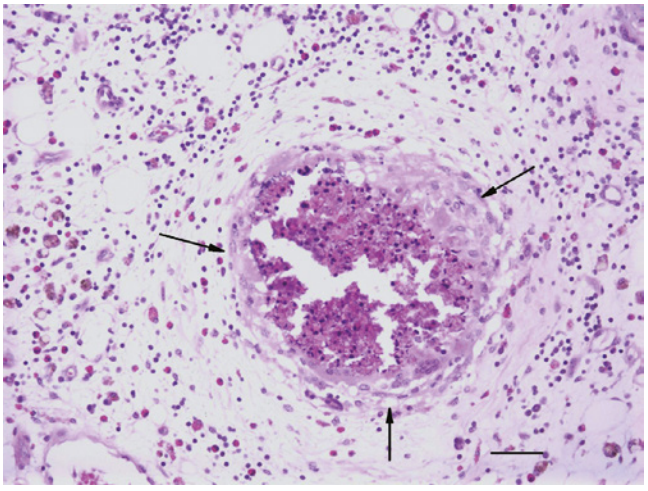

FIGURE 17.2 Granuloma in a bone marrow core biopsy section from a dog with a disseminated fungal infection. H&E stain; bar, 200 µm.

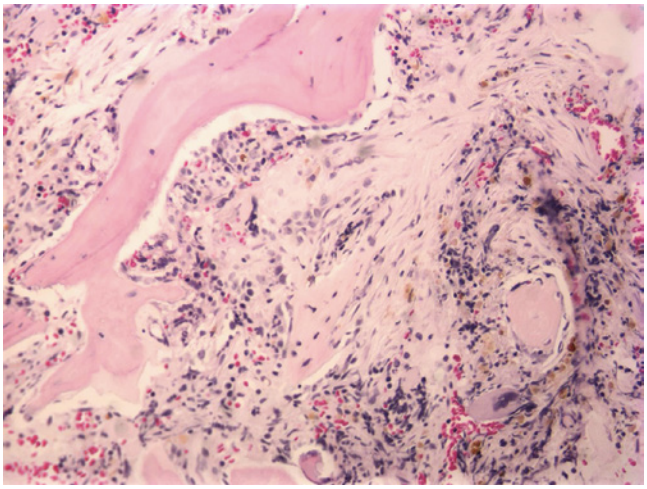

FIGURE 17.3 Secondary myelofibrosis in a bone marrow core biopsy section from a dog. H&E stain.

The etiopathogenesis of secondary myelofibrosis is uncertain. The coexistence of myelofibrosis and myelonecrosis in many dog and cat bone marrow specimens strongly suggests that fibrosis may be equivalent to scar tissue in other damaged tissues. Several fibrogenic cytokines have been identified. These include transforming growth factor-β, platelet-derived growth factor, platelet factor-4, and epidermal growth factor. In bone marrow, fibrogenic cytokines are produced by megakaryocytes and macrophages. Constant high levels of thrombopoietin in mice induce megakaryocyte hyperplasia and myelofibrosis.[7,44] Myelofibrosis has been induced in rodents by injection of a variety of cytokines, including thrombopoietin, erythropoietin, and megakaryocyte growth factor.[44,45] Increased megakaryocytes or dysmegakaryopoiesis has been seen infrequently in dogs with secondary myelofibrosis. Hemosiderosis has also been incriminated as a cause of secondary myelofibrosis.

Secondary myelofibrosis occurs relatively frequently and is associated with moderate to severe nonregenerative anemia and less frequently with thrombocytopenia or leukopenia.[33] If the causative agent is removed or effectively treated, the fibrosis is typically reversible with the tissue reverting to normal hematopoietic tissue.[28,33] Collagen and fibroblastic myelofibrosis has been observed in 4.2% of canine clinical bone marrow specimens and in 9% of feline clinical bone marrow specimens evaluated at a veterinary teaching hospital.[36,37] The distribution of fibrosis in marrow sections varies. Fibrosis can be multifocal or diffuse and randomly distributed or paratrabecular. Reticulin fibers are most frequently diffusely distributed in the marrow, but in some early lesions can be focally distributed around blood vessels.

In dogs, secondary myelofibrosis has been associated with IMHA, acute leukemias/lymphomas, idiopathic myelonecrosis, congenital pyruvate kinase deficiency, congenital nonspherocytic anemia, nonhemic malignant tumors, whole body irradiation, and certain drug treatments (see Chapters 15 and 16).[18,26,33,38,42] Most affected dogs have a moderate to severe nonregenerative anemia, some are thrombocytopenic, but leukopenia is a rare finding. Ovalocytes are infrequently seen in the peripheral blood. In one study of 19 dogs with secondary myelofibrosis, half of the dogs recovered from their anemia with supportive therapy. Treatments with immunosuppressive doses of prednisone or with erythropoietin may be useful.

A periparturient myelofibrosis, associated with severe nonregenerative anemia, has been reported in young female beagle dogs.[20] Myelonecrosis was identified in one of three dogs reported; therefore, the fibrosis may have occurred secondary to acute bone marrow injury.

Secondary myelofibrosis is a frequent finding in cat bone marrow specimens.[3,38] Both collagen and reticulin fibrosis are frequent causes of failure to obtain a sample when aspirating cat bone marrow. Major causes of secondary myelofibrosis in cats include myelodysplastic syndromes, acute myeloid leukemia, IMHA, feline infectious peritonitis, and chronic renal failure.[3,33]

Myelofibrosis has been reported as an inherited disorder in pygmy goats.[5] At birth, these goats have a nonregenerative anemia, neutropenia, and thrombocytopenia. All animals die at 6–12 weeks of age. Severe myelofibrosis was identified at necropsy. Other necropsy findings included extramedullary hematopoiesis and megakaryocytic hyperplasia and dysplasia.

Osteosclerosis

Osteosclerosis (also termed myelosclerosis) is a condition of excessive and unorganized production of trabecular bone. Alternatively, osteopetrosis is a congenital condition of dogs and humans characterized by severe nonregenerative anemia or pancytopenia and generalized increased bone density.[15] Osteosclerosis appears as irregular fingers or spurs of bone extending from the trabeculae into the hematopoietic space (Figure 17.4). These sites usually contain increased numbers of osteoblasts and osteoclasts.[18] When severe, the associated marked thickening of bone can be visualized radiographically.[9,12,18] Osteosclerosis is almost always associated with concurrent severe myelofibrosis. Severe osteosclerosis can obliterate or markedly reduce the size of the hematopoietic space. Osteosclerosis along with severe myelofibrosis occurs terminally in dogs with pyruvate kinase deficiency and has been associated with feline leukemia virus (FeLV) infection.[9,12,22]

Serous Atrophy of Fat/Gelatinous Transformation

The paratrabecular space within normal marrow is occupied almost totally by hematopoietic cells or adipocytes. In processing paraffin-embedded tissues, the lipid is dissolved out and the space within adipocytes appears clear and homogeneous. Serous atrophy of fat/gelatinous transformation is a condition in which there is loss of fat cells as well as depletion of hematopoietic cells from bone marrow and replacement by increased amounts of ground substance (Figure 17.5).[25] This is usually associated with starvation. Remaining adipocytes, depleted of fat, tend to take on a pink to blue hue. Acid mucopolysaccharides in the background may stain pink or blue with H&E stain and stain with Alcian blue and periodic acid shift stains.[25] This material may appear granular or fibrillar.

Serous atrophy of fat/gelatinous transformation has been documented in sheep, goats, primates, rodents, and cats. In sheep and goats, it has been associated with neglect or loss of teeth. In cats, it has been associated with prolonged anorexia due to chronic disease.[40,41] Affected cats had pancytopenia in the blood and marked hypoplasia of bone marrow. Associated conditions included chronic renal failure and oral and gastric ulcers.

CHRONIC INFLAMMATION AND MYELOFIBROSIS IN LABORATORY ANIMALS

Chronic Inflammation

Increased numbers of macrophages can be seen in the bone marrow of laboratory animals in response to test compound-related cytotoxicity, or as a background incidental finding.[8] Granulomatous inflammation has been reported in rodents as a background finding, but also as a direct compound-related effect. Lesions usually consist of focal or multifocal aggregates of epithelioid macrophages that are sometimes vacuolated, with or without the presence of multinucleated giant cells and phagocytized cell debris (Figure 17.6). As lesions become more chronic, hemosiderin-laden macrophages or cholesterol clefts may be seen.

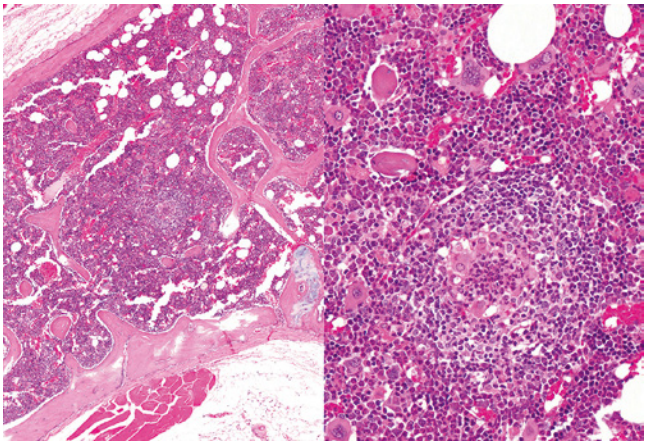

FIGURE 17.6 Granulomatous inflammation in a mouse. Note the presence of degenerate neutrophils and cellular debris surrounded by epithelioid macrophages. H&E stain (left 8× right 40×). (**Source:** Images courtesy of Michelle Cora, National Toxicology Program.)

Myelofibrosis

Fibrosis of the bone marrow has been reported in various forms in laboratory animals. Myelofibrosis can be seen as a background finding in aging rats, but also a consequence of compound administration, whole body irradiation, and certain viral infections.[19,27,29] As opposed to the human condition, primary idiopathic myelofibrosis as a specific condition has not been documented in rodents. Lesions may be focal or multifocal and are characterized by an increase in fibroblasts, stromal cells, and eosinophilic reticulin/collagen fibers (Figure 17.7).[8] In aged mice, myelofibrosis was observed in 43% of female mice, but in <1% of male mice.[24] In another study of aged NMRI mice, >90% of females and ovariectomized females had evidence of myelofibrosis as well as some castrated males.[23] This study indicates that estrogen may not be a major factor in development of myelofibrosis in mice.

In toxicology studies, fibrosis is occasionally seen in association with bone marrow cytotoxicity, but is frequently associated with test compounds that stimulate megakaryocyte or platelet production.[19] Examples include thrombopoietic agents (e.g., romiplostim) and polyethylene glycolylated peptide MPL (myeloproliferative leukemia virus oncogene) agonists. Similar to other species, cytokine products of megakaryocytes, platelets,

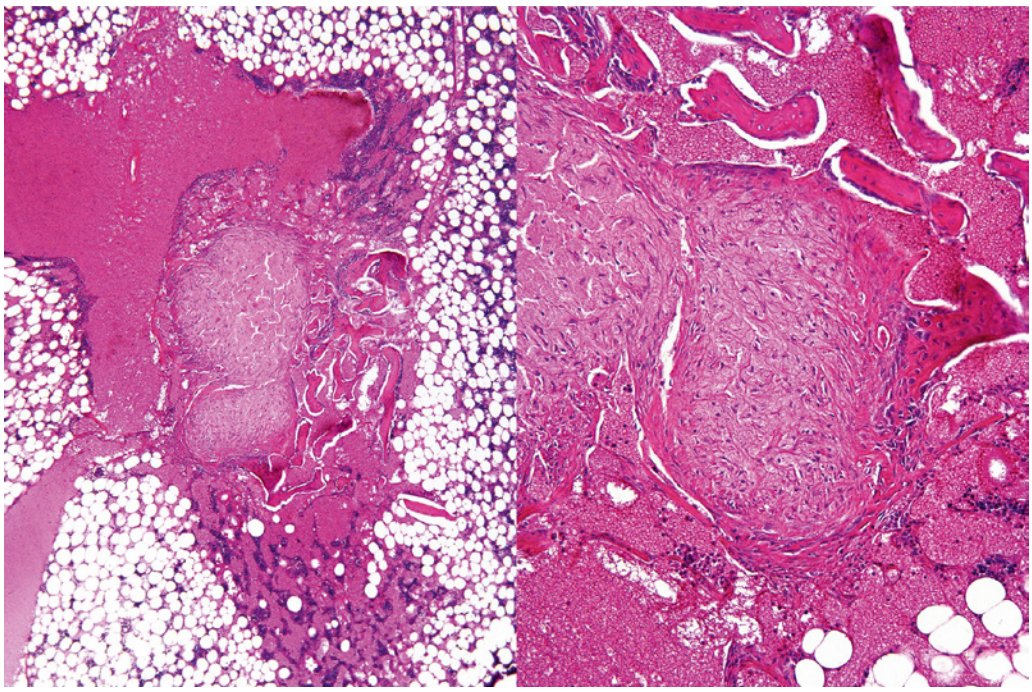

FIGURE 17.7 Fibrosis and hemorrhage in the bone marrow of a rat. Note the presence of increased trabecular bone around and adjacent to the area of fibrosis. H&E stain (original objective magnification: left 6× right 16×). (**Source:** Images courtesy of Michelle Cora, National Toxicology Program.)

and monocytes (e.g., transforming growth factor-β and platelet-derived growth factor) have been implicated as contributing to the development of myelofibrosis in rodents.[14] A myelofibrosis-like condition was described in genetically modified mice that have a deletion in megakaryocytic regulatory genes (GATA-1).[6]

Myelostromal Proliferation

Myelostromal proliferation has been described as a rare condition of bone marrow in the rat.[29] Lesions are characterized by a relatively nondescript uniform population of stromal cells or histiocytes with finely vacuolated cytoplasm that sometimes contains iron-positive inclusions. Extracellular stroma that is trichrome-negative often surrounds individual cells; however, overt atypia is not usually seen. Notably, the appearance of these lesions has been compared to that of histiocytic sarcoma.[29]

Acronyms and Abbreviations

BLV, bovine leukemia virus; BMSC, bone marrow stromal cell; BVDV, bovine viral diarrhea virus; CFU-GM, colony-forming units-granulocyte–monocyte; CPV, canine parvovirus; CSFV, classical swine fever virus; EIAV, equine infectious anemia virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; FPV, feline panleukopenia virus; PCR, polymerase chain reaction.

BONE MARROW PATHOLOGY

The response of the bone marrow to infectious agents is variable, depending on the organism involved, the nature and chronicity of infection, and the presence of other diseases. Responses are generally nonspecific, and can occur with other, noninfectious disease. Visualization of the organism on marrow cytology or histology can occur in some infections, facilitating the diagnosis. The marrow response to common companion or domestic animal infectious diseases known for their marrow involvement is described in the following text.

RICKETTSIAL INFECTION

Bacteria within the families *Rickettsiaceae* and *Anaplasmataceae* of the order *Rickettsiales* cause a variety of diseases in dogs, cats, horses, and cattle; however, marrow changes are best documented for infections caused by *Ehrlichia canis*. *Ehrlichia canis* is the etiologic agent of canine monocytic ehrlichiosis, and is transmitted most commonly by the vector *Rhipicephalus sanguineus*. The disease has acute, chronic, and subclinical syndromes. Bone marrow in the acute phase of the disease is typically hypercellular. An increase in the bone marrow myeloid to erythroid ratio was described three to four weeks post infection in experimental canine ehrlichiosis.[22,31] Megakaryocytes were increased one week after infection, reflecting the hematopoietic response to the persistent thrombocytopenia seen with this disease (see Chapter 80). Morulae can be present in bone marrow but are difficult to find, with one to four morulae per 1000 oil immersion fields seen in one study of acute ehrlichiosis.[15] Chronic ehrlichiosis produces a pancytopenia, secondary to severe bone marrow hypocellularity (see Chapters 33 and 40).[3] Marrow aspirates are poorly cellular, with cells consisting of low numbers of stromal cells, fibroblasts, and macrophages. Hematopoietic precursors are few or absent. Core biopsies show a severely hypocellular marrow filled with adipose tissue.[3] Mastocytosis also has been reported in the chronic phase of ehrlichiosis.[17] Bone marrow plasmacytosis has been reported with ehrlichiosis, and is independent of the phase.[16,33] Myelofibrosis does not appear to play a significant role in the development of the myelosuppression seen with chronic ehrlichiosis.[14]

Anaplasma platys is another rickettsial pathogen that can affect the bone marrow. Although previously thought to only affect circulating platelets, thus producing a thrombocytopenia, the organisms have also been

documented to infect megakaryocytes and promegakaryocytes within bone marrow.[25]

PROTOZOAL INFECTION—LEISHMANIA

Leishmaniasis is a disease caused by protozoal organisms of the genus *Leishmania*, and is transmitted in Mediterranean regions by the bite of an infected female sand fly. Several forms of the disease, including cutaneous, mucocutaneous, and visceral forms, have been identified in dogs. A mild anemia and thrombocytopenia are the most frequent hematologic findings. Microscopic examination of fine-needle aspirates of lymph nodes or bone marrow and serology and PCR are frequently used diagnostic methods (Figure 18.1). In one study, *Leishmania* spp. amastigotes were observed in the marrow of 92.6% of clinically affected dogs.[26] Another study in dogs naturally infected with *Leishmania infantum* showed that the most common pathological features of the bone marrow were megakaryocytic dysplasia, erythrophagocytosis, erythroid dysplasia, and emperipolesis.[5] Severe histiocytosis and a moderate to marked plasmacytosis of the marrow have also been reported.[18,19]

VIRAL INFECTION

Parvovirus

Feline panleukopenia virus (FPV) and canine parvovirus (CPV) are both parvoviruses that cause bone marrow injury and leukopenia, neutropenia, and lymphopenia. These viruses have a broad tropism for mitotically active cells. It is unknown whether the reduction in marrow cells is due primarily to virus replicating in and killing cells, or due to more indirect effects. FPV can kill both erythroid and myeloid colony progenitor cells in bone marrow cultures, although at low viral doses there is greater suppression of the formation of myeloid colony-forming units-granulocyte–monocyte (CFU-GM).[10] Viral replication of FPV in myeloid cells may lead to the neutropenia seen after FPV infection. In a study of 76 cats with clinical FPV, 84% showed complete bone marrow depopulation and dilation of the vascular sinuses, 5% had no significant marrow change, and 6% had marrow hypercellularity with granulocytic hyperplasia.[4]

In 75 dogs with clinical CPV, 92% had marrow depopulation, one dog showed no changes, and five dogs had marrow hypoplasia.[4] In another study using experimentally infected puppies, leukopenia and neutropenia only occurred in dogs with severe enteric disease. Viral replication in the bone marrow was sparse.[12] In both FPV and CPV, the severe neutropenia observed is probably the result of both neutrophil loss or consumption in the infected gut and bone marrow suppression.[20]

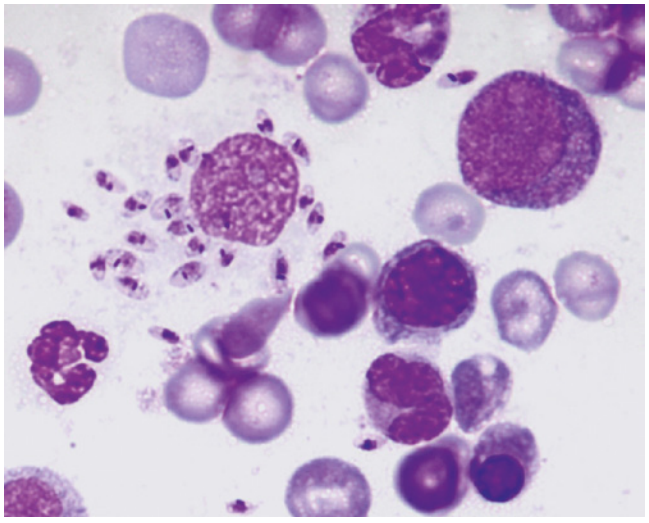

FIGURE 18.1 *Leishmania* organisms in bone marrow from a dog; Wright–Giemsa stain. (**Source:** Courtesy of Dr. Rick Cowell)

Retrovirus

Feline leukemia virus (FeLV, subfamily *Oncornavirinae*) and feline immunodeficiency virus (FIV, subfamily *Lentivirinae*) are retroviruses that are major infectious pathogens in domestic cats (see Chapters 53 and 60). FeLV infects hematopoietic cells, lymphoid cells, and accessory cells in the hematopoietic microenvironment. Marrow nucleated cells become infected with the virus two to six weeks after exposure, and virus can be detected in circulating leukocytes at that time.[8] After regression, one third to one half of cats transiently harbor latent virus in marrow myelomonocytic cells and stromal fibroblasts.[11] The types of marrow change seen in FeLV are highly variable. Early viremia can be accompanied by pancytopenia and marrow hypocellularity.[21] Marrow necrosis, with nuclear swelling and karyolysis, has rarely been described.[28] FeLV-C-induced pure red cell aplasia shows almost a total lack of marrow erythroid precursor cells, with normal myeloid and megakaryocytic precursors (see Chapters 38 and 60).[27] FeLV-induced myelodysplastic syndromes can show marrow hypercellularity, megaloblastic maturation abnormalities, reticulin fibrosis, and increased numbers of immature cells and blast cells (see Chapter 67).[2,13] Marrow myelophthisic disease, where the marrow is filled with blast cells, can be observed in FeLV-induced leukemias or lymphoma. Active viral replication is thought to be required for the majority of pathogenic mechanisms in which FeLV causes marrow suppression; however, regressive FeLV infection without viremia may also be responsible.[9,29]

FIV produces progressive CD4 T-cell depletion. Marrow morphologic abnormalities, marrow suppression, and peripheral blood cytopenias can be seen. Cytopenias (neutropenia, anemia) have been attributable to direct infection of the bone marrow stromal cell (BMSC) population.[24] BMSC types include fibroblastic/adventitial/reticular cells, macrophages, endothelial cells, adipocytes, and myofibroblasts, of which macrophages are productively infected with FIV.[1]

Bovine leukemia virus (BLV) is an oncogenic retrovirus, which produces lymphoma in adult cattle. Bone marrow involvement is not a prominent feature.

Equine Infectious Anemia Virus

The equine infectious anemia virus (EIAV) is a lentivirus of the family *Retroviridae* (see Chapters 34 and 37). Infection of horses with EIAV produces a persistent viremia and recurrent episodes of anemia, thrombocytopenia, and fever. In one study using experimentally infected foals with severe combined immunodeficiency, bone marrow changes were described after the onset of thrombocytopenia.[32] The postthrombocytopenia samples had a moderate to marked decrease in bone marrow cellularity, with an increase in intercellular homogeneous eosinophilic material. Individual cell necrosis or apoptosis was not observed. A moderate increase in adipocytes and reticulin fibers was noted. Denuded megakaryocyte nuclei were also observed. In another study, the total megakaryocyte area and megakaryocyte nuclear area were increased. Numbers of megakaryocytes were slightly increased.[23]

Bovine Viral Diarrhea Virus and Classical Swine Fever Virus

Bovine viral diarrhea virus (BVDV) and classical swine fever virus (CSFV) are related viruses (family *Flaviviridae*, genus Pestivirus), both known to infect and damage megakaryocytes of the marrow and produce a subsequent thrombocytopenia, but other marrow lesions are not present. In a study using calves infected with type II BVDV, histologic evaluation of the bone marrow showed an increased number of megakaryocytes. Approximately one half of the megakaryocytes were immature or had undergone nuclear loss or pyknosis.[30] Infection of calves with type II BVDV also reduced the number of CFU-GM cultured from bone marrow. This suggests that suppression of granulopoiesis may contribute to the prolonged neutropenia associated with BVDV infection. Experimental infection of pigs with a virulent strain of CSFV also produced changes in megakaryocytes, with abnormal nuclei and micromegakaryocytes seen.[7] Myeloid and erythroid cell depletion and lymphocyte apoptosis have also been described in experimentally infected pigs.[8]

FUNGAL INFECTION

Blastomycosis, histoplasmosis, coccidioidomycosis, and cryptococcosis are common systemic fungal diseases of the dog and cat. Although all of these diseases can involve the bone marrow, marrow involvement is most frequently described in histoplasmosis.

Histoplasma capsulatum is a soil-borne, dimorphic fungus that infects dogs and cats through inhalation of conidia from the mycelial phase, which subsequently converts to yeast in the body. The disseminated form of the disease predominantly affects the liver, spleen, gastrointestinal tract, bone, bone marrow, integument, and eyes. Primary gastrointestinal and pulmonary histoplasmosis can also occur.

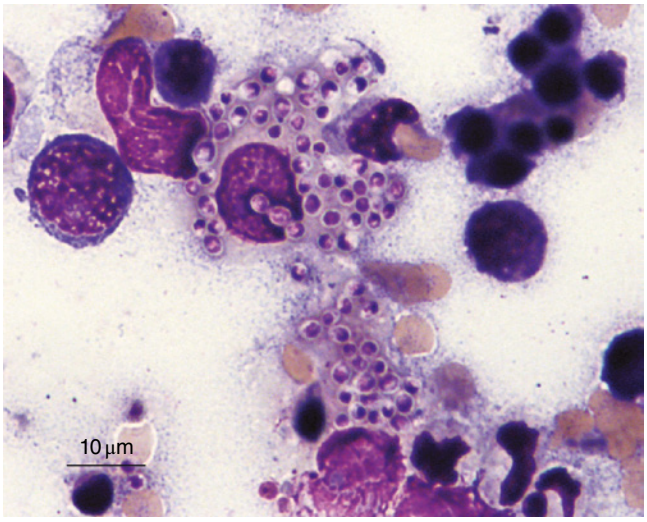

FIGURE 18.2 Histoplasma organisms in bone marrow from a cat; Wright–Giemsa stain. (**Source:** Courtesy of Dr. James Meinkoth, Oklahoma State University)

In the bone marrow, large numbers of organisms can be found within macrophages (Figure 18.2). Anemia is a frequent finding, but pancytopenia accompanied by granulomatous inflammation of the bone marrow has also been reported.[6]

BFU-E, burst-forming unit-erythroid; CD, cluster of differentiation; CFU-E, colony-forming unit-erythroid; CMP, common myeloid progenitor; DNA, deoxyribonucleic acid; E2A, Transcription Factor 3; EKLF, erythroid Krüppel-like transcription factor; EMP, erythrocyte macrophage protein; EPO, erythropoietin; EPOR, erythropoietin receptor; FasL, Fas ligand; FOG-1, friend of GATA; GATA1 and GATA2, GATA-binding protein 1 and 2; GM-CSF, granulocyte/macrophage colony-stimulating factor; HIF-1, hypoxia-inducing factor-1; HSC, hematopoietic stem cell; ICAM-4, intercellular adhesion molecule-4; IGF-I, insulin-like growth factor-I; IL, interleukin; IFN-γ, interferon gamma; JAK2, Janus kinase 2; kDa, kilodalton; LDB1, LIM Domain Binding 1; LMO2, LIM Domain Only 2; LRF, Leukemia/Lymphoma Related Factor; mRNA, messenger ribonucleic acid; MEP, megakaryocyte/erythroid progenitor; RBC, red blood cell; RNA, ribonucleic acid; RT-PCR, reverse transcriptase polymerase chain reaction; TNF, tumor necrosis factor; SCF, stem cell factor; SCL, stem cell leukemia; SOCS, suppressor of cytokine signaling; STAT, signal transducers and activators of transcription; TNF, tumor necrosis factor; TPO, thrombopoietin; TRAIL, TNF-related apoptosis-inducing ligand; VCAM, vascular cell adhesion molecule; VLA-4, very late antigen-4.

Erythropoiesis is the proliferation and progressive differentiation of hematopoietic stem cells (HSCs) (see Chapters 2 and 4) into hemoglobinized RBCs. In normal animals, erythropoiesis and RBC mass are regulated by cellular oxygen levels. RBCs originate from HSCs by first committing to the erythroid lineage to form erythroid progenitor cells, which morphologically resemble lymphocytes, then differentiating into precursors cells that can be identified morphologically, and finally undergoing a series of division and differentiation steps until the nucleus is extruded (in mammals) to form reticulocytes. Each of these stages is initiated and regulated by specific humoral, microenvironmental, cell surface and transcription factors. This chapter describes erythropoiesis using information gained primarily from studies in mice, rats, and humans. Species-specific information is provided when available.

DEFINITIONS

Basal erythropoiesis is erythropoiesis that occurs to replace naturally senescent RBCs and therefore maintain normal RBC mass. Stress erythropoiesis refers to erythropoiesis that occurs in response to an anemic stimulus, such as blood loss, hemolysis, or pregnancy.

STEM CELL TO ERYTHROCYTE

General

The commitment of multipotent HSCs into cells committed to specific blood cell lineages is depicted in Figure 19.1. Differentiation from the common myeloid progenitor (CMP) to megakaryocytic/erythroid progenitor (MEP) is associated with expression of various gene-specific transcription factors, growth factor receptors, functional proteins, and cell surface receptors, and is influenced by a variety of growth factors.[2] Gene-specific transcription factors are predominantly activators of transcription and usually function as a complex of proteins that binds to specific DNA sequences. MEPs differentiate into burst-forming unit-erythroids (BFU-Es), which are programed to differentiate only into erythroid cells, but resemble lymphocytes microscopically. These cells are identified by their growth from a single cell to several thousand cells in culture. The colony-forming unit-erythroid (CFU-E) differentiates from BFU-E. In culture, each CFU-E divides into 8–32 cells. These progenitor cells differentiate into microscopically recognizable precursor cells. Figure 19.2 depicts the various stages of erythroid precursor differentiation. The earliest precursor is a rubriblast (Figure 19.2), followed by the prorubricyte, basophilic rubricyte, polychromatophilic rubricyte, and metarubricyte. The erythroid precursor differentiation process is a series of differentiation steps that results in a progressive decrease in cell size, a gradual increase in cytoplasmic hemoglobin concentration, and gradual condensation of nuclear chromatin. In general, this results in a gradual decrease in cytoplasmic basophilia along with decreasing size of the nucleus. The metarubricyte nuclei are then extruded to produce polychromatophilic RBCs, which present as reticulocytes with vital stains such as new methylene blue. All of the precursors except

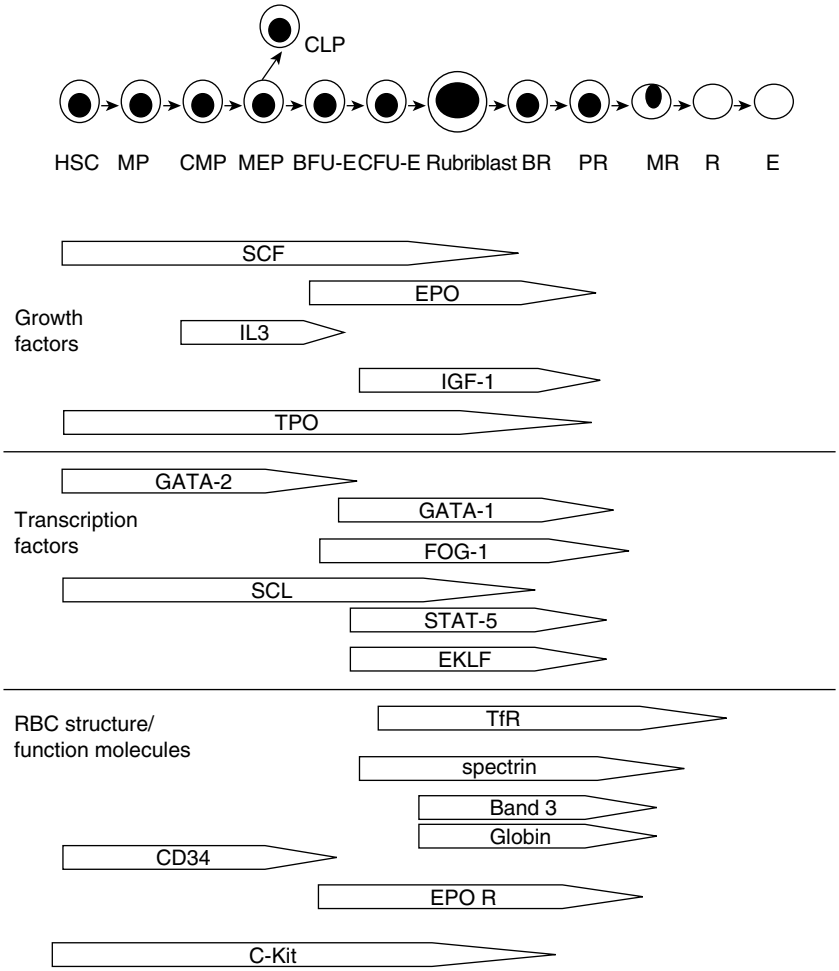

FIGURE 19.1 Approximate timing of the response to certain growth factors, activation of transcription factors, and expression of erythroid-specific molecules in erythropoiesis. Abbreviations: BFU-E, burst-forming unit-erythroid; BR, prorubricyte/basophilic rubricyte; CFU-E, colony-forming unit-erythroid; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; EKLF, erythroid Krüppel-like factor; EPO, erythropoietin; EPOR, erythropoietin receptor; FOG-1, friend of GATA1; HSC, hematopoietic stem cell; IGF-1, insulin-like growth factor-1; IL-3, interleukin-3; MEP, megakaryocytic/erythroid progenitor; MP, multipotential progenitor; MR, metarubricyte; PR, polychromatophilic rubricyte; R, reticulocyte; Rub, rubriblast; SCF, stem cell factor; SCL, stem cell leukemia gene; STAT, signal transducer and activator of transcription; TfR, transferrin receptor; TPO, thrombopoietin.

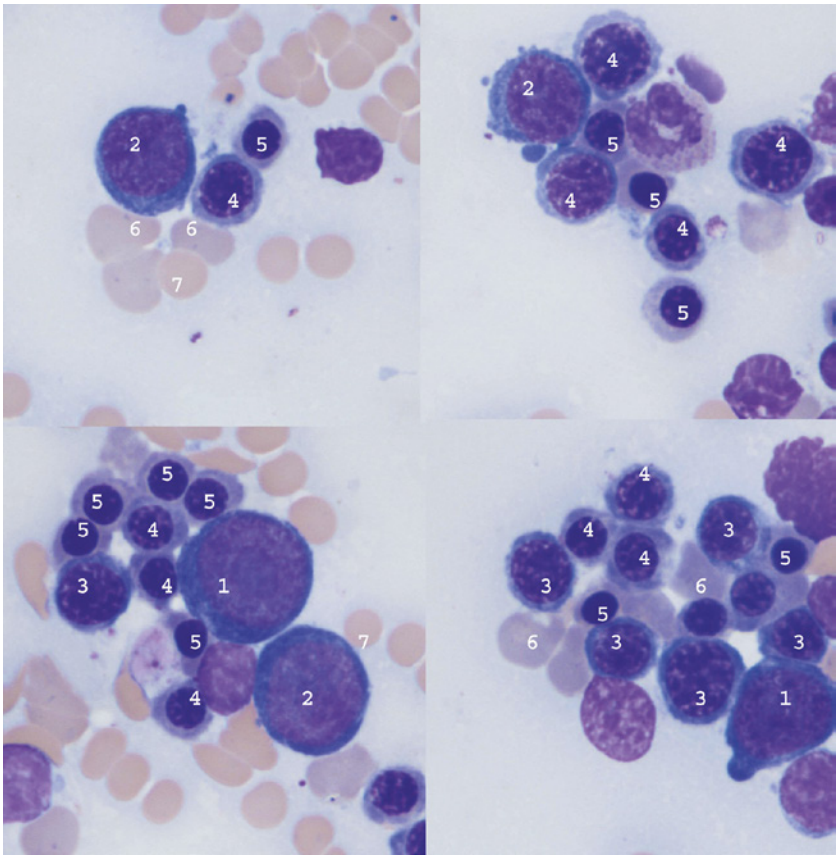

FIGURE 19.2 The various stages of erythroid precursors are shown. (1) Rubriblast; (2) prorubricyte; (3) basophilic rubricyte; (4) polychromatophilic rubricyte; (5) metarubricyte; (6) reticulocyte; (7) RBC.

metarubricytes are capable of division. In theory, 16 metarubricytes will be produced from each rubriblast; however, the actual percentages of each precursor type in a marrow evaluation may be slightly different from this ratio.

This is likely because each stage matures for a variable number of days, and thus a sample of marrow at a snapshot in time will not reflect the true "pyramid."

The nomenclature for erythroid precursors in humans and mice differs from that used in veterinary medicine. The earliest erythroid precursor is called a proerythroblast and subsequent cells are called basophilic erythroblasts, polychromatophilic erythroblasts, and orthochromatic erythroblasts (Table 19.1).

TABLE 19.1 Nomenclature of erythroid precursors.

Veterinary terminology	Human/mouse/research terminology
Rubriblast	Proerythroblast
Prorubricyte	Basophilic erythroblast
Basophilic rubricyte	Basophilic erythroblast
Polychromatophilic rubricyte	Polychromatophilic erythroblast
Metarubricyte	Orthochromatic erythroblast
Reticulocyte	Reticulocyte
Erythrocyte	Erythrocyte

Development and Maturation of Reticulocytes

Nuclear expulsion from metarubricytes is associated with changes in intermediate filaments and microtubules that result in rearrangement of the membrane cytoskeleton.[21] Extruded metarubricyte nuclei express phosphatidylserine and are rapidly ingested by bone marrow macrophages. Reticulocytes then exit the bone marrow, although the exact mechanism is unknown. Reticulocytes contain residual mitochondria, Golgi membranes, ribosomes, and microtubular components, and can have approximately 35% more volume than mature RBCs.[36] During maturation in the circulation, reticulocytes gain hemoglobin and lose organelles, membrane surface area, volume, and numerous cell-surface proteins. Cell-surface proteins are lost in the form of exosomes, or membrane blebs, that contain proteins specifically selected for removal (see Chapter 22).[19]

Stress reticulocytes are released from the bone marrow during times of erythropoietic stress.[25] Stress reticulocytes are larger and less mature than normal reticulocytes, and contain more mitochondria, ribosomes, and other organelles. Their membranes are more mechanically rigid and unstable, and they possess adhesive proteins that are normally lost before release.

Reticulocytes in Veterinary Species

The number of reticulocytes circulating during health varies among species (see Chapter 23).[17] Some species have circulating reticulocytes in health (dogs, cats, rodents, rabbits, pigs, guinea pigs), whereas others (cows, goats, sheep) have circulating reticulocytes only during a regenerative response. Horses, with rare exceptions,[40] do not have circulating reticulocytes even during a regenerative response.[6,30]

MOLECULAR CONTROL OF ERYTHROPOIESIS

Proliferation and differentiation of erythroid cells include cell divisions accompanied by a serial reduction of proliferative ability and increased erythroid-specific gene expression. The general sequence of molecular events for erythroid proliferation and differentiation is: (1) growth factor binding to its receptor; (2) activation of membrane-associated kinases; (3) phosphorylation of the cytoplasmic portion of the receptor and of other intermediate molecules; (4) activation of transcription factors; and (5) transcription-factor-dependent synthesis of either additional transcription factors or erythroid-specific functional proteins, depending upon the stage of erythropoiesis. Examples of erythroid-specific functional proteins include RBC-specific spectrins, globins, ankyrin, band 4.1, and glycophorins (cell-surface molecules).[21]

Cytokines and Growth Factors Regulating Erythropoiesis

Erythropoietin (EPO) is the principal hormonal regulator of erythropoiesis. EPO is a 34.4 kilodalton (kDa) glycoprotein (165 amino acids) that is produced primarily by peritubular interstitial fibroblasts of the kidney in adult animals. A small amount of EPO is produced in the liver during anemia.[20] Low tissue oxygen tension induces *EPO* gene expression through transcriptional activation and also induces *EPO* messenger ribonucleic acid (mRNA) stabilization.[5,7,41] Hypoxia upregulates EPO by allowing accumulation of hypoxia-inducible factors-1 and -2 (HIF-1 and HIF-2). These transcription factors bind a responsive element in the EPO gene. In severe hypoxia, production of EPO is increased up to 1000-fold.[7] EPO is highly conserved among species, and recombinant human EPO can support proliferation and differentiation of erythroid progenitors from a variety of species including horses and cats.

The EPO receptor (EPOR) is an integral membrane protein with seven tyrosine phosphorylation sites in its cytoplasmic domain. Each of these domains appears to regulate different aspects of erythropoiesis. Some phosphorylation sites may be dispensable for steady-state erythropoiesis, but required for stress erythropoiesis.[22] Signaling through the EPOR is mediated by prebound Janus kinase 2 (JAK2), a phosphokinase. JAK2 phosphorylates several tyrosine residues in the cytoplasmic domain of the EPOR, which results in recruitment of a number of cytoplasmic signaling proteins. Several pathways critical to survival and differentiation of erythroid progenitors and precursors are then activated. The signal transducers and activators of transcription (STAT)5 pathway, which results in upregulation of the Bcl-x_L anti-apoptotic protein, is an important example of one of these pathways. The EPOR is expressed on early cluster of differentiation of 34-positive (CD34+) hematopoietic progenitors, increases in number to its highest in CFU-E and rubriblasts, and then decreases gradually during precursor differentiation (Figure 19.1). Neither EPO nor EPOR is required for generation of BFU-E or CFU-E, but both are required for proliferation and development of later stages of erythroid precursors and for production of mature RBCs.[42]

Interleukin-3 (IL-3) is a multilineage cytokine produced by macrophages, activated T lymphocytes, mast cells, eosinophils, and bone marrow stromal cells. IL-3 acts on HSCs and progenitor cells to induce proliferation and self-renewal. It also primes progenitor cells to respond more vigorously to EPO.[1]

Stem cell factor (SCF), also known as steel factor, mast cell growth factor, and c-kit ligand, is expressed by bone marrow stromal cells and acts through its receptor, c-kit (CD117).[4] Its mRNA is also expressed in BFU-E, suggesting a potential autocrine or paracrine function. SCF markedly enhances the activity of EPO, allowing for proliferation and differentiation of progenitors and precursors.

Granulocyte–macrophage colony-stimulating factor (GM-CSF), produced by T cells, stimulates production of primarily neutrophils, monocytes, and eosinophils. GM-CSF may enhance erythroid progenitor development, although GM-CSF knockout mice are hematologically normal.

Thrombopoietin (TPO) is a 45–70 kDa (depending on glycosylation) glycoprotein produced in the liver, kidney, skeletal muscle, and bone marrow stroma. It appears to be required for maintenance of HSCs in G_0 and therefore their self-renewal capacity.[28] TPO also acts as a costimulatory agent with EPO to promote BFU-E growth in vitro and to support proliferation and maintenance of erythroid progenitor cells in vivo.[3]

Insulin-like growth factor-1 (IGF-1) and insulin both enhance the growth and differentiation of erythroid cells. IGF-1 decreases apoptosis of progenitors and enhances heme synthesis and nuclear condensation and enucleation.[24]

Glucocorticoids enhance erythroid colony formation in vitro and in vivo by stimulating erythroid progenitor proliferation and inhibiting differentiation.[39] Glucocorticoids act through a nuclear glucocorticoid receptor that subsequently directly affects transcription by binding to glucocorticoid response elements in DNA.

Humoral inhibitors of erythropoiesis include tumor necrosis factor (TNF), TNF-related apoptosis-inducing ligand (TRAIL), IL-1, and interferon gamma (IFN-γ).[31] TNF and IL-1 not only inhibit erythroid progenitors, but also suppress EPO secretion. Immature erythroid cells are susceptible to cell death due to TNF and IFN-γ upregulation of "death" receptors.[9]

Transcription Factors

Several transcription factors are activated during RBC development as a result of binding of hematopoietic cytokines to cell-surface receptors. The activated transcription factor then translocates to the nucleus to enhance transcription of specific genes. The DNA that is transcribed is either an erythroid-specific structural or functional gene (e.g., spectrin and globin) or a gene encoding a protein that is involved in initiation of the next step in differentiation (e.g., another transcription factor).

Pleiotropic Transcription Factors

The stem cell leukemia (*SCL*) gene is a pleiotropic (not erythroid-specific) transcription factor that is crucial for hematopoiesis; *SCL* null mice die in utero at day 8 without any blood cell formation.[33] *SCL* also enhances erythroid proliferation and differentiation while repressing myeloid differentiation.

GATA-binding protein 2 (GATA2) is expressed in early HSCs. It appears to be necessary for proliferation and survival of stem cells, but dispensable for terminal erythroid differentiation. Erythroid progenitor cells of GATA2 null mice stop differentiating at the rubriblast stage.[37]

Erythroid-Specific Transcription Factors

STAT5 is required for erythropoiesis and is enhanced by EPO and SCF. STAT molecules are mobile cytoplasmic transcription factors that are activated by the JAK family of protein tyrosine kinases. STAT molecules are latent, but become activated and translocate to the nucleus upon tyrosine phosphorylation. STAT5 binds to specific DNA sequences to upregulate genes involved in tissue-specific functions and regulation of cell growth.[34] STAT5 knockout mice are severely anemic in utero and their fetal liver cells show increased apoptosis. Some adult STAT5 knockout mice have normal hematocrits, but have ineffective hematopoiesis during erythropoietic stress.[34] These mice generate increased numbers of proerythroblasts during erythropoietic stress, but have increased apoptosis in the more mature stages.

GATA-binding protein 1 (GATA1) is essential for both primitive and definitive erythropoiesis, and plays a key role in the differentiation of rubriblasts to mature RBCs.[42] GATA1 is responsible for expression of many erythroid-specific or erythroid-predominant genes, including cytoskeletal proteins, the transferrin receptor, EPOR, and the friend of GATA1 transcription factor (FOG-1). GATA1 also maintains expression of Bcl-x_L and EPOR, which promote late erythroid precursor survival and differentiation, while repressing GATA2, a molecule that induces proliferation of earlier stages.

Erythroid Krüppel-like transcription factor (EKLF) is essential for primitive and definitive erythropoiesis and for adult β-hemoglobin production. Its disruption in mice results in accumulation of fetal γ-globin and inability to produce adult β-globin.[27] EKLF appears also to regulate expression of other erythroid-specific genes including dematin, cytoskeletal proteins, transcription factors, and heme synthesis proteins.[15]

LMO2 (LIM domain only 2), LDB1 (LIM domain binding 1), E2A (transcription factor 3), and LRF (leukemia/lymphoma related factor) are all transcription factors that have been defined as important for erythropoiesis using murine knockout models, and, in general, act as multiprotein complexes to stimulate the production of RNAs essential for erythropoiesis.[14]

Other Molecules and miRNAs

Bcl-x_L is an anti-apoptotic protein that is associated with the mitochondrial membrane. Bcl-x_L prevents apoptosis of hemoglobinizing rubricytes.[29] Mice that have a conditional knockout of the Bcl-x_L gene have severe anemia and splenomegaly. The bone marrow and spleens of these mice accumulate early rubricytes, but are deficient in maturing cells. Bcl-x_L expression is EPO-dependent via STAT5, and is increased during terminal differentiation stages when hemoglobin synthesis is greatest.[12]

JAK2 is associated with the EPOR and is responsible for downstream signaling. EPO binding to the EPOR changes conformation of the receptor and thereby activates JAK2, which causes tyrosine phosphorylation of the cytoplasmic domain, and subsequent recruitment of signaling proteins including STAT5. JAK2 knockout mice die during embryogenesis with severe anemia. The most important function of JAK2 appears to be activation of STAT5.[11]

FOG-1 is a nuclear protein that binds to GATA1 and acts as its cofactor in transcription.[18] FOG-1 mediates both transcriptional activation as well as repression (e.g., of GATA2)and FOG-1 knockout mice die of anemia in utero.[38] GATA2 repression is dependent on FOG-1, and thus FOG-1 may facilitate GATA switching, leading to erythroid differentiation.

miRNAs are small RNAs that regulate the expression of their specific genes. Typically, they downregulate mRNA by either degradation or translational inhibition (or sometimes both), and therefore decrease the expression of their target gene. miRNAs regulate several aspects of erythropoiesis including erythroid lineage determination, erythroid progenitor proliferation, terminal erythroid differentiation, and enucleation. miR-24, -150, -221, -222, and -223 appear to inhibit erythroid differentiation and proliferation. For example, miR-223 downregulates LMO2, which is a critical transcription factor that is upregulated during erythroid differentiation of CD34+ progenitor cells. By contrast, miR-144 and -451 are induced during erythroid differentiation, and appear important for late erythroid cell maturation.[14]

Negative Regulators of Erythropoiesis

Fas and Fas ligand (FasL) are members of the TNF receptor and TNF superfamilies, respectively, and are expressed as integral membrane proteins. When FasL from one cell interacts with Fas from another cell, clustering of Fas initiates an intracellular caspase cascade

and apoptosis. These molecules are coexpressed on a small percentage of immature erythroid cells in murine bone marrow and are responsible for erythroid precursor apoptosis during basal erythropoiesis.[22] Both of these molecules are downregulated in response to EPO, allowing erythroid precursor survival and differentiation.

Suppressor of cytokine signaling (SOCS) competes for the binding site of STAT5 on the cytoplasmic tail of the EPOR. STAT5 can then no longer bind or be activated to produce its downstream effects. SOCS also participates in the degradation of JAK2. SOCS is induced by a number of cytokines, including EPO.[32]

MICROENVIRONMENT

Erythroblastic islands are one component of the microenvironment (see Chapters 3 and 4) that is essential for erythropoiesis. Erythroblastic islands comprise a central macrophage surrounded by 10–30 erythroid cells from CFU-Es to reticulocytes.[23] The macrophage projects cytoplasmic processes to which erythroid cells adhere via erythroblast macrophage protein (EMP), very late antigen-4 (VLA-4), and intercellular adhesion molecule-4 (ICAM-4). These proteins bind to the macrophage receptor proteins EMP, vascular cell adhesion molecule-1 (VCAM-1), and integrins αv and α4, respectively. Interestingly, the transcription factor EKLF upregulates ICAM-4 on erythroid precursor cells.[16] The macrophage cell surface molecule CD163 also may be important in binding to erythroid cells and in promoting erythropoiesis.[8]

The central macrophage has a unique phenotype, including a high level of expression of F4/80 and the Forssman glycosphingolipid (a 7-transmembrane spanning receptor, best described in the mouse), marked adhesiveness, a pronounced ability to endocytose, and inability to generate a respiratory burst. Although erythroblastic islands are critical for erythroblast proliferation and differentiation, macrophage function related to erythropoiesis is incompletely understood. Central macrophages may produce positive and negative regulators of erythropoiesis, supply iron for hemoglobin production, and play a role in nuclear extrusion and phagocytosis of the extruded nucleus.

Molecules Involved in Adhesion

ICAM-4 is a transmembrane protein belonging to the immunoglobulin superfamily of adhesion receptors, and is predominantly expressed on erythroid cells.[35] ICAM-4 mediates binding of rubricytes to rubricytes and rubricytes to macrophages, and is upregulated by the transcription factor EKLF. It is expressed during terminal differentiation of erythroid cells, beginning with the rubriblast. EMP is a 36 kDa transmembrane protein expressed on the surface of erythroid cells and macrophages, and is involved with interactions between erythroid cells and between erythroid cells and macrophages.[23] Absence of EMP severely limits the number of erythroblastic islands and results in marked apoptosis of erythroid cells. VLA-4, also known as $\alpha 4\beta_1$ integrin, is expressed on immature erythroid cells and binds to VCAM-1 on macrophages. Integrin αV is expressed on macrophages and binds to ICAM-4 on immature erythroid cells. Fibronectin is an extracellular matrix glycoprotein that binds to all stages of immature erythroid cells via the VLA-4 and VLA-5 integrins.[26]

ERYTHROKINETICS

Massive amplification from HSC to mature RBCs is required to create 4×10^{11} mature RBCs from 2×10^4 stem cells.[4] Erythrokinetics encompasses the rates of proliferation and maturation from HSC to mature RBCs. Long-term and short-term repopulating cells have been identified in transplantation experiments in mice, and probably represent hematopoietic cells that are less mature than BFU-Es. These cells take months to differentiate into later stages of erythroid cells.[13] BFU-Es take about 10–14 days to develop into rubriblasts in culture, whereas CFU-E maturation takes about 3–5 days. In health, there are approximately 50 rubricytes and 113 reticulocytes for every rubriblast in the bone marrow.[10] Approximately five mitotic divisions occur over 5 days before a rubriblast loses its nucleus and becomes a reticulocyte. In most species, reticulocytes spend 2–3 days maturing in bone marrow before being released to the circulation.

Acronyms and Abbreviations

ADP, adenosine diphosphate; dCytb, duodenal cytochrome B; DMT-1, divalent metal iron transporter-1; Hgb, hemoglobin; ID, iron deficiency; IRP, iron regulatory protein; kD, kilodalton; MPS, mononuclear phagocyte system; NADH, nicotinamide adenine dinucleotide (reduced form); NADPH, nicotinamide adenine dinucleotide phosphate (reduced form); PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; RBC, red blood cell; SM, sphingomyelin; SMAD, small mothers against decapentaplegic; TfR, transferrin receptor.

The main function of RBCs is to carry oxygen to tissues. All energy in RBCs that is devoted to maintaining cell shape, membrane structure, enzymatic functions, reduced iron in hemoglobin, and other functions does so to optimize oxygen delivery to tissues. Recently, mammalian erythrocytes have also been shown to participate in the innate immune response by binding inflammatory molecules and producing antimicrobial reactive oxygen species.[2] It is well known that the erythrocytes of birds, amphibians, and fishes can produce cytokine-like factors, upregulate viral response genes, and sequester pathogens through surface binding or phagocytosis.[2] Erythrocytes also play numerous roles in hemostasis in both procoagulant and anticoagulant ways.[59] For example, erythrocytes release ADP and thromboxane A_2, both of which increase platelet adhesion and aggregation (procoagulant). Another procoagulant mechanism is the exposure of phosphatidylserine (PS) on the outer membrane leaflet. Alternatively, RBCs make the fibrin network more porous, which is anticoagulant.

ERYTHROCYTE STRUCTURE

Overall Structure

Mammalian RBCs have no nuclei and no organelles, and thereby no ability to synthesize proteins. The full complement of functional proteins must be present by the time the reticulocyte matures. Human RBCs are composed (by mass) of 61% water, 32% protein (mostly hemoglobin), 7% carbohydrates, and 0.4% lipids. Isolated RBC membranes are composed of approximately 20% water, 40% protein, 35% lipid, and 6% carbohydrate.[43]

Membrane Structure

Membrane Lipids

The RBC membrane phospholipid bilayer is composed of phosphatidylcholine (PC), phosphatidylethanolamine (PE), sphingomyelin (SM), and PS, as well as other less abundant phospholipids.[56] This composition varies with species. For instance, sheep, cows, and goats have little to no PC, whereas horses, dog, and rats have abundant PC.[51] Sheep have approximately twice the SM content as other species.[19] The bilayer is vertically asymmetrical, with PS and PE located almost exclusively on an inner PL layer. The asymmetry is maintained and/or altered by the activities of enzymes termed flippases[14] and floppases, Type-IV P-type ATPases, and ABC transporters.[34,50] Other lipids in the bilayer include glycolipids and cholesterol, and these are embedded in the phospholipids.

Lipid Rafts

Lipids rafts are specialized membrane microdomains that are rich in cholesterol and sphingolipids and also contain specific membrane proteins. They are isolated as detergent-resistant membranes because of their insolubility in nonionic detergents.[30] Examples of proteins localized in these microdomains include glycophosphatidylinositol-anchored proteins, flotillins, and stomatin.[39,45]

Erythrocyte Deformability

The erythrocyte membrane must be flexible and resilient in order to repeatedly pass through small capillaries for oxygen delivery to the tissues, all the while maintaining a life span of at least 6 weeks (depending on the species). The deformability and resistance to fragmentation are dependent on the biconcave shape, the viscoelastic properties dependent on the spectrin cytoskeleton, and the red cell viscosity, which is dependent on hemoglobin content. The first two properties are related to the structure of the membrane cytoskeleton. The exact structure of the RBC membrane and its associated structural and integral membrane proteins is still being elucidated. A general explanation of what is currently known is given in the following text.

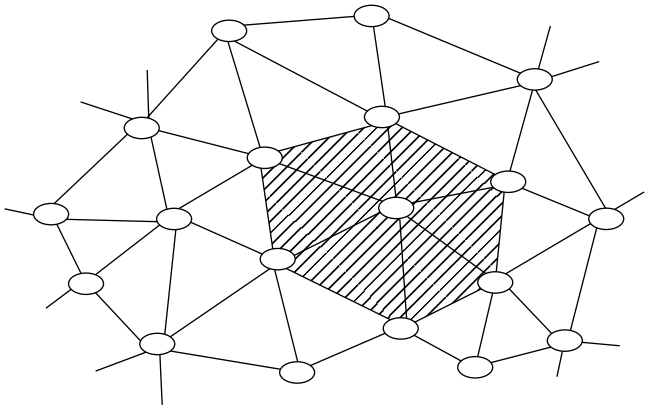

FIGURE 20.1 Lattice structure provided by spectrin tetrameters in the cytoskeleton of erythrocytes.

Cytoskeletal Proteins

Cytoskeletal proteins are located on the cytoplasmic side of the plasma membrane and function to help maintain cell shape, membrane deformability, membrane stability, and the lateral mobility of some integral membrane proteins.[60] They are considered "peripheral proteins" because they are not embedded within the membrane but rather are anchored to the cytoplasmic side of the bilayer.

Alpha and beta spectrin subunits are the largest and most abundant proteins in the cytoskeleton. They are elongated and self-associate to form $\alpha_2\beta_2$ tetramers, which then associate end to end into a pseudohexagonal network of molecules that lies just underneath the plasma membrane. The spectrin lattice is anchored to other proteins and to the bilayer at select areas of the hexagon. The most current model of the erythrocyte membrane shows that spectrin molecules are secured to the lipid bilayer at "nodes" called junctional complexes (Figure 20.1). One of these complexes, the ankyrin complex, is made up of ankryin, band 3, band 4.2, CD47, and glycophorin A. The spectrin molecule is directly associated with the ankyrin molecule. The other complex, the junctional complex, is made up of glut 1, band 3, stomatin, glycophorin C, band 4.1, p55, adducins, and is associated with the membrane via actin, tropomyosin, and tropomodulin. Bands 4.1 and 4.2 proteins are named for their migration during one-dimensional electrophoresis.[3]

Integral Membrane Proteins

Band 3 or the anion exchange protein is an integral membrane protein composed of dimers, tetramers, and other large oligomers. It is responsible for anchoring the cytoskeleton to the membrane, anion exchange, and binding of glycolytic enzymes, hemoglobin, and hemichromes. The anion exchange function is primarily for delivering CO_2 to the lungs in exchange for Cl^-.

Glycophorins are heavily glycosylated integral membrane proteins. They carry most of the sialic acid residues and, therefore, negative charge on the surface of the RBC. Other cell surface molecules that RBCs carry are shown in Table 20.1.

TABLE 20.1 Selected Erythrocyte Surface Molecules in the Human and/or Mouse.

Molecule	Synonyms	Function
CD35	Complement receptor 1	Binds complement fragments
CD36	Platelet glycoprotein IV	Unknown
CD38	N/A	NAD glycohydrolase
CD44	H-CAM, gp85	Hyaluronic acid binding
CD47	Integrin-associated protein	May be a senescence marker
CD49d/ CD29[a]	VLA-4, α4β1 integrin	Adhesion to fibronectin, V-CAM
CD55	Decay-accelerating factor	Neutralizes complement activation
CD59	Complement-regulatory protein	Inhibits complement membrane
CD71[a]	Transferrin receptor	Iron acquisition
CD147	N/A	Recirculation of RBC from spleen
CD239	Basal cell adhesion molecule/Lutheran	Laminin binding

[a]Reticulocytes only.

HEMOGLOBIN STRUCTURE, SYNTHESIS, AND METABOLISM

Hemoglobin is an iron–porphyrin–protein complex. Other iron–porphyrin–protein complexes include myoglobin and heme-containing enzymes such as catalase, peroxidase, and cytochromes. The porphyrin–iron–protein hemoglobin molecule occupies a central role in physiology by binding, transporting, and delivering oxygen to tissues. Hemoglobin is synthesized within developing RBCs and its synthesis is coordinated with the developmental stages of the erythroid precursors.

Hemoglobin Structure

Hemoglobin is composed of two α-polypeptide and two β-polypeptide chains and is approximately 64 kDa in molecular weight. Each chain contains a heme prosthetic group held firmly within a hydrophobic cleft (otherwise known as the "heme pocket"). The entire molecule is, therefore, a globular tetramer. This globular structure permits a cooperative interaction of oxygen binding that gives the sigmoid oxygen–Hgb saturation curve.

Hemoglobin Synthesis

Heme is a planar molecule composed of two elements, a tetrapyrrole protoporphyrin IX and a central iron molecule. The iron is supplied by ferritin, the cytosolic storage form of iron. Heme biosynthesis is an enzymatic process requiring both mitochondrial and cytosolic enzymes. Figure 20.2 shows the sequence of reactions leading to the synthesis of PROTO IX, heme, and Hgb. The initial step of heme synthesis occurs in mitochondria. It requires vitamin B_6 (pyridoxine) and is catalyzed by δ-aminolevulinic acid (ALA) synthase. ALA is then translocated to the cytosol. In the cytosol, two moles of ALA are condensed to form porphobilinogen (PBG), a reaction catalyzed by ALA-dehydratase (ALA-D). ALA-D is strongly inhibited by lead, leading to the anemia associated with lead poisoning. The remainder of the process is depicted in Figure 20.2.

Synthesis of α- and β-globin chains occurs in the ribosomes and polyribosomes in the cytoplasm. Each globin chain contains a cleft or heme pocket that is lined by largely nonpolar amino acid side chains that impart a hydrophobic nature to the pocket. The nonpolar (vinyl and methyl groups) side of heme is positioned in the hydrophobic pocket of each globin chain. The addition of heme to the pockets of globin is followed by a dimerization of the α- and β-globin chains, which is then followed by spontaneous formation of hemoglobin tetramers. Hemoglobin synthesis is ongoing through the reticulocyte stage.

Control of Hemoglobin Synthesis

Synthesis of heme and globin chains is finely coordinated so that there is little or no free heme or globin in the cytoplasm of developing erythroid cells. Heme governs ribosomal translation of globin chain synthesis.[55] Moreover, α- and β-chain synthesis is coordinated. Excess α-chains inhibit their own synthesis while stimulating β-chain synthesis, while excess β-chains inhibit their own synthesis.[28,52]

Hemoglobin Turnover

Hemoglobin is turned over after the extravascular or intravascular destruction of RBCs. In health, extravascular hemolysis occurs as RBCs age and are subsequently trapped in the spleen and phagocytosed by splenic macrophages. Hemoglobin is catabolized within a cell. When RBCs undergo intravascular hemolysis, the hemoglobin is released into the circulation in its free form. Free plasma Hgb is quickly cleared by several mechanisms. The most important is binding of free Hgb to haptoglobin followed by clearance of the complex by macrophages.[27] The half-time for free Hgb clearance is 20–30 minutes. Minor pathways for Hgb clearance are (1) oxidation to methemoglobin (MetHgb) that can be excreted, (2) hydrolysis of the MetHgb to release its ferriheme (ferric heme, hematin, hemin) that is complexed to hemopexin for transport to the mononuclear phagocyte system (MPS), and (3) binding of ferriheme to albumin (methemalbumin) for transport to the MPS. When there is excess intravascular hemolysis, such that the binding capacity of plasma haptoglobin is exceeded, Hgb may be cleared via glomerular filtration. In this event, hemoglobinuria may occur, or the proximal renal tubular cells may catabolize Hgb.[17] When Hgb is internalized into macrophages, it is degraded by hydrolysis into its globin and heme moieties. The globin chains are systematically degraded by proteolytic enzymes to release the constituent amino acids.

Heme Catabolism and Bilirubin Formation

The initial step in the heme catabolic pathway is enzymatic cleavage of the heme ring at the α-methene bridge to release linear tetrapyrrole biliverdin, iron, and carbon monoxide. This reaction is catalyzed by microsomal heme oxygenase in the presence of cytochrome P-450, oxygen, and reduced NADPH. Heme oxygenase activity is highest in the spleen, and there is some activity in the liver, bone marrow, and renal tubular cells. Iron is oxidized to the ferric form, released, and transported as transferrin for storage as hemosiderin or ferritin in the liver and as ferritin in the bone marrow for subsequent reuse.[53] Biliverdin, a green pigment, is reduced in macrophages to bilirubin, a yellow pigment, by the action of the enzyme biliverdin reductase in the presence of NADPH. The virtual absence of biliverdin reductase in birds accounts for the green color of avian bile. Bilirubin is a nonpolar compound and must be bound to albumin to remain soluble in aqueous plasma. The bilirubin–albumin complex is transported to the liver, and at the hepatocyte surface, albumin is released. The first step involving the hepatocyte surface is the uptake or transport of bilirubin across the hepatocyte membrane by a transporter system. The second step in the hepatocyte is conjugation of bilirubin to glucuronic acid, primarily as the diglucuronide and with some monoglucuronide. This reaction is catalyzed by the enzyme glucuronyl transferase. The bilirubin glucuronides are highly polar and are therefore soluble compounds. The third step in the hepatocyte is the transport of bilirubin glucuronide into the bile canaliculi and thence the biliary system. This canalicular transport is the rate-limiting step in hepatic bilirubin metabolism.[29] A small amount of the glucuronides may also be transported back into the circulation, so that, normally, both unconjugated and conjugated bilirubin are present in the circulation.

Fetal Hemoglobin

The synthesis of α-globin chains remains constant during stages of gestational development and throughout adult life. Different types of non-α-globin chains are synthesized and account for the different types of Hgb appearing during development and in adult life. At the embryonic stage, most animals synthesize only embryonic chains designated as ε chains (i.e., embryonal Hgbs). Fetal Hgb (HgbF) is composed of two γ-chains and two α-chains, although not all animals produce HgbF. Ruminants possess a mixture of adult and fetal Hgb at birth, and HgbF is replaced by adult Hgb in the first few months of life.[4] Although HgbF rapidly declines after birth, the capacity to synthesize it remains, and HgbF may appear in responsive anemias. Dogs, cats, horses, and pigs lack HgbF and are born with adult Hgb that has replaced the embryonal Hgb during gestation.[10,32]

Hemoglobin Types in Animals

With the possible exception of pigs, two or more types of Hgb normally occur in several domestic animal species.[9,31,32] Most polymorphisms are determined genetically and are usually associated with multiple amino acid substitutions.[32] The Hgb of cats has a unique structure containing 8–10 reactive sulfhydryl groups per molecule compared to other animals that have only two to four per Hgb molecule.[37] The presence of the readily oxidizable groups is regarded as the basis for the ease of Heinz body formation in the cat (see Chapter 32). Sheep and goats synthesize HgbC in response to severe anemia.[26] Sheep normally have HgbA and goats HgbA and HgbB, and the switch to HgbC during anemia is mediated by erythropoietin.[5] Carbon dioxide decreases oxygen affinity for HgbC more than it does for normal adult Hgbs.[26,61]

IRON METABOLISM

Iron is an essential component not only of hemoglobin and myoglobin, but also of many enzymes. Iron-containing enzymes include NADH dehydrogenase,

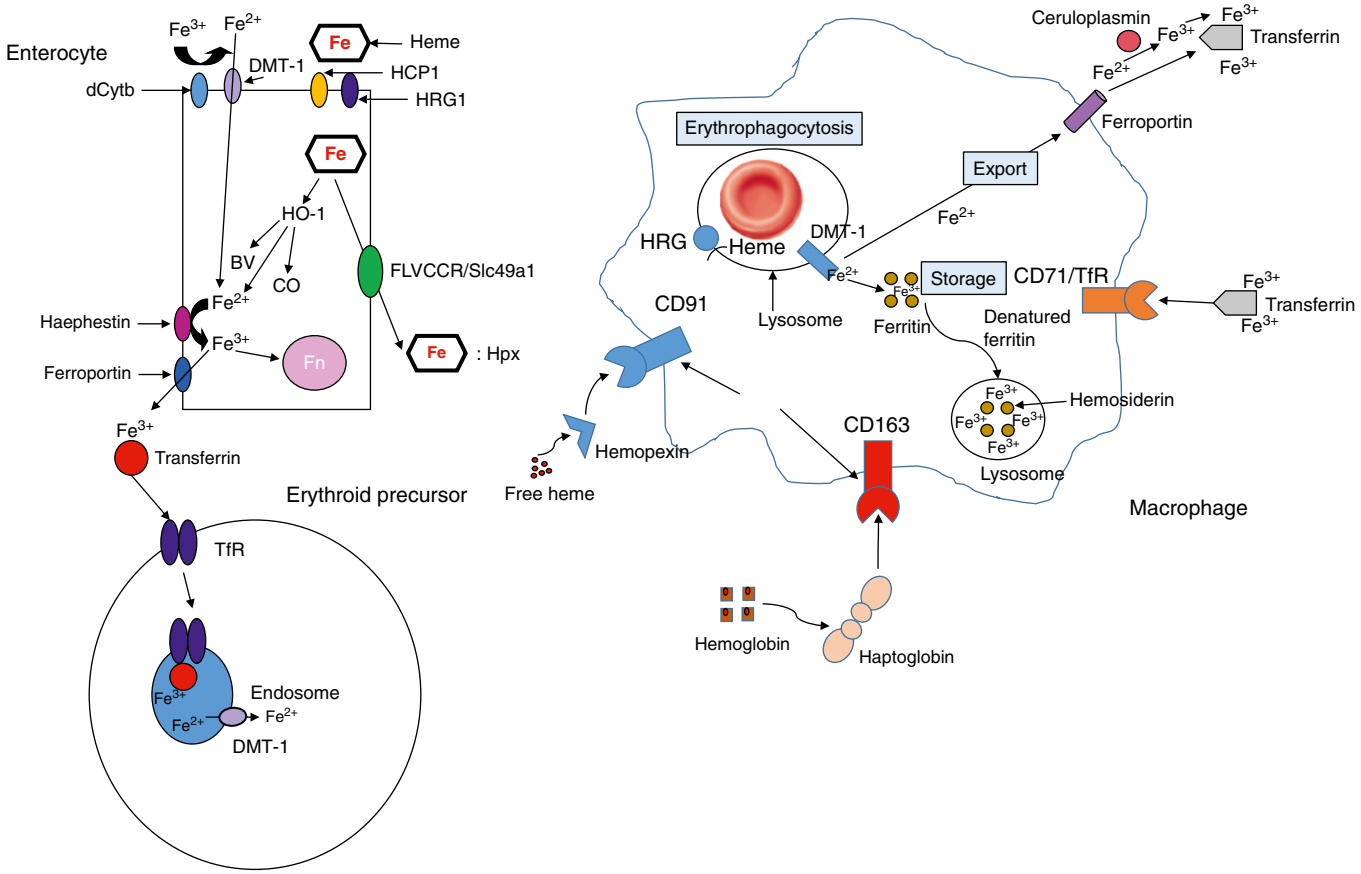

FIGURE 20.3 A schematic of iron metabolism including absorption from enterocytes, transport in circulation, utilization by the erythroid precursors, and recycling by macrophages.

lipoxygenases, superoxide dismutase, ribonucleotide reductase, fatty acid desaturases, and phosphatases.[38] These enzymes function in energy generation, prostaglandin synthesis, free radical detoxification, synthesis of DNA, synthesis of fatty acids, and signal transduction. Iron is provided to cells of the body by three sources: (1) absorption from the gut, (2) recycling from senescent RBCs, and (3) liver and macrophage storage iron (Figure 20.3).

Absorption in Intestine

Absorption of iron is regulated; excretion is not (iron is lost through epithelial sloughing of gut, skin, urothelium). Iron absorption takes place in the proximal duodenum, and it is absorbed either as heme or nonheme iron. Although most iron utilized in physiologic mechanisms is that recycled from hemoglobin iron, total body iron stores are regulated by the duodenum to prevent whole-body iron accumulation or deficit.

Intestinal Absorption of Nonheme and Heme Iron

Iron is stabilized in the ferric form by the acidity of the gastric fluid. Apical duodenal cytochrome B (dCytb) reduces ferric to ferrous iron. Ferrous iron is transported to the basolateral membrane by intracellular mechanisms that are unclear. At the basolateral surface, hephaestin, a copper-containing enzyme, reoxidizes iron to its ferric state. Ferroportin then exports iron out of the cells into the portal circulation, where it is carried bound to transferrin. Once in the circulation, iron is carried to the liver to be stored, or to the erythroid precursors in the bone marrow to be incorporated into hemoglobin. Heme iron is absorbed via heme by the apical heme transporter (apical heme carrier protein 1).[46] Iron is then released from heme via the action of heme oxygenase. It can then be exported from the cell via ferroportin. Heme can also be exported directly using the FLVCR/SLC49A1 transport protein.[16]

Cellular Iron Uptake

Iron is taken up by most cells (i.e., not enterocytes) via the cell surface transferrin receptor (TfR). The expression level of this receptor is directly related to the iron requirements of the cell.[6,15] The cell surface transferrin receptor functions as a dimer, with each 90 kDa monomer embedded in the membrane with one single transmembrane-spanning region. Iron-binding transferrin (holotransferrin) binds to the TfR at physiologic pH and the transferrin–iron–TfR complex is internalized into an endosome. The low pH of the endosome

causes the release of Fe^{3+} from the transferrin and the iron is then reduced to Fe^{2+}. Ferrous iron is then exported to the cytoplasm.[41,47] A newly discovered protein, the product of the *HFE* gene, forms a complex with the TfR and appears to regulate its ability to import iron.[7]

Macrophage Handling of Iron

Intracellular iron is derived from many sources. These include erythrophagocytosis of senescent red cells, scavenging hemopexin-bound heme and haptoglobin-bound hemoglobin, and endocytosis of transferrin bound iron via transferrin receptor 1. Once senescent RBCs, heme, and hemoglobin are endocytosed, heme is degraded by heme oxygenase-1 (HO-1) to release iron (and biliverdin), which is then exported from the endosome via divalent metal iron transporter-1 (DMT-1). Alternatively, heme can be exported from the phagolysosome via HRG1 (slc48a1). Once iron is present in macrophages, it can be exported through ferroportin, where it is oxidized by ceruloplasmin so it can bind transferrin, or it can be stored in the macrophage cytoplasm in ferritin. Should ferritin stores become maximally filled, then hemosiderin begins to accumulate in the lysosome (Figure 20.2).

Selected Molecules Involved in Iron Metabolism

The uptake of iron by the duodenum and by individual cells in the body is regulated by total body iron levels and intracellular iron levels, respectively.[1]

Many molecules involved in iron regulation have been discovered in recent years. Although there are still gaps in our knowledge of the physiologic processes, several important molecules have been identified in research involving humans and rodents, and are described in the following text.

Divalent Metal Iron Transporter-1

DMT-1 is expressed in the enterocytes of the villi and not in the crypts,[11] and is responsible for transporting iron from the enterocyte to the circulation, and from endosomes of macrophages to the cytoplasm. It is associated with phagosomal membranes in macrophages and plasma membranes and endosomes of cells that use the TfR complex for iron acquisition.[23,24]

Ferrireductase Duodenal Cytochrome b

DMT-1 transports Fe^{2+} into the enterocyte from the duodenal lumen. Since Fe^{3+} is the dietary form that exists in the lumen, it must be reduced. The duodenal cytochrome b, located on the apical membrane of the enterocyte, acts as such a ferric reductase.[11]

Hephaestin

Hephaestin, a copper-dependent transmembrane ferroxidase, is an approximately 150–160 kDa protein with 50% homology to ceruloplasmin. It is highly expressed in the small intestine, primarily in the basolateral membrane of enterocytes, and is colocalized with ferroportin.[44] Hephaestin is responsible for oxidizing Fe^{2+} to Fe^{3+} so that it can be transported out of the enterocyte into the plasma.

Ferroportin

Ferroportin is expressed on the membrane of duodenal enterocytes (basolateral), placental trophoblasts, and macrophages distributed in various tissues.[1,13,18] It is the only mammalian cellular iron exporter. It exports iron from enterocytes into the circulation (from dietary iron) and from macrophages to the circulation (from recycled erythrocyte iron). Its expression levels are regulated by hepcidin binding and internalization of the protein, and also by iron levels.

Hepcidin

Hepcidin should be considered a molecule that regulates iron systemically. Hepcidin regulates iron export from enterocytes and macrophages by binding to and causing degradation of ferroportin.[22] It is synthesized as a propeptide in the liver and circulates as a 25 amino acid disulfide-rich peptide. Synthesis is increased by iron loading to decrease iron absorption, and decreased by anemia and hypoxia to increase iron absorption.[42,58] It is also increased in inflammation, secondary to interleukin-6 production, and causes the iron trapping in macrophages during anemia of inflammatory disease.[22] Iron may control hepcidin synthesis through a signaling pathway dependent on bone morphogenic protein 6 (BMP) which acts as a paracrine factor through the BMP receptor (BMPR) in hepatocytes, causing the small mothers against decapentaplegic (SMAD) pathway to induce the hepcidin promoter.[57] BMPR has a coreceptor, hemojuvelin, the loss of which can cause significant iron overload because of impaired hepcidin production.[36] Kupffer cells also appear to regulate hepcidin expression; when Kupffer cells are eliminated, hepcidin expression is increased and serum iron is decreased.[54]

Anemia and hypoxia decrease hepcidin synthesis by increasing erythropoietic activity.[33] Erythroid precursors produce erythroferrone (ERFE) in response to erythropoietin, and ERFE downregulates hepcidin expression.[57]

Transferrin Receptor 1

The transferrin receptor is described under the heading "Cellular Iron Uptake."

Transport and Storage of Iron

Transport of Iron

Transport of iron from one compartment or tissue to another through the circulation (e.g., enterocytes to bone marrow cells) is accomplished by the carrier

protein transferrin. Serum transferrin is a soluble 78 kDa protein that binds one or two iron atoms in their ferric (3^+) form.

Storage of Iron

Iron is stored in developing RBCs, and other cells, as ferritin, an iron–protein complex.[48,49] The protein moiety, apoferritin, consists of at least 24 monomers of either H or L subunits. Each subunit is shaped like a short rod and these rods are assembled as a hollow sphere. Apoferritin has a molecular weight of 441 kDa and can store as much as 4500 molecules (31%) of iron.[35] The maximal weight of ferritin can be approximately 800 kDa, but ferritin more commonly is less than that (620 kDa) with roughly 18% iron. The method of iron movement in and out of the molecule is through "channels," and it enters as the ferrous form and is oxidized in the catalytic ferroxidase center to be stored as the ferric form.[8,12] Iron is released either by a reversal of the process or by digestion of ferritin by lysosomes and reduction to the ferrous form.[25] Hemosiderin is found in cells of the MPS, predominantly in macrophages of the liver (Kupffer cells), spleen, and bone marrow. Hemosiderin can be seen as golden granules in hematoxylin-and-eosin-stained histologic sections, and may appear green to black in Wright–Giemsa-stained cytologic preparations. It is a "stripped down" version of ferritin, whereby the apoferritin protein shell has been removed, leaving approximately 25–30% of iron by weight.[20]

Iron Regulatory Proteins

Proteins involved in iron metabolism are predominantly regulated at the post-translational level by the interplay of iron-responsive elements (IREs) and cytosolic iron-binding proteins referred to as iron regulatory proteins (IRPs). The IREs are stem-loop or hairpin structures located in the 3′ or 5′ untranslated regions of the messenger RNAs (mRNAs) that act as nucleic-acid-binding sites for the IRPs. The binding affinity of IRPs is reversibly regulated by the intracellular concentration of iron. When the intracellular concentration of iron is low, IRPs have a high affinity for IREs, and when cells are iron replete, the affinity is low.

Ferritin and aminolevulinate synthase (rate-limiting enzyme in heme biosynthesis) mRNAs have a single IRE in the 5′ end at the beginning of the coding region. Binding of the IRP inhibits translation; thus, when iron is low, the IRP binds to the IRE and translation is inhibited, whereas when iron is high, IRPs lose affinity and translation of those proteins occurs.[40] Thus, when ferritin is required for storage of increased intracellular iron, translation is upregulated. On the other hand, the transferrin receptor mRNA has an IRE on the 3′ end. When iron is low, the binding of the IRP inhibits the breakdown of the mRNA and thereby stimulates the translation of the protein. Thus, low iron upregulates TfR so that cells become more iron avid.[21] In summary, IRPs regulate mRNA translation by binding to IREs, and binding is stimulated by low iron. However, sometimes binding stimulates translation (TfR) and sometimes binding inhibits translation (ferritin).[40]

Acronyms and Abbreviations

Cb_5R, cytochrome-b_5 reductase; DPGM, diphosphoglycerate mutase; DPGP, diphosphoglycerate phosphatase; 1,3DPG, 1,3-diphosphoglycerate; 2,3DPG, 2,3-diphosphoglycerate; EMP, Embden–Meyerhof pathway; FAD, flavin adenine dinucleotide; GAPD, glyceraldehyde phosphate dehydrogenase; G6P, glucose 6-phosphate; G6PD, glucose-6-phosphate dehydrogenase; GPx, glutathione peroxidase; GR, glutathione reduction; GSH, reduced glutathione; GSSG, oxidized glutathione; HK, hexokinase; HK^+, high potassium; LK^+, low potassium; LMB, leucomethylene blue; MB, methylene blue; O_2^-, superoxide; PFK, phosphofructokinase; 3PG, 3-phosphoglycerate; P_i, inorganic phosphate; PGK, phosphoglycerate kinase; PK, pyruvate kinase; PPP, pentose phosphate pathway; SOD, superoxide dismutase.

Erythrocytes provide vital functions of oxygen transport, carbon dioxide transport, and buffering of hydrogen ions. These functions do not require energy per se, but energy in the form of ATP, NADH, and NADPH is needed to keep the cells circulating for months in a functional state despite repeated exposures to mechanical and metabolic insults.

Mature mammalian erythrocytes do not have nuclei; consequently, they cannot synthesize nucleic acids or proteins. The loss of mitochondria during the maturation of reticulocytes results in a loss of Krebs cycle and oxidative phosphorylation capabilities, and prevents the synthesis of heme or lipids de novo in erythrocytes. Energy needs of mature erythrocytes are met solely by anaerobic glycolysis in the Embden–Meyerhof pathway (EMP). Although metabolic demands are lower than in other blood cell types, erythrocytes still require energy in the form of ATP for maintenance of shape, deformability, phosphorylation of membrane phospholipids and proteins, active membrane transport of various molecules, partial synthesis of purine and pyrimidine nucleotides, and synthesis of glutathione. A minor shunt for carbohydrate metabolism, the pentose phosphate pathway (PPP), provides the erythrocyte with additional critical protection against oxidative damage.[10]

MEMBRANE TRANSPORT

The erythrocyte lipid bilayer is impermeable to most molecules. Consequently, various membrane protein transport systems are utilized for movement of molecules into and out of erythrocytes. Water and carbon dioxide are transported across erythrocyte membranes using water channels called aquaporins.[10] Band 3 appears to function as a channel for the movement of anions, especially bicarbonate and chloride, and various compounds including phosphoenolpyruvate and pyridoxal-5-phosphate.[7] Defective anion transport and marked spherocytosis with membrane instability occur in anemic cattle with an inherited deficiency of band 3 protein.[13]

Major interspecies, and in some cases intraspecies, differences occur in cation transport and subsequently

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

in intracellular Na^+ and K^+ concentrations.[10] Animal species with high intracellular K^+ concentrations (horse, pig, and some ruminants) have an active Na^+/K^+-pump that exchanges intracellular Na^+ for extracellular K^+ with the hydrolysis of ATP. In addition to individuals with high K^+ erythrocytes, some sheep, goats, buffalo, and most cattle erythrocytes have relatively low K^+ and, consequently, high Na^+ erythrocytes. These low K^+ erythrocytes have low Na^+/K^+-pump activity and high passive K^+ permeability.

Nucleated erythroid precursors and reticulocytes in cats and dogs are high K^+ cells. However, mature erythrocytes from cats and most dogs are low K^+ erythrocytes. With reticulocyte maturation, the Na^+/K^+-pump activity disappears, resulting Na^+ and K^+ concentrations near those predicted for the Donnan equilibrium with plasma.[15] However, many clinically normal Akitas, Shibas, Jindos, and other East Asian dog breeds have high K^+ erythrocytes.[3,10] Erythrocytes from these dogs have substantial Na^+/K^+-ATPase activity, and some of these dogs also have increased glutamate transport, which results in high reduced glutathione (GSH) concentrations. These high K^+/high GSH erythrocytes promote *Babesia gibsoni* replication compared to low K^+/normal GSH erythrocytes.[26] Other pathways of sodium and potassium transport occur to variable degrees in certain species.[10]

Excessive intracellular Ca^{2+} promotes the suicidal death of erythrocytes (eryptosis);[23] consequently, erythrocytes actively extrude Ca^{2+} using a calcium pump having Ca^{2+}-activated, Mg^{2+}-dependent ATPase activity and operating as Ca^{2+}/H^+ exchanger. The calcium pump is activated by a calcium-binding protein called calmodulin.[10]

Amino acid transport in erythrocytes provides amino acids for synthesis of glutathione.[10] In addition, amino acid transporters may be responsible for efflux of amino acids during reticulocyte maturation.[10]

Species vary in their permeability to glucose, with human erythrocytes being very permeable and pig erythrocytes being poorly permeable. Erythrocytes of other domestic animals appear to be intermediate between these extremes.[10] Glucose movement into erythrocytes requires glucose transporters. Glucose transporter 1 is present in mature erythrocytes of mammals that cannot synthesize ascorbic acid (humans, higher primates, guinea pigs, and fruit bats). Glucose transporter 1 is also present in neonatal erythrocytes of other mammals, but it is replaced by glucose transporter 4 in adult erythrocytes of these species.[18] An exception is that adult erythrocytes from all Japanese Akita dogs and some Shiba dogs contain both glucose transporters.[20,21] Erythrocytes from adult pigs lack a functional glucose transporter and, therefore, have limited ability to utilize glucose for energy.[10]

Erythrocyte cell membranes from most animal species have a nucleoside transporter. Rabbit, pig, and human erythrocytes exhibit substantially more adenosine uptake than those of other species studied. Erythrocytes from dogs exhibit more adenosine uptake than those of cats, goats, or cattle, and erythrocytes from horses and most sheep appear to be nearly impermeable to adenosine. While dog erythrocytes are permeable to adenosine, they are impermeable to inosine. Dog and cat erythrocytes exhibit adenine uptake and incorporation into nucleotides, but values are much lower than those of human, rabbit, or rodent erythrocytes.[10]

Other erythrocyte transporters include urea transporter-1 and ferroportin-1. The lipid-raft, integral membrane stomatin appears to play a role as a membrane-bound scaffolding protein that can modulate some transport proteins.[24] Because membrane proteins interact with one another, a deficiency in one protein can result in secondary deficiencies in other proteins. Decreased amounts of several membrane proteins were reported in a dog with hemolytic anemia believed to have a defect in band 3.[1]

CARBOHYDRATE METABOLISM

Although substrates such as ribose, fructose, mannose, galactose, dihydroxyacetone, glyceraldehyde, adenosine, and inosine may be metabolized to some extent, depending on the species, glucose is the primary substrate for energy needs of erythrocytes from all species except the pig. Inosine appears to be the major substrate for pig erythrocytes. Its production by the liver is sufficient to meet erythrocyte energy requirements.[27]

Once glucose enters the cell, it is phosphorylated to glucose 6-phosphate utilizing the hexokinase enzyme. The glucose 6-phosphate is then metabolized through either the Embden–Meyerhof pathway or the pentose phosphate pathway as shown in Figure 21.1.

EMBDEN–MEYERHOF PATHWAY AND ATP PRODUCTION

A net of two molecules of ATP is produced for each molecule of glucose metabolized to two molecules of lactate in the Embden–Meyerhof pathway. Because mature erythrocytes lack mitochondria, the Embden–Meyerhof pathway is the only source of ATP production in these cells. Reactions catalyzed by hexokinase, phosphofructokinase (PFK), and pyruvate kinase (PK) appear to be rate-limiting steps in glycolysis, with the PFK reaction being most important under physiologic steady-state conditions.[10]

At physiologic pH values, high concentrations of inorganic phosphate (P_i) stimulate glycolysis through the Embden–Meyerhof pathway by reducing the ATP inhibition of PFK. Conversely, glycolysis is inhibited by short-term phosphate deficiency, primarily by decreasing intracellular inorganic phosphate for glyceraldehyde phosphate dehydrogenase. Decreased glycolytic rates result in decreased erythrocyte ATP concentrations and hemolytic anemia in experimental dogs made severely hypophosphatemic by hyperalimentation. Hemolytic anemia associated with hypophosphatemia has also been reported in diabetic cats and a diabetic

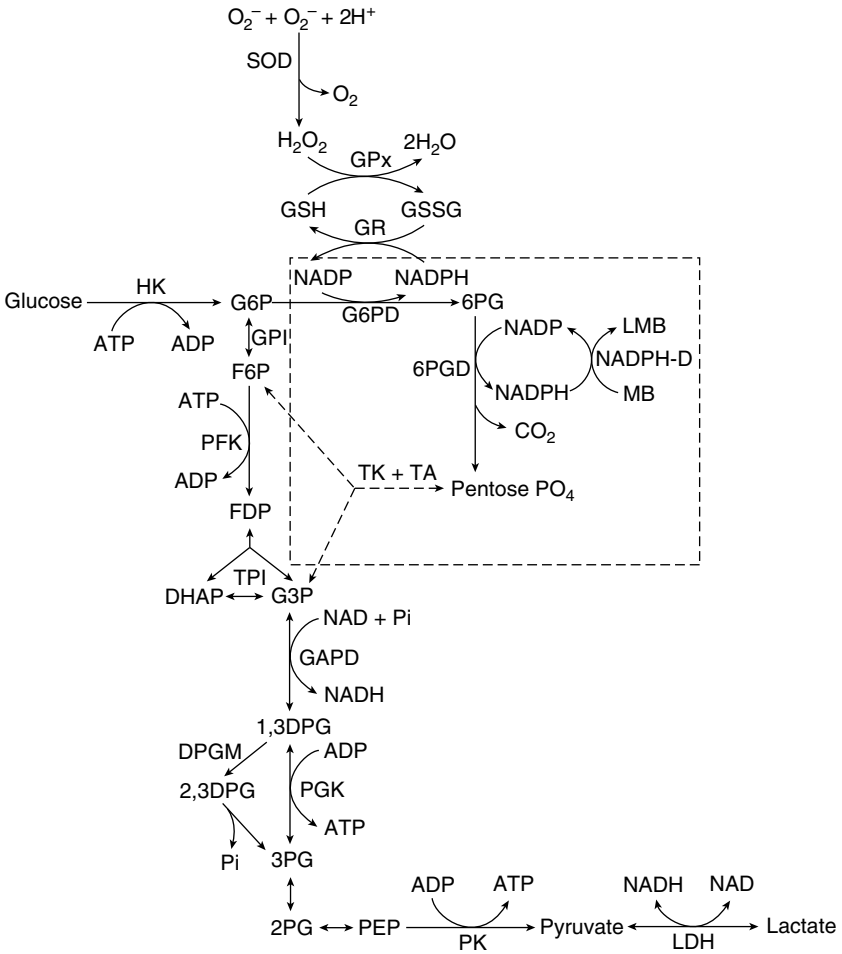

FIGURE 21.1 Metabolic pathways of the mature erythrocytes. (**Source:** Courtesy of John Harvey. This figure was published in Harvey.[10] ©Elsevier 2008)

dog following insulin therapy, in a cat with hepatic lipidosis, and in postparturient cattle in which decreased erythrocyte ATP concentrations have been measured.[10]

Because mature erythrocytes depend solely on anaerobic glycolysis for ATP generation, deficiencies of enzymes involved in glycolysis result in shortened erythrocyte survival. Insufficient ATP generation in deficient erythrocytes can result in echinocyte formation. PK-deficient dogs and cats have mild to severe regenerative hemolytic anemia. PK-deficient dogs exhibit marked iron accumulation in the liver and die from liver failure or myelofibrosis.[9] PFK-deficient dogs have compensated hemolytic anemia with sporadic episodes of intravascular hemolysis and hemoglobinuria.[9] PFK-deficient dog erythrocytes are alkaline fragile, because 2,3-diphosphoglycerate (2,3DPG) concentration is decreased in these cells. A decrease in 2,3DPG, the major impermeant anion in dog erythrocytes, results in higher intracellular pH. Episodes of intravascular hemolysis occur when PFK-deficient dogs develop alkalemia secondary to hyperventilation.[9]

DIPHOSPHOGLYCERATE PATHWAY AND OXYGEN AFFINITY OF HEMOGLOBIN

Molecules of 1,3-diphosphoglycerate produced by the glyceraldehyde phosphate dehydrogenase reaction may be utilized by the phosphoglycerate kinase reaction in

the Embden–Meyerhof pathway or may be converted to 2,3DPG by the diphosphoglycerate mutase reaction (Figure 21.1). 2,3DPG degradation to 3-phosphoglycerate is catalyzed by diphosphoglycerate phosphatase activity. The diphosphoglycerate pathway or shunt bypasses the ATP-generating phosphoglycerate kinase step in glycolysis; consequently, no net ATP is generated when glucose is metabolized through this pathway.

Erythrocytes of dogs, horses, pigs, and man normally contain high concentrations of 2,3DPG, whereas those of cats and domestic ruminants have low concentrations. In erythrocytes from most mammalian species, 2,3DPG decreases the oxygen affinity of hemoglobin. When the oxygen affinity of hemoglobin is studied in hemolysates, removal of 2,3DPG and ATP (termed "stripping") from species with low 2,3DPG erythrocytes results in considerably lower oxygen affinities than removal from hemoglobin of species with high 2,3DPG erythrocytes. Because stripped hemoglobins from species with high 2,3DPG erythrocytes have high oxygen affinities, it appears that 2,3DPG is needed within erythrocytes of these species to maintain hemoglobin oxygen affinity within a physiologically useful range.[10]

The flow through the diphosphoglycerate pathway is regulated by the overall glycolytic rate. The formation of 2,3DPG is stimulated by increased phosphate concentration and increased pH. Hypoxic conditions stimulate 2,3DPG synthesis primarily by inducing hyperventilation with resulting alkalosis. Conversely, acidosis and hypophosphatemia result in decreased 2,3DPG concentrations. PFK deficiency inhibits glycolysis above the diphosphoglycerate shunt and results in decreased 2,3DPG concentration. By contrast, the concentration of 2,3DPG is increased in dogs with PK deficiency because the metabolic block occurs below the diphosphoglycerate shunt.[9]

Erythrocyte 2,3DPG increases in anemic dogs and cats. The resultant decrease in hemoglobin oxygen affinity would seem to be beneficial in response to anemia in the dog. 2,3DPG concentration is much lower in cat erythrocytes than in dog erythrocytes, and cat hemoglobins are generally less responsive to 2,3DPG than dog hemoglobin; consequently, the physiologic significance of this increase seen in anemic cats is unclear.[10] Increased 2,3DPG has also been reported in erythrocytes from horses with hypoxic conditions.[4] In the case of severe hypoxic hypoxemia, the response might be detrimental, because hemoglobin cannot be fully saturated.[10] Erythrocyte 2,3DPG, as well as ATP, decreases in blood stored for transfusions.[2,14]

OXIDANTS AND OXIDATIVE INJURY

Animals are exposed to low levels of oxidants in their environment and from normal metabolic processes in the body. Reactive oxygen species and reactive nitrogen species are formed as products of normal cellular metabolism. At low to moderate concentrations, nitric oxide and superoxide free radicals are involved in signal transductions between cells. When generated at higher concentrations in disease states, these free radicals (and even more potent oxidative metabolites that they produce) can overwhelm protective systems within the body, producing cellular injury and/or destruction.[10]

Cumulative injury from these exposures may account for the normal aging and removal of circulating erythrocytes. Some metabolic disorders, including diabetes, inflammation, hyperthyroidism, neoplasia, erythrocyte parasites, intense exercise, and ischemia/reperfusion, can generate oxidants in sufficient amounts to result in increased oxidant injury and shortened erythrocyte life spans, but the anemia (when present) is generally mild. A wide variety of drugs and environmental agents either exist as free radicals or can be converted to free radicals by cellular metabolic processes. These free radicals can be more damaging than reactive oxygen species and reactive nitrogen species.[10]

Oxidants may damage erythrocyte hemoglobin, enzymes (especially sulfhydryl groups), and membranes (especially polyunsaturated lipids). Methemoglobin forms when hemoglobin iron is oxidized from the ferrous to the ferric state. Methemoglobin is unable to bind oxygen, but its presence alone does not result in shortened erythrocyte life span.[10]

Heinz bodies are inclusions that form within erythrocytes following the oxidative denaturation of the globin portion of hemoglobin. They bind to the inner surface of erythrocyte membranes, and their presence can result in premature erythrocyte phagocytosis. Heinz bodies are frequently recognized in erythrocytes from cats because of the susceptibility of cat hemoglobin to form Heinz bodies, combined with a poor ability of the cat spleen to remove Heinz bodies from erythrocytes. Even normal cats may have low numbers of Heinz bodies (<5%).[10]

Oxidative membrane damage results in premature phagocytosis of injured erythrocytes. Oxidative injury to erythrocyte membranes may result in the adhesion of opposing areas of the cytoplasmic face of the erythrocyte membrane and the formation of eccentrocytes and pyknocytes. Eccentrocytes have primarily been recognized in dog and horse erythrocytes.[11] Intravascular hemolysis may occur when severe membrane injury is present.

PENTOSE PHOSPHATE PATHWAY AND PROTECTION AGAINST OXIDANTS

The pentose phosphate pathway generates NADPH, the major source of reducing equivalents in the protection of erythrocytes against oxidative injury. Normally, only about 5–13% of glucose metabolized by erythrocytes flows through the pentose phosphate pathway (Figure 21.1), but this flow can be accelerated markedly by oxidants.[10] NADPH is needed to maintain glutathione and thioredoxin in their reduced states, and it is important in maintaining catalase in a functional form. Defects in the pentose phosphate pathway can render erythrocytes susceptible to endogenous and

exogenous oxidant injury. Glucose-6-phosphate dehydrogenase is the rate-controlling enzyme in the pentose phosphate pathway. A persistent hemolytic anemia with eccentrocytosis has been described in an American saddlebred colt with <1% of normal glucose-6-phosphate dehydrogenase activity.[25]

Glutathione is of central importance in the protection against oxidant injury. It is a tripeptide of glutamic acid, cysteine, and glycine that is synthesized de novo in erythrocytes of animals from constituent amino acids via two ATP-requiring reactions. Glutathione deficiency occurs in some sheep because of a deficiency of γ-glutamylcysteine synthetase, the first enzyme involved in glutathione synthesis, and in other sheep deficient in the amino acid transporter responsible for cysteine transport into erythrocytes, thereby limiting cysteine uptake and restricting glutathione synthesis.[10]

Reduced glutathione (GSH) has a highly reactive sulfhydryl group that may act nonenzymatically as a free radical acceptor to counteract oxidant damage. GSH also functions as an electron donor in various reductive enzyme reactions including glutathione peroxidase, phospholipid hydroperoxide glutathione peroxidase, glutathione S-transferase, and glutaredoxin.[10]

GSH binds to various oxidized thiols, including those present in hemoglobin and peroxiredoxins,[10,22] which contributes to the reduced GSH concentrations measured during oxidative injury to erythrocytes. These glutathionylation reactions can be reversed by glutaredoxin and GSH.[22]

Oxidized glutathione produced by these various reactions is reduced back to GSH by using the flavin adenine dinucleotide (FAD)-dependent glutathione reductase reaction that requires NADPH. Horses with erythrocyte FAD deficiency have markedly reduced glutathione reductase activity, decreased GSH concentration, and prominent eccentrocytosis.[12] If not reduced, oxidized glutathione can be transported out of erythrocytes.[10]

Superoxide dismutase within erythrocytes is a copper- and zinc-containing enzyme that promotes the dismutation of two superoxide (O_2^-) molecules to H_2O_2 and oxygen (Figure 21.1). The importance of superoxide dismutase as an oxidant defense in erythrocytes is unclear.[6] Although generally considered protective, superoxide dismutase may actually increase oxidant injury in conditions where H_2O_2 catabolism is compromised.[10]

Glutathione peroxidase catalyzes the conversion of H_2O_2 to water. It also catalyzes the reduction of fatty acid hydroperoxides and 1-monoacylglycerol hydroperoxides. Another glutathione peroxidase in erythrocytes termed phospholipid hydroperoxide glutathione peroxidase participates in the reduction of more complex phospholipid hydroperoxides using GSH.

Catalase is a heme-containing enzyme that also destroys H_2O_2 by conversion to water and oxygen. Except for dogs, mammalian erythrocytes generally have high catalase activities. Dogs and humans with acatalasemia do not develop hemolytic anemia.[10]

Recent studies suggest that peroxiredoxins may be more important in protecting against H_2O_2 than glutathione peroxidase or catalase.[16] Peroxiredoxins are a ubiquitous family of enzymes that reduce hydrogen peroxide, organic hydroperoxides, lipid hydroperoxides, protein hydroperoxides, and peroxynitrite.[19] Peroxiredoxin-2 is the third most abundant protein in the cytoplasm of erythrocytes after hemoglobin (98% of the total protein) and carbonic anhydrase. Peroxiredoxin-2 functions primarily as a noncatalytic scavenger of hydrogen peroxide; however, oxidized peroxiredoxin-2 is slowly regenerated using reduced thioredoxin, and oxidized thioredoxin is reduced by NADPH using thioredoxin reductase.[16] Peroxiredoxin-2 maintains hemoglobin stability and is essential in protecting erythrocytes from oxidative stress.[8]

Thioredoxin may also be important in the direct scavenging of free radicals. Thioredoxin and glutaredoxin are small proteins with two closely associated cysteines in their active sites. The reduced forms of these proteins interact with and reduce intramolecular protein disulfides that form in oxidatively damaged proteins. Oxidized glutaredoxin is reduced by GSH.[10]

Selenium is incorporated as selenocysteine at the active site of a wide range of selenoproteins, including glutathione peroxidase, phospholipid hydroperoxide glutathione peroxidase, and thioredoxin reductase in erythrocytes.[10] Heinz body hemolytic anemia has been reported in selenium-deficient cattle grazing on St. Augustine grass.[10]

Vitamin E (α-tocopherol) is lipid-soluble and the most important antioxidant in the cell membrane. It donates reducing equivalents to lipid peroxyl radicals, converting them to less toxic lipid hydroperoxides.[10] Oxidized vitamin E can be reduced by ascorbate, presumably at the aqueous–lipid interface of the lipid bilayer.[10] Hemolytic anemia secondary to vitamin E deficiency has been reported in monkeys and premature human infants, but Heinz body formation has not been recognized.[5]

Dehydroascorbate can be reduced to ascorbate nonenzymatically by GSH and enzymatically via the glutaredoxin reaction, by a separate GSH-dependent dehydroascorbate reductase enzyme, and by the thioredoxin reductase reaction. Reduced ascorbate serves as an antioxidant by donating one or two electrons to a variety of oxidants, including oxygen-free radicals and peroxides.[10]

METHEMOGLOBIN FORMATION AND REDUCTION

About 3% of hemoglobin within erythrocytes is oxidized to methemoglobin each day in normal animals. However, methemoglobin usually accounts for less than 1% of total hemoglobin, because it is constantly reduced back to hemoglobin by a methemoglobin reductase, also called cytochrome-b_5 reductase, enzyme reaction present in erythrocytes.[10] In this reaction, electrons are transferred from NADH generated in glycolysis to

ferricytochrome-b_5 using FAD as the enzyme-bound prosthetic group; then the resulting ferrocytochrome-b_5 reduces methemoglobin nonenzymatically to hemoglobin. Methemoglobin reduction is more corrective than protective. Methemoglobin forms at much higher levels in the presence of oxidative compounds. An inherited deficiency in cytochrome-b_5 reductase in dogs and cats results in persistent methemoglobinemia with minimal or no clinical signs.[9] Methemoglobinemia also occurs in horses that have decreased cytochrome-b_5-reductase activity secondary to erythrocyte FAD deficiency.[12] One dog with congenital methemoglobinemia has been reported with a cytochrome-b_5 defect rather than a cytochrome-b_5-reductase defect.[17]

Methylene blue is used to treat toxic methemoglobinemia. It causes methemoglobin to be reduced faster than occurs by the relatively slow NADH-dependent methemoglobin reductase reaction. Methylene blue is reduced to leucomethylene blue by NADPH-dependent diaphorase activity (Figure 21.1), and leucomethylene blue reacts spontaneously with methemoglobin, reducing it to hemoglobin and regenerating methylene blue.[10]

Acronyms and Abbreviations

AChE, acetylcholinesterase; AST, aspartate amino transferase; Bc, conjugated bilirubin; BRBC, biotinylated RBCs; Bu, unconjugated bilirubin; CAT, catalase; CD47, thrombospondin-1 receptor; ECM, extracellular matrix; Fas, first apoptosis signal receptor; FADD, Fas-associated death domain FSC, forward scatter; GLUT1, glucose transporter 1; GPx, glutathione peroxidase; GPA, glycophorin A; GSH, glutathione; Hct, hematocrit; Hgb, hemoglobin; HO-1, heme oxygenase-1; Hsp 70, heat shock protein 70; KCC, potassium chloride cotransporter; LC3, microtubule-associated protein light chain 3; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; NMB, new methylene blue; NO, nitric oxide; PAF, platelet -activating factor; PRDX2, peroxiredoxin-2; PS, phosphatidylserine; RNA, ribonucleic acid; ROS, reactive oxygen species; RPI, reticulocyte production index; SIRPα, signal-regulatory protein alpha; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; FLS, fluorescent light scatter; SOD, superoxide dismutase; TfR, transferrin receptor; TrxR, thioredoxin reductase; Trx, thioredoxin.

The anuclear RBC life span is characterized by three phases. A brief reticulocyte maturation period featuring rapid changes is supported by a high rate of metabolism and translation activity. The mature cell phase involves months of precise functioning under rigorous circulatory conditions. In the final, relatively brief senescence phase, RBCs incur age-associated functional and structural lesions culminating in removal from the circulation, predominantly by cells of the mononuclear phagocyte system, and are recycled. The synthetic activities of reticulocytes, their maturation and release, and the processes of erythrocyte senescence and destruction are covered in this chapter.

RETICULOCYTE MATURATION

Formation of Mature RBCs

A reticulocyte is produced when a late-stage nucleated erythroid precursor (metarubricyte) expels its nucleus. The reticulocyte then develops into a mature circulating RBC in 3–4 days, but at inception it is quite distinctive from the mature cell.[23] In contrast to the relatively uniform biconcave shape of mature cells in many species, reticulocytes are larger, round to lobulated cells with considerably more surface area and less cytoplasm.

Late-stage metarubricytes and maturing reticulocytes are found primarily in erythroblastic islands in the bone

marrow where they can be sheltered until better prepared for circulatory stresses.[2] The maturation process from reticulocyte to mature erythrocyte involves complex mechanisms that include: (1) hemoglobinization for optimal oxygen transport; (2) plasma membrane remodeling; (3) cytoskeleton rearrangement; (4) removal of obsolete organelles; and (5) release into circulation.

Hemoglobinization is achieved by endocytic activities mediated through internalized membrane vesicles and clathrin-coated pits.[29] Clathrin proteins form a hexamer in the plasma membrane to facilitate the uptake of macromolecules. Together with clathrin-coated pits, transmembrane receptors, transporter proteins, and other transport/endocytic functions actively provide essential "building blocks" (amino acids, iron, etc.) for terminal protein translation and synthesis of other cellular components. At this stage, the remaining 20–30% of total hemoglobin must still be produced.[74] These production activities require an actively synthesizing cytoplasm containing ribosomes, polyribosomes, RNA, and mitochondria, all of which will be removed within the next 3–4 days.

In vitro studies indicate that the youngest reticulocytes have significantly decreased membrane stability and deformability compared to later stage reticulocytes and mature RBCs.[85] The junctional complex interactions between spectrin–actin–protein 4.1 are considered frail in reticulocytes, in part explaining the superior mechanical stability in mature RBCs.[46] Exosomes play a major role in the cell membrane remodeling process by reducing membrane surface area.[5,21] Briefly, exosomes are formed by endocytic invaginations of membrane that are assembled into multivesicular structures. These structures then fuse with the internal cell surface where small (~60 nm) membrane-bound vesicles (exosomes) are released. Some estimates suggest that exosomes account for most of the membrane loss associated with maturation, about 30% in rats. The membranes of released exosomes have features such as phosphatidylserine (PS) exposure that allow recognition and removal by macrophages as apoptotic bodies, avoiding the incitation of inflammation or possibly an autoimmune response.[5] Exosome release coupled with cytoskeleton maturation and stability leads to smaller size and improved RBC deformability.

The remodeling and stability of the cell are also required to form the characteristic biconcave shape and to increase shear resistance. Studies in mice and humans show that reticulocyte tubulin and cytosolic actin are tagged by ubiquitin molecules and are degraded via the ubiquitin–proteasome pathway, whereas the major RBC cytoskeleton proteins such as spectrin, membrane actin, ankyrin, protein 4.1, protein 4.2, p55, and tropomodulin are stable during maturation.[26,46]

Late reticulocyte maturation requires degradation of cellular components that are not needed in mature RBCs; this process allows for a more efficient transport of hemoglobin. Several mechanisms are involved in the clean-up of organelles. Elimination of mitochondria occurs via programmed cell death (mitoptosis) and autophagy (mitophagy), and starts at the time of enucleation. These two mechanisms overlap and mitoptosis leads to autophagosome formation (mitophagy).[33,57] Simultaneously, a specific 15-lipoxygenase initiates degeneration of mitochondria by producing reactive oxygen species (ROS), which will target the mitochondria for proteasomal degradation. Damaged mitochondria can form small vesicles that are subsequently released by membrane blebbing as mitoptotic bodies.[21,50]

Exocytosis via the endosome–exosome pathway promotes the clearance of organelles such as smooth and rough endoplasmic reticulum (ER), ribosomes, and the Golgi apparatus.[57] Other cell components not needed in the mature RBC are selectively enriched in exosomes, including transferrin receptor (TfR or CD71), fibronectin, insulin, glucose transporters, nucleosides, and amino acids.[21] TfR removal is important to prevent oxidative damage caused by iron overload; thus, after the extrusion of the nucleus and loss of mitochondria, the process of heme formation stops and there is enough intracellular iron for heme formation. Heat shock protein 70 (Hsp 70), a chaperone protein, has been strongly implicated in the enrichment of TfR and probably other membrane proteins into exosomes.[21,22] Membrane Na+/K+-ATPase is also removed from reticulocytes of carnivores that switch to low K^+:high Na^+ cytoplasm in mature RBCs.

Autophagy also plays a major role in organelle clearance. Studies in vitro with human reticulocytes have shown that autophagosomes and endosomes will form large autophagic compartments that will fuse with the cell membrane to release cell contents by exocytosis.[27] The autophagosomes are formed from the double membrane originated in the ER, and contain autophagic proteins such as the microtubule-associated protein light chain 3 (LC3), which is a marker of autophagy. The autophagosome will then fuse with endosomes and lysosomes for further degradation. The formation of a hybrid autophagosome/endosome is demonstrated by the colocalization of LC3 and plasma-membrane-derived glycophorin A (GPA), band 3, and glucose transporter 1 (GLUT1).[26] These endosome vesicles, however, do not contain proteins such as actin, ankyrin, and spectrin, suggesting the membranes forming vesicles released by blebbing are unlinked to the cytoskeleton. This fine adjustment of the plasma membrane provides stability and deformability to the mature erythrocyte.[26]

While degradation of most organelles happens in the bone marrow, messenger RNAs (mRNAs) are degraded in the blood stream.[57] This process is mediated by RNAases such as the pyrimidine 5′ nucleotidase. The deficiency or inhibition (e.g., lead toxicity) of pyrimidine 5′ nucleotidase causes accumulation of RNA resulting in basophilic stippling.[77]

Reticulocyte Release

As cells mature, several changes prepare the cell for release from the marrow into the circulating pool. The membrane receptors that tether reticulocytes to fibronectin and thrombospondin in the marrow

extracellular matrix (ECM) are gradually lost, apparently through transfer to exosomes. In addition, surface sialic acids are also decreased, which reduces negative charge repulsion between reticulocytes and endothelial cells.

Subsequent contact of reticulocytes with adventitial and endothelial cells initiates thinning of the adventitia and separation between endothelial cell junctions that allows diapedesis of RBCs through pores into circulation.[4] Erythropoietin (EPO) stimulates the early release of reticulocytes.[30] In species where some reticulocytes are allowed to circulate in health, they appear to be preferentially sequestered for a period in the spleen where reticulocyte "ripening" allows for further hemoglobinization, membrane remodeling, and cytoskeletal stabilization. Splenic retention is apparently mediated through residual fibronectin receptors on reticulocytes.[65]

Reticulocyte Identification and Counting

Reticulocytes are identified based on their appearance when exposed to supravital stains (see Chapter 23). The maturation time for aggregate and punctate cells and the maturation stage at which reticulocytes are normally released from the marrow vary with species. Dogs normally release aggregate reticulocytes from the bone marrow (usually ≤1.0%/day), which then complete maturation in roughly 24 hours. Punctate forms are short-lived and are seen in insignificant numbers. Cats normally release low numbers of aggregate reticulocytes in health (<0.4%). These have a short circulating maturation time of about 12 hours to become punctate cells, which then circulate for 10–12 days and may represent 10% of RBCs in health.[81] Horses do not release reticulocytes from bone marrow in health and only rarely in regenerative anemia. However, RNA-containing equine RBCs can be recognized by automated technology, which might improve sensitivity in assessing equine anemia.[13] Reticulocytes are not typically seen in the peripheral blood of cattle, sheep, or goats except in response to anemia. Healthy laboratory animal species that have shorter RBC life spans and higher rates of erythropoiesis typically release reticulocytes at rates equal to or greater than are seen in dogs. Reticulocyte reference intervals have been published for some species (see section IX).

Cat aggregate reticulocyte counts and polychromatophilic cell proportions are lower than seen in healthy dogs or dogs with similar degrees of anemia, suggesting inherently inferior responsiveness to anemia. This species comparison may be misleading because bone marrow regenerative robustness is reportedly greatest in the cat among common domestic species.[81] Accordingly, the feline punctate reticulocyte counts may be quite high, exceeding $4 \times 10^6/\mu L$. It appears that the rapid aggregate cell maturation in circulation masks the overall intensity of regeneration in cats. Historically, punctate reticulocyte counts in cats have been omitted in many laboratories. Because aggregate cells are so short-lived and elevated punctate counts in cats do reflect a recent regenerative response, reporting of both types is advisable. Omission of punctate counts may lead to misclassification of anemia.

The implementation of flow-cytometry-based techniques of reticulocyte counting using nucleic acid stains such as thiazole orange has removed the subjectivity of manual methods and demonstrated that reticulocytes are a heterogeneous population of cells with different stages of maturation from enucleation to mature RBCs.[64]

However, RBC inclusions such as Howell–Jolly and Heinz bodies[71], presence of RBC-associated pathogens,[67,68] and other cellular elements such as leukocyte cytoplasmic fragments,[62] giant platelets,[71] and spurious artifacts may interfere with the counts. Concurrent evaluation of blood smears should minimize these possible interferences.

When assessing marrow responsiveness, the reticulocyte percent can be easily misinterpreted because the percentage depends not only on marrow production, but also on the number of mature cells in circulation. The same number of reticulocytes per microliter of blood will represent a very different percentage when accompanied by normal numbers of mature cells (Hct 45) versus greatly reduced mature RBC numbers (Hct 15). To correct for this, the reticulocyte percent is multiplied by the total RBC count to obtain the "absolute reticulocyte count" (reticulocytes/μL). Healthy dogs and cats, by manual methods, generally have ≤80 000/μL and ≤60 000/μL absolute reticulocyte counts, respectively. If the RBC count is not available, the Hct can be used to calculate a "corrected reticulocyte percent," which makes a similar adjustment for the effect of relative RBC mass on reticulocyte percent. This value is obtained by multiplying the patient reticulocyte percent times the patient Hct/normal Hct. The normal Hct value is typically 45 for dogs and 37 for cats, values that roughly represent the middle of their respective species reference intervals.

As severity of anemia increases, reticulocytes tend to be released earlier in the marrow maturation process. Because more immature reticulocytes circulate longer, reticulocyte counts will be higher, but this reflects prolonged circulation time rather than increased production. This overestimation of marrow responsiveness can be corrected by calculating the "reticulocyte production index" (RPI). In humans and presumably in dogs, it is estimated that the reticulocyte circulating maturation time increases by 0.5 days for each 10-unit decrease in Hct. At Hct 45, the normal maturation time is 1 day. Therefore, the maturation time at Hct 35 is 1.5 days, at Hct 25 it is 2 days, and at Hct 15 it is 2.5 days. The RPI is calculated by dividing the corrected reticulocyte percentage (or absolute reticulocyte count) by the above-mentioned maturation factor. For example, if a patient has a Hct of 25 (maturation time = 2 days) and a corrected reticulocyte percentage of 3, the RPI is 3.0/2 = 1.5. This substantially reduces the estimation of marrow responsiveness. The RPI adjustment is not recommended in other species due to lack of information on the impact of various Hct levels on circulating maturation times.

RBC LIFE SPAN

Species Variation

After release from marrow, RBCs circulate throughout the vascular system thousands of times before being removed, disassembled, and recycled by macrophages. The RBC life span varies characteristically between species and the differences are, at least partially, explained by different metabolic rates. Comparative studies reveal that RBC life span correlates positively with species longevity (years) and with body mass. That is, larger mammals tend to live longer and have longer RBC life spans when compared to smaller species. Smaller species have higher rates of oxidative metabolism and presumably accrue oxidative injury at higher rates, reducing both longevity and RBC life span. This relationship is illustrated by comparison among common mammalian species where the RBC life span is approximately 140–145 days for horses, 130 days for cattle, 115 days for goats, 100–115 days for dogs, 73 days for cats, and 43 days for mice.[78]

Other complementary experimental evidence suggests that RBC life span in health may be influenced by RBC antioxidant status, where the RBC potential life span in several mammalian species (n = 10) correlated significantly with the RBC levels of superoxide dismutase (SOD), glutathione peroxidase (GPx), and glutathione (GSH).[41] Additionally, RBC viability may be negatively influenced by corporal aging, at least in small laboratory animals. RBCs from old rats are reported to have lower quantities of several antioxidant enzymes compared to young rat RBCs.[24] Reticulocytes from old rats have lower SOD activity, and increased quantities of catalytically inactive SOD, suggesting an age-associated defect in erythropoiesis.[24] These differences are associated with altered RBC survival as evidenced by a reported 40–60% shorter RBC life span in old mice and rats versus young animals.[1,25] Although limited information is available for larger animals, a similar pattern of shorter RBC life span with age has been suggested for greyhounds.[63]

Rheological Compromise

Based on evidence that cell density and cell age were positively correlated, early RBC aging studies concentrated heavily on identifying "worn out" cells with severely compromised rheological abilities. Since then, some well-designed comparative studies using in vivo aged rabbit biotinylated RBCs, hypertransfused mouse RBCs, and human dense RBCs have confirmed that some rheological compromise accompanies cell aging.[49,79] However, the magnitude and significance of these changes in explaining RBC clearance remain equivocal. Although mild decreases in deformability were observed, fairly constant surface area to volume ratios (sphericity) and a slight decrease in diameter offset that change; thus convincing support that the RBCs would be compromised in traversing sinusoids was lacking. More recently, Franco and collaborators,[20] using a combination of density gradient and flow cytometry techniques, reported that normal human RBCs fail to show increasing density past the early stages of circulation. Interestingly, they observed that biotin-labeled human RBCs retrieved at >126 days of age (end of life span) generally display an irregular morphology with uneven distribution of band 3 and increased presence of IgG; the latter potentially indicating a clearance mechanism. The authors suggest that the irregular morphology would likely be considered artifact or unspecific poikilocytosis in blood smear evaluations when they are in fact senescent RBCs.[20]

Decreased Metabolic Rate

Senescence of RBCs reportedly involves the decrease of metabolic rate evidenced by the decrease of multiple glycolytic enzymes such as pyruvate kinase (PK), phosphofructokinase (PFK), glucose-6-phosphate dehydrogenase (G6PD), and hexokinase in humans.[28,34] In addition, the transport of glucose across the RBC membrane is decreased.[7] Thus, the capacity to metabolize glucose is decreased by approximately 2.5 times in older RBCs.[48]

MECHANISMS OF RBC CLEARANCE

The mechanisms of RBC clearance may be multiple and the importance of each may vary with species. It appears that the best supported clearance mechanisms are designed to remove old RBCs well before significant decrement in individual cells might compromise overall RBC functionality. Thus, redundancy in mechanisms to ensure timely clearance is not surprising. RBC aging is reported to involve decreased metabolic rate, accumulation of oxidative damage, alterations in and loss of cell membrane, decreased cell volume, increased density, and increased immunogenicity.[48] Given the inability of RBCs to synthesize new proteins, aging changes depend mostly on modifications of pre-existing molecules that activate complex molecular pathways. These pathways will ultimately result in a nonlinear, nonrandom, rapid terminal stage process culminating in RBC clearance by the reticuloendothelial system.[3]

Morphological Changes and Membrane Modulation

The RBCs undergo multiple morphologic changes, such as loss of cell membrane with membrane-bound hemoglobin by vesiculation and loss of cations, which result in decreased cell volume and increased deformability.[48] Approximately 15–20% of hemoglobin is gradually lost by vesiculation over the RBC's life span with greater loss in the second half of the life span. These vesicles are removed, at least in part, by a process similar to the "pitting" of Heinz bodies by the spleen.[84] Vesiculation is also associated with the removal of senescent cell antigens, perhaps preventing premature removal of RBCs. These vesicles are characterized by the presence of glycophorin

A, PS, and IgG on their outer membrane and, thus, are rapidly removed from circulation by phagocytosis.[83]

Decreased cell volume and modulation of the cell membrane result in decreased membrane fluidity and decreased levels of sialic acid and thrombospodin-1 receptor (CD47). CD47 is an integrin member of the Ig superfamily that binds to the signal-regulatory protein alpha (SIRP α), a transmembrane protein on macrophages forming a "don't eat me" signal.[54] Conversely, there is an increase exposure of "eat me" signs, such as PS.[6,48]

Accumulation of Oxidative Damage

ROS are a family of unstable reactive molecules derived from molecular oxygen generated continuously as a by-product of metabolism.[87] The ROS family includes free radicals such as superoxide anion (O_2^-), nitric acid (NO^-), hydroxyl radical (HO^-), and reactive compounds such as hydrogen peroxide (H_2O_2), peroxynitrite ($ONOO^-$), hypochlorous acid (HOCl), and lipid radicals.[8] When in excess, ROS are implicated in the oxidation of biological molecules such as nucleic acids, proteins, carbohydrates, and lipids.[11]

RBCs are particularly susceptible to oxidative injury because of continuous exposure to endogenous and exogenous sources of ROS. Erythrocytes accumulate large amounts of hemoglobin during development. Hemoglobin is an iron–porphyrin–protein complex, whereas iron is a pro-oxidant element and transforms H_2O_2 into the most reactive free radical OH^-.[69] Auto-oxidation of hemoglobin to methemoglobin and O_2^- also represents an endogenous source of ROS production.[56] Exogenous sources include ROS released from neutrophils, macrophages, and endothelial cells, primarily in the microvasculature,[56] and exposure to oxidants.

Given their high susceptibility, RBCs also have intricate antioxidant mechanisms that prevent ROS generation, neutralize ROS, or limit deleterious effects of ROS. The primary oxidant defense mechanism consists of components that will directly intercept ROS intracellularly, including SOD, catalase (CAT), GPx,[56] thioredoxin reductase (TrxR)/thioredoxin (Trx),[58] and the peroxiredoxin-2 system (PRDX2).[60] Other mechanisms include plasma membrane oxidoreductases, which are electron transport systems that enable erythrocytes to respond to changes in redox environments.[40] The absence of nuclei in mature erythrocytes makes them even more susceptible to oxidative damage given their inability to synthesize new proteins in response to oxidative insults.

RBCs' aspartate amino transferase (AST) activity declines significantly with aging.[33] AST is one of the enzymes responsible for glutamate biosynthesis. The RBC membrane is impermeable for this amino acid. AST uses serum aspartate and α-ketoglutarate (permeable) to reversibly form oxaloacetate and glutamate.[18] Glutamate is necessary for the synthesis of GSH, which plays a central role protecting RBCs from oxidative damage.

RBC oxidative stress has been implicated in shortening of the RBC's life span and in impairing cellular deformability needed for effective oxygen transport and delivery to tissues.[56] Furthermore, defects in enzymes critical to antioxidant responses are implicated in the mechanism of mild chronic to severe acute hemolysis.[55]

The most common consequence of oxidant injury to RBCs is the formation of methemoglobin, eccentrocytes, and Heinz bodies. Cat erythrocytes are remarkably sensitive to systemic oxidative injury attributed to the presence of eight reactive sulfhydryl groups per hemoglobin molecule. When the number of free radicals exceeds antioxidant defenses, oxidation of the sulfhydryl groups on the globin chains will form Heinz bodies.[10] This can result in acute life-threatening hemolytic anemia (Heinz body anemia)[10] or can be responsible for decreased erythrocyte life span without anemia due to increased RBC clearance via oxidative stress-induced eryptosis (discussed in the following text).[42]

Several indications of compromised antioxidant capacity have been observed in dense and in vivo aged RBCs from various species. A few examples include decreases in total free thiol and reduced GSH, glutathione reductase activity, and increases in methemoglobin,[31] membrane-bound hemichrome (denatured hemoglobin),[35] and lipid peroxidation by-products.[32] Although there has been controversy over the significance of reported compromises in antioxidant defenses,[12] the presence of irreducible denatured hemoglobin bound to membranes is difficult to dismiss as clear evidence of antioxidant decline. At least two different pathways have been proposed whereby interaction of oxidized Hgb with the membrane might lead to RBC removal. One is hemoglobin–spectrin cross-linking leading to increased membrane rigidity, decreased deformability, and/or stimulation of membrane proteolysis with subsequent breakdown in membrane integrity.[75] In the other pathway, oxidized Hgb binds to and clusters band 3 protein leading to opsonization and clearance.[80,86]

A number of other lesions in senescent RBCs have been proposed as playing a role in clearance. With evidence for some decline in antioxidant capabilities, there is also a risk of lipid peroxidation that could facilitate RBC removal by either compromising deformability[66] or triggering recognition by macrophages.[72] The latter is suggested to occur through exposure of PS on the outer leaflet of the lipid bilayer. Whether secondary to oxidative injury, depletion of energy, or other mechanisms, there is ample evidence that the presentation of negatively charged PS on the outer layer of RBCs leads to phagocytosis by macrophages.[6,72]

IgG Binding

Autologous immunoglobulin binding to the most dense (presumably aged) human RBCs and increased phagocytosis of these RBCs by autologous macrophages were first described by Kay.[39] Fab-dependent IgG binding and phagocytosis suggested the involvement of specific receptor recognition by the IgG.[38] Supporting Kay's findings, several other density-gradient-centrifugation-based studies have also reported increased immunoglobulin binding in the most dense RBCs.[35] Furthermore,

using the mouse hypertransfusion model of in vivo aging, autologous IgG was identified only in the oldest RBCs and was associated with in vitro phagocytosis.[73] Increased IgG binding to dog biotinylated RBCs ≥104 days old has been demonstrated, although the ability of the IgG binding to mediate phagocytosis was not tested.[9] By contrast, in vivo aged rabbit biotinylated RBCs failed to show terminal increases in IgG binding,[14] which further highlights the need for caution in extrapolating information between species. In the rabbit biotinylation model, older RBCs were found to expose more PS than younger RBCs.[6] This may well be an important mechanism for clearance of senescent RBCs in the rabbit where IgG binding does not appear to be a significant factor.[14] Recognition of PS exposure on RBCs by macrophages can be at least partially mediated by lactadherin, a PS-binding glycoprotein produced by macrophages.[15]

The identity of the epitope responsible for antibody binding to senescent RBCs has been controversial, although it is not unreasonable to consider that more than one epitope may develop and that this could vary between species. The anion transport protein (band 3 on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE)) has received the most support as an important site, although other sites such as glycophorin A and aminophospholipids have also been proposed. Band 3 reportedly becomes antigenic through either proteolytic cleavage revealing a 62 kDa immunoreactive fragment, or by horizontal redistribution of the transmembrane protein into immunoreactive clusters. Exposure of the cryptic 62 kDa antigen by proteolysis is proposed to occur as a consequence of cumulative oxidative injury.[37] Interestingly, cat RBCs exposed to activated neutrophils show evidence of proteolysis and increased IgG binding.[82] These changes contribute to the accelerated clearance of RBCs in the anemia of inflammatory disease due to a combination of oxidation and serine protease activity. Lower level, cumulative injury could conceivably play a role in RBC injury and clearance under normal homeostasis, as described by Kay et al.[37]

The role of band 3 clustering in initiating autologous antibody binding has been well documented in senescent and diseased RBCs.[35] It is theorized that unclustered band 3 does not sustain antibody binding because the senescent cell IgG binds weakly and requires a two-point attachment to form a stable association. Normally, the distance between band 3 molecules is too great for the binding of both Fab portions of IgG. Clustering of band 3 can be accomplished by several methods, including binding of denatured Hgb at the cytoplasmic domain of band 3 or by chemical agents such as zinc, melittin, and acridine orange.[76] These chemical agents also cause autologous IgG binding apart from hemichrome formation, supporting the premise that it is the clustering of band 3 and not the oxidation process per se that creates the signal for IgG binding.[76] Removal of the clustering agents leads to reversal of the clustered distribution and elution of antibodies.

Denatured Hgb has a specific high-affinity binding site on the cytoplasmic domain of band 3. This binding leads to a horizontal redistribution of band 3 into a clustered arrangement that is then recognized on the external surface by autologous antibodies. This pathway illustrates how an early intracellular compromise in maintaining reduced Hgb could initiate a morphologic change on the external cell surface leading to opsonization and phagocytosis. Membrane aggregates showing enrichment and colocalization for hemichromes, band 3, and IgG have been identified in a variety of conditions, including dense human RBCs,[35] sickle RBCs,[36] and thalassemic RBCs.[86] The pathway of Hgb denaturation leading to band 3 clustering and opsonization is at least partially supported by in vivo RBC aging studies. Dog biotinylated RBCs show increased membrane-bound Hgb and increased IgG binding late in the RBC life span, although these changes have not yet been specifically colocalized to band 3 clusters,[70] as has been documented in the human studies.

Opsonization of RBCs secondary to band 3 clustering may play a notable role in the pathogenesis of several hemolytic anemias of significant importance to veterinary medicine. Heinz body hemolytic anemia occurs in several species as a result of exogenous intoxicants and, in the cat, associated with certain metabolic diseases. Because Heinz bodies bind to the cytoplasmic domain of band 3, subsequent clustering and opsonization may lead to an immune-mediated component in clearance of these cells.

Zinc intoxication in dogs is frequently associated with severe hemolytic anemia. Strong regenerative responses with spherocytosis and inflammatory leukograms have led clinicians to initially diagnose this as immune-mediated hemolytic anemia. Given the clear role of zinc in clustering of band 3 with subsequent opsonization, this toxicity is likely an immune-mediated process. Although initially counterintuitive, this condition is consistently reported as Coombs-test-negative. However, this is very consistent with the reversible nature of band 3 clustering by zinc. Washing of the RBCs removes zinc, and presumably leads to dispersion of the band 3 clusters and elution of the antibodies.

Complement

Another factor likely to be important in the efficient removal of IgG-opsonized RBCs is amplification of the signal by complement. Turrini and coworkers showed that when band 3 in human RBCs was clustered using $ZnCl_2$, a sequence of IgG binding, complement binding, and in vitro phagocytosis followed.[76] Phagocytosis was maximal in the presence of clustered band 3, IgG, and complement. Inactivation of complement reduced phagocytosis by 80%, which demonstrated IgG's weak capacity to initiate phagocytosis alone and emphasized complement's importance in amplification. However, phagocytosis was virtually eliminated if IgG or band 3 clustering was removed, showing the

absolute requirement for these steps. This work complemented previous reports describing the presence of C3b–IgG complexes on oxidatively stressed and density-gradient-derived "senescent" human RBCs.[47] Interestingly, only low numbers of IgG (an increase of <20 IgG/RBC) were needed to stimulate significant complement deposition.[47] Quantitative studies on antibody binding to dense RBCs have generally reported an increase of only a few hundred IgG per RBC.[35,38] With amplification, this degree of antibody binding should be a more than adequate signal to initiate phagocytosis.

RBC Programmed Cell Death

Programmed cell death of erythrocytes (eryptosis) is a coordinated mechanism to eliminate injured cells before senescence occurs. In this process, RBCs undergo shrinkage, blebbing, and surface exposure of PS with subsequent phagocytosis of eryptotic cells and particles.[42] Shrinkage happens, at least in part, by an increase in cytosolic Ca^{2+}, which stimulates calcium-sensitive K^+ channels and parallel efflux of Cl^-; thus, driving water out of the cell, which results in shrinkage. Increased intracellular Ca^{2+} is also involved in membrane blebbing by stimulation of the Ca^{2+}-dependent cysteine protease calpain, which degrades the cytoskeleton. In addition, Ca^{2+} stimulates the calcium-dependent enzyme scramblase, which flips the PS-rich cytosolic leaflet of the plasma membrane, exposing PS.[19]

Many substances trigger eryptosis by increasing cytosolic Ca^{2+} including arsenic, aluminum, lead, lithium, selenium, and zinc, as well as amphotericin B, leukotriene C4, retinoic acid, and hemin.[42] When cell shrinkage occurs, RBCs release platelet-activating factor (PAF), which activates an erythrocyte sphingomyelinase promoting the breakdown of sphingomyelin, resulting in ceramide formation. Ceramide further stimulates eryptosis by enhancing the effects of Ca^{2+} in eryptotic RBCs.[43] Given that PAF activity does not require increased cytosolic Ca^{2+}, this mechanism is Ca^{2+}-independent.[45] Triggers of eryptosis through the effect of ceramide include amyloid, copper, and vitamin K3.[42] Eryptosis may also be elicited by ligation to specific surface antigens such as CD47, CD95 (first apoptosis signal receptor, FasR), and glycophorin C.[19]

Oxidative stress may also trigger eryptosis by activation of Ca^{2+} and Cl^- channels promoting Ca^{2+} influx and Cl^- efflux, contributing to cell shrinkage.[17] RBCs also express oxidant-sensitive caspases; pro-caspase-3 present in mature RBCs is cleaved to active caspase-3 when oxidative stress is present.[53] Caspase-3 targets band 3 in RBC membranes weakening the band 3 and protein 4.2 interactions and increasing PS exposure.[51,53] Mature RBCs also contain Fas, FasL (Fas ligand), Fas-associated death domain (FADD), and caspase 8. Their presence is associated with loss of aminophospholipid translocase activity and with PS externalization, suggesting that Fas-dependent signaling processes play a role in regulating RBC clearance through PS exposure.[52]

Excessive eryptosis may cause anemia; although with adequate regeneration there may be a compensated hemolytic process (normal Hct and reticulocytosis). In addition, excessive eryptosis may hamper microcirculation due to the binding of eryptotic bodies to endothelial cells.[43]

Several disorders are associated with excessive eryptosis including iron-deficiency anemia, diabetes, renal insufficiency, hemolytic anemia, sepsis, and myelodysplastic syndrome.[42] Interestingly, acceleration of eryptosis tends to limit the life span of intraerythrocytic pathogens limiting their growth, as noted in *Plasmodium falciparum* infection in human RBCs.[44]

EPO, the most potent stimulator of erythropoiesis, can inhibit eryptosis by its actions on Ca^{2+}-permeable channels.[59] In the same fashion, catecholamines, endothelin 1, and NO also counteract eryptosis.[42]

Most of the studies of eryptosis are based on human or rodent animal model RBCs. Thus, it is likely that variation might occur between other veterinary species. Future studies to determine additional or species-specific triggers and inhibitors of eryptosis, additional pathways and interactions, as well as the role of eryptosis in the pathogenesis of diseases are needed for animal species.

RBC DESTRUCTION

The primary organs of RBC clearance are the spleen, liver, and bone marrow. Phagocytized RBCs are digested within macrophage phagolysosomes, and hemoglobin is dissociated into heme and globin. Globin is further digested and resulting amino acids are reutilized. Heme breakdown produces iron, biliverdin, and small amounts of carbon monoxide. Heme oxygenase-1 (HO-1) is the rate-limiting enzyme in heme degradation and is responsible for release of iron. Heme iron may be stored in macrophages or exported to the circulation by ferroportin.[16,61] Biliverdin is converted within the macrophage to bilirubin (unconjugated, Bu) that is relatively water-insoluble. As bilirubin leaves the cell, it attaches noncovalently to albumin to improve solubility and to be transported to the liver. Bu uptake by hepatocytes and conjugation with glucuronides (most species) produce the water-soluble conjugated bilirubin (Bc) that is excreted by active transport into biliary canaliculi for excretion into the intestines. There Bc is broken down to urobilinogen which is either reabsorbed or is converted to stercobilinogen, which contributes to the dark brown color of feces, and excreted. Reabsorbed urobilinogen is either taken up by hepatocytes and excreted in the bile or enters general circulation and is excreted in the urine.

Acronyms and Abbreviations

Advia, Advia 2120®, 120, or 2120I; AO, acridine orange; BCB, brilliant cresyl blue; CH retic, hemoglobin concentration reticulocyte; CHr, cell hemoglobin of reticulocytes; EDTA, ethylenediaminetetraacetic acid; LaserCyte® hematology analyzer; ProCyte dx, IDEXX Laboratories ProCyte dx® hematology analyzer; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCVr, mean corpuscular volume reticulocyte; mRNA, messenger ribonucleic acid; NMB, new methylene blue; RBC, red blood cell; Sysmex, Sysmex XT 2000iV® TO, thiazole orange.

This chapter describes technical aspects of enumeration of reticulocytes and Heinz bodies. Related material is described in Chapters 25, 32, 142, and other chapters. Evaluation of reticulocytes is a critical step in the evaluation of anemia (see Chapter 25). One major type of anemia is Heinz body anemia and that diagnosis requires detection and enumeration of the number and approximate mass of Heinz bodies in erythrocytes.

RETICULOCYTE STAINING AND COUNTING

Reticulocytes are the stage in the maturation of erythroid cells between the metarubricytes and mature RBCs. Reticulocytes lack a nucleus but retain some ribosomal mRNA material. The basic principle of different methods identifying reticulocytes is to stain mRNA in the cells so that they can be differentiated from mature RBCs and nucleated RBCs. Both manual and automated methods can be used. The preferred specimen for reticulocyte quantification is anticoagulated blood, usually as EDTA. Specimens are suitable for clinical diagnosis if stored at room temperature for up to 48 hours and likely up to 4 days at 4 °C. Specimens should be free of clots, hemolysis, or other gross defects. Sample-induced errors (usually false increases) in reticulocyte counting include Howell–Jolly bodies, Heinz bodies, basophilic stippling, blood parasites, and large platelets with abundant RNA.[19] Factors that affect determination of the total RBC count affect the absolute reticulocyte count.

Manual Methods

RNA is a polyanion and can be stained with many cationic dyes including brilliant cresyl blue (BCB), new methylene blue (NMB), purified azure B, acridine orange (AO), thiazole orange (TO), auramine O, oxazine 750, polymethine, and pyronin Y. The two stains used most frequently for manual counting of reticulocytes in blood smears are new methylene blue (1% NMB in saline plus 1.6% potassium oxalate) and brilliant cresyl

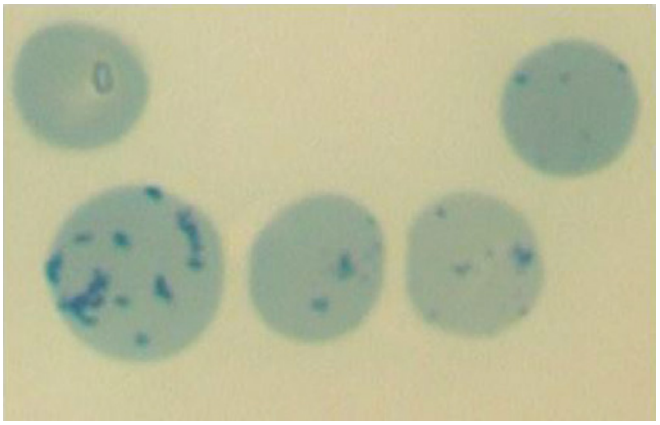

FIGURE 23.1 Feline reticulocytes. The photo shows three punctate reticulocytes on the right, an aggregate reticulocyte on the lower left, and an erythrocyte (with an artifact) on the upper left. The upper right punctate reticulocyte has three dots (ribosomal material) and it therefore just makes the definition of a reticulocyte.

blue (1% in saline). Equal amounts of blood and stain are mixed and allowed to stand at room temperature: 10 minutes for NMB and 15–30 minutes for BCB. One may increase the proportion of blood if the animal is very anemic. The mixture is remixed, and blood smears are made. Purified azure B has been recommended to replace new methylene blue or brilliant cresyl blue.[18] Counterstaining with a Romanowsky stain (e.g., Wright–Giemsa) gives a darker reticulum with BCB. For birds, mix three drops NMB to one drop EDTA blood and allow the mixture to incubate at room temperature for 10 minutes before making the smear.

Microscopic evaluation of 1000 stained non-nucleated erythroid cells is used to determine the percentage of reticulocytes. That percentage multiplied by the absolute erythrocyte count gives the absolute reticulocyte count per given volume (microliter or liter). Other granular material may be present and should be recognized. Heinz bodies stain a lighter blue with BCB and NMB than the more intensively colored purple reticulocyte granules.

Reticulocytes are defined as RBCs that contain more than two dots of ribosomal material. This is not to indicate that cells with one to two dots have too little mRNA to be reticulocytes, but that reticulocyte stains often have granular precipitate and cells with more than two dots are more certainly reticulocytes. Identification of the division between feline aggregate and punctate reticulocytes is more difficult and subjective (Figure 23.1). Tvedten defines aggregate reticulocytes as having more than 15 dots or as RBC having one or more aggregates of dots. Reticulocytes counted in birds should be the ring form reticulocyte, in which aggregates of ribosomes are arranged in a ring around at least half of the nucleus. Estimation of polychromasia is easier than identifying reticulocytes in birds.[12]

Automated Methods

Automated systems have better precision and accuracy than manual methods because much larger numbers of cells are enumerated, interobserver variation is avoided, and variation in staining quality such as stain precipitates and staining intensity is minimized. Time needed to perform the test is greatly decreased; therefore, reticulocyte evaluation has become routinely available. The coefficient of variation for manual counting of reticulocytes may be 8–23%, while for flow cytometric counting it may be less than 3%. However, stains and detection methods vary in sensitivity and specificity.[13] Automated reticulocyte counts may be erroneously increased due to the presence of Heinz bodies, Howell–Jolly bodies, blood parasites, and leukemic cells.[3,14]

Automated veterinary instruments, designed for reference laboratories and validated to enumerate canine, feline, and equine reticulocytes, include the Sysmex® and the Advia®.[13] The Sysmex XT 2000iV® uses fluorescence flow cytometry with a semiconductor laser for enumerating reticulocytes. Cells are stained with polymethine, a fluorescent stain, which is optimized to stain RNA. The IDEXX ProCyte dx® and the new Sysmex XN-V® also use that method. In one study, Sysmex® canine reticulocyte counts had high correlation ($r = 0.90$) with manual counts.[13] Sysmex® reticulocyte counts in cats (Figure 23.2) correlated well with manual aggregate reticulocyte counts ($r = 0.86$), but not with manual punctate reticulocyte counts ($r = 0.50$). A mean positive bias of the Sysmex® reticulocyte count over the manual aggregate count was about 6% (range −2% to +19%). This suggested that some punctate reticulocyte were included with the Sysmex® automated reticulocyte count. Equine reticulocytes were detected by the Sysmex®, but too few were seen in manual reticulocyte counts to validate any accuracy. The highest absolute reticulocyte counts were seen in horses with highest RBC counts and in foals.[13]

The automated reticulocyte analysis of the Advia uses a reagent solution formulated to maintain pH 7.4 as a preferred value, with an osmolality preferably about 292 ± 5 mOsm. At these pH and osmolality ranges, the concentration of the cationic dye, oxazine 750, required for RNA staining is preferably about 9.0 µg/mL to about 10.5 µg/mL. The buffer enhanced penetration results in the dye staining RNA in the reticulocytes in about 20–30 seconds or less. The concentration of dye in the reagent of the method minimizes nonreticulocyte staining of mature RBCs, which leads to a good signal separation from the background noise.[5,27]

The Advia 2120® automated reticulocyte counts (Figure 23.2) had excellent correlation to manual reticulocyte counts in 32 dogs ($r = 94$, slope 0.98) and to manual feline aggregate reticulocyte counts in 33 cats ($r = 94$, slope 1.16) (unpublished data). However, there was poor correlation with feline punctate reticulocytes. Equine reticulocytes are reported by the Advia.[25]

Two in-clinic hematology instruments (IDEXX LaserCyte® and Oxford Science ForCyte®) have been evaluated for reticulocyte counting in dogs and had fair correlation coefficients compared with the Advia, and moderate random error for canine reticulocyte counting.[1] The LaserCyte® compared well with the Advia for feline reticulocyte counts. The LaserCyte uses NMB to

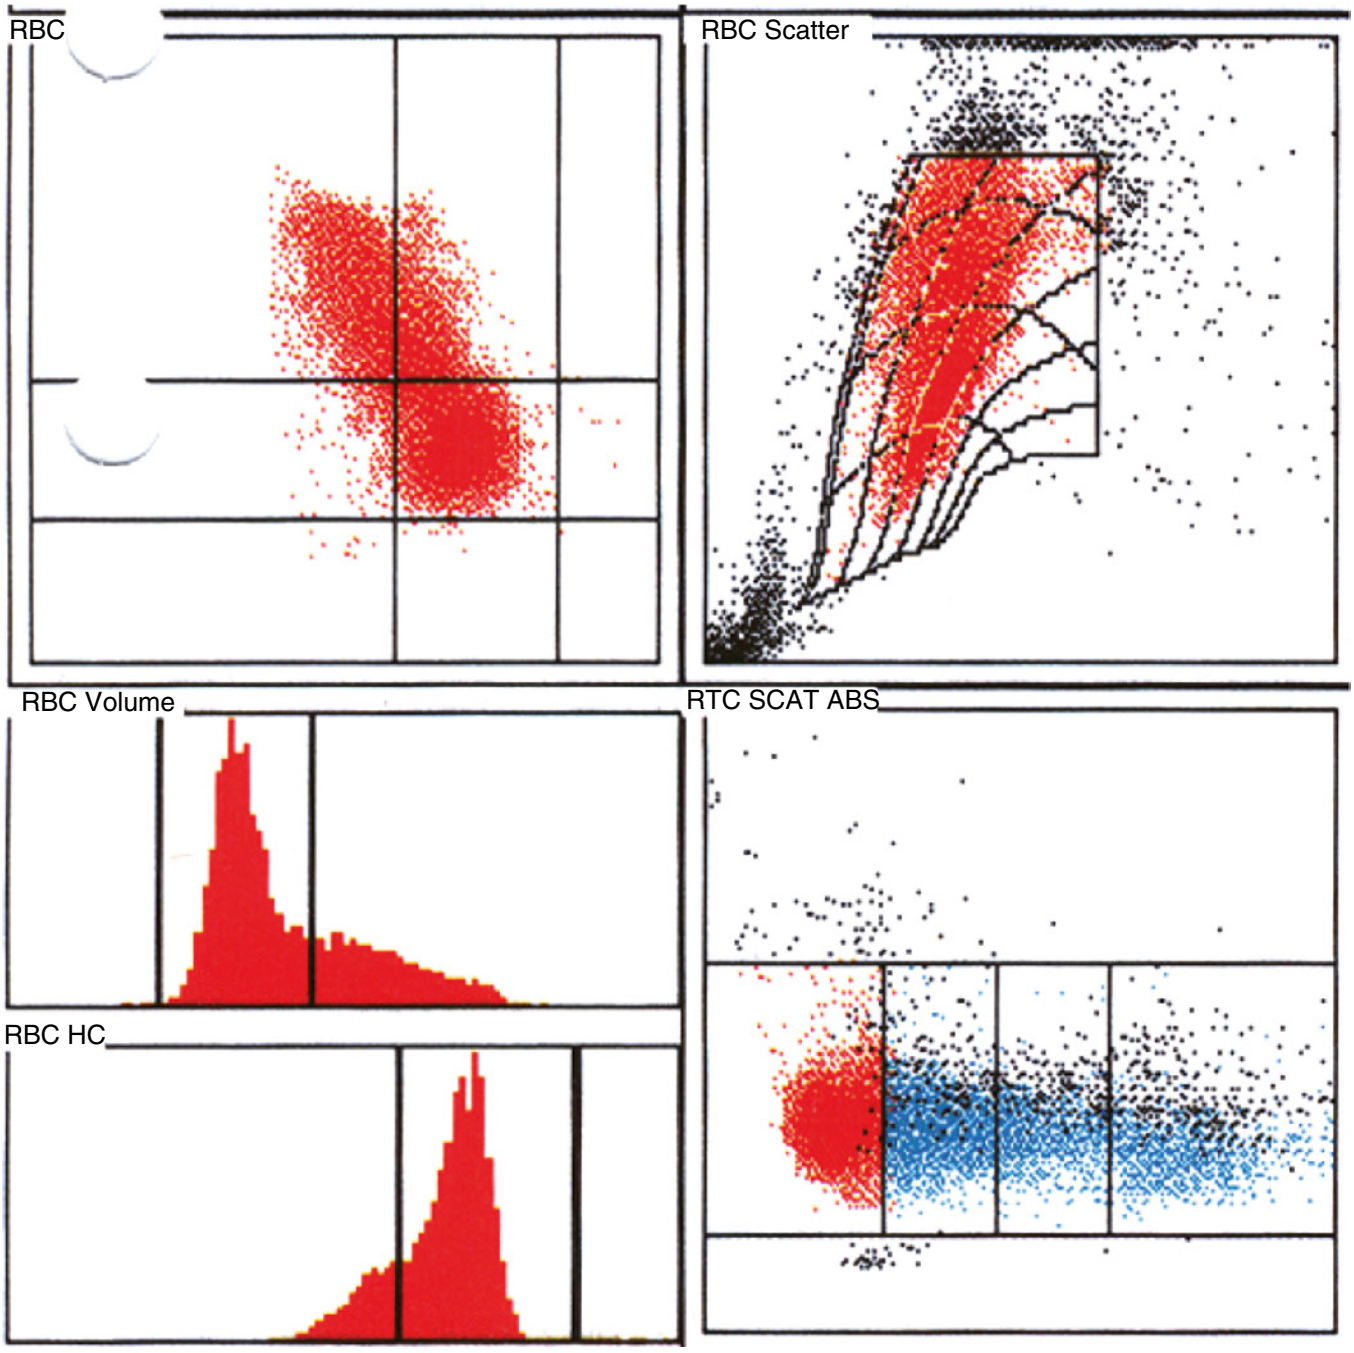

FIGURE 23.2 Advia 2120 graphics of a dog with a regenerative anemia and 21% reticulocytes. The RTC SCAT ABS cytogram (lower right) shows reticulocytes as blue dots extending to the right of mature RBCs (red). The reticulocytes are divided into three groups based on RNA content. Those to the far right have the most RNA. The other four graphics show RBCs analyzed by size and hemoglobin concentration. These illustrate well-distinct populations of mature normocytic normochromic RBCs and immature macrocytic hypochromic RBCs. The RBC Scatter cytogram colors cells red that were considered to be mature erythrocytes. Black dots were cells not considered to be erythrocytes or reticulocytes.

stain reticulocytes, which are then differentiated from RBCs by different extinction and laser light scatter. The LaserCyte was compared to Advia and manual reticulocyte counting in 250 anemic dogs in which two-thirds had a regenerative anemia defined by more than $60 \times 10^3/\mu L$ reticulocytes on manual counts.[26] Weissert et al. found fair correlation ($r = 0.66–0.72$), but a negative bias combined with a proportional error for the LaserCyte® absolute reticulocyte count compared to the manual and Advia methods. Thus, they recommended instrument specific cut-off values for the LaserCyte to separate nonregenerative from regenerative anemia which have reticulocytes of $<35 \times 10^3/\mu L$ or $>75 \times 10^3/\mu L$, respectively.[26] Evaluation of the IDEXX ProCyte

dx® showed moderate imprecision for reticulocyte counts in the dog and cat with coefficients of variation of 16% and 22%, respectively, compared to the Advia and fair correlation for cat reticulocytes (r_s = 0.77).[10]

Other stains, such as TO, AO, and auramine O, have been used for flow cytometry evaluation of reticulocytes.[5] Perkins and Grindem[18] showed that of these three dyes, TO best identified distinct peaks corresponding to aggregate and punctate reticulocytes from cats, while using a dedicated reticulocyte cytometer, the Sysmex R-1000, and a software package, Retic-count® (Becton Dickinson Immunocytometry Systems, San Jose, CA). Thiazole orange was brighter than auramine O or AO, but required longer incubation times, and the commercially prepared reagent was expensive. Punctate reticulocytes appeared as a widened RBC peak or a shoulder off the mature peak. Aggregate reticulocytes formed a separate peak. Indistinct separation of the punctate reticulocytes required a standardized protocol and use of template histogram regions. Percentages of automated counts correlated fairly well manual count results.[18]

Reporting Methods

Reticulocytes are reported both as a percentage of nonnucleated RBCs and absolute number per liter or microliter. The absolute number of reticulocytes is recommended for interpretation. However, the total RBC count is needed to calculate the absolute count (RBC × percent reticulocytes; see Chapter 22).

Reticulocytosis without Anemia

In a multicenter study, Fuchs et al. evaluated 3956 cats and 11 087 dogs admitted to seven German veterinary clinics.[7] Reticulocytosis without anemia (RWA) was observed in a low proportion of blood samples: 3.1% (124/3956) in cats and 4.4% (492/11 087) in dogs.[9] Scanning electron microscope studies on the red pulp in the spleen of cats and dogs indicate that immature erythroid cells attach to splenic macrophages.[2,11,22] Therefore, one explanation previously given for reticulocytosis in nonanemic dogs was that it could be a physiologic reaction to excitement, in which splenic contraction results in increased reticulocyte numbers in blood.[4] But only 1.8% of cats and 1.5% of dogs with reticulocytosis without anemia were considered healthy in the study by Fuchs.[9] Diseases associated with RWA included blood loss/anemia, cardiac/respiratory disorders, gastrointestinal disorders, and inflammatory disorders, as well as cancer. Increased RBC turnover may have resulted in a reticulocytosis without anemia. The severity of underlying causes/conditions is reflected in a mortality rate of approximately one-third of patients: 38% in cats and 30% in dogs with reticulocytosis without anemia.[9]

Other Indicators of Reticulocyte Status

The Advia hematology analyzer identifies the volume and hemoglobin concentration of each individual RBC analyzed and keeps track of which erythroid cells are reticulocytes or erythrocytes (Figures 23.3 and 23.4). The Advia can report reticulocyte size (MCVr) and hemoglobin concentration (CHr) and several other indices. CHr and MCVr have been shown to be sensitive indicators of iron deficiency and response to therapy in dogs (Figure 23.3).[6] Reticulocytes in iron deficiency are relatively smaller (more microcytic) than normal reticulocytes. But reticulocytes in iron deficiency are still relatively macrocytic and hypochromic compared to the patient's own erythrocytes (Figure 23.3). Reticulocyte indices may be monitored for diagnosis and response to treatment. For example, when assessing values after experimental iron replacement in iron-deficient dogs, the MCVr increased from 65 fL before iron treatment to 82 fL after 11–12 days of iron supplementation, and CHr increased from about 16 pg up to 22 pg.[6] Note that CHr may also be reduced in portosystemic shunting, anemia of inflammation, and breed-associated microcytosis.[21]

The hematology analyzer ProCyte dx reports a reticulocyte hemoglobin equivalent (RET-He, new: RETIC-HGB), which is used similarly to CH retic in the diagnosis of iron deficiency.[8]

HEINZ BODY STAINING AND COUNTING

Heinz bodies are formed from denatured, precipitated hemoglobin resulting from oxidative damage. See Chapter 32 for different causes. Oxidation of sulfhydryl groups causes denaturation of hemoglobin. Oxidation of the exposed β-93 cysteine residues present in hemoglobin results in sulfhemoglobin formation.[20] Sulfhemoglobin and denatured hemoglobin are less soluble than normal hemoglobin, so they precipitate to form Heinz bodies that bind to the cell membrane. Oxidation damage to the membrane causes eccentrocyte formation.

Manual Methods

Heinz bodies may be seen on blood smears routinely stained with Romanowsky-type stains if they are large enough to bulge from the surface of the RBC or if they appear lighter and somewhat refractive compared to the rest of the hemoglobin in the RBC. Heinz bodies are more clearly seen in ghost cells as hemoglobin colored bodies attached to the RBC membrane (Figure 23.4). Heinz bodies are more easily evaluated on blood smears stained for enumeration of reticulocytes (e.g., NMB- or BCB-stained smears) (Figure 23.4 and Chapter 32). For birds, two drops of NMB can be mixed with one drop fresh EDTA blood and incubated at room temperature for 30 minutes before making the smear.[15]

Heinz bodies may be small, granular, and numerous, and may be mistaken for reticulocytes (Figures 23.4 and 23.5) in blood smears with reticulocyte staining. This error may falsely elevate the reticulocyte count. Small granular Heinz bodies may not be

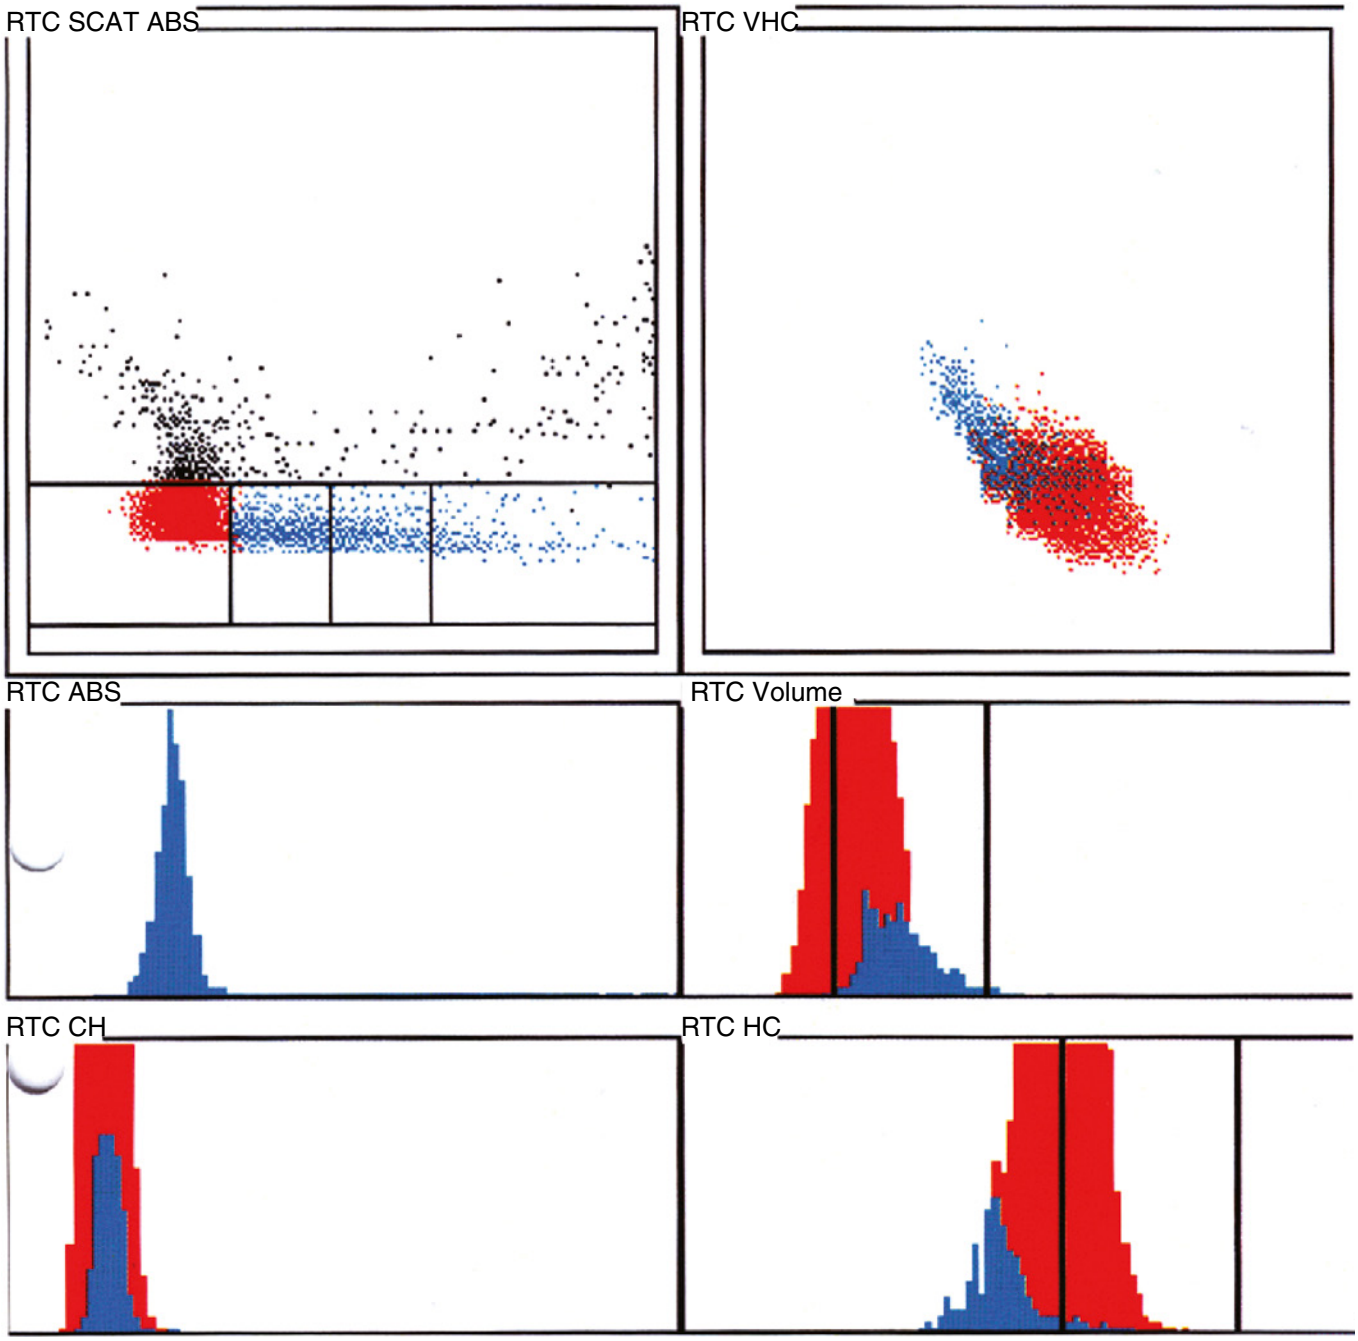

FIGURE 23.3 Advia 2120 reticulocyte graphics from a dog with iron deficiency. Note that the reticulocyte (RTC) cluster in RTC SCAT ABS cytogram (upper left) is lower along the y-axis than the cluster in Figure 23.2, reflecting that reticulocytes in iron deficiency anemia are smaller than normal reticulocytes. But the reticulocytes (colored blue) were macrocytic and hypochromic when compared to the patient's mature RBCs colored red RTC VHC cytogram, RTC volume histogram, and RTC HC histogram.

recognized as such to those expecting a single large round Heinz body seen typically in cats. Heinz bodies stain a lighter blue than ribosomal material in reticulocytes on NMB- or BCB-stained smears, so should not cause confusion with reticulocyte identification. Howell–Jolly bodies are nuclear remnants, stain a darker purple, and have a more distinct border than Heinz bodies.

The total mass of denatured hemoglobin (Heinz body material) is reflective of the magnitude of toxic injury; therefore, reports should indicate whether Heinz bodies are small or large, how much granular Heinz body material also is present in the RBC, and how much other damage to RBC is seen. Blood turbidity may be measured to estimate the amount of Heinz body material.[16]

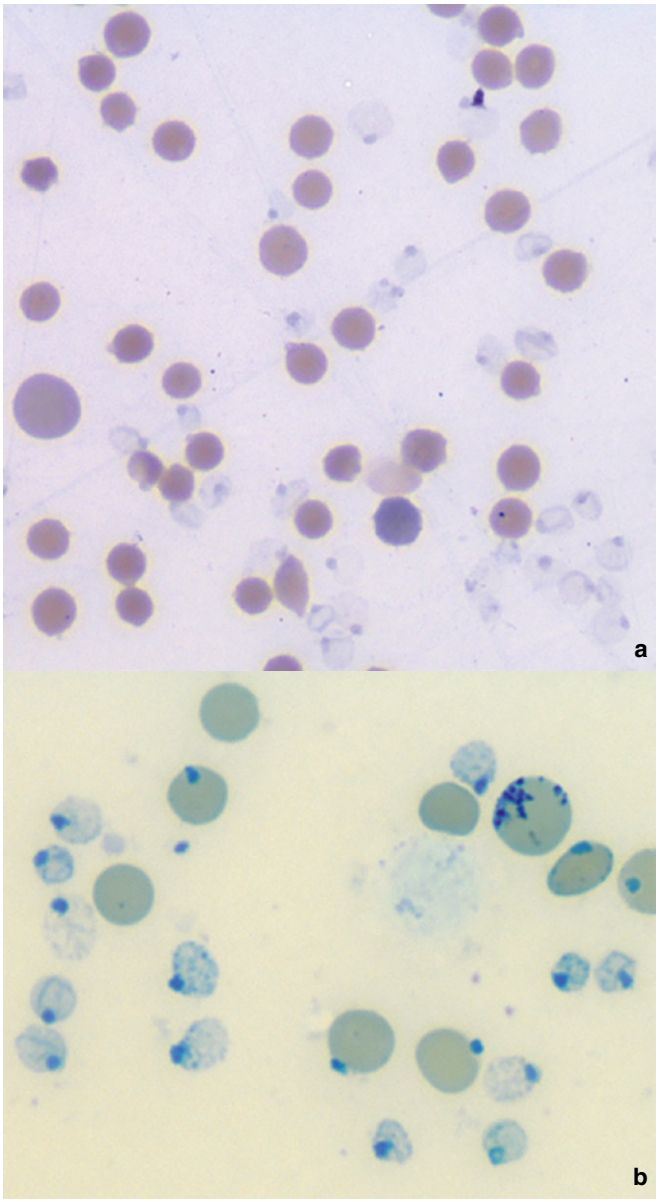

FIGURE 23.4 Blood smear of a lamb with copper poisoning. (a) May–Grünwald–Giemsa stain. Larger Heinz bodies are seen in some of the intact erythrocytes, but even many small Heinz bodies are seen in ghost cells; (b) A brilliant-cresyl-blue-stained smear in which Heinz bodies are more apparent. There is only one reticulocyte (upper right). The small Heinz bodies can easily be mistaken for reticulocytes.

Oxidative toxins that form Heinz bodies also cause other changes such as methemoglobin formation, eccentrocytes, ghost cells, and pyknocytes. These other disease changes (and the presence of Heinz-body-induced artifacts, see in the following text) should be evaluated before a final hematology report is released from the laboratory. The presence and severity of those additional changes should be included in the report. The pattern and amount of change in Heinz bodies,

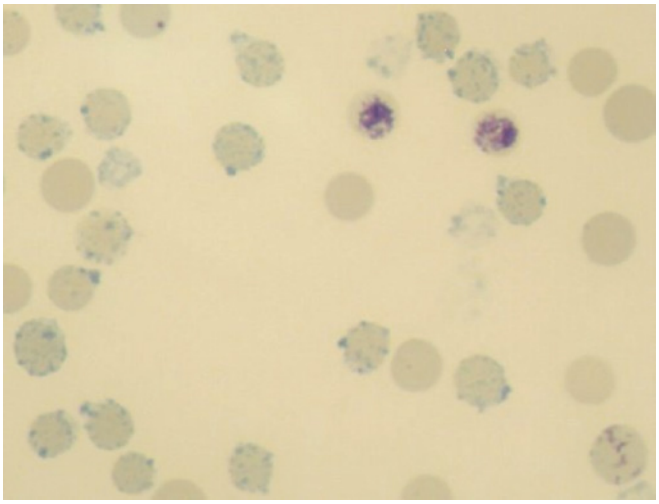

FIGURE 23.5 Brilliant-cresyl-blue-stained blood smear of a dog with onion toxicity. There are only two reticulocytes with dark blue–purple granules in the upper right. Most of the RBCs have many small Heinz bodies which are lighter-blue-stained granular bodies.

eccentrocytes, and methemoglobin vary with different oxidative toxins and species.[17]

Heinz bodies in the blood sample may cause artifacts such as false increases in the mean corpuscular hemoglobin (MCH) and the mean corpuscular hemoglobin concentration (MCHC). The errors cause an overestimation of hemoglobin concentration. These errors are due to suspended Heinz bodies causing increased optical density of lysates of blood for hemoglobin concentration determined by spectrophotometric methods and also by increased high-angle scatter of erythrocytes containing Heinz bodies evaluated by laser hematology instruments.[23]

Species Variations

The size of Heinz bodies varies greatly. Heinz described them as 1–2 μm in diameter in dogs, rabbits, and guinea pigs. They are largest in cats, in which they may be up to one-third the diameter of the RBC.[24] Heinz bodies in cats are predominately distinct, large round structures. However, in dogs and other species, they may be multiple, small granular bodies that can be mistaken for reticulocytes (Figures 23.4 and 23.5).

Acronyms and Abbreviations

DIC, disseminated intravascular coagulation; FAD, Flavin adenine dinucleotide; GN, glomerulonephritis; HJ, Howell–Jolly body; IMHA, immune-mediated hemolytic anemia; MCV, mean corpuscular volume; NMB, new methylene blue; nRBC, nucleated red blood cell.

Evaluation of RBC morphology is a critical step in thorough blood smear evaluation and can aid in identifying many different metabolic disorders, indicate oxidative damage, or help localize a disease process. There are four features of red blood cell morphology that should be evaluated: color, size, shape, and inclusions.

NORMAL ERYTHROCYTE MORPHOLOGY AND DISTRIBUTION

The typical RBC shape for multiple veterinary species is the disc or biconcave disc (i.e., discocyte) resulting in a high surface area to volume ratio making the RBCs deformable. Central pallor can be observed to variable degrees in these species on examination of a peripheral blood smear. Central pallor is most prominent in the dog and less so in cats and horses. Poikilocytosis is a frequent finding in young ruminants and is considered to be normal, especially in goats (Figure 24.1). In certain deer breeds, antelope, and some breeds of sheep and goats, drepanocytes (also termed *sickle cells*) can be observed in vitro. This phenomenon occurs when the oxygen tension of blood is high (e.g., exposure to atmospheric oxygen during mixing of samples or smear preparation) or the pH is between 7.6 and 7.8. The sickling is due to variants of hemoglobin that form insoluble, elongated polymers under these conditions.[25]

The monolayer of the peripheral blood smear allows for evaluation of red blood cell arrangement. In most species, RBCs are individualized; however, some species are prone to rouleaux formation in which the RBCs line up in a column, resembling a stack of coins (Figure 24.2). Although it may be a normal finding in cats and horses, it can be accentuated by elevated plasma protein concentrations.[25] Rouleaux must be differentiated from agglutination. Agglutination is disorderly aggregation of RBCs (Figure 24.3). Agglutination can be observed in immune-mediated hemolytic anemia (IMHA) and as an in vitro change in horses given heparin.[33] Rouleaux is disrupted by diluting the blood with saline, but agglutination is not (see Chapter 107).

VARIATION IN ERYTHROCYTE MORPHOLOGY

Hemoglobin Content

Many species will have low numbers of circulating reticulocytes. This can result in noticeable polychromasia and anisocytosis. A polychromatophilic RBC contains organelles such as ribosomal RNA and mitochondria. When stained with a Romanowsky stain, the presence of these structures will cause the cytoplasm to stain grayish-blue (Figure 24.4). The RNA network and organelles precipitate, becoming more obvious if the blood is stained with new methylene blue (NMB). Increased polychromasia can indicate a regenerative response to anemia, but is not as sensitive as a reticulocyte count because not all reticulocytes are polychromatophilic. Horses do not have circulating reticulocytes and thus do not have polychromasia in their peripheral blood.

Patients with iron deficiency anemia can develop hypochromasia (see Chapter 27). Since iron is necessary for heme synthesis, erythrocytes from patients with iron deficiency can have decreased hemoglobin content. These cells have a thin rim of hemoglobin with increased area of central pallor (Figure 24.5). True hypochromasia needs to be differentiated from torocytes. A torocyte is usually considered an artifact.[25] These cells have an increase in central pallor, but it is abrupt rather than a gradual decrease in the rim of hemoglobin. Other causes of hypochromasia include prolonged copper deficiency or deficiency of vitamin B6.[20]

Cell Size

Anisocytosis is a general term that describes variation in cell size. Healthy animals will have mild anisocytosis, likely from the presence of low numbers of circulating reticulocytes. Reticulocytes are often larger than mature erythrocytes, so they are described as macrocytes. Other causes of macrocytosis include feline leukemia virus,

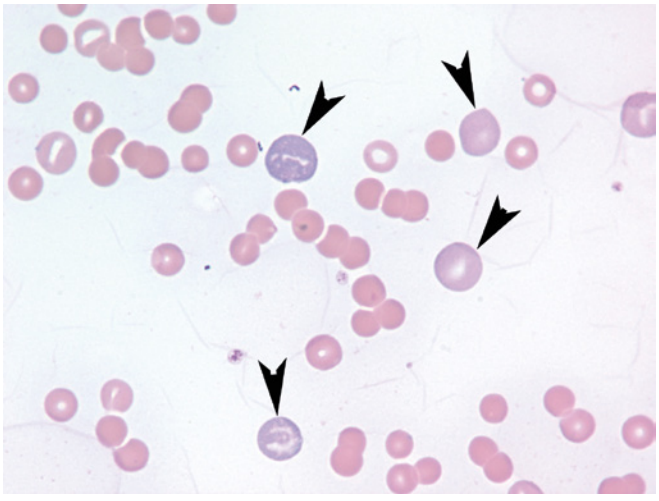

FIGURE 24.4 Blood smear from a dog showing polychromatophilic RBCs (arrows). These cells are larger than mature RBCs with grayish-blue cytoplasm. Wright–Giemsa stain.

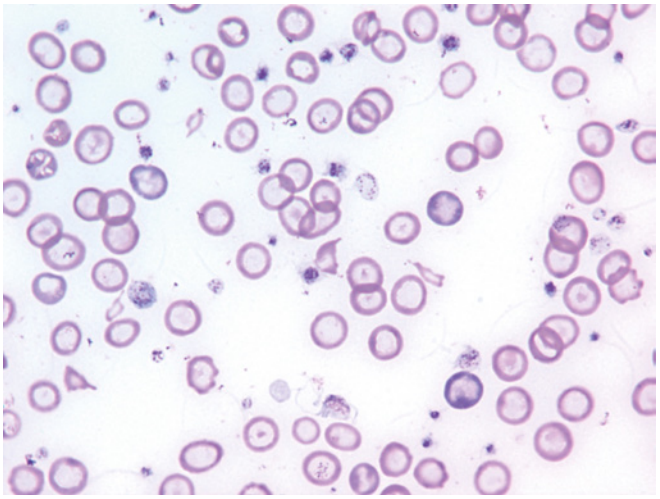

FIGURE 24.5 Blood smear from a dog with iron deficiency anemia. Notice marked hypochromasia. Wright–Giemsa stain.

myelodysplastic syndromes, and some congenital and hereditary conditions (see Chapters 30, 31, and 67). Generally, animals with these conditions will have an overall increase in their mean corpuscular volume (MCV). Microcytosis or small red blood cells can be observed with several different disease processes, the most common of which is iron deficiency (see Chapter 27). Due to the impaired heme synthesis, the red blood cells undergo an additional division. Other causes of microcytes include hereditary microcytosis (Akita and Shiba Inu) and familial dyserythropoiesis of English Springer Spaniels (see Chapter 31).[18,25]

Poikilocytosis

Poikilocytosis is a general term for variation in RBC shape; it can occur in a variety of conditions, so poikilocytosis is nonspecific. Further, some species are more prone to poikilocytosis than others. For instance, echinocytes are a common finding in pigs. Goat kids less than 3 months of age and some adults, particularly adult angora goats, are prone to marked poikilocytosis. Their RBC can vary in shape, and triangular, spindle, fusiform, matchstick, oblong, and pear-shaped erythrocytes can be observed. Anemic goats can form hemoglobin C, which makes them more prone to poikilocytosis.[25,27] Camelids, avians, and reptiles have oval RBCs as their normal shape. Types of poikilocytes and the common disease and associated species can be found in Table 24.1.

Acanthocytes

Specific changes occurring in the membrane structure, hemoglobin condition, and bone marrow architecture can result in specific changes in RBC morphology. Acanthocytes have irregularly spaced spicules generally 2–20/cell. The name is derived from the Greek for "thorn" (Figure 24.6). The changes in the RBC membrane of these cells are associated with increased cholesterol content of the membrane, which is thought to

Hyponatremia	Dog
Normal breed characteristic	Dog (Akita, Shibas)

expand the outer layer of the lipid bilayer; however, other studies suggest acanthocytes can also result from RBC fragmentation.[47] In dogs, liver disease, portosystemic shunts, hemangiosarcoma, disseminated intravascular coagulation (DIC), lymphosarcoma, gastrointestinal disease, glomerulonephritis (GN), osteosarcoma, and high cholesterol diets have been associated with acanthocytosis.[22,43,47,48] In cats with liver disease, acanthocytes are reported as the most common poikilocyte.[10]

Codocytes

Codocytes (also termed target cells) resemble a bull's eye (Figure 24.7). They have a central area of hemoglobin surrounded by a pale rim with hemoglobin at the periphery of the cell. Similar to acanthocytes, codocytes have an increased amount of cholesterol resulting in an overall increase in the surface area of the erythrocyte membrane. Codocytes are often observed in patients with iron deficiency, cholestatic liver disease, and postsplenectomy; however, codocytes are also frequent findings in regenerative anemias.

Dacryocytes

Dacryocytes are teardrop-shaped cells that may occur when the RBC membrane is damaged and distorted as cells pass through narrow marrow or splenic sinusoids (Figure 24.8).[25] In human medicine, these cells are commonly associated with myelofibrosis or myelophthisis. In dogs, they have been reported with myeloproliferative disorders and hypersplenism.

Eccentrocytes

Eccentrocytes (also termed erythrocyte hemighosts) are RBCs with eccentrically shifted hemoglobin within the cell, leaving a pale, hemoglobin-free area.[21] These cells may progress to pyknocytes, which are eccentrocytes in

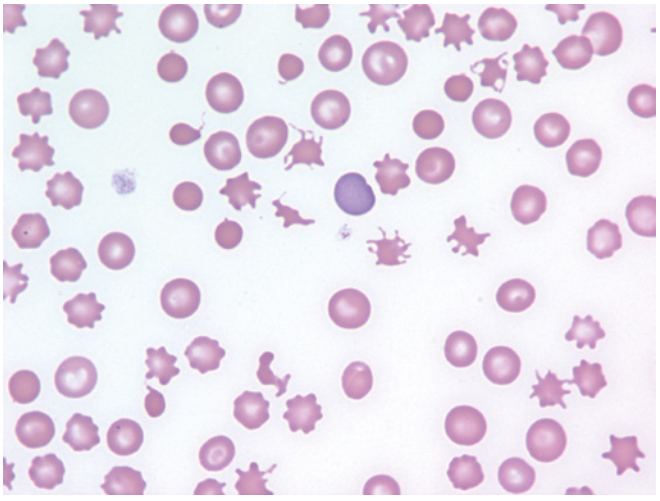

FIGURE 24.6 Blood smear from a dog showing acanthocytes with varying numbers of irregularly spaced projections. Wright–Giemsa stain.

which the cell membrane has collapsed. Eccentrocytes have been reported to be easier to visualize on NMB-stained preparations.[36] These cells are associated with oxidative damage to the erythrocyte membrane and cytoskeleton.[6] In horses, eccentrocytes have been observed with red maple toxicity (*Acer rubrum*), erythrocyte glucose-6-phosphate dehydrogenase deficiency, and flavin adenine dinucleotide (FAD) deficiency (see Chapter 32).[21,41] In dogs, eccentrocytes have been observed with ingestion of substances known to cause oxidative damage, such as onions, vitamin K, garlic, and acetaminophen. Additionally, eccentrocytes have recently been described in dogs with diabetes mellitus, T cell lymphoma, and severe infections.[6] Cattle receiving intravenous hydrogen peroxidase may have circulating eccentrocytes.[42]

Echinocytes

Echinocytes are spiculated red blood cells with evenly dispersed, short projections. Their shape can vary from discoechinocytes to highly spiculated spheroechinocytes or even ovaloechinocytes (Figure 24.9). Echinocytes can be subclassified based on particular morphologic features. Type I echinocytes have irregular or angular edges, but do not have distinct spicules. Type II echinocytes have multiple blunt spicules. Type III echinocytes are ovoid or spherical with 10–30 regularly spaced spicules. Echinocytes (also termed crenation) can occur as an artifact from sample handling, prolonged sample storage, or during slide preparation. These cells occur commonly in pigs, in vitro.[15] Echinocytes form when the outer leaflet of the lipid bilayer of the RBC membrane is expanded relative to the inner layer. Mechanisms of echinocyte formation include depletion of ATP, administration of amphipathic drugs, calcium loading, or when RBCs are dehydrated. In dogs, echinocytes have been reported with glomerulonephritis, lymphoma, hemangiosarcoma, and other neoplasms, immune-mediated hemolytic anemia, pyruvate kinase deficiency, rattlesnake envenomation, and doxorubicin

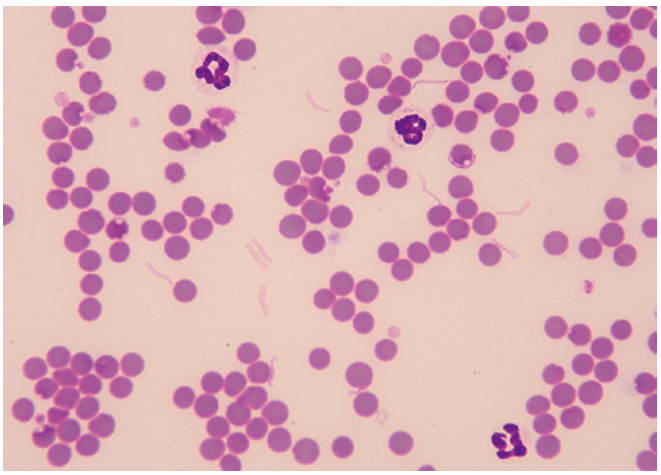

FIGURE 24.10 Blood smear from a dog with viper envenomation. Many erythroid loops are noted. Wright–Giemsa stain. (Image courtesy: Dr. Carlo Masserdotti.)

toxicosis among others.[3,5] In one study, dogs with greater than 90% echinocytes were used to confirm a clinical suspicion of rattlesnake envenomation[8] (Figure 24.10). In addition to echinocytes, small structures, termed "erythroid loops," have been identified as a result of viper venom.[31] Cats likely have echinocytes with many of these diseases as well, but echinocytes have been specifically reported with chronic doxorubicin administration.[35] In horses, echinocytes have been observed with diseases causing hyponatremia and hypochloremia, such as colitis or exercise.[17,25]

Elliptocytes

Elliptocytes are oval-shaped, non-nucleated RBCs that are normal in camelid species. In people, hereditary ovalocytosis has been associated with a protein band 3 abnormality as well as mutated spectrin.[12,37] In veterinary species, ovalocytes are occasionally described

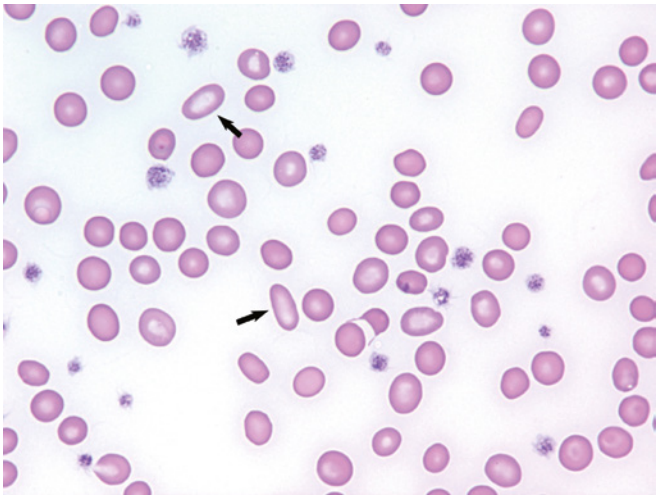

FIGURE 24.11 Blood smear from a dog. Ovalocytes are indicated with arrows. Wright–Giemsa stain.

(Figures 24.9 and 24.11). Hereditary ovalocytosis has been reported in a dog with protein band 4.1 deficiency,[40] but also in myelofibrosis, glomerulonephritis, and myelodysplastic disease.[23] In cats, elliptocytes have been reported with myeloproliferative disorders, hepatic disease, and with chronic doxorubicin administration.[10,35]

Keratocytes

Keratocytes are spiculated RBCs that frequently have only one to two spicules and indicate RBC fragmentation (Figure 24.12); thus, the RBC appears to have "horns" (*kerat* is the Latin term for *horn*). The formation of keratocytes has been associated with microvascular injury, especially when there is deposition of fibrin strands. The opposing sides of the damaged RBC may fuse leading to formation of a blister. Bursting of the blister is thought to result in progression to a keratocyte.[25] Keratocytes have been reported in cats with liver disease[10] and in dogs and cats with chronic doxorubicin administration and hemangiosarcoma.

Leptocytes

Leptocytes are thin RBCs that can fold and take on the shape of other poikilocytes such as codocytes, knizocytes (central fold giving the appearance of a central bar of hemoglobin), or stomatocytes. Leptocytes can be observed in iron deficiency and cholestatic liver disease.[25]

Schistocytes

Schistocytes are red blood cell fragments usually resulting from direct physical damage to RBCs secondary to vascular abnormalities or turbulent blood flow. The shape of the fragments may vary from pointed or triangular to spiculated (Figure 24.13). Microangiopathic fragmentation has been described in dogs in a several different disorders including DIC, GN, hemangiosarcoma, myelofibrosis, dyserythropoiesis, and chronic doxorubicin toxicosis.[3,13,47] Schistocytes have also been identified as a common feature of DIC in calves.[24] However, they are uncommon in the horse and cat,[14] though schistocytes have been reported in cats with hepatic disease.[10]

Spherocytes

Another result of RBC fragmentation is spherocytes. Spherocytes are RBCs that have lost their biconcave shape and have become round like a sphere. On a blood smear, these cells have lost their central pallor and appear slightly darker and often a little smaller than healthy RBCs (Figure 24.14). IMHA is a common cause of this poikilocyte. They occur secondary to antibody binding on the membrane or complement fixation. Part of the membrane may be phagocytized or just punctured resulting in the change in shape. These cells have

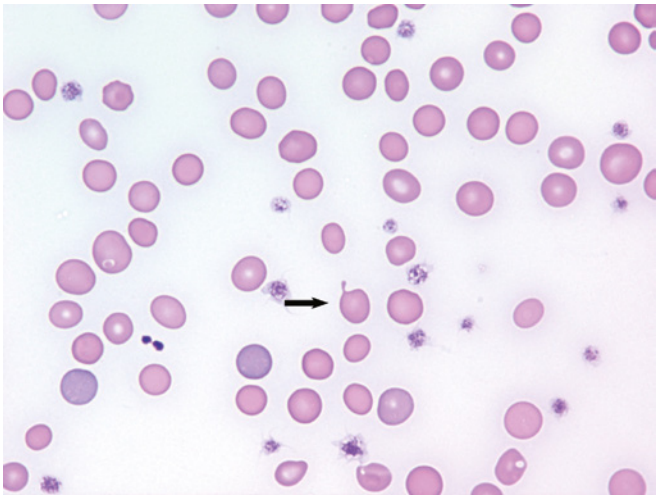

FIGURE 24.12 Blood smear from a dog. Occasional keratocytes are indicated by arrow. Wright–Giemsa stain.

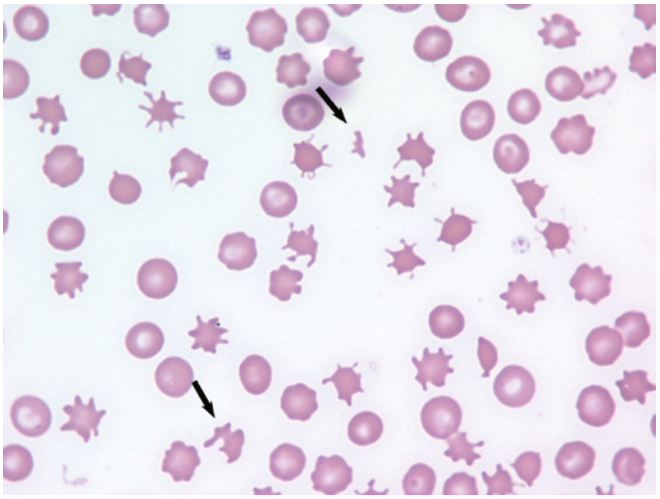

FIGURE 24.13 Blood smear from a dog. Severe poikilocytosis with schistocytes indicated with arrows. Wright–Giemsa stain.

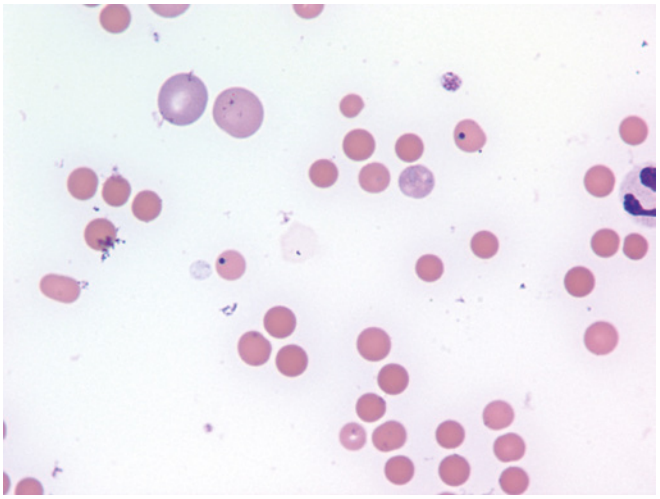

FIGURE 24.14 Blood smear from a dog showing many spherocytes. Wright–Giemsa stain.

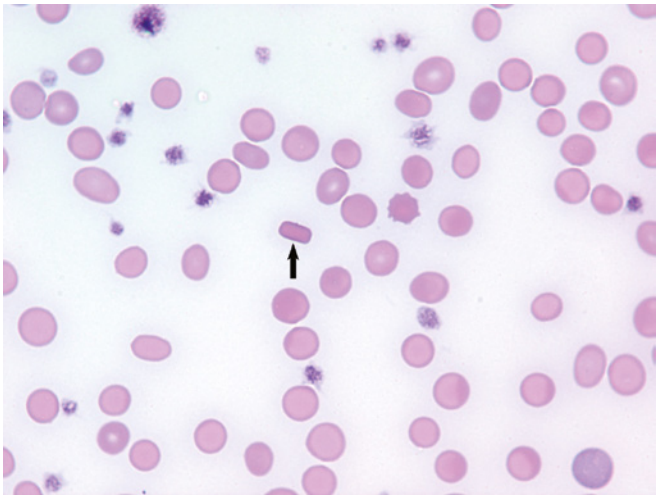

FIGURE 24.15 Blood smear from a dog showing hemoglobin crystals (arrow). Wright–Giemsa stain.

been associated with other diseases as well, including coral snake, rattlesnake and bee sting envenomation, and anaplasmosis infection in cattle.[34] Spheroechinocytes have been reported in Basenjis with pyruvate kinase deficiency and in goat erythrocytes treated with lysolecithin.[5,25,26] Spherocytes are most obvious in dogs, likely because they have prominent central pallor. In other species such as the cat and horse, spherocytes are difficult to identify.

Not all spherocytes are formed secondary to fragmentation. Spherocytes can be caused by a molecular defect in one or more of the proteins of the RBC cytoskeletal network. Double knockout mice with defects in actin-binding proteins affect erythrocyte shape and membrane integrity leading to pronounced spherocyte formation.[9] Spectrin deficiency has been identified in a group of Dutch Golden Retrievers (see Chapter 30).[39]

Stomatocytes

Stomatocytes are RBCs that have a narrow elongated band of central pallor resembling a mouth on dried blood smears. In actuality, these cells are more bowl-shaped in wet-mount preparations. Several breeds of dogs have been identified with hereditary stomatocytosis, including Alaskan Malamutes with concurrent chondrodysplastic disease, Drentse Patrijshond with stomatocytosis-hypertrophic gastritis, and Miniature and Standard Schnauzers (see Chapter 30).[4,38] The Drentse Patrijshonds often have a normal MCV, whereas the Schnauzers and Malamutes have an increased MCV.[4,38]

Hemoglobin Crystals

Hemoglobin crystals are unstable hemoglobin that precipitates in the RBC. These dense staining, rhomboid or rod-shaped crystals lead to decreased deformability of the erythrocyte (Figure 24.15). Crystals may be found in human patients with Hemoglobin C disease and sickle cell anemia, particularly after splenectomy. In veterinary medicine, hemoglobin crystals are infrequently reported, and their cause is uncertain. Nonetheless, they have been described in dogs, llamas, and horses with FAD deficiency.[7,41]

ERYTHROCYTE INCLUSIONS

Basophilic stippling represents the spontaneous aggregation of ribosomes and polyribosomes in RBC. In Romanowsky-stained samples, affected RBCs contain uniformly distributed punctate, basophilic structures (Figure 24.16). Basophilic stippling may be seen in cattle and other ruminants as a part of the regenerative response to anemia. It may be associated with exuberant regeneration in other species including the dog and cat. However, if basophilic stippling and increased numbers

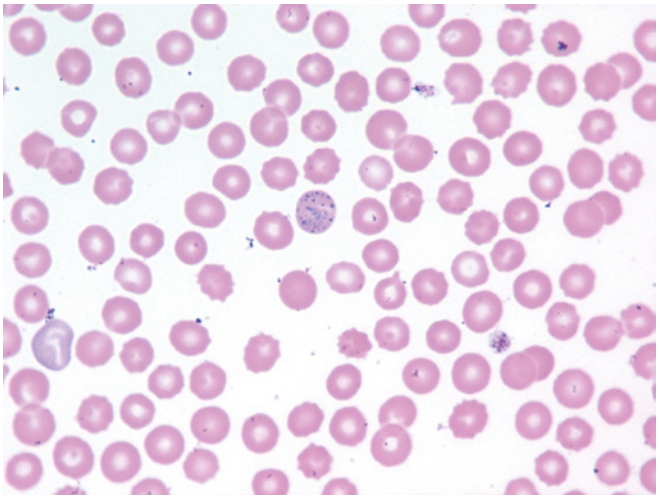

FIGURE 24.16 Blood smear from a dog showing basophilic stippling. Wright–Giemsa stain.

of nucleated RBC (nRBC) are present in the absence of a severe anemia, lead toxicity should be considered.

Cabot rings are ring or figure-eight-shaped structures identified as a normal finding in camelids and are thought to originate from the mitotic spindle.[29] These structures are not considered clinically significant in camelids; however, they have been reported in dogs with dyserythropoiesis.[29]

Nucleated RBCs in circulation can also be part of a regenerative response to anemia. These cells, depending on their level of maturity, usually have polychromatophilic or hemoglobinized cytoplasm and a round nucleus (Figure 24.17). The metarubricytes have a small, pyknotic nucleus, but less mature cells have a stippled chromatin pattern. When nRBCs accompany a regenerative response, polychromasia and anemia should also be observed. However, nRBCs may occur in the absence of anemia in diseases affecting the spleen and bone marrow. Myeloproliferative disorders and infiltrative marrow diseases such as solid tumor metastases and myelofibrosis can result in high numbers of nRBCs, occasionally with less mature erythrocyte precursors, rubriblasts, and prorubricytes in circulation. Low numbers of circulating nRBCs can be observed in splenectomized animals or in dogs or cats with hemangiosarcoma, hemophagocytic histiocytic sarcoma, and pure red cell aplasia.[19,30,46] Cats with myelodysplastic syndromes, hepatic lipidosis, upper respiratory infections, and hemangiosarcoma can have normoblastemia.[19] Lead toxicity is commonly associated with metarubricytosis; however, these patients are usually not anemic. Polled Hereford calves with congenital dyserythropoietic anemia and dyskeratosis are reported to have increased nucleated red blood cells in circulation and these cells often exhibit an atypical morphology.[28]

Nuclear remnants, not expelled as RBCs leave the bone marrow, are termed Howell–Jolly (HJ) bodies. They are round, deeply basophilic structures that may vary in size (Figure 24.18). Howell–Jolly bodies are normally removed by the spleen. However, in cats and horses, species having a nonsinusoidal spleen, low numbers are normally seen in circulation. Increased numbers of HJ bodies can be seen as part of a regenerative response to anemia, in animals with hypofunctioning spleens, or in splenectomized patients. There are also reports of increased numbers of HJ bodies in nonanemic miniature and toy poodles with hereditary macrocytosis (see Chapter 31).

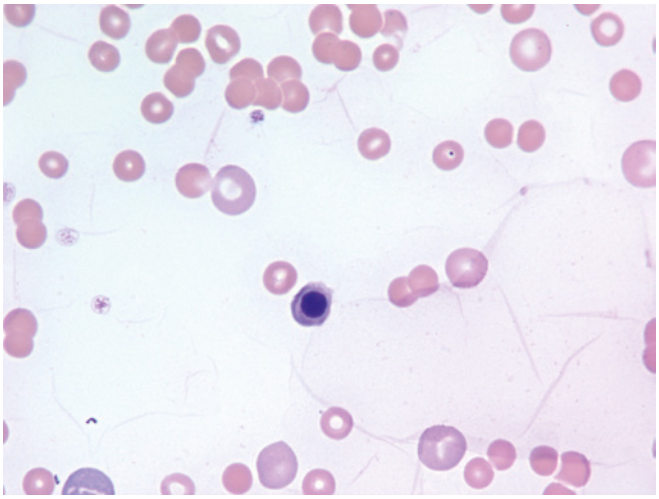

FIGURE 24.17 Blood smear from a dog showing occasional metarubricytes as part of a regenerative response. Wright–Giemsa stain.

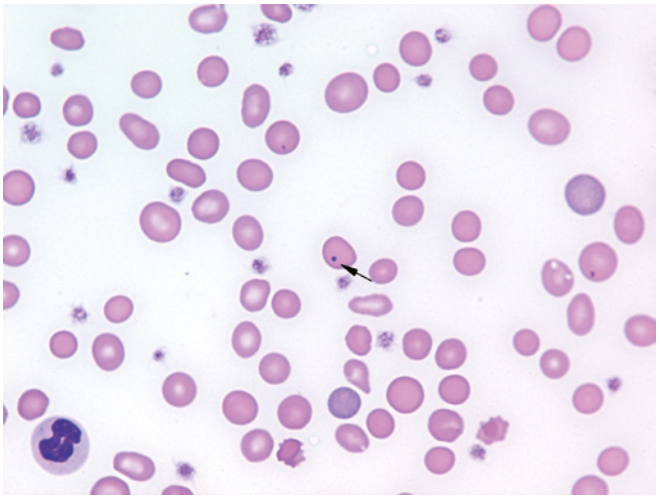

FIGURE 24.18 Blood smear from a dog. Howell–Jolly bodies are nuclear remnants observed in the cytoplasm of red blood cells (arrow). Wright–Giemsa stain.

Oxidative damage can result in a number of morphologic changes to the RBCs including the formation of Heinz bodies.[1,2,11,16,32,49] Heinz bodies are small aggregates of oxidized hemoglobin that can occur as hemoglobinized projections extending from the cell or as pale areas within the cell (Figure 24.19a). With Romanowsky stains, the Heinz bodies are pale or hemoglobinized, but with NMB, they are bluish-green and much more obvious (Figure 24.19b). Many toxins and diseases have been reported to cause Heinz bodies (see Chapter 32).

Iron observed in mature RBCs is referred to as siderocytes or Pappenheimer bodies. With Romanowsky stain, the iron appears as irregularly shaped, pale basophilic material, whereas ferric iron forms a bright blue pigment when stained with Prussian blue. Siderocytes have been reported in the blood in association with myeloproliferative disorders, lead toxicity, and hemolytic anemia. Sideroblasts are nucleated erythroid precursors with iron in their cytoplasm. These cells have been reported with myelodysplastic syndromes and myeloproliferative disorders and in inflammatory diseases in dogs and cats.[44–46]

Artifactual changes can occur that mimic true pathologic fragmentation or inclusions. Stain precipitate or drying artifact can mimic red blood cell parasites or inclusions such as HJ bodies. A commonly observed artifactual change associated with prolonged drying of blood smear preparations produces refractile RBC inclusions. Additionally, crenation of RBCs can occur as an artifact of drying. Usually, artifactual crenation will occur in thick areas of blood smear.

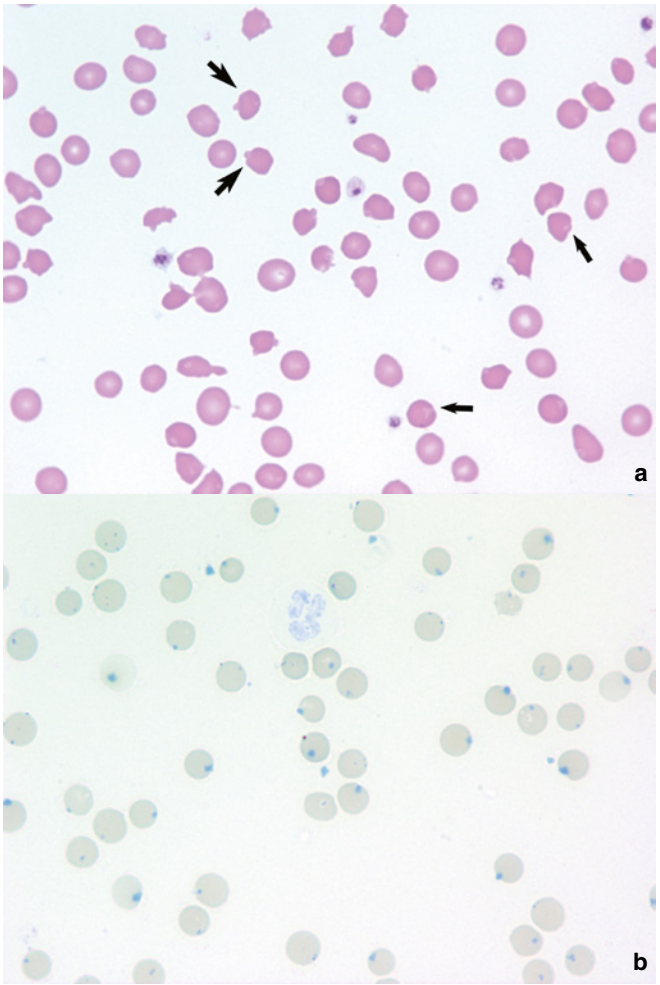

FIGURE 24.19 Blood smear from a cat. (a) Wright–Giemsa stain: Many Heinz bodies are observed and can appear as projections from the RBC membrane (large arrow) or as pale areas near the membrane (small arrow); (b) New methylene blue stain: Heinz bodies are more obvious with vital stains.

Acronyms and Abbreviations

Advia, Siemens Advia 2120® hematology system; CRP, corrected reticulocyte percentage; EIA, equine infectious anemia; FeLV, feline leukemia virus; fL, femtoliter; Hct, hematocrit; Hgb, hemoglobin; IMHA, immune-mediated hemolytic anemia; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; NRBC, nucleated red blood cell; PRCA, pure red cell aplasia; RDW, red cell distribution width; RPI, reticulocyte production index; RTC-VHC, reticulocyte volume hemoglobin concentration cytograms; Sysmex, Sysmex XT-2000iV® hematology system.

This chapter discusses initial and general diagnosis of anemia based primarily on laboratory findings. Erythrocyte morphology (see Chapter 24) and many specific causes of anemia are described elsewhere. Blood loss anemia diagnosis has expanded discussion in this chapter. Diagnosis of the cause of anemia uses certain characteristics of blood to place the anemia into pre-established classes or categories useful for diagnosis. Several classification systems are used and are based on various tests and observations. The systems overlap and classifications by one system (e.g., macrocytic hypochromic anemia) may be identifying the same change or process in RBCs as another classification (e.g., reticulocytosis, polychromasia, and regenerative anemia). Thus, different terms frequently lead to a similar diagnosis. Despite the classification system used, the goal of diagnosis should be to provide the most specific and correct diagnosis to allow appropriate treatment or other action by the attending clinician.

CLINICAL MANIFESTATIONS OF ANEMIA

The clinical signs that prompt an animal's owner to seek a clinician to diagnose and then treat an anemia include weakness, lack of stamina, pale mucous membranes, icterus, and hemoglobinuria or hematuria (red urine). Anemia which is too mild to cause these signs is more often detected by initial hematological examination of patients. The purpose of laboratory testing is to provide unbiased, objective evidence that supports or refutes a clinical or tentative diagnosis. Laboratory diagnosis of the cause of anemia should be based first on laboratory conclusions founded on numerical test results of hematology instruments, but also importantly on subjective interpretation of cell morphology in blood smears and graphical reports from hematology instruments. This avoids bias, which can come from submitting the clinician's tentative diagnosis, clinical signs, age, breed, and other clinical information. After making the basic

laboratory conclusions, the other sources of information should be utilized to influence the final conclusions or diagnosis. This permits laboratory results to suggest new possibilities not considered by the veterinarian submitting the sample and avoid "premature closure" too early in the diagnostic process.

PRESENCE AND SEVERITY OF ANEMIA

The first step in evaluation is to determine if the animal has anemia and, if present, to evaluate the severity. Laboratory parameters routinely used are hematocrit (Hct), total erythrocyte count (RBC count), and hemoglobin (Hgb) concentration. PCV is essentially the same as Hct, though implies a centrifugal method of analysis. Hematocrit will be used in this chapter to describe severity of anemia, but Hgb concentration is used often in Europe and in human medicine. Table 25.1 gives useful approximate guidelines. Hct versus PCV will vary a few percentage units.

If Hct, RBC count, and Hgb concentration are not similarly decreased in anemia, then erythrocytes are not normal in size and Hgb content. Changes in erythrocyte indices (mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC)) should help explain any discordance in relative decreases (see section on classification by erythrocyte volume and Hgb concentration later in this chapter). For example, in iron deficiency anemia with severe microcytosis, RBC count will not be decreased as much as Hgb concentration or Hct, and therefore not reflect the severity of the anemia as well. Even normal numbers of microcytic erythrocytes may not contribute to a normal Hgb concentration per unit volume of blood and the smaller erythrocytes will be packed into a smaller volume of the blood (PCV).

Pre-analytical and analytical errors may also cause discordance among Hct, Hgb concentration, and RBC count. For example, lipemia may erroneously increase Hgb concentration (and MCHC). This error among others indicates that hematology samples should be taken from fasted animals just as is recommended for chemistry analysis. Erythrocytes swell in EDTA with time, so Hct (and MCV) will be falsely increased in older samples (mailed in), while Hgb should still reflect the severity of an anemia. Heinz bodies may make erythrocytes more fragile, so they lyse in the microhematocrit centrifuge, lowering the PCV. Heinz bodies remaining in suspension after erythrocytes are lysed increase the optical density and falsely increase Hgb concentration. Heinz bodies in erythrocytes make them more optically dense to laser hematology instruments, also causing a falsely increased cell Hgb concentration and MCHC.

Severity of an anemia is useful in diagnosis. Table 25.1 provides some guidelines for classifying severity. Moderate to severe anemias are more likely important or primary problems. For example, primary bone marrow disorders like chronic myelofibrosis can cause very severe anemia (e.g., Hct 6–8%), while secondary suppression of bone marrow (e.g., anemia of inflammation) is characteristically mild to moderate. Severe anemia or rapid decline in erythroid mass should stimulate more aggressive diagnosis and treatment, while mild to moderate anemia in animals with severe inflammatory or neoplastic disorders is expected as a secondary problem.

Clinical information such as breed and age affect interpretation (see Chapter 140). Sight hounds like greyhounds normally have a higher Hct (about 50–65%) compared to other dog breeds (37–55%), and therefore a mild anemia in a greyhound will have a Hct within the reference intervals for most other canine breeds. Puppies have lower Hct than adult dogs (as well as lower plasma protein and higher reticulocyte numbers). For example, a 6-week-old puppy can have a Hct of 26–30%, reticulocytes of 4.5%, and plasma protein of 5.0–5.6 g/dL. Thus, a normal puppy can appear to have a regenerative, blood-loss-type anemia when using adult reference intervals for interpretation.

The patient's hydration status must be considered. Hematocrit reflects severity of anemia only when the animal has regained normal hydration and blood volume. It may take 1–2 days after blood loss before blood volume is restored to normal and the Hct shows the severity of the anemia.[2] Acute hemolytic anemia may also not have a Hct reflecting the severity of anemia at the time of presentation to a clinic.

TABLE 25.1 Guidelines for classification of severity of anemia.

	Dog	Horse	Cat/ruminant
Mild	30–37[a]	30–33	20–26
Moderate	20–29	20–29	14–19
Severe	13–19	13–19	10–13
Very severe	<13	<13	<10

[a]Values are hematocrit or packed cell volume in percent. Guidelines were determined by D. J. Weiss.

Appearance of Microhematocrit Tubes

Use the appearance of the plasma and buffy coat of the microhematocrit tubes to aid in diagnosis (Figure 25.1). Hemolytic anemia has often icterus or hemolysis seen in the plasma. The severity of the icterus or hemolysis is reflected by the intensity of the color. RBC fragmentation can be detected by noting a red layer on top of the buffy coat. Methemoglobin can give a brown or at least a darker color to the blood. Lipemia can be detected. Lipemia predisposes erythrocytes to lysis as an artifact. Lipemia will increase osmotic fragility, Hgb, and MCHC as an artifact.

CLASSIFICATION SYSTEMS

Classification by Strength of Erythropoiesis

Determination of bone marrow's effective erythropoiesis (function) divides anemia into those with no or relatively weak evidence of erythropoiesis (nonregenerative) or those with good evidence of active and effective erythropoiesis (regenerative) (Table 25.2). The anemia is classified

FIGURE 25.1 Examples of different appearances of microhematocrit tubes. (a) Tube from a normal dog; (b) Tube showing severe anemia with an increased buffy coat, which indicates an increase in leukocytes or platelets; (c) Severe anemia with icteric plasma and probable extravascular hemolysis or perhaps hepatic disease; (d) Severe anemia with hemolytic plasma, indicating possible intravascular hemolysis. A red layer above the buffy coat indicates the presence of RBC fragments; (e) Severe hemolysis and a thick layer of RBC fragments over the buffy coat; (f) Dog with leukemia and a very thick buffy coat; (g) Lamb with copper poisoning and severe methemoglobinemia indicated by the brown color; (h) Lipemia with whitish turbid plasma and a faint layer of RBC fragments on top of the buffy coat.

TABLE 25.2 Canine and feline relative and absolute reticulocyte guidelines.

		Feline	
Strength of regeneration	**Canine reticulocytes (%)**	**Aggregate reticulocytes (%)**	**Punctate reticulocytes (%)**
Relative			
None	1[a]	0–0.4[a]	1–10[a]
Weak	1–4	0.5–2	10–20
Moderate	5–20	3–4	20–50
Strong	21–50	>5	>50
Absolute			
None	60[b]	<15[b]	<200[b]
Weak	150	50	500
Moderate	300	100	1000
Strong	>500	>200	>1500

[a]Values are percentage of non-nucleated RBCs that are reticulocytes. The percentage of canine reticulocytes or feline aggregate reticulocytes should approximately predict the percentage of polychromatophils on a blood smear.
[b]Reticulocytes × 10^9/L or reticulocytes × 10^3/μL.

as regenerative if signs of increased erythropoiesis seem adequate for the severity of anemia, duration, species characteristics, treatments, and likelihood of multiple etiologies. Regenerative or responsive anemia should have normal bone marrow function. Regenerative anemias are caused by loss of erythrocytes from the body (external blood loss) or lysis of the erythrocytes within the body (hemolytic anemia and internal blood loss). Regenerative anemia is usually easier to diagnose than nonregenerative anemia. Nonregenerative anemia should have significant primary or secondary bone marrow dysfunction, which is often without an apparent cause.

Bone marrow regeneration in species that display consistent reticulocyte responses (e.g., dog, cat, pig, and rat) is usually evaluated by the reticulocyte response (see chapters on individual species characteristics). The strength of increase in the absolute reticulocyte count per unit volume of blood best reflects how effective bone marrow erythropoiesis is in the patient (Table 25.2). The percentage of reticulocytes is a ratio of reticulocytes to total non-nucleated erythroid cells. With increasingly more severe anemia, there are increasingly fewer mature erythroid cells. This exaggerates the % reticulocytes. If 1% reticulocytes is normal for a dog, 3% reticulocytes may sound increased, but if there are 1/3 as many erythrocytes, there has been no increase in the absolute number of reticulocytes released from the bone marrow. Absolute counts (% reticulocytes × total erythrocyte count) are preferred for interpretation. The corrected reticulocyte percentage (CRP) and reticulocyte production index (RPI) are other methods for interpreting the reticulocyte response when the total erythrocyte count (RBC) is not available to calculate an absolute reticulocyte count. Guidelines for and the clinical usefulness of CRP or RPI are not well established or widely understood in veterinary species.

Use Table 25.2 for approximate guidelines to interpret approximately how great an increase in reticulocytes indicates mild, moderate, or marked bone marrow responses. The value of 60 reticulocytes × 10^9/L (or 60 000 reticulocytes × 10^3/μL) in Table 25.2 is a mean, reference value for canine reticulocytes in general and should not be interpreted to mean that less than 60 × 10^9/L is nonregenerative and greater than 60 × 10^9/L is a regenerative anemia. This is a common error in interpretation and diagnosis. Diagnosis is not mathematics with one correct number. Use reference values for reticulocytes established for the particular hematology instrument used and species. For example, a reference interval for canine reticulocytes with the Advia 2120® is 10–110 × 10^9/L not <60 × 10^9/L.

Reticulocyte numbers are best interpreted at the time of an expected peak of reticulocytes, which is 4–8 days

after onset of the anemia. Guidelines for interpretation of reticulocyte numbers in Table 25.2 are for the peak reticulocyte response and may be misleading early in an anemia (i.e., pre-regenerative) when reticulocyte numbers have not increased yet, or late in an anemia when reticulocyte numbers decline (10–14 days).[6] Late in an anemia, the number of macrocytic hypochromic erythrocytes (Figure 25.2) is more reflective of the strength of the initial regenerative response than the reticulocyte number, which may be declining or back to normal.

Feline punctate reticulocytes have a long half-life in blood and therefore may accumulate in large numbers (Table 25.2). The kinetics of feline aggregate reticulocyte responses are similar to those of other species, but maximal responses are weaker (Table 25.2) than those expected in dogs.[6] Aggregate reticulocytes may not be increased unless the anemia is severe.

Microscopic identification of aggregate and punctate reticulocytes is time consuming and subjective when many reticulocytes are present (see Chapter 23). The automated reticulocyte counts of the Advia 2120 and Sysmex XT-2000iV® detect primarily feline aggregate reticulocytes and not punctate reticulocytes.[3] Use a quick screen of a reticulocyte-stained blood smear for an estimate of punctate reticulocyte percentages.

It is important that laboratories indicate the type of feline reticulocyte reported. Sometimes, only "reticulocytes" are reported without specifying the type. In Table 25.2, note that the number of aggregate reticulocytes indicating a strongly regenerative anemia is the same absolute number as the number of punctate reticulocytes indicating no regeneration. Duration of the feline regenerative response may be interpreted by pattern of changes in the two types of reticulocytes. A strong increase in aggregate reticulocytes but little to no increase in punctate reticulocytes indicates an early response (3–6 days after onset of anemia), while late in a response (9–20 days) there may be very many punctate reticulocytes, but no increase in aggregate reticulocytes.[6] The Advia erythroid graphics illustrate well the increased numbers of macrocytic hypochromic cells, and in the author's opinion are a better indication of an erythroid response than absolute reticulocyte numbers, especially later in the response.

Other indicators of effective erythropoiesis in anemia are less specific for erythropoiesis than reticulocytosis; however, these may be useful in species without consistent reticulocyte responses. Nucleated RBCs (NRBCs) are useful indicators in ruminants (e.g., cattle, llamas) to reflect regeneration.[5] NRBC numbers are frequently reported as a relative ratio of NRBC/100WBC, so marked changes in WBC count can affect this ratio. Basophilic stippling, especially in ruminants, and Howell–Jolly bodies suggest a regenerative anemia (Figure 25.5f). RBCs produced during active and increased erythropoiesis are larger. Thus, macrocytosis and anisocytosis suggest active erythropoiesis and may be the only indicators in peripheral blood of horses. Horses release very few or no reticulocytes into circulation. Macrocytosis and anisocytosis can be detected by the MCV (e.g., >52 fL in horses), RBC cytograms and histograms (Figure 25.3), or blood smear evaluation. RBC distribution width (RDW) indicates the amount of anisocytosis. NRBC, macrocytosis, Howell–Jolly bodies, and anisocytosis are caused by disorders other than regenerative anemia, such as glucocorticoid treatment, heat stroke, dysmyelopoiesis, myeloproliferative disorders, prolonged storage of EDTA blood, etc., and are thus not specific indicators of regeneration.

Classification by Erythrocyte Volume and Hemoglobin Concentration

Disease changes in erythrocytes may cause sizes that are microcytic (smaller), normocytic, or macrocytic (larger), and erythrocyte hemoglobin concentration changes are hypochromic (reduced) and normochromic (normal concentration). Hyperchromic changes (increased MCHC or increased optical density detected in erythrocytes by hematology instruments) indicate an erroneous result and not a disease-related change. Pre-analytic and analytic errors, such as hemolysis, lipemia, or Heinz bodies, cause artifacts that imply the erythrocytes contain more hemoglobin per unit volume than a normal cell filled with hemoglobin. The error causing a hyperchromic result should be identified by the laboratory and those results not reported to the veterinarian without explanation.

The three important diagnostic patterns are macrocytic hypochromic anemias (regenerative anemias with large, young RBCs that are not fully hemoglobinized), normocytic normochromic anemias (nonregenerative anemias with residual normal erythrocytes), and microcytic hypochromic anemias, which are usually iron deficiency anemias.

The MCV and MCHC are reported by most hematology instruments and have been used for this type of classification. MCV and MCHC are mean values (one single number) and as such unfortunately are too insensitive to usually and correctly identify the three main patterns. The numbers of abnormal erythrocytes are often too small to pull mean values like MCV or MCHC outside of wide reference intervals. Blind use of MCV and MCHC results may give erroneous conclusions like macrocytic normochromic anemia, which can suggest a completely incorrect cause.

Computer graphics (cytograms and histograms) of hematology analyzers such as the Advia 2120 (see Figure 25.2) can detect diagnostic changes in erythrocyte volume or Hgb concentration and are exceptionally good tools in anemia diagnosis. For example, microcytic hypochromic cells can often be detected in iron deficiency while the MCV and MCHC are still normal.

The Advia determines hemoglobin concentration by a spectrophotometric method (like most instruments), but also based on a summation of individual cell hemoglobin concentrations from its analysis of laser light scatter (Mie analysis). The latter is called cell hemoglobin concentration mean (CHCM), which is more correct in the case of lipemia causing a false increase in the spectrophotometric (cyanmethemoglobin) method.

Regenerative anemia in horses can be diagnosed by a macrocytic normochromic pattern on Advia cytograms

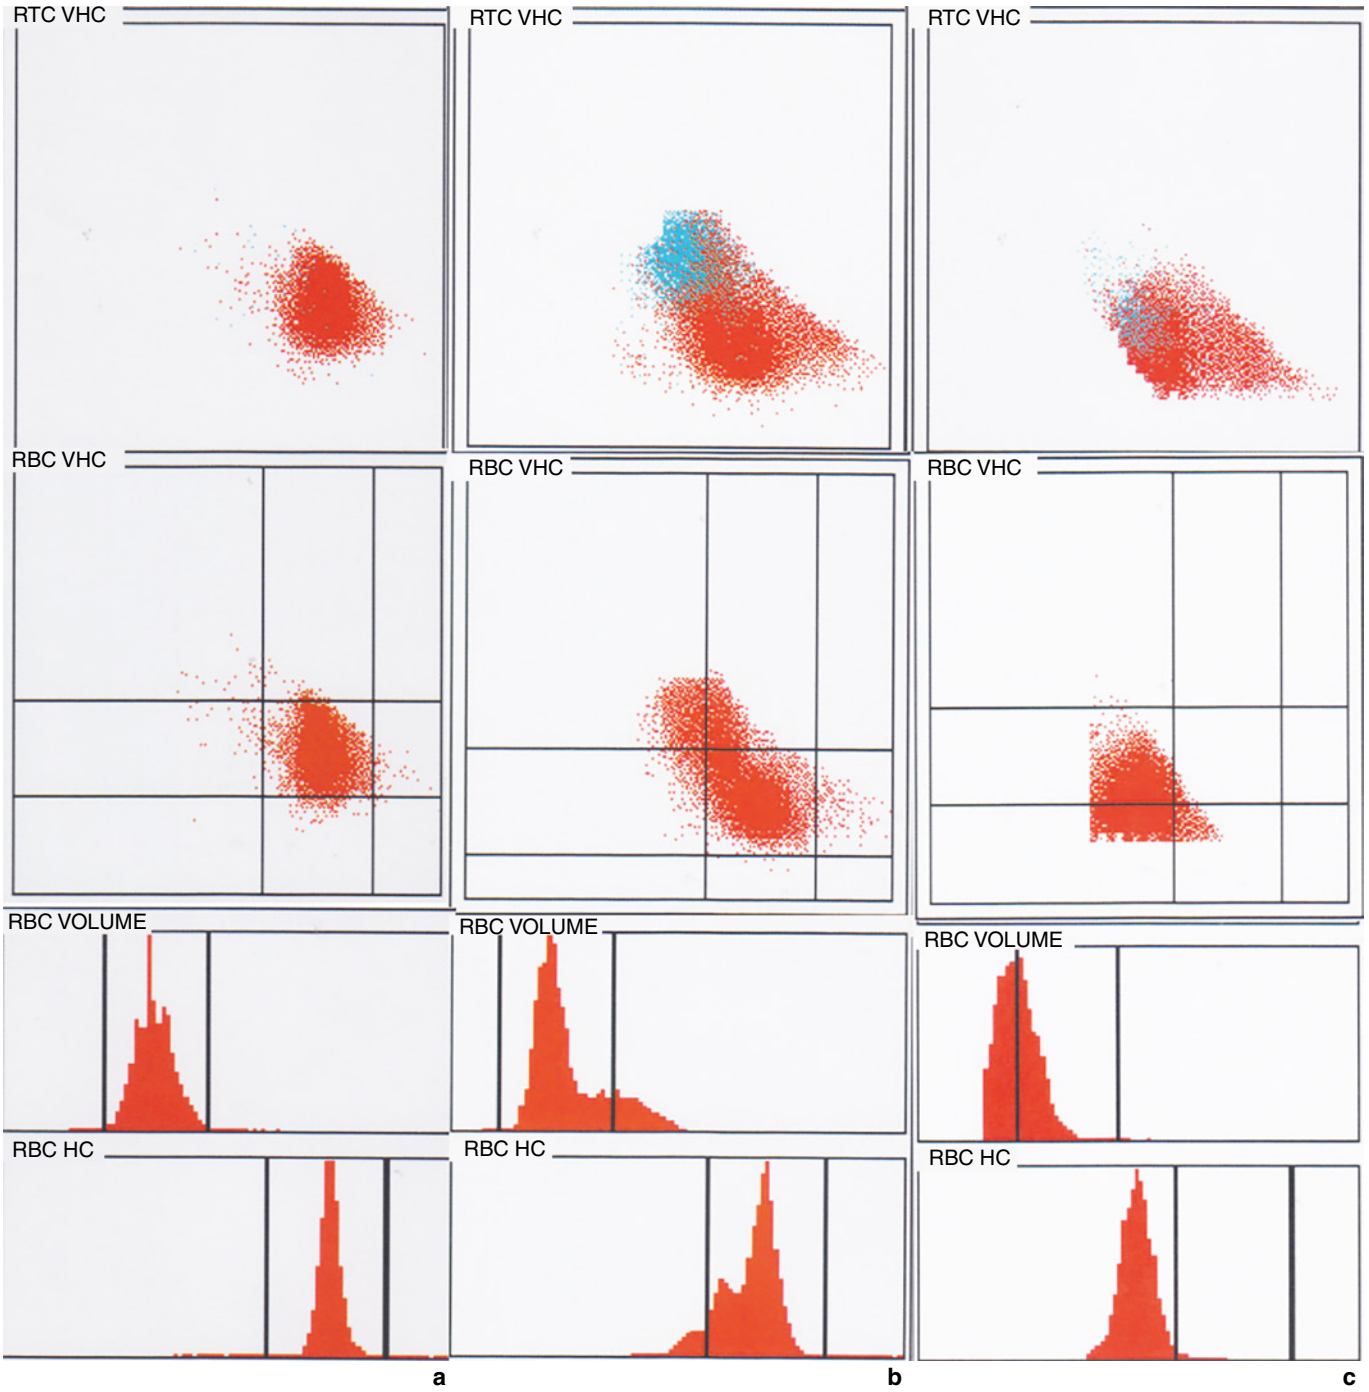

FIGURE 25.2 Composite of Advia 2120 reticulocyte volume hemoglobin concentration cytograms (RTC VHC), RBC cytograms (RBC VHC), RBC volume histograms, and Hgb concentration histograms (RBC HC) from two dogs and one cat that illustrate the three main types of anemia based on size and hemoglobin concentration of RBC. (a) The left column was from a dog with nonregenerative IMHA and had only occasional reticulocytes (blue dots) in the RTC VHC. It was a normocytic normochromic anemia with almost all RBCs in the central box of the 9-box RBC cytograms (RBC VHC); (b) The center column was from a cat with blood loss anemia. The RTC VHC and RBC VHC cytograms show two populations of erythrocytes. The macrocytic hypochromic (upper left cluster) erythrocytes in RBC VHC are blue reticulocytes in the RTC VHC cytogram. A second population of normocytic normochromic erythrocytes is in the central box of the nine-box RBC cytogram. These erythrocytes were present prior to blood loss. Part of the cluster of macrocytic hypochromic cells remains in the central box; (c) The right column was from a dog with iron deficiency and microcytic hypochromic anemia. Its reticulocytes were also microcytic and are lower in the right RTC VHC cytogram compared with the cat.

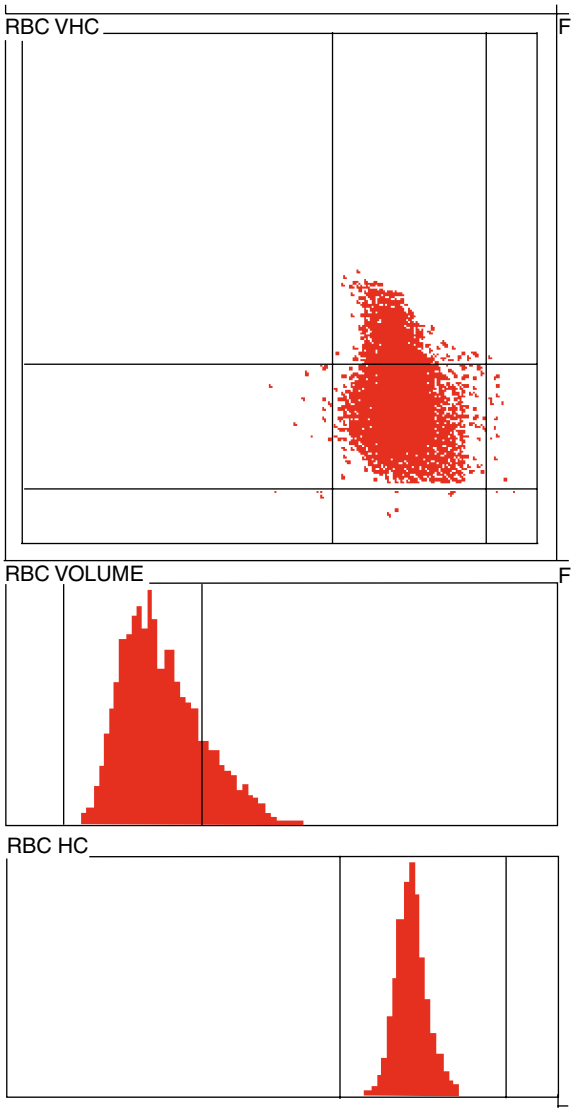

FIGURE 25.3 Regenerative response in a horse with immune-mediated hemolytic anemia. There is a macrocytic normochromic population of RBCs seen in the Advia 2120 RBC graphics. This horse did not have increased reticulocytes detected by the Advia 2120.

and histograms (Figure 25.3). Horses even with a strong regenerative anemia often have no reticulocyte response. Cats have relatively weak aggregate reticulocyte responses, which often fails to affect the MCHC and MCV, but may be clearly detected in Advia's RBC graphics (Figures 25.2 and 25.4). Macrocytic normochromic erythrocytes in the absence of polychromasia in cats can suggest feline leukemia virus (FeLV) infection or myelodysplastic syndromes. Some poodles have macrocytic erythrocytes as a familial defect. Swelling of erythrocytes is a common artifact in day-old samples. Macrocytic hypochromic RBCs occur (as in stomatocytosis) because the RBCs swell greatly and quickly in vitro. In contrast to pernicious anemia in people, macrocytic normochromic changes in MCV and MCHC should not indicate vitamin B12/folic acid deficiency in veterinary patients. Vitamin B12/folic acid deficiency is a rare condition in domestic animals. When it occurs, it is not a cause of macrocytic normochromic anemias. Cobalamin (vitamin B12) malabsorption has been reported in Giant Schnauzers, but causes a normocytic normochromic anemia (see Chapter 31).[1]

Classification by Blood Smear Morphology

Blood smear evaluation is an essential procedure in classification of anemia, especially hemolytic anemias. Many subjective observations critical to diagnosis can only be made by a trained microscopist. Some examples include identification of blood parasites, spherocytes, autoagglutination, ghost cells, Heinz bodies, eccentrocytes, pyknocytes, and hypochromasia (Figure 25.5). Many morphological changes may be seen and reported with erythrocytes, but reports should be restricted to findings likely to affect the final diagnosis. Changes that can suggest numerical errors include clumping of platelets or leukocytes (see Chapter 24).

Classification by Etiology

The ultimate goal of diagnosis is correct classification of anemia by etiology or etiologies in case of multiple causes (see chapters on specific causes). The path to the final diagnosis varies with each case. The likely etiology may be identified in the history. Substances known to cause Heinz body anemia, such as acetaminophen/paracetamol in cats or red maple tree branches and leaves in horses, can be identified by proper questioning of the owner.

DIAGNOSTIC APPROACHES

Anemia diagnosis should begin with a CBC including blood smear evaluation. Hematology instruments provide abundant automated enumerations such as reticulocyte counts, but many diagnoses will be missed without blood smear evaluation. Instrument graphics can illustrate changes in erythrocyte populations well. If the diagnosis is not obvious from the history, physical examination, and CBC, then additional testing is indicated. Additional tests are chosen based on the situation, species, and probability of different causes of anemia for a location. For example, anemia with hemoglobinuria in a young dog with a tendency to eat foreign bodies can indicate radiographic examination to look for zinc-containing metallic foreign bodies in the stomach. Gastric radiographs are not usually considered a diagnostic method for anemia, but may be the most important diagnostic test in that situation.

A simple, algorithmic approach to selected anemias reflects the previous discussion (Figure 25.6). One must add one's own interpretation and knowledge to any algorithm to consider additional information or factors in a given situation. After documenting the presence and severity of the anemia, the strength of the bone marrow's response should be determined. Hemolytic

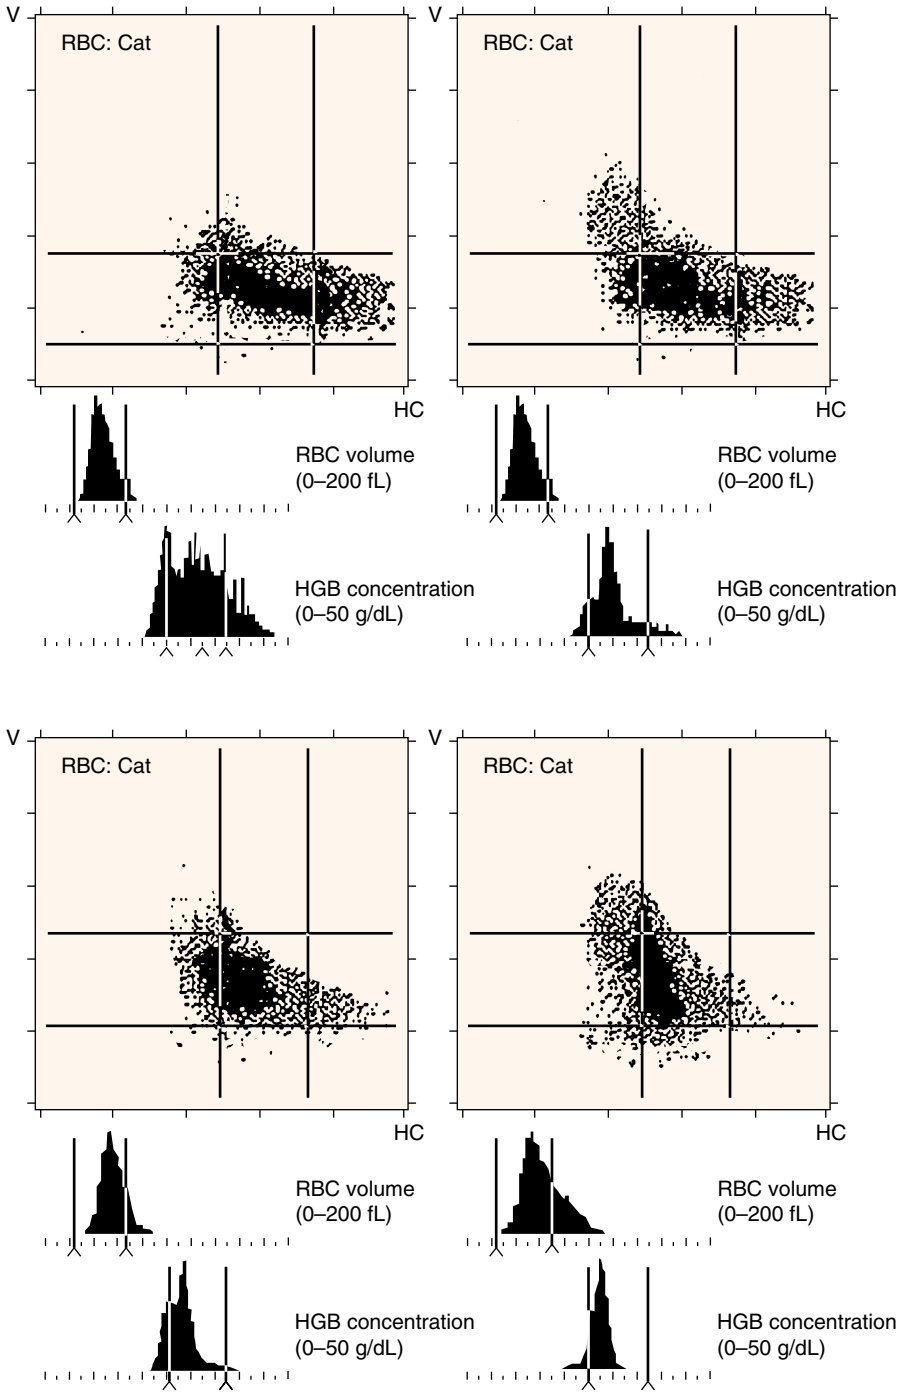

FIGURE 25.4 Composite of four sets of RBC cytograms and histograms over 1 week from a cat with Heinz body anemia from eating baby food containing onion powder. The sequence begins on the upper left, and progresses to upper right, lower left, and finally lower right. The third set (lower left) looks the most normal and may be used for comparison. That RBC cytogram has one dark, round cluster that is normocytic normochromic erythrocytes. The cells should be in the center box, but the grid was not aligned well. The lightly dispersed dots extending to the right are RBCs with Heinz bodies that appeared hyperchromic. Note that, on the first set (upper left), this extension is very dark, indicating many RBCs appeared hyperchromic because 84% contained large Heinz bodies. The MCHC was falsely high (44 g/dL) on that day. The Hgb concentration histogram was bimodal with a larger right peak of hyperchromic RBC. The smaller left peak was normochromic cells (grid was offset). The final set of graphics (lower right) shows a good regenerative response in the RBC cytogram with mainly macrocytic and slightly hypochromic RBC (i.e., reticulocytes) extending above and to the left of the normal cells. The RBC volume histogram shows many of the cells (about 1/3) were macrocytic. The HGB histogram shows very few hyperchromic cells, because RBCs with Heinz bodies dropped to 17% and Heinz bodies were smaller. The sequence shows well the loss of hyperchromic erythrocytes with Heinz bodies and the developing regenerative response with young, macrocytic cells.

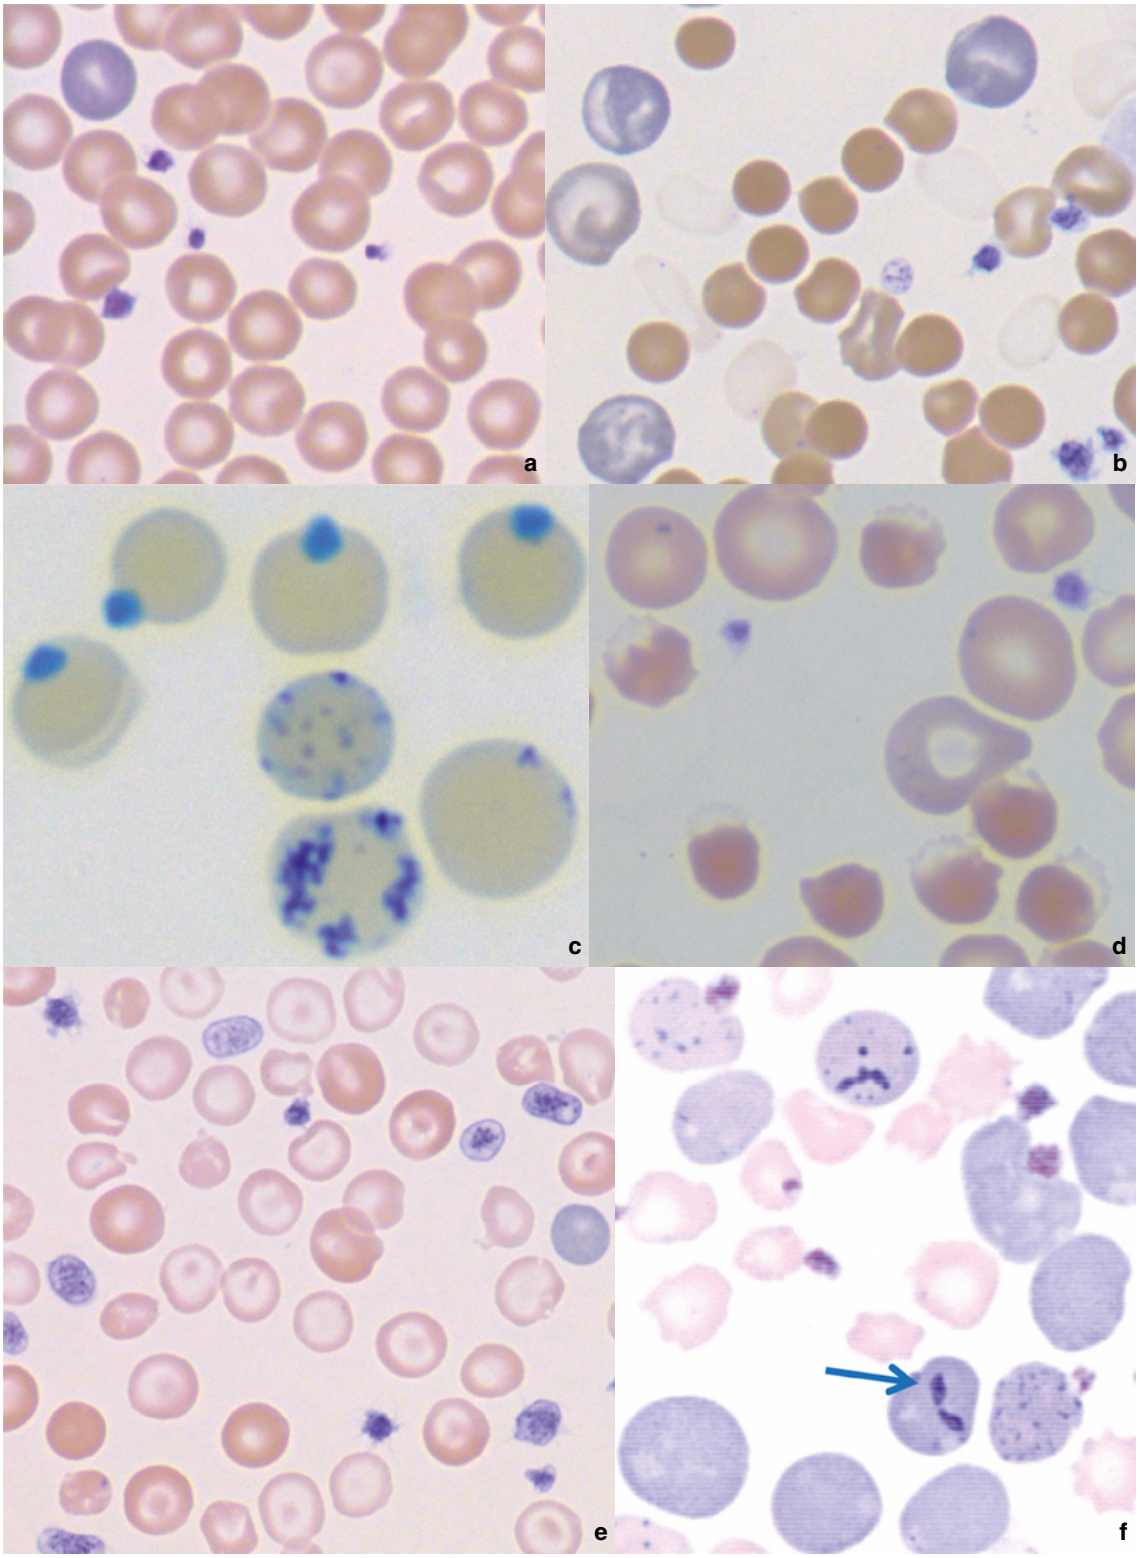

FIGURE 25.5 Composite of six photomicrographs of blood smears with diagnostic morphology. Use erythrocytes for size comparison (about 5–7 μm in diameter). Smears were stained with Giemsa except for brilliant cresyl blue stain in panel (c). (a) Normal dog; (b) Dog with IMHA. The photo has four polychromatophils (reticulocytes), more than 10 spherocytes, and six ghost red cells; (c) Four feline erythrocytes with Heinz bodies, one punctate reticulocyte with only three to four dots, one aggregate reticulocyte with 18 dots, and one aggregate reticulocyte with four aggregates of dots; (d) Eccentrocytes from a dog with onion poisoning. Indistinct Heinz bodies are also present. The spherical portion of eccentrocytes (pyknocytes) may be confused with spherocytes; (e) Smear from a dog with iron deficiency and severe hypochromasia; (f) *Babesia* (arrow), polychromatophils, and basophilic stippling in a roe deer. See Chapter 24 for more on erythrocyte morphology.

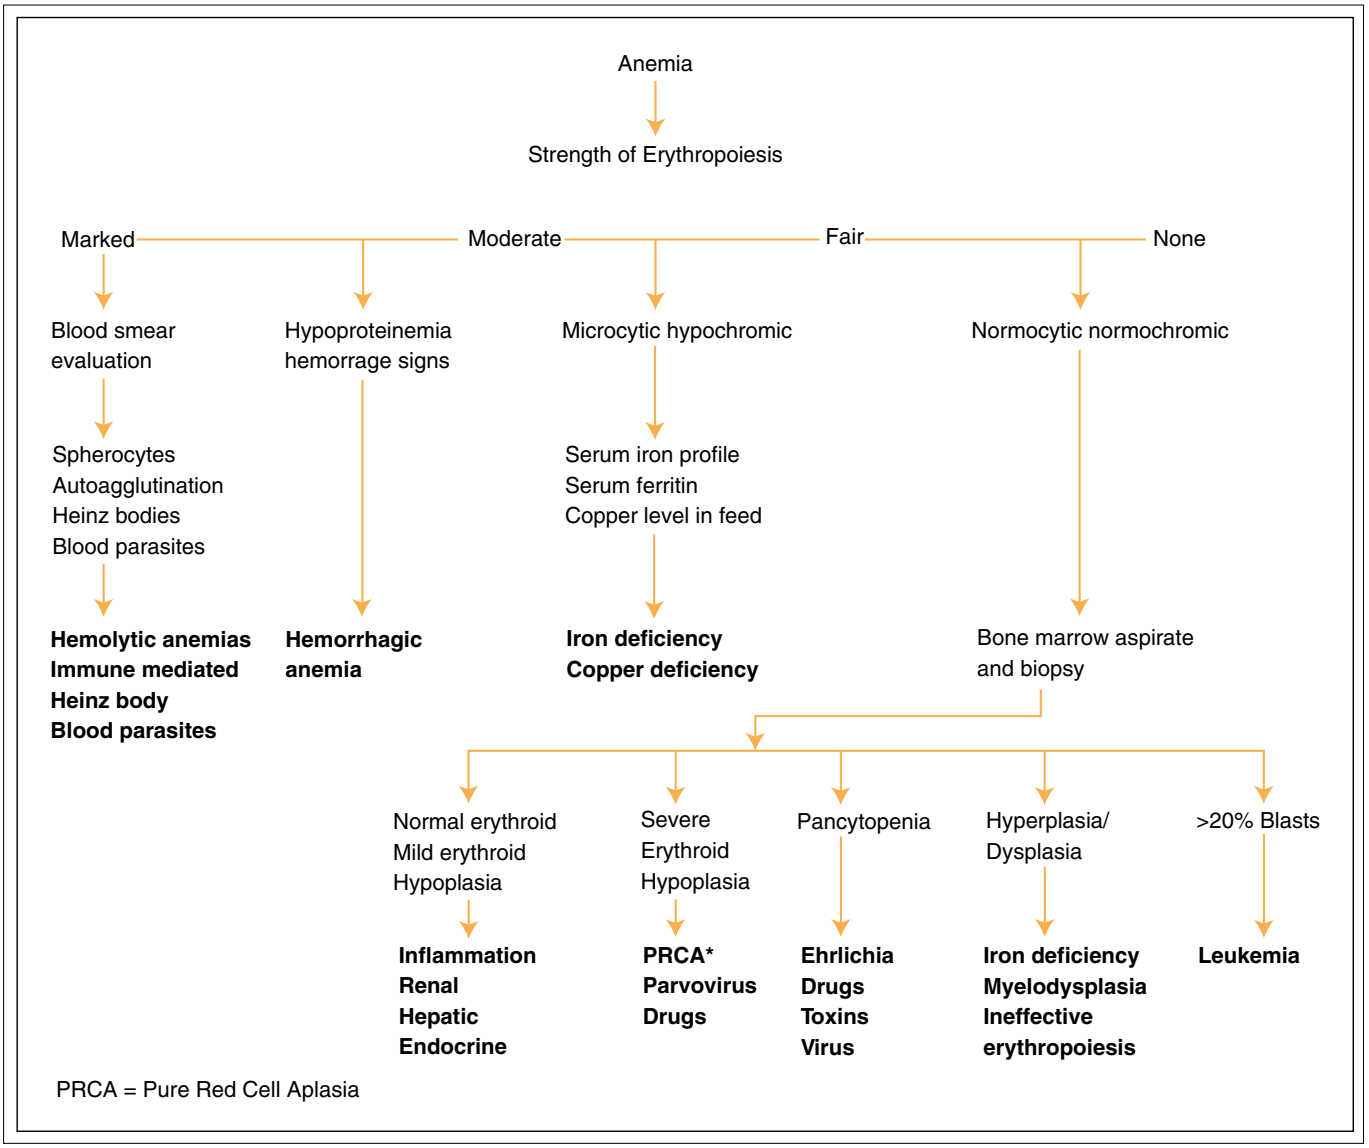

FIGURE 25.6 Algorithm for diagnosis of anemia. Anemia is documented and evaluated for severity. The strength of erythropoiesis is determined usually by reticulocyte evaluation. The marked to moderately regenerative anemias should be hemolytic or hemorrhagic. Blood smear evaluation frequently identifies the type of hemolytic anemia. Diagnoses are given in bold. Hypoproteinemia and clinical signs indicate hemorrhagic anemia. Microcytic hypochromic anemia most often indicates iron deficiency that varies from nonregenerative to moderately regenerative. Nonregenerative and inadequately regenerative anemias with normocytic and normochromic RBCs may be diagnosed by bone marrow evaluation.

anemias are usually the most regenerative (Table 25.3). Blood smear analysis frequently provides specific evidence of the cause of the hemolysis such as spherocytes, autoagglutination, ghost cells, Heinz bodies, eccentrocytes, or blood parasites (Figure 25.5). Icteric or hemolytic plasma, splenomegaly, or urinalysis evidence of hemoglobinuria suggests hemolytic anemia. If a regenerative anemia lacks indicators of hemolysis, then a blood loss anemia should be suspected. Hypoproteinemia or low normal plasma protein can support external blood loss as a diagnosis.

BLOOD LOSS ANEMIA

Blood loss can be external or internal (Table 25.4). Internal blood loss mimics hemolytic anemia in that erythrocytes are broken down within the body and plasma proteins are not lost from the body. External blood loss causes loss of plasma proteins as well as erythrocytes, so plasma protein concentration should be evaluated. Hypoproteinemia or low–normal plasma protein combined with regenerative anemia strongly suggests external blood loss. Plasma protein is replaced much quicker than erythrocytes, so hypoproteinemia is more associated with recent and

TABLE 25.3 Selective causes of hemolytic anemias.

Immune-mediated	Idiopathic, viral (equine infectious anemia, EIA), drugs, blood parasites, neonatal isoerythrolysis, transfusion reaction
Heinz body	Onions, vitamin K_3, phenothiazine, acetaminophen, phenacetin, acetanilide, phenylhydrazine-HCl, benzocaine, red maple, methylene blue, phenazopyridine, copper toxicity, selenium deficiency, *Brassica* sp. ingestion
Toxic hemolysis	Zinc, copper, water in calves, l-sorbose
Hypophosphatemia	Postparturient hemoglobinuria, refeeding syndrome, diabetes mellitus
Blood parasites	*Anaplasma, Babesia, Haemobartonella, Eperythrozoon, Theileria, Trypanosoma, Sarcocystis, Cytauxzoon*
Bacteria	Leptospira, *Clostridium novyi*
Hereditary RBC enzyme deficiencies	Pyruvate kinase, phosphofructokinase, glucose-6-phosphate dehydrogenase

TABLE 25.4 Selected examples of hemorrhagic anemia.

Trauma	Hit by car, penetrating wounds, surgical trauma
Bleeding lesions	Intestinal neoplasms, gastrointestinal tract ulceration, burns, infections
	Parasites
	Hookworms, coccidia, *Haemonchus*
	Fleas, lice
	Hemostatic disorders
	Thrombocytopenia, thrombopathy
	Acquired coagulopathy (e.g., warfarin toxicity, hepatic disease)
	Hereditary coagulopathy, von Willebrand disease, disseminated intravascular coagulation

large volume blood loss. Evidence of bleeding comes from history, diagnostic imaging, fluid cytology, etc. Chronic blood loss causes iron deficiency anemia. Iron deficiency anemia due to bleeding occurs more quickly in young, growing animals that are rapidly producing erythrocytes and using iron stores.

Time after onset of blood loss greatly affects the pattern of laboratory results. Indicators of the erythroid mass in the body (Hct, Hgb concentration, RBC count) may even increase during the first few hours after blood loss. This is most prominent in horses with very contractile spleens, but can be seen in dogs during controlled experimental situations.[4] The spleen holds about 20% of the erythrocyte mass, and splenic contraction can mask an anemia for the first 1–2 hours after blood loss, especially in horses.

The rapidity of fluid replacement and restoration of normal vascular volume after bleeding affect how rapidly remaining erythrocytes and plasma protein in the vascular system are diluted. It may take 1–2 days for the Hct to reflect the true severity of the anemia (Figure 25.7). Withholding access to water can delay decreases in the Hct. Aggressive fluid therapy can reduce the Hct rapidly and even cause hemodilution.

Time affects the expected number of reticulocytes. Blood loss anemia is regenerative, but no increase in reticulocytes is expected for the first 1–3 days during which it is termed a preregenerative anemia. Peak reticulocytosis is expected 4–8 days after onset (Figure 25.7).[6] Reticulocyte numbers decrease by 2 weeks after onset, but macrocytic hypochromic erythrocytes remain in circulation to give evidence of prior regeneration. This late stage macrocytic hypochromic response may be shown by Advia graphics.

Blood loss anemia (Table 25.4) becomes less regenerative with time due to loss of nutrients like iron and protein. Chronic, severe blood loss causes iron deficiency anemia, which becomes progressively more nonregenerative (see Chapter 27). About half of iron deficiency anemia cases still have enough reticulocytosis to be called regenerative.The author believes that confusion has occurred with interpretation of platelet counts related to blood loss. A common misconception is that blood loss by itself causes thrombocytopenia. This belief may cause other potential sources of thrombocytopenia to be overlooked. Actually, blood loss is an experimental method to cause thrombocytosis in dogs (Figure 25.7b).[2] Severe thrombocytopenia causes blood loss, but not vice versa. Blood loss together with aggressive fluid therapy can cause thrombocytopenia.

NONREGENERATIVE ANEMIA

Mild to moderate nonregenerative anemia is often secondary to conditions such as inflammation, renal or hepatic disease, endocrine disease, neoplasia, etc. The primary problems are diagnosed by tests more specific for them (e.g., leukogram, clinical chemistry, endocrinology, cytology, etc.). The cause of the anemia is usually clinically inferred from the type of disease present (e.g., if renal failure is present, then the anemia is likely anemia of renal disease).

Bone Marrow Evaluation

Bone marrow evaluation is indicated in nonregenerative anemias that have had adequate time (e.g., 3–6 days) to respond. Bone marrow is especially indicated if there is a bicytopenia or pancytopenia present. The anemia should be a nonregenerative type. Pancytopenia is a deficiency of cells in all three cell lineages. Likely causes include *Ehrlichia canis*, other bacteria, virus of that species, and exposure to various drugs and toxins.

Bone marrow evaluation is most complete when based on diagnostically useful smears of an aspirational biopsy, histologic sections of a cortex-to-cortex biopsy, and a CBC on blood taken the same day. However, small core cortex-to-cortex biopsies may have artifacts that inhibit adequate diagnosis. Erythroid hypoplasia, pure red cell aplasia (PRCA), myelofibrosis, aplastic

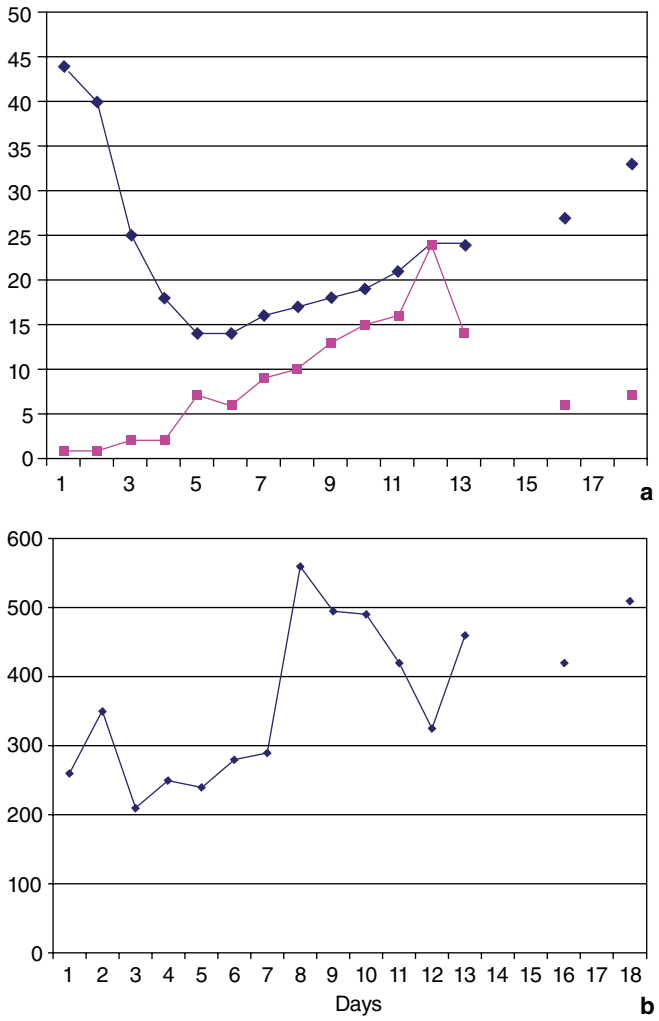

FIGURE 25.7 (a) Hematologic changes associated with canine blood loss anemia. A mature, healthy, research Beagle dog had 200–250 mL of blood removed each day for 3 consecutive days.[2] Equal volumes of saline and serum were infused intravenously to replace lost blood volume. Blood removal occurred on days 2–4 in the figure.[2] Hematocrit (blue line with diamonds) and reticulocyte values (red line with squares) are given in percent on *y*-axis. Days are on the *x*-axis in panel (a). Day 1 was the control value before bleeding. Note that hematocrit does not reach its lowest values until days 5 and 6. The hematocrit was still low (33%) on day 18, which was 14 days after the last bleeding. Reticulocytes peaked at 24% on day 12, which was 8 days after the last bleeding and fell to 6–7% on days 16 and 18; (b) Thrombocytosis occurring after canine blood loss. Platelet counts ($\times 10^9$/L) on the *y*-axis are from the same dog in Figure 24.5a. The dog had normal platelet counts before, during bleeding on days 2–4, and 3 days after the last bleeding. It had thrombocytosis on day 8 and higher than baseline platelet counts on days 9–18, which was 5–14 days after the last bleeding.

pancytopenia (fatty marrow), and leukemia clearly cause nonregenerative anemia.[7] A severe decrease in only the erythroid line is called pure red cell aplasia and may be caused by immune-mediated damage or viruses such as parvovirus in dogs and FeLV in cats (see Chapter 38). Drugs and toxins cause a wide variety of effects on the bone marrow (see Chapters 15 and 16).

Ineffective erythropoiesis, with an adequate to increased number of erythroid cells seen in the marrow, but a nonregenerative anemia seen in the CBC, can also occur. Causes of ineffective erythropoiesis include infections, drug reactions, myelodysplastic syndromes, and idiopathic causes. Erythroid hyperplasia and nonregenerative anemia occur in iron deficiency and will be accompanied by a lack of hemosiderin in macrophages. Precursor-directed immune-mediated anemia may be suggested by finding active phagocytosis of rubricytes by macrophages in the marrow (personal communication, Mike Scott).

Myelodysplastic syndromes are indicated by the presence of a hypercellular marrow, cytopenias, and abnormal cell morphology such as megaloblastic rubricytes, dwarf megakaryocytes, binucleated cells, nuclear fragments, and increased blast cells (see Chapter 67).

Acronyms and Abbreviations

EPO, erythropoietin; JAK, Janus kinase; P_{50}, the partial pressure of oxygen at which hemoglobin is half-saturated with oxygen; P_aO_2, arterial partial pressure of oxygen; PCV, packed cell volume; RBC, red blood cell; rPDA, reversed patent ductus arteriosus; S_aO_2, arterial hemoglobin oxygen saturation.

RBC production is predominantly regulated by the hormone erythropoietin (EPO; see Chapter 19). When oxygen sensors located in the renal cortex become hypoxic, hypoxia-inducible factors are generated and incite EPO gene transcription.[26,54] The resultant EPO then stimulates erythropoiesis in the bone marrow, increasing RBC numbers and subsequently the oxygen-carrying capacity of the blood.

Erythrocytosis is defined as an increase in RBC numbers, hemoglobin concentration, and calculated hematocrit or PCV above established reference intervals. Erythrocytosis and the term polycythemia are often used interchangeably. However, the concurrent expansion in platelet and neutrophil numbers that typically accompanies the clonal form of polycythemia (polycythemia vera) in humans has led to a lack of consensus on the appropriateness of this exchange.[48] Based on pathogenesis, erythrocytosis can be classified into relative or absolute categories. Absolute erythrocytosis can be further characterized as primary (polycythemia vera) or secondary (Figure 26.1).

RELATIVE ERYTHROCYTOSIS

Relative erythrocytosis is characterized by an increase in PCV due to a decrease in plasma volume rather than an increase in RBC production and mass. In dogs and cats, this occurs secondary to fluid losses often coupled with insufficient water intake and is the most common form of erythrocytosis. In animals with a muscular splenic capsule, such as the horse and dog, catecholamine-induced splenic contraction can cause the release of stored RBCs from the red pulp resulting in a transient mild erythrocytosis unassociated with clinical signs; the increase in PCV occurs in the absence of any increase in RBC production.

ABSOLUTE ERYTHROCYTOSIS

Absolute erythrocytosis, defined as a true increase in RBC mass, can develop from primary or secondary causes.

Primary Erythrocytosis (Polycythemia Vera)

Primary erythrocytosis results from autonomous proliferation of erythroid precursors that require little to no EPO for differentiation. The prototypical primary erythrocytosis, also called polycythemia vera, is a chronic myeloproliferative disorder resulting from the clonal expansion of hematopoietic progenitor cells

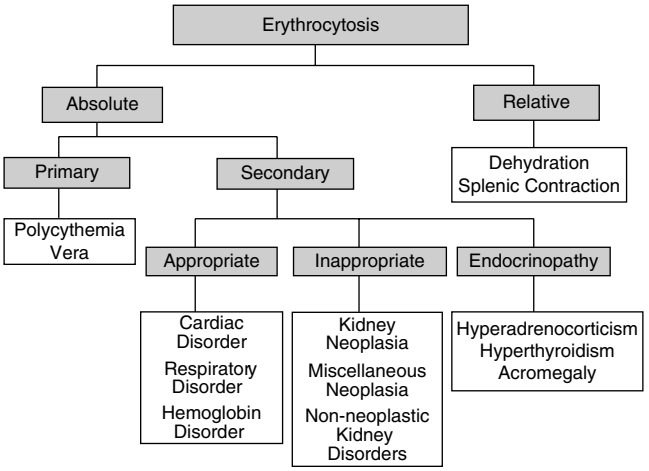

FIGURE 26.1 Flow chart for classification of erythrocytosis.

often driven by a Janus kinase 2 (JAK2) genetic mutation in humans.[31,59] An identical JAK2 mutation also has been identified in a dog with primary erythrocytosis.[1]

In humans, polycythemia vera is associated with splenomegaly, leukocytosis, and thrombocytosis, and may progress to myelofibrosis or leukemia.[26,48] However, many of those features are absent in dogs and cats with primary erythrocytosis. It remains unclear whether primary erythrocytosis in companion animals is the same disease as polycythemia vera in humans, or whether it represents a variant with isolated erythrocytosis. Regardless, primary erythrocytosis is a disease with variable age of onset in cats (median, 5–7 years) and dogs (median, 7 years).[10,62] Dogs with primary erythrocytosis are more frequently female, whereas affected cats are commonly male.[62] However, a recent report concluded no sex predilection for cats with primary erythrocytosis.[10] Primary erythrocytosis also has been diagnosed in the horse and ferret.[32,34]

Secondary Erythrocytosis

Secondary erythrocytosis develops from excessive production of EPO. If EPO is secreted in response to systemic hypoxia, then the resultant erythrocytosis represents an *appropriate* compensatory response. If, on the other hand, the increased EPO secretion is not associated with systemic hypoxia, then the response is *inappropriate* (Figure 26.1). Endocrinopathy-associated erythrocytosis is another type of secondary erythrocytosis resulting from hormonal (other than solely EPO-mediated) stimulation of erythropoiesis.

Appropriate Secondary Erythrocytosis

In physiologically appropriate erythrocytosis, the EPO-mediated increased RBC mass increases the oxygen-carrying capacity of the blood in an attempt to improve inadequate tissue oxygenation. For example, congenital heart anomalies resulting in right-to-left shunting with blood bypassing the lungs (e.g., tetralogy of Fallot, reversed patent ductus arteriosus [rPDA]) cause decreased oxygen saturation in the blood, which appropriately stimulates EPO production and resultant erythrocytosis.[5,6,19,20,28,37,40] Similarly, chronic severe pulmonary disease can cause decreased oxygenation of blood and may lead to erythrocytosis.[12,47] Hereditary high-oxygen affinity hemoglobinopathies in humans cause decreased release of oxygen to tissue and consequent erythrocytosis.[18,48] Although this type of hemoglobin disorder has not been described as a cause of pathologic erythrocytosis in companion animals, impaired oxygen transport from chronic methemoglobinemia in dogs and cats with methemoglobin reductase deficiency may cause mild erythrocytosis.[22] High-altitude dwelling also can result in an appropriate secondary erythrocytosis.[48]

Inappropriate Secondary Erythrocytosis

Excess production of EPO in the absence of systemic hypoxia, termed physiologically inappropriate erythrocytosis, is caused by: (1) EPO-secreting tumors of the kidneys or other organs, or (2) kidney disorders that result in regional hypoxia leading to increased EPO production. In humans, kidney neoplasms, as well as tumors of the liver, adrenal gland, uterus, and cerebellum, have been associated with inappropriate production of EPO and erythrocytosis.[48,54] Tumor-related erythrocytosis has been described with renal carcinoma,[9,46,60,61] renal lymphosarcoma,[5,16,38] renal fibrosarcoma,[21] nasal fibrosarcoma,[7] cecal leiomyosarcoma,[51] and schwannoma[65] in the dog, with renal carcinoma[5,25,29] and splenic hemangiosarcoma[52] in the cat, and with lymphoma in the horse.[30] Non-neoplastic kidney abnormalities in humans (e.g., renal cysts, hydronephrosis, glomerulonephritis)[54] and rarely in dogs (e.g., renal cryptococcosis, pyelonephritis)[27,61] have been reported as potential causes of erythrocytosis. For two dogs with glomerulonephropathy and erythrocytosis attributed to polycythemia vera, the kidney disorder was speculated to be a consequence, rather than a cause, of the erythrocytosis.[41,49] Genetic defects in the oxygen-sensing pathways responsible for some forms of congenital erythrocytosis in people have not yet been identified in companion animals.[48]

Endocrinopathy-Associated Erythrocytosis

Hormones other than EPO, such as cortisol, testosterone, thyroxine, and growth hormone, also may stimulate erythropoiesis either directly or indirectly through increased production of EPO or alternate pathophysiologic mechanisms.[13,48] In dogs, increased cortisol or testosterone concentrations associated with adrenal hyperactivity may produce mild erythrocytosis.[13] Similarly, cats with increased thyroxine concentrations from hyperthyroidism may have mildly increased RBC count.[45] Acromegalic cats with excess growth hormone may develop mild erythrocytosis,[45] but similar hematologic findings are usually absent in dogs with acromegaly.[50] The mild erythrocytosis in these endocrine

disorders is insufficient to result in clinical signs, and is usually discovered incidentally during routine diagnostic evaluation for the endocrinopathy.

CLINICAL SIGNS OF ERYTHROCYTOSIS

The clinical signs of both primary and secondary erythrocytosis include erythema (brick-red or ruddy color) of mucous membranes, neurologic disturbances (lethargy, ataxia, weakness, seizures, blindness, behavioral change), bleeding episodes (epistaxis, hematemesis, hematochezia, melena, hematuria), or polyuria and polydipsia. Most of these clinical manifestations are attributed to increased blood viscosity from the expanded RBC mass. In fact, the blood viscosity rises steeply as PCV increases.[4,55] The hyperviscosity slows blood flow, distends capillaries and small vessels, may increase the likelihood of thrombosis and rupture of these vessels, and may impair tissue oxygen delivery.[4,18,54] Ischemic myopathy may be responsible for the increased creatinine kinase activity reported in many cats with primary erythrocytosis.[10] Vascular changes characteristic of hyperviscosity frequently can be visualized on ophthalmologic examination (i.e., dilated and tortuous retinal vessels, sometimes accompanied by retinal hemorrhage). The polyuria and polydipsia have been attributed to hyperviscosity and increased blood volume leading to impaired vasopressin release.[60]

Laboratory test results may be skewed by extreme erythrocytosis. Hypoglycemia may be noted, and explained by enhanced glucose utilization by the increased number of RBCs in vivo or in vitro. Whole blood samples collected into sodium citrate anticoagulant tubes may result in prolonged prothrombin and activated partial thromboplastin times because of excess citrate concentration for the relatively smaller volume of plasma in patients with profound erythrocytosis.[26]

DIAGNOSTIC APPROACH

Before an extensive diagnostic workup is started, remember that many sighthound breeds, such as the Greyhound, normally have mild erythrocytosis when their PCV is compared to standard canine reference intervals.

In most animals, the first step in determining the reason for erythrocytosis is to exclude relative causes. Relative erythrocytosis usually results in a mild increase in PCV, rarely exceeding 60–65%.[23,62] However, the PCV may be as high as 70–80% in some dogs with the acute hemorrhagic diarrhea syndrome due to rapid fluid loss into the gut. This observation emphasizes that the magnitude of increase in PCV does not necessarily differentiate between relative and absolute erythrocytosis. The dehydration and hemoconcentration of relative polycythemia usually are identified by clinical findings (e.g., dry mucous membranes, reduced skin turgor), laboratory variables (e.g., hyperproteinemia, prerenal azotemia), and response to rehydration with intravenous fluid therapy. Excitable or anxious dogs with mild erythrocytosis suspected to be caused by splenic contraction should have another blood sample collected under less-stressful circumstances. Rarely, animals with repeatable mild increases in PCV and no obvious evidence of fluid loss may require direct measurement of RBC mass with radioisotope-labeled autologous RBCs to differentiate relative from absolute causes. However, these studies seldom are performed in clinical practice.

Once relative erythrocytosis is excluded, the next step is to differentiate primary and secondary causes of absolute erythrocytosis. Serum EPO measurement has been used in a number of published reports to differentiate between these two types of erythrocytosis. In secondary erythrocytosis, an increased EPO concentration would be expected, whereas EPO should be low in primary erythrocytosis. Although most dogs and cats with primary absolute erythrocytosis have low to low-normal EPO concentration and many animals with secondary absolute erythrocytosis have higher EPO values, results discordant with the expected findings and overlap with normal animals limit the diagnostic utility of EPO determinations.[3,5,17,24] Fluctuations in EPO secretion, production of hematopoietic growth factors not detected by the EPO assays, or renal hypoxia secondary to hyperviscosity may explain these findings.[5,33] Repeat EPO determinations, even following phlebotomy, have been suggested in problematic cases.[3,17,18,26,54] Because of these limitations, EPO measurements should complement but not supplant a thorough diagnostic evaluation of animals with erythrocytosis. Furthermore, current availability of validated EPO assays for dogs and cats is limited. Additional efforts to match diagnostic features of polycythemia vera in humans with primary erythrocytosis in companion animals have been unrewarding. Routine examination of bone marrow in affected dogs and cats is not useful because both primary and secondary erythrocytosis are characterized by erythroid hyperplasia. Therefore, a diagnosis of primary erythrocytosis typically is made by excluding common causes of secondary erythrocytosis.

Arterial blood gas analysis including determination of partial pressure of oxygen (P_aO_2) and hemoglobin oxygen saturation (S_aO_2) is useful in assessing tissue oxygenation. A P_aO_2 less than 80 mmHg indicates hypoxemia and S_aO_2 less than 95% reflects tissue hypoxia, both values warranting consideration of appropriate secondary erythrocytosis. If initial collection of arterial blood is thwarted by hyperviscosity, sampling may be repeated following cautious phlebotomy.[23] Alternatively, capillary S_aO_2 may be measured noninvasively with a pulse oximeter. Examination of cardiac and pulmonary systems by thoracic auscultation, thoracic radiographs, electrocardiography, and echocardiography may help determine the cause of appropriate erythrocytosis. Studies to confirm a right-to-left cardiac shunt include selective angiography and contrast echoaortography.[14,20] In dogs with rPDA, cyanosis of the vulvar or preputial (but not the oral) mucous membranes may be detected at rest or following exercise; similarly, lower P_aO_2 values

may be identified at the tail or hindlimbs compared to head or forelimbs.[14] This differential hypoxia in rPDA develops because deoxygenated blood shunts from the pulmonary artery into the aorta distal to the left subclavian artery and brachycephalic trunk, allowing more oxygenated blood to travel to the head and forelimbs. Abnormal hemoglobin variants with increased oxygen affinity in humans can be recognized by demonstrating normal P_aO_2 and S_aO_2 values, but reduced partial pressure of oxygen when hemoglobin is half-saturated with oxygen (P_{50}).[23,54] These hemoglobinopathies have yet to be confirmed as a cause of pathologic erythrocytosis in companion animals. However, some investigators have proposed that the higher PCV (and lower hemoglobin P_{50}) in Greyhounds may indicate that the hemoglobin of this breed has a greater affinity for oxygen.[56]

Once systemic hypoxia is excluded as the cause of erythrocytosis, conditions causing inappropriate EPO production should be considered. To locate the source of EPO in these disorders, results of physical and neurologic examinations, abdominal ultrasonography, intravenous urography, and computed tomography or magnetic resonance imaging should be helpful.

TREATMENT

With relative erythrocytosis due to dehydration, fluid therapy should be administered, and the underlying disorder should be addressed. The PCV will usually normalize with successful management. For relative erythrocytosis resulting from splenic contraction, no treatment is necessary.

In primary erythrocytosis, the goal of therapy is to reduce and maintain the PCV within reference intervals, thereby alleviating clinical signs and preventing any potential thrombotic and hemorrhagic complications. The optimal treatment, however, is unknown. In dogs and cats, the disease has been managed with phlebotomy alone[15,35,36] or in combination with other modalities, leeching,[39] radioactive phosphorous,[35,53,64] or chemotherapeutic agents, such as doxorubicin[41] and busulfan.[35] Phlebotomy and leeching must be repeated on a regular basis to maintain the PCV within reference intervals and can lead to iron deficiency and hypoproteinemia. Radioactive phosphorus induces prolonged remission and reduces morbidity, but is not readily available and may increase the risk of leukemia in treated humans.[26,48] Some of the chemotherapeutic drugs used to treat humans with polycythemia vera also may be leukemogenic.[26,48] However, it remains unknown whether leukemic transformation in these instances represents complications of treatment or natural progression of this chronic myeloproliferative disease.[26,48] The infrequent development of leukemia in dogs and cats with primary erythrocytosis may be further proof that it is indeed distinct from polycythemia vera in humans, or may merely reflect the prolonged time (10–15 years) needed for leukemic transformation in humans.[26] Anecdotal reports of successful control of primary erythrocytosis in dogs with chlorambucil after phlebotomy also have been mentioned.

Hydroxyurea, an antineoplastic drug, is most commonly used to manage primary erythrocytosis in dogs and cats. Side effects of hydroxyurea include anorexia, vomiting, bone marrow hypoplasia, mild alopecia, and sloughing of the nails.[44] Cats also may develop methemoglobinemia and hemolytic anemia with Heinz bodies, especially with high doses.[63] The effects of hydroxyurea are enhanced by reducing the PCV to approximately 50–60% with phlebotomy (10–20 mL/kg) and simultaneous fluid replacement.[43,44] Then, hydroxyurea is given at a loading dose of 30 mg/kg PO daily for 7–10 days, followed by 15 mg/kg PO daily in single or divided doses.[43,44,57] Alternate dosing schedules for cats have been reported.[8,10,11,63] Complete blood and platelet counts should be monitored at 7–14-day intervals until the PCV has normalized, then every 1–3 months. If leukopenia, thrombocytopenia, or anemia develops, hydroxyurea should be discontinued until the blood count returns to normal, and then resumed at a lower-maintenance dosage or dose frequency.[43,44] In humans, the JAK2 inhibitor ruxolitinib, pegylated interferon-alpha, and busulfan are considered for patients with polycythemia vera resistant to, or intolerant of, hydroxyurea.[42,58,59] Further studies on the safety and efficacy of these drugs for companion animals with primary erythrocytosis are needed.

In inappropriate secondary erythrocytosis, treatment should be directed toward the underlying cause, when feasible. Erythropoietin-secreting tumors should be surgically removed if practical, or managed with chemotherapy and/or radiation therapy. Preoperative phlebotomy to normalize the PCV may help reduce morbidity and mortality.

In appropriate erythrocytosis secondary to systemic hypoxia, as in some cardiac diseases, treatment of the underlying problem is recommended, if possible. Unfortunately, the two most common types of congenital heart defects associated with polycythemia in pets are not easily amenable to surgical correction: rPDA cannot be corrected surgically because of the attendant pulmonary hypertension, and mortality is high for attempted surgical correction of tetralogy of Fallot.[19] If correction is not possible, then long-term maintenance of the desired PCV can be accomplished with cautious phlebotomy (5–10 mL/kg) and hydroxyurea therapy as outlined for primary erythrocytosis; alternate protocols using hydroxyurea also have been successful.[37] However, because the erythrocytosis in these cases represents a compensatory response to tissue hypoxia, the PCV should be maintained between 55% and 60% rather than attempting normalization.[3] This degree of erythrocytosis seemingly is sufficient to minimize clinical signs associated with the systemic hypoxia as well as the polycythemia-associated hyperviscosity. Other investigators have recommended maintaining the PCV at even higher values (62–68%), or simply relieving clinical signs without concern about attaining a specific PCV.[2,6,48] Regardless, phlebotomy and drug administration in these patients should be performed with careful monitoring.

Acronyms and Abbreviations

MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RDW, red blood cell distribution width; TIBC, total iron-binding capacity; CHr, reticulocyte hemoglobin content; MCVr, reticulocyte mean cell volume; PSS, portosystemic shunt.

Iron is an essential component of all living organisms, playing a role in many metabolic processes, particularly those involving electron transfer. Copper is a component of several metalloproteins including hephaestin, ceruloplasmin, cytochrome c oxidase, superoxide dismutase, urate oxidase, dopamine β-hydroxylase, ascorbic acid oxidase, and tyrosine oxidase. Iron absorption, metabolism, and utilization in erythropoiesis are discussed in Chapter 20. In this chapter, disorders of iron and copper metabolism will be discussed.

IRON PHYSIOLOGY

Iron is an element that is crucial to many biological processes. While its deficiency can lead to anemia, iron excess can pose serious problems, as iron readily participates in the Fenton reaction, resulting in deleterious free radical formation.[37,49] Because of the potential to induce oxidant damage, iron is tightly regulated in normal, healthy animals. Please see Figure 27.1 for an overview of mammalian iron regulation. Since there is no direct excretion mechanism,[54] iron levels are controlled by regulating the amount absorbed by the gastrointestinal tract. Both heme and nonheme forms of iron are transported into enterocytes, where iron can either be stored in ferritin when iron stores are replete, or absorbed into the bloodstream when there is a need for iron. Ferritin stores that have become oversaturated with iron degrade to become hemosiderin (see Chapter 20). When there is a need for iron, it is exported from the enterocyte via ferroportin,[6] oxidized by hephaestin, and then bound to the serum protein transferrin.[4] Transferrin shuttles iron to cells throughout the body, but the majority is used by erythroid precursors in the bone marrow to produce heme.

In addition to iron absorbed from the gastrointestinal tract, a large proportion of iron utilized by the body is recycled from the breakdown of senescent red blood cells by splenic macrophages.[56] These macrophages

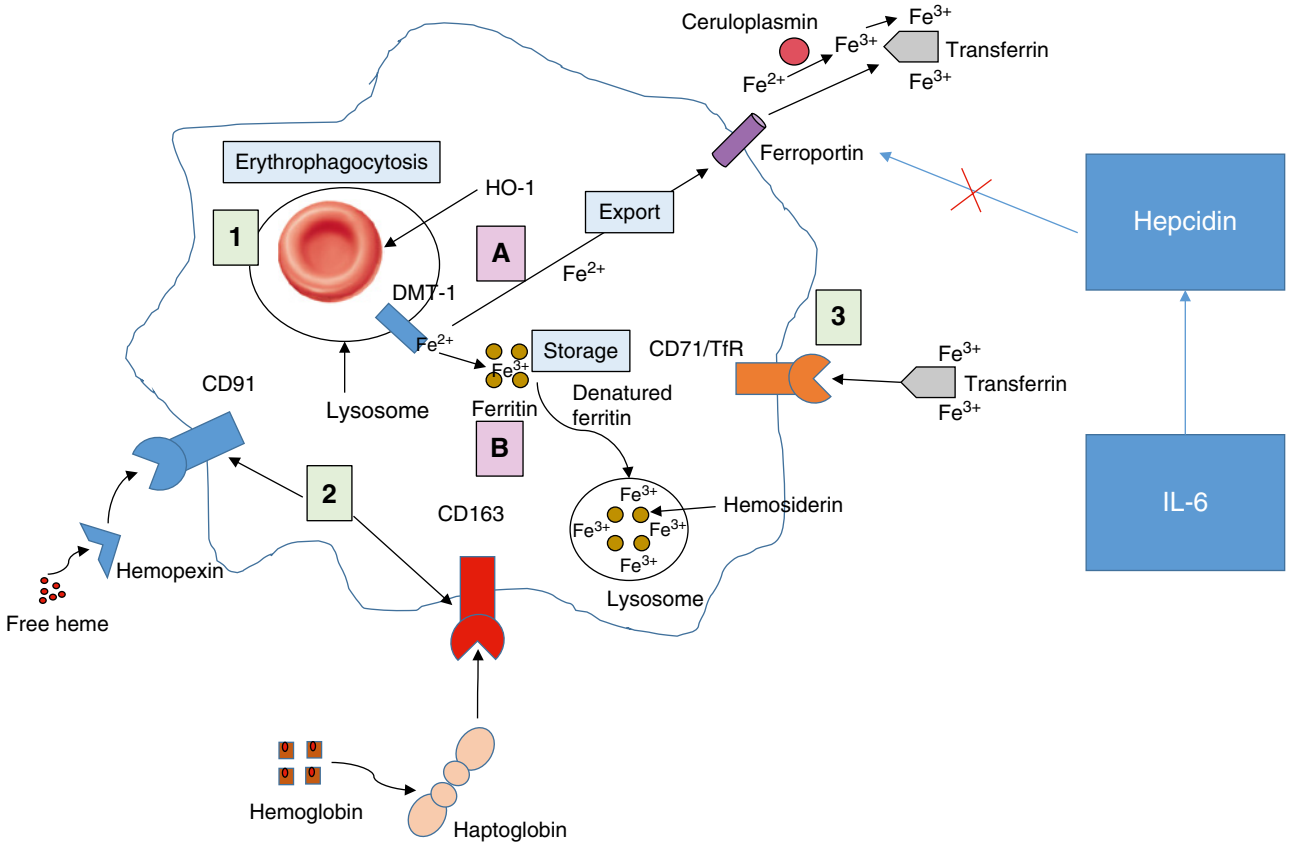

FIGURE 27.1 Iron regulation in mammals. This image demonstrates the mechanisms of iron entry and export from a macrophage. (1) Iron can enter the macrophage via phagocytosis of RBCs, (2) by receptor-mediated endocytosis of heme–hemopexin or hemoglobin–haptoglobin, (3) or by receptor-mediated endocytosis of transferrin-bound iron. After iron is broken down and released within the cell, it may be exported via (A) ferroportin, or (B) stored as ferritin. Once ferritin becomes saturated, it can become denatured over time, resulting in hemosiderin. In the presence of either iron overload or inflammation, hepcidin is produced by the liver, which results in the degradation of ferroportin, preventing iron export from cells.

phagocytize red blood cells and subsequently breakdown heme to release iron. This iron may be exported to the circulation via ferroportin, where it is then oxidized by ceruloplasmin, a copper-containing protein, to bind to transferrin. If not exported, it can be stored within the macrophages as ferritin.

The cellular export of iron is regulated by the peptide hormone hepcidin.[46] Hepcidin is produced by the liver in response to high tissue levels of iron and inflammation. Hepcidin binds to ferroportin, resulting in its degradation. This loss of ferroportin prevents iron from being absorbed from the gastrointestinal tract and also cuts off iron cycling from splenic macrophages. This causes a drop in serum iron levels and restricts iron availability to the bone marrow for heme production, which can eventually cause anemia,[32,24] as described in the following text.

TESTS FOR EVALUATION OF IRON DISORDERS

Serum Iron Concentration

Iron is transported in plasma by the iron transport protein apotransferrin, which carries up to two Fe^{3+} ions. The apotransferrin–Fe^{3+} complex is called *transferrin*. Under normal conditions, approximately one-third of the iron-binding sites of transferrin are occupied by Fe^{3+}. Serum iron concentration refers to the Fe^{3+} bound to transferrin and typically does not include hemoglobin-bound iron until hemolysis is moderately increased. Serum iron is quantified by releasing the iron bound to transferrin using strong acidification, followed by a series of reactions that culminate in a colored reaction product proportional to iron concentration. Serum iron is typically below the reference interval in iron deficiency, inflammatory diseases,[16,52] and after exogenous erythropoietin is administered without iron supplementation.[5] Serum iron concentration is also decreased by glucocorticoid administration to ruminants.[50] Serum iron is typically increased above the reference interval in hemolytic anemias, dyserythropoiesis, hypoplastic anemia, aplastic anemia, iron overload, and in dogs and horses given glucocorticoids.[17,42,55]

Percent Saturation, Serum Total Iron-Binding Capacity, and Unbound Iron-Binding Capacity

There are several tests that may be included as part of an iron panel. Percent saturation refers to the number of filled iron-binding sites present on the serum protein

transferrin. Each unit of transferrin can bind two iron molecules. Normally, transferrin is approximately at 30% saturation in domestic mammals. With iron deficiency, the percent saturation is typically decreased. The total iron-binding capacity (TIBC) is an indirect measure of the total serum transferrin concentration and can be measured either directly or indirectly. TIBC is directly measured in much the same way as serum iron, but preliminary steps allow full saturation of transferrin followed by release of transferrin-bound iron prior to measurement. Thus, the term "total iron-binding capacity." TIBC is increased in absolute iron deficiency in humans, horses, cattle, and pigs, but does not appear to be increased in clinical iron deficiency in dogs.[16] TIBC is decreased or in the low–normal range in inflammatory diseases.[7] Unbound iron-binding capacity, or UIBC, is an indirect measurement of TIBC. Since transferrin typically binds iron at only 30% of its capacity, the UIBC represents the remainder of binding sites for iron. Thus, the sum of the serum iron and the UIBC equals the TIBC. The UIBC is measured by adding a known quantity of iron, in excess, in order to fully saturate the transferrin. The remaining nonbound iron is then measured and subtracted from the known amount added.

Serum Ferritin

Serum ferritin is measured by immunologic methods. Assays to quantitate human serum ferritin are available in kit form and automated immunoassay instruments. In general, immunoassays to quantitate human serum ferritin cannot be used to quantify serum ferritin in other species. Quantitative immunoassays must be calibrated with a standard curve of known concentrations of the purified analyte from the species of interest in order to determine the concentration of the analyte in the unknown sample. Although there is serologic cross-reactivity between serum ferritins of some species,[28] in general, serum ferritins tend to be immunologically species-specific.[19] Therefore, it is likely that individual assays still must be developed and calibrated for each species.

ELISA tests have been developed for serum ferritin in the dog,[8] cat,[7] horse,[15,18,26] pig,[13,25] cow,[17] northern fur seals *(Callorhinus ursinus)*,[5] black (*Diceros bicornis*) and white (*Ceratotherium simum*) rhinoceroses,[23] and black and white ruffed lemur *(Varecia variegata)*.[3] In all cases, serum ferritin was purified from each species and quantitated by chemical methods. Polyclonal antisera or monoclonal antibodies were raised to the ferritin and used to develop tests for the dog, cat, horse, pig, and cattle. In some instances, there was sufficient species cross-reactivity to allow use of antisera or monoclonal antibodies to serum ferritin of one species to develop an ELISA for another species. Anti-equine ferritin polyclonal antibodies were used for the rhinoceros,[24] mouse monoclonal anti-dog ferritin antibody for the northern fur seal,[5] and anti-human ferritin polyclonal antibodies for the lemur ELISA test.[3] Each ELISA is calibrated with a standard curve of known concentrations of the ferritin purified from the species being measured. Non-human serum ferritin assays are offered by the Comparative Hematology Laboratory at Kansas State University.

Despite being an acute phase protein, serum ferritin correlates with tissue iron stores in normal domestic animals.[43] Increased serum ferritin occurs in animals with increased iron stores associated with chronic hemolytic anemias and repeated blood transfusions. Other causes of high serum ferritin concentrations include benign hemophagocytic disorders and malignant histiocytosis. Serum ferritin is also transiently increased in horses by intense exercise. Serum ferritin is decreased in animals with iron deficiency. Serum ferritin loses sensitivity when iron deficiency occurs in the face of inflammation, as the increase due to the acute phase response masks the decrease due to decreased storage.

Bone Marrow Iron

Bone marrow aspirates or core biopsies can be stained with Prussian blue to detect blue-staining hemosiderin, a tissue storage form of iron. Bone marrow aspirates used for Prussian blue staining should contain several unit particles to ensure adequate material is present for assessment of marrow iron. Animals with iron deficiency lack stainable iron in bone marrow; however, lack of stainable iron is not necessarily predictive of iron deficiency.[11] Healthy noniron-deficient cats and some cattle lack stainable iron in bone marrow.[14]

IRON DEFICIENCY

Types of Iron Deficiency and Causes

There are two broad classifications of iron deficiency: absolute and functional. Absolute iron deficiency is caused by insufficient gastrointestinal iron absorption, an iron-poor diet, or, most commonly in veterinary species, chronic hemorrhage.[31] Sources of hemorrhage include gastrointestinal ulcers, gastrointestinal neoplasia, hemorrhagic colitis, urinary bladder neoplasia, thrombocytopenia, inherited hemostatic disorders, and severe ectoparasite burden in small/young animals.[31] Deficiency due to an iron-poor diet is rare except in low-birth-weight neonatal animals that are nursing.[41] Milk contains low concentrations of iron; therefore, nursing animals can easily become iron-deficient as they grow.[23] Piglets reared without access to soil are highly susceptible to iron deficiency. This is prevented by administration of intramuscular iron dextran injections in piglets.[48] Inflammatory bowel disease and other disorders diffusely affecting the gastrointestinal tract may also cause iron deficiency due to decreased iron absorption by compromised bowel function in addition to mucosal blood loss.[33,38] Clinical features associated with iron deficiency vary somewhat depending on the cause of the iron deficiency and the presence of other concomitant disorders. Clinical signs that may be present include pale mucous membranes, lethargy, weakness, weight loss, stunted growth, hematuria, dermatitis, hematochezia, and melena. Iron-deficient animals have increased susceptibility to infection. This is because iron is required for normal T-cell function and bactericidal activity of macrophages.[20]

In contrast to absolute iron deficiency is functional iron deficiency, which is associated with inflammation.

In functional iron deficiency, iron stores within the body are adequate, but they are not accessible for hemoglobin production. When inflammation is present, the liver is stimulated to produce the peptide hormone hepcidin (Figure 27.1). Hepcidin binds to and degrades the only known cellular iron exporter, ferroportin. Without ferroportin, iron cannot enter the bloodstream from the gastrointestinal tract. Neither can it be exported from macrophages, which play a key role in iron cycling due to their primary function in breakdown of red blood cells. Clinical features of functional iron deficiency depend on the primary disease process, but these patients typically develop anemia, which is often referred to as anemia of chronic disease or anemia of inflammatory disease.

Laboratory Features

CBC Findings

Findings for absolute and functional iron deficiency are similar. Because iron is required for hemoglobin synthesis (see Chapter 20), deficiency impairs this process, altering erythrocyte and reticulocyte indices. Once iron deficiency has depleted iron stores, anemia usually develops, which is detected on CBCs by a decreased RBC count, hematocrit, and hemoglobin concentration. Mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) are two major erythrocyte indices that may also reflect iron deficiency. MCV usually decreases with absolute iron deficiency. One study theorized this may be due to iron-deficient cells undergoing additional cell divisions to achieve adequate hemoglobin concentration; however, this has not been proven.[47] MCHC also classically decreases with absolute iron deficiency, as less iron is available to produce hemoglobin. Functional iron deficiency is typically associated with a normocytic, normochromic anemia. However, microcytosis may develop if inflammation continues for an extended period of time.[22,32] The RBC distribution width (RDW) is frequently increased in absolute iron deficiency because of the coexistence of microcytes and normocytes in the blood. The greatest disadvantage of MCV and MCHC in evaluation of patient iron status is that their values do not move beyond the reference interval until late in the course of disease when there are enough affected erythrocytes to shift the mean value. Thus, these tests lack sensitivity in detection of iron deficiency. Visual inspection of cytograms generated by flow-cytometer-based hematology analyzers may detect low numbers of microcytic and/or hypochromic red blood cells when MCV and MCHC are within reference intervals. Thrombocytosis is also frequently present in cases of both absolute and functional iron deficiency. The pathogenesis of thrombocytosis seen in absolute iron deficiency is poorly understood. In functional deficiency, it is likely secondary to inflammatory cytokines that are known to stimulate thrombopoiesis.[21]

Because reticulocytes have been recently produced, they most accurately reflect the current iron status of the bone marrow.[36,45] Because changes in reticulocyte indices may occur before changes in mature erythrocyte indices, they offer increased sensitivity in detecting iron deficiency. The most extensively studied reticulocyte indices include reticulocyte hemoglobin content (CHr) and reticulocyte mean cell volume (MCVr), both of which decrease with iron deficiency.[9,36,40,45] Other indices reported may include reticulocyte hemoglobin concentration, percentage of hypochromic reticulocytes, percentage of reticulocytes with low/high CHr, and percentage of microcytic/macrocytic reticulocytes.

RBC Morphological Findings

Alterations in RBC morphology are commonly noted in iron-deficient animals. Hypochromic RBCs have a narrow rim of lightly stained hemoglobin and a larger than normal area of central pallor. Keratocytes, schistocytes, and target cells are also frequently present in iron deficiency. Tear-drop-shaped RBCs called *dacryocytes* and folded RBCs are commonly noted on blood films in iron-deficient camelids.[29] The mechanism responsible for these shape alterations is uncertain. When iron deficiency anemia is the result of hemorrhage, reticulocytosis is frequently present in the early stages.

Portosystemic Shunts

Portosystemic shunts (PSS) are vascular connections between the portal and systemic circulation that divert blood around the liver. These vessels may occur congenitally or arise secondary to portal hypertension associated with chronic hepatic disease. Most affected dogs have mild microcytosis and hypochromasia, but are not anemic.[28] Although iron metabolism is clearly affected in dogs with PSS, it is most likely secondary to sequestration rather than absolute iron deficiency. This is evidenced by a normal or reduced TIBC accompanied by a variable transferrin saturation, normal to increased serum ferritin concentrations, and increases in liver iron stores after experimental PSS induction. In spite of the fact that the microcytosis and anemia of PSS appear to be functional, hepcidin mRNA has been shown to be unchanged after PSS correction.[10] Further research is needed to fully characterize the mechanism of iron dysregulation in PSS.

OTHER MICROCYTIC OR HYPOCHROMIC ANEMIAS

Microcytic or hypochromic anemias have been associated with sideroblastic anemia and refractory anemia with ringed sideroblasts. Refractory anemia with ringed sideroblasts is a type of myelodysplastic syndrome (see Chapter 67).[12]

Sideroblastic Anemias

The hallmark of sideroblastic anemias is the presence of ≥5 large iron aggregates within RBCs (i.e., siderocytes) or erythroid precursors (sideroblasts), or the presence of iron distributed in a ring around the nucleus of erythroid precursor cells (i.e., ringed sideroblasts). Sideroblastic anemia in dogs is rare, and association with clinical disease has primarily been seen in dogs with inflammatory diseases.[51] The hemogram in these dogs is characterized by moderate to severe nonregenerative anemia that is frequently hypochromic and sometimes microcytic, in spite of elevated serum iron concentrations. There are also dysplastic features in the erythroid lineage of the bone marrow.

COPPER DEFICIENCY

Copper deficiency can develop in ruminants eating forage from copper-deficient soils. Secondary copper deficiency can occur when copper intake is adequate, but use is impaired by high dietary molybdenum or sulfate. Affected animals generally have a microcytic hypochromic anemia; however, normocytic anemias have been reported in experimental copper deficiency in dogs.[3] Microcytosis and hypochromasia are the result of functional iron deficiency. Functional iron deficiency results from a decrease in production of the copper-containing proteins ceruloplasmin, hephaestin, and cytochrome oxidase that are required for iron transport.[25] Hephaestin is involved in release of iron from intestinal enterocytes. Ceruloplasmin facilitates mobilization of iron from the liver and tissues other than enterocytes.[53] Pigs with acute experimental copper deficiency have low serum iron, but pigs with chronic experimental copper deficiency develop increased serum iron concentration and have many sideroblasts present.[25] This may be due to a deficiency of the copper-containing enzyme cytochrome oxidase in erythroid precursor cells. Cytochrome oxidase is involved in reducing ferric to ferrous iron in mitochondria for use in heme synthesis.

IRON OVERLOAD

Iron overload can result from acute iron toxicity or chronic accumulation that results in hemosiderosis or hemochromatosis. Iron overload can result in saturation of transferrin, leading to increased levels of non-transferrin-bound iron. Non-transferrin-bound iron can freely interact with cells, resulting in the production of hydroxyl radicals and subsequent organ damage.[35]

Acute Iron Toxicity

Acute iron toxicity results from administration of large doses of iron to animals (the dose depends on the species). Parenteral administration of large amounts of iron to ruminants results in respiratory distress, icterus, and central nervous system signs.[39] In dogs, oral intake of >20 mg/kg of iron can result in gastrointestinal distress, followed by cardiovascular shock, icterus, vomiting, bloody diarrhea, and hypovolemic shock.[1] Excess iron given orally can override the normal mechanisms that regulate intestinal absorption. Hepatotoxicity has been documented in neonatal foals after ingestion of a nutritional supplement containing ferrous fumarate iron at a concentration lower than that required to induce acute iron toxicity in adult horses.[30]

Hemosiderosis and Hemochromatosis

Hemochromatosis refers to accumulation of iron in tissue with associated organ injury and dysfunction, while hemosiderosis refers to accumulation of iron within tissues without evidence of organ injury or dysfunction. Hemosiderosis occurs locally within tissues at sites where hemorrhage has occurred and in a more disseminated way during conditions such as chronic hemolytic conditions.

Primary Hemochromatosis

Primary (hereditary) hemochromatosis has been described in related Salers cattle, captive black rhinoceros, and certain birds.[2,27,34] Affected Salers cattle had a history of stunted growth, poor hair coat, and weight loss, with iron accumulation in multiple tissues and increased serum iron and percent saturation of transferrin.

Secondary Hemochromatosis

Secondary hemochromatosis is most frequently associated with hemolytic anemias, repeated blood transfusions, parenteral iron administration, or dietary iron overload. Dietary iron overload does not appear to be a problem in animals except in a few wild animal species housed in captivity.[26] Hemolytic anemias are associated with increased iron absorption. When the hemolysis is chronic, increased intestinal absorption results in iron accumulation within hepatocytes as well as within macrophages. Liver fibrosis eventually develops. Secondary hemochromatosis associated with blood transfusions was reported in a dog given regular transfusions over a long period of time.[44]

Acronyms and Abbreviations

ADP, ALAD-deficient porphyria; AIP, acute intermittent porphyria; ALAS, δ-aminolevulinic acid (ALA) synthase; ALAD, ALA dehydratase; CEP, congenital erythropoietic porphyria; CPO, coproporphyrinogen oxidase; DSH, domestic short-haired; EPP, erythropoietic protoporphyria; HCP, hereditary coproporphyria; HEP, hepatoerythropoietic porphyria; HMBS, hydroxymethylbilane synthase; PBG, porphobilinogen; PCT, porphyria cutanea tarda; PPO, protoporphyrinogen oxidase; UROD, uroporphyrinogen decarboxylase; UROS, uroporphyrinogen synthase; UV, ultraviolet; VP, variegate porphyria.

Porphyrias are a complex group of rare but important diseases that arise due to defective heme production. Because defects can arise at any of the eight enzymatic steps responsible for the production of heme and there are nine different genes encoding those enzymes, porphyrias manifest in a variety of ways, most commonly recognized by veterinarians because of cutaneous photosensitization in cattle or because of pink, red, or brownish discoloration of teeth, bones, soft tissues, or urine in multiple species, including cattle. This chapter will provide a basic description of the disorders associated with defective heme production including an update of what has been reported in the veterinary literature.

NORMAL HEME SYNTHESIS

The synthetic pathway for heme originates in mitochondria, progresses into the cytosol, and then returns to mitochondria for the final stages (see Figure 20.2 in Chapter 20). There are eight different enzymatic steps involved in heme formation (Table 28.1). The first enzymatic reaction is the rate-limiting step. All other enzymes are normally more active than the first, with each step progressing to formation of the next heme precursor without significant production of side products. Precursors are listed in Table 28.1 and discussed in more detail in the following text.

Enzymes: ALAS, δ-aminolevulinic acid (ALA) synthase; ALAD, ALA dehydratase; HMBS, hydroxymethylbilane synthase; UROS, uroporphyrinogen III synthase; UROD, uroporphyrinogen decarboxylase; CPO, coproporphyrinogen oxidase; PPO, protoporphyrinogen oxidase; FECH, ferrochelatase.

Porphyrias: ADP, ALAD-deficient porphyria; AIP, acute intermittent porphyria; CEP, congenital erythropoietic porphyria; PCT, porphyria cutanea tarda; HEP, hepatoerythropoietic porphyria; HCP, hereditary coproporphyria; VP, variegate porphyria; EPP, erythropoietic protoporphyria.

Heme is incorporated into various protein matrixes to create the hemoproteins, including hemoglobin, myoglobin, cytochromes, catalases, peroxidases, and endothelial nitric oxide synthase. Tissues that produce the most heme are bone marrow and liver. Approximately 80% of overall heme production occurs in bone marrow for hemoglobin (in nucleated erythrocytes and reticulocytes, since mitochondria are necessary for synthesis). Approximately 15% of overall heme production occurs in the liver, largely for incorporation into microsomal cytochrome P450 enzymes, but also catalase and other cytochromes.

ABNORMAL HEME SYNTHESIS

Heme synthesis enzyme defects are predominantly recognized in either erythropoietic or liver tissue. Hence, the different porphyria diseases are often classified as either erythrocytic or hepatic (or in combination). Porphyrias are often also categorized as either acute neurovisceral or cutaneous, depending on symptoms.

Porphyrins are a class of macrocyclic aromatic compounds composed of four pyrrole rings connected by methine bridges. All porphyrin compounds absorb light intensely at 400–410 nm and can cause cell damage and discoloration of tissues. During normal heme synthesis, porphyrins are not produced in significant amounts, except for the last precursor, protoporphyrin IX, into which iron is inserted for the final product of heme. The other heme precursors are not porphyrins and their chemical structures do not absorb light energy or fluoresce. However, if these precursors do not go on to make heme, they can build up to toxic concentrations themselves or undergo alternative reactions, which result in pathologic porphyrin products. The major porphyrins derived from aberrant heme synthesis are shown in Figure 28.1.

GENERAL CONSEQUENCES OF DEFECTIVE HEME SYNTHESIS

Porphyria is often suspected because of reddish-brown discoloration of tissues and/or cutaneous lesions of photosensitivity. When porphyrins are present early in life, they are particularly noticeable in the reddish-orange staining of the teeth and dentine. Dentine discoloration can also be evident in adults. Pink, reddish-orange, to brownish discoloration of urine is often readily visible and may be the presenting complaint. Urine that contains precursors may not be discolored initially, but

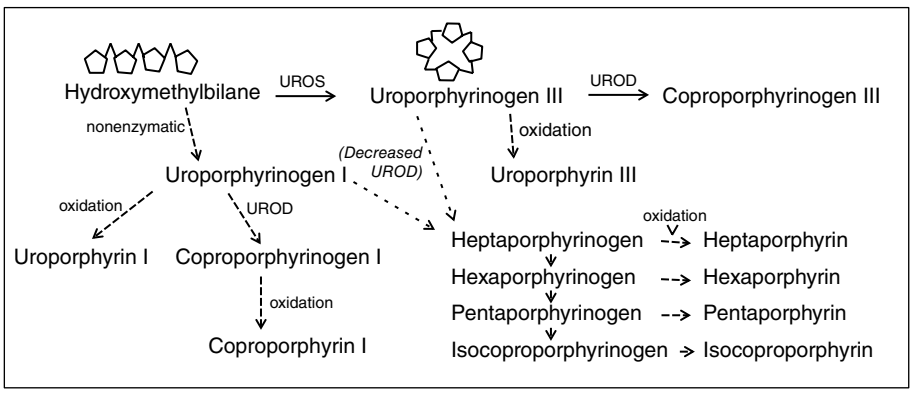

FIGURE 28.1 Pathways for aberrant porphyrin production when UROS or UROD activity is deficient (dashed and dotted lines) for heme synthesis.

become so when substances conjugate and oxidize over time. Urine reagent strip blood pads should remain negative, as their reaction requires heme iron. Animals may show signs of photosensitivity or be poor-doing.

Deficiencies in the activity of all but the first three heme synthesis enzymes are to some degree associated with cutaneous lesions (although not in all cases, depending on which enzyme and species affected). Cutaneous lesions are due to the photosensitive nature of porphyrins. Porphyrins absorb ultraviolet (UV) light energy, causing transition to an excited energy state. The excited porphyrin may directly react with cellular structures or transfer the energy to molecular oxygen to form reactive oxygen species which act as powerful oxidants for many biologically important compounds.[2]

Photohemolysis is not likely to play a significant role in the hemolytic anemia associated with some porphyrias. Although in vitro exposure to UV light resulted in lysis of erythrocytes from human erythropoietic porphyria cases, this affect was not thought to occur in vivo.[13,15] High concentrations of porphyrins are thought to alter the erythrocytes in some unknown way, which results in their early removal from circulation.[18] A direct effect is supported by finding decreased erythrocyte survival time in cows with erythropoietic porphyria, despite no exposure to sunlight.[18]

The underlying mechanism of the microcytosis described in many cases of porphyria has not been elucidated, but microcytosis is not necessarily surprising, since porphyrias are associated with decreased heme production and altered iron metabolism.

Acute neurovisceral signs (fatigue, abdominal pain, nausea, vomiting, constipation, neuropathies, or mental disturbances) have only been described for humans, although seizures have occasionally been reported in cattle.[6,25] The cause of these neurovisceral effects is not well understood, but it is thought that δ-aminolevulinic acid (ALA) and/or porphobilinogen (PBG) are neurotoxic.

With porphyrias, disease manifestations and severities and patterns of porphyrin and precursor accumulation can be widely variable, even within named disease entities. In affected people or animals, patterns of accumulation can fluctuate episodically and severity of clinical signs can vary with age, either improving or worsening over time. Potential contributors to the complexity of the porphyria disease processes, many of which are poorly understood, include: the high number of different genetic defects associated with all of the different heme synthesis enzymes; potential defects in transcription factors or other heme-synthesis-related substances or pathways; altered regulation of heme biosynthesis by accumulated substances; external influences; and species differences.

TESTING

Suspicion of the presence of porphyrins can be substantiated by their characteristic reddish fluorescence when exposed to UV light. When a Wood's lamp or other UV light that includes the Soret band (400–410 nm) is shone on teeth, urine, or blood-containing porphyrins, an intense pink or red fluorescence is seen. This is virtually pathognomonic of porphyria, but not necessarily the type.

It is beyond the scope of this chapter to delve into the different testing methods for porphyrias. Definitive diagnosis of specific porphyria disease entities requires measuring products of defective heme synthesis in urine, blood, or feces (excretory routes are dependent on water solubility), measuring the activity of enzymes important for heme synthesis, and/or enzyme genetic analysis for specific known mutations or characterization of new ones. Unfortunately, other than a few genetic tests (see Section "Animal Porphyrias"), no known veterinary diagnostic laboratory offers testing for porphyria (some screening test methodologies are described in Kaneko[19]). There are specific human diagnostic laboratories that perform porphyria testing, but they may not accept animal samples. A source for these laboratories is the American Porphyria Foundation's website: https://porphyriafoundation.org (For patients; About porphyria; Diagnosis or For healthcare professionals; Diagnosis and testing). If one finds a laboratory willing to assess veterinary samples, consider also submitting comparable samples from an unrelated, healthy animal of the same species. Once collected, samples need to be protected from light exposure. Measuring the different heme precursors and porphyrins to determine which predominate is useful in supporting a disease diagnosis, but may not be definitive.

ENZYMATIC STEPS OF HEME SYNTHESIS AND ASSOCIATED PORPHYRIAS

In order to provide a comprehensive overview of the porphyrias, this section will provide a brief description of each of the eight different enzymatic steps in heme synthesis (see Table 28.1) and their associated porphyrias as seen in humans. Porphyrias that have been described in animals will be more thoroughly discussed in the next section. In humans, hundreds of different genetic defects have been detected across the different enzymes.[5]

δ-Aminolevulinic Acid Synthase

δ-Aminolevulinic acid synthase (ALAS) is a mitochondrial enzyme and the rate-limiting enzyme in the synthesis of heme. ALAS catalyzes the condensation reaction of glycine and succinyl-CoA to form ALA. There are two different genes encoding two different ALAS enzymes: ALAS1 is expressed ubiquitously and ALAS2 is expressed only in erythroid precursors. Although no mutations in ALAS1 have been identified, ALAS1 plays a role in some other porphyria diseases. In liver, ALAS1 is inducible as a response to increased demand (e.g., induction of P450 enzyme synthesis) or to excess accumulation of heme biosynthetic intermediates.[5] Heme insufficiency also leads to increased ALAS1

activity because feedback inhibition is lacking. This overexpression of hepatic ALAS1 is associated with neurovisceral signs. Diseases due to abnormal ALAS2 activity have only been identified in people: X-linked sideroblastic anemia with decreased ALAS2 activity (microcytosis possible) and a gain of function mutation in ALAS2 leading to excess protoporphyrin production and subsequent photosensitivity and liver damage.[27]

δ-Aminolevulinic Acid Dehydratase

δ-Aminolevulinic acid dehydratase (ALAD) is a cytosolic enzyme that catalyzes the condensation reaction of two molecules of ALA to form PBG, which contains a pyrrole ring structure. There is only one ALAD gene, but two different promoters: one "housekeeping" and the other erythroid-specific. ALAD-deficient porphyria (ADP) is extremely rare in humans and only one suspect case has been reported in animals. In ADP, ALAD activity is markedly deficient, resulting in high ALA and coproporphyrin III excretion in urine and elevated erythrocyte protoporphyrin. Clinical manifestations are similar to other acute neurovisceral porphyrias, with potentially severe neurological symptoms.[4,5,27]

Since lead inhibits ALAD, lead toxicity can result in increased urinary excretion of ALA and clinical manifestations similar to ADP.[5]

Hydroxymethylbilane Synthase

Hydroxymethylbilane synthase (HMBS) is also known as porphobilinogen deaminase (PBGD) and was previously called uroporphyrinogen I synthase. It is a cytosolic enzyme that, like ALAD, has only one gene, but different housekeeping and erythroid-specific promoters. HMBS combines four molecules of porphobilinogen into a linear tetrapyrrole called hydroxymethylbilane.

Human acute intermittent porphyria (AIP) is typically associated with approximately 50% decreased HMBS activity; it is autosomal dominant and the most common acute porphyria in humans. Most people with the defect do not exhibit clinical signs. However, if liver ALAS1 activity is induced by concurrent conditions or inducing substances, nonspecific neurovisceral manifestations can result. During an attack, urine may become dark red but erythrodontia (reddish discolored teeth) is only seen in extremely rare homozygous cases.[10] The most significant finding for tentative diagnosis is an elevated urinary PBG concentration. AIP has also been reported in cats.[10,11]

Enzymatic activity of HMBS can also be inhibited by high concentrations of protoporphyrinogen and coproporphyrinogen, which likely play a role in other hepatic porphyria diseases.[4,5]

Uroporphyrinogen III Synthase

Uroporphyrinogen synthase (UROS) was previously called uroporphyrinogen III cosynthase. It is a cytosolic enzyme that also has different housekeeping and erythroid-specific promoters. UROS facilitates the transformation of the linear tetrapyrrole, hydroxymethylbilane, into a tetrapyrrole ring structure called uroporphyrinogen III, the only isotype able to progress in the heme biosynthetic pathway.

Congenital erythropoietic porphyria (CEP) is an autosomal recessive disorder caused by markedly decreased UROS activity, which results in accumulation of nonenzymatically formed, nonphysiologic and pathogenic porphyrin isomers (see Figure 28.1). It is rare in humans, but one of the more commonly described porphyrias across different animal species.

In humans, CEP manifests as chronic, severe blistering cutaneous photosensitivity, mild to marked hemolytic anemia, and possible discoloration of teeth and urine.

Uroporphyrinogen Decarboxylase

Uroporphyrinogen decarboxylase (UROD) is a cytosolic enzyme that facilitates decarboxylation of uroporphyrinogen (containing eight carboxyl groups), to coproporphyrinogen (containing four carboxyl groups). A deficiency in UROD activity causes the most common form of porphyria in humans, porphyria cutanea tarda (PCT), as well as the less common but more severe hepatoerythropoietic porphyria (HEP), which has complex patterns of porphyrin accumulation. There are a few reports of suspected UROD deficiency in sheep and pigs; however, definitive diagnoses have not been made.[26,30] PCT may or may not have an inherited mutation in the UROD gene and relies on acquisition of other susceptibility factors to cause liver UROD inhibition. HEP is due to homozygous or compound mutations of the UROD gene, which markedly decrease both liver and erythrocyte UROD activity. PCT typically exhibits milder cutaneous photosensitivity only in adults, while HEP is more similar to CEP with severe photosensitivity and possible anemia and discoloration of teeth and urine, often manifesting in early childhood. Decreased UROD activity results in high levels of urine uroporphyrin I and heptacarboxyl porphyrin III with isotype III porphyrins predominating overall (see Figure 28.1). High fecal and urine isocoproporphyrin concentration is unique to PCT and HEP.[5]

Coproporphyrinogen Oxidase

Coproporphyrinogen oxidase (CPO) is a mitochondrial enzyme, which catalyzes a side chain modification to convert coproporphyrinogen III to protoporphyrinogen IX.[4] Hereditary coproporphyria (HCP) is an autosomal dominant hepatic porphyria associated with half-decreased CPO activity. HCP manifests very similar to AIP except that cutaneous lesions similar to PCT can occasionally occur.[5] In this disease, large amounts of coproporphyrin, mostly type III, are excreted in urine and feces. During acute attacks, urinary ALA, PBG, and uroporphyrin are also increased. There are no documented cases of HCP in animals.

Protoporphyrinogen Oxidase

Protoporphyrinogen oxidase (PPO) is a mitochondrial enzyme that oxidizes protoporphyrinogen IX to

protoporphyrin IX. Mutations in PPO are causative for variegate porphyria (VP), an autosomal dominant disorder that manifests in either acute neurovisceral attacks similar to AIP, cutaneous photosensitivity similar to PCT, or both.[4] It has not been reported to occur in animals. Excretory products are similar to CPO with the addition of high fecal protoporphyrin concentrations. Plasma porphyrin analysis is effective in diagnosing VP.[5]

Ferrochelatase

Mitochondrial ferrochelatase (FECH) facilitates the insertion of iron into the protoporphyrin heme backbone. Erythropoietic protoporphyria (EPP) is caused by mutations of the ferrochelatase gene and subsequent decreased enzymatic activity. In humans, heredity is complex, as an autosomal dominant disorder that requires the presence of a second molecular defect.[5,27] The disorder is autosomal recessive in cattle.[5,16] Protoporphyrin is the only heme pathway intermediate that significantly accumulates in EPP, predominantly accumulating in bone marrow reticulocytes, with excess amounts detectable in circulating erythrocytes, plasma, bile, and feces.[4,5] Diagnosis is often based on the high accumulation of protoporphyrin in erythrocytes.[27] The protoporphyrin is free, in contrast to the zinc-complexed protoporphyrin associated with other porphyrias, although assays typically do not make a distinction.[5] Humans with EPP have an acute, painful, erythemic, nonblistering photosensitivity that can be lifelong. Mild microcytic nonregenerative anemia is frequently reported.[5,27]

ANIMAL PORPHYRIAS

Reports of naturally occurring porphyria in animals implicate five of the enzymes involved in heme biosynthesis, two of these are only suspected and not proven (Table 28.2). Definitively diagnosing specific porphyrias can be difficult, given the scarcity and/or difficulty of enzymatic and genetic testing combined with the low incidence of these diseases. Measuring intermediates of heme formation and porphyrins may provide supporting evidence for the different porphyrias, but can be challenging to perform and results can be confusing. Enzyme activity and/or genetic analysis are usually necessary for definitive diagnosis. Porphyria is typically suspected in animals because of cutaneous photosensitivity and/or discoloration with subsequent fluorescence of tissues or urine. Acute hepatic porphyrias without those features would be very difficult to detect in animals, given the nonspecific neurovisceral signs associated with them. Being mindful of often variable and incomplete testing between investigations, this section is a review of porphyrias as reported in animals.

TABLE 28.2 Porphyrias reported in animals.

Disorder*	Enzyme defect*	Major accumulated substances	Reported animals
ADP	ALAD	ALA in urine	Suspect cat
AIP	HMBS	ALA, PBG, URO III in urine; URO I and III in teeth	Cats
CEP	UROS	URO I, COPRO I in urine and RBC; COPRO I in feces	Cattle, swine, cats, hedgehog, rabbit, fox squirrels
PCT	UROD	URO, COPRO, heptaporphyrins in urine	Sheep, possibly swine
EPP	FECH	Protoporphyrin IX in feces and RBC	Cattle, dogs, possibly chickens

* See acronyms, Table 28.1.
ALA, δ-aminolevulinic acid; PBG, porphobilinogen; URO, uroporphyrin; COPRO, coproporphyrin; PROTO, protoporphyrin.

ALAD-Deficient Porphyria

A cat that presented with frequent seizures and vague gastrointestinal signs was suspected to have ADP after lead toxicity was ruled out.[36] Suspicion was based on consistently elevated ALA concentrations in urine. Urine porphyrin concentration was not elevated as is typically seen in humans with ADP; no enzymatic or genetic analysis was performed. Findings in this cat were also consistent with a different rare human disorder associated with decreased ALAD activity, hereditary tyrosinemia.[5,12] A diagnosis of ALD in this cat cannot be considered definitive.

Acute Intermittent Porphyria

AIP has been recently diagnosed in four lines of cats as well as two additional cats.[10,11] Unlike in humans with AIP, which present with neurovisceral symptoms, these cats were identified because of erythrodontia and brownish urine, similar to CEP. Teeth and bone fluoresced under UV light. Urinary porphyrins were elevated as with CEP; however, patterns of individual heme precursors and porphyrins were more consistent with AIP. Type I porphyrin isomers predominate in CEP, whereas in these cats (as in humans), high concentrations of urinary uroporphyrin and coproporphyrin types I and III as well as ALA and PBG were detected. In contrast to humans where PBG concentration elevates mostly during acute attacks, levels were constitutively elevated in cats.[10] Porphyrin concentrations were also constitutively elevated in liver and spleen tissue, bone, teeth, and erythrocytes. Enzyme assays detected decreased activity of HMBS but not of UROS; HMBS activity was decreased by half in liver and by half or more in erythrocytes. Genetic analysis revealed unique mutations of the HMBS gene in each of the cat lineages and each additional cat, with no relevant mutations of the UROS gene. Similar to humans, disease inheritance

was autosomal dominant except for in one cat lineage where it was recessive. Mild regenerative anemia and microcytosis were observed in several of the cats. Neurovisceral manifestations were not appreciated. These cats easily could have been diagnosed with CEP without enzymatic and genetic testing; previous cases of porphyria in animals may have been misclassified. DNA mutation testing for AIP is currently available for cats.[a]

Congenital Erythropoietic Porphyria

CEP has been proven in a domestic short-haired (DSH) cat and has been suspected in other cats, typically presenting for erythrodontia. In the proven case, similar to humans, there were marked increases in uroporphyrin I and coproporphyrin I in urine, plasma, and erythrocytes and their precursors; urinary ALA and PBG were not increased.[9] UROS activity in erythrocytes was <1%. Mutations of the UROS gene were characterized and shown to decrease the enzyme's activity and stability. This cat was not anemic, but increased polychromasia and basophilic stippling were observed. A family of Siamese cats was also thought to have CEP.[14] These cats had discolored and fluorescent urine and tissues, as well as increased concentrations of uroporphyrin, coproporphyrin, and protoporphyrin in all tissues evaluated. Marked elevations in concentrations of urinary uroporphyrin I and fecal coproporphyrin I were detected. This marked predominance of the type I isomers is the strongest evidence for CEP. These cats may have had mild photosensitivity, as evidenced by seasonally periodic episodes of nasal and ocular discharge. They were generally listless, likely correlating with severity of anemia. These cats also had renal disease, but it was uncertain if or how that was related to the porphyria. In a few other case reports in which CEP was only speculative, cats had discolored bones and teeth that fluoresced, but no biochemical or genetic testing was performed.[1,33] CEP in cats differs from humans and cattle in that cutaneous lesions are not seen. Consistent with other species, anemia appears variable. DNA mutation testing for CEP is available for cats.[a]

In cattle, CEP was first reported in South African Shorthorns, but more commonly affects Holstein-Friesians.[3,17,34] Occasional listings of other affected breeds, including Jamaica Red and Black, Ayrshire, and Hereford cattle, refer to isolated, decades-old reports.[17,34] A more recent case report of CEP in a Longhorn calf in the United Kingdom theorizes Shorthorn ancestry.[17] Another recent suspected case was reported in a Gir calf.[28]

Cattle with CEP are often detected due to purplish pink to brownish red discoloration of teeth, brownish-colored bones, and amber to red–brown-colored urine. Pink to red florescence confirms porphyrins as the cause of the discoloration. Cattle with CEP are also often detected due to lesions of the nonpigmented areas of the skin. Severity of cutaneous lesions varies between individuals, from nonexistent to exhibiting erythema, denudation, vesicle formation, or necrosis.[7,17,20,29] Severity is related to the amount of porphyrin accumulation, coat color and density, and the amount of sun exposure.[7,20] The hemolytic anemia associated with CEP varies in severity between individual cattle and can be present at birth. CEP can cause retarded growth and lack of condition. Clinical signs are mitigated by keeping affected cattle out of sunlight.

Biochemically, high concentrations of uroporphyrin I and coproporphyrin I are present in urine and erythrocytes, predominantly metarubricytes. A high amount of coproporphyrin I is also excreted in feces. Porphyrin concentrations tend not to be significantly elevated in plasma, but elevated erythrocyte protoporphyrin concentrations have been reported in cattle.[17,20]

Activity of UROS is not typically measured, but has been shown to be decreased in cattle with CEP.[23,31] A decrease in activity of approximately 20% was reported, although activity was figured on a per-gram of hemoglobin basis using hemolysates. Since it was not taken into account how many reticulocytes with higher activity were present versus mature red cells and given that CEP is a recessive disorder, enzyme activity is likely lower than what was reported.[23,31]

Definitive causative mutations of the UROS gene have not been identified in cattle; however, genetic analysis of a family of Danish Holstein cattle was supportive of a mutation affecting UROS. These cattle had photodermatitis, discoloration of tissues, and a high concentration of bone uroporphyrin consistent with decreased UROS activity.[3]

Data regarding porphyrias in pigs is incomplete. Pigs with discoloration of bones and soft tissues have been sporadically observed in slaughterhouses. Cases can often be traced to a particular sow or boar and typically cease through breeding and removing newborns with discolored deciduous teeth.[34] Both autosomal dominant and recessive inheritance have been suggested in different reports. It is difficult to determine how many of the early swine cases suspected to have CEP were accurately diagnosed, since diagnosis was predominantly based on physical characteristics. At least in one early study, urine porphyrins were measured and found to be elevated, with the majority being the type-I isomer, which is supportive of CEP in that study.[29] Pigs have not exhibited photosensitization, but may exhibit poor growth and variable anemia. Disease severity can fluctuate with age. The most recent report of pig porphyria appears to be from 1995, within which the authors suspected a mixed porphyria of UROS and UROD activity deficiencies (see in the following text).[30]

Porphyria was diagnosed in a 6-month-old hedgehog that presented for pink urine.[37] The urine, teeth, feet, and spines fluoresced under UV light. There were marked increases of uroporphyrin (90–95% type I isomers) and coproporphyrin in the urine. Urine and feces from this hedgehog and its nonclinical mother also showed a pattern of porphyrin intermediates with a high proportion of highly carboxylated porphyrins in comparison to two normal hedgehogs that had only fully decarboxylated intermediates.

A New Zealand white rabbit was noted to have pink-tinged teeth on necropsy (the cause of death was determined to be septicemia from pasteurellosis) and its teeth

[a]http://research.vet.upenn.edu/penngen

and bone fluoresced pink.[32] Collected urine contained elevated amounts of uroporphyrin and coproporphyrin compared to a control rabbit's urine, while ALA and PBG concentrations were similar between the two rabbits. Porphyrin levels, especially hexaporphyrin, were also increased in liver tissue.

Markedly low UROS activity appears to be ubiquitous in fox squirrels, which do not exhibit clinical disease.[24] In comparison to gray squirrels, fox squirrels all have less UROS activity and have browner bones and teeth, which fluoresce pink. Erythropoiesis is increased, but the squirrels are not anemic.

Porphyria Cutanea Tarda

A flock of German blackface sheep contained a few poor-doing individuals with anemia and light brown discolored urine.[26] Consistent with PCT, these individuals were heterozygous for a UROD point mutation and had high levels of porphyrins in urine, predominantly uroporphyrins, coproporphyrins, and heptaporphyrins. No mutations were detected in the UROS gene. Activity of UROD and UROS were not measured, which could have definitively confirmed if the porphyria was due to decreased UROD activity.

UROD deficiency might have been present in a Belgian Landrace pig condemned at slaughter due to mahogany-colored tissues. Tissues from this pig contained increased concentrations of multiple decarboxylation products of uroporphyrinogen, typical of UROD deficiency, although a preponderance of isomers I in comparison to isomers III suggests there may have also been decreased UROS activity.[30]

Erythropoietic Protoporphyria

EPP is most common in Limousin cattle, but also described in the Blonde d'Aquitaine breed.[25] Cattle exhibit photosensitization, and seizures have been reported.[6,16,25] Cutaneous lesions most commonly occur on the head (especially ears, muzzle, periocular) and dorsum. Crusting, exudation, ulceration, or alopecia may be seen. The animal may be painful, pruritic, or photophobic. Animals can do better if kept out of sunlight and photosensitivity can decrease as the animal ages. Cattle are not anemic, and discoloration of teeth and urine do not occur.[20]

EPP is characterized by markedly high concentrations of protoporphyrin in erythrocytes and feces. Whole blood fluoresces because of high protoporphyrin levels in reticulocytes and plasma. Nonsymptomatic heterozygotes can be detected because of increased total porphyrins in plasma and erythrocytes. The aberrant ferrochelatase protein resulting in decreased activity is an autosomal recessive trait.[8] Genetic testing can be requested through the North American and Canadian Limousin Foundations and Australian Limousin Breeders' Society.[b,c,d]

[c]http://www.limousin.com/about-us/dna-testing/
[d]https://www.limousin.com.au/member-services/dna-testing

Chickens with elevated protoporphyrin levels consistent with EPP were detected at a poultry-meat-processing plant in Japan.[35] Several broiler chickens with dark green to black livers were collected for analysis. Interestingly, all chickens collected were female; they had mild growth retardation with mildly enlarged livers. Protoporphyrin IX concentration was markedly elevated in liver, bone marrow, and feces when compared to unaffected chickens. Ferrochelatase activity was not measured and genetic analysis was not performed. Protoporphyrin pigments were detected in lung as well as liver on histologic examination. The chickens came from several different farms, but all were progeny from a common breeder farm.

No inherited form of protoporphyria has ever been described in dogs; however, a spontaneous, transient form of the disease was described in a breeding colony of German Shepherd dogs.[21] These dogs had hepatobiliary lesions with no evidence of cutaneous photosensitivity. High concentrations of protoporphyrin IX and low ferrochelatase activity were measured in the affected dogs' livers. All dogs that survived made a full clinical recovery; a cause was not determined. A case of congenital EPP with associated progressive pigmentary hepatopathy, microcytosis, and chronic dermatopathy was recently reported in a young dog.[22] This dog had markedly high protoporphyrin concentrations in plasma, erythrocytes, feces, and liver, with a predominance of metal-free protoporphyrin.

Canine Pyruvate Kinase Deficiency
Feline Pyruvate Kinase Deficiency

Acronyms and Abbreviations

AMP, adenosine monophosphate; BFU-E, burst-forming unit-erythroid; CFU-E, colony-forming unit-erythroid; DNA, deoxyribonucleic acid; DPG, diphosphoglycerate; EDTA, ethylenediaminetetraacetic acid; G6PD, glucose-6-phosphate dehydrogenase; L-M-P-PFK, liver, muscle, platelet phosphofructokinase; L-M1/M2-R-PK, liver, muscle, red blood cell pyruvate kinase; PFK, phosphofructokinase; PK, pyruvate kinase.

As the committed erythroid precursor cells proliferate and develop into mature RBCs in the bone marrow, their cellular metabolism undergoes many changes. And while the burst-forming unit-erythroid (BFU-E) and colony-forming unit-erythroid (CFU-E) cells are geared to massively expand the erythroid cell line, which is under the control of erythropoietin, major metabolic and structural shifts occur, particularly during the later erythroid stages, to achieve the highly specialized functions of mature RBCs (see Chapters 19, 20, and 21).[42] To that end, during rubricyte and metarubricyte (also known as normoblasts) stages until the reticulocyte stage, heme and alpha- and beta-globin syntheses are in full force to produce hemoglobin, reaching one-third of a mature RBCs mass.

Heme synthesis occurs in both mitochondria and cytoplasm involving several enzymatic steps (see Chapter 20). Hereditary enzymatic defects in heme synthesis, also known as porphyrias, cause tissue (bone and teeth) accumulation and urinary as well as fecal excretion of a variety of heme precursors and porphyrins, and can lead to hematological, neurological, gastrointestinal, and cutaneous signs. Porphyrias and their classification and characterization to the molecular level in cats, pigs, sheep, and cattle are described in Chapter 28.

While sickle cell disease and thalassemias are the most common RBC disorders in humans, interestingly, no hemoglobinopathies causing anemia have thus far been documented in domestic animals.

Hereditary methemoglobinemias, either due to a cytochrome b5 (methemoglobin) reductase deficiency or a yet unknown mechanism, have been observed in dogs, cats, and even rhesus monkeys, and are typically associated with cyanosis and erythrocytosis rather than anemia (see Chapter 26).[23,34,36,41]

Glucose-6-phosphate dehydrogenase (G6PD) of the hexose-monophosphate shunt is the most common hereditary (and only X-chromosomal) RBC enzyme deficiency in humans (Figure 29.1); these patients are generally not anemic, but can develop hemolytic crises with oxidative stress (drugs, infections, fava beans [favism]).[2] While in a large canine survey only a single Weimaraner dog was found to have a reduced G6PD activity without any hematological abnormalities,[78] an American Saddlebred colt with G6PD had anemia with eccentrocytosis.[41,66] Furthermore, horses with RBC flavin adenine dinucleotide deficiency have both eccentrocytosis (attributable to severe deficiency in glutathione reductase activity) and methemoglobinemia (attributable to cytochrome b5 reductase deficiency); the dual enzyme deficiency occurs because flavin adenine dinucleotide is a required cofactor for both enzymes.[31]

Although various erythrocytic membrane defects have also been described affecting cytoskeletal proteins,

such as spectrin and band 4.1, others remain undefined and may involve enzymatic pumps to maintain electrolyte and calcium homeostasis as suspected for stomatocytosis in the Alaskan Malamute and Miniature and Middle Schnauzers (see Chapter 30).[84]

Devoid of a nucleus and mitochondria, the metabolism of the mature mammalian RBCs is fairly restricted, and its energy is solely generated by anaerobic glycolysis, also known as the Embden–Meyerhof pathway (Figure 29.1, see Chapter 21).[42] Metabolism of one molecule of glucose to two molecules of lactate leads to the net production of two molecules of ATP. The rate of glycolysis depends on the need for ATP of RBCs to maintain the shape, deformability, membrane transport, and

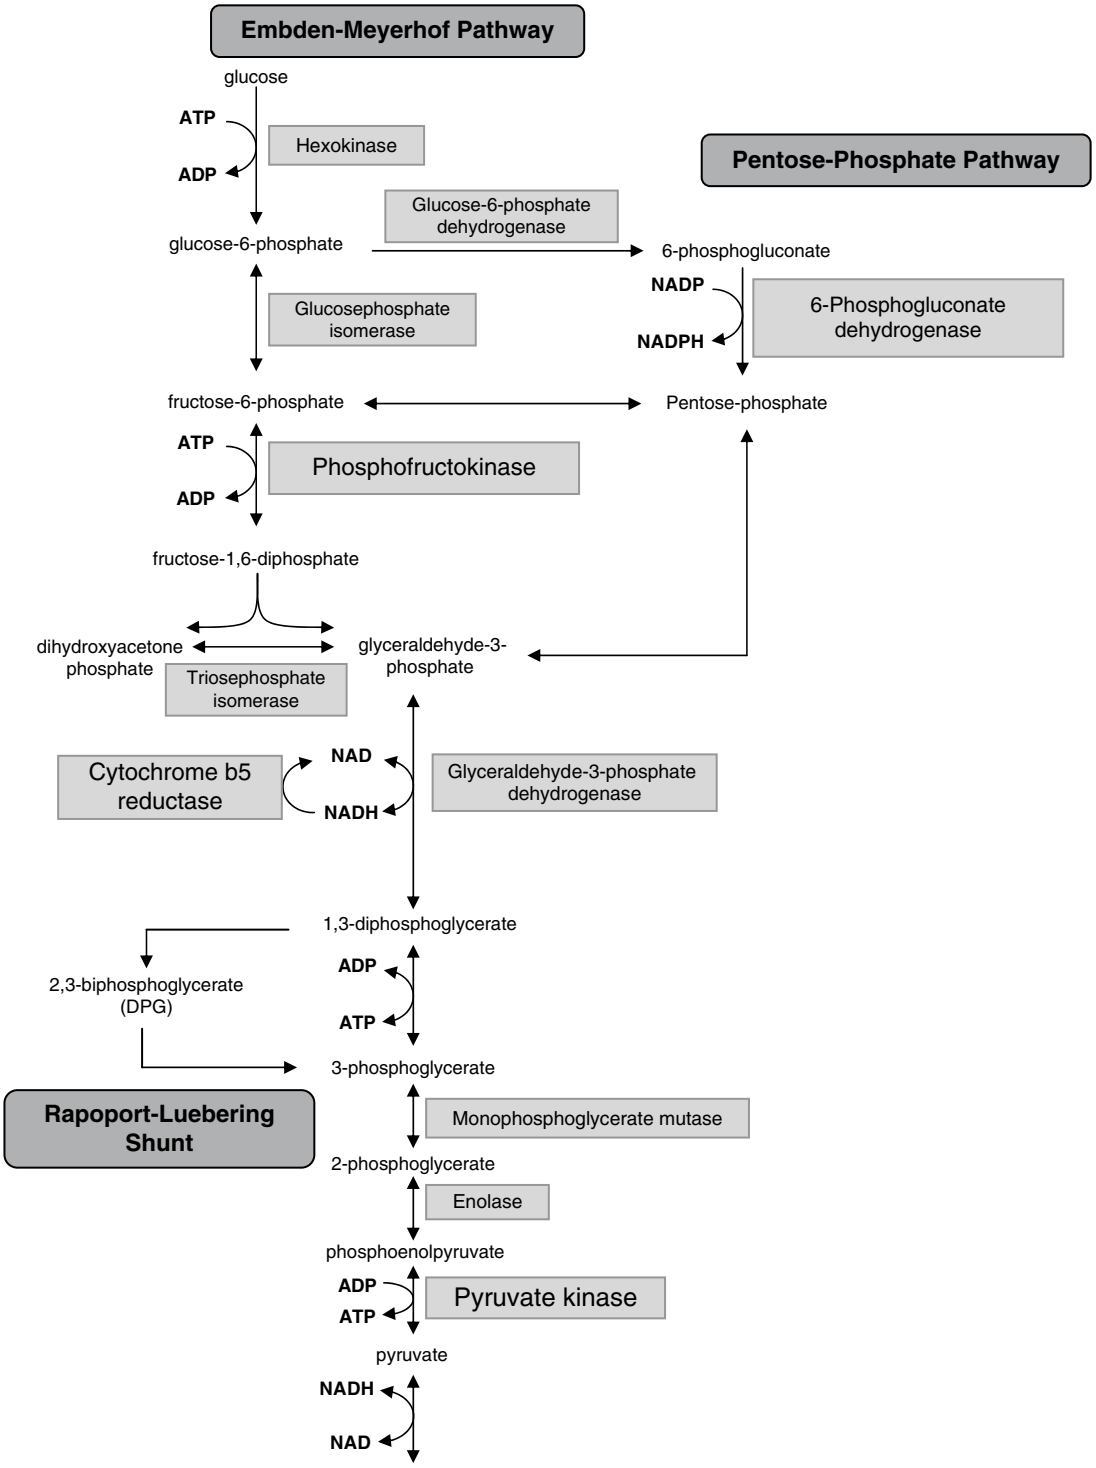

FIGURE 29.1 Embden–Meyerhof (anaerobic glycolytic) pathway with hexose-monophosphate and Rapoport–Luebering shunts in RBCs (simplified). ATP, adenosine triphosphate; ADP, adenosine diphosphate.

metabolic functions, such as phosphorylation and synthesis of purines, pyrimidines, and glutathione. Over a dozen enzymes are involved in glycolysis, which are associated with the two ancillary pathways, unique to RBCs, the pentose-phosphate (hexose-monophosphate) pathway and Rapoport–Luebering shunts. Some of these enzymes exist in different isoforms allowing for cell- and tissue-specific expression and regulation. The key regulatory enzyme of anaerobic glycolysis is phosphofructokinase (PFK). Whereas ATP is the most important inhibitor of PFK activity, inorganic phosphate, AMP, and ADP action is stimulatory. In addition, glucose-1,6-biphosphate and fructose-2,6-biphosphate are activators. Under maximally activating conditions for the enzyme PFK, an enzyme distal in glycolysis, pyruvate kinase (PK), becomes rate-limiting (Figure 29.1).

It is, therefore, not surprising that a deficiency of either PFK or PK activity will lead to RBC malfunction and premature RBC destruction, thereby causing hemolytic anemia. Although both erythroenzymopathies impair the same metabolic pathway, their metabolic and hematological abnormalities and clinical presentations are distinctly different and can vary between species. Subsequently, both erythroenzymopathies will be reviewed separately and contrasting features between the two disorders as well as affected species will be highlighted.

PHOSPHOFRUCTOKINASE DEFICIENCY

Phosphofructokinase (EC 2.7.1.11) catalyzes the regulatory phosphorylation step of fructose-6-phosphate to fructose-1,6-biphosphate. There are three isoforms of PFK, referred to as muscle (M-PFK), liver (L-PFK), and platelet (P-PFK), that are encoded by three different genes.[86] The active PFK enzyme is a homotetramer or heterotetramer composed of one or more isoforms; each of these combinations provides unique enzyme kinetic properties. Their expression is cell- and tissue-specific and developmentally regulated. Skeletal muscle contains exclusively M-PFK homotetramers.[60] Human RBCs express equal amounts of M- and L-PFK, whereas in canine RBCs, the M-PFK isoform predominates in a ratio of 86:14 over P-PFK.[86] Furthermore, during myogenesis[8] and erythropoiesis as well as postnatal development,[32] the isoform composition in these cells changes from L-PFK to M- and P-PFK. Deficiency of M-PFK has been associated with hemolysis and myopathy in humans and dogs, whereas in horses and Holstein calves, PFK deficiency apparently did not cause any hematologic abnormalities[83] and will, therefore, not be discussed here.

Muscle-type PFK deficiency, also known as Tarui–Layzer syndrome, is a rare genetic disorder in humans characterized by metabolic myopathy and a well-compensated hemolytic disorder.[26,69] PFK-deficient humans exhibit exercise intolerance, muscle weakness, and muscle cramping on exertion. Because of the residual half-normal PFK activity in affected RBCs, contributed by L-PFK isozymes and lack of alkaline fragility of human RBCs, overt clinical signs of hemolysis occur rarely. In fact, human patients can overcompensate their hemolytic component, and develop a mild erythrocytosis, because PFK-deficient erythrocytes do not readily release oxygen from hemoglobin. The ensuing tissue hypoxia accelerates erythropoiesis. Several mutations in the M-PFK gene have been described in human patients.[61]

Canine Phosphofructokinase Deficiency

Canine M-PFK deficiency was first described as an autosomal recessive trait in English Springer Spaniels in 1985 and was the first defect characterized at the molecular level for a common inborn error in dogs.[10,11,13,14,24,75] PFK-deficient spaniels have a nonsense mutation in the last exon of the M-PFK gene.[76,77] The resulting change from a tryptophan codon to a stop codon causes truncation of the M-PFK protein by 40 amino acids, leading to rapid degradation and complete deficiency of the M-PFK enzyme.[59,77] Cocker Spaniels,[20] Whippets,[9] a Mexican Street Dog and mixed breed dogs with PFK deficiency have the same mutation, while the Wachtelhund[45] has a different M-PFK mutation. Affected dogs completely lack PFK activity in muscle and have 8–22% of control PFK activity in RBCs due to residual P- and L-PFK expressions (other tissues appear less affected, as they express higher levels of other PFK isoforms).[16,32,35,38,86] The metabolic block at the PFK step results in deficiency of ATP and diphosphoglycerate (DPG) in RBCs, reduced blood lactate production, and accumulation of sugar phosphates and glycogen in muscle; hence, also the term glycogenosis or glycogen storage disease type VII.[11,12,16] This metabolic pattern is also known as a metabolic crossover, indicating the specific metabolic block in a pathway.

In erythroenzymopathies, the mechanism of accelerated lysis is generally not known, but it is assumed to be caused by energy depletion. In dogs, the compensated hemolytic disorder of PFK deficiency is accentuated by life-threatening hemolytic crises. A unique mechanism has been documented to be responsible for intravascular lysis, namely, an increased alkaline-induced hemolysis.[10] Although incompletely understood and possibly related to an aberrant RBC calcium homeostasis, canine RBCs are more alkaline fragile than cells from other species.[43,87] The RBC calcium homeostasis is disturbed in PFK deficiency, which results in an energy imbalance that accelerates adenine nucleotide pool depletion. Ca^{2+}-calmodulin activation of RBC AMP deaminase contributes to this metabolic dysregulation and limits ATP, thereby likely contributing to increased RBC lysis.[70] In vivo, the intracellular pH of RBCs is determined by organic phosphate and chloride anions. Because PFK-deficient RBCs have markedly decreased DPG concentrations, chloride ions move in and increase RBC pH.[10,12,31] Thus, PFK-deficient RBCs start lysing at about pH 7.4 (Figure 29.2a). Consequently, even minor systemic alkalemia or hyperthermia can induce intravascular hemolysis. Alkalemia is associated with any form of hyperventilation.[10,14]

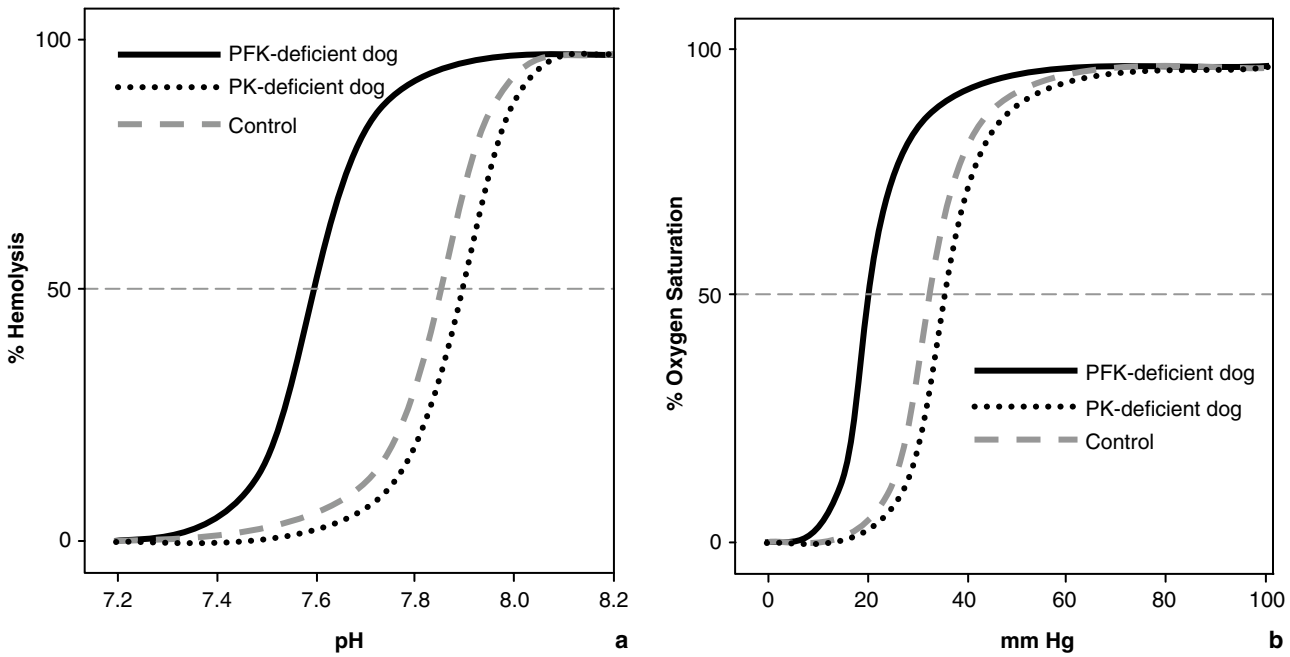

FIGURE 29.2 (a) Alkaline fragility of RBCs from a phosphofructokinase (PFK)-deficient English Springer Spaniel and pyruvate kinase (PK)-deficient Beagle compared to a healthy control dog. RBCs were incubated at various pH values for 1 hour at 37°C 24 hours after collecting the blood samples. Note that RBCs from PFK-deficient dog are very alkaline fragile, while those from PK-deficient dogs behave like controls; (b) Hemoglobin–oxygen dissociation curve of RBCs from PFK-deficient English Springer Spaniel and PK-deficient Beagle. Note the severe left shift of the curve of the PFK-deficient cells (higher hemoglobin–oxygen affinity, P_{50} = 17 mmHg), while PK-deficient canine RBCs are slightly right-shifted (lower hemoglobin–oxygen affinity, P_{50} = 32 mmHg) compared to canine control blood (28 mmHg).

The low DPG content of PFK-deficient RBCs markedly increases oxygen affinity and this is reflected in a left shift of the hemoglobin–oxygen dissociation curve.[10,11] The relative tissue hypoxia impairs, for instance, muscle and other tissue metabolism and stimulates renal erythropoietin synthesis and erythropoiesis. Therefore, aside from the occasional hemolytic crises associated with anemia, the chronic hemolytic disorder can be fully compensated with a robust regenerative response even at normal hematocrit. However, erythrocytosis as seen in PFK-deficient humans does not occur in affected dogs.

Sporadic intravascular hemolytic crises associated with pigmenturia, anemia, or jaundice are the hematological hallmark findings of PFK deficiency in dogs.[10,14,37] These episodes are induced by hyperventilation-associated events such as excessive panting and barking, strenuous exercise, and high environmental temperatures. Thus, guests or a new pet at the patient's home, a visit to the veterinary clinic, boarding, and training for field trialing can precipitate hemolysis. These crises can be first observed at a few months of age, although some animals may not experience any problems until several years of age, or they may be completely missed until the owner looks for them. During these episodes, which generally last one to several days, affected animals can have pale to severely icteric mucous membranes, are lethargic, inappetent, and often febrile, and splenomegaly may be noted. Thus, PFK deficiency can readily be confused with immune-mediated and other acquired hemolytic anemias. Pigmenturia is characterized by hemoglobinuria during crises, whereas hyperbilirubinuria is persistently strong. The anemia may become life-threatening with hematocrits as low as 5%, but is always macrocytic, hypochromic, and strongly regenerative with corrected and absolute reticulocyte counts of 4–25% and 200,000–1,200,000/μL, respectively. The apparent half-life of chromium-labeled PFK-deficient RBCs is 16 days compared to 20–28 days for normal canine cells. Besides polychromasia, marked anisocytosis and normoblastosis (but no poikilocytosis) are observed on microscopic examination of a blood smear. Yet unexplained, leukocytosis and hyperglobulinemia also may be present. The plasma may be discolored because of hemoglobinemia and hyperbilirubinemia. Transient hyperkalemia is due to lysis of high potassium containing reticulocytes and young RBCs.[10,14]

The debilitating exertional metabolic myopathy typically seen in human PFK-deficient patients is less commonly observed and frequently milder in affected dogs. PFK-deficient dogs may develop muscle signs on exertion, even only for a short distance.[3,15,16,57,58] In fact, muscle cramping in one of the limbs even after mild exercise is the most dramatic presentation.[15] Affected dogs may suddenly refuse to run and have high serum creatine kinase activity. Despite a complete lack of PFK activity in muscle, clinical signs of myopathy in deficient dogs are generally mild and rare, presumably due to the high oxidative rate of canine skeletal muscle.[79] Nevertheless, major impairments in oxidative and anaerobic muscle

metabolism have been demonstrated experimentally.[3,57,58] Aside from the acute signs of cramping, affected dogs may only show clinically mild exercise intolerance and intermittent muscle wasting. The serum creatine kinase activity is normal to slightly increased, except during crises. PFK-deficient skeletal muscle accumulates slightly more glycogen and occasionally amylopectin, an abnormal glycogen.[15,33] Interestingly, a couple of Whippets with PFK deficiency also showed clinical signs of a cardiomyopathy probably resulting from the M-PFK isozyme deficiency in heart muscle.[9]

PFK deficiency is an autosomal recessive trait[11] and occurs commonly in the English Springer Spaniel breed.[21,49] Since the first description in 1985,[10] hundreds of cases have been documented, but the gene frequency remains unknown. A randomized survey of American Kennel Club (AKC)-registered championed and bred English Springer Spaniels in 1998 revealed that 4% of field trial and 2.7% of show (bench) English Springer Spaniels were still carriers. Based on extensive pedigree analyses, a common ancestor goes at least back to the 1960s, if not earlier. PFK deficiency also has been reported in American Cocker Spaniels,[20] a Mexican Street Dog and several mixed breed dogs and Whippets.[9] As they all had the same disease-causing DNA mutation, these animals must have a common ancestor. By contrast, the rare PFK-deficient Wachtelhunds have a different M-PFK mutation.[45]

PFK deficiency may be suspected based upon signalment, family history, typical clinical signs, and suggestive laboratory test abnormalities. While the pigmenturia is generally marked (i.e., orange to black), it may not be noted by the owners, particularly with a female dog, and other signs may be mild unless the dog is rigorously exercised. A definitive diagnosis requires proof of the PFK mutation or reduced RBC PFK enzyme activity. A simple PCR-based DNA test accurately identifies PFK-deficient dogs (homozygotes, affected; two mutant alleles) and carriers (heterozygotes; one mutant and one normal allele) in the English Springer Spaniel, American Cocker Spaniel, a Mexican Street Dog and Whippet, as well as the mixed breed dogs (also Wachtelhund, albeit a breed-specific mutation).[9,19,20,45,77] EDTA-anticoagulated blood, but also a drop of blood dried on special filter paper (Guthrie paper), buccal swabs with a cytobrush, and even sperms from a semen bank or formalized tissues can be suitable sources for DNA extraction and PCR testing. Whereas the PCR test and differentiation are simple and permit a diagnosis of deficient, carrier, and normal animals from the first day of life, the PFK enzyme activity test is cumbersome and not accurate until two months of age. Normal and affected neonatal dogs express large quantities of L-PFK in RBCs, which increases the overall PFK activity.[32] As the PCR-based test is mutation-specific, the measurement of PFK enzyme activity may, however, be indicated in other breeds and species, where the same disease is suspected. The PCR-based PFK test is recommended for use as a screening test for English Springer Spaniels (1) with suspicious clinical signs, (2) related to affected or carrier dogs, (3) used for breeding, and (4) prior to training for field trialing. In Whippets a Mexican Street Dog and American Cocker Spaniels, PFK deficiency seems to be more isolated, and, thus, general screening is not recommended.

PFK-deficient dogs can have a normal life expectancy, if crises-inducing situations are avoided.[14] Dogs experiencing a hemolytic crisis are provided supportive care including, if needed, type-matched blood transfusions and in case of repeat transfusions cross-matched blood. Fever and excessive panting or barking should be avoided whenever possible. Diamox, a carbonic anhydrase inhibitor, may acidify the blood, and aspirin and dipyrone may counter the fever accompanying hemolysis, thereby preventing further intravascular lysis during an acute crisis; however, they have not been proven effective in clinical practice. Similarly, because of disturbed purine metabolism, adenine could be considered as treatment, but efficacy and safety data are lacking.[70] Despite massive intravascular hemolysis, hemoprotein-induced acute nephropathy has not been observed. Nevertheless, hemolytic dogs should be well-hydrated. Affected dogs recover from these crises within days. The management of the cardiomyopathy seen in PFK-deficient Whippets may represent one of the breed-specific complications limiting their life expectancy.[9]

Finally, experimental bone marrow transplantation has successfully corrected the hematological abnormalities and abolished the hemolytic crises. Moreover, the corrected RBCs also normalized the hemoglobin–oxygen affinity and, thereby, positively affected oxygenation of muscle and aerobic muscle function.[57,58] Because of the morbidity- and mortality-associated bone marrow transplantations even when a dog leukocyte antigen (DLA)-matched donor (PFK carrier or normal) sibling is available and the relatively mild signs, when preventative measures are instituted, bone marrow transplantation cannot be recommended for this inborn error of metabolism.

PYRUVATE KINASE DEFICIENCY

Pyruvate kinase (EC 2.7.1.40) catalyzes the ATP-generating conversion of phosphoenolpyruvate to pyruvate and is, therefore, an important regulator in the terminal glycolytic pathway (Figure 29.1). There are two different genes coding by alternative splicing a total of four developmentally dependent and tissue-specific PK isoforms.[44,56,64,65] The PKLR gene encodes RBC (R-PK) and liver (L-PK) isoenzymes, whereas the PKM gene generates the muscle (M1-PK) and M2-PK isoforms. R-PK is expressed almost exclusively in mature RBCs and has a different first exon making the amino-terminal sequence longer when compared to that of L-PK. By contrast, erythroid precursors express M2-PK and switch to R-PK isoforms during differentiation to mature RBCs.[56] Erythrocytic PK deficiency causing hemolytic anemia has been described in humans, dogs, cats, and mice.[48,61,62,80]

Pyruvate kinase deficiency is the most prevalent hereditary nonspherocytic hemolytic anemia caused by a

glycolytic enzymopathy.[61,81] Many mutations in the PKLR gene have been found to cause R-PK deficiency in human patients; some of them are common in certain ethnic (Amish) and geographical regions.[6,61] Most of the patients, however, are compound heterozygotes with two different mutant alleles. Clinical signs in PK-deficient humans are very variable, ranging from a mild compensated hemolytic disorder to severely anemic patients who become transfusion-dependent, may develop iron overload (particularly when receiving regular transfusions), and die during early childhood. Splenectomy has been shown to be helpful in some human patients with severe anemia; iron chelation and bone marrow transplantation are other options.[26,81] While clinical manifestations of PK deficiency in dogs are similar to humans, PK-deficient cats show signs more like PFK-deficient dogs.

Canine Pyruvate Kinase Deficiency

In 1971, erythrocytic PK deficiency was first recognized in Basenji dogs.[71] It served as the classic example of an inborn error of metabolism in veterinary medicine, despite the fact that the biochemical derangements turned out to be more complex, making a clinical diagnosis more difficult. R-PK deficiency occurred most frequently in Basenjis in the past,[18,71,72,89] but has recently been more frequently reported in Beagles[17,30,46,67] and West Highland White Terriers[5,45–47,74] and occasionally in Cairn Terriers,[71] Labrador Retrievers,[46] Pugs,[46] Miniature Poodles, Dachshunds,[50] Chihuahuas, and American Eskimo Toy dogs. In Basenjis, a single base-pair deletion in exon 5 of the R-PK gene has been identified causing a frameshift and severe truncation of the protein.[89,90] By contrast, a six base insertion ambiguously positioned at the 3′-end of exon 10 in the R-PK sequence was found in West Highland White Terriers.[74] This insertion results in the in-frame addition of two amino acids, threonine and lysine, and is likely also the causative mutation in Cairn Terriers,[70] a related breed. In the Labrador Retrievers, a missense, and in Beagles and Pugs, different missense mutations have been found,[46] while in the other breeds, a disease-causing mutation has yet to be confirmed. Despite the varied mutations in R-PK, the biochemical changes and clinicopathologic manifestations of PK deficiency in any of the reported canine breeds appear identical.

The R-PK deficiency in RBCs of affected dogs can be demonstrated by agarose gel electrophoresis, immunoblotting, and immunoprecipitation studies.[18,39,40] However, all affected dogs express M2-PK in RBCs, which increases total RBC PK activity of affected dogs, and, therefore, is misleading. For instance, the Miniature Poodles with nonspherocytic anemia and osteosclerosis may well have had R-PK deficiency,[68] despite high RBC PK activity in vitro. By contrast, M2-PK expression is very rarely observed in human patients. This M2-PK isozyme, which is normally present in erythroid precursor and white blood cells, appears to be heat-labile and dysfunctional in vivo, because affected RBCs show a severe metabolic block at the PK step.[18] Besides the accumulation of proximal glycolytic metabolites in RBCs, the DPG content is also increased. The resulting right shift of the hemoglobin–oxygen dissociation curve allows for improved oxygen delivery, thereby ameliorating the clinical signs of severe anemia in PK-deficient dogs.

PK-deficient dogs frequently present for evaluation at a few months to a couple of years of age because of intermittent weakness and exercise intolerance. They appear to adapt very well to the severe anemia, presumably due to the favorable tissue oxygenation. They may also be serendipitously found when observing very pale mucous membranes in a clinically asymptomatic puppy. The hematocrit ranges persistently between 12% and 28%; the anemia is highly regenerative with corrected reticulocyte counts of 10–90%. Echinocytes have been documented.[71] In contrast to canine PFK-deficient RBCs, canine PK-deficient RBCs have normal alkaline fragility and readily release oxygen (Figure 29.2). The apparent erythrocyte half-life is only 5.8 days compared to 19–28 days in normal dogs.[18] Hepatosplenomegaly, due to extramedullary erythropoiesis and hemosiderin deposition, may also be noted, in fact some dogs may develop hemochromatosis.[4,71] Affected dogs die because of anemia or hepatic failure between 1 and 9 years of age, with Basenjis and Labrador Retrievers having a more severe form than Beagles and West Highland White Terriers.

Interestingly, all PK-deficient dogs develop progressive myelofibrosis and osteosclerosis that remain unexplained and do not occur in other species with PK deficiency.[4,5,17,18,30,45,47,50,70,71,73] The osteosclerosis may be identified by radiography of long bones as early as at 1 year of age and completely obstructs the marrow cavities by 3 years in Basenjis, but may occur later in other breeds.

A diagnosis of PK deficiency is strongly suggested by the concurrent occurrence of a highly regenerative severe anemia and osteosclerosis in a dog. Generally, routine screening tests rule out or are not supportive of acquired anemias and the anemia is persistent and appears well-tolerated. PCR-based PK tests are available for several breeds (https://www.vet.upenn.edu/research/academic-departments/clinical-sciences-advanced-medicine/research-labs-centers/penngen/tests-worldwide). These DNA tests are accurate to detect affected and carrier dogs in these breeds. However, because they are mutation-specific, they cannot be used for other breeds. In other breeds, cumbersome PK enzyme activity assays using agarose gel electrophoresis, immunologic, and heat-lability methods specific for R-PK are required due to M-PK expression. PK carriers do not express M-PK and, therefore, have intermediate (approximately 50% of normal) RBC PK activity. Unfortunately, the PK activity assays are not very accurate in detecting carriers, as the carrier and normal ranges overlap.[18] PK deficiency has most commonly been reported in the Basenji, West Highland White Terrier, and Beagle breeds, but the PK mutation frequency remains unknown in all canine breeds.

Affected dogs are managed symptomatically in clinical practice. Because of the excellent DPG-facilitated oxygen release from hemoglobin, PK-deficient dogs adapt well despite severe anemia. They rarely need transfusions except in their terminal stages. Bone marrow transplantation, performed experimentally,[88]

corrects the hemolytic anemia and halts the osteosclerosis and hemosiderin deposition, whereas splenectomy has not been shown to be effective in slowing the hemolysis and anemia in dogs.

Feline Pyruvate Kinase Deficiency

In the early 1990s, erythrocytic pyruvate kinase deficiency was identified and characterized in domestic short-haired cats and Abyssinian, Somali, and other breeds.[7,22] A 13 base-pair deletion at the 3′-end of exon 5 in the R-PK cDNA, is caused by a splicing defect and results in a severe reduction in RBC PK enzyme activity.[7,27,54] In cats there is no anomalous M2-PK expression in RBCs and no osteosclerosis, which are observed in all PK-deficient dogs. Since the original observations of the PK-deficient Abyssinian and Somali cats, over 3000 have been screened; approximately 12% are affected and 24% are carriers, making this one of the most frequent causes of anemia in these breeds. Since then, many more PK-deficient purebred and domestic short-haired cats have been reported from Europe,[27–29,52,53,63,85] Australia,[1,55] and Japan.[54] Interestingly, a specific pathogen-free research colony of domestic cats also carries this same PK mutation and was responsible for an unexplained mild to moderate intermittent anemia.

Affected cats have chronic intermittent hemolytic anemia that might not first be recognized until advanced age. The anemia is intermittent, mild to severe with PCV ranging from 5 to 35%. It is slightly macrocytic-hypochromic and slightly to strongly regenerative (reticulocyte count 45,000–290,000/μL).[25,52,53] Moreover, PK-deficient cats frequently have a marked lymphocytosis and hyperglobulinemia, which remains unexplained. Many of these features are similar to cats with increased RBC osmotic fragility with splenomegaly in the same breeds.[51,82] However, PK-deficient cats typically have a greater regenerative response and only mild splenomegaly and normal or only mild osmotic fragility (Figure 29.3). Extrahepatic biliary obstruction due to bilirubin calculi is seen in affected cats.[9,29] It should be noted that many deficient cats remain completely asymptomatic for years, and the associated anemia may not be the primary reason for a PK-deficient cat's illness.

PK-deficient cats frequently do not require treatment, just like PK- and PFK-deficient dogs. However, during a crisis, deficient cats may need to be transfused with AB-blood-type compatible blood. In case of severe splenomegaly or persistently severe anemia, splenectomy appears to reduce the severity of the hemolytic crises.[25]

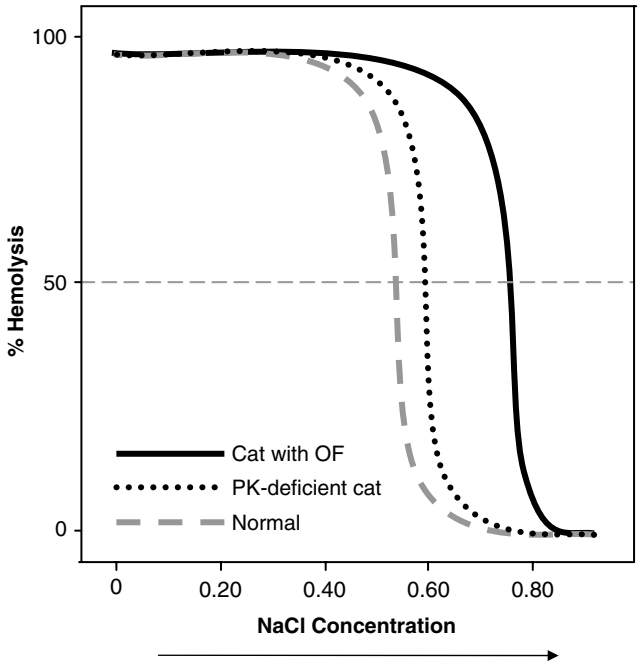

FIGURE 29.3 Erythrocyte osmotic fragility (OF) curve from a PK-deficient Abyssinian cat and an Abyssinian with increased OF and splenomegaly. RBCs were exposed in vitro to different saline concentrations from 0% (water) to 0.85% (physiological saline) at room temperature for 30 minutes.

  High Membrane Na,K-ATPase Activity in Dogs

Acronyms and Abbreviations

DHS, dehydrated hereditary stomatocytosis; GLAST, glutamate aspartate transporter; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; HSt, hereditary stomatocytosis; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; OHS, overhydrated hereditary stomatocytosis; RBC, red blood cell; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

To survive repeated passages through the microcirculation, RBCs must be very durable and flexible, undergoing marked reversible deformation under these high-shear-stress conditions. The RBCs do not fragment despite these contortions and maintain a constant membrane surface area as they traverse circulatory beds.[56] These important properties are determined by three major components of their membranes: a lipid bilayer, integral or transmembrane proteins, and a membrane skeletal network (Figure 30.1). A lipid bilayer provides a permeability barrier between the cytosol and the external environment. Major constituents of the membrane skeleton mechanically support the plasma membrane and are organized into a lattice-like meshwork that is linked with both integral membrane components and cytoskeletal elements. Some of the transmembrane proteins embedded within the lipid bilayer ensure selective permeability to maintain RBC homeostasis. Accelerated destruction of RBCs (hemolytic anemia) may occur when these properties of the RBC membrane are affected or deficient by some genetic defects. This chapter reviews the current progress in the investigation of inherited red cell membrane disorders in animals.

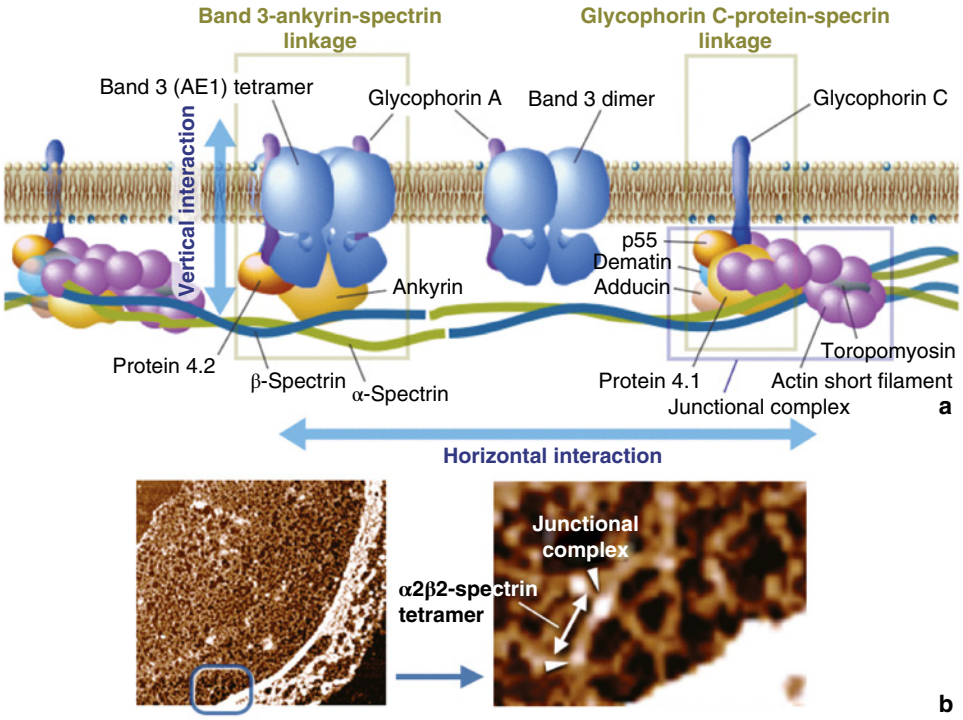

FIGURE 30.1 A schematic diagram illustrating structural and functional organization of RBC membrane proteins. Membrane protein–protein associations are divided into two categories: (a) vertical interactions involving band 3–ankyrin–spectrin linkage and glycophorin C–protein 4.1R–spectrin linkage; (b) horizontal interactions involving the spectrin heterodimer contact (tetramer formation) and association of spectrin tetramer at the distal ends with F-actin at the junctional complex consisting of actin, 4.1R, and adducin.

HEMOLYTIC ANEMIAS CAUSED BY HEREDITARY RED CELL MEMBRANE DEFECTS

The membrane protein–protein and protein–lipid interactions are critical determinants of red cell morphology and mechanical stability, as evidenced by the numerous hereditary RBC disorders in humans attributed to mutations of the membrane.[2,22,55,57,58,82] These interactions are divided into two categories (Figure 30.1): (1) vertical interactions involving the band 3–ankyrin–spectrin and glycophorin C–protein 4.1R–spectrin binding, both of which attach the spectrin–actin network to the plasma membrane and stabilize the lipid bilayer, and (2) horizontal interactions involving spectrin dimer–dimer association (tetramer formation), and contact of the distal ends of spectrin with F-actin by the aid of protein 4.1R and adducin within the junctional complex. In general, the loss of vertical linkage between membrane skeleton and lipid bilayer causes decreased membrane cohesion leading to membrane loss (e.g., hereditary spherocytosis (HS)). Weakening of horizontal linkages between skeletal proteins results in decreased membrane mechanical stability, leading to membrane loss (e.g., hereditary elliptocytosis (HE) and pyropoikilocytosis).[2,22,55,56] The severity of the anemia is directly related to the extent of the membrane surface area loss in both of these defects; loss of membrane not only compromises the ability of the RBC to deliver oxygen to the tissues, but also results in premature removal from the circulation by the spleen. The reader is directed to Chapter 20 for details of the structural organization of the normal RBC membrane.

HEREDITARY SPHEROCYTOSIS

The cardinal features of HS are hemolytic anemia of varying severity, spherocytosis, increased RBC osmotic fragility (OF), and splenomegaly.[67] In human medicine, HS is classified as mild, moderate, or severe based on hemoglobin levels and reticulocyte counts.[2,22,55,56,63] A mild HS is distinguished by a well-compensated hemolytic anemia, minimal numbers of spherocytes on the peripheral blood smear, and only a slight reticulocytosis, whereas these features are more remarkable with moderate and severe forms of the disease. The pathophysiology of HS involves two major factors: intrinsic membrane defect, and selective sequestration of HS cells in the spleen. Hence, anemia can be significantly improved by splenectomy in human HS patients [2,63]. Typical forms of HS need to be distinguished from other hemolytic anemias having spherocytes, such as immune-mediated hemolytic anemia by Coombs testing as well as unstable hemoglobin and oxidative damage by Heinz body screening. HS is now considered to be a disorder of vertical interactions of the membrane proteins, although the primary molecular defects are heterogeneous including deficiencies or dysfunctions of spectrin, ankyrin, band 3, and protein 4.2.[2,24,55–57,63,82] Consequently, the lipid bilayer is destabilized, leading to membrane

vesiculation and surface area loss, and spherocyte formation.[22,63]

Hereditary Band 3 Deficiency in Cattle (Band 3$^{Bov.Yamagata}$) and Other Animal Species

Band 3 (anion exchanger 1, AE1) is the most abundant transmembrane protein in mammalian RBCs,[62] accounting for about 25% of the total membrane proteins. Hereditary band 3 deficiency in Japanese Black cattle (band 3$^{Bov.Yamagata}$) is associated with HS and is inherited by an autosomal dominant trait.[31] Homozygous affected animals totally lack band 3 due to an R664X nonsense mutation of the AE1 gene (*SLC4A1*) and show mild to moderate, chronic hemolytic anemia (hematocrit, 25–35%), acidosis, and growth retardation. Carrier cattle heterozygous for the R664X mutation also have spherocytosis and impaired anion transport activity due to partial deficiency of RBC band 3 (about 30%). However, the hemolysis is well-compensated. In heterozygous animals, mutant band 3 is rapidly degraded in the endoplasmic reticulum without translocation to the plasma membrane and has a dominant-negative effect on the expression of wild-type band 3.[32,33]

Band 3 has two major functions:[8,36,62,79,80] (1) it mediates a rapid Cl^-/HCO_3^- exchange across the plasma membrane, increasing up to fivefold the capacity of the blood to carry CO_2 from tissues to lungs and maintaining blood acid–base homeostasis together with the isoform expressed by α-intercalated cells of the renal collecting duct; and (2) it also participates in maintaining mechanical properties of RBC membranes by forming the band 3–ankyrin–spectrin complex. Various mutations leading to disorders and partial deficiency of RBC band 3 associated with abnormal RBC morphology (spherocytosis and ovalocytosis) have been reported in humans.[34,37,58] Only one case of complete deficiency[67] and an aberrant nearly total deficiency[62] in humans, both of which were associated with life-threatening hemolytic anemias, have also been reported to date. The most surprising finding, therefore, is that cattle with total lack of band 3 survive and may thrive in adulthood. They suffer from extremely severe hemolytic anemia shortly after birth and exhibit jaundice and splenomegaly. Although the mortality rate is high during this period, beyond this crisis period, jaundice subsides and hemolysis becomes modest.

RBC membranes from homozygotes of band 3$^{Bov.Yamagata}$ are deficient in spectrin, ankyrin, actin (by 20–50%), and protein 4.2, resulting in a distorted and disrupted membrane skeletal network (Figure 30.2). They are extremely unstable and demonstrate the spontaneous loss of surface area by invagination, vesiculation, and extrusion of exosome-like microvesicles, thereby leading to the formation of spherocytes with irregular contours, gouging, and pitting (Figure 30.3). RBCs from homozygous and heterozygous cattle show significantly increased osmotic fragility with 50% hemolysis at 0.75% and 0.65–0.70% NaCl, respectively (normal, 0.45–0.55% NaCl) (Figure 30.4). These findings are consistent with a remarkably decreased surface

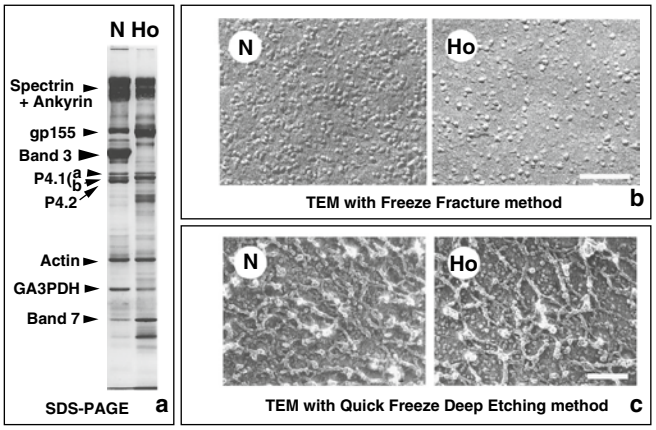

FIGURE 30.2 Abnormal RBC membrane structures in bovine band 3 deficiency (band 3$^{Bov.Yamagata}$). (a) SDS-PAGE profiles of RBC membrane proteins from the normal (N) and the homozygote for R664X mutation (Ho). A 66-kDa protein only found in the homozygote was albumin. gp155 indicates a transmembrane protein characteristic to ruminant RBCs[28]; (b) Markedly reduced number of intramembrane particles in homozygous RBCs (Ho) compared to normal RBC on electron micrographs by the freeze fracture method; (c) Disrupted membrane skeletal network in band-3-deficient RBCs visualized by the quick freeze deep etching method. The membrane skeletons in band-3-deficient RBCs (Ho) are disrupted and distorted with filaments of uneven length and width compared with the well-organized normal RBCs (N). Scale bars = 0.1 μm.

area/volume ratio of RBCs from both homozygotes and heterozygotes due to the mechanical instability of their RBC membranes. Despite these severe changes, the affected animals show no reticulocytosis and no noticeable intravascular hemolysis. However, the protein 4.1a/4.1b ratio, which is a good marker of RBC aging,[27,30] is remarkably reduced and paralleled by increased erythropoiesis. These demonstrate the functional importance of band 3–ankyrin–spectrin association in maintaining mechanical stability of the membrane,[45] but not in assembly of the membrane skeletal architecture.

Total deficiency of band 3 also results in defective Cl^-/HCO_3^- exchange.[31] The Cl^- influx into the RBCs from homozygotes requires approximately 2 hours to reach transmembranous equilibrium even at 37 °C (less than several seconds in normal RBCs). Band 3 deficiency causes mild acidosis with decreases in the HCO_3^- concentration and total CO_2 in the blood. However, these values remain in the normal range. As CO_2 in blood rarely reaches saturation, it is suggested that the additional CO_2-carrying capacity facilitated by band 3 is probably not as critical as has been believed previously,[35,36,78,79] except under high-stress conditions such as vigorous exercise or high altitude.

Transgenic mice with complete band 3 deficiency,[64,76] as well as only the case of total band 3 deficiency in human,[67] have similar RBC features. These studies demonstrate that band 3 indeed contributes to RBC membrane organization, CO_2 transport, and acid–base homeostasis. In band 3 knockout mice, glycolytic enzymes that normally exist as multienzyme complexes

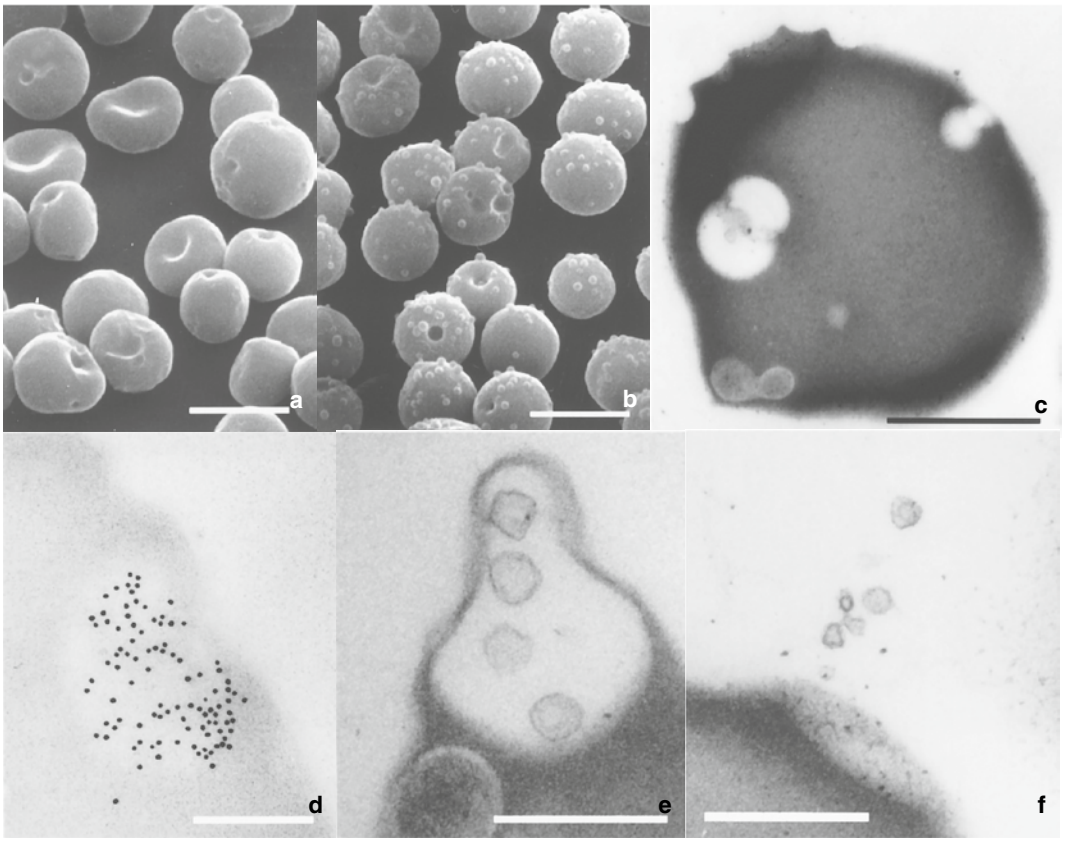

FIGURE 30.3 Morphologic anomaly in bovine band 3 deficiency. (a) and (b) Scanning and (c)–(f) transmission electron micrographs of RBCs from a homozygous animal of band $3^{Bov.Yamagata}$. (a) The proband RBCs look like potatoes and greatly vary in size, principally being spherocytic and stomatocytic with irregular contours; (b) When blood is allowed to stand for several hours at ambient temperature, numerous small globules are observed on the surface; (c)–(f) Marked endocytosis-like invagination, exocytosis-like projections, fusion of vesicles inside the cell, and extrusion of microvesicles, leading to surface area loss; (d) The vesicles in the cytoplasm contain plasma proteins as determined by immunoelectron micrography using antibovine albumin antibodies. Scale bars = 5 μm (a) and (b), 1 μm (c), and 0.2 μm (d)–(f).

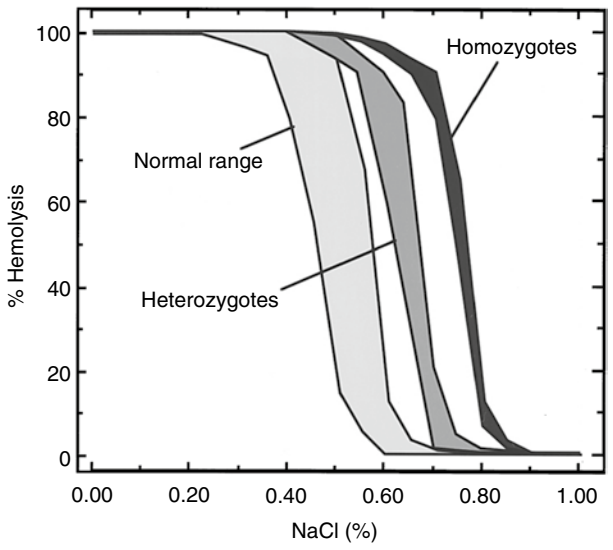

FIGURE 30.4 Increased RBC osmotic fragility in bovine band 3 deficiency. Data for normal cattle (n = 15) as well as homozygotes (n = 4) and heterozygotes (n = 8) of band 3 deficiency.

on the inner surface of RBC membranes are not membrane-associated but distributed throughout the cytoplasm. The assembly of some glycolytic enzymes on the membrane is likely a general phenomenon of mammalian RBCs and stability of these interactions depends primarily on band 3.[9]

The use of sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) to explore alterations in protein profiles of the RBC membrane and molecular genetic techniques has greatly increased our understanding of the pathophysiology of HS. A recent report described the application of proteomics to explore the cause of a presumed RBC membrane protein deficiency in a Jack Russell Terrier presenting with hereditary hemolytic anemia.[5]

Spectrin and Ankyrin Deficiencies in Animals

Several mutations that affect components of the RBC membrane skeleton have also been reported in mice.[4,87] These include spectrin deficiencies in house[22,46] and deer mice[71] as well as ankyrin deficiency in nb mice[87] with

moderate to life-threatening hemolytic anemia and fragile short-lived spherocytes. A quantitative spectrin deficiency with an autosomal dominant inheritance was reported in Dutch Golden Retrievers.[74] The affected dogs had markedly reduced RBC spectrin concentration that was 50–65% of unaffected dogs and exhibited increased RBC osmotic fragility. However, the disorder was not associated with either spherocytosis or elliptocytosis. The exact mechanism for this occult spectrin deficiency without morphological anomaly remains to be clarified.

HEREDITARY ELLIPTOCYTOSIS

The principal lesion of human HE involves heterogeneous defects in horizontal membrane protein interactions (Figure 30.1) resulting in a mechanically unstable membrane (e.g., abnormal spectrin structure affecting the spectrin heterodimer contacts/dimerization as previously described or deficiency/dysfunction of protein 4.1).[22,55,58,82] Common HE is morphologically characterized by elliptocytes and rod-shaped RBCs in some patients. While the majority of the cases of HE are asymptomatic, a severe form, hereditary pyropoikilocytosis (HPP), characterized by hemolytic anemia and jaundice is also recognized. The red blood cell morphologic findings in these cases resemble that seen in severe burn patient including poikilocytes, fragments or schistocytes, microspherocytes, and rare elliptocytes.[66]

Ovalocytosis, spherocytic HE, is a rare condition in which both oval RBCs lacking central concavity and spherocytes are present on the blood film. It is likely that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape. The weakened horizontal connections facilitate reorganization of the skeleton, which follows axial deformation of cells by a prolonged shear stress.[55,58,82] Although camelid RBCs are elliptocytic by nature, the molecular basis and physiologic importance of this unique feature remain unknown.

Hereditary Protein 4.1 Deficiency in Dogs (HE in Dogs)

Canine HE was discovered by Smith et al.[75] The proband exhibited elliptocytosis, membrane fragmentation, microcytosis, and poikilocytosis without anemia (Figure 30.5). RBC mechanical stability was markedly decreased, and osmotic fragility was remarkably increased. The proband RBC membranes were deficient in protein 4.1R (4.1Ra and 4.1Rb). The parents of the proband had decreased amounts (approximately 50% of normal) of protein 4.1R and some elliptocytes.

Protein 4.1R binds to both spectrin and actin to form spectrin–4.1R–actin ternary complex through its 10-kDa spectrin–actin binding domain (SABD)[12]. The SABD contains amino acid sequences encoded by a 21-amino acid erythroid-specific exon (exon 16) and a 59-amino acid constitutive exon.[10] Immunoblotting of RBC membrane proteins from the proband showed the presence of a small amount of 76-kDa polypeptide lacking the 21-amino acid segment and a very faint band of normal 4.1R. Reverse transcription (RT)-PCR analysis and sequencing of cloned reticulocyte 4.1R cDNA consistently showed that mRNA lacking exon 16 was the predominant form with only a small quantity of normal mRNA. Therefore, the functional defect in the HE dog is likely due to the combined influences of two factors: a quantitative deficiency of protein 4.1R and a failure to activate efficiently expression of an alternatively spliced exon 16 in the SABD during erythropoiesis.[11] The primary cause leading to inefficient erythroid-specific alternative splicing has not been defined.

Spectrin Anomaly with Elliptocytosis in a Dog

An elliptocytosis was reported in a mixed-breed dog.[14] Although the elliptocytosis was asymptomatic and was not associated with hemolytic anemia, the dog's RBCs had decreased deformability and stability when subjected to shear stress. This is consistent with nonhemolytic HE in humans due to structural abnormality in either the α- or β-spectrin. Molecular analysis revealed that the elliptocytosis was probably due to T2110M mutation in β-spectrin, a region of spectrin that is critical for the self-association of spectrin dimers. This would be expected to result in reduced formation or reduced stability of tetramers.

HEREDITARY STOMATOCYTOSIS

Stomatocytes are uniconcave or bowl-shaped RBCs in suspension but have a slit-like appearance, an artifact on dried blood films (Figure 30.6). Two distinct phenotypes having abnormalities in membrane cation permeability leading to changes in RBC volume have been identified in humans: dehydrated hereditary stomatocytosis (DHS) and overhydrated hereditary stomatocytosis (OHS).[2,55] DHS is associated with a well-compensated

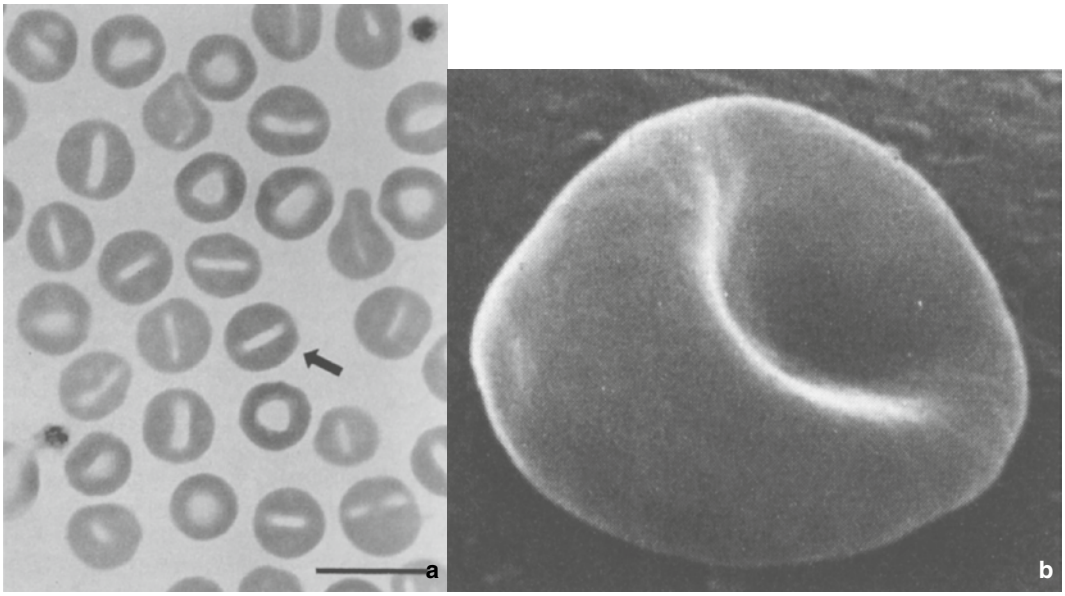

FIGURE 30.6 Erythrocyte morphology of canine hereditary stomatocytosis (hydrocytosis). (a) Numerous stomatocytes (arrow) with a slit-like appearance are present on a Wright–Giemsa-stained blood smear from a Miniature Schnauzer. (**Source:** Reproduced with permission[7]) Scale bar = 10 μm; (b) Scanning electron micrograph of a typical stomatocyte from an affected Alaskan Malamute. (**Source:** Reproduced from Pinkerton et al.[65] with permission)

hemolytic anemia with less than 10% stomatocytes usually seen on blood smears. By contrast, stomatocytes are a major feature of RBC morphology in OHS. An important characteristic of these stomatocytosis patients is a marked predisposition to thrombocytosis and development of hypercoagulability after splenectomy.[2,22]

OHS (hydrocytosis) is a heterogeneous group of disorders in humans characterized by moderate to severe hemolytic anemia with stomatocytes, an elevated mean corpuscular volume (MCV), and a reduced mean corpuscular hemoglobin concentration (MCHC). The principal lesion involves a remarkable increase of Na^+ influx into RBCs, resulting in a marked increase of intracellular Na^+ and water content and a corresponding decrease of K^+.[54,94] The molecular basis of this permeability defect is unknown. Human OHS is frequently associated with reduced contents of a 31-kDa integral membrane protein stomatin, which may function in regulation of cation transport and a stretch- or pressure-sensitive system, in the RBC membrane from OHS patients.[17,19,44,77] It is reported that stomatin–actin association is necessary for maintaining the structure and modulating the function of stomatin in RBCs.[88]

Hereditary Stomatocytosis in Dogs and Cats

Hereditary stomatocytosis (HSt) is recognized in dogs and cats with undefined etiologies. All disorders appear to be transmitted as autosomal recessive traits.

HSt in Miniature and Standard Schnauzers

Stomatocytosis has been reported in Miniature and Standard Schnauzers (Figure 30.6a) without clinical signs of disease.[6,7,23] Hereditary stomatocytosis in Schnauzers is characterized by macrocytosis, relatively high packed cell volume, remarkably decreased MCHC, and increased osmotic fragility. Erythrocyte survival is only slightly shortened. Affected Miniature Schnauzers are of normal stature. Stomatin is not deficient from the erythrocyte membrane in affected Standard Schnauzers.[59]

HSt in Chondrodysplastic Alaskan Malamute Dwarf Dogs

In Alaskan Malamutes, chondrodysplasia (short-limbed dwarfism) occurs along with stomatocytosis.[17,18] The affected Malamutes have macrocytosis, decreased MCHC, increased osmotic fragility, shortened RBC survival, reticulocytosis, erythroid hyperplasia, and increased iron turnover (Figure 30.6b).[65] Although heterozygous carriers have minor changes in their RBCs, they have a normal RBC life span and no dwarfism. RBC Na^+ concentration and water content are increased in affected dogs.

The pathogenesis of stomatocyte formation in Malamutes and Schnauzers is attributed to an increase in monovalent cation and, consequently, increased water content of RBCs as is reported in human HSt. However, the exact nature of membrane defects leading to the changes in RBC indices in these breeds is obscure.

Familial Stomatocytosis-Hypertrophic Gastritis in Dogs

Familial stomatocytosis-hypertrophic gastritis is a multiorgan disease with hemolytic anemia, HSt, and hypertrophic gastritis described in the Drentse Patrijshond breed.[72,73] The main clinical signs are diarrhea, jaundice, and ataxia and paresis of the pelvic limbs. Pathologic

findings involve hypertrophic gastritis, progressive liver disease, renal cysts in aged subjects, and polyneuropathy.[72]

Erythrocytes from affected dogs show increased osmotic fragility. In contrast to Malamutes and Schnauzers with stomatocytosis, RBCs from affected Patrijshonds have normal MCV, slightly increased cell water with basically normal content, and fluxes of Na and K, suggesting a different mechanism for stomatocyte formation.[73] Affected dogs have normal RBC membrane protein profile, but a decrease of phosphatidylcholine with altered fatty acid composition and simultaneous increase of sphingomyelin in both RBCs and plasma. It is suggested that this polysystemic disease is a disorder of lipid metabolism in which defective membrane function and RBC shape change are induced by abnormal phospholipid composition of the plasma. This is supported by a shortened half-life of RBCs from normal dogs after transfusion into dogs with this syndrome.[73] Stomatocytic shape change may be attributed to membrane surface loss, presumably due to abnormal phospholipid composition of the bilayer. The exact relation between anomaly in phospholipid and hypertrophic gastritis and the primary cause of this syndrome are unknown.

Hemolytic Anemia with Increased Erythrocyte Osmotic Fragility in Cats

A hereditary RBC defect is suspected in Abyssinian and Somali cats with Coombs negative hemolytic anemia.[41,42] The affected cats exhibited recurrent anemia (hematocrit, 15–25%); severe splenomegaly with extramedullary hematopoiesis, hemosiderosis, congestion, and lymphoid hyperplasia; loss of body mass; macrocytosis; and a few stomatocytes. The anemia was variably regenerative. The osmotic fragility of their RBCs is markedly increased. Splenectomy partially corrected the anemia and prevented hemolytic crises, but long-term survival remains unknown. More recently, a similar condition was described in domestic short-haired and cats of other breeds (Ocicat and Siamese). A moderate to severe macrocytic hypochromic anemia was described in these cats with red cells showing increased osmotic fragility. Most of these cats also had moderate to severe splenomegaly with marked extramedullary hematopoiesis.[81]

DIAGNOSTIC APPROACHES TO ERYTHROCYTE MEMBRANE DEFECTS

Genetic aberrations of RBC membranes described in the earlier text are feasibly surveyed by evaluating RBC morphology, osmotic fragility, and RBC parameters. The OF test[3,61] is a simplified means to estimate the surface area/volume ratio of RBCs. It is most valuable in the diagnosis of HS, but is also useful in evaluation of most forms of HE and overhydrated HSt (hydrocytosis). False positives may be detected in other conditions associated with spherocytosis, such as immune-mediated hemolytic anemia. Several laboratory tests, such as Coombs test and Heinz body screening, may be required to eliminate a possibility that hemolytic anemia and abnormal RBC shapes result from extrinsic factors. As exemplified for bovine HS in Figure 30.2a, SDS-PAGE analysis followed by some immunochemical, biochemical, and biophysical techniques often provides insights into primary defects of membrane skeletal and integral proteins resulting in HS, HE, and HPP.

Other Testing for Diagnosis of Red Cell Membrane Disorders

In 2011, the International Council for Standardization in Haematology (ICSH) guidelines for diagnosis of nonimmune hereditary red cell membrane disorders suggested various screening tests that might be considered.[40] The best screening test for these disorders is osmotic gradient ektacytometry. This instrument monitors the extent of RBC shape change within a particular osmotic gradient under a known shear stress; the deformability profiles that are generated are well correlated to specific red cell membrane disorders. The major limitation of this procedure is the limited availability of the instrumentation and testing must be performed within 48 hour of sample collection. Another diagnostic approach is direct mutational analysis of the various genes responsible for these disorders. However, this is a case-by-case consideration for identifying a putative genetic mutation, particularly when family history is not helpful. Next generation sequencing (NGS) technologies for use in the diagnosis of red cell membrane disorders also have recently been reported.[1,40] After identifying the protein gene mutation using NGS in the patient, other family members can be tested by PCR and sequencing to confirm the inherited mutation.

MEMBRANE TRANSPORT DEFECTS

Deficiency and dysfunction of membrane transport systems may affect RBC homeostasis. Particularly, defects in transport of amino acids involved in glutathione metabolism have been reported to generate hemolytic anemia when RBCs are exposed to extrinsic factors including oxidants.

Amino Acid Transport Deficiency in Animals

Red blood cell glutathione deficiency, inherited as an autosomal recessive trait, occurs in Finnish Landrace sheep.[83] Affected animals are not anemic, but have shortened RBC life span.[84] This is possibly caused by increased oxidant sensitivity as exemplified by Heinz bodies. Affected sheep are more likely to become anemic after the administration of oxidants in vivo.[86] RBCs from the affected animals are defective in the transport system for various amino acids including cysteine.[47,92,93] Consequently, cysteine uptake and glutathione synthesis are limited, and glutathione concentrations in RBCs are decreased to approximately 30% of normal. The transport deficiency appears to develop during reticulocyte maturation.[85]

A similar defect of amino acid transport is found in about 30% of thoroughbred horses,[16] but seems to cause no clinical signs. The lesion appears to result in increased amino acid levels and glutathione deficiency in some cases.

High Membrane Na, K-ATPase Activity in Dogs

Although canine reticulocytes have a considerable amount of membrane Na, K-ATPase (Na/K-pump) activity, its activity is rapidly lost during maturation into mature RBCs.[26,50] Proteolytic degradation[26] and extrusion of vesicles (exosomes)[38,43] are likely involved in this process. As a consequence, dogs usually have RBCs with low K^+ and high Na^+ concentrations (LK RBCs).[60] However, some Japanese Shiba and mongrel dogs have HK RBCs with high K^+ and low Na^+ concentrations, because the Na, K-ATPase protein and its activity are retained in mature RBCs.[26,49,53] This HK phenotype representing immaturity of erythroid precursor cells[26,29,43,50,51] is inherited in an autosomal recessive manner[48,49,53] and has also been found in Japanese Akitas[13] and several breeds of Korean dogs.[21] Although dogs with HK RBCs are not anemic, their RBCs have shortened life spans,[51] increased osmotic fragility, increased MCV, and normal mean corpuscular hemoglobin (MCH) values, suggesting an increase in RBC water.[49] The genome-wide linkage analysis identified the mutations in the translocator protein 2 (TSPO2) gene as the molecular cause for HK RBC trait.[39] The defect of cholesterol-binding membrane protein TSPO2 causes the delays in multifaceted events during terminal erythroid differentiation and cell-cycle progression,[39] resulting in immature RBC phenotypes in HK dog RBCs.[29,43,50] Due to the leak of K^+ from RBCs, blood from HK dogs may cause pseudohyperkalemia in vitro after storage or on delaying plasma or serum separation.[13]

Canine RBCs possess a high-affinity Na^+-dependent transport system for glutamate and aspartate,[15,25] which resembles the kinetic and pharmacologic properties of the glutamate aspartate transporter (GLAST) in the brain.[68–70] The increased concentration gradients of Na^+ and K^+ across the membrane produced by the presence of Na, K-ATPase with high activity accelerate transport of glutamate and aspartate into HK RBCs.[25] The concentration of reduced glutathione is increased five to seven times that of normal because the feedback inhibition of γ-glutamylcysteine synthetase by glutathione is released by glutamate accumulated in these cells at about 90 times that in normal RBCs.[48] Some variant dogs of HK phenotype that lack the increase of RBC glutathione have been reported,[20,69] suggesting that several independent mutations have emerged in these breeds.[69]

The accumulation of glutathione in the canine HK RBCs only provides improved protection against oxidative damage induced by acetylphenylhydrazine, but these RBCs are more susceptible to oxidative damage induced by 4-aminophenyl disulfide,[52] onions,[47,89] and sodium n-propylthiosulfate,[91] one of the hemolytic thiosulfate compounds isolated from onions.[90] The increased glutathione concentration accelerates the generation of superoxide through its redox reaction with the aromatic disulfide,[52] but the exact mechanism by which HK RBCs are more sensitive to the thiosulfates remains to be clarified.

CHAPTER 31

Congenital Dyserythropoiesis

DOUGLAS J. WEISS

Pathogenesis
Poodle Macrocytosis
Inherited Selective Malabsorption of Cobalamin Clinical Condition
Congenital Dyserythropoiesis, Polymyopathy, and Cardiac Disease in English Springer Spaniels
Congenital Anemia, Dyskeratosis, and Progressive Alopecia in Polled Hereford Calves

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; RDW, RBC distribution width.

Congenital conditions associated with dysplastic features in RBCs and bone marrow include Poodle macrocytosis,[3,11] inherited selective malabsorption of cobalamin,[5,6,10] congenital dyserythropoiesis, polymyopathy, and cardiac disease in English Springer Spaniels,[7] hereditary stomatocytosis in Alaskan Malamutes (see Chapter 30), and congenital anemia, dyskeratosis, and progressive alopecia in polled Hereford calves.[12,13] In general, these conditions are characterized by dysplastic changes in RBCs or erythroid precursor cells associated with ineffective erythropoiesis.[15]

PATHOGENESIS

Recent studies in human medicine have identified more than 40 mutations in genes specifically involved in DNA repair, maintenance of genomic stability, and ribosome and telomere biology that are involved in bone marrow failure syndromes.[1,9] Mutations in ribosomal proteins are associated with a variety of specific human conditions.[9] These various ribosomal mutations appear to affect cells primarily through the p53 signaling pathway resulting in p53-dependent cell cycle arrest and apoptosis.[9] Aldehyde dehydrogenase 2 deficiency has been identified in people with Fanconi anemia.[14] Aldehyde dehydrogenase 2 is a mitochondrial enzyme that is essential for the metabolism of aldehydes. Aldehydes are genotoxic, specifically causing DNA cross-linking that may lead to hematopoietic failure. Both ribosomal mutations and many mutations in genes involved in DNA repair predispose patients to develop myelodysplastic syndromes or acute leukemias.[1]

POODLE MACROCYTOSIS

Poodle macrocytosis is a familial condition, affecting both sexes, that occurs mostly in Toy and Miniature Poodles.[3,11] Affected dogs do not have associated clinical signs, are not anemic, and do not have reticulocytosis. The most distinctive feature in the blood is marked macrocytosis with mean cell volumes varying between 85 and 105 fL.[3,11] Metarubricytosis is a frequent finding and some of these cells have nuclear-cytoplasmic asynchrony. Additionally, Howell–Jolly bodies are increased in number and tend to be large and multiple (Figure 31.1). Bone marrow is characterized by marked dyserythropoiesis and the morphologic changes resemble those associated with vitamin B_{12} deficiency. Features of dyserythropoiesis include megaloblasts, binucleation, multinucleation, irregular nuclear shapes, nuclear fragmentation, nuclear-cytoplasmic asynchrony, and nuclear bridging (Figure 31.2).[3] Nuclear bridging is a unique feature seen in Poodle macrocytosis that is rarely seen in other congenital or acquired types of dyserythropoiesis

or in myelodysplastic syndromes (Figure 31.3). Mitotic figures are increased in number. The nature of the hematopoietic defect has not been investigated. Bone marrow cytologic abnormalities in Poodle macrocytosis have some similarity to those seen in congenital dyserythropoietic anemia type I of children as well as those in Hereford cattle with congenital anemia, dyskeratosis, and progressive alopecia.[6,12,13] The mutated gene in congenital dyserythropoietic anemia type I of children has been identified as CDAN1.[8] The cellular function of this protein remains unknown.

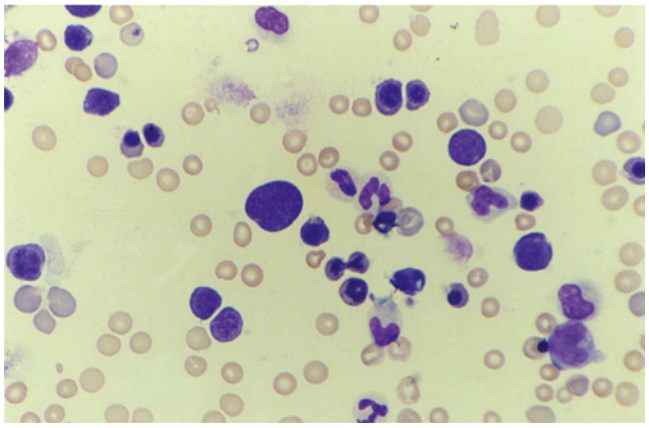

FIGURE 31.3 Bone marrow aspiration smear from a dog with Poodle macrocytosis. Notice the presence of a rubricyte with nuclear bridging (center of photo).

INHERITED SELECTIVE MALABSORPTION OF COBALAMIN

An inherited selective malabsorption of cobalamin (vitamin B_{12}) has been identified in Giant Schnauzers and has been reported in Border Collies, in a Beagle, and a cat.[4,5,10] Cobalamin is obtained in all species by absorption from the intestinal tract. Cobalamin can be produced by microorganisms in the gastrointestinal tract of ruminants, but must be liberated from digestion of foodstuffs by other species. Cobalamin is essential as a cofactor for the activity of the enzymes methylmalonyl-CoA mutase and methionine synthase.[2] Deficiency of methylmalonyl-CoA mutase results in methylmalonic acidemia and aciduria.[2] Deficiency of methionine synthase causes homocysteinemia and inhibits conversion of 5-methyltetrahydrofolate to tetrahydrofolate.[2] Tetrahydrofolate is an essential cofactor for enzymes of purine and pyrimidine synthesis.[2] Resultant inhibition of nucleic acid synthesis is most noticeable as inhibition of hematopoiesis in adult animals.[4,5] Inhibition of nuclear maturation typically results in a nonregenerative anemia, with megaloblastosis, neutropenia, and hypersegmented neutrophils.[4,5] Although humans and nonhuman primates develop a macrocytic anemia with cobalamin deficiency, the anemia in dogs, rodents, horses, pigs, and ruminants is normocytic and normochromic.[4,5] Both large and small RBCs are present in the blood of dogs with cobalamin deficiency.[4,5] This results in an increase in red cell distribution width (RDW), but the mean cell volume remains within the reference interval.

Clinical Condition

Inherited selective malabsorption of cobalamin in Giant Schnauzers is an autosomal recessive condition caused by lack of a receptor for intrinsic factor–cobalamin complex (i.e., cubilin) on the brush border of the small intestine and renal tubular epithelial cells.[4,5] Affected dogs develop anorexia, lethargy, and cachexia by 2–3 months of age. Blood cell morphology is characterized initially

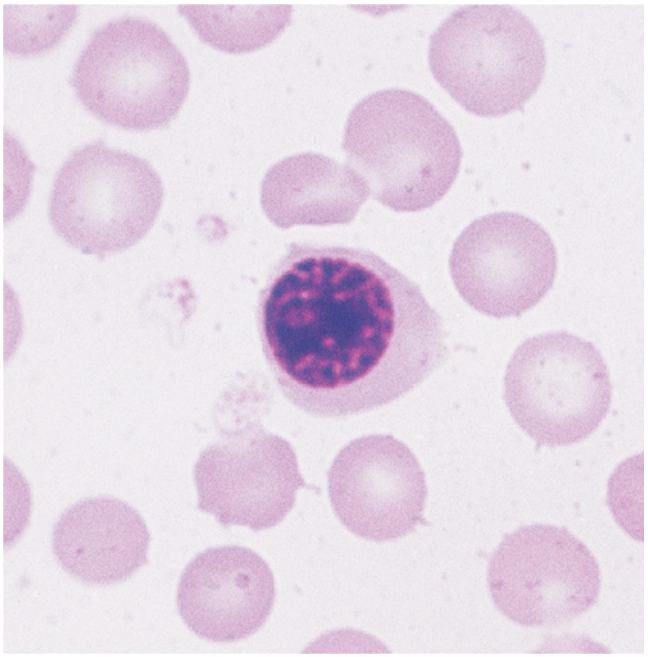

FIGURE 31.4 Blood from a dog with selective malabsorption of cobalamin. Notice the presence of a megaloblast exhibiting an immature nucleus and a fully hemoglobinized cytoplasm.

by a mild neutropenia followed by development of a chronic nonregenerative normocytic normochromic anemia, acanthocytosis, and increased RDW.[4,5] RBC morphology is characterized by many small RBCs, ovalocytes, and occasional megaloblasts (Figure 31.4). Occasional hypersegmented neutrophils and giant platelets are also present. Bone marrow granulocytes are characterized by hypersegmented neutrophils and giant bands and metamyelocytes. Erythroid cells in marrow are characterized by nuclear-cytoplasmic asynchrony and abnormal nuclear chromatin clumping.

Diagnosis of cobalamin deficiency is best made by determining serum cobalamin concentrations.[4,5] Low serum cobalamin concentration appears to be the earliest indicator of cobalamin deficiency. Increased serum methylmalonic acid and serum total homocysteine concentrations can also be measured.

Affected dogs respond well to daily injections of vitamin B_{12}.[4,5] Alternatively, one megadose of 1 mg of vitamin B_{12} is sufficient to maintain an affected dog in remission for 1 month. Complete resolution of hematologic signs and growth retardation occurs with parenteral administration of cyanocobalamin.

CONGENITAL DYSERYTHROPOIESIS, POLYMYOPATHY, AND CARDIAC DISEASE IN ENGLISH SPRINGER SPANIELS

Congenital dyserythropoiesis, polymyopathy, and cardiac disease have been described in three related English Springer Spaniels.[7] Clinical signs included regurgitation, stunted growth, stiff gait, skeletal muscle wasting, cardiomegaly, megaesophagus, and generalized muscle atrophy that was most pronounced in temporal muscles. All dogs had a mild to moderate microcytic normochromic nonregenerative anemia with marked metarubricytosis. Alterations in RBC morphology included spherocytes, schistocytes, dacryocytes, codocytes, and vacuolated RBCs. Bone marrow was characterized by erythroid hyperplasia and dyserythropoiesis. Features of dyserythropoiesis included lobulated nuclei, marked binucleation, arrested mitotic figures, and cytoplasmic vacuolization. The hematologic condition remained stable, but the polymyopathy was slowly progressive.

CONGENITAL ANEMIA, DYSKERATOSIS, AND PROGRESSIVE ALOPECIA IN POLLED HEREFORD CALVES

Hereford calves with congenital anemia, dyskeratosis, and progressive alopecia have a congenital syndrome characterized by dyserythropoiesis and progressive alopecia associated with dyskeratotic hyperkeratosis.[12,13] A familial pattern has been demonstrated which is consistent with a simple autosomal recessive mode of inheritance.

Clinically, the condition is slowly progressive, but is frequently fatal.[12] Iron, cobalamin, and folate deficiencies were ruled out, as causes and viral agents were not identified in affected calves. Affected calves have a macrocytic normochromic anemia with a mild reticulocytosis. Dyserythropoiesis in bone marrow is characterized by multinuclearity, nuclear bridging, irregular nuclear shapes, and irregular chromatin patterns. These dysplastic changes resemble those associated with Poodle macrocytosis and congenital dyserythropoiesis type I in humans.[2,6]

Acronyms and Abbreviations

FDA, Food and Drug Administration; G6PD, glucose-6-phosphate dehydrogenase; GPx, glutathione peroxidase; GR, glutathione reductase; GSH, reduced glutathione; HB, Heinz body; HK, high potassium; MB, methylene blue; NAPQI, *N*-acetyl-*para*-benzoquinoneimine; PAP, *para*-aminophenol; PDB, paradichlorobenzene; PG, propylene glycol; PS, phosphatidylserine; SAMe, *S*-adenosylmethionine; SMCO, *S*-methylcysteine sulfoxide; SOD, superoxide dismutase; TBARs, thiobarbituric acid reactive substances.

PATHOPHYSIOLOGY OF OXIDATIVE INJURY

RBCs are highly specialized cells that cyclically perform the critical function of oxygen transport in a wide range of potentially hostile environments. Oxygen carried by the RBC is a strong oxidant, since it can generate highly reactive derivatives, such as superoxide free radical (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\bullet}OH$) by reacting with iron. These oxidants are constantly produced, and the inability to synthesize proteins de novo limits the RBC's arsenal to preformed enzymes including superoxide dismutase (SOD), glutathione reductase (GR), glutathione peroxidase (GPx), and reduced glutathione (GSH) (see Chapter 21). When these anti-oxidant systems

are overwhelmed, oxidative damage to RBCs occurs, which can either be seen grossly and/or microscopically or can be occult. Oxidative modification of the RBC membrane and oxidant-induced clustering of band-3 alter the rigidity and therefore the circulating life span of RBCs.[50,49]

Visually Evident Oxidation

Heinz bodies (HBs), eccentrocytes, and methemoglobin are all visible consequences of RBC oxidative injury. When present in the context of an anemia, a causative association is supported. In the context of a nonanemic animal, it is plausible that the erythropoietic drive is compensating for a shortened RBC life span. This compensation may cause a mild reticulocytosis. In 1890, Dr. Robert Heinz first described round structures protruding from the surface of RBCs of humans and animals exposed to certain types of coal tar drugs.[28] These structures, which were associated with RBC destruction, were subsequently called Heinz bodies and can be found on the surface of RBCs in several species secondary to oxidative injury. Heinz bodies are formed by denatured clumps of precipitated hemoglobin on the inner surface of the RBC (Figure 32.1). These structures can more easily be seen with new methylene blue (MB) staining (Figure 32.2). RBCs plagued by this precipitation of hemoglobin have decreased deformability, which presumptively leads to hemolysis and/or accelerated removal, as extrapolated from ex vivo filtration studies.[12,34]

Eccentrocytes (alternatively referred to as erythrocyte hemighosts) are erythrocytes characterized by the concentration of hemoglobin on one side of the cell leaving a pale or clear portion on the other side (see Chapter 24).[9]

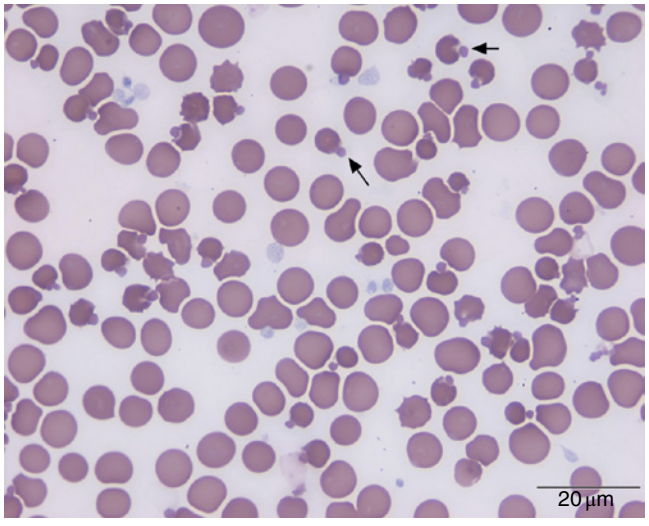

FIGURE 32.1 Photomicrograph of a blood smear from a horse with red-maple-leaf-induced Heinz-body hemolytic anemia. 100× objective, Wright–Giemsa stain. The arrows indicate prominent Heinz bodies along the margins of the RBCs. Note the prominent anisocytosis. (Case material provided by Dr. Laura Snyder)

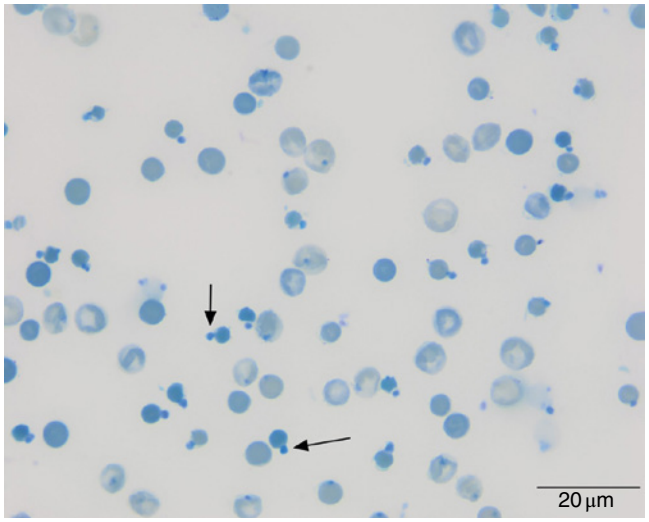

FIGURE 32.2 Photomicrograph of a blood smear from a horse with red-maple-leaf-induced Heinz-body hemolytic anemia. 100× objective, new methylene blue stain. The arrows indicate prominent Heinz bodies along the margins of the RBCs. (Case material provided by Dr. Laura Snyder)

The term eccentrocytes was first applied in dogs given acetylphenylhydrazine, a drug used to treat polycythemia.[25] Two theories exist regarding the formation of these cells. First, direct damage to the RBC membrane with adhesion of the opposing faces of the membrane has been proposed.[9] Disulfide-linked polypeptide aggregates have been identified in the RBC membranes from patients with the quintessential eccentrocytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency. The majority of the links were intramolecular and concentrated on cytoskeletal anchoring proteins. Intermolecular aggregates were more spectrin-associated.[21] Second, the membrane lesion may form secondary to precipitation of oxidized hemoglobin and bystander oxidation of the membrane.[57]

Methemoglobin is formed by the oxidation of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) in the heme groups and can be seen alone or in combination with HBs and/or eccentrocytes. Methemoglobinemia is grossly visible by the brown discoloration of blood, which can be confirmed by placing a drop of blood on a white piece of paper.[20]

Visually Occult Oxidation

Many diseases with an alternative primary etiology causing an anemia have a contributory oxidative component. Eryptosis, a form of programed cell death that results in accelerated clearance of RBCs occurs in the context of immune-mediated anemias and oxidative stress. Oxidative stress can result in the activation of Ca^{2+} channels in the membrane and Ca^{2+} entry into the cell. The inward flux of Ca^{2+} ultimately leads to membrane scrambling, exposure of phosphatidylserine (PS) on the outer leaflet, and cell shrinkage due to water loss. In people, a plethora of diseases including diabetes, hepatic failure, cancer, chronic kidney disease, hemolytic

disease, and inflammation all present with concurrent evidence of oxidative stress and increased numbers of eryptotic RBCs.[6]

SPECIFIC CAUSES OF OXIDATIVE INJURY IN DOMESTIC SPECIES

Feline Species

Increased Susceptibility of Feline Hemoglobin

Feline hemoglobin is structurally different from that of other mammalian species. Cats possess two species of hemoglobin, based on differences in the β-chain. Feline hemoglobin also has eight sulfhydryl groups, as opposed to the two on human hemoglobin and that of other domestic species.[54] The sulfhydryl groups contribute to a lower oxygen affinity and resistance to allosteric inhibitors, but also render feline hemoglobin more susceptible to oxidation.[12,18]

The feline spleen is non-sinusoidal and is relatively inefficient at removing HBs from RBCs because of the large pores in splenic pulp venules, which allow RBCs to enter without deformation. This is thought to contribute to the routine presence of low numbers of small HBs in feline blood.

Because RBCs may circulate relatively unimpeded in the feline spleen, splenic destruction of RBCs is thought to not be the major mechanism for the development of anemia in cases of oxidative stress in cats. Thus, additional mechanisms are likely present, such as increased rigidity of the RBC membrane. Alterations in surface charge distribution and hemoglobin electrophoretic migration patterns have been documented in the context of oxidative injury, but the contribution of these alterations to accelerated clearance is not fully elucidated.[12]

Acetaminophen (Paracetamol)

Acetaminophen toxicity is the leading cause of acute liver failure in people in the United States and Canada. In people and most mammals, hepatotoxicity occurs when GSH is depleted and glucuronidation and sulfation pathways are saturated, leading to metabolism of acetaminophen by P450 enzymes that generate a highly reactive metabolite, *N*-acetyl-*para*-benzoquinoneimine (NAPQI). NAPQI forms protein adducts by reacting with sulfhydryl groups on cysteine and lysine residues. Protein adduct formation on mitochondrial proteins precipitates oxidative stress, mitochondrial dysfunction, and ultimately cell death.[37]

Dogs and cats with acetaminophen toxicity are unique, because they tend to develop methemoglobinemia with signs of cyanosis, depression, facial edema, dyspnea, and vomiting occurring 2–4 hours post intoxication.[3] Oxidative hemolytic anemia is usually seen 48–72 hours post intoxication.[35] Cats were once thought to have increased susceptibility to acetaminophen toxicity due to low hepatic levels of a specific uridine diphosphate-glucuronosyltransferase.[23] However, feline acetaminophen metabolism is primarily by sulfation, with glucuronidation playing a minimal role (less than 1.5%).[35] Sulfation pathways are less robust, allowing accumulation of toxic metabolites.

The metabolite responsible for the hematological manifestations of acetaminophen toxicity has not been definitively identified. NAPQI was hypothesized to be the culprit responsible for oxidizing both hemoglobin and ferrous iron resulting in HB and methemoglobin formation, respectively. However, the RBC lacks the P450 enzymes required to generate this metabolite, and the mechanism by which this metabolite would escape from hepatocytes and enter the RBC remains unclear, given both its electrophilic nature and propensity to react with mitochondrial proteins.

More recent work found that a minor acetaminophen metabolite, *para*-aminophenol (PAP), can react with oxyhemoglobin in a redox fashion.[35] In experiments incubating canine and feline RBCs with PAP or NAPQI ex vivo, PAP elicited formation of methemoglobin, whereas NAPQI and the parent compound had no effect.[35] Additionally, the lack of hepatic N-acetyltransferase activity in the dog and limited activity in the cat may contribute to increased formation of the PAP metabolite.[35]

There is no safe dose of acetaminophen for cats. Toxic doses as low as 10 mg/kg of body weight have resulted in death in cats. In one case report, even exposure to an empty bottle that previously held acetaminophen resulted in classic symptoms of toxicity.[3]

Diabetes Mellitus

Oxygen-radical-mediated damage has been recognized in both humans and animals with diabetes mellitus. Oxidative damage is caused by the formation of radicals secondary to glucose auto-oxidation, compromised antioxidant systems, oxidized plasma lipoproteins, alterations in inflammatory mediators, as well as changes in antioxidant nutrient status.[13] Cats with diabetic ketoacidosis can have significantly more HBs than cats with nonketotic diabetes and healthy controls.[13] In one study, the percentage of HBs in diabetic cats showed a moderate positive correlation with plasma ß-hydroxybutyrate concentration and an inverse correlation with serum chloride concentration and RBC glutathione concentrations.[13] In this study, the ketoacidotic cats were mildly anemic.

Cats with diabetes mellitus may become severely hypophosphatemic. Hypophosphatemia may impair phosphorylation of glucose to glucose-6-phosphate, preventing glucose entry into the pentose monophosphate shunt and thus impair formation of GSH; decreased GSH could further result in increased HB formation.[1]

Propylene Glycol

Although propylene glycol (PG) itself is "generally recognized as safe" by the FDA and is nontoxic in vitro to RBCs, it has been proven to be deleterious to feline

RBCs.[12] Experimental feeding of PG to cats at a dose of 1.6 g/kg, roughly equivalent to the 6–13% previously used in semi-moist cat food, for 5 weeks resulted in formation of HBs and decreased RBC life span, but not the development of anemia. Feeding cats a higher dose, 8 g/kg/day for 3 weeks, resulted in a mild anemia with punctate reticulocytosis and bone marrow erythroid hyperplasia.[11] Despite the absence of anemia in the majority of exposed cats, the species-specific evidence of RBC oxidative injury pushed the FDA's Center for Veterinary Medicine to prohibit the use of PG in cat food.

Hyperthyroidism

To the authors' knowledge, only one study has looked at the association between hyperthyroidism and the development of HBs in cats.[10] In this study, 15 out of 21 cats with hyperthyroidism had an increased percentage of HBs and their presence usually did not result in overt anemia.[10]

Lymphoma

One study investigated the relationship between lymphoma and HB formation.[10] In this study, 15 out of 17 cats with lymphoma had increased numbers of HBs.

Phenazopyridine

Use of phenazopyridine (Pyridium®), alone or in combination with other drugs, is contraindicated in cats, because of the high risk of dose-related methemoglobinemia and HB formation.[26]

Methylene Blue

MB is used in veterinary medicine to therapeutically reduce methemoglobin, or less commonly as a urinary antiseptic.[17,46,47] Intravenous administration of single or limited doses of MB to treat methemoglobinemia did not result in anemia despite an increase in the number of HB-containing RBCs.[46] Methemoglobinemia due to a cytochrome B5 reductase deficiency was responsive to treatment with methylene blue.[47]

Benzocaine

Benzocaine is an ethyl ester of *p*-aminobenzoic acid that is used as a local anesthetic in several over-the-counter medications (e.g., Lanacane®). To our knowledge, only one case of benzocaine intoxication has been reported in cats.[59]

Onions

Onions (*Allium cepa*) are considered to cause oxidative damage through thiosulfate compounds that form disulfide bonds with hemoglobin or GSH.[61] Onion intoxication is far less common in cats than dogs, probably due to the more finicky eating habits of cats. However, baby food, commonly fed to sick anorexic cats, may contain onion powder causing HB formation and sometimes anemia. The rate and degree of HB formation vary depending on the concentration of onion powder in the baby food.[61]

Canine Species

Plants of the Allium Family (Onions/Garlic/Chives)

All types of onions (i.e., raw, cooked, or dehydrated) can be toxic to dogs.[29] In onions, *n*-propyl disulfide, sodium *n*-propyl thiosulfate, sodium *trans*-1-propenyl thiosulfate, and sodium *cis*-1-propenyl thiosulfate are thought to be the agents responsible for oxidative injury.[61,60] Ingestion of garlic (*Allium sativum*) and Chinese chive (*Allium tuberosum*) can also result in oxidative injury.[60] The oxidative agent present in garlic is sodium 2-propenyl thiosulfate.[60] In cases of natural intoxication with garlic and/or Chinese chive, eccentrocytosis seems a more prominent feature of anemia than HB formation.[60] In dogs, there seems to be a correlation between the animal's weight and the development of HBs in cases of onion/garlic/Chinese chive intoxication, as HB anemia is mostly seen in small breeds. So-called high potassium (HK) breeds (e.g., Akitas, Japanese mongrels, Shibas, Jindos, and Chinese Shar-Peis) are more susceptible to onion-induced oxidative damage than non-HK dogs.[61]

Acetaminophen (Paracetamol)

Acetaminophen can result in both hepatic damage (zone-3 hepatocellular necrosis) and oxidative injury (eccentrocytes, HBs, and methemoglobinemia) in dogs. The toxic dose in dogs is around 200 mg/kg body weight.[48] Clinical signs may include tachycardia, tachypnea, blue-gray or pale brown mucous membranes, facial edema, as well as brown urine and blood.[5] The mechanisms for RBC oxidative damage are discussed in the feline section. Given the low therapeutic window and availability of alternatives, this medication should be avoided.

Skunk Musk

Spraying with skunk musk is a rare cause of HB anemia and methemoglobinemia in dogs.[5] Skunk musk contains thiols which may potentially react with oxyhemoglobin, forming methemoglobin thiol radicals and hydrogen peroxide.[5] Both thiol radicals and hydrogen peroxide are highly reactive substances that may react with sulfhydryl groups on hemoglobin, resulting in the formation of HBs.

Zinc

Most cases of zinc-induced hemolytic anemia are related to ingestion of zinc-containing material. Skin ointments, pennies minted in the USA after 1982, and metallic objects such as toys or nuts coated with zinc represent the three most common sources of exposure.[5,24] Most dogs with zinc intoxication are young (less than 2 years of age), presumably since younger animals are more

likely to ingest foreign objects than older animals. Vomiting secondary to gastrointestinal irritation is the most common clinical presentation. In one study,[24] smaller dogs (mean weight 6 kg) were more likely to be intoxicated than larger dogs. Smaller dogs have smaller pylori, making it more difficult for objects to pass from the stomach into the small intestine, allowing more time for erosion by gastric acid, thus freeing more zinc for absorption. A dose-related effect may also be involved.[24] The pathophysiology of zinc-induced hemolysis in veterinary medicine is not completely understood, but inhibition of GR and enzymes of the hexose-monophosphate pathway probably play a role. Not all dogs with zinc intoxication develop RBC oxidative injury with formation of HBs or eccentrocytes.[24]

Naphthalene

Naphthalene, derived from coal tar, can be found in mothballs, driveway sealants, and toilet bowl deodorizers.[16] Naphthalene is metabolized by the liver to α-naphthol, ß-naphthol, α-naphtholquinone, and ß-naphtholquinone.[16] The metabolite responsible for the hemolytic crisis and HB anemia is α-naphthol.

Naphthalene intoxication seems relatively common in human medicine, but, to our knowledge, is rare in veterinary medicine with only one case reported in a dog.[16]

Diabetes Mellitus

Pathophysiology and mechanisms for oxidative injury to RBCs in dogs with diabetes mellitus are similar to those in cats. Similar to cats, dogs with diabetic ketoacidosis are at greater risk for oxidative damage than nonketoacidotic animals.[9] In a retrospective analysis, 8/33 (24%) dogs with diabetes mellitus had eccentrocytosis, versus 36.8% of the dogs with diabetic ketoacidosis.[35]

T Cell Lymphoma

In a retrospective study, several dogs with T-cell lymphoma had eccentrocytes indicative of RBC oxidative injury. The mechanism for oxidative injury is unclear and detailed information regarding the stage of lymphoma and drug history were not provided in the study.[9]

Vitamin K and Vitamin K Antagonists

Both vitamin K administration and vitamin K antagonist intoxication have been reported as causes of oxidative injury in dogs.[9,19] In cases of vitamin K administration, both vitamin K_3 and vitamin K_1 may result in HB formation, with vitamin K_3 being more toxic than vitamin K_1.[11] Vitamin K_3 reacts with hemoglobin and oxidizes oxyhemoglobin to methemoglobin with production of an intermediate, the semiquinone radical.[19] Semiquinone can combine with O_2 to produce H_2O_2 and contribute to RBC membrane damage. In the study by Caldin et al.,[9] more dogs that were intoxicated with vitamin K antagonists had eccentrocytosis than dogs with vitamin K administration. It is therefore possible that HBs present in dogs treated with vitamin K were present prior to vitamin K administration. Different explanations are possible for oxidative injury in cases of vitamin K antagonist intoxication. First, vitamin K antagonists themselves may have oxidative potential. It is also possible that an additive to the drug has oxidant properties. Finally, pathological abnormalities caused by vitamin K antagonism (e.g., acidosis caused by blood loss) may lead to oxidative damage.[9] In conclusion, both vitamin K administration and vitamin K antagonist intoxication can cause oxidative damage to RBCs, resulting in the formation of HBs and/or eccentrocytes.

Benzocaine

Rare cases of HB anemia/methemoglobinemia have been reported in dogs secondary to benzocaine-containing products.[27,15]

Equine Species

Red Maple Leaves

Dried red maple (*Acer rubrum*) leaves can induce toxicosis with oxidative injury to the RBC membrane and hemoglobin, resulting in hemolytic anemia characterized by HBs, eccentrocytes, and/or methemoglobinemia.[4] There does not seem to be a sex, breed, or age predisposition for this condition and most cases seem to occur either during the summer or fall.[4] Clinical signs may include tachypnea, tachycardia, icterus, cyanosis, scleral petechiation, and brownish discoloration of urine and blood. Signs appear as soon as 24 hours after ingestion with a peak of 72 hours after ingestion.[22] In one study of 32 horses with red maple leaf intoxication, 19 horses did not survive. However, HBs or eccentrocytes were noted in only 33% of affected animals, and no relationship was found between hemoglobin or methemoglobin concentration and mortality.[4] Studies have identified putative toxic metabolites and a role for microbial metabolism in their production.[2,7]

Garlic and Onions

Garlic can be used as an antifungal ingredient in livestock feed in order to prevent mycotoxin contamination.[40] Horses fed freeze-dried garlic at a dose of 0.2 g/kg of body weight or more showed signs of oxidative injury to RBCs with anemia and presence of HBs; these changes occurred 4 days after initial feeding and were associated with sweating.[40] Complete recovery occurred within 5 weeks after cessation of garlic supplementation. Horses that graze on pastures containing wild onions have also developed HB hemolytic anemias.[41]

Phenothiazine

Phenothiazine was one of the first broad-spectrum veterinary anthelmintics. Phenothiazine is degraded in the gastrointestinal tract to phenothiazine disulfide, an oxidative

metabolite.[23] Clinical signs associated with intoxication in horses may include tachycardia, anorexia, dullness, pale mucous membranes, and opaque brown urine. The toxic dose seems to be 30 g or more. Anemia usually develops over a period of 6–13 days after administration.

Lymphoma

To our knowledge, there is only one case report of HB anemia associated with lymphoma in a Quarter Horse filly.[45] In a recent review of equine lymphoma, none of the anemic horses had morphological evidence of oxidative injury, but the majority had evidence of agglutination, suggesting an immune-mediated component.[36] The contribution of oxidative injury to increased RBC destruction has not been studied in horses with lymphoma.

Bovine/Ovine Species

Selenium/Copper Deficiency

Selenium deficiency with or without concurrent copper deficiency can be seen in cattle and sheep.[53,38] In cattle, selenium deficiency can lead to a marked decrease in the selenium-containing enzyme GPx, whereas copper deficiency may result in HB anemia because SOD is a copper-containing enzyme. SOD protects RBCs from oxidative damage caused by accumulation of superoxide.[55] If both selenium and copper deficiencies are present concurrently, a cumulative effect may be present because both enzymes are required to detoxify superoxide free radicals. Cattle grazing on St. Augustine grass displayed a high incidence of HBs and an associated anemia that responded to selenium supplementation.[38]

Copper Intoxication

In sheep, copper toxicosis may also result in hemolytic anemia due to oxidative damage. Sheep are thought to be more susceptible to copper intoxication than other species due to lower rates of biliary excretion.[51] The copper:molybdenum ratio in the diet has also been implicated as a determinant of hepatic copper levels in sheep.[39] When liver copper increases, there is increased hepatocyte turnover enhancing both cell division and apoptosis.[20] When the rate of hepatocyte apoptosis and loss exceed replacement, copper is released into circulation resulting in intravascular hemolysis. Copper intoxication is also possible in cattle, but is less common than in sheep.[55] There have been multiple case reports of copper toxicity causing HB hemolytic anemia and hemoglobinuric nephrosis in Boer goats.[8,14] A breed sensitivity has been proposed, but no genetic cause of the increased incidence has been found.

Brassica

Forage brassicas (cabbage, kale, forage rape) constitute a feed with high nutritional value, allowing a reduction in the purchase of concentrates.[43] However, brassicas contain sulfur compounds such as *S*-methylcysteine sulfoxide (SMCO) which is first converted in the rumen to thiosulfonate. Thiosulfonate is further metabolized to n-propyl disulfides, dipropyl disulfides, and dipropenyl disulfides. All three disulfides are oxidizing agents, with dipropenyl disulfides being the most powerful.

When cattle are fed brassica-type plants, HB numbers peak at 10 days to more than 4 weeks after the initiation of feeding. In extreme cases, the hematocrit may fall to 30–50% of initial values.[43] The severity and rapidity at which the anemia develops is proportional to the amount of *Brassica* in the diet. Total recovery is achieved when *Brassica* is completely removed from the diet. RBC parameters return to reference intervals 3–4 weeks after complete removal of the plants.

Onions/Garlic/Chives

Onions, garlic, and other plants of the *Allium* family contain SMCO. Cattle are less susceptible to onion toxicity than dogs and cats, but are more susceptible than sheep and goats.[44] Ruminal fermentation of SMCO leads to the formation of oxidative metabolites.[44] The results of studies in cattle are discordant. One study looking at onion feeding in cattle showed that feeding up to 25% cull onions on a dry-matter basis resulted in HBs and mild decreases in RBCs, hemoglobin, and packed cell volume, but did not result in clinical anemia. In other studies, anemias have been life-threatening. Cows fed approximately 20 kg onions/cow/day for 6 weeks developed methemoglobinemia and a hemolytic anemia that was fatal in five cows, and cows consuming vegetable waste have also developed clinical anemia.[31,44] Similar to the horse, sheep grazing on pastures containing wild onions have developed HB hemolytic anemia.[32,52]

Oak Leaves and Shrubs

Oak trees and shrubs are present in most countries, and ingestion of immature leaves or freshly fallen acorns is the most common source of intoxication. Immature leaves and acorns are rich in tannic acid that is hydrolyzed to phenolic compounds including gallic acid. Gallic acid is hypothesized to be further metabolized to pyrogallol and resorcinol.[42] Pyrogallol can trigger oxidation of hemoglobin to methemoglobin,[42] resulting in oxidative damage to RBCs. In studies administering oak leaves or commercial tannic acid orally to calves, the response differed. Calves fed oak leaves developed renal disease characterized by hematuria and glucosuria with pyrogallol detected in serum as early as 3 hours post administration, whereas calves given high doses of tannic acid developed methemoglobinemia.[42]

Miscellaneous Species

Avian

Crude oil contains polycyclic aromatic hydrocarbons (PAHs) that cause oxidative HB hemolytic anemia in oiled sea birds. The cause-and-effect relationship has

been documented by oral dosing of birds with crude oil, which has recapitulated the severe anemias documented in birds exposed to the PAHs via environmental oil spills.[33,56]

Reptiles

Snakes are highly sensitive to acetaminophen and develop a severe methemoglobinemia. Comparison of metabolic pathways in liver homogenates showed that snakes lack phenol-type glucuronidation and N-acetyltransferase activity.[30]

Mink

Mink orally dosed with propylene glycol develop a strongly regenerative anemia characterized by both eccentrocytosis and a marked increase in the number of HB.[58]

- Plasmodium

Acronyms and Abbreviations

CNS, central nervous system; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; IMHA, immune-mediated hemolytic anemia.

A seemingly ever-increasing number of rickettsial, mycoplasmal, and protozoal agents are being recognized as the cause of anemia in veterinary species. The anemia is often hemolytic in nature; however, with some organisms the anemia is nonregenerative resulting from either cytokine suppression of hematopoiesis or bone marrow pathology. Of importance to the veterinary hematologist is that many of these organisms can be visualized on blood films, providing a definitive diagnosis.

RICKETTSIA

The order *Rickettsiales* contains many organisms that cause significant hematologic disease in veterinary species. Many of the genera in this order have undergone reclassification. The order now contains two families, *Anaplasmataceae* and *Rickettsiaceae*. The *Anaplasmataceae* are intracellular parasites that grow within a cytoplasmic vacuole in the host cell as opposed to the *Rickettsiaceae* which infect the host cell cytoplasm or nucleus and are not bounded by a vacuole.

Ehrlichiosis

Dogs may be infected with a variety of ehrlichial organisms including *Ehrlichia canis*, *Ehrlichia chaffeensis*, *Ehrlichia ewingii*, Panola Mountain *Ehrlichia sp*., and *Ehrlichia muris*. Marked cross-reactivity of the resulting antibody response on serologic assays and to some degree cross-reactivity on molecular testing can lead to difficulty in definitively identifying the causative agent unless sequencing of a PCR amplicon is performed for confirmation.[1,42] Severe clinical disease is most commonly seen with *E. canis* infection, while infection with *E. ewingii* is generally milder and infection with *E. chaffeensis* causes inapparent to mild disease. Despite causing milder disease, infection with *E. ewingii* and *E. chaffeensis* is much more common in areas with high vector tick populations, and this must be considered in interpreting serologic test results.[42]

Canine Monocytic Ehrlichiosis

E. canis is the most significant cause of canine monocytic ehrlichiosis worldwide, as far as clinical disease severity. Transmission is by tick vectors (primarily *Rhipicephalus sanguineus*) and direct blood inoculation. Organisms replicate in cells of the mononuclear phagocyte system and can be seen in lymphocytes, monocytes, or macrophages.[55] Within mononuclear cells, organisms multiply by binary fission within a cytoplasmic vacuole. They appear by light microscopy as round, variably sized, basophilic cytoplasmic inclusions termed morulae that have a punctate, granular appearance (Figure 33.1). Parasitemia in peripheral blood is extremely low and transient following initial infection, so they are rarely found on routine examination of peripheral blood smears from affected animals.

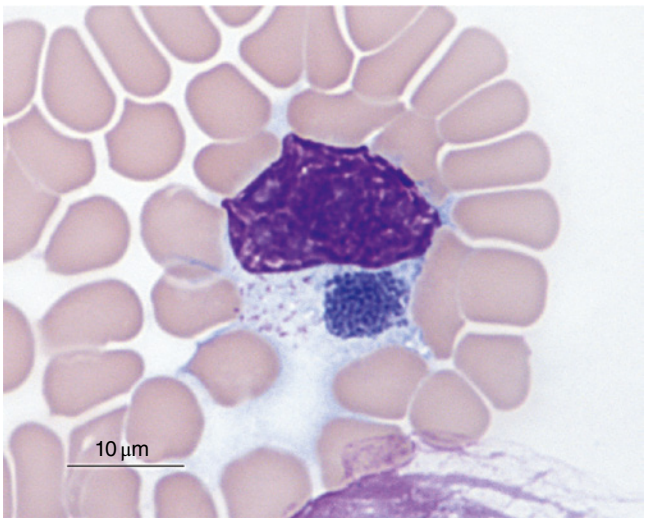

FIGURE 33.1 Blood film from a dog with *E. canis* infection. A morula is present in a disrupted large granular lymphocyte. The morula has the distinctive punctate, granular appearance. Aqueous Romanowsky stain.

Prolonged examination of buffy coat preparations increases identification, but is still generally unrewarding.[1] Morulae may be identified on cytologic preparations of tissue aspirates (lymph node, spleen, bone marrow, respiratory wash) during acute disease; however, diagnosis is most often confirmed by a combination of serology and PCR.

Hematologic findings depend on the stage of infection. Acute infection is associated with thrombocytopenia, which may be marked and associated with clinical bleeding (e.g., epistaxis), and nonregenerative anemia. Leukopenia and neutropenia are less consistent. Following acute infection, there is a subclinical phase during which anemia typically resolves but thrombocytopenia may be persistent. Dogs that develop the severe chronic phase typically have profound pancytopenia. Bone marrow aspirates obtained in these animals are hypocellular with marked reductions of all hematopoietic cell lines.[13] German Shepherd dogs are particularly prone to severe clinical disease.[42]

Canine Granulocytic Ehrlichiosis

The causative agent of granulocytic ehrlichiosis is *E. ewingii*.[2] Transmitted by *Amblyomma americanum*, *E. ewingii* has been reported from the Southern and Southeastern United States.[32] Clinical disease is considerably milder than that caused by *E. canis* and generally consists of nonspecific clinical findings such as fever, lethargy, and anorexia.[42] Polyarthritis is one clinical manifestation of infection that occurs in a minority of infected dogs, but should prompt consideration of this disease in endemic areas.

Thrombocytopenia, often marked, is the most common hematologic change in most reports, and provides an index of suspicion for this disease in endemic areas. Anemia is also a common finding. Most reports describe a relatively nonspecific mild to moderate nonregenerative anemia.[32] However, a recent review reported immune-mediated hemolytic anemia (IMHA) in approximately 15% of cases.[61] These dogs were extensively tested as being negative for co-infections leading the authors to suggest infection with this organism may be an underappreciated cause of immune-mediated hemolysis.[61] While there is some evidence to suggest *E. ewingii* infection may be persistent, such infections are not associated with a chronic-phase pancytopenia as is seen with *E. canis*.[61]

Morulae of *E. ewingii* are found predominantly in neutrophils and rarely in eosinophils. Morulae are similar in appearance to those of *E. canis*, although they sometimes have a "packeted" appearance rather than fine punctate granulation typical of *E. canis*. Organisms are seen in the peripheral blood only transiently during acute infection (approximately 2 weeks), but parasitemia is often high enough to allow diagnosis by microscopy.[1,32] Organisms may be identified in neutrophils of synovial fluid samples in dogs with polyarthritis. No specific serologic test for *E. ewingii* exists, but infection can be confirmed by appropriate PCR testing which is commercially available.[32,61]

Anaplasmosis

Historically, members of the genus *Anaplasma* infect RBCs of ruminants causing hemolytic anemia. However, with the reclassification of several *Ehrlichia spp*. as *Anaplasma spp*., members of this genus may infect RBCs (*Anaplasma marginale*), granulocytes (*Anaplasma phagocytophilum*), or platelets (*Anaplasma platys*). Anemia is not a main feature of *A. platys* infection and is not discussed in this chapter.

Granulocytic Anaplasmosis

A. phagocytophilum now includes the organisms previously described as *Ehrlichia phagocytophila*, *Ehrlichia equi*, and the human granulocytic ehrlichiosis (HGE) agent.

Granulocytic Anaplasmosis in Dogs

A. phagocytophilum infection in dogs is widespread. In the United States, it occurs most commonly in the Upper Midwest and along the Pacific coast.[33] Clinical signs are nonspecific and include fever, anorexia, depression, lymphadenopathy, and splenomegaly.[33] Some dogs may manifest either a neutrophilic polyarthritis or acute central nervous system (CNS) signs, including seizures.

Thrombocytopenia, mild to severe, is the most common hematologic abnormality and occurs in the majority of cases.[33] Mild to moderate anemia is also common.[33] Anemia is typically nonregenerative, but sporadic reports of immune-mediated hemolysis, as evidenced by regenerative anemia and spherocytosis and/or a positive Coombs test, have been reported in some cases.[18,47]

Morulae are similar to those of *E. ewingii* and are present at detectable levels during the acute phase of infection (approximately 4–14 days) in many cases.[16] Morulae may also be found in neutrophils upon examination of cytologic preparations of synovial fluid of dogs manifesting polyarthritis.

Granulocytic Anaplasmosis in Horses

A. phagocytophilum infection in horses has been reported from many states in the USA as well as Canada, Brazil, and Europe.[44] It can be transmitted by *Ixodes pacificus* and *Ixodes scapularis* and by direct blood inoculation from infected animals.[60] It causes a febrile illness characterized by anorexia, limb edema, petechiation, icterus, and reluctance to move. Clinical disease is less severe in horses under 4 years of age. The predominant hematologic finding is a profound thrombocytopenia, but variable neutropenia and mild normocytic, normochromic anemia may also be present.[29,67] The parasitemia may be high with morulae readily seen in peripheral blood neutrophils during acute infection.

Granulocytic Anaplasmosis in Ruminants

A. phagocytophilum causes the disease known as tick-borne fever, the most common tick-borne disease of animals in Europe. Disease is most common in cattle and sheep. Disease in cattle commonly manifests as abortion with reduced milk yield and as respiratory disease. In sheep, young lambs have a febrile illness, while abortions may be seen in ewes. Unlike erythrocytic anaplasmosis in ruminants, anemia is not a prominent feature of the clinical disease.

Erythrocytic Anaplasmosis in Ruminants

Anaplasmosis is a significant cause of disease characterized by marked hemolytic anemia in cattle.[41] Two species are described: *A. marginale* is widespread and *Anaplasma centrale* occurs in South America and South Africa. Wild ruminants are reservoirs, but do not usually manifest disease.

A. marginale infection causes fever and mild to marked hemolytic anemia in cattle. Decreased milk production and abortion add to economic loss. Numerous tick species serve as biological vectors and mechanical transmission may also occur via flies or medical procedures (needles, dehorning, etc.). The hemolysis is primarily extravascular; hemoglobinemia and hemoglobinuria are not seen. Disease is most pronounced in older animals; calves 6–9 months old are relatively resistant and disease is mild, unless they are splenectomized. *A. centrale* is generally less pathogenic than *A. marginale*, causing mild or inapparent disease in cattle, sheep, and goats.

Organisms are visible in erythrocytes during acute infection. They are round, 0.5–1 μm, basophilic bodies often present on the periphery of RBCs (Figure 33.2). They resemble Howell–Jolly bodies, from which they must be differentiated. *A. centrale* organisms are similar, but not peripherally located in the RBCs. Although long thought to occur only in RBCs, *A. marginale* has been shown to invade microvascular endothelial cells both in vivo and in vitro.[17]

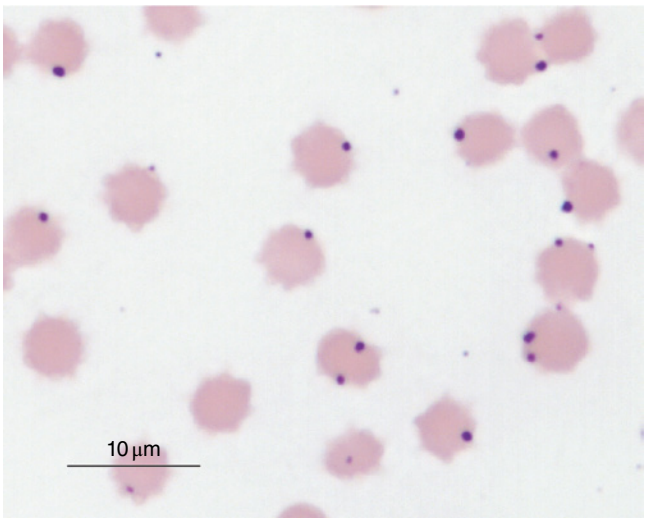

FIGURE 33.2 Blood film from a steer experimental infection with *A. marginale*. Marked parasitemia with more than 50% of erythrocytes containing inclusions. Note the marginal position of most organisms. Aqueous Romanowsky stain.

After infection, parasitemia increases until the hemolytic crisis, frequently with more than 50% of the RBCs infected.[41] After development of the anemia, parasite numbers decline due to removal of infected RBCs. Cattle that survive acute infection develop lifelong persistent infections. Persistent carriers are immune to clinical disease upon reinfection, but act as important reservoirs for infection of ticks and mechanical transmission to other animals.

Anaplasma ovis causes anaplasmosis in sheep and goats. The disease occurs in tropical and subtropical regions throughout the world. Morphologically, *A. ovis* is similar to *A. marginale*.

HEMOTROPHIC MYCOPLASMAS (HEMOPLASMAS)

Epierythrocytic parasites previously known as *Haemobartonella* and *Eperythrozoon* have been reclassified to the genus *Mycoplasma* and renamed, some with the designation *Candidatus* indicating they are incompletely described. As a group, these hemoplasmas have worldwide distribution, infect a wide variety of vertebrate animals, and share similar characteristics and morphologic features.[53] On routine blood films they are small basophilic round, rod, or ring-shaped organisms that appear on RBCs individually or in chains. Organisms are typically found in depressions and invaginations in RBC membranes and appear connected to the membrane by delicate fibrils.[77]

Hemoplasmas vary in their ability to cause clinically apparent disease, but infected animals may remain carriers despite antibiotic therapy; parasitemia may re-emerge in times of stress. Hypoglycemia secondary to glucose consumption by the bacteria has been reported in heavily parasitized pigs, sheep, llamas, and calves, however, rapid bacterial glycolysis *in vitro* may also cause artifactually decreased blood glucose concentrations.[14] Historically, diagnosis has relied upon detection of hemoplasmas on blood films. Organisms are generally found associated with the RBC membrane, but sometimes may be free in the plasma (Figure 33.3). Hemoplasmas dissociate from erythrocytes and die after a variable time in EDTA.[57] In aged samples, dead organisms can appear as pale pink clumped granular material in the background of the blood film (Figure 33.4). Development of sensitive PCR assays capable of discriminating between various hemoplasmas has greatly enhanced diagnosis of these parasites, and has led to the identification of several new *Mycoplasma* species.

Canine Hemotrophic Mycoplasmas

Two hemoplasmas, *Mycoplasma haemocanis* (previously *Haemobartonella canis*) and "*Candidatus* Mycoplasma haematoparvum," infect domestic canines. *M. haemocanis* causes acute hemolytic anemia in dogs that are splenectomized, immunocompromised, or have concurrent infections.[52] These dogs usually have sufficient circulating parasites to be easily demonstrated on blood films. Anemia may be severe; spherocytes may be observed and Coombs test results may be positive. By contrast, healthy dogs typically develop chronic, asymptomatic infections with sporadic, low-grade parasitemia.[52]

Transmission is presumed to occur via arthropod vectors and has been experimentally demonstrated with the brown dog tick, *R. sanguineus*. Transmission of organisms may also occur via blood transfusion from asymptomatic carriers, but the recipient must be splenectomized or otherwise severely compromised for hemolytic disease to occur.[52]

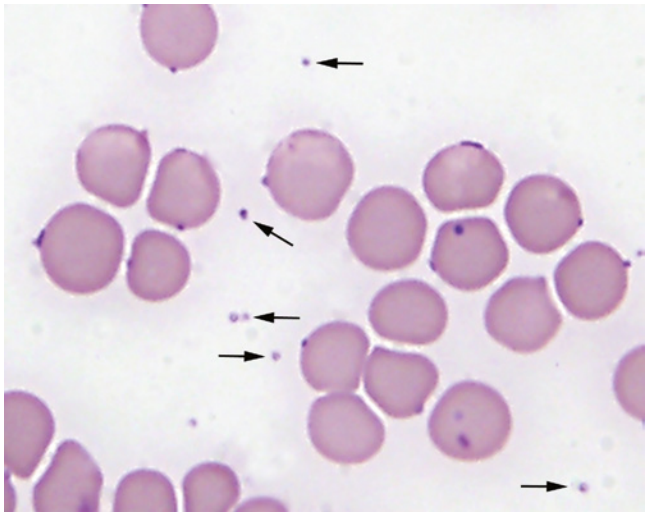

FIGURE 33.3 Blood film from a cat with *M. haemofelis* infection. Organisms are visible on the surface of erythrocytes and free in the background (arrows). Aqueous Romanowsky stain.

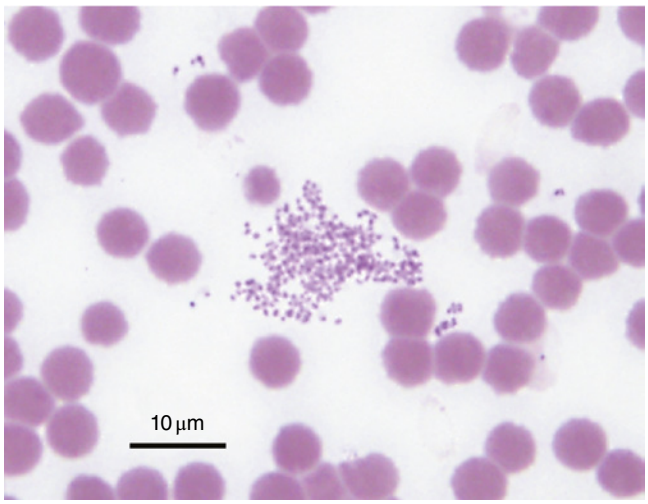

FIGURE 33.4 Blood film from a cat with *M. haemofelis* infection prepared from aged blood. Organisms have detached from erythrocytes and are degenerating, appearing as clumps of pink granular material in the background. Aqueous Romanowsky stain.

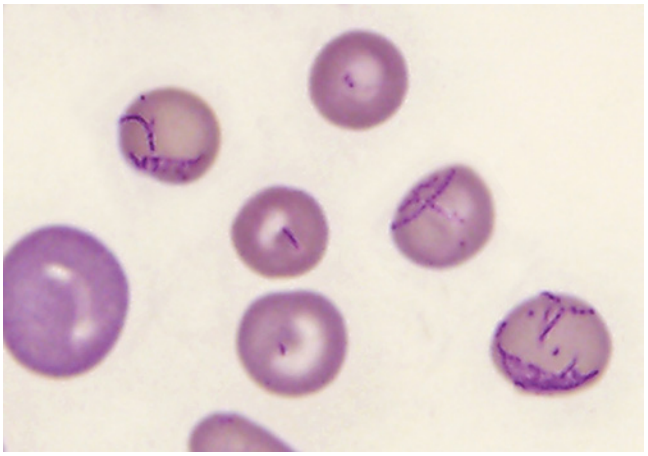

FIGURE 33.5 Blood film from a dog with *M. haemocanis* infection. Organisms are visible as chains of cocci on the surface of erythrocytes. Aqueous Romanowsky stain, 1000×.

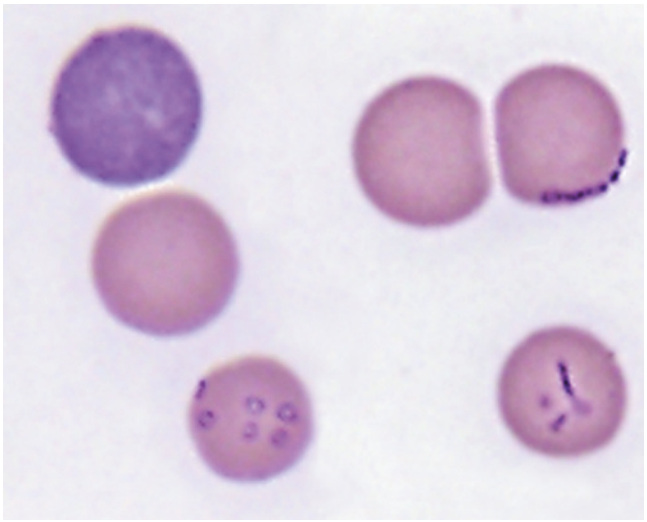

FIGURE 33.6 Blood film from a cat with *M. haemofelis* infection. Organisms are visible as chains of cocci and individual ring forms on the surface of erythrocytes. Aqueous Romanowsky stain, 1000×.

On routine blood films, *M. haemocanis* organisms are quite pleomorphic, but have a tendency to form long chains across the surface of the RBCs, sometimes with "violin bow" morphology. Individual organisms are 1–3 µm and can appear round, rod-shaped, or in ring form[77] (Figure 33.5).

"*Candidatus* Mycoplasma haematoparvum" was originally identified in a California dog with a T-cell lymphoproliferative disease that had undergone splenectomy and blood transfusions, but has since been identified in nonanemic dogs in numerous regions of the world.[3,71] Molecular characterization found the organism to be most similar to "*Candidatus* Mycoplasma haemominutum" in cats. These organisms are smaller than *M. haemocanis* or *Mycoplasma haemofelis* (<0.3 µm), and therefore are more difficult to appreciate on blood films.

Feline Hemotrophic Mycoplasmas

Three hemoplasmas, *M. haemofelis* (previously *Haemobartonella felis*), "*Candidatus* Mycoplasma haemominutum," and "*Candidatus* Mycoplasma turicensis," are currently known to infect domestic cats. *M. haemofelis* was previously described as the large variant or Ohio strain to differentiate it from the small variant or California strain that was later named "*Candidatus* M. haemominutum."[53]

M. haemofelis causes an acute hemolytic anemia characterized by variable numbers of circulating RBC parasites. Unlike *M. haemocanis*, disease occurs in immunocompetent hosts; however, retrovirus infection (feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV)) may be a predisposing factor in some cases. Hemolysis is primarily extravascular and results in a regenerative anemia that may be severe. Erythrocyte agglutination may be present and Coombs test results are frequently positive. Parasitemia is cyclic, with a gradual increase in parasite numbers over a period of days followed by a sudden decline; infected erythrocytes may disappear from circulation in as little as 2 hours.[35] Cats that recover remain carriers despite treatment, with variable low-grade parasitemia.

Transmission is presumed to occur by arthropod vectors such as fleas, but experimental evidence of such transmission is lacking. Transmission has been accomplished by blood transfer and is suspected to occur through biting and fighting activity.[70] Iatrogenic transmission can occur via blood transfusions and screening of potential blood donors using PCR-based DNA tests is recommended.[34] Vertical transmission from queens to kittens may also occur.

Morphology of *M. haemofelis* on routine blood films is similar to that described for *M. haemocanis*, with round (<0.8 µm), rod (up to 1.5 µm), and ring forms observed singly, in clusters, and short chains (Figure 33.6).

"*Candidatus* Mycoplasma haemominutum" is reported to be about half the size of *M. haemofelis*, hindering visualization on blood films. Prevalence investigations utilizing PCR-based DNA tests indicate there is substantial subclinical infection in domestic cats, supporting the experimental evidence that "*Candidatus* M. haemominutum" is less pathogenic than *M. haemofelis*.[72] However, there is evidence that immunosuppressed cats or those coinfected with *M. haemofelis*, FIV, or FeLV may develop clinically significant anemia.

"*Candidatus* Mycoplasma turicensis" is relatively common, widely distributed, and often associated with "*Candidatus* M. haemominutum" co-infection.[72] Like "*Candidatus* M. haemominutum," disease in cats infected with "*Candidatus* Mycoplasma turicensis" was most often observed in immunosuppressed cats infected with FIV or FeLV.[79]

Swine Hemotrophic Mycoplasmas

Two hemoplasmas, *Mycoplasma suis* and *Mycoplasma parvum* (previously *Eperythrozoon suis* and *Eperythrozoon*

parvum), are known to infect swine.[25] *M. suis* has a worldwide distribution and causes hemolytic anemia accompanied by icterus in neonatal pigs, feeder pigs, and pregnant sows. Splenectomy of latently infected animals results in a marked increase in parasitemia, as does immunosuppressive therapy. On routine blood films, *M. suis* may appear as small (approximately 1 µm) cocci, rods, or ring forms occurring individually, in chains, or in clusters. Similar to *M. haemofelis*, parasitemia is frequently transient. PCR-based DNA tests are proving sensitive and specific for the diagnosis of *M. suis* in the absence of demonstrable parasitemia.[37]

M. parvum is a coccoid or ring-shaped organism approximately half the size of *M. suis*. Infection in splenectomized pigs resulted in few clinical signs even at peak bacteremia.[25]

Ruminant Hemotrophic Mycoplasmas

Two hemoplasmas, *Mycoplasma wenyonii* and "*Candidatus* Mycoplasma haemobos" are currently known to infect cattle. *M. wenyonii* occurs worldwide and is typically thought of as an opportunistic pathogen, resulting in clinical anemia in splenectomized or otherwise compromised cattle. Parasitemia without anemia has been reported associated with fever and mammary, scrotal, or hind limb edema.[54,68] The mode of transmission for *M. wenyonii* is unknown, but presumed to occur via vectors such as lice, flies, ticks, and mosquitoes. Iatrogenic infection from blood transfer by contaminated needles and equipment may also occur.

On blood films, *M. wenyonii* organisms are small and pleomorphic but frequently coccoid or ring-shaped, and may be found free in the background in large numbers.[68] Parasitemia is transient, however, and PCR-based DNA tests may be more sensitive than microscopy for detection of latent infections.[76]

"*Candidatus* Mycoplasma haemobos" is considered nonpathogenic and has been detected in several countries in dairy cattle. "*Candidatus* Mycoplasma haemobos" is often seen as a co-infection with *M. wenyonii* and does not appear to cause significant disease.[36]

Mycoplasma ovis (previously *Eperythrozoon ovis*) infects sheep and goats. While frequently considered relatively nonpathogenic, the severity of hemolytic anemia with acute infection is variable depending upon age, nutrition status, concurrent worm burden, and possibly *M. ovis* strain differences.[53,56] Fatal disease occurs more often in lambs than in adults. Natural transmission may occur via arthropod vectors such as mosquitoes and ticks, and iatrogenically by blood transfer. On blood films, *M. ovis* organisms are coccoid, rod, or ring-shaped, 0.5–1 µm in diameter, and are frequently seen free in the background.

Camelid Hemotrophic Mycoplasmas

"*Candidatus* Mycoplasma haemolamae," originally described as an eperythrozoon-like parasite, affects llamas, alpacas, and camels. Anemia varies from mild to severe, with more severe clinical signs found in younger animals that are stressed or have other concurrent diseases; adults may be asymptomatic. Heavy parasitemia has been identified in crias as young as 1 day of age, suggesting vertical transmission in utero. On blood films, "*Candidatus* M. haemolamae" organisms are coccoid to ring-shaped, 0.5–1 µm in diameter, and are often free in the background[62] (Figure 33.7). Asymptomatic carriers have been identified using a DNA-based PCR assay.[73]

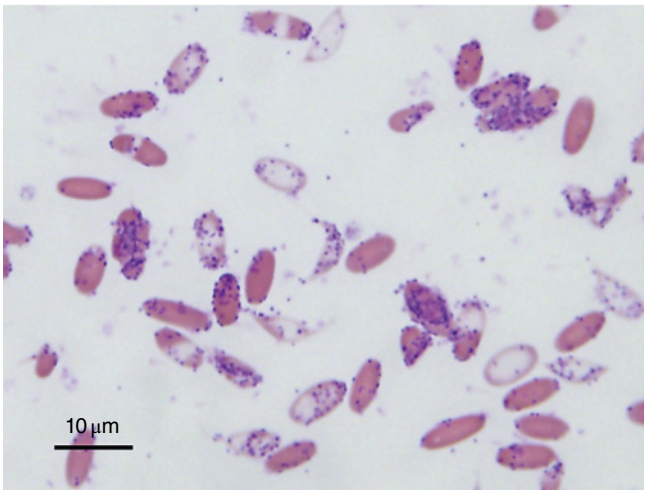

FIGURE 33.7 Blood film from a llama with "*Candidatus* M. haemolamae" infection and iron deficiency. Large numbers of coccoid organisms are present on the surface of erythrocytes and free in the background. Aqueous Romanowsky stain.

PROTOZOA

Members of two groups of apicomplexan protozoal erythroparasites, the *Babesias* and *Theilerias*, have undergone reorganization subsequent to genetic sequencing and phylogenetic studies. Historically, morphology and features of their life cycles defined them. Neither genera form pigment in the parasitized cell (as opposed to *Plasmodium* and *Hemoproteus*). Both are transmitted by ixodid ticks, but transovarial tick transmission occurs with *Babesia* species and not with *Theileria* species.[49] Additionally, *Babesia* sporozoites directly invade erythrocytes, while *Theileria* sporozoites first invade lymphocytes or macrophages to form schizonts.[49]

Theileriosis

Ruminants

There are multiple *Theileria* species that affect domestic and wild ruminants primarily in Africa, Europe, Australia, and Asia. The life cycle of these parasites involves a schizont stage, typically within lymphocytes, in addition to piroplasms within RBCs.[49] An interesting feature of the life cycle of some *Theileria* is the reversible transformation and clonal expansion of lymphocytes that occurs as a direct result of infection.[26]

Theileria parva is the most economically important, causing the rapidly fatal bovine disease East Coast fever in Africa.[10] The schizont stage of *T. parva* is the major cause of pathology. Anemia is typically mild and nonregenerative, but may become severe as erythroid precursors in bone marrow are infected. *Theileria annulata* causes tropical theileriosis in cattle from the Mediterranean to Asia.[10] Both the schizont stages and erythrocytic piroplasms are pathogenic, with severe hemolytic anemia and icterus a common occurrence. *Theileria hirci* (also known as *Theileria lestoquardi*) causes a similar hemolytic disease in sheep and goats in Asia and Africa. Several organisms have been described in oriental theileriosis (*Theileria sergenti*, *Theileria orientalis*, *Theileria buffeli*) and at this time it is unclear if these represent different subspecies or strains of the same parasite.[39] Oriental theileriosis is often benign, but hemolytic disease has been reported with some cases.[69] Many other *Theileria* species have been described, including *Theileria mutans*, *Theileria verifera*, *and Theileria taurotragi* in cattle and *Theileria cervi* in deer and elk, but seem to be less pathogenic under most circumstances.[39]

On routine blood films, theilerial piroplasms are pleomorphic, occurring as round, rod, comma, piriform, signet-ring, and racquet shapes, with occasional tetrad (Maltese cross) formation (Figure 33.8). The particular species cannot be determined based on morphology. Schizonts may be identified in lymphocytes from lymph node biopsies or aspirates.

Equines

The small piroplasm formerly described as *Babesia equi* has been renamed *Theileria equi*.[48] *T. equi* causes fever, hemolytic anemia, and icterus in horses in tropical and subtropical regions of the world. It is not yet endemic in the United States despite the presence of appropriate tick vectors and recognition of sporadic cases. The anemia varies from mild to severe, and subclinical infections may be detected by serology. *T. equi* piroplasms are small (1–2 μm) round to oval signet-ring structures within RBCs. Dividing stages may appear piriform in Maltese-cross arrangement.[48]

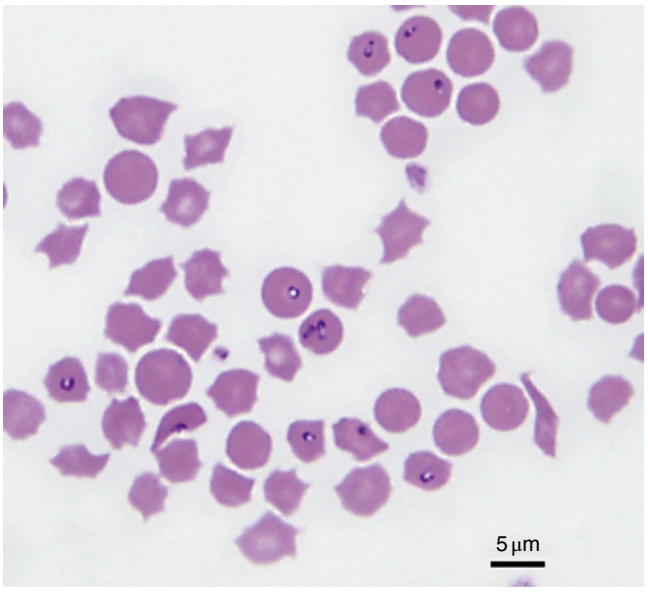

FIGURE 33.8 Blood film from a white-tailed deer with *T. cervi* infection. Small round to oval "signet-ring" piroplasms are present within erythrocytes. Aqueous Romanowsky stain.

Babesiosis

In contrast to *Theilerias*, pathogens of the genus *Babesia* are limited to RBCs within the host. Sporozoites injected into the host directly attach to, penetrate, and multiply within erythrocytes.[80] They are classified morphologically as large (>3 μm) or small (<3 μm). Organisms exit by rupturing the host RBC and then invade new RBCs. Hematologic findings are primarily hemolytic anemia, although thrombocytopenia is also common with many *Babesia* infections.

Canines

Large Canine Babesia Large canine *Babesia* appear as large (up to 5 μm), single, or paired piriform bodies (Figure 33.9). Large Babesia have historically been called *Babesia canis*. The organisms appear as large (up to 5 μm), single, or paired piriform bodies and based on differences in clinical syndromes, vectors, serologic tests, and cross-immunity were previously divided into subspecies (*B. canis canis*, *B. canis vogeli*, and *B. canis rossi*). Recently, they have been identified as three distinct species: *B. canis*, *B. vogeli*, and *B. rossi*.[65]

B. vogeli is the large *Babesia* found in the United States and also occurs in Africa, Europe, Asia, and Australia. It

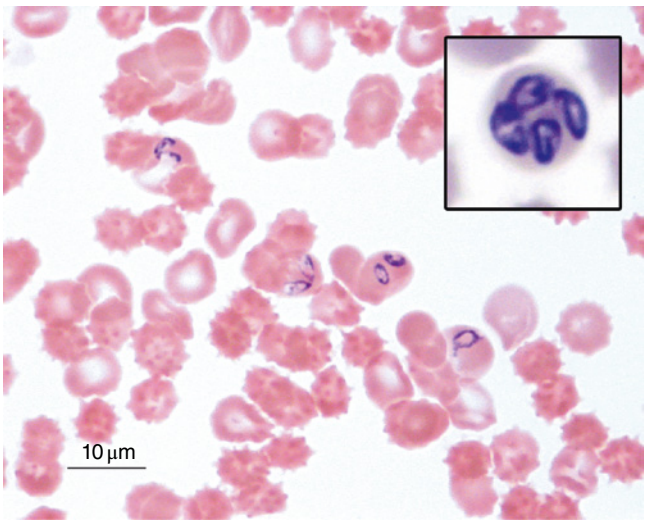

FIGURE 33.9 Blood film from a dog with *B. canis* infection. This dog did not have evidence of hemolysis (note lack of polychromasia) and probably represents a recurrent parasitemia in a chronically infected dog with subsequent immunosuppression from concurrent illness. Note the characteristic paired, piriform organism in erythrocytes. Inset: Erythrocyte containing four organisms. Aqueous Romanowsky stain.

causes relatively mild disease and is endemic in many populations of kenneled Greyhound dogs.[11] Infections are often subclinical with clinical disease most common in pups. Hematologic manifestations include a hemolytic anemia and thrombocytopenia. Parasites are rarely seen in the peripheral blood of subclinically affected animals and diagnosis generally is made by serology.

B. rossi[65] is the most virulent strain and is found in Africa. It causes a severe, hemolytic anemia which can be both intravascular and extravascular. Thrombocytopenia is also common. This parasite can induce a wide spectrum of disease manifestations unrelated to hemolysis, referred to as "complicated" babesiosis.[38]

B. canis is found in Europe and is of moderate pathogenicity. A fourth, genetically distinct, large *Babesia* has been identified in immunocompromised dogs in the Eastern United States. Based on molecular analysis, this organism is most similar to Babesia bigemina.[9,66]

Small Canine Babesia *Babesia gibsoni* has long been recognized as a problem of dogs in Asia, Africa, and Europe and has now been identified as an emerging infection of dogs in the USA.[8] In the United States, the majority of the affected dogs are American Pit Bull Terriers (APBT) or dogs that have been bitten by Pit Bulls.[43] Acutely, the organism causes a hemolytic anemia and thrombocytopenia.[8,51] Surviving dogs remain subclinical carriers and the incidence of such carriers is quite high in certain populations of APBTs.[43]

B. gibsoni can be transmitted between dogs by tick vectors, direct blood inoculation, or transplacental transmission.[31,51] In most endemic areas, *B. gibsoni* is transmitted by *Haemaphysalis* ticks.[8] It is not known if there is a competent tick vector in the United States. Clinical signs are nonspecific and generally relate to the hemolytic anemia. The anemia is regenerative; spherocytosis and positive direct Coombs test results suggest an immune-mediated component. Marked thrombocytopenia is a common finding and may occur prior to and last longer than parasitemia and/or anemia.[51] Parasitemia is detectable in the acute phase of infection, but is generally low. Parasites are small (1–2.5 µm) and pleomorphic.[43] The most common shape is a signet-ring, although elongated forms are also seen (Figure 33.10). Splenectomized animals show more severe clinical signs, more profound anemia, and a greater parasitemia than in animals with an intact spleen.[51] Serologic tests and PCR are useful for detecting chronically infected animals and have been used in prevalence studies.[7]

Babesia conradae is a small *Babesia* identified in a group of dogs (Greyhounds and Greyhound mixes) from California with a history of coyote fighting.[21] These dogs were anemic (regenerative), leukopenic, and thrombocytopenic and had multiple co-infections with *M. haemocanis*, "*Candidatus* Mycoplasma haematoparvum," and *E. canis*.[24]

Babesia vulpes (previously *Theileria annae* and *Babesia microti*-like) has been identified in the RBCs of dogs and foxes in North America and Europe. Foxes are thought to be subclinical carriers, while dogs are more severely affected with hemolytic anemia, thrombocytopenia, and azotemia.[5]

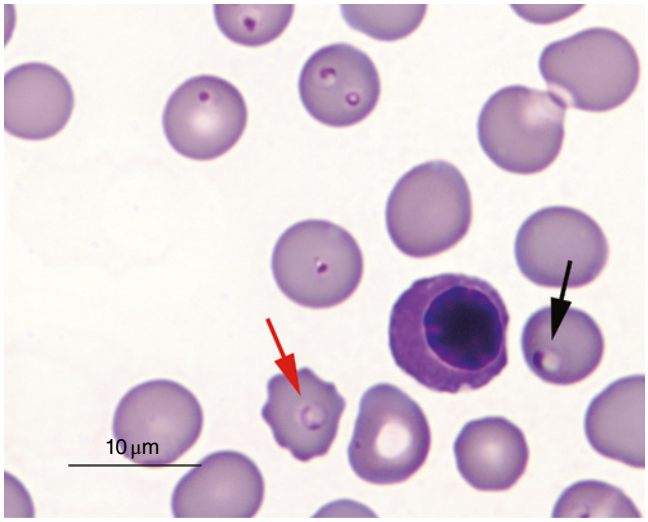

FIGURE 33.10 Blood film from an American Pit Bull Terrier with *B. gibsoni* infection. This dog suffered an acute hemolytic crisis following splenectomy for removal of a splenic tumor. Note the varying sized organisms, many of which have the classic signet-ring appearance. In some, the nuclear material is punctate (black arrow), while in others the nuclear material is spread along the periphery of the ring (red arrow). Aqueous Romanowsky stain.

Ruminants

There are four widely recognized species of *Babesia* in cattle: *Babesia bovis*, *Babesia bigemina*, *Babesia divergans*, and *Babesia major*. *B. divergans* and *B. major* are reported in cattle in Europe.[74] *B. bovis* and *B. bigemina* are the most widespread and of most economic significance. *Rhipicephalus* ticks serve as vectors, although iatrogenic transmission by direct blood transfer also occurs.

B. bigemina is a large piroplasm often appearing as the classical pair of piriform organisms. *B. bovis* is a small piroplasm frequently seen as a single round body. Both organisms cause an acute febrile illness and hemolytic episode. Calves infected at less than 8 months of age often develop subclinical disease due to innate resistance.[22] Release of replicating parasites from red cells causes intravascular hemolysis with resultant hemoglobinemia and hemoglobinuria. Increased osmotic fragility of all RBCs may result in massive terminal hemolysis despite reduced parasitemia.[22] Marked accumulation of *B. bovis*-parasitized RBCs in small cerebral capillaries can result in ischemia. The associated CNS signs are termed "cerebral babesiosis."

Two species, *Babesia ovis* and *Babesia motasi*, cause disease in sheep and goats in Africa, Asia, and Europe.[74] *B. ovis* is a small oval piroplasm, while *B. motasi* is larger and is commonly seen as paired, piriform organisms.

Equines

Babesia caballi is the only true equine *Babesia* species, since *B. equi* has been properly reclassified as *T. equi*. It is a large, piriform organism often appearing in pairs with an acute angle. It is tick transmitted, and transovarial

transmission may occur through several generations of ticks. The distribution of *B. caballi* includes Africa, the Americas, Asia, and Europe. Despite the presence of potential tick vectors, it is not a significant disease in the USA. Disease induced by *B. caballi* is generally much less severe than that of *T. equi*. Pronounced clinical signs and severe anemia are uncommon. Hemoglobinuria is not typical. The parasitemia is generally extremely low, even in splenectomized animals.[23] Foals are immune for the first 6–9 months of life from passive immunity and innate factors.

Felines

Babesia felis is a small piroplasm reported regularly in cats from coastal regions of South Africa.[59] No vector has been identified, although it is assumed to be tick-borne. It is most common in young adult cats, which may have severe regenerative anemia, hyperbilirubinemia, and agglutination. The parasitemia is variable and may be extremely high.

Feline Cytauxzoonosis

Cytauxzoon felis is a hemoparasite of wild and domestic cats. Historically most common in the South Central and Southeastern United States, its geographic distribution appears to be constantly expanding. The disease is tick-borne, most efficiently transmitted by *A. americanum*.[63] Bobcats, and possibly other wild felids, as well as domestic cats serve as a reservoir host.[40]

Cytauxzoon piroplasms are found in erythrocytes with schizogony occurring in macrophages of various tissues. The schizogonous phase precedes erythroparasitemia and is responsible for the marked clinical disease with parasitized intravascular macrophages becoming greatly enlarged and obstructing the lumen of vessels. Clinical signs include profound depression, dehydration, marked fever, and icterus. Anemia, generally nonregenerative, is a common finding that develops relatively late in the course of disease. Leukopenia and/or thrombocytopenia commonly precede or occur concurrently with anemia.

Diagnosis is usually confirmed by identification of piroplasms on peripheral blood films. While piroplasms are extremely pleomorphic, the characteristic shape most easily differentiated from artifact is the signet-ring. This is a small ring (approximately 1–3 μm) with a round or linear thickening of nuclear material at one point of the ring[78] (Figure 33.11). Clinical signs precede parasitemia, so organisms may not be present at the time of presentation. Parasitemia tends to increase as infection progresses.

Schizont-containing macrophages can be identified in impression smears of many tissues including lung, spleen, liver, lymph nodes, and bone marrow, and may also be observed on peripheral blood films late in the disease course. Parasitized macrophages become greatly enlarged and have a large, prominent nucleolus (Figure 33.12). Identification of schizonts in tissue aspirates can confirm a diagnosis in patients that are not yet parasitemic. PCR may also be used to confirm infection

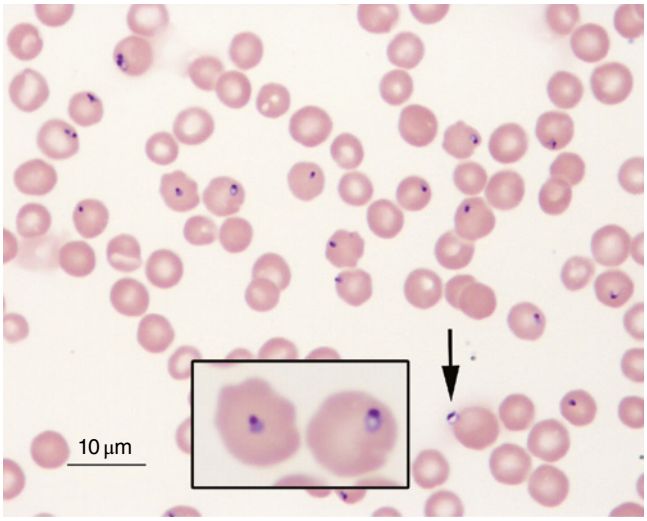

FIGURE 33.11 Blood film from a cat with terminal cytauxzoonosis. In fatal cases, parasitemia typically progressively increases with time. Organisms are variably sized and somewhat pleomorphic. Only some demonstrate the characteristic signet-ring shape. One extracellular piroplasm is present (arrow). Inset: Higher magnification of two piroplasms. In the larger one on the right, the inner portion of the ring can be seen to be lighter than the erythrocyte. Aqueous Romanowsky stain.

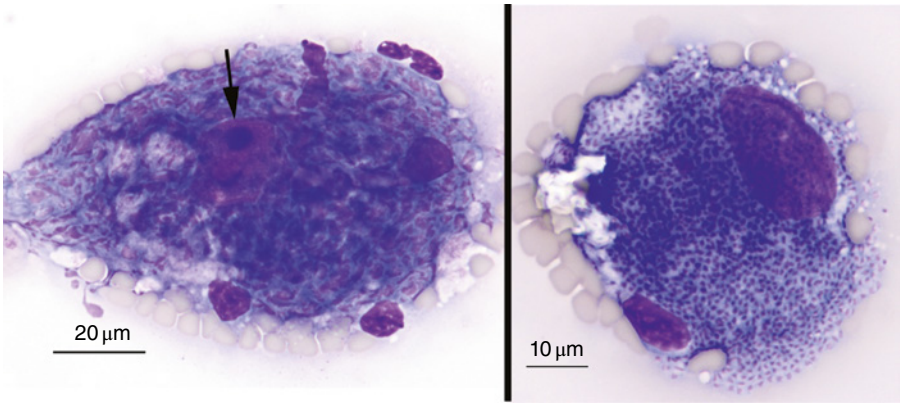

FIGURE 33.12 Large mononuclear cells with *C. felis* schizonts form the feathered edge of a blood film of a cat with cytauxzoonosis. The schizont on the left is less mature. Nuclear material is visible as variably sized, amorphous purple areas within the basophilic schizont. The schizont on the right, from the same blood film, is more mature. Nuclear material has transformed to fine punctate inclusions of developing merozoites. Aqueous Romanowsky stain.

with parasite DNA being detectable by this method several days prior to visualization by microscopy.[63]

The prognosis for cats with cytauxzoonosis has historically been grave with mortality rates approaching 100%. Successful treatment using a combination of atovaquone and azithromycin has been reported, but mortality rates are still high.[19] Survival of cats unrelated to treatment and identification of a high prevalence of asymptomatic carriers in hyperendemic regions have been reported and suggest the presence of less virulent strains in certain regions.[12,50,64] Recovered cats remain persistently parasitemic and may serve as a source of infection of other domestic cats.[63]

Trypanosomiasis

Trypanosomes are flagellated protozoal organisms. They are not a significant cause of anemia in animals in North America.

Trypanosoma cruzi, etiologic agent of Chagas disease, has been reported in dogs in several states.[6] The organisms may be found in the peripheral blood in the acute stages of infection; however, anemia is not a significant finding. Organisms are fusiform, approximately 15–20 µm in length, with a centrally located nucleus and small basophilic subterminal kinetoplast (Figure 33.13).

Trypanosoma theileri is a larger organism (up to 100 µm in length) that occurs in cattle worldwide. This organism is fairly prevalent, but is considered nonpathogenic.[28]

Anemia in animals is caused by a variety of African trypanosomes including *Trypanosoma congolense* and *Trypanosoma vivax* in cattle; *Trypanosoma brucei and T. congolense* in goats and sheep; *T. brucei* in horses and donkeys; and *T. brucei and T. congolense* in dogs.[20] Anemia is most often identified in chronic disease and the pathogenesis is complex.[4] In acute disease, RBC membranes are damaged directly by hemolysins released from trypanosomes. Extravascular RBC removal also occurs in the spleen, bone marrow, and lungs secondary to coating of erythrocytes with trypanosomal antigens.[20]

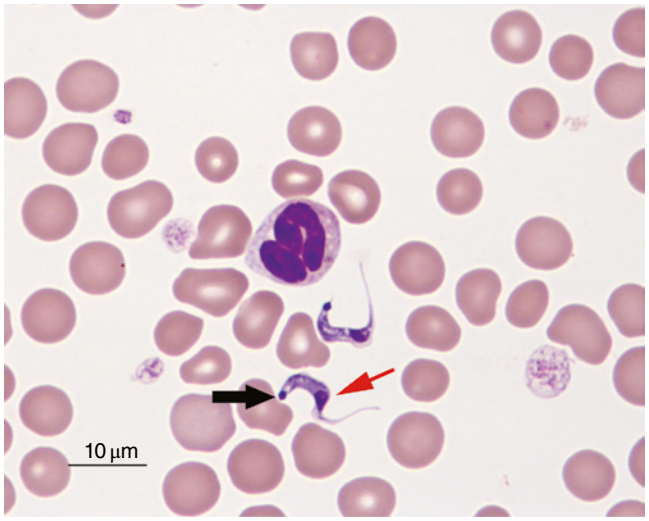

FIGURE 33.13 Blood film from a dog with *T. cruzi* infection. This dog was treated with multiple immunosuppressive agents for immune-mediated hemolytic anemia. Organisms were visible on follow-up blood films after resolution of anemia. Note the dark, subterminal kinetoplast (black arrow) and larger purple nucleus (red arrow). Aqueous Romanowsky stain.

Sarcocystosis

While several different species of *Sarcocystis* have been reported to cause anemia in ruminants including cattle, sheep, and goats, hematologic disease appears to be minimal in comparison to the large numbers of animals infected.[27] There is no parasitic stage of *Sarcocystis* that infects erythrocytes, thus there are no specific hematologic findings. Anemia related to sarcocystosis is thought to be due to hemolysis. In experimental infections, it reaches a nadir at about 1 month post inoculation. Second generation meronts are maturing in endothelium at that time, suggesting that microangiopathy due to vasculitis may play a role in the anemia. Calves inoculated with *Sarcocystis cruzi*, the most pathogenic species for cattle, developed a severe anemia attributed to extravascular immune-mediated hemolysis, and had evidence of a consumptive coagulopathy attributed to endothelial cell damage and disseminated intravascular coagulation.[30] The anemia is reportedly minimally regenerative, possibly due to superimposed anemia of inflammatory disease.[45]

Haemoproteus

Many different species of *Haemoproteus* can affect birds and reptiles. In general, they are considered relatively nonpathogenic, although co-infection with other hemoparasites may have detrimental effects in wild populations. Clinical disease seems to be associated with the tissue stages of parasite development, rather than the RBC stages. Anemia may develop in parasitized animals that are ill, injured, or immunocompromised, with a few reports of mortality associated with anemia occurring in young quail and pigeons. Parasitemia is frequently observed in raptors undergoing rehabilitation for illness or injury, and the magnitude of parasitemia often decreases as birds recover.[58]

Haemoproteus gametocytes are generally present within erythrocytes, although extraerythrocytic forms may occasionally be seen on blood films (Figure 33.14). Gametocytes vary in appearance depending on their stage of development, and may be round, oval, or elongated.[15,46] Large forms typically encircle the erythrocyte nucleus without displacing it. Gametocytes usually contain refractile yellow to brown iron pigment (hemozoin), a result of hemoglobin digestion ("malarial pigment").

Plasmodium

Parasites of the genus *Plasmodium* are the cause of malaria in humans and many animal species. Numerous different *Plasmodium* species have been identified. In veterinary medicine, malarial parasites are most often

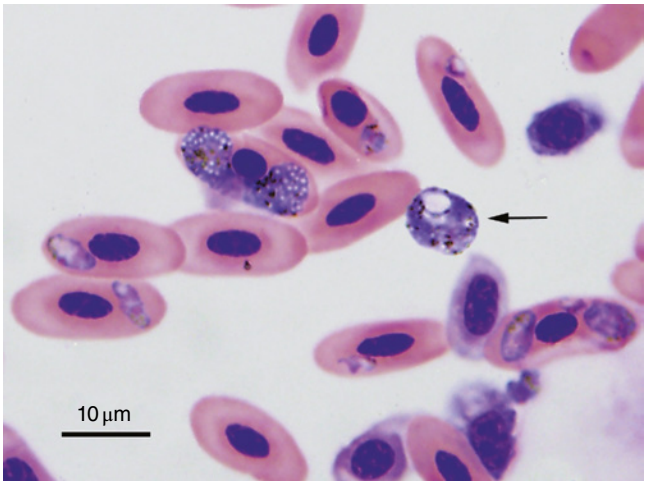

FIGURE 33.14 Blood film from an owl with *Haemoproteus* infection. Several different stages of intracellular gametocytes containing yellow–brown hemozoin pigment are visible, which surround but do not displace the nucleus. One extracellular form is present (arrow). Wright's stain.

encountered in birds and reptiles. Some species of birds seem more susceptible to clinical disease (canaries, penguins, ducks, pigeons, raptors, domestic poultry), while others may be asymptomatic carriers. Reported disease manifestations include hemolytic anemia, leukocytosis, lymphocytosis, hepatomegaly, splenomegaly, and death.[15]

Gametocytes contain yellow-brown iron pigment (hemozoin), similar to that found in *Haemoproteus* gametocytes. Gametocytes may be elongated or round depending on the particular species; round forms tend to displace the host cell nucleus, unlike *Haemoproteus* (Figure 33.15). Schizonts may be found in peripheral blood RBCs, thrombocytes, and leukocytes. They have a variable appearance depending upon the stages of the developing merozoites, which may appear fused or as distinct basophilic structures. Trophozoites are round to oval with an eccentric nucleus, resulting in a signet-ring appearance. Features of *Plasmodium* useful to differentiate it from *Haemoproteus* are presence of schizonts in peripheral blood, developing parasite stages within leukocytes and thrombocytes in addition to RBCs, and displacement of the host cell nucleus.[15] However, there are significant differences in the appearance of these parasites in blood cells; depending upon the particular *Plasmodium* species observed, schizonts may only be observed within RBCs, and the host cell nucleus may or may not be displaced. Those interested in detailed morphologic descriptions of avian haemosporidia are referred to the comprehensive monograph by Valkiunas.[75] Recently developed DNA-based PCR assays should prove helpful to better understand and classify the various morphologic variants.

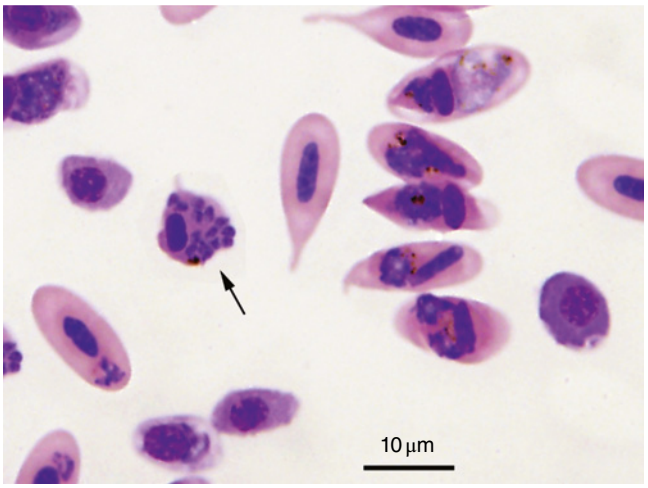

FIGURE 33.15 Blood film from a golden eagle with *Plasmodium* infection. Developing gametocytes containing yellow–brown hemozoin pigment displace erythrocyte nuclei. One erythrocyte contains developing merozoites (arrow). Wright's stain.

CHAPTER 34

Anemia Associated with Bacterial and Viral Infections

GEORGE M. BARRINGTON and DEBRA C. SELLON

Clostridium Perfringens Infections (Yellow Lamb Disease, Bacillary Hemoglobinuria, Clostridial Myonecrosis)
Clostridium Haemolyticum or C. Novyi Type D Infections (Bacillary Hemoglobinuria, Red Water Disease)
Corynebacterium Pseudotuberculosis Infections
Leptospirosis
Equine Infectious Anemia

Acronyms and Abbreviations

AGID, agar-gel immunodiffusion; C-ELISA, competitive enzyme-linked immunosorbent assay; EIA, equine infectious anemia; EIAV, equine infectious anemia virus.

Many bacterial and viral infections can directly or indirectly cause anemia. This chapter's primary topics are the anemias associated with infections by *Clostridium*, *Corynebacterium*, *Leptospira*, and equine infectious anemia virus (EIAV) (Table 34.1). Anemias caused by feline viruses (i.e., feline leukemia virus and feline immunodeficiency virus), rickettsial bacteria (e.g., *Rickettsia*, *Ehrlichia, Anaplasma*), or mycoplasmal bacteria (e.g., *Mycoplasma haemocanis*, *Mycoplasma haemofelis*) are described in Chapters 18, 33, 53, and 60, respectively.

Most anemias associated with bacterial and viral infections are caused by the inflammatory reaction (i.e., anemia of inflammatory disease, see Chapter 39). Infections may cause more severe anemias if they result in hemorrhage (vascular damage, thrombocytopenia), RBC fragmentation (vasculopathy, coagulopathy), or generalized bone marrow damage (marrow necrosis or replacement, see Chapters 16 and 17).

Infectious agents, their products, or the animal's specific response to the agent may cause an anemia via three major processes: (1) damaged circulating RBCs causing intravascular or extravascular hemolysis, (2) damaged erythroid precursors causing erythroid hypoplasia, and (3) damaged hematopoietic or supportive stromal cells causing general marrow hypoplasia.

CLOSTRIDIUM PERFRINGENS INFECTIONS (YELLOW LAMB DISEASE, BACILLARY HEMOGLOBINURIA, CLOSTRIDIAL MYONECROSIS)

Yellow lamb disease occurs in spring nursing lambs of Northern California and Oregon[23] and in lambs and calves in Canada, Australia, New Zealand, and South Africa.[33] Hemolytic anemias are not described in most enteric diseases caused by *C. perfringens* type A.

Clinical signs include depression, fever, weakness, pale mucous membranes, anemia, hemoglobinuria, icterus, and diarrhea. Death may occur within 6–12 hours of onset of illness especially if icterus and hemoglobinuria are present.[23,33] Changes in blood are consistent with massive intravascular hemolysis.[6,33,48]

The α-toxin causes hydrolysis of membrane phospholipids (Figure 34.1) and resultant lysis of RBCs, WBCs, platelets, endothelial cells, and myocytes.[43] Studies have

TABLE 34.1 Bacterial and viral infections that cause anemia.[a]

Organism	Disease	Susceptible animals
Clostridium perfringens type A	Yellow lamb disease, enterotoxemic jaundice, or yellows in lambs; clostridial myonecrosis in horses	Lambs, calves, captive Siberian ibex, horses
Clostridium haemolyticum (or *C. novyi* type D)	Bacillary hemoglobinuria, red water disease	Cattle, sheep
Corynebacterium pseudotuberculosis	(Experimental infection)	Sheep
Leptospira interrogans serogroups	Leptospirosis	Calves, lambs, pigs, perhaps rhinoceros, possibly dogs
Equine infectious anemia virus	Equine infectious anemia, swamp fever	Horses, ponies, donkeys, mules

[a] Feline leukemia virus, feline immunodeficiency virus, rickettsial bacteria (e.g., *Rickettsia, Ehrlichia, Anaplasma*), and mycoplasmal bacteria (*Mycoplasma haemocanis, Mycoplasma haemofelis*) not included.

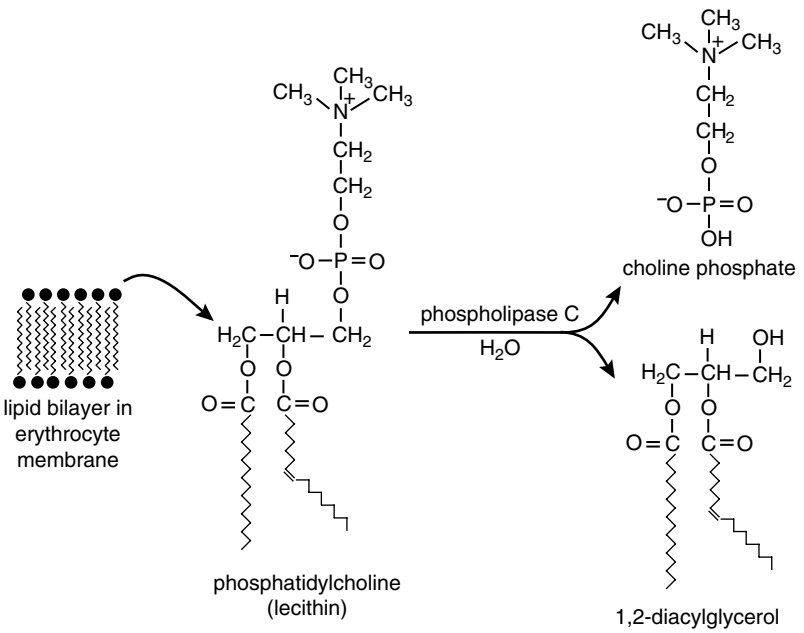

FIGURE 34.1 Action of phospholipase C on the RBC membrane. Phospholipase C catalyzes the hydrolysis of two RBC membrane lipids—phosphatidylcholine and sphingomyelin—that are the predominant phospholipids in the outer hemileaflet of the RBC membrane. The reaction shows hydrolysis of phosphatidylcholine into its hydrophilic portion (choline phosphate) and hydrophobic portion (1,2-diacylglycerol). In a similar reaction, phospholipase C catalyzes the hydrolysis of sphingomyelin to ceramide and sphingosine 1-phosphate (not shown).

demonstrated that α-toxin activates the sphingomyelin metabolic system as well as phospholipase C leading to hemolysis.[26,27,34,35] Furthermore, sensitivity to α-toxin hemolysis varies between species and is proposed to depend on the phospholipid composition of cell membranes.[14] A recent study demonstrated that α-toxin can impair erythroid differentiation in vitro;; however, inhibitory effects on erythroid differentiation were not detected in vivo, but may have been masked by a concurrent increase in plasma erythropoietin.[45]

C. perfringens type A is a part of intestinal microbiota in animals, but increased bacterial growth has been associated with highly proteinaceous diets,[46] overfeeding,[44] and starchy foods.[42] After production by the bacteria, α-toxin is absorbed by intestinal mucosa, enters the blood, and damages cell membranes. Major postmortem findings include evidence of massive intravascular hemolysis, renal hemoglobin casts, destruction of capillary walls leading to intestinal mucosal necrosis, centrilobular hepatic necrosis, and serosal, petechial, and ecchymotic hemorrhages. In calves, abomasal hemorrhage and ulceration may be present. Small intestine may be hyperemic, but rapid autolysis may obliterate the lesions; large, Gram-positive bacilli may be found in the mucosa and submucosa.[32]

A diagnosis of yellow lamb disease is confirmed by detecting α-toxin in intestinal contents or blood from fresh carcasses via serum-neutralization tests in mice and guinea pigs.[5] Polymerase chain reaction assays can detect the α-toxin gene (also known as cpa gene) of *C. perfringens* type A.[10]

Horses with *C. perfringens* infections such as clostridial myonecrosis may develop immune-mediated intravascular and extravascular hemolysis.[1,9,30,48]. The inciting factor in immune-mediated erythrocyte destruction is unconfirmed, but it has been postulated that

toxin-induced damage to erythrocyte membranes may alter surface antigens resulting in an autoimmune response.[30]

CLOSTRIDIUM HAEMOLYTICUM OR *C. NOVYI* TYPE D INFECTIONS (BACILLARY HEMOGLOBINURIA, RED WATER DISEASE)

Bacillary hemoglobinuria is a fatal disease that occurs naturally in cattle and experimentally in sheep. It can be a seasonal disease (summer and early fall) and is associated with liver fluke migration. It is endemic in poorly drained or swampy areas of the Gulf Coast states, Western United States, South America, Wales, Eastern Europe, and New Zealand.[44,46]

Bacillary hemoglobinuria is rarely recognized antemortem because the severe hemolysis causes rapid deterioration and death. When seen, clinical signs include malaise, reluctance to move, arched back, bloody diarrhea, fever, rapid and shallow breathing, and blood-tinged froth from nostrils. The classic port-wine urine of hemoglobinuria is uncommon.[40] If the affected animal survives the initial crisis, icterus and a regenerative anemia can develop. In experimental infections, severe anemia and death are seen within 3 days of inoculation. Calves and ewes develop fever, a gradual to precipitous drop in hematocrit values, mild to moderate leukocytosis, and increased aspartate transaminase activity (either due to RBC or hepatocyte damage).[28]

RBC damage is caused primarily by a β-toxin, a phospholipase C (lecithinase), that hydrolyzes phosphatidylcholine and sphingomyelin (Figure 34.1). The β-toxin is not related serologically to the phospholipase of other clostridial species.[41] The β-toxin is produced by two clostridial organisms, *C. haemolyticum* and *C. novyi* type D. Other minor hemolysins are reported as products of *C. haemolyticum*.[22]

After spores are ingested, organisms cross the intestinal mucosa and are transported to liver and other organs in macrophages. Spores may persist in Kupffer cells for a long time. Anaerobic conditions, such as those induced by hepatic biopsy and the presence of liver parasites, stimulate growth of organisms and production of toxins.[25] Absorption of β-toxin into blood leads rapidly to intravascular hemolysis, damaged endothelial cells, icterus, hemoglobinuria, and death.[40]

Necropsy findings may include pale and icteric mucous membranes, petechial and ecchymotic subcutaneous hemorrhages, copious amounts of red-tinged abdominal and thoracic fluid, hemoglobinuria, renal hemoglobin casts, congested or hemorrhagic lymph nodes, extensive edema, and bloody intestinal contents. Characteristic liver lesions are foci of hepatic necrosis surrounded by a reddened reaction zone.[44]

Diagnosis is usually made from the combination of clinical signs (rapid deterioration and death) and gross and microscopic postmortem findings. Numerous Gram-positive bacilli may be found in liver, spleen, blood, and abdominal fluid, but their presence must be interpreted with caution. Fluorescent antibody testing or immunohistochemistry for detection of the organism in fresh liver tissue can be performed.[18] Confirmation of bacillary hemoglobinuria can be made by demonstration of *C. haemolyticum* in the liver of affected animals by culture or polymerase chain reaction to detect the *C. haemolyticum* β-toxin gene.[25]

CORYNEBACTERIUM PSEUDOTUBERCULOSIS INFECTIONS

C. pseudotuberculosis causes caseous lymphadenitis and other forms of abscessation in sheep and goats. A distinct, species-specific biotype of the organism causes "pigeon fever" with cutaneous or internal abscessation in horses. *C. pseudotuberculosis* produces an exotoxin that has sphingomyelin-specific phospholipase D activity. When experimentally given intravenously in sheep, the exotoxin causes an acute, severe intravascular hemolytic anemia.[15,19] The exotoxin causes alterations in the phospholipid composition of RBC membranes leading to spherostomatocyte formation and pitting of RBC membranes.[3] Natural infections with *C. pseudotuberculosis* may not cause a hemolytic anemia due to the production of antitoxin against the phospholipase D during early stages of the disease. The anemia observed in affected animals is likely anemia of inflammatory disease.

LEPTOSPIROSIS

Leptospirae are saprophytic spirochetes that live in moist habitats throughout the world and infect humans, most domestic animals, and many wild animals.[17] In domestic animals, leptospirosis with hemolytic anemia is seen primarily in calves, lambs, and pigs.[4,47] A leptospiral infection may be a cause of acute hemolytic anemias of black rhinoceros.[13] Many serovars of *Leptospira* are reported to cause anemia in dogs, but the mechanism for the anemia is not understood.[16]

When the hemolytic state is present, the clinical signs and clinicopathologic abnormalities can include fever, depression, anorexia, anemia, hemoglobinemia, hemoglobinuria, icterus, neutrophilia, and petechial or ecchymotic hemorrhages. In experimental infections in calves, RBC fragility was increased.[31] Several explanations for the hemolytic process have been proposed; experimental evidence in lambs indicates involvement of an IgM cold agglutinin.[2,12] A study by Lee et al. suggested that sphingomyelin H (SphH) is a novel hemolysin which functions as a direct pore-forming protein among pathogenic *Leptospira*.[21] Direct membrane damage of sheep erythrocytes and mammalian cells is due to SphH in vitro;; further studies are necessary, however, to confirm the pathogenic role of SphH in animal models.

In lambs, major necropsy lesions include hemoglobinuria, icteric membranes and tissues, severe renal

tubular necrosis with casts, and periacinar hepatocellular necrosis.[11] A hemolytic anemia caused by leptospirosis is confirmed by finding leptospiral spirochetes in urine or other fluids by direct dark-field microscopic examination, culture of organisms with specific media, animal inoculation, and by serologic testing. Either ELISA or agglutination tests can detect IgM agglutinins within 7–9 days of onset of disease.[47] Diagnosis should be based on finding at least a fourfold increase in titer to either *pomona* or *icterohaemorrhagiae* serogroups over the course of infection.

EQUINE INFECTIOUS ANEMIA

Equine infectious anemia (EIA) is caused by EIAV, which is classified in the family Retroviridae and the Lentivirus genus.[24,36] This disease of equids occurs worldwide, but is most common in hot, humid climates (see Chapters 18 and 37).

The virus is spread via the bites of hematophagous flies (tabanids, deer flies) or iatrogenically through blood-contaminated fomites. It persists in mononuclear phagocytes and cannot be eliminated from an infected horse.[38] Intermittent episodes of fever, dependent edema, anemia, and thrombocytopenia are associated with emergence of novel antigenic variants of EIAV with associated upregulation of viral replication.[37] Most horses ultimately develop a broad immune response that controls viral replication and these infected horses show few if any recognizable clinical signs (inapparent carrier horses). By contrast, a few infected horses are unable to control viral replication and develop classic clinical signs of "swamp fever" that include fever, weight loss, persistent anemia and thrombocytopenia, and hypergammaglobulinemia.[24]

During episodes of viremia and fever, clinicopathologic abnormalities may include anemia, thrombocytopenia, and either neutropenia or neutrophilia. In acute disease, thrombocytopenia is the most consistent hematologic abnormality and is a result of both decreased platelet survival and decreased platelet production. Platelets are believed to be removed from circulation by tissue macrophages as a response to surface binding of complement or immune-complexes. Increased inflammatory cytokines (tumor necrosis factor-α, transforming growth factor-β, interferon-α) suppress megakaryocytopoiesis and dampen the bone marrow response that should occur in response to increased platelet destruction.

The anemia of EIA is a result of decreased RBC life span and decreased RBC production.[24,37] In acute disease, it is possible, but uncommon, for horses to experience intravascular hemolysis. The association of EIAV envelope glycoprotein with RBC membranes activates complement and causes a C3-fraction coating of RBCs and resultant hemolysis.[7,8,39] Infected horses may be Coombs positive. Morphologic changes in RBCs may include anisocytosis due to macrocytosis, spherocytes (difficult to detect in equine blood), and

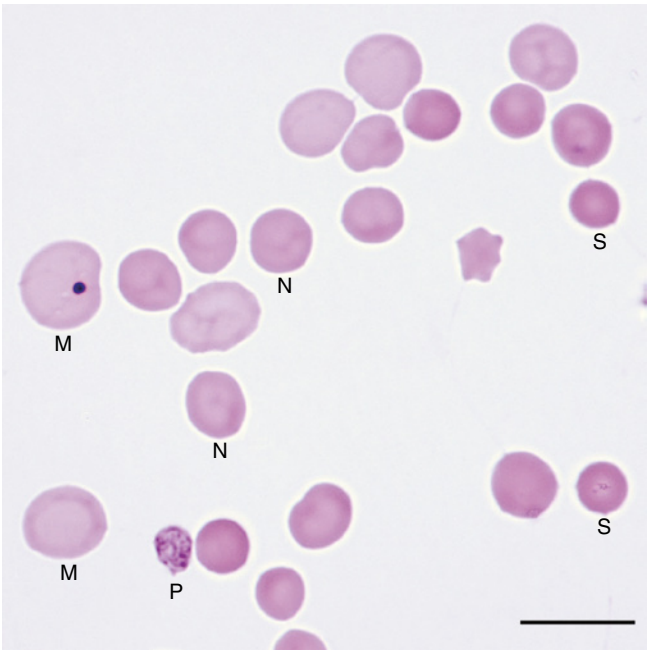

FIGURE 34.2 Blood film from a horse with acute hemolytic anemia due to EIA. The blood film contains macrocytes (M; one contains a Howell–Jolly body), two possible spherocytes (S), normocytes (N), and a platelet (P). Modified Wright stain; bar, 10 μm.

sideroleukocytes (Figure 34.2). Specific immune responses are not required for the development of anemia because foals with severe combined immune deficiency become profoundly anemic after experimental infection.[29] The pathogenesis of the progressive anemia observed in chronically infected horses is likely multifactorial with decreased RBC production, extravascular hemolysis, and anemia secondary to chronic inflammatory disease (see Chapter 39).

Because of the persistent nature of EIAV infection, detection of serum antibody to the virus confirms the diagnosis. Most infected horses are seropositive within 45 days of infection.[24] The Coggins test, an agar-gel immunodiffusion (AGID) assay which detects antibody against the virus's group-specific core protein, p26, has been the most widely used diagnostic test for EIA. Competitive ELISA (C-ELISA) are widely available and are considered more sensitive but less specific than the AGID assay. Discrepancies between AGID and C-ELISA results are most often resolved by western immunoblot assay to better characterize antibody responses against specific viral proteins.[20]

Acronyms and Abbreviations

AIHA, autoimmune hemolytic anemia; ALT alanine transaminase; ANA, antinuclear antibody; DAT, direct antiglobulin test; DIC, disseminated intravascular coagulation; HIVIG, human intravenous immunoglobulin; IL, interleukin; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; NRIMA, nonregenerative immune-mediated anemia; PIMA, precursor-targeted immune-mediated anemia; PRCA, pure red cell aplasia; PTE, pulmonary thromboembolism; SLE, systemic lupus erythematosus; Th2, type 2 T helper cells; Tregs, regulatory T cells.

Immune-mediated hemolytic anemia (IMHA) is a common cause of severe and often life-threatening anemia in dogs. IMHA can be classified as either primary (idiopathic or autoimmune) if no triggering factor is identified, or secondary if an underlying cause is suspected to have triggered the immune-mediated process (Figure 35.1). Distinction between primary and secondary IMHA is therapeutically important, because secondary IMHA may show poor treatment response and recurrence if the underlying cause is not recognized and eliminated.

PATHOGENESIS

Primary IMHA

Primary (or nonassociative) IMHA, a classical autoimmune disorder with no recognized underlying cause, is the most frequent form of IMHA in dogs. Primary IMHA is also commonly known as autoimmune hemolytic anemia (AIHA). The condition typically affects young adult and middle-aged animals (median age about 6 years), and is most common in Cocker Spaniels, English

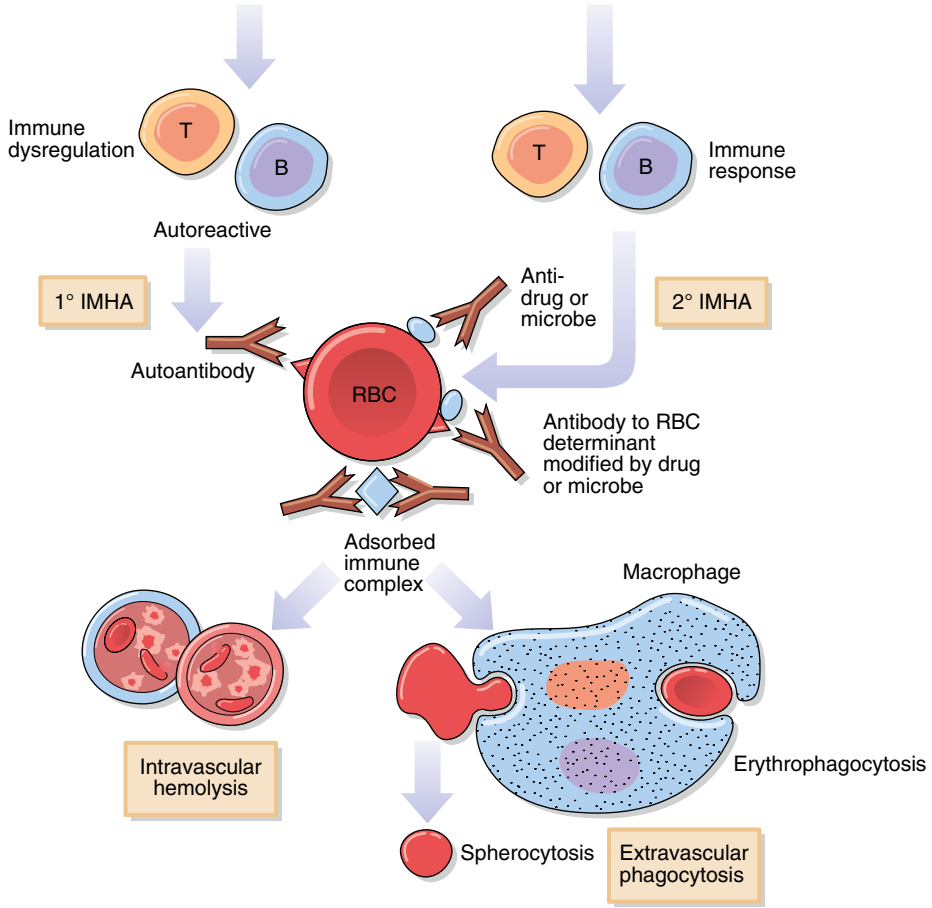

FIGURE 35.1 Pathogenesis of IMHA. IMHA may be primary (autoimmune) or secondary to an underlying triggering cause. In primary IMHA, predisposing factors interact to allow activation of self-reactive T and B cells and production of autoantibody specific for an antigen of the RBC membrane. In secondary IMHA, the erythrocyte can be an "innocent bystander" in an immune response that generates immune complexes that nonspecifically adsorb to the RBC surface, or generates antibodies that may be directed against RBC membrane components antigenically similar to non-RBC antigens associated with the underlying disease, or against membrane components modified by the underlying disease, or against an antigen such as a drug or microbe attached to the RBC membrane. The RBC may be destroyed following complement fixation and formation of the "membrane attack complex" (intravascular hemolysis), or interact with phagocytic cells that express surface Fc and complement receptors, in which case the RBC may be entirely removed by erythrophagocytosis (extravascular hemolysis), or suffer partial loss of its cell membrane to form a spherocyte.

Springer Spaniels, Poodles, Miniature Schnauzers, Maltese Terriers, Hungarian Vizslas, Airedale Terriers, and Old English Sheepdogs, although it can occur in any breed.[5,23,37,39,50,66,68] Breed predispositions and transmission through pedigrees strongly suggest that there is an inherited susceptibility to IMHA, and a strong association between several DLA-79 gene mutations and multiple immune-mediated diseases, including IMHA, has been demonstrated in dogs.[13] Both susceptibility and protective haplotypes of class II loci of the major histocompatibility complex have been identified in English Cocker Spaniel and Springer Spaniel dogs.[31] Neutered dogs (both male and female) appear to be more prone to IMHA than intact dogs of either sex.[6,50,68]

There is much interest in unraveling the complex immunopathogenesis of autoimmune diseases in order to develop novel targeted immunotherapies. Since the canine disease shares many aspects with human IMHA and experimental rodent models of the disease, investigations of spontaneously arising canine primary IMHA have been conducted. Classically, an autoantibody-mediated disease would reflect an immune system imbalance where a lack of function of natural regulatory T cells (Tregs) would permit inappropriate activation of type 2 T helper cells (Th2). This in turn activates autoreactive B lymphocytes by providing stimulatory signals allowing B-cell activation, clonal proliferation, and immunoglobulin class switch, resulting in the production of IgG or IgM erythrocyte-specific autoantibodies. However, the most detailed study of immune function in canine IMHA failed to identify a simple reduction in the proportions of Tregs or other T-cell subsets or in production of the signature cytokine associated with Treg function, interleukin (IL)-10. Instead, an elevation in pro-inflammatory cytokines (IL-2, IL-6, CXCL8, and tumor necrosis factor-α) was found in the affected dogs.[60] This finding is not unexpected and is likely to be relatively nonspecific, with

other studies reporting no difference in pro-inflammatory cytokine profiles between dogs with IMHA and dogs with bacterial sepsis.[27] It remains possible that other T cell subsets (Th1, Th17) may play a role in the immunopathogenesis of canine primary IMHA, but this has yet to be explored.

Secondary IMHA

Secondary (or associative) IMHA is suspected to develop in response to a triggering process, including various medications and a range of infectious, inflammatory, and neoplastic diseases. It can affect dogs of any age or breed, and can be suspected in patients with a signalment atypical for primary IMHA, such as in geriatric animals. In many instances, direct causation cannot be established. While the hemolytic anemia associated with canine babesiosis has been clearly shown to have an immune-mediated component, the link between other infectious agents such as *Mycoplasma haemocanis*,[67] bartonellosis, and rickettsial organisms is not as well established.[14] Neoplasia, heartworm infection, medications, and vaccinations have also been implicated in the pathogenesis of IMHA, but definitively established causation has not been shown.[14] Secondary IMHA has also been reported following bee stings and elapid snake bites.[44,45] Interestingly, a seasonal increase in incidence has been found for IMHA in dogs in some areas (e.g., spring and summer in Southern California), potentially suggesting some as yet identified environmental or infectious factor.[33,68]

Mechanism of Pathogenesis

The mechanism underlying typical cases of IMHA is antibody-mediated cytotoxic (Type II) destruction of circulating RBCs. Although most cases of IMHA share this common mechanism, the disease is otherwise highly variable among individuals. In primary IMHA, both the pattern of immunoglobulin and complement involvement in RBC destruction, as well as the site of antibody attachment to RBC membranes, vary widely between patients. Although the most common immunoglobulin type involved in canine primary IMHA is IgG, less commonly IgM may also be implicated, along with variable involvement of complement, or both IgG and IgM combined.[23] Dogs with a combination of IgG and IgM anti-RBC autoantibodies tend to have lower hematocrits, more spherocytes, and more autoagglutination.[23] Antibodies have been reported to attach to various components of the RBC membrane, particularly glycophorins and the band 3 anion transport protein, but also to a range of other proteins, including calpain, complement component 3, and peroxiredoxin 2.[62] Given the range of different immunoglobulins and antigenic targets involved, it is probably overly simplistic to think of IMHA as a single disease syndrome: rather, it is in actuality a heterogenous mix of different diseases with different presentations, prognoses, and responses to therapy.

Antibody attachment to RBC membranes triggers cell destruction by several mechanisms. Complement fixation and formation of membrane attack complexes directly damage RBC membranes. The osmotic effects of hemoglobin draw extracellular water into the cytoplasm, resulting in swelling and rupture of the RBC while still in circulation ("intravascular hemolysis") (Figure 35.2). In the absence of direct RBC lysis, antibody attachment to cell membranes can still lead to an accelerated rate of destruction of affected RBCs by tissue macrophages within the mononuclear phagocytic system, a process that occurs outside of the circulation ("extravascular hemolysis"). Mononuclear phagocytic system destruction of RBCs is mediated by Fc and complement receptors on the macrophage surface, receptors which bind the Fc component of the antibodies and/or complement attached to the RBC membranes. Since the mononuclear phagocytic system is located throughout the body, extravascular hemolysis can occur in many organs, but typically is most pronounced in the spleen and liver.

In some patients with high levels of anti-RBC antibodies, individual antibodies can bind to multiple different RBCs simultaneously, causing agglutination. Patients that exhibit significant RBC agglutination at body temperature may be susceptible to an increased

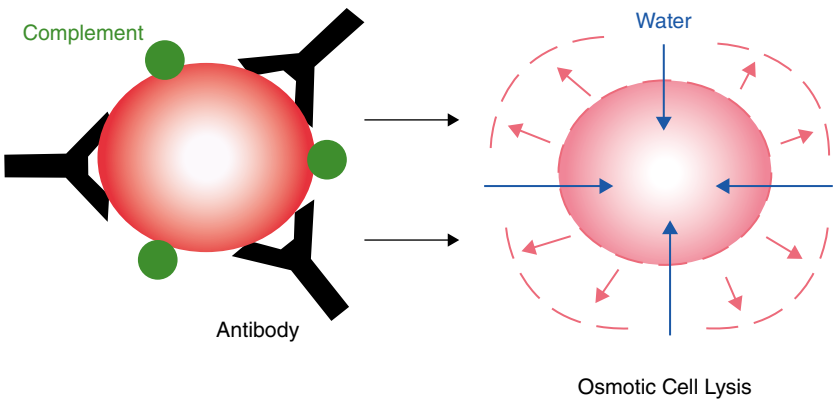

FIGURE 35.2 Intravascular hemolysis. Antibody attachment, complement fixation, and formation of membrane attack complexes directly damage RBC membranes. The osmotic effects of hemoglobin draw extracellular water into the cytoplasm, resulting in swelling and rupture of the RBC while still in circulation ("intravascular hemolysis").

rate of extravascular hemolysis, since clumping of RBC within the vasculature may slow their passage through vessels and facilitate their removal by the mononuclear phagocytic system.

Marrow Involvement

Primary IMHA is caused by antibodies directed against circulating mature RBCs, with the marrow typically mounting a healthy regenerative response to the resultant anemia. By contrast, if antibodies are directed against membrane components that are present only on marrow erythroid precursors, and not on mature RBCs, nonregenerative anemia can develop without peripheral hemolysis (see Chapter 38). This condition is termed precursor-targeted immune-mediated anemia (PIMA) or nonregenerative immune-mediated anemia (NRIMA), and dogs with PIMA/NRIMA often have hypercellular bone marrows with erythroid hyperplasia, erythroid precursor erythrophagocytosis, and maturation arrest, with or without myelofibrosis.[35,57] Some affected dogs have bone marrow changes consistent with pure red cell aplasia (PRCA), where all stages of marrow RBC precursor are reduced or absent. Both conditions can have an immune-mediated pathogenesis, with PRCA being a more severe form of disease, and the two being best differentiated by the increase in early erythroid precursors and erythrophagocytosis seen in PIMA/NRIMA, with few erythroid precursors present in PRCA. If antibodies are directed against cell membrane components that are present both on mature RBCs and their marrow precursors, the patient will present with the rapid RBC loss seen with typical IMHA, but will have an inappropriately poor regenerative response. These so-called "poorly regenerative IMHA" patients have inappropriately low reticulocyte counts in response to anemia, and are a relatively common manifestation of canine IMHA (typically, about 30% of cases, but reported to have a prevalence as high as 60% in some studies).[5,48,54,68]

Interestingly, in some dogs with IMHA, lack of regenerative responses appears to be due to a functional iron deficiency (a mechanism comparable to "anemia of chronic disease").[53] Acute phase proteins such as C-reactive protein are markedly elevated in some dogs with IMHA and, since anemia of chronic disease is thought to be a functional iron deficiency mediated by acute phase proteins (hepcidin in particular), it should perhaps not be surprising that this mechanism may affect erythropoiesis in IMHA patients.[53] Microcytosis is also seen in association with myelofibrosis, a potential characteristic of IMHA, PIMA/NRIMA, and PRCA,[69,71] and may represent altered regulation in iron homeostasis.[58]

In secondary IMHA, antibodies may be directed against the RBC membrane, but alternatively they may be directed against a foreign antigen (such as a drug or virus) that is attached to the RBC membrane, against normal RBC membrane components that are antigenically similar to non-RBC antigens associated with the underlying disease process, or against membrane components that are normally hidden but are exposed by the underlying disease.

Cold Reactive Antibodies

Typical IMHA is caused by antibodies that exert their effects at body temperature, so-called warm reactive antibodies. Some dogs, however, have anti-RBC antibodies that are only reactive at much lower temperatures. Although such cold reactive antibodies may be associated with minimal harmful effects, their presence can potentially cause specific unique clinical syndromes, and can also arguably lead to a false positive diagnosis of IMHA if agglutination testing is performed only at cold temperatures.[66] Anti-RBC antibodies that are reactive at cold temperatures can uncommonly cause agglutination within the vasculature of the extremities, particularly in colder weather, and cause some degree of intravascular hemolysis within the extremities, manifesting as transient hemoglobinemia and hemoglobinuria.[43]

CLINICAL PRESENTATION

Clinical Signs

Clinical signs typically associated with IMHA reflect the presence of both anemia (lethargy, weakness, collapse, pale mucous membranes, and a hemic heart murmur) and compensatory responses caused by tissue hypoxia and stimulation of the sympathetic nervous system (tachypnea, tachycardia, and bounding pulses).[37,48,50,59] Hemic heart murmurs are low-grade systolic murmurs thought to be associated with reduced blood viscosity, and are typically not auscultated until the hematocrit falls to below approximately 20%. Some dogs may also show clinical signs of an ongoing immunological or inflammatory process such as anorexia and, uncommonly, low-grade fever or lymphadenopathy.[37,48] Surprisingly, although the mononuclear system within the spleen and liver is usually the main site of RBC destruction, organomegaly is only variably present in animals with IMHA.[37,50]

Extravascular hemolysis with phagocytosis of antibody-coated RBCs by the mononuclear phagocytic system can overwhelm hepatic ability to process the excess bilirubin associated with the breakdown of hemoglobin within macrophages. Therefore, hyperbilirubinemia, bilirubinuria, and tissue jaundice are often seen during acute severe episodes of IMHA (Figure 35.3).[37,50] Profound hyperbilirubinuria can, rarely, cause neurological signs due to excessive bilirubin entering the brain through the blood–brain barrier ("kernicterus").[63] Since intravascular hemolysis is relatively uncommon (reported in around 5% of canine IMHA cases), hemoglobinemia and hemoglobinuria are observed infrequently.[59] Hemoglobinuria can cause a dark brown to near black urine discoloration colloquially known as "port wine" urine (Figure 35.4). Hemoglobinuria can also sometimes cause a reddish urine discoloration that mimics true hematuria.

Dogs with slowly progressing anemia due to subacute or chronic IMHA may not show significant clinical

FIGURE 35.3 Jaundice. Severe jaundice in a Schnauzer with IMHA.

FIGURE 35.4 Hemoglobinuria. Tubes containing urine samples from two consecutive days from a dog with IMHA. The bottom tube is from the first day, and demonstrates the dark discoloration typical of the hemoglobinuria seen with intravascular hemolysis. By the second day, the intravascular hemolysis had resolved, and hemoglobinuria had cleared (top tube).

signs despite the presence of severe anemia. In these patients, the extra bilirubin released by RBC breakdown occurs at a rate slow enough to allow the liver to process the bilirubin, and jaundice does not necessarily occur.[37] In those non-jaundiced patients with suspected IMHA, definitive establishment of the presence of hemolysis can be very challenging.

Secondary Complications

Thromboembolic disease may develop in a portion of dogs with IMHA, and is particularly common in those animals with acute severe anemia receiving high-dose glucocorticoid therapy, especially those with marked leukocytosis.[40] Pulmonary thromboembolism (PTE) is the most well-recognized manifestation of this complication,[6,17,37] but emboli may also effect the kidneys, spleen, heart, or lymph nodes.[6,68] Many dogs with IMHA appear to be prothrombotic, as evidenced by high levels of activated platelets, increased levels of tissue factor and phosphatidylserine positive microparticles, and a range of altered hemostatic and thromboelastographic markers suggestive of hypercoagulability.[4,12,16,17,32,54,70] Risk factors for development of these complications are reported as thrombocytopenia, hyperbilirubinemia, hypoalbuminemia, elevated serum alkaline phosphatase, a negative Coombs test, cage confinement, recumbency, and the presence of indwelling catheters.[6] Pulmonary thromboembolism should always be suspected in those anemic patients that suddenly develop severe and persistent dyspnea,[17] although other causes of dyspnea such as cardiogenic pulmonary edema or acute bacterial pneumonia should also be considered.

Disseminated intravascular coagulation (DIC) has also been reported as a complication of IMHA,[6,54] but clinically significant DIC is probably uncommon, and associated hemorrhage is rare. Concurrent immune-mediated thrombocytopenia (IMT) ("Evans syndrome") or PTE can both cause some of the laboratory abnormalities that are typically associated with DIC, such as thrombocytopenia, decreased fibrinogen and antithrombin, and increased fibrin degradation products and D-dimers,[6,12,15,17] possibly leading to an overdiagnosis of DIC in IMHA patients.[46] Transient ascites has also been reported, possibly due to acute cor pulmonale secondary to PTE, or alternatively due to either serositis or extramedullary hematopoiesis within the peritoneal cavity.[3,37]

DIAGNOSIS

Diagnostic testing performed in a patient with IMHA can serve many purposes. Determination of an appropriate treatment plan as well as prognosis can be highly reliant on knowing whether the IMHA is a primary or secondary disease process, understanding the unique disease manifestation, and recognizing associated complications. Specific diagnostics that are indicated will vary from individual to individual dog, and may include first demonstrating that IMHA is present, followed by determining the type of IMHA, identifying underlying or concurrent diseases, and recognizing when specific treatment interventions are needed.

Hematology

Hematology in patients with IMHA typically reveals a moderate to severe anemia, which is most commonly regenerative, with anisocytosis, polychromasia, spherocytosis, a high corrected reticulocyte percentage, a high absolute reticulocyte count, and, sometimes, increased numbers of nucleated RBCs.[37] In some cases, reticulocyte counts may be inappropriately low,[5,50] either because of the presence of antibodies directed against RBC precursors, due to functional iron deficiency, or

because the anemia is peracute. The bone marrow typically takes between 3 and 5 days to mount a strong regenerative response to anemia, so reticulocyte counts prior to that time will be normal or "pre-regenerative" in dogs with peracute IMHA.

White cell and neutrophil counts are often moderately to markedly increased,[37,39,40,48,50,54] probably in response to both nonspecific bone marrow stimulation and the pro-inflammatory processes associated with RBC breakdown.[34,60] Occasionally, white cell counts can be high enough to mimic myelogenous leukemia,[48] a reaction sometimes called a "leukemoid response."[40] Platelet counts are often normal, unless the animal also has IMT or platelet consumption secondary to PTE or DIC.[5,6,15,37,39,46,50,54,59] Evans syndrome may affect up to approximately 20% of dogs with IMHA,[6,59] but the frequency of Evans syndrome may be overestimated if the effects of PTE or DIC on platelet counts are not considered as an alternative diagnosis to IMT.[15,46] True Evans syndrome is most likely in those IMHA patients with marked thrombocytopenia.[15,46] IMHA may also occur concurrently with immune-mediated neutropenia and, rarely, all three cytopenias may occur in one patient.[28]

Agglutination

Examination of blood smears in dogs with IMHA may reveal microscopic autoagglutination (clumping) of RBCs. Such agglutination can also form very large rafts of tightly clumped RBCs that, when a blood or microhematocrit tube containing anticoagulated blood is closely inspected, are visible to the naked eye as multiple red speckles. Similar speckles can however be created by rouleaux formation. Rouleaux are stacked arrays of loosely adhered RBCs that have a higher tendency to form in the presence of systemic inflammatory diseases (high acute-phase proteins). Rouleaux can occur in normal dogs as well, and will disperse with saline washing. Clinicians should therefore perform a saline washing process to differentiate rouleaux from genuine autoagglutination (Figure 35.5).

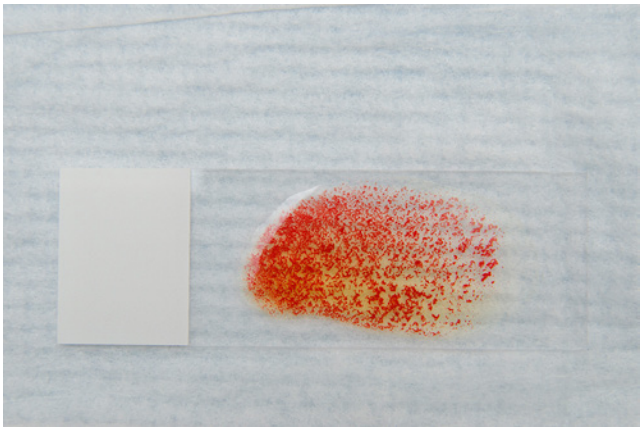

FIGURE 35.5 Saline slide agglutination. Positive saline slide agglutination, denoted by obvious red speckles against a white background, in a jaundiced dog with IMHA.

A simple in-house "slide agglutination test" can be performed by adding one drop of anticoagulated whole blood to two to four drops of saline on a microscope slide, and then swirling the slide against a white background for approximately 1 minute to observe for the persistence of gross RBC speckles (Figure 35.6). A cover slip can then be placed over the slide to facilitate microscopic examination for microagglutination. Care should be taken to perform the test using blood and saline that are warmed to at least room temperature, in order to avoid detection of cold agglutination of dubious clinical relevance. Cell washing techniques using repeated centrifugation and multiple (typically three) saline washes have been reported to decrease the diagnostic sensitivity and increase the diagnostic specificity of testing for agglutination.[7]

The presence of autoagglutination after saline washing is strongly suggestive of a diagnosis of IMHA, and also suggests that the condition is more likely to be acute and severe. An absence of autoagglutination, however, does not rule out IMHA, and negative autoagglutination has been reported in some studies to be a common result in dogs with IMHA.[23,37,54]

Autoagglutination can affect hematology results generated by automated analyzers. Small clumps of agglutinated RBCs may be recorded as a single cell, and large clumps may not even be recorded as RBCs resulting in an artifactually high mean corpuscular volume or a lowering of the calculated hematocrit. Since the hemoglobin within all RBCs is still measured by the analyzer, this leads to an erroneously high estimation of mean corpuscular hemoglobin concentration (MCHC). When agglutination is suspected to be the cause of a lower hematocrit, a manual PCV, which is not affected by RBC clumping, should be performed on well-mixed, anticoagulated blood.

Spherocytosis

Cell morphology can also be used to aid in the diagnosis of IMHA. Spherocytes are small spherical erythrocytes that, when present in large numbers, strongly suggest a diagnosis of either primary or secondary IMHA. The presence of only a small number of spherocytes, such as one to two per high-powered field, should not be overinterpreted as evidence of IMHA, especially since other hemolytic conditions can also cause spherocytosis. The absence of spherocytes does not exclude a diagnosis of IMHA, since spherocytes are only variably present in IMHA patients.[5,7,23,37,50,54,68] Spherocytes are formed when tissue macrophages remove a piece of RBC membrane without cell destruction or a significant loss of cytoplasm. The RBC volume remains normal, and RBCs are deformed into a spherical shape with a smaller diameter and loss of central pallor (Figure 35.7).

Ghost Cells

"Ghost cells" are RBCs that have ruptured in the circulation as part of intravascular hemolysis, and that have lost some or all of their hemoglobin content as

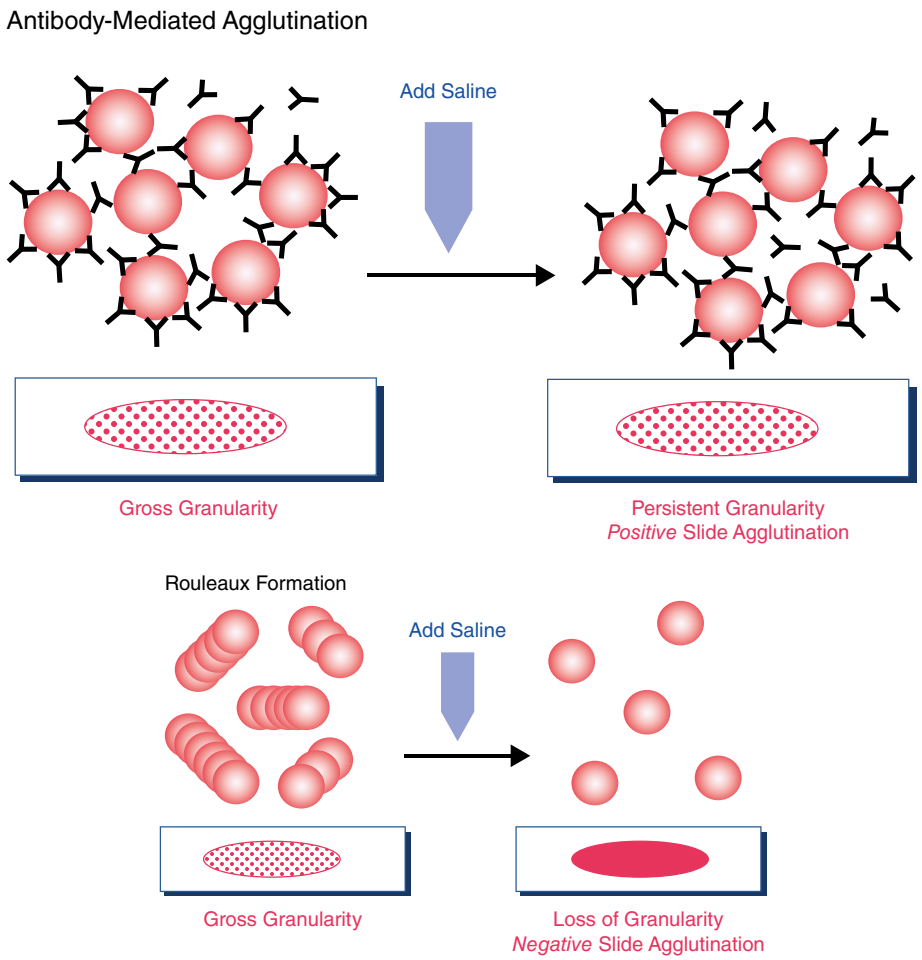

FIGURE 35.6 Saline slide agglutination test. In some dogs with IMHA, antibodies can bind to multiple different RBCs simultaneously, causing agglutination. These agglutinated RBCs are visible as red speckles. Similar speckles can be created by rouleaux, a weak nonimmune linear stacking of RBCs. A saline slide agglutination test is used to differentiate rouleaux from autoagglutination. Two to four drops of saline are added to one drop of anticoagulated (EDTA) blood on a microscope slide at room temperature, and the slide is swirled against a white background. Agglutination is seen grossly as persistent speckles despite dilution with saline (rouleaux, in contrast, disperse with saline), and microscopically as nonlinear clumps of RBCs.

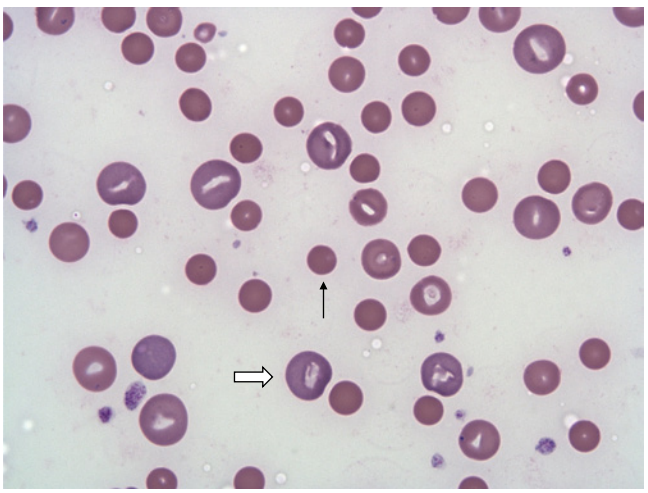

FIGURE 35.7 Blood smear. Typical blood smear from dog with IMHA, demonstrating spherocytosis (small RBCs without central pallor, denoted by black arrow), and the polychromasia and anisocytosis seen with the regenerative forms of IMHA (larger, bluer RBCs, denoted by hollow arrow).

part of this process. The residual RBC membranes linger and appear as empty erythrocytes. Ghost cells can be seen with intravascular IMHA, but also with nonimmune causes of intravascular hemolysis such as zinc toxicity. Ghost cells are only of diagnostic significance in blood smears that are made shortly after blood collection, since prolonged storage of anticoagulated blood prior to performance of blood smears can lead to a marked artefactual increase in the presence of ghost cells.

Other RBC Changes

Beyond revealing direct evidence of immune-mediated RBC lysis, careful examination of RBC morphology on blood smears may also suggest an underlying cause of either immunological or nonimmunological hemolysis. Diagnostically useful RBC abnormalities include detection of organisms such as *M. haemocanis* or *Babesia* species (which may cause secondary IMHA), Heinz bodies or eccentrocytes (suggesting hemolysis secondary to

oxidative damage), and schistocytes (suggesting a microangiopathic hemolytic process such as DIC, hemangiosarcoma, or caval syndrome).

Serum Biochemistry/Urinalysis

Serum biochemistry and urinalysis are often normal in dogs with IMHA. Potential abnormalities that may be seen in some patients include mild, moderate, or even marked elevation of liver enzymes (thought to indicate hepatic hypoxia secondary to severe anemia)[50] and variable hyperglobulinemia. Since serum protein and albumin are usually normal in IMHA patients, hypoproteinemia and hypoalbuminemia could support occult blood loss rather than hemolysis, or the presence of another illness. Mild to marked hyperbilirubinemia and bilirubinuria may be seen in dogs with acute severe hemolytic anemia,[50] but many dogs with IMHA will have normal bilirubin levels.[37,39,54]

Since the liver is usually able to cope with all but the transient overwhelming bilirubin loads produced by acute severe hemolysis, severe hyperbilirubinemia for more than 3–5 days, even in the markedly anemic animal, usually indicates the presence of concurrent hepatic disease or biliary obstruction. An exception to this may be the patient who is receiving multiple ongoing transfusions that potentially increase the hemolytic load.

Intravascular Hemolysis

Hemoglobinemia and hemoglobinuria are typically uncommon, transient events that indicate the presence of severe intravascular hemolysis.[37] Hemoglobinemia can be detected clinically in centrifuged whole blood samples as pink to red supernatant serum or plasma, and can lead to falsely elevated MCHC. While hemoglobinuria will test positive for "blood" on urine dipsticks, unlike hematuria, RBCs will not be detected on urine sediment examination in dogs with hemoglobinuria, and centrifuged urine samples will not separate into two layers of infranatant RBCs and supernatant urine.

Immunologic Testing

Specific immunological testing can be used to support a tentative diagnosis of IMHA. The most widely used test is the direct antiglobulin test (DAT) or Coombs test, which detects antibodies and/or complement bound to RBC membranes (see Chapter 143).[7,49] A standard DAT as provided by many laboratories may use a polyvalent mix of antibodies directed against IgG, IgM (to a variable extent), and complement, and is performed at body temperature. The end point of the typical DAT test is RBC agglutination (Figure 35.8). The addition of antibodies that detect and bind to IgG, IgM, or complement on the RBC membrane serves to facilitate the agglutination of RBCs in samples that would otherwise not have true autoagglutination. This process would be expected to increase test sensitivity compared to slide agglutination, albeit with a potential decrease in test specificity. Modifications of the routine screening DAT that have been shown to increase its diagnostic value include running the test at different temperatures and a wide range of titers, and using individual monovalent antibodies against IgG, IgM, and complement factor C3 as well as a standard polyvalent antibody/complement mix.[49,66] Positive DAT results at 4 °C; however, may arguably be of dubious diagnostic significance unless the patient has clinical signs consistent with cold-antibody-type agglutination or intravascular hemolysis.[66]

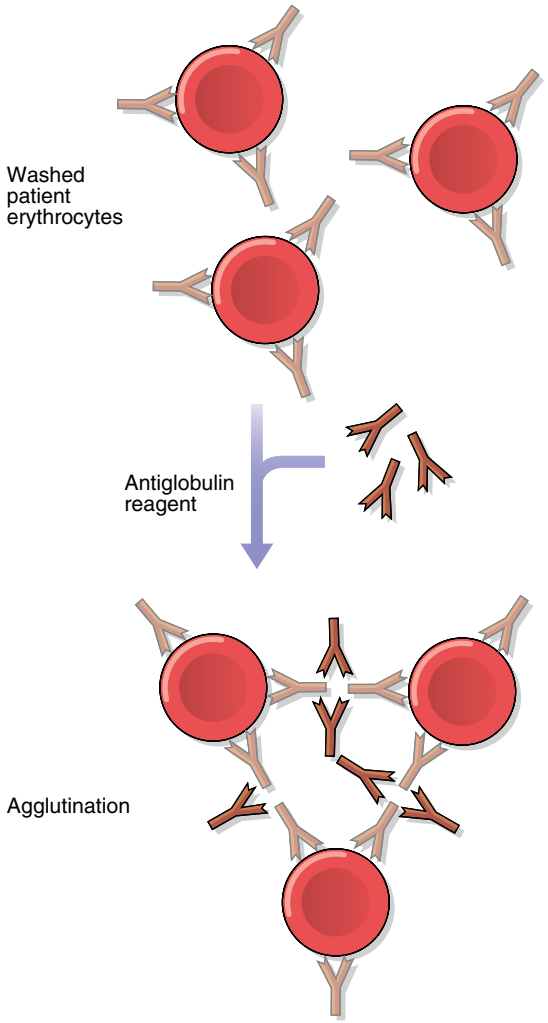

FIGURE 35.8 Principle of the Coombs test. A suspension of washed patient RBCs with membrane immunoglobulin or complement attached in vivo is incubated with an antiglobulin reagent that cross-links these immunoreactants, forming a lattice that appears grossly as an agglutinate of RBCs.

Strictly interpreted, a positive DAT result strongly supports a diagnosis of IMHA, while a negative test result suggests a nonimmunological cause of hemolysis.[7] Depending on the methodology used by the laboratory, the diagnostic accuracy of the DAT can vary from mediocre to high:[7,49] without careful attention to test methodology, false negative and false positive results can occur relatively commonly.[66] Veterinarians should therefore be aware that since IMHA can potentially occur in the presence of a negative DAT[37,50,54,59,68]

and, conversely, since a positive test does not absolutely prove the presence of IMHA, sometimes a tentative diagnosis must be made based on clinical judgement despite the presence of an apparently discrepant DAT result.

Various other immunological tests for detecting anti-RBC antibody have been reported, including an enzyme-linked immunosorbent assay, a direct enzyme-linked antiglobulin test, and flow cytometric detection of membrane-bound antibodies (see Chapter 143).[2,23] In-house rapid test kits are now also becoming available for performance of a DAT in tube-based or immunochromatographic format. Such tests provide a simple "positive/negative" result and can have value in an emergency setting or where traditional DAT testing is not available. Regardless of whether a DAT or an alternative test for anti-RBC antibody is used, clinicians should be aware that a positive result merely records the presence of antibody, and does not determine whether IMHA is primary or secondary. Interestingly, in some dogs with IMHA, Coombs tests (and other measures of anti-RBC antibody such as slide agglutination) can remain positive for many months following apparent clinical remission with immunosuppressive therapy.[7,9] Arguably, patients with persistently positive Coombs tests are at a greater risk of disease relapse if therapy is tapered too soon.

Rarely, IMHA (with or without IMT) will be merely one component of systemic lupus erythematosus (SLE), a multisystemic immunological disturbance. Measurement of serum antinuclear antibody (ANA) may therefore be indicated in those patients displaying evidence of the concurrent involvement of more than one body system, such as IMT, glomerulonephritis, polyarthritis, polymyositis, or immune-mediated skin disease. By contrast, ANA is probably not indicated (and is often negative) in those patients suspected to have uncomplicated IMHA.[54,68]

Screening for Secondary IMHA

Since IMHA can be the result of secondary causes, confirmation of a diagnosis of IMHA is only the first diagnostic step. Primary IMHA can only be diagnosed with absolute certainty once potential underlying causes have been thoroughly investigated and eliminated. This can present a diagnostic dilemma, because a complete search for these underlying causes can be expensive and, in the case of primary IMHA, ultimately fruitless. However, treatment for IMHA is unlikely to be effective if the underlying cause is not addressed. Failure to respond to therapy may indicate the need for more extensive diagnostic investigation.

Standard screening tests for underlying disease which ideally should be performed in all animals with IMHA include hematology (including careful examination of a blood smear), serum biochemistry, urinalysis, heartworm testing in endemic areas, and thoracic and abdominal radiography.[14] Blood smear examination and serologic and/or PCR testing for hemotropic organisms are also often indicated. *M. haemocanis*, an uncommon cause of significant anemia in dogs, can cause hemolysis in splenectomized dogs, immunosuppressed dogs, and dogs that have been transfused from a donor harboring the organism. Babesiosis should be considered as a potential cause of IMHA in particular breeds, geographic areas, and clinical circumstances. In North America, e.g., *Babesia canis vogeli* (also known as *Babesia vogeli*) should be considered in Greyhounds and dogs that have received transfusions from Greyhounds, *Babesia gibsoni* should be considered in Pit Bull Terriers and other fighting breeds, or dogs that have been bitten by or received transfusions from Pit Bull Terriers, and *Babesia conradae* should be considered in Californian dogs. Since arguably rickettsial diseases may also predispose to secondary IMHA, testing for rickettsial species may also be indicated in endemic areas, as may testing for bartonellosis or leishmaniosis. Further tests that might be considered in patients at risk for occult neoplasia (especially lymphoproliferative disease) include abdominal ultrasonography, lymph node aspiration cytology, and bone marrow analysis.

Marrow Analysis

Bone marrow analysis (aspiration cytology and/or core biopsy histopathology) is also typically indicated in dogs that are believed to have the nonregenerative forms of IMHA, or dogs that have suspected IMHA with concurrent neutropenia and thrombocytopenia ("pancytopenia"). Pure red cell aplasia is characterized by a relative or complete lack of RBC precursors within the marrow, whereas cytological or histopathological evidence of an erythroid "maturation arrest" (preponderance of immature precursors, with an absence of more mature RBC precursors) suggests PIMA/NRIMA. Marrow cytology and/or histopathology may also reveal macrophages phagocytosing erythrocytes or RBC precursors ("erythrophagocytosis"), plasma cell hyperplasia, and myelofibrosis.[69] In such patients, when available, techniques such as immunofluorescent or immunoperoxidase staining of marrow samples may confirm the presence of antibodies directed against RBC precursors. Underlying causes of secondary IMHA, such as lymphoid neoplasia, may also uncommonly be detected by bone marrow analysis.

Diagnostic Algorithm

Given that false positive and false negative results have been reported with practically all tests that have been associated with a diagnosis of IMHA, a diagnostic algorithm based on multiple test results has been recently suggested that categorizes the likelihood of a final diagnosis as "diagnostic," "supportive," "suspicious," or "not IMHA."[14] In an anemic dog, a definitive diagnosis is based on the presence of at least two indicators of immune-mediated destruction (such as spherocytes, a positive slide agglutination, or positive Coombs test) and at least one indicator of hemolysis (jaundice/hyperbilirubinemia/marked bilirubinuria, hemoglobinemia/hemoglobinuria, or ghost cells), in the absence of other obvious causes of anemia. A suspicious diagnosis of

IMHA is based on the presence of only one indicator of immune-mediated destruction in the absence of indicators of hemolysis, while a supportive diagnosis has more indicators of immune-mediated destruction or hemolysis, but does not meet the strict criteria required for a definitive diagnosis.[14] In pragmatic clinical terms, clinicians may also need to use an appropriate response to immunosuppressive therapy as a guide to a final diagnosis in patients that are suspected to have IMHA, but that do not meet initial criteria for a definitive diagnosis.

THERAPY

Veterinarians have been successfully treating individual dogs with IMHA for many years. Unfortunately, overall survival rates for canine IMHA patients are in general unsatisfactory, with many published studies reporting long-term survival rates of not much better than 50%.[5,6,15,18,21,25,29,39,48,50,59,68] Deaths (naturally occurring or euthanasia) occur either during initial hospitalization, or at a later date due to disease recurrence or owner intolerance of long-term medication.[68]

Since effective treatment cannot proceed without a correct diagnosis, a thorough workup is always recommended during the initial management of IMHA, with particular emphasis on detecting and potentially eliminating underlying triggers for secondary IMHA. Given a working diagnosis of primary IMHA, standard therapy during an initial crisis will typically include immunosuppressive doses of glucocorticoids with or without other immunosuppressive agents, transfusion as needed, and medications designed to prevent PTE ("thromboprophylaxis"). Even if an underlying cause for secondary IMHA has been identified and removed, immunosuppressive therapy may still be indicated during the initial treatment phase.

Glucocorticoids

Glucocorticoid therapy is a mainstay of both the emergency management and the chronic treatment of IMHA. Oral prednisolone (or prednisone) can be initiated at a starting dose of approximately 2–3 mg/kg once daily, although lower doses may be considered in large breed dogs, which seem to be particularly susceptible to steroid side effects. For larger dogs, prednisolone doses can be reduced to 1–1.5 mg/kg daily, or to 50–60 mg/m^2 daily, or "capped out" at a total dose of 50–60 mg daily. Injectable dexamethasone (0.2–0.4 mg/kg) is a reasonable alternative to oral prednisolone in dogs that cannot tolerate oral medications, though there is minimal evidence that intravenous steroid therapy hastens recovery. Commonly encountered glucocorticoid side effects include polydipsia, polyuria, polyphagia, and hyperventilation. If drug doses are not tapered over the first weeks to months of therapy, eventual signs of iatrogenic hyperadrenocorticism such as alopecia, abdominomegaly, hepatomegaly, muscle wasting, weakness and predisposition to infection, hypertension, diabetes mellitus, and pancreatitis are likely to occur. Adjunctive therapy (additional immunosuppressive agents, or splenectomy) may enable more rapid glucocorticoid dose reduction.

Immunosuppressive Agents

Immunosuppressive therapy with drugs such as azathioprine (2 mg/kg orally once daily), mycophenolate mofetil (8–12 mg/kg orally twice daily), microemulsified ("modified") cyclosporine (5–10 mg/kg orally twice daily), or leflunomide (2 mg/kg once daily) can also be commenced concurrently with prednisolone.[48,50,59,61,65,68] Some clinicians prefer to begin these drugs at the same time as prednisolone, especially in dogs with severe or immediately life-threatening IMHA. Others prefer to start therapy with prednisolone alone, and to then add in another immunosuppressive agent if prednisolone is ineffective after approximately 1–2 weeks of therapy, or if steroid side effects are unacceptable. Although azathioprine, mycophenolate, and cyclosporine are all available in injectable forms, there is minimal evidence that intravenous administration hastens recovery during crises. Cyclophosphamide, which was historically recommended in dogs with severe IMHA, has been associated with increased mortality rates, and is not recommended.[5,21,37]

Azathioprine (a purine analog antimetabolite), leflunomide (a pyrimidine synthesis inhibitor), and mycophenolate mofetil (a purine inhibitor) all target B and T lymphocytes. Azathioprine is usually well-tolerated, although hepatotoxicity, typically characterized by a rapid rise in serum alanine transaminase (ALT) that resolves with drug discontinuation, is seen in about 15% of treated dogs.[64] Azathioprine may also cause a mild nonregenerative anemia in some patients, which rarely affects the patient clinically. Other potential side effects, such as pancreatitis and severe myelosuppression, are uncommon to rare. Mycophenolate mofetil is often well-tolerated in dogs, but gastrointestinal signs, especially diarrhea, can occur commonly.[65] Gastrointestinal side effects have the potential to be severe, but are often dose-dependent. Limited literature is available on the use of leflunomide for the treatment of IMHA in dogs. The most commonly reported side effects associated with the use of leflunomide include diarrhea and lethargy, with unexplained hemorrhage and hepatopathies reported infrequently.[19,51]

Cyclosporine works by inhibiting calcineurin, which is needed for T-lymphocyte activation.[1] It is typically well-tolerated in dogs and, since it is not myelosuppressive, is likely the drug of choice for poorly regenerative forms of IMHA. Unlike azathioprine and mycophenolate, cyclosporine is approved for use in small animals (for management of atopic dermatitis and, in some countries, anal furunculosis), and therefore comes in a range of veterinary capsule and liquid formulations that allow for accurate dosing in small dogs without the need for drug compounding. Cyclosporine bioavailability varies widely between formulations, and only the

microemulsified form has sufficient bioavailability to be suitable for use in canine IMHA patients. Given that bioavailability is unpredictable, even with the microemulsified formulation, cyclosporine doses should be adjusted based on subsequent therapeutic drug monitoring (whole blood drug levels or pharmacodynamic monitoring of T-cell function). Cyclosporine can cause gastrointestinal disturbances, gingival hyperplasia, and, uncommonly, hepatotoxicity.

All canine IMHA patients receiving immunosuppressive therapy are at increased risk for bacterial infections (including cystitis, pneumonia, and pyoderma), and are also at risk for unusual and potentially severe infectious diseases such as toxoplasmosis, neosporosis, and opportunistic fungal infections. For this reason, clinicians should avoid overly aggressive immunosuppression unless patients have particularly severe forms of IMHA. The use of cyclosporine, arguably the most potent of the immunosuppressive drugs, without therapeutic drug monitoring, and the utilization of so-called "triple therapy" (a combination of a glucocorticoid and two other immunosuppressive drugs given concurrently) are particularly associated with an increased risk of infection.[10,20] Once immunosuppressive therapy is commenced, clinicians should be particularly vigilant for eruptions of underlying infectious diseases (particularly babesiosis and mycoplasmosis) that may in fact have been the underlying cause of secondary IMHA, but that were missed during the initial diagnostic investigation.

Dogs with Evans syndrome may also be treated with a single intravenous bolus of vincristine (0.02 mg/kg),[15,46] although vincristine is not indicated in dogs with IMHA alone. Vincristine is extremely corrosive if extravasated. Single vincristine doses are otherwise typically well tolerated, except in breeds that are prone to the MDR1 (ABCB1) gene mutation (such as Collies, Shetland Sheepdogs, Australian Shepherds, and Longhaired Whippets), in which the mutation should be tested for before starting the drug.

Supportive Care

Canine IMHA patients with severe anemia will be suffering from generalized tissue hypoxia, and will benefit from reducing oxygen demand by instituting strict cage rest until anemia responds to transfusion and/or drug therapy. Hemoglobin oxygen saturation is already near maximal, and supplementation with oxygen therefore is expected to be of minimal benefit, with the potential exception of patients suspected to have PTE. Since patients with IMHA have a normal blood volume, intravenous plasma or crystalloid or colloid fluid therapy is of little benefit and may contribute to volume overload.

Thromboprophylaxis

Since dogs with IMHA are prone to PTE, thromboprophylaxis is indicated during the initial treatment phase, except in those dogs with low platelet counts due to concurrent IMT.[61] Anticoagulant therapy with a heparin-based protocol is typically recommended.[4,24] Unfractionated heparin (typically administered as a starting dose at 150–200 U/kg subcutaneously four times daily, or as a constant rate infusion) can be utilized, ideally with dosing adjustments based on an inhibition of factor Xa assay when available,[4,24] or based on attaining a prolongation of partial thromboplastin times by at least 1.5 times baseline values. Alternatively, low-molecular-weight forms of heparin such as dalteparin (150 U/kg subcutaneously three times daily) or enoxaparin (0.8–1 mg/kg subcutaneously four times daily) may allow safer and more effective anticoagulation, particularly if Xa assays cannot be performed.[47] Newer human oral anticoagulants, such as rivaroxaban (0.9 mg/kg orally once daily), are also just starting to be used in IMHA dogs to prevent PTE.[42] Antiplatelet therapy, such as oral clopidogrel (1–4 mg/kg once daily) and/or low-dose aspirin (1–2 mg/kg once daily), can also be considered in addition to anticoagulant therapy, and can be safely and easily continued as part of long-term management.[41,68]

Transfusion

Cage rest and drug therapy alone can be successful in most dogs with non-life-threatening IMHA. However, initial response to therapy can sometimes be delayed (up to a week or more). Until response is seen, transfusion may be needed in dogs with life-threatening acute and marked anemia (signs of severe compromise, such as collapse, nystagmus or stupor, or a PCV of less than about 12%). Transfused RBCs often have a very short life span (days or even hours) in dogs with IMHA, and transfusions can in theory increase the rate of hemolysis ("add fuel to the fire"). Transfusions should therefore be avoided when possible in stable dogs with IMHA. However, in those IMHA patients that are severely compromised, blood transfusions are life-saving, and should not be withheld.

Since IMHA patients are typically normovolemic, and do not need additional plasma, packed red blood cells are preferable to whole blood, although whole blood may be an acceptable alternative when packed cells are not available. Cross-matches are typically difficult to interpret in dogs with autoagglutinating IMHA, and in such patients, universal or type-matched donors should be used when possible. Multiple transfusions, potentially as often as every day or two, may be needed in very severely affected dogs. Volume overload after transfusion can become a significant risk in dogs that have already recently received high volumes of blood or other fluids. In these dogs, blood transfusions should be given slowly (maximum rate of about 5 mL/kg/hour). Fresh packed red blood cells (less than 7–10 days old) are preferable to products that have been stored for a longer period,[22] and appear to be associated with a lower incidence of post-transfusion hemolysis.[36] Bovine purified polymerized hemoglobin can be considered as a means of providing several days of oxygen-carrying support for the severely anemic patient, but is not an available or financially feasible option for most cases.

Plasma transfusions are of minimal therapeutic benefit in dogs with IMHA.

Additional Therapeutic Options

Unfortunately, some dogs with severe IMHA, despite appropriate standard drug therapy and multiple transfusions, succumb to severe anemia during the first weeks of treatment. Additional treatment options which may be used in a refractory crisis include human intravenous immunoglobulin, therapeutic plasma exchange (plasmapheresis), splenectomy, and liposomal clodronate.

Human intravenous immunoglobulin (HIVIG) is a pooled preparation of immunoglobulin obtained from the plasma of multiple healthy blood donors. HIVIG as a 6–12 hour infusion at doses ranging from 0.5 to 1 g/kg variably causes rapid and sometimes sustained remission of IMHA,[30,55] although definitive proof of efficacy is lacking.[56,72] The proposed major mechanism of action of HIVIG in IMHA patients is that the infused antibodies bind to and overwhelm available macrophage Fc receptor sites, leaving no receptors left to bind antibody-coated cells.[30,55] The use of HIVIG in dogs is associated with few side effects,[56] although there is some concern that treated dogs have a higher incidence of PTE.[55] Because of the high risk of adverse immunologic reactions, previously treated dogs should not receive a second dose of HIVIG.[30,55]

Therapeutic plasma exchange can be a very effective method of rapidly removing unbound anti-RBC antibodies from the circulation,[8] and can also be used to reduce hyperbilirubinemia in dogs with kernicterus.[63] Therapeutic plasma exchange, although expensive and currently of limited availability, has been reported to reduce the severity of autoagglutination and decrease transfusion dependency in canine IMHA patients.[52]

Splenectomy is potentially a particularly effective treatment for IMHA because many different splenic elements contribute to the mechanisms reducing circulating RBC numbers: anti-RBC antibody production (plasma cells), antibody-coated RBC destruction (mononuclear phagocytic system), and RBC sequestration (splenic vasculature).[11] Splenectomy is the treatment of choice for some humans with chronic IMHA, with higher reported remission rates than medical therapy alone. Many human IMHA patients (60–80%) subsequently maintain adequate RBC counts without further medical therapy. Splenectomized patients that do require further treatment frequently demonstrate an improved response to medical therapy. Splenectomy has therefore been recommended early in the course of chronic human IMHA. Splenectomy has not been thoroughly clinically evaluated in a large group of canine IMHA patients, although case series reporting splenectomy in dogs with IMHA showed some promising results.[11,26] Early splenectomy in canine IMHA is not currently strongly recommended, because rates of remission are unpredictable and medical therapy is often better tolerated than in people. Splenectomy may be indicated in canine patients that are refractory to glucocorticoids and immunosuppressive agents, particularly if associated drug side effects are unacceptable. Life-threatening post-splenectomy complications in people (overwhelming infection, DIC) are uncommon in the dog. The most commonly reported post-splenectomy complication in dogs, erythrocyte parasitemia (mycoplasmosis or babesiosis), usually responds well to medical therapy. Persistent IMHA post-splenectomy indicates ongoing erythrocyte destruction by the non-splenic mononuclear phagocytic system.

Liposomal clodronate has marked macrophage-depleting properties, and may have potential rapid benefits comparable to effects of splenectomy.[38] When clodronate, a bisphosphonate, is incorporated into liposomes, it is then preferentially phagocytosed by cells in the mononuclear phagocytic system, causing rapid apoptosis and depletion of macrophages. Liposomal clodronate has been used with apparent therapeutic benefit in a small number of dogs with IMHA.[38] Although the drug is commercially available for experimental purposes, it is not currently available for medical use.

Follow-Up Monitoring

During initial treatment of IMHA, the hematocrit should be monitored at least daily until an appreciable response to immunosuppressive therapy is observed, and the hematocrit rises above approximately 20% in dogs. The hematocrit should then be monitored at least weekly until the anemia resolves completely. Given an adequate initial treatment response, drug therapy should be gradually tapered to acceptable maintenance doses that can be given safely long-term without significant side effects. Once well-tolerated maintenance doses of glucocorticoids and other immunosuppressive drugs are attained, therapy should arguably be continued for at least several months, with monthly monitoring of the hematocrit. Presuming that an underlying cause of IMHA has not been identified and eliminated, tapering therapy too rapidly increases the risk of a life-threatening relapse. Once anemia has been in remission for approximately 3–6 months, therapy can be cautiously withdrawn. The hematocrit should be monitored regularly over the months following cessation of therapy to enable early detection of potential relapses. Uncommonly, affected dogs may need ongoing immunosuppressive therapy for years, or even for life, to prevent severe relapse of IMHA. Exposure to potential triggers that were strongly suspected to have caused an initial episode of secondary IMHA in an individual patient, such as medications or vaccinations, should be avoided whenever possible. In general, medications and vaccinations probably do not need to be avoided in patients with a history of primary IMHA.

ACKNOWLEDGMENT

Drs. Andrew Mackin and Jillian Haines want to especially acknowledge the contributions of the late Dr. Michael Day, for his guidance in writing this chapter.

Red Blood Cell Group Incompatibilities

Acronyms and Abbreviations

ACVIM, American College of Veterinary Internal Medicine; C3, complement component 3; CAD, cold agglutinin disease; Fc, fragment crystallizable region of the immunoglobulin heavy chain; FeLV, feline leukemia virus; FIP, feline infectious peritonitis; FIV, feline immunodeficiency virus; Hct, hematocrit; IgG, immunoglobulin G; IL, interleukin; IgM, immunoglobulin M; IMHA, immune-mediated hemolytic anemia; MDS, myelodysplastic syndrome; MHC, major histocompatibility complex; PCR, polymerase chain reaction; PCV, packed cell volume; PIMA, precursor-targeted immune-mediated anemia; PRCA, pure red cell aplasia; PTU, propylthiouracil; RBC, red blood cell; Th, T helper cell; Treg, regulatory T cell.

Immune-mediated hemolytic anemia (IMHA) is an uncommon cause of anemia in cats,[29] and occurs less commonly in cats than dogs.[19] It is usually caused by the binding of antibodies to mature RBC membranes, causing their accelerated and premature removal from the circulation by mononuclear phagocytes. In some cases, the immune attack is thought to be directed against erythroid precursors in the bone marrow, resulting in a nonregenerative anemia from ineffective erythropoiesis or pure red cell aplasia (PRCA, see Chapter 38).[8,38,45] If the initiating cause of IMHA is unknown, the disease has been traditionally called primary or idiopathic IMHA or autoimmune hemolytic anemia. When IMHA is believed to have been initiated by an underlying disease (e.g., infectious agents, neoplasia) or drugs, it has been called secondary IMHA. The American College of Veterinary Internal Medicine (ACVIM) released a consensus statement on the diagnosis of IMHA in dogs and cats in 2019. In this consensus statement, it was proposed to use new nomenclature of "non-associative" and "associative," to replace primary and secondary IMHA, respectively.[19] This nomenclature appropriately reflects the possibility that all triggers may not have been definitively ruled out, and that while a comorbidity may have been identified, this does not necessarily prove causation. A retrospective study of 107 cats with IMHA showed that approximately two-thirds of cases are primary/non-associative and one-third are secondary/associative,[39] which is contrary to the older literature.[18,37] Hemolytic transfusion reactions and neonatal isoerythrolysis due to blood group incompatibilities are also variants of immune-mediated anemia, and will be addressed at the end of this chapter.

PATHOGENESIS

IMHA is a type II immune complex hypersensitivity reaction.[6] Antibodies, usually IgG or IgM, react with antigens on the RBC membrane. Once bound to RBCs, certain types of Ig classes can activate complement. Erythrocytes are then destroyed through Fc- and complement-receptor-mediated phagocytosis by macrophages primarily in the spleen, liver, and bone marrow (i.e., extravascular hemolysis), and/or through direct complement-mediated lysis (i.e., intravascular hemolysis) (Figure 36.1). In cats, hemolysis is primarily extravascular, with RBC agglutination present in many cases.[28,39] Intravascular hemolysis has only been reported in cats with immune-mediated anemia secondary to blood group incompatibilities.[13,20,26]

While the basic pathogenesis of IMHA is still not completely understood, it is generally considered to be

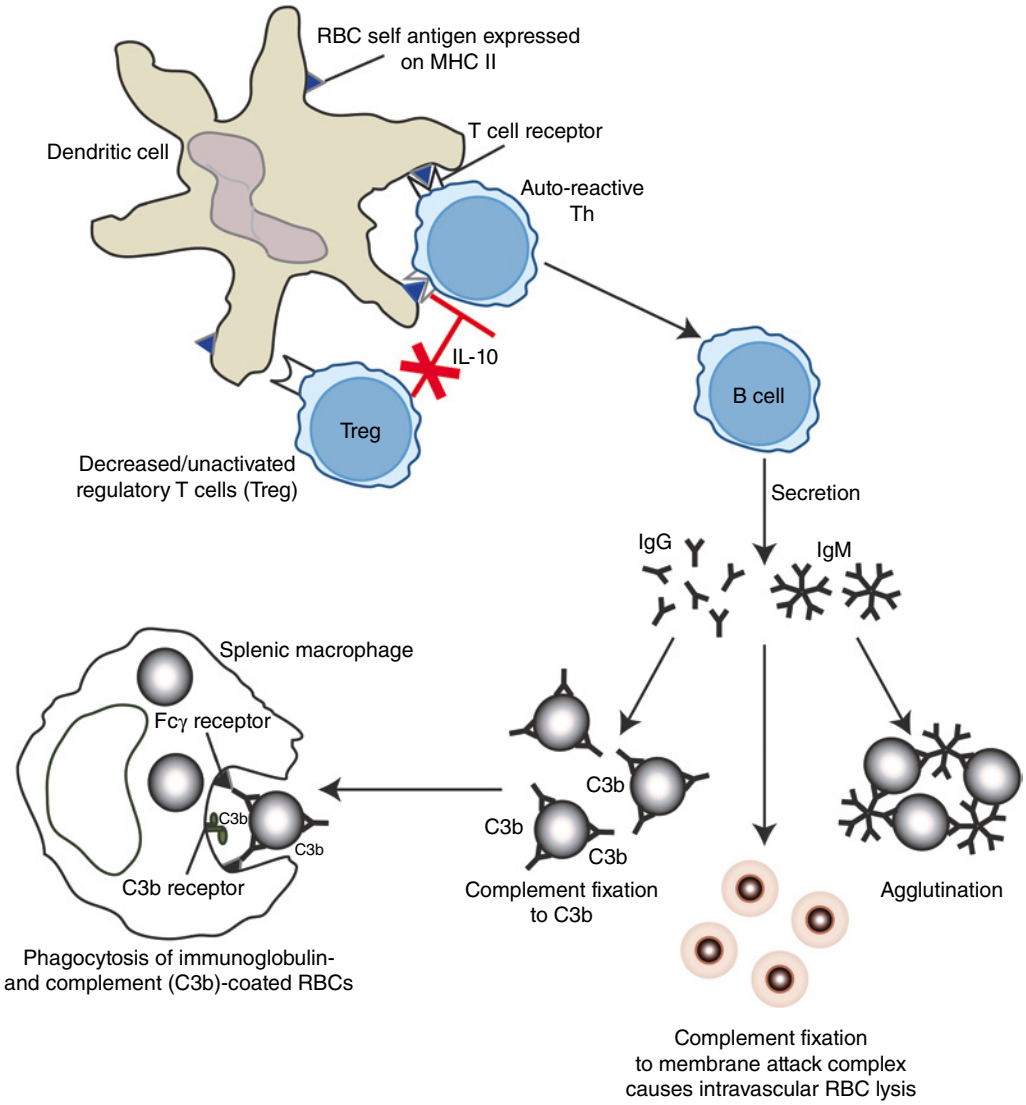

FIGURE 36.1 Proposed pathogenesis of IMHA based on studies in humans and murine models. A self-RBC antigen, which was previously cryptic or inefficiently or not processed, is expressed on the surface of dendritic or other antigen-presenting cells in conjunction with major histocompatibility type II (MHC II) proteins. The self-RBC antigen and MHC II (not shown) are recognized by autoreactive T helper cells (Th). Concurrently, regulatory T cells (Treg), which normally keep the immune system in check through secretion of anti-inflammatory cytokines, such as IL-10, are suppressed, leading to proliferation of autoreactive Th cells. Both Th1 and Th2 cells can activate B cells, which secrete immunoglobulins (IgG and/or IgM) that specifically recognize the RBC self-antigen. Complement activation by IgM or certain IgG classes leads to deposition of C3b on RBCs. Macrophages in the spleen, liver, and bone marrow recognize the Fc portion of immunoglobulin and bound C3b through specific receptors and remove the immunoglobulin- and C3b-coated RBCs prematurely from the circulation. Formation of the membrane attack complex of complement (C6-9) on RBCs causes them to lyse intravascularly. Alternative mechanisms by which Th cells can be activated are processing of a foreign peptide that cross-reacts with RBC antigens or microbial superantigens that cause hyperstimulation of the immune system. (Sources: Barcellini[6]; Barros et al.[7])

a loss or failure of self-tolerance.[6,7] Based on studies in humans and rodent models, T cell dysregulation is thought to be crucial for IMHA. Autoreactive helper T cells (Th), including pro-inflammatory T cells that secrete interleukin (IL)-17, react to RBC antigens[6,46] that were either cryptic or not efficiently processed or presented on dendritic cells.[7] These antigens can be intrinsic to the RBC ("self" antigens) or foreign proteins (e.g., drugs or infectious agents) that bind to or modify RBCs rendering them antigenic, or that express antigenic determinants that mimic those on RBCs ("molecular mimicry"). Regulatory T cells (Treg), which normally inhibit autoreactive Th cells, may be concurrently suppressed.[6,7] Specific RBC antigens responsible for IMHA in cats have not been identified and the role of Treg or Th in cats with IMHA has not been elucidated.

CLINICAL SIGNS

Clinical signs in cats with IMHA are primarily attributable to the anemia and consist mostly of lethargy and inappetence or anorexia.[8,28,37] Some cats may demonstrate vomiting, pica, weight loss, obstipation, and polydipsia.[8,28,37,49] On physical examination, cats have pale pink or rarely icteric mucous membranes, tachycardia, tachypnea, and heart murmurs and gallop rhythms.[8,28,49] Some cats have splenomegaly, hepatomegaly, or lymphadenopathy.[28,37] Cats with secondary/associative IMHA may display additional signs related to their underlying disease.

DIAGNOSIS

Current diagnostic criteria for IMHA are aimed at documenting an underlying immune-mediated pathogenesis for the anemia, which includes agglutination and a positive direct Coombs test.[19] In the absence of these findings, the diagnosis of IMHA depends on a positive response to immunosuppressive therapy.[8,38,43,48] Unlike dogs, spherocytes are not included in the diagnostic criteria for IMHA in cats.[19] This is because spherocytes are difficult to detect in cats, due to their smaller erythrocytes, which generally lack central pallor.

IMHA typically results in a moderate to severe anemia with a hematocrit (Hct) or PCV ranging from 6–22% (average, 9–13%).[28,29,37,39] The anemia may be regenerative or nonregenerative, although the latter appears to be more common. In a recent retrospective study of 107 cats with IMHA, the anemia was nonregenerative in 56% of cats with primary/non-associative IMHA, with a median absolute reticulocyte count of 32.5 × 10^3/μL. Cats with secondary/associative IMHA had a similar median absolute reticulocyte count of 38.6 × 10^3/μL.[39] In another study, 58% of 19 cats with primary/non-associative IMHA had a nonregenerative anemia.[28] Lack of regeneration may be due to duration, presence of concomitant disease, or targeting of erythroid precursors, rather than mature RBCs (Figure 36.2).

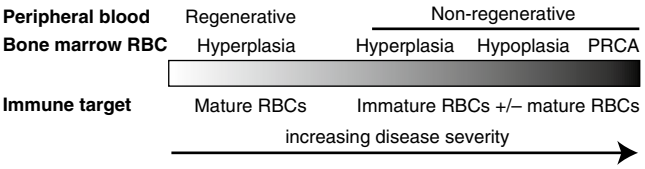

FIGURE 36.2 The IMHA continuum. The disorder can manifest anywhere on a spectrum of disease, ranging from a regenerative anemia with bone marrow erythroid hyperplasia to a nonregenerative anemia with no to few erythroid precursors in the marrow, that is, PRCA (see Chapter 38).

Agglutination

Agglutination can be detected microscopically on a Wright's-stained blood smear by the presence of three-dimensional RBC aggregates, which are often most obvious at the base of the smear. Agglutination can be differentiated from rouleaux formation with a saline agglutination or dispersion test or "in-saline agglutination test" (see Chapter 35).[19,41]

The ACVIM consensus statement recommends using warmed or room temperature saline for washing or saline agglutination tests, based on reports of persistent agglutination in normal dogs at 4 °C.[19] As for cats, one study used 4 °C for detection of persistent agglutination in cats with and without anemia (n = 60 per group).[41] None of the nonanemic cats had persistent agglutination at 4 °C in this study, but some anemic cats without IMHA agglutinated, indicating agglutination at this temperature is not specific for IMHA. It is worth noting that agglutination can occur as a consequence of EDTA-associated binding of a nonpathogenic antibody to RBCs.[36] In this report, there was no other clinical or hematologic evidence of hemolysis, emphasizing the importance of using multiple diagnostic criteria to reach a diagnosis of IMHA.

Direct Coombs Test

The direct Coombs test, also known as the direct antiglobulin test or DAT, detects antibody and complement bound to the surface of patient RBCs. This is in contrast to the indirect antiglobulin test, which detects unbound antibody in serum, and is infrequently used in veterinary medicine.[43] While flow cytometry can also be performed to detect antibody and/or complement binding in dogs, there are no reports of its use in cats at this time[19,43] (for more on the Coombs test and its methodology, see Chapters 35 and 43).

The sensitivity of the Coombs test for the diagnosis of IMHA in cats varies from 27%[39] (using >1:16 Coombs positive as a cutoff) to 82%[41] (positive result regardless of titer). With nonregenerative variants, 50% of cats in two studies had a positive Coombs test, supporting concurrent peripheral and intramedullary destruction of erythrocytes.[8,38] Specificity varies, depending on the use of cutoff titers and temperature of analysis, but ranges from 93% (77/83) in nonanemic cats[2] to 95% (89/94) in anemic or nonanemic cats[41] with polyvalent antisera at

37 °C. This indicates that positive reactions can be seen in anemic cats that do not fulfill criteria for IMHA, and that the Coombs test alone should not be relied upon for a diagnosis. Additionally, the Coombs test does not differentiate between primary/non-associative and secondary/associative IMHA.[28,41]

Other Clinical Pathologic Findings

Clinical pathologic results indicating intravascular hemolysis, including ghost cells in a freshly made blood smear, can also be used to support a diagnosis of IMHA, as long as other causes of intravascular hemolysis, such as oxidant injury, are excluded.[19] Ghost cells can be artifacts of smear preparation, therefore a diagnosis of intravascular hemolysis should not solely be based on the presence of these cells in a blood smear, without hemoglobinemia and/or hemoglobinuria as additional support. Intravascular hemolysis is usually a feature of blood group incompatibilities.[13,20,26]

Hyperbilirubinemia or icterus, in the absence of liver disease or cholestasis, including bile sludging in cats, can also be provided as support for IMHA, particularly if there is only a positive saline agglutination test or Coombs test.[19]

Bone Marrow Aspiration

A bone marrow aspirate is not indicated in a regenerative IMHA; however, it should be considered if the anemia is persistently nonregenerative. Up to 40% of cats with IMHA continue to have a nonregenerative anemia 5 days after beginning immunosuppressive therapy, indicating that duration alone is not a contributing reason for lack of regeneration in up to one-third of cats.[39] A bone marrow aspirate is recommended in such cases to determine the status of the erythropoietic response and to help identify or exclude underlying causes, such as primary or infiltrative bone marrow neoplasia and myelodysplastic syndrome (MDS, see Chapter 67). In the absence of bone marrow neoplasia or other causes that could inhibit erythropoiesis, lack of regeneration is usually attributed to targeting of erythroid precursors in the marrow, called precursor-targeted immune-mediated anemias or PIMA.[30] This precursor targeting can result in ineffective erythropoiesis, decreased production, or lack of production of RBCs (PRCA). Ineffective erythropoiesis and PRCA are reported to occur with similar frequency in cats with nonregenerative forms of IMHA.[8,45] Ineffective erythropoiesis is characterized by erythroid hyperplasia in a typically hyperplastic marrow. Erythroid maturation may be left-shifted (more immature than mature precursors) or incomplete, where maturation only appears to proceed to a specific stage. Incomplete maturation has been called "maturation arrest,"[45] a term which should be avoided, because there is no evidence that there is a true arrest in maturation. By contrast, an absence or marked decrease in erythroid precursors would be consistent with PRCA (see Chapter 38). Phagocytized erythroid precursors in marrow macrophages, known as rubriphagocytosis, provide additional cytologic support for intramedullary destruction of erythroid precursors.[30] Stainable iron within macrophages may be seen in all forms of immune-mediated anemia in cats due to increased RBC turnover or lack of erythroid production.[8,9,38,39,45] A small cell lymphocytosis in marrow is a common finding in cats with IMHA, particularly those with PIMA, and may argue for an immune-mediated pathogenesis.[8,38,39] Lymphoid hyperplasia has been described, as both distinct follicles or a diffuse infiltrate, in the bone marrow of cats with primary/non-associative and secondary/associative IMHA with higher proportions in the former (30%, 14/47) than the latter (6%, 1/18).[39] Lymphocytes constituted a median of 20% of bone marrow cells in the latter study, with higher numbers being reported in cases of PRCA (up to 45%).[38]

The main differential diagnosis for a cat with a nonregenerative anemia and ineffective erythropoiesis is MDS. In MDS, there is marked dysplasia in erythroid or other hematopoietic cells,[10] whereas only mild to moderate erythroid dysplasia is seen in cats with PIMA. Myelofibrosis is seen in just over half of MDS cases,[9] whereas it was only documented in 7% (2/28)[45] and 25% (2/8)[8] of cats, with nonregenerative IMHA in two different studies. Lastly, the presence of siderocytes or sideroblasts[10] argues for an MDS, as these are considered uncommon in cats with PIMA in the authors' experience. Ultimately, however, the distinction of PIMA from MDS may rely on response to immunosuppressive therapy.

FEATURES OF IMHA

Demographics

In a retrospective study of 107 cats with IMHA, those with primary/non-associative were significantly younger (median 4.2 years old) than cats with secondary/associative IMHA (median 6.8 years old).[39] A young age predilection (<4 years old) in primary/non-associative IMHA is further supported by other studies.[8,28,38] While some case series have shown a male predominance,[8,28,37] this is not a consistent finding.[38,39]

Hematologic and Coagulation Findings

Unlike dogs with regenerative IMHA,[15,23] inflammatory leukograms are not a common finding in cats.[28,39] In two different studies, 15% and 32% of cats with primary/non-associative IMHA had a lymphocytosis,[28,39] which consisted of B cells in one cat.[39] The lymphocytosis resolved rapidly with treatment in the latter study. Cats with primary/non-associative IMHA had higher median lymphocyte counts (median 2.4 × 10^3/μL, range 0.4–20.0 × 10^3/μL) than those with secondary/associative IMHA (1 × 10^3/μL, 0.1–17.4 × 10^3/μL).[39] While this may be due to their younger age and an epinephrine response, antigenic stimulation could also be occurring. The latter hypothesis is supported by increased lymphocytes in the bone marrow of cats with IMHA.[8,38,39]

Cats with primary/non-associative IMHA may also have other cytopenias. Thrombocytopenia is reported in 42–67% and neutropenia in 17–53% of cats with primary/non-associative IMHA, including both regenerative and nonregenerative cases.[8,28,39] Marked thrombocytopenia (<30,000/μL) has been documented in one cat with primary/non-associative IMHA,[28] and two cats with PRCA,[8] although both thrombocytopenia and neutropenia are not common features of PRCA.[8,38] These studies did not state how many cats were pancytopenic.

Coagulation data was only provided in one study of cats with primary/non-associative IMHA.[28] In this study, the prothrombin time (PT) and activated partial thromboplastin time (aPTT) were prolonged in 30% (3/10) of these cats.[28] Based on prolongation of the PT and aPTT ± thrombocytopenia, disseminated intravascular coagulation was diagnosed in one cat and suspected in two other cats, the incidence of which is lower than reported for dogs with IMHA.[15] Thrombosis is rarely definitively documented in cats, being identified ultrasonographically in hepatic or portal vessels in one of 107 cats (<1%) with IMHA.[39] By contrast, thrombosis is a known complication of IMHA in dogs.[17]

Biochemical Findings

Biochemical results largely reflect the consequences of anemia, including hypoxic liver injury (increased transaminase activity)[8,28] and excessive bilirubin production.[28] Hyperbilirubinemia (median 0.7 mg/dL, range 0.2–1.9 g/dL) was documented in 68% of cats with primary/non-associative IMHA in one study.[28] Bilirubin concentrations are lower in cats with nonregenerative versus regenerative forms of IMHA.[39] Serum albumin concentrations were significantly lower in cats with secondary/associative IMHA (mean 2.7 ± 1.1 g/dL) versus primary/non-associative IMHA (3.2 ± 0.7 g/dL).[39] This may reflect a negative acute phase response in cats with other disorders. Hyperglobulinemia (median 4.1 g/dL, range 2.8–8.6 g/dL) was documented in 53% of cats with primary/non-associative IMHA.[28] In a study that compared cats with primary/non-associative and secondary/associative IMHA, globulin concentrations were similar between the two groups.[39] Hyperglobulinemia further supports the hypothesis of antigenic stimulation in some cats with IMHA.

Treatment, Response, and Survival

The mainstay of treatment for primary/non-associative IMHA is immunosuppressive doses of glucocorticoids.[28,39] This can be used alone or in combination with other immunosuppressive agents, such as cyclosporine, mycophenolate, or chemotherapeutics such as chlorambucil or cyclophosphamide.[5,39] Before initiating immunosuppressive therapy, a thorough evaluation for underlying disease should be performed (see the next section titled "Triggers of Secondary/Associative IMHA"). Blood transfusions are frequently given to symptomatic cats (53–93% in two studies[8,28]) and multiple transfusions may be required over a short time frame. Other common adjunctive therapies include crystalloid fluids, histamine or H_2-receptor antagonists, and doxycycline or other antibiotics.[28,39]

One study provided data on the early response rate of cats with nonregenerative primary/non-associative IMHA. Within the first 5 days of treatment, a regenerative response was seen in 45% (18/40), the anemia remained nonregenerative in 40% (16/40), 8% (3/40) died or were euthanized, and 8% (3/40) of the cats did not have reticulocytes reassessed. For those cats that survived beyond 5 days, 52% (25/48) attained a Hct ≥ 25% within 1 month of discharge. Of the nonresponsive cats, 48% (11/23) died or were euthanized within 1 month.[39] These data are in line with other studies, which show that most cats have a regenerative response or a Hct or PCV ≥ 25% within 1 month of treatment.[8,28]

Relapses, as documented by a decrease in Hct or PCV, can occur while immunosuppressive therapy is being tapered or in some cases as long as 7 or 10 months after discontinuation of all medications.[8,28] Reported relapse rates are 27–31%, occurring from 56 to approximately 300 days after diagnosis, and are often a reason for euthanasia.[8,28] The survival time for cats with primary/non-associative IMHA was longer than those with secondary/associative IMHA with median survival times of 516 days versus 14 days, respectively (not including death or euthanasia during hospitalization), indicating comorbidities are a negative prognostic indicator.[39]

TRIGGERS OF SECONDARY/ ASSOCIATIVE IMHA

Evaluation for potential triggers or comorbidities in cats with IMHA should include a thorough history with attention to drug exposure and travel, and a search for infectious, inflammatory, and neoplastic disorders. In the 2019 ACVIM consensus statement, the authors critically and systematically evaluated data from published veterinary studies to determine the level of evidence for presumed triggers of IMHA. High- and intermediate-level evidence indicates the trigger likely induces IMHA, whereas low-level evidence indicates the trigger is unlikely to result in IMHA or there is insufficient information to answer this question.[19]

Infectious Agents

Any recent or recurrent infection could be a possible contributing factor to the development of IMHA.[19] There is a high level of evidence for *Mycoplasma haemofelis* (Chapter 33) inducing IMHA, hence, the frequent incorporation of empirical doxycycline therapy pending PCR results.[8,19,28,39,42,50] Genetic testing for *M. haemofelis* is recommended in all cats with IMHA.[19] Experimental studies suggest the anemia likely results from the parasite damaging RBCs and unmasking cryptic antigens.[19,50] As for other less pathogenic *Mycoplasma* species, there is negligible to low level or no evidence that *Candidatus*

Mycoplasma haemominutum and *Candidatus Mycoplasma turicensis* induce IMHA in cats, respectively.[19,42] There is low to intermediate level of evidence[19] that *Mycoplasma gatae*, a nonhemotropic mycoplasma, induces IMHA based on a case report of a cat with inflammatory joint disease and Coombs-positive anemia.[47]

There is intermediate-level of evidence that *Babesia felis* causes IMHA in cats and that adjunctive immunosuppressive therapy is not necessary in infected cats.[19] Primaquine phosphate is the treatment of choice.[4] Genetic testing is recommended for cats from endemic regions with compatible clinical signs (see Chapter 33).[19]

During the 1970s and 1980s, 43–60% of cats with IMHA were feline leukemia virus (FeLV)-positive,[18,37] whereas the prevalence of FeLV infection in IMHA cats is now much lower (approximately 3%).[21,25] Regardless, FeLV and feline immunodeficiency virus (FIV) testing are recommended in all sick cats per the American Association of Feline Practitioners.[19] Cats positive for FeLV have a higher risk of anemia (typically nonregenerative),[25] thrombocytopenia, and neutropenia.[21] While some studies document intermediate-to-high level of evidence for FeLV inducing IMHA, the consensus was that there is a low of evidence for an association overall.[19] See Chapter 60 for more information on FeLV.

There is negligible evidence that FIV, feline infectious peritonitis (FIP), *Leishmania*, or localized bacterial infections induce IMHA in cats, however, additional mechanistic studies are needed.[19,21,25,35,39]

Inflammatory Disease

Reported underlying inflammatory conditions in cats with secondary/non-associative IMHA include pancreatitis, cholangitis, glomerulonephritis, chronic interstitial nephritis, urinary tract infection, suspected pyelonephritis, and polyarthritis.[18,39,49] A significant association between pancreatitis and IMHA in cats was documented in one study of 155 sick cats, with 27% of cats (3/11) with IMHA having pancreatitis,[49] interpreted as low-to intermediate-level of evidence.[19] However, the overall prevalence of concurrent IMHA and pancreatitis was low in that study (2%).[49]

Neoplasia

In a retrospective study of 107 cats with IMHA, 15% of all cases and 46% of secondary/associative IMHA cases had underlying neoplasia.[39] While neoplasia, predominantly that of hematopoietic origin including lymphoma, MDS, acute myeloid leukemia, histiocytic sarcoma, and multiple myeloma, has a relatively high prevalence in cats with IMHA,[18,27,28,37,39] overall there is negligible to low-evidence for a cause and effect relationship.[19]

Vaccines and Drugs

There are no studies directly evaluating a link between vaccination and IMHA in cats, unlike in dogs where there is mixed evidence supporting or negating an association.[19] In one study of 19 cats diagnosed with primary/non-associative IMHA, 16% of cats were vaccinated in the 4 weeks prior to initial presentation.[28]

TABLE 36.1 Mechanisms of drug-induced secondary immune-mediated hemolytic anemia.

Hapten	Antibodies primarily recognize the drug, which is bound to RBC proteins. The RBCs are subsequently destroyed as an innocent bystander
Immune complex	Antibodies (usually IgM) primarily recognize the drug–RBC protein complex
Autoimmune	Anti-RBC or anti-erythropoietin antibodies are induced by the drug (due to probable cross-reactivity). Hemolysis can proceed in the absence of the inciting drug
Adsorption	Drugs can induce the nonspecific binding of immunoglobulins, complement components, and other proteins to RBC membranes. Although this can result in a positive Coombs test, RBC survival is usually unaffected

Sources: Cunningham and Silberstein[6]; Packman[33]

There are various proposed mechanisms of how drugs may induce IMHA (see Table 36.1).[16,33] Although any drug has the potential to cause IMHA, reports in cats are scarce.[19] There is intermediate to strong evidence that propylthiouracil (PTU), a drug used to treat hyperthyroidism, is a trigger for IMHA.[3,19,34] Carbimazole, another medication for hyperthyroidism, was implicated as the trigger in a single case report.[32] Warfarin toxicity reportedly resulted in a weak positive Coombs anemia in a single cat.[18] Aside from PTU, the prevalence of drug-induced IMHA in cats is low or potentially underreported.[19] However, as with other categories of triggers, the lack of evidence does not preclude the possibility of a drug or toxin triggering IMHA.[19]

Miscellaneous Causes

There is a report of five closely related, FeLV- and FIV-negative, 6–7-week-old British Shorthair kittens with a moderate to severe regenerative anemia and a non-neoplastic, nonpainful, multicentric lymphadenopathy.[1] IMHA was suspected based on the absence of hemorrhage, the presence of many splenic and hepatic erythrophagocytic macrophages on histologic examination, and grossly visible agglutination in one case. However, a direct Coombs test was negative in the two cats in which it was run. Additionally, immunosuppressive treatment with corticosteroids was unsuccessful in two cats.[1] Further research is needed on this rare condition.

Other immune-mediated conditions that have been associated with secondary IMHA include presumptive graft-versus-host disease in a cat after bone marrow transplantation[14] and systemic lupus erythematosus.[31] The cat in the latter report was Coombs-negative; however, a regenerative anemia with hyperbilirubinemia with a predominance of unconjugated bilirubin was present.[31]

Cold Agglutinin Disease

The term "cold agglutinin" gets its name from the finding of persistent agglutination in a Coombs test at 4 °C.[40] While typically cold reactive antibodies are thought to be nonpathogenic, given their presence in low titers in healthy animals,[2,18] there are cases in which they are pathogenic and indicative of cold agglutinin disease (CAD), a rare form of IMHA.[40]

In cats, there are rare reports of CAD, although it is possible that the condition is underreported or underrecognized.[11,22,50] Three kittens from two separate litters of Birman kittens from the same queen developed tail-tip necrosis and were diagnosed with presumptive neonatal isoerythrolysis involving cold-reactive agglutinins based on the queen and the second male cats' blood types. Coombs testing on the kittens was not performed.[11] An anemic cat with ear-tip cyanosis and histopathologic evidence of thrombosis of small superficial vessels was suspected to have CAD based on a positive saline agglutination test in refrigerated heparinized blood diluted 1:1 in saline. The clinical signs in this cat resolved after removal of a lead foreign body.[22] Cold agglutinins have also been identified with experimental *M. haemofelis* infections and were suspected to contribute to the anemia in these cats.[50] Persistent agglutination at 4 °C can be seen in healthy nonanemic cats,[2,18] and should not be interpreted as a pathologic finding without other clinical or laboratory supportive evidence.

RED BLOOD CELL GROUP INCOMPATIBILITIES

Three main blood types are present in cats: A, B, and AB.[12,24] In addition, cats may express the *Mik* antigen, the inheritance of which is unknown.[44] Immune-mediated RBC destruction through intravascular and extravascular hemolysis occurs in cats exposed to incompatible blood types through transfusions or via colostrum ingestion with neonatal isoerythrolysis.[12,13,20,26] These hemolytic reactions do not require prior sensitization because cats develop naturally occurring alloantibodies against RBC antigens by 2–3 months of age[12,20,44] (see Chapters 96 and 107 for more information).

Acronyms and Abbreviations

AGID, agar gel immunodiffusion test; AIHA, autoimmuine hemolytic anemia; CR1, complement receptor 1; CR3, complement receptor 3; cELISA, competitive enzyme-linked immunosorbent assay; EIA, equine infectious anemia; EIAV, equine infectious anemia virus; EMA, equine merozoite antigens; Fcγ receptor, fragment crystallizable gamma receptor; Hgb, hemoglobin; JFA, jaundiced foal agglutination (test); MAC, membrane attack complex; NI, neonatal isoerythrolysis; qPCR, quantitative polymerase chain reaction; RAP, apical merozoite protein rhoptry; USDA, United States Department of Agriculture.

Immune-mediated hemolytic anemia (IMHA) is an immunohematologic syndrome where destruction of RBCs is accelerated by the attachment of antibody, with or without complement, to the erythrocyte (type II hypersensitivity reaction). Horses and cattle have no breed or gender predilection for IMHA, with occurrence seen less frequently than in dogs but considered to be an important cause for anemia.[3,6,8,10,16,28,30,36,41,45] IMHA can either be primary (idiopathic) or secondary. Primary IMHA occurs when antibodies are directed against the unaltered cell surface antigens. Examples of primary IMHA are autoimmune disease, neonatal isoerythrolysis (NI), or incompatible blood transfusions. Secondary IMHA occurs when antibodies are formed against substances that antigenically alter the surface of red cell.[10,17,36] Affected horses most commonly have secondary IMHA with causes reported to include neoplasia, *Rhodococcus equi* infection in foals, *Clostridium sp*., drug administration, and infections (Table 37.1). IMHA is an infrequent cause of anemia in cattle with both primary and secondary IMHA reported (Table 37.1).

This chapter provides an overview of the major causes of immune-mediated anemia in ruminants and horses, with focus on immune-mediated hemolytic disease, neonatal isoerythrolysis, equine piroplasmosis, and equine infectious anemia (EIA).

TABLE 37.1 Causes of immune-mediated hemolytic anemia (IMHA) in equine and ruminants.

	Horses	Cattle
Primary IMHA	Incompatible blood transfusion[2,8,22,27] Neonatal isoerythrolysis [4,11,12,18,21,23,37] Autoimmune hemolytic anemia (idiopathic)[3,8,28,36,45]	Incompatible blood transfusion[2,14,22] Neonatal isoerythrolysis[19,34,37] Autoimmune hemolytic anemia (idiopathic)[6,10,14,16,30,41]
Secondary IMHA infectious	*Clostridium perfringens*[31,44] *Clostridium sp.*[1] Equine infectious anemia[26] Injection abscesses[1] Leptospirosis[7] Piroplasmosis[20,35,39,45–47] *Rhodococcus equi*[15] *Streptococcus spp.*[13]	Anaplasmosis[14] *Salmonella dublin*[17] Pneumonia[14] Trypanosomiasis[9] *Theileria*[14,30,40]
Drugs/toxins	Penicillin[24,33] Sulfonamides[37] *Pistacia*[5,42]	Foot and mouth vaccine[30] Sulfonamides[30]
Neoplasia	Lymphosarcoma,[25,32] melanoma, other neoplasia[27]	
Other systemic diseases	Protein-losing enteropathy[29] Purpura hemorrhagica[13]	Mastitis[30] Metritis[30]

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Primary IMHA resulting from an idiopathic loss of self-tolerance to RBC surface antigens is a rare condition in large animals.[2,3,28] Secondary IMHA in equine and ruminants tends to be associated with infection, exposure to drugs or toxins, or neoplasia. Drug-induced hemolytic anemia is a type II hypersensitivity reaction in which destruction of RBCs occurs by one of three mechanisms: (1) the drug and antibodies combine to active complement and destroy the bystander RBC; (2) the drug acts as a hapten, a molecule that is not inherently immunogenic but binds to a carrier protein and covalently binds to RBC; or (3) the drug modifies the RBC membrane such that antibody coats the RBC (see Chapters 12 and 15).[38] A number of equine cases of IMHA associated with penicillin as a hapten exist and trimethoprim–sulfamethoxazole as a hapten has been noted in horses and cows.[24,30]

RBC destruction secondary to infectious disease is also a type II hypersensitivity reaction. For example, lipopolysaccharide and hemagglutinin subunits of EIA bind to RBCs resulting in antibody coating and binding CE complement (see Chapter 34).[26,39]

Pathogenesis of Immune-Mediated Hemolytic Anemia

Destruction of RBCs in IMHA is due to the removal of the antibody-coated RBCs by macrophages primarily in the spleen and liver (extravascular hemolysis) or less frequently mediated by complement (intravascular hemolysis). Specifically, RBC bound with IgG is cleared from circulation via cells of the fixed mononuclear phagocytic system expressing a specific Fcγ receptor and most predominantly in the spleen. Immunoglobulin-coated RBCs can fix C3 and are cleared by macrophages with CR1 and CR3. Alternatively, some immunoglobulin bound to RBCs activates the entire complement cascade with formation of the membrane attack complex (MAC) and results in intravascular lysis of RBCs.[8,37] Autoantibodies are further classified as warm or cold reactive. Warm RBC autoantibodies react strongly at 37 °C, are associated with severe anemia, and are predominantly IgG. Cold RBC autoantibodies react strongly at 4 °C and tend to be of the IgM class.[2] A special subset of cold autoantibodies that are active at 30 °C are thought to cause a cryopathic or cold hemagglutinin disease, in which IgM agglutinates in the peripheral circulation of the extremities (distal limbs, ears, etc.) and causes ischemic necrosis and gangrene. This form of IMHA has been reported in Friesian heifers as a consequence of *Salmonella dublin* infection.[17] Cold RBC autoantibodies that react only at 10–15 °C appear to not cause pathology, as they have been demonstrated in the serum of healthy horses.

Clinical Features of Immune-Mediated Hemolytic Anemia

Primary and secondary IMHA are clinically indistinguishable. Onset of hemolytic disease is variable depending on the rate of destruction, severity of anemia, and on the underlying disease process. Common clinical signs include fever, obtundation, icterus, and hemoglobinuria. With severe profound hemolysis (PCV < 15%), clinical signs include: tachycardia, tachypnea, cold extremities, pale mucous membranes, muscle weakness, and heart murmurs. Some animals may have an apparent splenomegaly based on ultrasound and transrectal palpation findings.

Diagnosis of Immune-Mediated Hemolytic Anemia

Diagnosis of IMHA is based upon multiple clinicopathological criteria: (1) RBC morphology changes consistent

with RBC destruction; (2) anemia; (3) autoagglutination; (4) a positive direct antiglobulin result (i.e., Coombs test) in a test validated for use in the horse or ruminant; and (5) elimination of other underlying causes of anemia.

Red cell morphology changes that have been described include marked poikilocytosis and echinocytes (type III > type II). Anemia of IMHA is usually quite severe with PCVs of <20%, but is typically regenerative as erythropoiesis is not affected. Unlike blood-loss anemia, horse with hemolytic anemia may develop very low levels of reticulocytosis.

Confirmation of anti-RBC antibody is done by use of a direct antiglobulin (Coombs) test (see Chapter 143). The patient's washed RBCs are incubated with antiserum to equine IgG, IgM, and complement. Specific identification of antibody-coated RBCs can be done using flow cytometry which detects low levels of cell-bound antibody. Flow cytometry can assess the therapeutic response and can monitor reduction of RBC-bound and platelet-bound IgG, IgM, and IgA in horses.[27]

Additional hematologic changes in IMHA include leukocytosis with neutrophilia, hyperfibrinogenemia, and hyperbilirubinemia associated pigmenturia. Urinalysis may indicate hemoglobinuria.

Further evaluation should focus on the identification of the underlying disease process. Transrectal palpation, abdominocentesis, and ultrasound examination should be performed for detection of intra-abdominal abscesses and neoplasia. Auscultation, thoracic radiographs, endoscopy, and ultrasonography of the chest should be done to determine lower airway disease or presence of thoracic masses. Transtracheal wash and/or thoracocentesis may be needed. Endoscopy of the upper airways and guttural pouches is recommended to look for potential *Streptococcus sp.* and lymphadenopathy. Additional laboratory tests included serology of various infectious diseases, particularly EIA, and bacterial culture. Lymphosarcoma has been associated with IMHA in horses, dogs, and humans, but not documented in cattle.[32]

Treatment of Immune-Mediated Hemolytic Anemia

Once IHMA diagnosis is made, therapy should include discontinuation of any drugs associated with IMHA. If a primary disease process or infection is involved, antimicrobial therapy may necessitate switching of the class of antimicrobials in use. Additional therapies to treat the underlying disease process should also be instituted.

Immunosuppressive doses of corticosteroids are indicated with the purpose of stabilizing RBCs, decreasing production of antibodies, the avidity of the antibody for RBCs, and the rate of clearance of antibody-coated RBC. It is important to note that corticosteroids may be less effective for treating IMHA with intravascular hemolysis mediated by IgM and complement.[8,27] Additionally, in horses chronically infected with EIA, steroid immunosuppression may result in recrudescence of the virus.[8,26] Horses with suspected IMHA should test negative for EIA prior to initiation of therapy. Dexamethasone can be used as a dose (0.1–0.2 mg/kg IV q 24 h), or prednisolone (1–2 mg/kg IV, IM or PO q 24 h). Once the PCV stabilizes at greater than 20%, tapering of the steroid dose to 0.1–0.2 mg/kg daily can be initiated. The PCV should be monitored until it normalizes. Treatment may be necessary for several weeks. In cases that are nonresponsive to corticosteroids, azathioprine can be used (3 mg/kg PO q 24 h). Cyclophosphamide and vincristine have also been used.[30,27] Blood transfusion is indicated if anemia becomes life-threatening; however, compatible blood donors may be difficult to find, and transfusion may exacerbate the hemolytic process. Splenectomy is utilized as a treatment modality in refractory cases of IMHA in dogs, but has not been described in large animals.

Blood transfusion in cattle is difficult and not commonly used because blood groups are complex and difficult to match (see Chapters 96 and 107). However, successful blood transfusion and treatment of a year-old Holstein heifer with IMHA has been reported.[16]

Prognosis for Immune-Mediated Hemolytic Anemia

The overall prognosis for horses with IMHA is dependent upon the underlying disease process. Horses with multiple recurrences of hemolysis are at high risk for having neoplasia and should be carefully examined. Reports of IMHA in cattle are too limited to make a reliable estimation of prognosis.

NEONATAL ISOERYTHROLYSIS

Pathogenesis of Neonatal Isoerythrolysis

Neonatal isoerythrolysis is caused by maternal alloantibodies directed against specific surface blood-group antigens on the affected foal's RBCs (see Chapter 96 for more detail).

In cows, sensitization occurs with vaccination for anaplasmosis and babesiosis. These vaccines contain large quantities of RBCs obtained from infected calves and induce antibodies against the A and F blood systems. If the sensitized cow is mated to a sire with these blood groups, the calf may be at risk of developing NI.[19,30,34,37]

Clinical Features of Neonatal Isoerythrolysis

Typically, foals and calves are normal at birth with signs developing as early as 5 hours after birth, but usually at 12–48 hours of age. Signs vary from subacute to peracute depending on the degree of anemia and rate of RBC destruction. Foals may present with lethargy, weakness, tachypnea, tachycardia, pale mucous membranes, icterus, pigmenturia, and hemodynamic shock. Death may occur if hemolysis is severe. Additionally, hypoxemia and tissue hypoxia may induce neurologic disorders, metabolic acidosis, and multiple organ failure.[12] Extreme elevations of unconjugated bilirubin can lead to bilirubin encephalopathy or kernicterus in foals.[18] Fulminant hemolysis in calves can trigger fatal

disseminated intravascular coagulopathy.[41] Mule foals may develop concurrent thrombocytopenic purpura.[4,23]

Diagnosis of Neonatal Isoerythrolysis

Neonatal isoerythrolysis should be considered in a newborn foal or calf presenting with weakness and icterus in the first few days of its life. It should be considered in a multiparous mare or mare with a previous history of foals with NI, but should also be considered even in a maiden mare. It should be considered in a cow vaccinated for anaplasma or babesia.

Anemia is the primary clinicopathologic finding in neonatal foals or calves with NI, with the PCV typically <20%. A decrease in the normal 3:1 ratio of PCV to hemoglobin may be noted due to the presence of free hemoglobin (Hgb) in serum. Other clinicopathologic findings include: hemoglobinemia and hemoglobinuria due to intravascular hemolysis and hyperbilirubinemia (20–40 mg/dL). If toxic hepatopathy occurs, liver enzymes, bile acids, and blood ammonia levels may be elevated.[4,8] In a retrospective study of NI, four out of 15 foals with NI had failure of passive transfer.[4,8]

Diagnosis of NI requires demonstration of maternal alloantibody binding to foal RBCs. Lytic assays are considered more accurate as alloantibodies act more strongly as hemolysins. Agglutination tests may be hindered by rouleaux formation of equine blood. Hemolytic assays involve the mare's serum mixed with foal RBCs and complement (pooled rabbit serum). If the serum contains alloantibodies, hemolysis results in pink/red supernatant and decreased RBC mass after centrifugation.[2,8] Similar hemolytic assays with appropriate bovine reagents can be performed in calves.[10,40]

The jaundiced foal agglutination (JFA) test consists of serial dilutions of the mare's colostrum in the presence of 5% RBC suspension from the foal. Agglutination is the end point of a positive test result (agglutination at dilutions of 1:16 or greater is considered significant). The JFA test is reported to correlate well with the hemolytic test and does not require an exogenous source of complement.[11] The Coombs test can be used to demonstrate the presence of antibodies or complement bound to foal RBC, but is not specific for the diagnosis of NI.[43]

Differential diagnosis of NI in foals presenting with weakness and icterus include septicemia, hypoxia, neonatal encephalopathy, equine herpesvirus-1, and leptospirosis. Potential causes of anemia in neonates include hemothorax, rib fracture, umbilical bleeding, and external hemorrhage.

Prevention and Treatment of Neonatal Isoerythrolysis

Prevention of NI is twofold: (1) determining whether the foal is at risk, and (2) protecting the foal from exposure to alloantibody. Determination of risk requires blood typing of the mare before parturition. Mares that test negative for Aa, Qa, Ua, or Pa should be considered at risk for making alloantibodies when exposed to antigen. Stallions bred to Qa/Aa-negative mares can also be blood-typed to determine if they are Qa/Aa-positive. Alternatively, the mare's serum can be screened for the presence of anti-RBC antibodies within 30 days before parturition using a panel of blood-typed RBCs or tested against the sire's RBCs. Before the foal is allowed to nurse, either a hemolytic test or JFA test should be performed.[4,8,12] In calves, screening of serum and colostrum of vaccinated cows with a saline agglutination test has been reported to be helpful in predicting the occurrence of NI.[19]

If the mare's colostrum has been determined to contain alloantibodies and the foal is positive for the specific antigen, the foal should be muzzled and not allowed to nurse for the first 30–48 hours postpartum. The mare's udder should be stripped regularly during this time to remove all colostrum and maintain milk production. Colostrum from an alternative source should be administered to the foal.

Foals that are diagnosed with NI should be immediately prevented from further exposure. Foals with mild anemia may only require exercise restriction to prevent clinical signs of NI. Use of corticosteroids to reduce the rate of clearance of sensitized RBCs may be beneficial. Broad-spectrum antibiotics are recommended, particularly with the use of corticosteroids for the prevention of secondary sepsis. In foals with clinical signs of NI, supportive therapy with oxygen insufflation may improve oxygen saturation. Weak and recumbent foals need supplemental nutrition, intravenous fluid therapy, and nursing care.[4,12]

In cases of severe anemia, a blood transfusion is needed. In addition to clinical signs (weakness, acidosis, tachypnea), parameters indicative of blood transfusion include: a PCV of <10–15%, RBC count $<3 \times 10^6$ cells/μL, and Hgb concentration ≤5 g/dL. The choice of donor is critical as the donor RBCs must be free of the specific reactive antigen. Donor whole blood should be from an Aa/Qa-negative universal blood donor. Suitable donors should be cross-matched (donor RBCs with mare or foal serum). The optimal choice for donor is the mare, but the mare's RBCs need to be washed to remove alloantibody-containing plasma. The foal's sire is the least desirable donor, as it has the same RBC antigenic factors as the foal. If a cross-matched donor is not available, a gelding that has had no history of receiving blood or blood products can be used. In the case of mule foals, because the offending antigen is the unique donkey antigen, RBCs from any horse could potentially be used for transfusion. Transfused RBCs have a 2–4-day life span in circulation. One to four liters of whole or washed RBCs are sufficient to induce clinical improvement. Depending on the foal's bone marrow response to anemia or continued hemolysis, additional transfusions may be needed.[2,4,12]

Prognosis for Neonatal Isoerythrolysis

Prognosis for NI depends on the degree of alloantibody antigenicity. Cases with acute anemia, hypoxemia, and onset of seizures have a guarded prognosis. Foals that continue to have hemolysis after transfusion develop secondary degenerative hepatopathy or have signs of kernicterus having a grave prognosis.

EQUINE INFECTIOUS ANEMIA

EIA is an important and reportable disease of horses and can be characterized by IMHA. Horses of all ages and breeds are susceptible to infection with equine infectious anemia virus (EIAV). Despite the development of a sensitive and specific federal regulatory test (Coggins test) and institution of regulatory guidelines for infected horses, EIA is still present in the United States, with outbreaks occurring sporadically throughout the country.[26]

Pathogenesis of Equine Infectious Anemia

Equine infectious anemia is caused by a nononcogenic retrovirus of the *Lentivirus* genus that infects macrophages (see Chapter 34). Natural infection occurs from the transmission of infected blood through the interrupted feeding of hematophagous arthropods (primarily *Tabanus spp*. and *Chrysops spp*.). Upon infection, the virus multiplies in the host macrophages, incorporates into the genome, and persistently infects the host. Viral replication has been found to occur at all times even during subclinical phases at reduced rates.[26]

Clinical Features of Equine Infectious Anemia

Three clinical forms of EIAV disease have been described and include: acute, subacute to chronic, and chronic inapparent (carrier). In acute infection, the virus invades the host macrophages and undergoes massive replication. Clinical signs of acute EIA are seen within 7–30 days after exposure and manifest as fever, depression, anorexia, and mucosal petechiae. Thrombocytopenia is common during initial infection and leukopenia with lymphocytosis and monocytosis also may occur. Anemia is not seen in this stage.[8,26]

In the subacute to chronic form of EIA disease, horses infected for longer than 30 days develop signs of weight loss, edema of the limbs and ventral abdomen, cyclical fevers, anemia, and icterus. Horses also can develop ataxia, abortion, colic, liver disease, and renal disease associated with viral infection. During the subacute to chronic form of disease, the PCV, RBC count, and Hgb levels decrease with hemolysis (see Chapter 34). Horses may succumb to infection either in the acute or subacute to chronic stage of disease, but most recover. Some horses have periodic recrudescence of the virus during periods of stress or treatment with corticosteroids, but a majority of horses remain clinically inapparent carriers of EIAV. No hematological abnormalities are detected in these horses.

Diagnosis of Equine Infectious Anemia

The Coggins test is still primarily utilized to diagnose EIA. The Coggins test is an agar gel immunodiffusion (AGID) test and detects serum antibodies against the EIAV gag p26 protein. The test is sensitive and specific but may provide false-negative results during the acute stage of EIA infection. Foals that have ingested colostrum from infected dams may have a false-positive test. Repeat testing of suspected horses after 10–14 days and of suspected foals after 6 months of age (as maternal antibody levels decrease) is advocated. Three other tests have been approved by the United States Department of Agriculture (USDA). These tests provide for more rapid testing and are more sensitive than the AGID, but are less specific and should be confirmed with the AGID.[26]

Treatment and Prevention of Equine Infectious Anemia

There is no treatment for EIAV infection. Individual states and federal government require the humane destruction and/or quarantine of EIAV-infected horses. State regulatory guidelines vary, but a physical quarantine of a 200-yard distance between affected horses and noninfected horses is required.

PIROPLASMOSIS/BABESIOSIS

Equine piroplasmosis or babesiosis is an infectious disease caused by two intraerythrocytic, apicomplexan equine-specific hemoprotozoa; *Babesia caballi and Theileria* (formerly *Babesia*) *equi*. These parasites and their tick vectors are endemic to most countries with tropical, subtropical, and temperate climates. Despite North America and Canada being considered free of the disease, repeated outbreaks have occurred in the United States.[40] Recently, a new species of piroplasmosis was identified in North America known as *Theileria haneyi*; however, the exact pathogenesis and virulence are unknown at this time.[20]

Horses that recover from the disease become inapparent carriers and are potential reservoirs, thus, creating a management issue in endemic and nonendemic areas. Untreated horses are lifelong carriers of *T. equi*, however, horses can clear *B. caballi*. Virulence of piroplasmosis varies greatly depending upon geographic location and potentially genetic differences.[46] The natural vectors for *T. equi* in North America include: *Dermacentor variabilis* and *Boophilus microplus*. Vectors for *B. caballi* include: *Dermacentor nitens*, *Dermacentor albipictus*, and *Amblyomma cajennense*. Transmission from dam to fetus had been reported. An outbreak in Florida and Texas was iatrogenic caused by contaminated blood transfusions as well as tick transmission.[40,47]

Pathogenesis of Piroplasmosis

The life cycles of *B. caballi* and *T. equi* are different. *B. caballi* invades erythrocytes directly, whereas the initial developmental stage of *T. equi* occurs in leukocytes. Asexual reproduction occurs and the numbers of merozoites increase. Erythrocytes lyse, which can result in both intravascular and extravascular hemolytic anemia. The hemolytic anemia is frequently accompanied by thrombocytopenia and coagulopathies. Severe disease can result in systemic inflammatory response syndrome, hypercoagulability, and multiorgan system dysfunction and death.[47]

Clinical Signs of Piroplasmosis

Clinical signs develop in horses exposed to infected ticks within 10–30 days for *B. caballi* and 12–19 days for *T. equi*. Clinical signs in horses that are via iatrogenic means (e.g., horses that receive a blood transfusion from an infected horse or syringes and needles reused without sterilization) vary depending upon the parasite dose, immune status of the horse, as well as the route of infection.[8,47] Clinical signs seen are lethargy, fever, petechiae, edema, and hemoglobinuria. Colic, respiratory, and neurologic signs have also been noted. Horses that survive the disease usually show few or mild clinical signs, but recrudescence can occur under stressful conditions with *T. equi*.

Horses infected with *T. equi* develop antibodies against equi merozoite antigens (EMAs) within 7–10 days of infestation.[8] Horses infected with *B. caballi* have an immune response to the apical merozoite protein rhoptry (RAP)1, which is less well understood.[9] Carrier horses are immune from reinfection, but coinfection with both parasites is possible.

Diagnosis of Piroplasmosis

In the acute stages of disease, diagnosis via a blood smear is feasible. Due to a low parasite load in the chronic stages of disease, identification visually is not possible. Therefore, serologic tests are used. The diagnostic method of choice is the EMA 1 and EMA 2 cELISA. ARAP1 cELISA can also be utilized.[8,47] Immunofluorescent tests are used in conjunction with the cELISA for disease confirmation. Duplex real-time quantitative PCR is available for *T. equi*.[8]

Treatment of Piroplasmosis

Treatment of piroplasmosis during the acute phase of the disease is supportive care; intravenous fluids, nonsteroidal anti-inflammatory drugs, pain control, and blood transfusions. Carrier status is protective against active disease and reinfection; therefore, elimination of the parasite is typically not performed. In nonendemic areas due to high transmission risk to other animals, options are enrollment in an approved treatment program, lifelong quarantine, or euthanasia.

Treatment of choice for clearance of the parasite is imidocarb dipropionate (2.2–4.4 mg/kg IM once q 72 h for four doses). Premedication with n-butylscopolamine (0.3 mg/kg IV) can counteract the anticholinesterase activity of imidocarb. Injection site reactions occur commonly and increased sensitivity to side effects along with fatal reactions has been seen in donkeys and mules. Clearance of the parasite is confirmed by serial negative qPCR or serology results.

Control of Piroplasmosis

Control tactics for piroplasmosis vary greatly among the endemic and nonendemic areas, but typically involve negative serology results. Federal and state regulatory officials must be notified within the United States if a horse tests positive. Nonendemic countries that border endemic countries cannot prevent introduction of ticks completely, therefore, measures must be taken to reduce horses tick exposure. At this time, no vaccination is available to prevent infection.[8]

Acronyms and Abbreviations

AIHA, autoimmune hemolytic anemia; BFU-E, burst-forming unit-erythroid; CFU-E, colony-forming unit-erythroid; DAT, direct antiglobulin test; FeLV, feline leukemia virus; Hct, hematocrit; IMHA, immune-mediated hemolytic anemia; M:E, myeloid to erythroid; nRBC, nucleated red blood cell; PIMA, precursor-targeted immune-mediated anemia; PRCA, pure red cell aplasia; rhEPO, recombinant human erythropoietin.

Immune-mediated nonregenerative anemias are caused by a spectrum of disorders that result in persistent anemia with lack of reticulocytosis and variable bone marrow findings depending on the stage of erythroid cell that is either inhibited or targeted for destruction (Figure 38.1). When erythroid progenitors (burst-forming unit-erythroid (BFU-E), colony-forming unit-erythroid (CFU-E)) or early-stage erythroid precursors are affected (i.e., rubriblasts), the condition results in pure red cell aplasia (PRCA), which is characterized by complete or almost complete lack of erythroid precursors in the bone marrow. Targeting of erythroid precursors results in precursor-targeted immune-mediated anemia (PIMA), which is characterized by ineffective erythropoiesis; the pattern of ineffective erythropoiesis varies among early-, mid-, and late-stage PIMA (see "Diagnosis" in the following text). Targeting of both erythroid precursors and RBCs (or polychromatophils), possibly via a common surface antigen or distinct surface antigens, results in concurrent PIMA and nonregenerative immune-mediated hemolytic anemia (nonregenerative IMHA), which is characterized by evidence of peripheral RBC destruction (e.g., spherocytosis, Coombs positivity, and/or red blood cell agglutination) and bone marrow findings of ineffective erythropoiesis. By contrast, targeting of RBCs results in IMHA, which is characterized by a strong regenerative erythroid response (i.e., reticulocytosis) and effective erythropoiesis with erythroid hyperplasia. Precursor-targeted immune-mediated anemia has historically been called nonregenerative immune-mediated anemia (NRIMA, NIMA) or nonregenerative immune-mediated hemolytic anemia (NRIMHA); the latter term may be considered inappropriate given the lack of evidence of peripheral RBC destruction, and therefore lack of concurrent IMHA, in most PIMA cases, and the former term does not differentiate PIMA from PRCA or preregenerative IMHA.

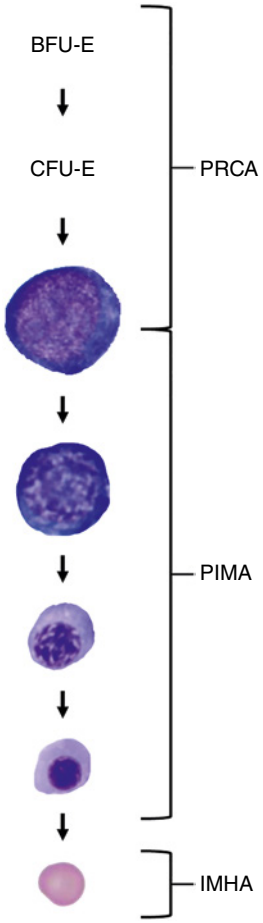

FIGURE 38.1 Schematics of the spectrum of immune-mediated anemias. Orderly erythropoiesis (left column) and resulting hematologic disorders (right column), depending on the stage of erythroid cell that is inhibited or targeted for destruction. Pure red cell aplasia and PIMA affect erythroid progenitors/early erythroid precursors and rubriblasts through metarubricytes, respectively, and are characterized by persistent nonregenerative anemias; by contrast, IMHA affects RBCs and is typically characterized by a strong regenerative erythroid response.

PRECURSOR-TARGETED IMMUNE-MEDIATED ANEMIA IN DOGS

Pathogenesis

Canine PIMA is defined by persistent nonregenerative anemia accompanied by ineffective erythropoiesis. Over the last decades, canine PIMA has been proposed to be caused by immune targeting and destruction of erythroid precursors. This mechanism has been recently demonstrated in a study that showed that a subset of mid- and late-stage PIMA dogs (five of 17 dogs) had increased surface-associated IgG on bone-marrow-derived erythroid precursors when compared to healthy dogs and to sick control dogs without PIMA.[8] In the same study, nRBC phosphatidylserine exposure was significantly higher in PIMA dogs than in healthy dogs, suggesting that apoptosis may also play a role in erythroid precursor targeting and destruction and in the pathogenesis of PIMA. The aforementioned study did not assess early-stage PIMA dogs; the definitive mechanism of the disease in this subset of dogs remains unclear but is presumed to be immune-mediated based on apparent responses to immunosuppressive therapy and relapses occurring after treatment tapering or discontinuation. Currently, canine PIMA is thought to be a primary (i.e., idiopathic) disorder.

Diagnosis

Dogs with PIMA are presented with signs of chronic anemia, and the main clinical complaint is lethargy.[2,7] Diagnosis of PIMA in dogs is based on three criteria, including (1) persistent nonregenerative anemia with duration of at least 5 days, (2) ineffective erythropoiesis, and (3) absence of dysplasia (i.e., dysplastic features in no more than rare cells of any lineage). Anemia is typically severe (Hct median 13%, range 4–28%), and the most common RBC morphologic abnormalities are macrocytosis[6] or elliptocytosis (i.e., ovalocytosis).[2] Mild microcytosis is an uncommon to rare finding.[2] Findings associated with IMHA (i.e., RBC agglutination, spherocytosis, ghost cells) are uncommon to rare in most PIMA dogs, and the vast majority of tested dogs are negative for the Coombs test.[2,7] Rubriphagocytosis (i.e., phagocytosis of intact erythroid precursors by macrophages) is present in most PIMA cases (92% of 66 cases) but is not specific of PIMA. Rubriphagocytosis in PIMA is usually relatively stage-selective (see "morphologic appearance of ineffective erythropoiesis" in the following text).[2]

Some dogs with PIMA have a history of other immune-mediated cytopenias (i.e., immune-mediated thrombocytopenia, immune-mediated neutropenia, or IMHA) or are presented with these cytopenias at the time of PIMA diagnosis or after resolving from PIMA. This supports the concept of multiple[12,14] or shifting [11,13,16,22,23] targets in immune-mediated diseases and hematologic disorders due to dysregulation of the immune system.

The morphologic appearance of ineffective erythropoiesis and bone marrow findings vary with the stage of erythroid precursor being targeted, but typically, ineffective erythropoiesis is characterized by expanded erythropoiesis up to the targeted nRBC stage.[2,6] In early-stage PIMA there is increased M:E ratio, erythroid hypocellularity, and maturation arrest/left shift at the stage of rubriblasts or prorubricytes, cells that may be found within macrophages. Other changes such as myeloid and megakaryocytic hyperplasia may also be present, and mild lymphocytosis or plasmacytosis may be seen in early-stage PIMA. Mid-stage PIMA is typically characterized by an M:E ratio within limits of health, erythroid normocellularity or hypercellularity, and an erythroid maturation arrest/left shift at the rubricyte stage with decreased metarubricytes; rubriphagocytosis of prorubricytes and early/mid-rubricytes is typically present. Late-stage PIMA is most common and characterized by a decreased M:E ratio, erythroid hyperplasia, and erythroid maturation arrest/left shift with decreased metarubricytes and/or polychromatophils; rubriphagocytosis of mid/late-rubricytes and metarubricytes is usually present.

Mild to marked collagen myelofibrosis, as evidenced by H&E and/or trichrome staining of bone marrow cores, is common in PIMA, affecting approximately 50% of PIMA dogs.[2] The cause of myelofibrosis in PIMA is unclear, but may be associated with a chronic inflammatory stimulus.[24,30]

In one study the constellation of moderate-severe nonregenerative anemia, anisocytosis, macrocytosis, and ovalocytosis was predictive of myelofibrosis in dogs, most of which had a diagnosis of PIMA.[6]

Due to collagen myelofibrosis in many PIMA dogs, poorly cellular or marginally adequate bone marrow aspirate samples (or "dry taps") may be a common occurrence, as has been described in a study of dogs with nonregenerative immune-mediated anemia.[20] In these cases, the diagnosis of PIMA relies on observation of left-shifted or arrested erythroid maturation with or without rubriphagocytosis on marginally adequate bone marrow aspirate samples and on the presence of myelofibrosis and ineffective erythropoiesis with expanded erythroid islands in bone marrow core specimens.

Differentials for PIMA include other conditions that can cause ineffective erythropoiesis and persistent nonregenerative anemia, such as phenobarbital-induced cytopenias.[17] Additional differentials include nutrient deficiency (e.g., iron or cobalamin) and familial dyserythropoiesis in English Springer Spaniels; these conditions are uncommon or display characteristic RBC morphologic abnormalities not typically seen in PIMA (e.g., microcytic hypochromic anemia in iron deficiency anemia, multilineage dysplastic changes in cobalamin deficiency). Primary myelodysplastic syndrome can also cause ineffective erythropoiesis and nonregenerative anemia, but dysplastic features should be prominent, while they are minimal or absent in PIMA.

The main differential diagnosis for early-stage PIMA is PRCA, since both can display marked erythroid hypocellularity. However, there is an absence or marked decrease in all erythroid precursor stages in PRCA, whereas early erythroid precursors may be prominent in early-stage PIMA, and early-stage rubriphagocytosis is typically present. These features are best seen cytologically, but expanded rubriblast islands may be seen in bone marrow core samples of early-stage PIMA dogs.

Treatment and Outcome

Glucocorticoids are the drug of choice for treatment of canine PIMA, including prednisone, prednisolone, or dexamethasone, the latter often being used during hospitalization. In one study, all PIMA dogs received prednisone at the median dosage of 2 mg/kg/d (range, 0.7–3.7 mg/kg/d), and 37 of 66 dogs received additional immune-modulating therapy in association with prednisone, including azathioprine (median dosage, 2 mg/kg/d; range, 1.3–2.6 mg/kg/d) and/or cyclosporine (median dosage, 8.4 mg/kg/q12h; range, 6.7–20.8 mg/kg/q12h).[2] Mycophenolate mofetil was used alone or in association with prednisone in a few PIMA cases, at the median dosage of 36 mg/kg/q12h (range, 25.9–46.1 mg/kg/q12h).[2] Cyclophosphamide has also been used in addition to steroids at the dosage of 0.5–2 mg/kg/d for 4 consecutive days a week.[18] Most dogs receive one or multiple blood transfusions during hospitalization.[2,20]

Most dogs respond to immunosuppressive treatment with some degree of reticulocytosis or improvement in Hct (i.e., 29 of 40[20] and 55 of 66 dogs, respectively).[2] Most dogs also achieve remission with a stable Hct ≥ 35% (i.e., 40 of 66 dogs)[2] or complete response with a Hct within or just below the reference interval (i.e., 22 of 40 dogs).[20] In one study, the median times for response and remission were approximately 1 month and 2 months, respectively.[2] Approximately 20% of dogs that achieved remission had a relapse at a median of 302 days after initial diagnosis of PIMA; in the dogs for which follow-up information was available, relapse was documented during weaning from immunosuppressive therapy or after therapy had been discontinued.[2]

Presence of collagen myelofibrosis was not significantly associated with time for regenerative response or median survival time; however, the median survival time for dogs without myelofibrosis (1429 days) was greater than two times that of dogs with collagen myelofibrosis (578 days).[2] One study reports two dogs with myelofibrosis that achieved complete response to treatment and suggests that myelofibrosis does not indicate a poor clinical outcome. This latter study reports resolution of myelofibrosis, as determined by serial bone marrow core biopsy specimens after treatment and resolution of anemia, but it is unclear if these dogs had reticulin or collagen myelofibrosis.[20]

Complications in management of dogs with PIMA include potential transfusion reactions from multiple blood transfusions, side effects of long-term treatment with immunosuppressive therapy (e.g., systemic infections, gastrointestinal bleeding, iatrogenic hyperadrenocorticism), and thromboembolism. Thromboembolism was diagnosed in two of 41 dogs with PIMA in one study (one before and one after treatment).[20] In a different study, nine of 66 and five of 66 PIMA dogs had confirmed or suspected thromboembolism, respectively, and thromboembolism was significantly associated with shorter survival time (54 days in dogs with a thromboembolic event vs. 1365 days in dogs without a thromboembolic event).[2] In the latter study, most dogs (29 of 66 dogs) received antithrombotic drugs at the time of PIMA diagnosis, including two of the nine dogs with confirmed thromboembolism. Antithrombotic therapy included unfractionated heparin, aspirin, and/or clopidogrel; heparin being used during hospitalization. The mechanism of thromboembolism and the optimal antithrombotic treatment in canine PIMA are unknown.

PRECURSOR-TARGETED IMMUNE-MEDIATED ANEMIA IN CATS

Pathogenesis

Precursor-targeted immune-mediated anemia seems to be less common in cats than in dogs, and there are few to rare studies describing this condition distinct from IMHA. The pathogenesis of feline PIMA is unclear, but

an immune-mediated mechanism is presumed based on favorable hematologic responses to immunosuppressive therapy. Its relationship with feline leukemia virus (FeLV) infections is unknown.

Diagnosis

Cats present with severe nonregenerative anemia, and anemia is normocytic normochromic.[3] Lack of response to anemia is determined by aggregate reticulocyte concentration below or within the reference interval. Abnormalities of platelet and WBC concentrations are not expected unless there is a comorbidity. The Coombs test is expected to be negative, but occasional animals may have a positive result.[3] Erythrophagocytosis was reported in the bone marrow of three cats with PIMA, but it is unclear if that involved phagocytosis of RBCs or erythroid precursors (i.e., rubriphagocytosis).[3] Bone marrow lymphocytosis or mild myelofibrosis may be seen in some cats.[3]

Treatment and Outcome

Glucocorticoids have been used to treat cats with PIMA, including oral prednisolone (median 3 mg/kg/d, range 2–4 mg/kg/d), oral methylprednisolone (2 mg/kg/d), and intravenous dexamethasone (0.6 mg/kg).[3] Adjuvant therapy has been used initially in addition to glucocorticoids or following a lack of response to glucocorticoids alone: cyclosporine (10 mg/kg/d) or chlorambucil (2 mg every other day). In one study, most cats achieved remission (defined as Hct > 25% with no clinical signs) in approximately 1 month, including all (2) cats with myelofibrosis.[3] In this study, relapses were common when tapering treatment, but anemia resolved with increasing dosages of glucocorticoids.

PURE RED CELL APLASIA IN DOGS

Pathogenesis

Pure red cell aplasia is an uncommon disorder and causes severe chronic nonregenerative anemia and clinical signs similar to PIMA. Most reported cases of PRCA in dogs are acquired and likely primary.[20,26] Secondary PRCA in dogs has been associated with recombinant human erythropoietin (rhEPO) treatment.[5,18] The mechanism of immune-mediated (primary or secondary) PRCA in people is unclear and is thought to involve (1) production of antibodies against membrane proteins expressed by erythroid progenitors or precursors, (2) cytotoxic T-cell-mediated destruction of erythroid progenitors or precursors, and/or (3) production of molecules (e.g., inhibitory or apoptotic cytokines) by cytotoxic T cells that affect the erythroid lineage and suppress erythropoiesis, among other mechanisms.[9,10,15]

A study investigating the mechanism of primary PRCA in dogs demonstrated that the IgG fraction of serum from a subset of dogs with PRCA inhibited formation of colony-forming units in vitro.[27] Results of the aforementioned study and response to immunosuppressive therapy in most cases[20,26] suggest that primary PRCA in dogs is immune-mediated.

Diagnosis

The main hematologic findings in PRCA are severe nonregenerative anemia with normocytic normochromic RBCs. Evidence of IMHA (i.e., Coombs positivity, spherocytosis, RBC agglutination) is not expected, unless in rare cases when there is concurrent targeting of erythroid progenitors or early-stage erythroid precursors and RBCs.

The bone marrow is characterized by complete lack of or presence of only rare erythroid precursors (i.e., marked erythroid hypoplasia or aplasia)[20,26] and lack of dysplasia in any cell lineage. The granulocytic and megakaryocytic lineages are unaffected, which differentiates this condition from aplastic anemia. Reporting a specific numeric M:E ratio in cases of PRCA may be inappropriate and inaccurate, since the very low numbers of nRBCs and their potentially uneven distribution on the glass slides would require several thousands of hematopoietic cells to be counted in order to achieve an accurate number. Therefore, the symbol > is usually used to convey an approximate estimate (e.g., M:E >99:1).

Bone marrow findings of PRCA and early-stage PIMA may be similar, but focally expanded erythroid islands composed of early-stage erythroid precursors is not expected in marrow cores of PRCA dogs. Also, in PRCA, all stages of erythroid precursors are expected to be decreased or absent.

Treatment and Outcome

The treatment for PRCA in dogs involves immunosuppression and is similar to that described in the earlier text for canine PIMA.[20,26] Combination of corticosteroids and adjuvant immunosuppressive or immunomodulatory drugs, such as azathioprine or cyclophosphamide, may be needed in some cases. One or more blood transfusions may be needed, depending on the time it takes for response to treatment to occur. It is unknown if outcomes differ between early-stage PIMA and PRCA.

PURE RED CELL APLASIA IN CATS

Pathogenesis

Pure red cell aplasia in cats, similarly to people and dogs, can be primary or secondary. The pathogenesis of primary PRCA in cats remains unclear, but an immune-mediated nature is presumed based on responses to immunosuppressive therapy.[19] Pure red cell aplasia secondary to treatment with rhEPO in cats is likely caused by the production of anti-rhEPO antibodies that may cross-react with native EPO.[5] Feline PRCA secondary to FeLV is caused by the virus subtype C (FeLV-C), which impairs differentiation of BFU-E into CFU-E and more mature stages of erythroid precursors.[1]

Diagnosis

Cats with PRCA have severe nonregenerative anemia (range 5–15%), which is normocytic and normochromic or hypochromic.[19,28,31] Cats with PRCA range from 6 months to 3 years old, with most cats being younger than 2 years old.[19,28,31] Clinical signs are often similar to PRCA in dogs and include lethargy, weakness, and pallor.[19,28,31] Abnormalities in white blood cell and platelet concentrations are not expected unless there is a concurrent disorder. The Coombs test is expected to be negative, but occasional positive results have been reported.[19] Bone marrow samples lack or contain only rare erythroid precursors, and the granulocytic and megakaryocytic lineages are expected to display no abnormalities,[19] although concurrent megakaryocytic aplasia has been reported in one case.[31] No dysplasia is seen in any cell lineage. Bone marrow lymphocytosis, represented by small lymphocytes, is not an uncommon finding.[19,28,31] In one study, these lymphocytes were typically arranged in small lymphoid aggregates as seen by examination of bone marrow cores, and in the two tested cats most were polyclonal B cells.[28]

Infections with FeLV-C are uncommon, and feline PRCA secondary to FeLV appears to be much less common than primary PRCA. Testing for FeLV is indicated in the workup of feline PRCA; however, FeLV positivity does not definitively rule out primary PRCA. Diagnostic sensitivity of PCR-based assays for FeLV is higher than ELISA-based assays,[29] so the former method is indicated to properly assess FeLV status in cats. Blood or bone marrow samples may be used for PCR testing, but positive results have been reported when using bone marrow but not blood samples in a few cats with latent FeLV infections and chronic nonregenerative anemias.[21] Some older studies report negative FeLV status in cats with PRCA based on serologic or ELISA testing only; it is possible that some of these cats were infected by FeLV, and the ELISA test yielded a false-negative result.

Treatment and Outcome

Cats with PRCA have been treated with corticosteroids in combination with or without other immunosuppressive or immunomodulatory drugs. In one study, most cats were treated with prednisolone at the dosage of 3.5–5.5 mg/kg/d and cyclophosphamide at the dosage of 2.5 mg/kg/d for 4 days, repeated every 3 days. Most cats responded with an increase in Hct or aggregate reticulocyte concentration within 1.5–4 weeks of treatment and had a Hct within the reference interval within 3–5 weeks.[17] Cyclosporine has also been used with success as an adjunctive drug to glucocorticoids in 10 cats with marked erythroid hypoplasia or PRCA.[25] A different study reports successful treatments in cats with PRCA using a combination of prednisone at the dosage of 4–8 mg/kg/d and chlorambucil at the dosage of 20 mg/m^2 every 2 weeks.[4] Similarly to PIMA and PRCA in dogs, many cats with PRCA require treatment with immunosuppressive drugs for months to years and some relapse after treatment is discontinued.[19,31] Most cats respond to a second course of immunosuppressive treatment.[17] Cats with PRCA often need one or multiple blood transfusions after diagnosis.[17,29]

CHAPTER 39

Anemia of Inflammatory, Neoplastic, Renal, and Endocrine Diseases

AGATA K. GRZELAK and MICHAEL M. FRY

Inflammation
Neoplasia
Renal Disease
Endocrine Disease

Acronyms and Abbreviations

AI, anemia of inflammation; CKD, chronic kidney disease; DIC, disseminated intravascular coagulopathy; DM, diabetes mellitus; EPO, erythropoietin; IDA, iron deficiency anemia; IMHA, immune-mediated hemolytic anemia.

Many pathologic conditions may cause secondary anemia. This chapter focuses on inflammation, neoplasia, renal disease, and endocrine disease as causes of anemia. These categories are not mutually exclusive—e.g., cancer and chronic kidney disease (CKD) often have an inflammatory component.[27,42,46] Much information is based on studies in people or in rodent research models; however, in general, the pathophysiologic principles are not species-specific. Anemia in individuals with these conditions is usually, but not necessarily, nonregenerative.

INFLAMMATION

For many years physicians and veterinarians have recognized that patients with infectious or inflammatory disease frequently develop anemia, and that this phenomenon is associated with altered iron homeostasis.[13,68] The condition is now known as anemia of inflammation (AI) and occasionally still referred to as anemia of chronic disease. Noninfectious conditions linked to AI include neoplasia, CKD, autoimmune disease, congestive heart failure, chronic pulmonary disease, and obesity.[68] Ultimately, any condition leading to prolonged immune activation can result in anemia. Affected individuals have low serum iron concentrations, but increased iron stores in the mononuclear phagocyte system—seemingly paradoxical findings that are consistent with iron-restricted erythropoiesis caused by iron sequestration. In contrast to patients with classical iron deficiency anemia (IDA), which can be regenerative or nonregenerative, and in advanced cases is microcytic and hypochromic (see Chapter 27), patients with AI typically have normocytic, normochromic, nonregenerative anemia. This pattern is recognized in domestic animals in both research and clinical contexts,[13,64,67] but exceptions can occur. A study that included both AI (n = 12) and IDA (n = 11) groups found microcytosis or hypochromasia in some dogs with AI (those abnormalities tended to be less severe than in dogs with IDA), but no reticulocytosis in dogs with AI.[61] Because a highly specific test is lacking, diagnosis of AI typically involves laboratory data, clinical findings, and exclusion of other causes of anemia.

A proposed evolutionary rationale for AI is that it results from an adaptation to limit microbial access to iron.[19] To this day, studies continue to unravel new molecular mechanisms involved in the development of AI. Many of the insights involve hepcidin, a hormone now generally accepted as the key mediator of AI (see Chapters 20 and 27).[68] Initially referred to as liver-expressed antimicrobial peptide (LEAP-1), hepcidin was subsequently identified as a type II acute phase protein and a key regulator of iron availability.[35,53] It is synthesized mainly by hepatocytes—hence the name hepcidin, intimating both its tissue of origin and its

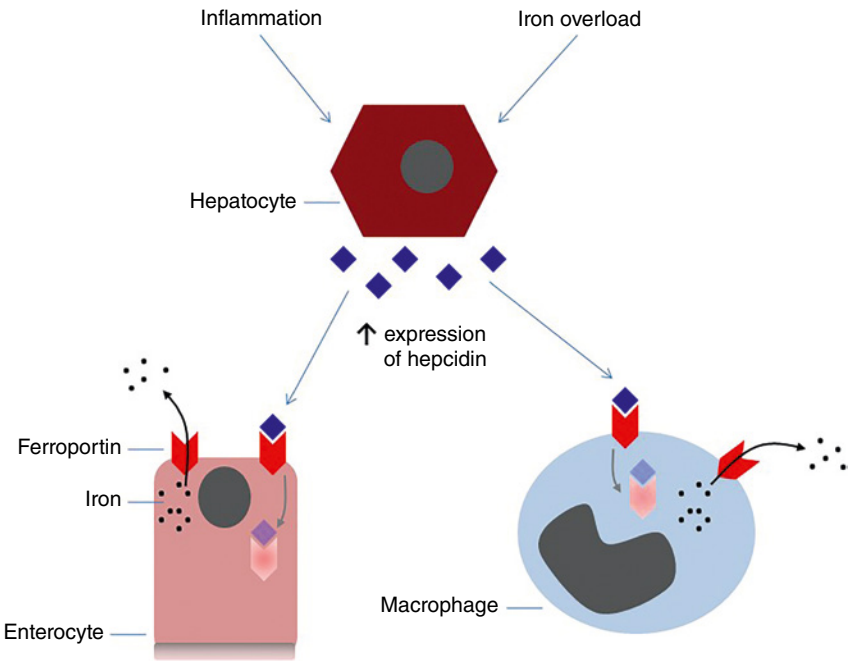

FIGURE 39.1 Hepcidin expression is increased by inflammation and iron overload. Hepcidin binds to ferroportin and causes its internalization and degradation, thus inhibiting efflux of iron into the plasma.

direct antimicrobial effects.[56] The bioactive form is a 25-amino acid peptide that exerts its effects by binding to the cell surface iron efflux protein, ferroportin, and inducing its internalization and degradation.[52] The effect of this interaction is to inhibit both absorption of dietary iron from intestinal epithelium and export of iron from macrophages and hepatocytes.[52]

Hepcidin expression increases in response to acute inflammation or iron overload (Figure 39.1) and decreases in response to hypoxia or iron deficiency.[21,51,53] Interleukin-6 plays a central role in increasing hepcidin production; however, other cytokines and multiple signaling pathways are involved.[51,68] AI also involves mechanisms other than hepcidin-mediated altered iron homeostasis.[68] This may be especially relevant in chronic inflammation, as some research has found persistent suppression of erythropoiesis despite normalization of hepcidin mRNA expression or serum iron concentration.[14,58] Inflammatory cytokines have been implicated directly or indirectly in inhibiting erythropoiesis—via decreased erythropoietin (EPO) production, decreased responsiveness to EPO, or direct effects on erythroid precursors—as well as decreasing erythrocyte survival.[26,31,36]

NEOPLASIA

Recognized causes of anemia in people and veterinary patients with neoplasia include disease- and treatment-related factors. Frequently, the cause of anemia is multifactorial. Anemia in people with cancer is recognized to have negative impacts on quality of life, prognosis, and response to therapy in some cancer types.[27] While neoplasia is one of the most frequently identified causes of anemia in dogs,[12] its deleterious effects have received relatively little attention in the veterinary literature. One study found anemia to be a negative prognostic factor in canine lymphoma patients compared to osteosarcoma patients.[47]

In principle, anemia can occur as a complication of virtually any type of neoplasia, but the risk is higher in some types of malignancy. Potential disease-related factors include inflammation (the link between cancer and inflammation goes at least as far back as Rudolf Virchow[29]), hemorrhage, immunologic dysregulation, nutritional deficiencies, space occupation or alteration of bone marrow microenvironment by neoplastic cells or fibrous tissue, and elaboration of myelotoxic factors by neoplastic cells (such as hyperestrogenism-induced bone marrow hypoplasia secondary to Sertoli cell tumor).[9,27,50,63] The most commonly recognized treatment-related factor contributing to anemia is myelosuppressive chemotherapy or radiotherapy;[27] hemolytic anemia has also been reported secondary to anti-neoplastic therapy.[27]

Anemia due to hemorrhage is a frequent finding in some types of neoplasia. Bleeding may occur directly from a neoplastic lesion, or from distant sites due to defective hemostasis. Hemoperitoneum is a frequent complication of splenic hemangiosarcoma in dogs.[28] Bleeding may be caused by rupture of the primary tumor, but exacerbated by other tumor-related pathology. Thrombocytopenia occurs in the majority of these cases and disseminated intravascular coagulopathy (DIC) is a frequent complication.[28] Anemia and clinical evidence of bleeding are frequent in dogs with gastrointestinal sarcomas and renal neoplasia.[10,17]

Destruction of erythrocytes or their precursors may occur via secondary immune-mediated disease, phagocytosis by neoplastic cells, oxidative insult, mechanical

damage (e.g., microangiopathic hemolysis), or increased apoptosis. Although proof of a causative relationship in animals is elusive, underlying neoplasia can be a differential diagnosis for immune-mediated hemolytic anemia (IMHA).[38] There are several documented cases of IMHA associated with lymphoma in the veterinary literature.[33,40,44,49] In a retrospective study on equine lymphoma, the majority of affected animals were anemic, and autoagglutination was a frequent finding.[44] Canine hemophagocytic histiocytic sarcoma (see Chapter 74) is characterized by malignant histiocytes that are erythrophagic; the large majority of affected dogs are Coombs-negative.[48] A similar condition has been reported in a cat and a cow.[20,39] An association between lymphoma and oxidative damage to erythrocytes, with or without anemia, has been documented in dogs and cats. A recent study found that anemia and eccentrocytosis (see Chapter 24) were more common in dogs with lymphoma than those with inflammatory bowel disease.[55] Another study of canine eccentrocytosis found the prevalence of the condition was only 1.4% (60 of 4251 dogs), but every animal with T-cell lymphoma (five of five) had eccentrocytosis; however, information about the prevalence of anemia in these dogs was not provided.[11] A study in cats found Heinz bodies to occur significantly more often in animals with lymphoma (15 of 17 cases) than in a healthy control group; however, anemia was not a consistent finding in affected individuals.[16] Myelodysplastic syndrome causes cytopenias in part via increased apoptosis of developing blood cells.[3] Eryptosis, an apoptosis-like mechanism of erythrocyte cell death, has been implicated as a contributing factor to anemia in people with many types of disease, including lung cancer.[8,59]

Many anti-neoplastic therapies are known to cause myelosuppression in humans and animals, and such treatment is likely to be a contributing factor to anemia in affected individuals. However, monitoring of hematologic toxicity of chemotherapy or radiotherapy typically focuses on neutrophils and platelets; the impact of myelosuppression on erythrocytes is less severe than on other blood cell types because of the long erythrocyte life span.[38] In the opinion of at least some veterinary oncologists, chemotherapy is more likely to cause treatment-limiting anemia as a result of gastrointestinal hemorrhage than as a result of myelosuppression (A LeBlanc, personal communication).

RENAL DISEASE

Nonregenerative anemia is an expected complication of CKD in humans and domestic animals, and is recognized to contribute to overall morbidity.[5,6,34] Decreased production of EPO is generally regarded as the predominant mechanism of anemia in patients with CKD; other potential contributing factors include inflammation, hemorrhage, iron deficiency, decreased erythrocyte survival, and antiproliferative effects of uremic toxins.[5] Many treatment-related factors are recognized as potential contributors to anemia in patients with renal disease, including repeated phlebotomy and side effects of medications (erythropoiesis-stimulating agents, iron supplementation, phosphate binders, and antacids); detailed discussion of those factors is beyond the scope of this chapter.[6,24,71]

Animals with CKD often have inappropriately low plasma EPO concentrations. In one study of dogs and cats, anemic animals without CKD had significantly increased plasma EPO concentration compared to healthy controls, while a similar increase was not present in animals with CKD.[57] In cats there was no overlap in EPO concentration between anemic animals with and without CKD; in dogs there was considerable overlap between those groups. Another study found no significant difference in EPO concentration between cats with CKD and healthy controls, but significantly lower EPO concentration in anemic cats with CKD than in nonanemic cats with CKD.[30]

It is not clear how frequently or to what degree factors besides decreased EPO production contribute to development of anemia in animals with renal disease. CKD is recognized to be a proinflammatory state in people,[46] and some evidence in the veterinary literature supports the hypothesis that CKD elicits AI. In one study, serum amyloid A concentration was higher in cats with CKD than in healthy controls, and higher in anemic cats with CKD than in nonanemic cats with CKD.[30] Other mechanisms by which CKD may promote anemia, but for which direct evidence in veterinary medicine may be lacking, include potentiation of AI due to decreased renal clearance of hepcidin;[22] decreased erythrocyte survival due to effects of uremic toxins and reactive oxygen species;[1,23,60] and hemorrhage due to uremic ulceration and impaired platelet function.[45]

ENDOCRINE DISEASE

Endocrinopathies are recognized to cause anemia in humans and animals. This section focuses on the relationship between anemia and several endocrine diseases that are well characterized in veterinary medicine: diabetes mellitus (DM), hypothyroidism, hyperthyroidism, and hypoadrenocorticism. Some of these conditions are associated with impaired renal concentrating ability, and decreased plasma volume may mask the severity of anemia.[42,62]

Anemia is common in people with DM and closely linked with CKD.[65] Conversely, DM does not seem to be widely recognized in veterinary medicine as a cause of anemia, and a study in cats found DM to be a negative risk factor for development of CKD.[25] A study in dogs, however, identified a potential mechanistic link between DM-related lipidopathy and anemia: erythrocytes from hyperlipidemic and dyslipidemic dogs with DM were more osmotically fragile than erythrocytes from controls; moreover, incubation in plasma from hyperlipidemic dogs with DM rendered control erythrocytes more fragile, whereas incubation in lipid-depleted plasma from the same diabetic dogs did not.[7] In the

same study, erythrocytes from dogs treated with glucocorticoids were significantly more fragile than controls, and erythrocytes from dogs with hyperadrenocorticism tended to be more fragile than controls (the difference did not reach statistical significance)—suggesting a possible similar mechanistic link between other endocrinopathies and anemia.

Cats with DM have a predisposition to Heinz body formation, but how this relates to development of anemia is not clear. One study found Heinz bodies to occur significantly more often in cats with DM (19 of 21 cases) than in a healthy control group, and the evidence presented suggested a causal relationship to anemia.[15] A subsequent study found that cats with diabetic ketoacidosis had more Heinz bodies than non-ketotic diabetic cats, but did not find a significant association between percentage of Heinz bodies and degree of anemia.[16] Heinz bodies were also detected in five cats with DM and hemolytic anemia associated with hypophosphatemia, but the hemolysis in these cats was presumed to be caused by hypophosphatemia.[2]

Nonregenerative anemia is a recognized complication of hypothyroidism in humans and animals, occurring in approximately one-third of cases in dogs.[32,54] Anemia develops primarily as a result of decreased erythropoiesis, with possible mechanisms including decreased EPO production, decreased responsiveness to EPO, and direct effects on hematopoietic stem cells and erythroid progenitor cells.[32,43]

Despite thyroid hormone effects in promoting erythrocyte production and the fact that hyperthyroidism is recognized as a cause of erythrocytosis,[37,69] anemia occurs in approximately 10–25% of people with hyperthyroidism.[32,69] Decreased erythrocyte survival and ineffective erythropoiesis have been suggested to play a role in development of anemia, but there is conflicting information in the scientific literature. Experimentally induced hyperthyroidism in rats resulted in increased erythrocyte osmotic fragility, suggesting decreased erythrocyte survival as a potential mechanism of anemia;[70] however, a study in people found decreased osmotic fragility in erythrocytes of hyperthyroid patients compared to controls.[4] Another study in people found evidence of both increased proliferation and increased apoptosis in hematopoietic stem cells from individuals with hyperthyroidism.[32] A study in cats found Heinz bodies to occur significantly more frequently in animals with hyperthyroidism (15 of 21 cases) than in a healthy control group, but not all affected animals were anemic and the study did not demonstrate a causal relationship between Heinz bodies and increased erythrocyte destruction.[15]

Dogs with hypoadrenocorticism often develop nonregenerative anemia, but the anemia may be masked by decreased plasma volume from dehydration.[18,66] The pathophysiology of anemia in hypoadrenocorticism is primarily attributed to decreased erythrocyte production, supported by the fact that glucocorticoids interact with EPO and stem cell factor to promote erythropoiesis.[62,66] Additionally, blood loss, especially from gastrointestinal hemorrhage, may also contribute to development of anemia in dogs with hypoadrenocorticism.[41,66]

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; FeLV, feline leukemia virus.

Aplastic anemia (also termed aplastic pancytopenia) is a clinical syndrome characterized by bicytopenia or pancytopenia in the blood and replacement of bone marrow by adipose tissue (Figure 40.1).[3,25,33] Excluded from this are pancytopenias associated with myelophthisic disorders, hypoplastic myelodysplastic syndromes, pure red cell aplasia, hemophagocytic syndrome, myelonecrosis, and infectious/inflammatory disorders of bone marrow.[3]

Aplastic anemia can occur in acute and chronic forms. If the bone marrow suppression occurs acutely, as is seen in some types of drug- or virus-induced aplasia, neutropenia typically develops within 1 week followed by thrombocytopenia at 9–14 days.[28] Anemia does not develop for an extended period of time, because of the long life span of RBCs. Therefore, acute aplastic anemia is typically characterized by a neutropenia and thrombocytopenia. Acute aplastic anemia is most frequently associated with destruction of rapidly dividing progenitor or proliferative cells in bone marrow. In chronic aplastic anemia, the hematologic dyscrasia develops more slowly and is characterized by moderate to severe normocytic normochromic nonregenerative anemia, neutropenia, and thrombocytopenia.[16] Chronic aplastic anemia is most frequently associated with stem cell destruction.

PATHOGENESIS

Many etiologic agents have been incriminated in aplastic anemia. These include infectious agents, chemical/physical agents, drugs, toxins, genetic mutations, and immune-mediated causes. The end result of each of these insults is decreased blood cell formation.[29,35] Although several mechanisms could lead to decreased hematopoiesis, direct injury to stem cells or progenitor cells appears to be the primary mechanism involved in clinical aplastic anemia.[25,35] In human patients, immune-mediated destruction of hematopoietic stem cells appears to play a central role in the pathogenesis of aplastic anemia.[23,33,35] The process involves a cell-mediated immune response including CD4 cells, CD8 cytotoxic T cells, regulatory T cells, Th17 cells, and natural killer (NK) cells.[33,35] Cytokines involved in inducing apoptosis of hematopoietic stem cells include interferon-gamma, tumor necrosis factor-alpha, and transforming growth factor-beta.[33,35] Although there is no direct evidence of an immune etiology in animals, clinical responses of dogs and cats with aplastic anemia to immunosuppressive therapy is suggestive of an immune-mediated etiology.[10,18,34]

Beyond the causative immune-mediated etiology, human aplastic anemia has been linked to clonal

hematopoietic disorders including progression to myelodysplastic syndromes (MDS) and acute myeloid leukemias.[25,33] A variety of clonal changes have been associated with aplastic anemia including gross cytogenic alterations and various clonal somatic mutations. These mutations tend to be similar to those associated with acute myeloid leukemias and congenital bone marrow failure disorders (see Chapter 31). The present theory is that immune-mediated depletion of stem cells and progenitor cells may permit clonal selection of pre-existing stem cells containing genetic mutations that were acquired as part of the normal aging process. These genetic mutations provide a selective growth advantage because they are less immunogenic or relatively resistant to cytotoxicity. Mutations in aplastic anemia patients that result in the loss of class 1 human leukocyte antigen alleles (i.e., involved in immune recognition) support a role of altered immunogenicity of hematopoietic clones in aplastic anemia.[25,33]

The finding of clonal hematopoiesis in aplastic anemia and frequent progression of aplastic anemia to MDS complicate the differentiation of aplastic anemia from hypoplastic MDS.[33] Further, both patients with aplastic anemia and MDS can respond to immunosuppressive therapy. Therefore, a subset of human patients are thought to have a combination of aplastic anemia and hypoplastic MDS. The presence of immune-mediated disease coexisting with MDS also complicates the diagnosis of immune-mediated hemolytic anemia with secondary dysmyelopoiesis (see Chapter 67).

DIAGNOSIS

Inclusion criteria for a diagnosis of aplastic anemia in humans are well-defined. They include: hemoglobin concentration <10 g/dL, reticulocytopenia, platelet count $<50 \times 10^3/\mu L$, a neutrophil count $<1.5 \times 10^3/\mu L$, and hypocellular bone marrow aspirates and core biopsies, as well a battery of ancillary diagnostic tests including cytogenetic analysis of the peripheral blood and bone marrow, fetal hemoglobin percentage in children, flow cytometry for phosphatidylinositol glycan-anchored proteins, liver function tests, vitamin B_{12} and folate concentrations, viral studies, testing for immune-mediated diseases, and diagnostic imaging.[16] Diagnostic recommendations for aplastic anemia in veterinary patients are not well-defined and currently minimally include evaluation of a complete blood count, bone marrow aspiration smear and core biopsy specimen, and ancillary diagnostic tests.[3,29] Fat content of bone marrow depends on location and depth of core biopsy. The bone marrow collection sites should be carefully chosen as fatty marrow samples can be obtained in healthy animals if an improper collection site is selected.[31] Magnetic resonance imaging has been recommended as a supportive diagnostic method for diagnosis of hypocellular fatty bone marrows.[10] Ancillary diagnostic tests should be chosen based on the species and case history. Animals should be evaluated for drug, chemical, and toxin exposure, exposure to specific infectious agents, and the presence of associated diseases such as chronic renal failure.[3,27]

MODELS OF APLASTIC ANEMIA

A variety of in vivo and ex vivo animal models of aplastic anemia have been described.[4] A mouse model has been used to study benzene-induced aplastic anemia. Use of this model has enabled investigators to identify a benzene-induced defect in the capacity of bone marrow stromal cells to process cytokines. A mouse model of busulfan-induced aplastic anemia has been extensively studied.[4] Busulfan treatment results in hematopoietic stem cell depletion with pancytopenia and bone marrow aplasia developing up to a year after treatment. Other studies suggest the presence of a qualitative defect in hematopoietic stem cells or hematopoietic stromal cells. Radiation injury has also been studied in several species.[5] Exposure of mice to 4 Gy ionizing radiation resulted in significant reduction in hematopoietic stem cells.

Immune-mediated aplastic anemia has been reproduced in mice by sublethally irradiating them and injecting them with heterologous lymphocytes.[4] Total body irradiation with 6 Gy and injection of 10 million lymph node cells produced a fatal pancytopenia within 2–3 weeks.

APLASTIC ANEMIA IN DOGS

Aplastic anemia was identified in 2.4% of clinical bone marrow specimens evaluated at a veterinary teaching hospital in the Northern USA.[28] Of these, the majority (1.7%) were idiopathic.[3] Other causes of aplastic anemia included infectious causes, drugs, toxins, and radiation. Alternatively, in Brazil, a retrospective study of bone

marrow aspirates from 65 dogs with pancytopenia revealed a 26% incidence of aplastic anemia.[7] This discrepancy is probably due to the high incidence of *Ehrlichia canis*, *Babesia* spp., and *Leishmania chagasi* and failure to perform bone marrow core biopsies that would have identified bone marrow stromal disorders as a cause of the pancytopenia.

Infectious Causes

Infectious agents that cause aplastic anemia include parvovirus, *E. canis*, and *L. chagasi* (see Chapters 18 and 33).[7] Puppies with parvovirus infection develop erythroid and myeloid hypoplasia. This is not a true aplastic anemia because the hypoplasia is accompanied by degenerative changes including myelonecrosis, edema, and hemorrhage (see Chapter 16). These changes could be caused by the cytotoxic effects of the virus or more likely the effects of secondary bacterial sepsis or endotoxemia on the marrow microvasculature. Parvovirus invades rapidly dividing myeloid and erythroid progenitor cells. Hematopoietic stem cells are not infected. Therefore, bone marrow rapidly regenerates if puppies survive the acute stage of the disease. Dogs with chronic *E. canis* infections and with *L. chagasi* infections develop hypoplastic bone marrows.[7] Appropriate diagnostic testing should be performed in endemic areas.

Drug-Associated Causes

Drugs that induce hematologic dyscrasias are discussed in Chapter 15. In this chapter, some general comments about drug-induced aplastic anemia are presented. The mechanism by which the drug induces suppression of hematopoiesis is important to clinical finding and outcome. Drugs that target progenitor or proliferative cells in marrow, such as anti-neoplastic drugs and sulfadiazine, result in acute aplastic anemia.[30] In some cases, these drugs are directly cytotoxic to rapidly proliferating hematopoietic cells, whereas other drugs act indirectly by inducing immune-mediated hematopoietic cell destruction. Affected dogs are typically neutropenic and thrombocytopenic but not anemic, and frequently undergo prompt hematologic recovery when the drug is withdrawn.[30] Drugs that target stem cells, such as estradiol and phenylbutazone, frequently cause chronic aplastic anemia that is characterized by pancytopenia.[30] Recovery is uncertain and when it occurs it may be delayed for months.

Idiopathic Aplastic Anemia

Idiopathic aplastic anemia was observed in 1.7% of clinical bone marrow specimens examined at a veterinary teaching hospital in the Northern USA and in 9% of pancytopenic dogs in Brazil.[3,7] Affected dogs tend to be young adult with no sex or breed predisposition. The history usually indicates a chronic onset of illness with nonspecific signs including lethargy, anorexia, and exercise intolerance. Fever, petechiae, and epistaxis may also be observed. The anemia varies from mild to severe and is normocytic and normochromic. Neutropenia is usually severe with leukocytes consisting mostly of small lymphocytes. Thrombocytopenia varies from moderate to severe. Bone marrow aspirates and core biopsy specimens are markedly hypocellular (Figure 40.1). In some dogs, small lymphocytes or plasma cells are increased in number.

Treatment of canine idiopathic aplastic anemia is not well-defined. Whole blood, packed RBC, or platelet transfusions are frequently needed. Broad-spectrum antibiotics are indicated to prevent opportunistic infections. Because of the clear connection with the human disease, a primary cell-mediated immune destruction of hematopoietic precursor cells has been suspected in canine idiopathic aplastic anemia. Although administration of immunosuppressive doses of prednisone alone appears to be ineffective as a treatment, administration of mycophenolate mofetil or cyclosporine or azathioprine with or without prednisone has been associated with recovery from idiopathic aplastic anemia.[10,18,34]

APLASTIC ANEMIA IN CATS

Aplastic anemia has been observed in 10% of feline clinical bone marrow specimens at a veterinary teaching hospital.[28] Conditions associated with aplastic anemia include chronic renal disease, feline leukemia virus (FeLV) infection, prolonged anorexia/starvation, cobalamin deficiency, *Leishmania infantum* infection, and adverse drug reactions including griseofulvin, chemotherapeutic agents, propylthiouracil, and methimazole.[15,24,28] Chronic renal disease is typically associated with nonregenerative anemia, and aplastic anemia is an infrequent finding. Some cats with aplastic anemia associated with chronic renal disease have serous atrophy of fat in bone marrow (see Chapter 17).[28] Serous atrophy of fat is typically associated with starvation. Starvation has been implicated in the pathogenesis of the marrow failure in people and other species.

FeLV infection has been associated with a variety of bone marrow disorders including aplastic anemia.[6,28] Cats usually have a severe normocytic normochromic anemia (hematocrit <10%), severe leukopenia, and thrombocytopenia. Affected cats frequently have secondary bacterial infections as a result of the neutropenia. Bone marrow is aplastic; however, the pathogenesis of the aplasia is unclear. Survival time for FeLV-associated aplastic anemia is usually short.

In one study of aplastic anemia in cats, 30% were classified as idiopathic.[28] Many affected cats had a history of prolonged partial or complete anorexia with associated cachexia.[28] One case had serous atrophy of fat and gelatinous transformation in bone marrow. Therefore, malnutrition/starvation may have played a role in the development of the aplasia in these cats.

Although not recognized as a clinical disorder, cat bone marrow appears to be uniquely sensitive to mycotoxins. Mycotoxin exposure results from ingestion of grain that becomes damp during storage permitting

growth of fungi. In a search for an experimental model for T-2 mycotoxicosis, sesquiterpene T-2 mycotoxin was administered to rats, mice, guinea pigs, rabbits, dogs, pigs, sheep, poultry, cattle, horses, and cats.[14] Only cats developed signs of hematotoxicity. This was characterized by pancytopenia and bone marrow was characterized by hypocellularity, hemorrhage, inflammation, and multinucleated giant cells. Although this is consistent with acute toxic injury rather than aplastic anemia, the bone marrow may become aplastic at a later stage of the disease.

APLASTIC ANEMIA IN HORSES

Several reports of equine aplastic anemia have been published. These reports appear to present distinct types of bone marrow aplasia including idiopathic, drug-associated, possible toxin-associated, genetic, and hypoplastic myelodysplastic syndrome. A case of idiopathic aplastic anemia was reported in a 2-year-old Quarter Horse.[2] This horse had severe pancytopenia and bone marrow aplasia typical of aplastic anemia and had no history of exposure to drugs, toxins, or infectious agents. The horse died from hemorrhage as a result of the bone marrow biopsy procedure.

Several suspected drug-induced aplastic anemia cases have been reported. Phenylbutazone has been incriminated as a cause of aplastic anemia. One horse developed aplastic anemia after treatment with penicillin, trimethoprim–sulfadiazine, oxytetracycline, phenylbutazone, dipyrone, flunixin meglumine, and isoxsuprine.[12] The horse was direct Coombs test positive suggesting an immune-mediated pathogenesis.

Aplastic anemia in a 9-week-old Clydesdale foal was associated with biliary hyperplasia and portal fibrosis.[17] Because of this combination of findings, an in utero or neonatal toxicity was suspected. A panhypoplasia of bone marrow has been reported in eight Standardbred horses sired by the same stallion suggesting genetic mutation as a cause.[11]

Finally, a severe nonregenerative anemia and leukopenia that initially had an aplastic bone marrow were reported in a 17-year-old Thoroughbred gelding.[26] Unusual features of this case were marked anisocytosis in the blood, normal numbers of megakaryocytes in bone marrow, and an increase in blast cells in bone marrow. Reevaluation of bone marrow several months later revealed a hypercellular marrow with an increase in lymphocytes and blast cells. This is suggestive of hypoplastic myelodysplastic syndrome (see Chapter 67).

APLASTIC ANEMIA IN RUMINANTS

Drug-Associated Causes

A case of aplastic anemia in a 14-day-old Holstein heifer was associated with prior administration of sulfamethazine, trimethoprim, and sulfadoxine for treatment of bloody diarrhea.[1] Detection of aplastic bone marrow 8 days after initiation of sulfa therapy fits with a drug-induced aplastic anemia.

Bracken Fern Ingestion

Bracken fern (*Pteridium aquilinum*) is typically eaten by ruminants when pastures are overgrazed. After repeatedly ingesting bracken fern, cattle, horses, sheep, and pigs develop aplastic anemia.[19] The major toxin is a thiaminase called ptaquiloside.[31,32] Thiamine depletion in cattle is thought to be involved in the pathogenesis of aplastic anemia. Species other than cattle are more likely to develop neurological signs related to polioencephalomalacia.[31] Development of urinary bladder neoplasia (i.e., chronic enzootic hematuria) is also linked to prolonged ingestion of bracken fern.[19]

Trichloroethylene-Extracted Soybean Oil Ingestion

Many cases of fatal aplastic anemia and renal injury in cattle in the 1950s were traced to feeding of trichloroethylene-extracted soybean oil meal.[13,22] Although trichloroethylene is no longer used to extract soybean oil, it and related compounds are widely used as solvents. The toxic factor was identified as *S*-(1-2-dichlorovinyl)-L-cysteine. Administration of a single dose of this compound intravenously at 4 mg/kg or 0.4 mg/kg per day for 10 days reproduces the aplastic anemia and renal injury.

Mycotoxin Ingestion

A variety of mycotoxins produce aplastic anemia in ruminants. Mycotoxin exposure occurs with ingestion of grain that is contaminated with fungi as a result of becoming damp during storage. Aplastic anemia has been documented in cattle and sheep ingesting feed contaminated with *Stachybotrys* spp.[21] Many other mycotoxins, including T-2 mycotoxin, trichothecene mycotoxin, trichothecene vomitoxin, diacetoxyscirpenol, ochratoxin, and zearalenone, appear to be directly cytotoxic to a variety of cells including hematopoietic precursor cells and lymphocytes.[5] As a result, many mycotoxins cause bone marrow hypoplasia/aplasia and lymphocyte depletion.[6] Initial changes in bone marrow consist of individual cell necrosis or apoptosis; however, by the time affected animals are evaluated clinically, the bone marrow frequently appears aplastic.[6] Depletion of primary and secondary lymphoid tissue may also be seen.

Idiopathic Aplastic Anemia in Calves

An idiopathic aplastic anemia has been identified in calves in Germany.[8] A search for inciting causes has been inconclusive. Circovirus DNA, similar chicken circovirus (chicken infectious anemia), and porcine circovirus were identified in five of 25 affected calves.

APLASTIC ANEMIA IN CHICKENS

Chicken infectious anemia is an emerging infectious disease of young chickens worldwide.[9,20] The disease is caused by a single-stranded DNA circovirus. Affected birds have aplastic anemia, generalized lymphoid atrophy, immunosuppression, and hemorrhages. The diagnosis is straightforward and is based on clinical and histological signs and testing for circovirus infection.[20]

Acronyms and Abbreviations

AML-1, acute myeloid leukemia-1; BaP, basophil progenitor; βc, common beta chain for GP140-type cytokine receptors; BMCP, basophil/mast cell progenitor; C/EBP, CCAAT/enhancer-binding protein; CD, cluster of differentiation; c-kit, receptor for SCF; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; CSF, colony-stimulating factor; CXCL12, CXC-chemokine ligand 12; CXCR4, CXCL12 receptor; EoP, eosinophil progenitor; G-CSF, granulocyte colony-stimulating factor; GATA, GATA-binding protein; G-CSFR, granulocyte colony-stimulating factor receptor; GFI-1, growth factor independent-1; GM-CSF, granulocyte-macrophage colony-stimulating factor; GM-CSFR, granulocyte-macrophage colony-stimulating factor receptor; GMP, granulocyte/monocyte progenitor; HSC, hematopoietic stem cell; ICAM-1, intercellular adhesion molecule-1; Id2, inhibitor of DNA binding 2; IL, interleukin; IL-3R, interleukin-3 receptor; IL-5R, interleukin-5 receptor; IL-6R, interleukin-6 receptor; IRF-8, interferon regulatory factor-8; Lin, lineage-specific antigen; miR, microRNA; MCP, mast cell progenitor; MDP, macrophage/dendritic cell progenitor; MEP, megakaryocyte/erythroid progenitor; MITF, melanocyte-inducing or microphthalmia-associated transcription factor; MPP, multipotential progenitor; mSCF, membrane-bound stem cell factor; NeuP, neutrophil progenitor; NGF, nerve growth factor; NK, natural killer cells; PAMP, pathogen-associated molecular pattern; PECAM-1, platelet cell adhesion molecule; pre-BMP, pre-basophil/mast cell progenitor; PRR, pattern recognition receptor; Sca-1, stem cell antigen-1; SCF, stem cell factor; TGF-β, transforming growth factor-β; TLR, toll-like receptor; TNF-α, tumor necrosis factor-alpha; TSLP, thymic stromal lymphopoietin; VCAM, vascular cell adhesion molecule.

In adult mammals, granulopoiesis occurs primarily in the bone marrow, with expansion to extramedullary sites in times of increased demand or with bone marrow disease. Most information about development and regulation of the granulocytic lineages has been obtained from human and rodent models. However, bone marrow cultured from common domestic species indicates that granulocyte development is similar.[6,17,38,41,46,48,50,52]

ROLE OF THE MICROENVIRONMENT

The hematopoietic microenvironment provides the physical structure and chemical milieu permissive for granulopoiesis. The microenvironment comprises the extracellular matrix and stromal cells that include endothelial cells, leptin-receptor-bearing adipocyte

lineage cells, osteoblasts, perivascular mesenchymal cells, Schwann cells, megakaryocytes, regulatory T cells, and macrophages. Granulopoiesis is regulated by growth factors and cytokines produced by cells in the microenvironment, interactions with the extracellular matrix, and growth factors and cytokines delivered from the blood. Commitment and differentiation are coordinated through changes in expression of cell surface markers, receptors, transcription factors, and signal transduction pathways in the hematopoietic precursors.

In adult mammals, granulocytic lineages originate from pluripotential hematopoietic stem cells (HSCs) within the bone marrow (see Chapter 2).[47] Proliferation, mobilization, and commitment of HSCs to granulocytic differentiation occur within niches along vascular sinusoids.[47] Homing and maintenance of HSCs and committed hematopoietic progenitor cells to the perisinusoidal niches require binding of the CXCL12 receptor (CXCR4) to the CXC-chemokine ligand 12 (CXCL12) on endothelial and stromal cells. Ultimately, as neutrophils mature, there is decreased expression of CXCR4, allowing release of neutrophils into the circulation.

LINEAGE COMMITMENT

Identification of HSCs and other early committed progenitors is based on detection of surface markers. In mice, HSCs are characterized by expression of stem-cell-associated antigen (Sca-1) and c-kit (stem cell factor receptor), but lack of expression of lineage-specific antigens (Lin); however, similar homologs have not yet been clearly identified in other species.[7] CXCL12 signaling appears necessary for maintenance and differentiation of HSCs to CD34+ multipotential progenitors (MPPs) that have multilineage potential but have lost the capability of self-renewal.[47] In the classic hierarchical model of hematopoiesis, MPPs commit to either common lymphoid progenitors (CLPs) or common myeloid progenitors (CMPs) (Figure 41.1). Murine CLPs are distinguished by expression of Lin−Sca-1+c-kit^{lo}, whereas CMPs are Lin−Sca-1−c-kit+CD34+.

CMPs give rise to several lineages, including granulocyte/monocyte progenitors (GMPs), megakaryocyte/erythroid progenitors (MEPs), and macrophage/dendritic cell progenitors (MDPs).[25] In mice, granulocytic lineages differentiate from GMPs to produce neutrophil progenitors (NeuPs), eosinophil progenitors (EoPs), and basophil/mast cell progenitors (BMCPs).[1,25,27] BMCPs subsequently give rise to basophil progenitors (BaPs), which complete their maturation in the bone marrow, and mast cell progenitors (MCPs), which circulate and undergo maturation in gastrointestinal mucosa, skin, lung, and heart.

Although it is helpful to envision progenitor development in the classical hierarchical model, recent alternative models suggest that there may be more plasticity in progenitor commitment. There also may be species differences in generation of eosinophil, basophil, and mast cell progenitors. Some evidence suggests that lineage commitment can occur within the MPPs or as early as some HSCs that have lost self-renewal capability.[8,37] This is evident in leukemic cell lines that express aberrant lineage markers and the ability to modify differentiation of cultured cells by varying culture conditions and transcription factor expression.

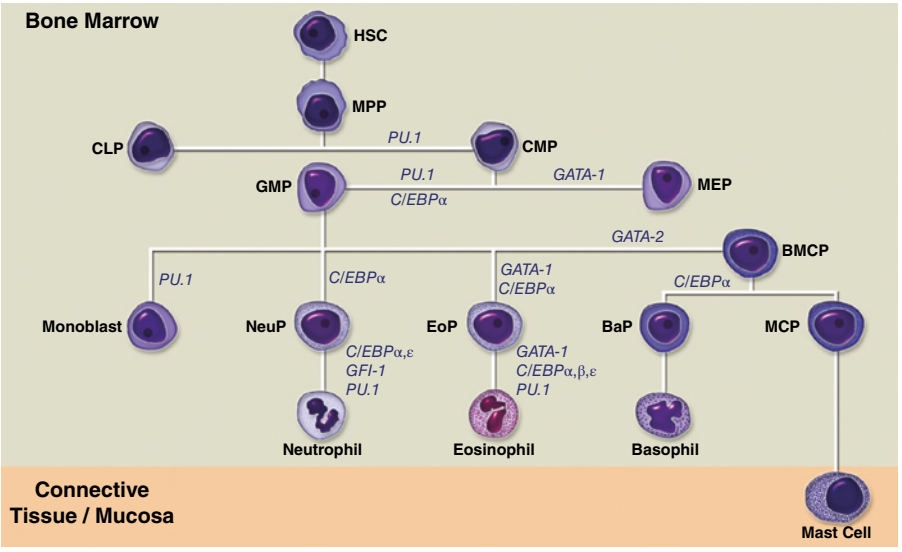

FIGURE 41.1 Granulopoiesis with transcriptional regulation indicated. MCP also may arise directly from MPP, depending on the species or mouse strain (BaP, basophil progenitor; BMCP, basophil/mast cell progenitor; C/EBP, CCAAT/enhancer-binding protein; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; EoP, eosinophil progenitor; GFI-1, growth factor independent-1; GMP, granulocyte/monocyte progenitor; HSC, hematopoietic stem cell; Id2, inhibitor of DNA binding 2; MCP, mast cell progenitor; MEP, megakaryocyte/erythroid progenitor; MPP, multipotential progenitor; NeuP, neutrophil progenitor). TRANSCRIPTION FACTOR REGULATION OF GRANULOPOIESIS

Commitment, differentiation, and maturation of granulocytic progenitors result from a coordinated program of transcription factor expression and gene activation and suppression (Figure 41.1).[25,34,35] This coordinated hierarchy impacts expression of receptors for colony-stimulating factors (CSFs) on hematopoietic progenitors, timing of adhesion molecule expression, and genetic programing that allow transition to committed lineages and functional maturation within a lineage.

Differentiation of MPPs to CMPs requires activation of PU.1, an Ets transcription factor family member.[25,34] PU.1, in conjunction with expression of CCAAT/enhancer-binding protein-α (C/EBP-α), a basic-region leucine zipper transcription factor, promotes transition to GMPs. Continued presence of C/EBP-α and diminished expression of PU.1 result in formation of early neutrophil precursors. This is in contrast to GMPs that maintain high levels of PU.1 but no longer express C/EBP-α, which results in commitment to monocyte production. Maturation of neutrophils beyond the promyelocyte stage and production of specific and gelatinase granules is dependent on increasing expression of PU.1 and C/EBP-ε. C/EBP-ε protein expression is highest in myelocytes and metamyelocytes and is key to stopping proliferation through cell cycle arrest and allowing terminal maturation. Growth factor independent-1 (GFI-1) also is required for transition to promyelocytes and for gelatinase and secretory vesicle formation. Increased production of neutrophils in response to infection and increased demand (termed "emergency" granulopoiesis) requires C/EBP-β to coordinate cytokine-induced proliferation and differentiation.[25] Unlike other C/EBPs, C/EBP-β is not downregulated by inflammatory cytokines and does not inhibit the cell cycle to the same degree, thus allowing amplification of granulopoiesis above steady state.

Production of EoP results from expression of GATA-1 (zinc finger family transcription factors) and continued high levels of C/EBP-α.[44,49] Further, differentiation of EoP to mature eosinophils requires GATA-1, C/EBP-β, PU.1, and inhibitor of DNA binding 2 (Id2). BMCP formation requires GATA-2 expression but inactivation of C/EBP-α.[1,44,49] For BMCPs to commit to production of basophils, there must be reactivation of C/EBP-α to produce BaPs, whereas continued downregulation of C/EBP-α and upregulation of melanocyte-inducing transcription factor (MITF, also called microphthalmia-associated transcription factor) is required for differentiation to MCPs.[12]

CYTOKINE REGULATION OF GRANULOPOIESIS

Granulopoiesis is regulated by cytokines that include stem cell factor (SCF) and CSFs.[3,5,27] Expression of surface receptors for these cytokines on hematopoietic cells is controlled by transcription factors so that sensitivity to individual cytokines coordinates with and facilitates proliferation and differentiation of the various lineages. Most hematopoietic cytokines are constitutively produced at low levels by a variety of cell types to maintain steady-state granulopoiesis, but levels increase in response to inflammation. Increased circulating levels of these cytokines in response to inflammatory mediators stimulate increased granulocyte production in times of high demand.

Stem Cell Factor

SCF (also termed kit ligand and mast cell growth factor) acts on some of the earliest hematopoietic progenitors and is required for survival and self-renewal of HSCs (see Chapter 2).[5,42] SCF is produced as either a membrane-bound (mSCF) or soluble form. mSCF appears to be critical for effective hematopoiesis because soluble SCF is unable to compensate for lack of mSCF in genetically engineered mice.[5] mSCF is found on osteoblasts, endothelial cells, and fibroblasts in the bone marrow, and plays a role in establishing progenitors in their appropriate bone marrow niches. SCF inhibits apoptosis and promotes entry of cells into the S phase of the cell cycle. SCF also potentiates the effects of other cytokines and CSFs to promote proliferation, especially of early committed progenitors. c-kit (CD117), a member of the type III receptor tyrosine kinase family, is the SCF receptor. Binding of SCF to c-kit results in homodimerization and autophosphorylation of the receptor. Expression of c-kit varies depending on the stage of hematopoietic cell development.[22] c-kit expression is present at low levels on quiescent HSCs and increases to its highest levels on early, actively proliferating granulocytic progenitors. With the exception of mast cells, c-kit expression declines with further maturation of granulocytic lineages.

Interleukin-3

Interleukin (IL)-3, a member of the short-chain α-helical bundle type 1 cytokine family, acts on some of the earliest hematopoietic progenitors.[3] It is primarily produced by activated T cells; however, other cell types, such as bone marrow stromal cells, natural killer (NK) cells, eosinophils, and mast cells, also can produce IL-3. IL-3 binds to a specific receptor (IL-3R), which is a heterodimer consisting of α- and β-chains. The α-chain (IL-3Rα or CD123) conveys ligand specificity. The common β-chain (βc or CD131) dimerizes with the α-chain–ligand complex to initiate signal transduction. Transcription of the IL-3Rα is controlled by transcription factors PU.1, GATA-1, and C/EBP-α, whereas constitutive expression of the βc appears to be controlled by PU.1. IL-3R is found on early progenitors such as CD34+ HSCs, MPPs, and CMPs. The primary effects of IL-3 are to promote proliferation, differentiation, and survival of the most primitive precursors by shortening the time in the G_0 stage of the cell cycle. Although IL-3R can be found on more mature granulocyte precursors, the growth-promoting effects of IL-3 continue to be important for eosinophils and basophils.

Granulocyte-Macrophage Colony-Stimulating Factor

Granulocyte-macrophage CSF (GM-CSF), a member of the short-chain α-helical bundle type 1 cytokine family, is

produced by a variety of cells including macrophages, T and B cells, bone marrow stromal cells, osteoblasts, fibroblasts, endothelial cells, neutrophils, eosinophils, and mast cells.[3,27] The receptor for GM-CSF (GM-CSFR) is a member of the GP140 cytokine receptor superfamily. GM-CSFR is a heterodimer that shares the same βc with the IL-3R, but has a unique α-chain (GM-CSFRα or CD116) that confers ligand specificity. Like IL-3R, transcription of the GM-CSFRα is controlled by PU.1, GATA-1, and C/EBP. GM-CSFR is expressed as progenitor cells commit to granulocytic and monocytic differentiation. Binding of GM-CSF to its receptor promotes progenitor survival by inhibiting apoptosis. GM-CSF promotes proliferation and maturation of granulocytes and macrophages.

Granulocyte Colony-Stimulating Factor

Granulocyte CSF (G-CSF) is a primary growth factor for neutrophil production. G-CSF is produced by a variety of cells including macrophages, monocytes, fibroblasts, and endothelial cells of the peripheral tissues and bone marrow.[3,27,30,35] The receptor for G-CSF (G-CSFR) is a member of the GP130 cytokine receptor superfamily and forms a homodimer or homo-oligomer upon ligand binding. G-CSFRs are expressed in highest concentrations by neutrophilic progenitors through mature neutrophils. Sensitivity to G-CSF increases with neutrophil maturation and is related to increasing numbers of G-CSFR.[35] Effects of G-CSF include stimulation of survival, proliferation, and terminal differentiation of neutrophils.

One control of G-CSF production is a feedback loop among G-CSF, IL-23, and IL-17. Under homeostatic conditions, macrophages produce IL-23, a proinflammatory cytokine. IL-23 stimulates IL-17 synthesis by Th17 lymphocytes and NK cells. IL-17 subsequently stimulates production of G-CSF and GM-CSF by endothelial and stromal cells both peripherally and within the bone marrow microenvironment. Phagocytosis of apoptotic and aging neutrophils by macrophages in peripheral tissues and bone marrow results in decreased production of IL-23, subsequent decreased IL-17 secretion, and ultimately decreased secretion of G-CSF. This feedback loop links production of G-CSF to steady-state turnover of aging neutrophils and keeps G-CSF at levels appropriate to support basal neutrophil production. Increased expression of CXCR4 may direct aging neutrophils back to the bone marrow for clearance by resident macrophages, abetting regulation of IL-23 production to maintain steady-state granulopoiesis.[34]

Products released by bacteria of the gut microbiome are implicated as a stimulus of steady-state granulopoiesis through toll-like receptor (TLR) signaling.[2,51] Low-level activation of the TLR-4/MyD88 pathway at the level of the gut and possibly the bone marrow results in a tonic production of inflammatory cytokines such as IL-17 and subsequently G-CSF to help set the size of the bone marrow granulopoietic pool in health.

Concentrations of G-CSF increase markedly in response to infection and help stimulate emergency granulopoiesis. Endotoxin and inflammatory mediators, such as tumor necrosis factor-α (TNF-α), IL-1β, and IL-17, induce G-CSF, thus driving increased neutrophil production and release during an inflammatory response.[35] Increased production of G-CSF by bone marrow stromal cells also may be mediated through direct sensing of pathogen products (pathogen-associated molecular patterns or PAMPs) via TLRs or other pattern recognition receptors (PRRs). Bone marrow stromal cells, HSCs, and progenitors cells may be capable of directly responding to PAMPs through activation of PRRs.[26] Elevated G-CSF shortens maturation time of neutrophilic precursors, decreases marrow transit time, stimulates release of neutrophils from the bone marrow, and prevents apoptosis.

High concentrations of G-CSF result in release of HSCs into the circulation. This technique has been used to harvest circulating HSCs for bone marrow transplantation in people. Release of HSC in response to G-CSF appears to be mediated in part by elaboration of neutrophil enzymes, such as neutrophil elastase, cathepsin G, and matrix metalloproteinase-9 within the bone marrow microenvironment.[27] These enzymes cleave adhesion molecules on HSCs and osteoblasts, thereby releasing HSCs.

Interleukin-6

IL-6 is a member of the GP130 cytokine family, and receptors for IL-6 (IL-6R) are found on some CD34+ hematopoietic precursors.[21] IL-6 can stimulate granulopoiesis via binding to membrane-bound IL-6R. GP130 signaling can also be initiated through "trans-signaling" wherein IL-6 is bound to a soluble form of its receptor and this complex heterodimerizes with GP130 to activate signaling. This latter mechanism appears to be important in granulopoiesis.[20,36] IL-6 can act synergistically with SCF to enhance granulopoiesis in culture and can partially compensate for lack of G-CSF in knockout mice.[27,36] IL-6 can act alone or synergistically with G-CSF to mediate bone marrow granulocytic hyperplasia during times of increased demand for neutrophils.

ROLE OF MICRORNAS IN GRANULOPOIESIS

MicroRNAs (miR) regulate HSC quiescence and proliferation of committed granulocyte precursors.[8] miR-130a confers resistance to the cell cycle inhibitory effects of transforming growth factor-β (TGF-β) in HSCs, myeloblasts, and promyelocytes. Concentrations of different miRs vary as development proceeds from myeloblast to metamyelocyte. For example, with increase in C/EBP-α, production of miR-223 increases, which inhibits translation of proteins that promote cell cycle arrest, thus allowing proliferation of neutrophils. miR-223 inhibits proliferation of eosinophil precursors, while miR-21 promotes eosinophil precursor proliferative responsiveness to IL-5.[49] miRs have also been implicated in the development of myeloid leukemias in people.

DEVELOPMENTAL STAGES OF GRANULOPOIESIS

Committed neutrophil, eosinophil, and basophil precursors undergo a similar maturation sequence (Figure 41.2). The myeloblast is the earliest member of

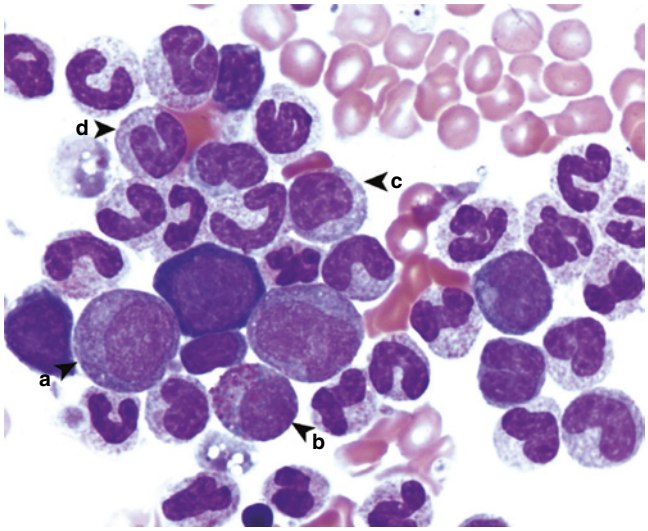

FIGURE 41.2 Granulocytic precursors in canine bone marrow aspirate. (a) promyelocyte; (b) eosinophilic myelocyte; (c) neutrophilic metamyelocyte; (d) band neutrophil. Wright–Giemsa stain; original magnification, 1000×.

granulocytic lineage recognizable by light microscopy. Myeloblasts are characterized by finely stippled chromatin, one to multiple nucleoli, and moderately basophilic cytoplasm. Initially, the cytoplasm lacks granules (type I myeloblast), but small numbers of primary or azurophilic granules begin to appear as myeloblasts mature (type II myeloblast). Promyelocytes (progranulocytes) are larger than myeloblasts and are characterized by increasing numbers of primary granules and decreasing cytoplasmic basophilia. A Golgi area may be apparent and is free of granules. The chromatin pattern remains finely stippled and nucleoli may or may not be present. As promyelocytes mature, primary granules become less apparent by light microscopy and secondary granules appear. Myelocytes are smaller than promyelocytes and are characterized by round to slightly oval nuclei with partially condensed chromatin and lightly basophilic cytoplasm containing secondary granules. Myelocytes are the earliest stage that commitment to a specific granulocytic lineage can most easily be discerned by light microscopy due to the presence of lineage-specific secondary granules. Myelocytes are the last stage at which cellular division occurs. For each myeloblast, there is the potential to produce 16–32 myelocytes.

Metamyelocytes and band granulocytes are no longer capable of cell division, but undergo nuclear maturation characterized by increasing condensation of chromatin and progressive nuclear segmentation. Metamyelocytes have bean-shaped to elongated nuclei, whereas bands have U- or an S-shaped nuclei with smooth, parallel sides. As these cells mature from metamyelocytes to bands, the cytoplasm becomes less basophilic and granule contents mature. Mature granulocytes have condensed chromatin and segmented nuclei with multiple lobes. The degree of segmentation varies with granulocyte type and species (see Section IX). In general, segmented neutrophils have three to five lobes, whereas eosinophils may be bilobed. Mature basophil nuclei may appear monocytoid to bilobed.

NEUTROPHILS

Differentiation from CMPs to GMPs is stimulated by IL-3, GM-CSF, and IL-6. Commitment of GMPs to neutrophil production and proliferation and maturation of myeloblasts to mature segmented neutrophils is primarily driven by G-CSF. Although IL-6 can stimulate granulopoiesis and partially compensate for a lack of G-CSF in knockout mice, G-CSF is required for functional maturation of neutrophils by increasing adhesion factors, chemotactic activity, phagocytosis, and production of bactericidal factors.[35]

Development of myeloblasts to segmented neutrophils is associated with changes in cell surface expression of adhesion molecules and receptors.[15] In people, maturation from myeloblasts to segmented neutrophils is accompanied by decreased surface expression of adhesion molecules that regulate retention in bone marrow such as CD29, CD31 (platelet cell adhesion molecule-1, PECAM-1), CD33, CD49d (binds to vascular cell adhesion molecule, VCAM), and CD49e (binds to fibronectin). There is increased expression of other adhesion molecules associated with neutrophil rolling and adherence (e.g., CD11b, CD11c) as cells mature (see Chapter 45). There is decreased expression of CD54 (intercellular adhesion molecule-1, ICAM-1) during neutrophilic maturation, but expression can be reactivated when neutrophils are exposed to high concentrations of G-CSF during inflammation. Receptors for immunoglobulin (CD16 and CD32) and receptors for modifiers of complement activity (CD11b, CD11c, CD35, and CD55) increase with maturation.

The formation of neutrophil granules is sequential, and the production of granule contents is in step with maturation of the cells (see Chapter 42). A "targeting by timing" model suggests that formation of vesicles is continuous, but protein production and thus packaging of granule contents are sequential and coordinated by transcription factors and cytokines.[8,25] Azurophilic or primary granules contain myeloperoxidase and are the first granules to form as myeloblasts transition to progranulocytes. Synthesis of azurophilic granule proteins is under control of GATA-1, C/EBP-α, C/EBP-γ, c-Myc, and acute myeloid leukemia-1 (AML-1). As c-Myc and AML-1 decrease, protein synthesis transitions to those proteins associated with specific granules. Specific or secondary granules are characteristic of myelocytes and have a strict requirement for C/EBP-ε. C/EBP-ε RNA and protein peak at the myelocyte stage and halt entry into the cell cycle and proliferation. This allows neutrophils to move from the proliferative into the maturation pool. The proteins found in tertiary or gelatinase granules are produced during the metamyelocyte stage as C/EBP-ε falls and C/EBP-β, C/EBP-ζ, and C/EBP-δ increase. Secretory granules form in band and segmented neutrophils during final maturation. Because

of the continuous nature of vesicle formation, overlap in granule contents or subsets of granule types can occur.

Under basal conditions, bone marrow transit time for neutrophils (time to go from myeloblast to segmented neutrophil) is approximately 6 days in dogs, cats, and horses.[4,6,13,38] Production time for neutrophils in calves is 6 days, but neutrophils are held in the bone marrow for one additional day before release.[45,46] Delivery of neutrophils to blood is related to the rapidity with which neutrophils are depleted from the circulation.[45] Although the steady state bone marrow reserve of neutrophils is similar in dogs and calves, the proliferative capacity of bone marrow in calves appears to be less than dogs. If neutrophils are depleted from the circulation, dogs react with leukocytosis and bone marrow hyperplasia characterized by a shortened production time from 6 to 2–3 days.[4,45] There is no apparent shortening of transit time in calves.[45,49] The mechanism underlying the failure of cattle to increase granulopoiesis and shorten bone marrow transit time is uncertain.

Increased demand for neutrophils results in release of inflammatory cytokines and increased production of G-CSF.[26,35] G-CSF is a key mediator of neutrophil mobilization from bone marrow reserves, stimulator of granulopoiesis, and initiator of functional maturation of neutrophil precursors. Dogs, cats, horses, and cattle all show a robust response to administration of G-CSF characterized by neutrophilia and granulocytic hyperplasia in bone marrow.[9,10,16,29,32,41]

EOSINOPHILS

There may be species differences in eosinophilopoiesis. In mice, EoPs originate from GMPs, whereas EoPs appear to arise directly from CMP in human cell lines.[44] EoPs are distinguished by expression of c-kit^{lo} and the IL-5 receptor (IL-5Rα^{hi}). GATA-1 is critical for development of EoPs from GMPs.[44,49] In addition, C/EBP-α, C/EBP-β, PU.1, and interferon regulatory factor-8 (IRF-8) support commitment to EoP. Differentiation and maturation from EoP to eosinophils require C/EBP-β, GATA-1, PU.1, and Id2. miRs also modulate eosinophilopoiesis, with miR-21 enhancing and miR-223 suppressing production of eosinophils.

The main cytokines driving eosinophil production are IL-3, GM-CSF, and IL-5. Eosinophils appear to lack receptors for G-CSF.[31] IL-3 and GM-CSF play a role in the early steps of proliferation and commitment of EoPs, whereas IL-5 is required for proliferation, terminal differentiation, and functional maturation of eosinophils.[44] The IL-5R shares the same signal transducing βc with IL-3 and GM-CSF, but has a unique α-chain (IL-5Rα or CD125) to permit specific binding of IL-5. Thus, eosinophils differ from neutrophils in that βc signal transduction is required through all stages of eosinophil production and maturation. Th2 T helper cells are the primary source of IL-5. IL-5 also can be produced by mast cells, eosinophils, Tc2 cells, γδ T cells, NK cells, and epithelial cells.[43] In addition to its role in proliferation and differentiation of eosinophils, IL-5 prevents apoptosis, stimulates release of eosinophils from the bone marrow, promotes adhesion of eosinophils to endothelial cells, and activates eosinophil effector function. Overproduction of IL-5 is associated with peripheral eosinophilia in transgenic mice and is observed in various naturally occurring and experimentally induced hypereosinophilic conditions. Interestingly, IL-5 knockout mice have normal basal numbers of eosinophils in their bone marrow, but fail to develop tissue or blood eosinophilia when stimulated by a parasite infection or inhalant allergen.[14,25] This suggests that IL-5 is necessary for an expanded eosinophilic response to inflammatory stimuli.

Bone marrow production time from myeloblast to mature eosinophils takes 2–6 days.[19] Secondary granules continue to mature through the segmented stage. Production of specific granule proteins occurs in response to transcription factors. For example, production of major basic protein is controlled by combinations of GATA-1 or PU.1 with various isoforms of C/EBP.[44]

BASOPHILS

Committed BaPs originate from CD34+ myeloid progenitors in the bone marrow. Although the sequence of intermediaries between MPPs and BaPs remains unclear, studies using murine bone marrow cells suggest that basophils share a common progenitor with mast cells (BMCP) and originate from GMPs.[12,18] A second common progenitor, the pre-basophil/mast cell progenitor (pre-BMP), has been described in mice and expresses different surface markers from BMCP.[18] Subsequent differentiation to either BaPs or MCPs is regulated by sequential expression of transcription factors.[12] Upregulation of GATA-2 in conjunction with downregulation of C/EBP-α induces differentiation to BMCPs capable of differentiating into either basophils or mast cells. Subsequent reactivation of C/EBP-α results in committed BaPs and production of basophils.[1,12,18] Maturation of BaPs occurs in the bone marrow, and transit time from myeloblasts to mature basophils takes 2–3 days.[14] Basophil precursors require βc signal transduction initiated by IL-3 and GM-CSF for proliferation and differentiation. IL-5, nerve growth factor (NGF), and TGF-β also act as growth factors. Unlike other granulocytes, a lineage-specific factor has not been identified. Although IL-3 appears to be the main growth factor promoting differentiation and maturation of basophil precursors, it is not required for steady-state conditions in IL-3-deficient mice.[33] However, IL-3 is needed for accelerated production in response to parasites.[33] Both IL-3 and GM-CSF increase effector function of basophils by increasing histamine production through induction of histidine decarboxylase, increasing IL-4 and IL-13 production, and enhancing migration of mature basophils into tissues.

An apparent separate population of basophils can be stimulated by thymic stromal lymphopoietin (TSLP) produced by epithelial cells.[33] Progenitors for this basophil subset in mice develop in either the bone marrow or spleen and do not depend on IL-3. These TSLP-dependent basophils appear functionally distinct from IL-3-dependent basophils in that they express a different pattern of cytokines and inflammatory mediators. TSLP-dependent basophils do not require IgE cross-linking for activation, which may explain why anti-IgE therapies do not work in all basophil-mediated diseases.

MAST CELLS

Mast cell progenitors originate from CD34+ hematopoietic progenitors in the bone marrow. Early development remains unclear and studies suggest various pathways, including common BMCPs descended from GMPs or direct derivation from MPPs or CMPs.[1,12,40] In addition to species differences in derivation of MCP, there may be differences among mouse strains.[40] Commitment to mast cell production from GMPs or CMPs requires high expression of GATA-2. Subsequent suppression of C/EBP-α and increased expression of MITF distinguishes MCP from BaP.[33,40] Committed MCPs exit the bone marrow and undergo proliferation, differentiation, and maturation in mucosal and connective tissues.[12] At the time of migration, these MCPs lack mature granules and the high-affinity receptors for the Fc portion of IgE.[39]

IL-3 and SCF are the primary growth factors for mast cell development.[23,24] Unlike other granulocytic lineages, MCPs maintain high levels of c-kit, the receptor for SCF.[12,28] Stimulation of c-kit promotes proliferation and differentiation of mast cells, and its effects may be potentiated by coincubation with IL-3. In addition, SCF binding to c-kit inhibits apoptosis and prolongs survival of mast cells. SCF is chemotactic for immature and mature mast cells and helps localize mast cells to tissues.[11]

Acronyms and Abbreviations

BMAP, bovine myeloid antimicrobial peptide; BPI, bactericidal/permeability-increasing protein; eCATH, equine cathelicidin; e-NAP, equine neutrophil antimicrobial peptide; FMLP, formyl-methionyl-leucyl-phenylalanine; hCAP, human cathelicidin protein; K9CATH, canine cathelicidin; LAMP, lysosome-associated membrane protein; MIF, migration inhibitory factor-related proteins; MRP, migration-related proteins; MPO, myeloperoxidase; NADPH, nicotinamide adenine dinucleotide phosphate; Nramp1, natural resistance-associated macrophage protein 1; PMAP, porcine myeloid antimicrobial peptide.

Neutrophils provide the first line of defense against pathogens by phagocytosis and microbial killing via membrane receptor and cell signaling regulation of cytoplasmic content release. Neutrophil constituents also can result in tissue damage if not adequately regulated. Neutrophils have additional functions (see Chapter 43) and species differences (see Section IX). This chapter will provide an overview of neutrophil cellular contents, including granules, subcellular organelles, cytosol components, and membrane-associated receptors.

NEUTROPHIL STRUCTURE

Mature, segmented neutrophils are approximately 10–12 μm in diameter and contain granules and subcellular organelles. Studies have used electron microscopy, including immunologic techniques, and cell disruption with cavitation followed by density-gradient centrifugation to yield cell fractions for analysis. Scanning electron microscopy has identified numerous small pseudopodia that increase the surface area for receptor contact and phagocytic function (Figure 42.1).

Mature neutrophils have a lobulated nucleus, primarily composed of heterochromatin with a thin central strand of euchromatin, few nuclear pores, and rarely an observed nucleolus[2] (Figure 42.1). Mature neutrophil nuclei can synthesize both RNA and protein.[20] This is important when neutrophils migrate to sites of inflammation and synthesize proteins and chemokines that regulate activation and resolution of the innate immune response.[20]

With the exception of numerous granules, neutrophil cytoplasm contains few organelles and a variable number of glycogen particles. A thin rim at the periphery of neutrophils contains a small area with numerous cytoskeletal proteins.[2]

NEUTROPHIL GRANULES AND SPECIES COMPARISONS

Neutrophil granules contribute to the host defense against pathogens via their matrix content, membrane receptors, and enzymatic modification of tissues. Neutrophil granules contain (1) antimicrobial proteins directed against bacteria, fungi, protozoa, and some

viruses, (2) proteases, (3) components of the respiratory burst, and (4) receptors for endothelial adhesion molecules, extracellular matrix proteins, bacterial products, and soluble mediators of inflammation.[6] Neutrophil granules have a phospholipid bilayer membrane surrounding an intragranular matrix that contains proteins for either exocytosis into the surrounding tissue environment or fusion with a phagosome. These proteins must be properly packaged and exocytosed in order to prevent widespread host tissue damage.[17]

Due to the potential for granule-induced tissue damage, feedback mechanisms occur whereby neutrophils can modulate their local responses and limit host tissue damage.[16] Human neutrophil primary granules contain anti-inflammatory proteins, including alpha$_1$-acid glycoprotein, an acute phase protein that modulates the expression of anti-inflammatory cytokines by macrophages, decreases neutrophil chemotaxis, and has other anti-inflammatory functions.[16] Alpha$_1$-acid glycoprotein recently was confirmed in bovine neutrophil granules.[16]

The granule types and contents have been best characterized in human neutrophils, from which much of the information is derived. In human neutrophils, well-defined granule types are primary (azurophil or myeloperoxidase-positive), secondary (specific), and tertiary (gelatinase) granules; the latter two are both peroxidase-negative. Secretory vesicles will be discussed separately from granules (Table 42.1).[1,3,6,24]

Species-specific distribution of granules and contents can be difficult to compare due to the use of different techniques for neutrophil analysis, such as fraction separation by centrifugation versus whole cell analysis.[24] Most species have neutrophil primary and secondary granules that retain the major enzymes. Some domestic animal species appear to have a third granule type that differs from tertiary granules of human neutrophils.[2] Granule differences in species may impact host response to the pathogenicity of microorganisms; however, this is not well-defined or correlated. This section will address neutrophil granule formation, release, and contents, and the known variations for species.

Neutrophil Granule Formation

Neutrophil granules are a continuous spectrum with differential production of granule contents during neutrophil development (Table 42.1). Primary granules are the first to be formed in the promyelocyte stage, while secondary granules are formed during the myelocyte and metamyelocyte stages.[3] Tertiary granules and secretory vesicles form in the references differ on including metamyelocyte, band and segmented neutrophil stages.[6]

Subsets of primary and secondary granules have been described based on variation in granule contents. Heterogeneity of granule proteins occurs due to segregation of proteins into their respective granules by timing of biosynthesis rather than sorting.[6,9] In this process, the proteins are produced by the endoplasmic reticulum in response to transcription factor expression at specific stages of neutrophil development. For example, primary granules are formed during the promyelocyte stage, when myeloperoxidase is expressed.[6]

Neutrophil Granule Release

The separation of proteins into different granules serves to (1) separate proteins to decrease the risk of untoward enzyme activation, protein degradation, or cellular damage, and (2) allow differential exocytosis of proteins based on varying neutrophil stimulation. This allows the availability of proteins for multiple neutrophil functions (Table 42.1).

Granule release is dependent on receptor-mediated neutrophil stimulation by a variety of molecules. Formyl-methionyl-leucyl-phenylalanine (FMLP), a

bacterial peptide used in vitro as a neutrophil activator, has species variation in neutrophil activation responses. FMLP activates neutrophils of humans, nonhuman primates, rabbits, guinea pigs, and mice; however, neutrophils of cattle, pigs, dogs, and cats have no FMLP response possibly due to a lack of FMLP receptors.[24]

When neutrophil granules are released, their primary and secondary granule contents are released into the phagocytic vacuole (phagosome), and secondary and tertiary granule contents are released into the extracellular environment.[3] During exocytosis, the granule or vesicle membrane becomes incorporated into the phagosome or neutrophil membrane, respectively. Membrane fusion is crucial, since the granule and secretory vesicle membranes contain many different receptors necessary for neutrophil extravasation, chemotaxis, migration, and immunomodulation.

There is significant overlap in the protein content and function of neutrophil granules; however, there is a general order of their exocytosis inversely related to the order of the granule formation.[6,14] First, secretory vesicles, that facilitate adhesion, are rapidly and completely mobilized during early neutrophil–endothelial interactions while L-selectin is simultaneously shed from the neutrophil surface.[6,19] The vesicles incorporate the vesicle adhesion proteins (e.g., CD11b/CD18), chemoattractant receptors, and complement receptors into the neutrophil cell membrane to permit firm adhesion.[19] This resulting firm adhesion to the endothelium aids in subsequent diapedesis and chemotaxis.[6] Second in order of release are tertiary granules that aid in neutrophil extravasation and migration via matrix-degrading enzymes, including gelatinase and membrane receptors.[6] Third to release are secondary granules that contain antimicrobial substances for microbial destruction and matrix-degrading metalloproteinases that aid in neutrophil tissue infiltration. Last to release are primary granules for microbial destruction that require the greatest stimulus to enter the phagosome for pathogen killing.[6]

Primary (Azurophilic) Granules

Primary granules form during the promyelocytic neutrophil stage and contain many antimicrobial compounds. In most species, except the bovine, primary granules are the largest and most dense granules,[2] and have heterogeneity in size and shape.[6] The major function of primary granules is the secretion of proteolytic enzymes and antimicrobial peptides into the phagocytic vacuole for pathogen killing. Many proteins in the primary granules are synthesized as preforms, but the propeptides are removed during granule maturation and are stored as an active conformation.[6] Additionally, the granule membrane contains a large amount of CD66c and CD63 antigens that have interactions in signaling and membrane adhesion.[20]

Primary granules contain myeloperoxidase (MPO), a potent microbicidal hemoprotein, that contributes to oxygen-dependent pathogen destruction by catalyzing the production of hypochlorite (OCl^-) from chloride and hydrogen peroxide produced by the oxidative burst.[6,14] MPO activity is typically lower in animals compared to humans, except for dogs and nonhuman primates.[18,24] The majority of studies have not detected MPO activity in chicken heterophils, but one study detected a partial DNA sequence and weak MPO activity.[12]

Other proteins within primary granules include cationic alpha-defensins that are powerful pore-forming antimicrobial peptides produced during the promyelocyte and myelocyte stages. Early forming primary granules are defensin-poor and later forming primary granules are defensin-rich.[6] Defensins kill a variety of bacteria, fungi, and viruses (see Chapter 43).

Alpha-defensins also have been identified in neutrophils of rabbits, guinea pigs, and hamsters, but not in mice, cattle, pigs, and birds. Beta-defensins have been identified in neutrophil dense granules of cattle and in avian heterophils, but not in sheep neutrophils.[13] Theta-defensins are in granulocytes of rhesus macaques and other Old World monkeys and orangutans, but not in great apes, humans, and New World monkeys.[13] Horse neutrophils contain only trace amounts of defensins, but do contain significant amounts of equinins (equine neutrophil antimicrobial peptides, e-NAP1 and e-NAP2). These novel proteinase inhibitors have antibacterial and antiviral activities but are structurally different from defensins.[4,15]

Human primary granules contain elastase and beta-glucuronidase that have a role in bacterial killing and endothelial cell and tissue damage during inflammation. A small degree of elastase activity is present in horse and pig neutrophils versus a large amount in rabbits.[24] Beta-glucuronidase has variable concentrations in the neutrophils of many species.[24]

Other human primary granule proteins include bactericidal/permeability-increasing protein (BPI), serprocidins, and granzyme B. BPI binds lipopolysaccharide (LPS) of Gram-negative bacteria, inducing growth inhibition, membrane damage, and mediation of bacterial phagocytosis.[6] Serprocidins, including elastase, cathepsin G, and proteinase 3, degrade extracellular matrix, aid in microbial death, and regulate the immune response.[11] Granzyme B is proposed to act on extracellular targets to enhance neutrophil migration through extracellular matrix and regulate apoptosis or activation in other cell types.[25]

Secondary (Specific) Granules

Secondary granules, formed during myelocyte and metamyelocyte stages, are smaller, less dense, and more numerous than primary granules (Figure 42.1).[2] They can be round, oval, elongated, or dumbbell-shaped.[1,6] Secondary granules have two major functions: (1) antimicrobial activity via peptides and proteases secreted into the phagocytic vacuole to destroy pathogens, and (2) tissue alteration assisting neutrophil migration via matrix metalloprotease release into the extracellular space.[3] Enzymes in secondary granules are stored as inactive latent proforms and are activated upon exocytosis.

The membrane of secondary granules contains membrane-bound molecules that are expressed on the cell surface, including CD11, CD18, CD66a, CD66b, NB-1 (CD177), FMLP receptors, C5a receptors, and cytochrome b_{558}, a component of NADPH oxidase.[6] When cells are stimulated, the surface expression of membrane proteins is increased, and some of the upregulated molecules may be derived from secondary granules. The importance of secondary granules in neutrophil function is apparent in people who lack secondary granules, since these patients are susceptible to repeated skin and respiratory infections, and have defective neutrophil chemotaxis and adhesion.

A major secondary granule component is apolactoferrin, an iron-binding protein that appears to (1) prevent bacteria from obtaining iron that is necessary for growth,[20] (2) modify hydroxyl radical formation, and (3) alter cell adhesion.[20] Haptoglobin released from secondary granules also can inhibit bacterial growth and inflammation.[20]

Secondary granules contain large amounts of antimicrobial substances, especially lactoferrin. Other antimicrobial proteins include hCAP-18 (a cathelicidin), alkaline phosphatase, and lysozyme.[6] Although defensins are stored in primary granules, some human neutrophil defensin-type proteins are stored in secondary granules and then constitutively exocytosed.[7] Collagenase and a small amount of gelatinase act as matrix-degrading enzymes. Release of collagenase augments neutrophil movement through degraded collagen, modifies the inflammatory process, and results in tissue remodeling.[20]

There are limited studies of animal secondary granules. Neutrophil antimicrobial lysozyme was deficient in monkeys, cattle, goats, sheep, cats, and hamsters, and only a small amount of activity was detected in horses, dogs, rats, and guinea pigs.[18,24] Alkaline phosphatase was undetectable in rhesus monkeys, cats, some mouse strains, chickens, and geese, and was low in dogs.[18] Cathelicidins were found in neutrophils of dogs (canine cathelicidin (K9CATH)), horses (equine cathelicidin (eCATH)), cattle (bactenecins, bovine myeloid antimicrobial peptide (BMAPs)), sheep, pigs (protegrins, prophenins, porcine myeloid antimicrobial peptide (PMAPs)), rabbits, guinea pigs, rats, mice, and birds.[13]

Tertiary (Gelatinase) Granules

Tertiary granules, formed during, band and segmented neutrophil stages, are slightly smaller than secondary granules, and fewer in number.[1,10] The major function of tertiary granules is via matrix metalloproteases and receptors required for neutrophil diapedesis and migration.[10] During neutrophil stimulation, both secondary and tertiary granules contain membrane proteins that are upregulated to the cell surface. These granule membranes contain important receptors and proteins, including natural resistance-associated macrophage protein 1 (Nramp1) that may deprive microorganisms of divalent cations.[3,6] The matrix of human neutrophil tertiary granules contains a large amount of gelatinase, released as a major matrix-degrading enzyme,[9] and small amounts of lactoferrin and lysozyme.[1]

Many species, including cattle, sheep, goats, dogs, cats, rabbits, rats, guinea pigs, and horses, have a third granule type that differs from human tertiary granules.[2]

In cattle, these granules are referred to as "large" or "dense" granules, and are the largest (0.4–0.5 μm) and most numerous in mature neutrophils.[8,27] These granules are readily mobilized and responsible for the majority of bovine neutrophil antimicrobial activity, containing lactoferrin, bactenecins (members of the cathelicidin family), and beta-defensins.[27] These are the only neutrophil granules known to contain defensins in bovine neutrophils, in contrast to human neutrophils where defensins are predominantly stored in primary granules.[27]

SECRETORY VESICLES

Secretory vesicles are structures similar to granules that are: 100–200 nm, widely distributed within the cytosol,[19] and identified on electron microscopy as smooth-surfaced vesicles by double-labeling with anti-albumin and either anti-CD11b/CD18 (Mac 1) or anticytochrome b_{558} antibodies.[1] The major function of secretory vesicles is their facilitation of neutrophil adhesion to endothelial cells via their protein and receptor content. In contrast to granules, secretory vesicles lack antimicrobial enzymes. Secretory vesicles contain proteins acquired from endocytosis of plasma (primarily albumin); therefore, they are classified as endocytic vesicles rather than true granules.[1,6]

Secretory vesicles provide an intracellular reservoir from which membrane proteins can be rapidly recruited to the cell surface after weak stimulation.[20] Secretory vesicles can be upregulated to the cell surface in the absence of extracellular calcium, in contrast to secondary and tertiary granules, which require extracellular calcium for release.[20]

Although lysosomes have not been identified in neutrophils, secretory vesicle membranes contain CD63 (lysosome-associated membrane protein-3; LAMP-3) and CD68, but they do not have LAMP-1 or LAMP-2.[1,5] Therefore, secretory vesicles are referred to as regulated secretory granules or lysosome-related organelles.[5] Additionally, secretory vesicle membranes contain many receptors important in extravasation and phagocytosis, including CD11b/CD18, CR1, FMLP-receptor, and CD14. Secretory vesicles also contain alkaline phosphatase, cytochrome b_{558}, and FMLP receptors.[20] Their matrix contains plasma proteins, including albumin.[1,19]

NEUTROPHIL PLASMA MEMBRANE

Constituents of the neutrophil plasma membrane include (1) membrane channels, (2) adhesive proteins, such as CD11/CD18 and CD62L (L-selectin), (3) receptors for various ligands, such as FMLP and C5a receptors that sense stimuli and activate neutrophils, (4) ion pumps, and (5) ectoenzymes. Neutrophil membrane CD13 can inactivate interleukin (IL)-8, eliminating its chemotactic activity, and neutrophil endopeptidase CD10 can inactivate the chemotactic peptide FMLP.[20] CD66 (a, b, c) can activate neutrophils,[20] and some CD45 antibodies inhibit neutrophil chemotaxis.[20] The components of the neutrophil membrane are not uniformly distributed and the membrane can increase the surface area for increased receptor–ligand interactions.

Studies also have indicated the presence of differentiated domains in the membrane called "lipid rafts." These rafts are large noncovalent complexes in cell extracts that contain important signaling molecules, including protein kinases and glycosyl phosphatidylinositol-linked membrane proteins.[20,21] These clusters of molecules may be important in transmembrane signaling by proteins in the complex, and proteins may enter these rafts when they are translocated to the cell surface.[21]

Lipids and carbohydrates also are important to neutrophil structure. Approximately half the neutrophil cellular phospholipid is within neutrophil membranes and secretory vesicles.[20] Neutrophil phospholipids are important sources of inositol 1,4,5-trisphosphate (IP3, a signal-transduction molecule involved in calcium release) and diacylglycerol, which activates protein kinase C. Arachidonic acid in phospholipids, especially phosphatidylcholine, is an important precursor for the production of leukotrienes, prostaglandins, thromboxanes, and lipoxins.[20] Cholesterol and triglycerides constitute most of the non-phospholipid neutrophil lipids.

NEUTROPHIL CYTOPLASM

Neutrophil cytoplasm contains many components common to all cells. A unique aspect is approximately 45% of neutrophil cytosolic proteins consist of migration inhibitory factor (MIF)-related proteins, also known as migration-related proteins (MRP). These cytosol proteins are loosely associated with the neutrophil plasma membrane and within secondary and tertiary granules.[23] MIF/MRP proteins are part of the S100 protein family of calcium-binding proteins expressed by circulating human neutrophils and monocytes. The quantity of MIF/MRP proteins associated with neutrophil plasma membranes increases after stimulation, with a role in neutrophil-mediated inflammation and cytokine production.[23]

Additional cytoplasmic components include annexin I (lipocortin I) that comprises approximately 3% of cytosolic proteins.[20] Annexin I is partially regulated by glucocorticoids and appears to be a mediator of the anti-inflammatory effects of glucocorticoids. Another notable cytoplasmic constituent is glycogen that enables neutrophil energy production via glycolysis and neutrophil function in low extracellular glucose environments.

Cytoplasmic lipid bodies, which are non-membrane-bound cytoplasmic inclusions, provide stores of esterified arachidonate for localized signaling proteins.[26] Their increase during inflammation is stimulated by cis-fatty acids and diglycerides, and is mediated by protein kinase C.

Like many cells, neutrophils contain a complex cytoskeleton that enables neutrophil chemotaxis,

phagocytosis, and exocytosis. Many proteins of this cytoskeleton have been identified, including actin, actin-binding protein, α-actinin, gelsolin, profilin, myosin, tubulin, and tropomyosin. Actin accounts for approximately 10% of neutrophil protein, and is critical for the mobility and migration of neutrophils.[22]

- Neutrophils in Cancer

Acronyms and Abbreviations

ANCAs, antineutrophil cytoplasmic antibodies; ARDS, acute respiratory distress syndrome; BAFF, B-cell-activating factor; BPI, bacteria permeability-enhancing factor; C, γ subfamily of chemokines; CC, β subfamily of chemokines; CXC, α subfamily of chemokines; CX_3C, δ subfamily of chemokines; CXCL8, interleukin-8; DAMPs, damage-associated molecular patterns; DC, dendritic cell; ECM, extracellular matrix; fMLP, N-formyl-methionyl-leucyl-phenylalanine; G-CSF, granulocyte colony stimulating factor; IBD, inflammatory bowel disease; ICAM, intercellular adhesion molecule; IFN-γ, interferon-gamma; IL, interleukin; IMHA, immune-mediated hemolytic anemia; LT, leukotriene; LPS, lipopolysaccharide; LFA-1, lymphocyte function-associated antigen-1; MPO, myeloperoxidase; NADPH, nicotinamide adenine dinucleotide phosphate; NETs, neutrophil extracellular traps; NK cells, natural killer cells; PAMPs, pathogen-associated molecular patterns; PRR, pattern-recognition receptors; PSGL-1, P-selectin glycoprotein ligand-1; ROS, reactive oxygen species; SIRS, systemic inflammatory response syndrome; SLE, systemic lupus erythematosus; TNF-α, tumor necrosis factor-alpha; VCAM-1, vascular cell adhesion molecule-1.

Neutrophils are the major pathogen-fighting innate immune cells recruited to sites of infection/inflammation to recognize, phagocytose, and kill pathogens through cytotoxic mechanisms, including production of reactive oxygen species (ROS), release of antimicrobial peptides, and expulsion of nuclear contents to form neutrophil extracellular traps (NETs). The overwhelming infections of cattle, dogs, and cats with either severe neutropenia or neutrophil adhesion deficiencies highlight the importance of functional neutrophils in immunity.[4,18] Neutrophils also play a complex role in the development of the adaptive immune response and in controlling inflammation. When unchecked, neutrophils can also affect significant host tissue damage, making neutrophils central in the development of many inflammatory and immune-mediated diseases.[24] This chapter reviews neutrophil function and the role of neutrophils in adaptive immunity, inflammation, and tissue injury.

NEUTROPHIL RECRUITMENT

Neutrophils originate in the bone marrow and reach sites of tissue inflammation or infection via the vasculature.[32] Neutrophils are considered to survive in circulation for 8–12 hours and up to 1–2 days in tissues, but based on recent studies they may actually circulate for up to 5 days.[41] The egress of neutrophils from blood occurs primarily in postcapillary venules mediated by the sequential interaction of neutrophil receptors and their ligands that are expressed on activated endothelial cells during inflammation (Figure 43.1).[24] During recruitment, neutrophils (1) attach (tether) to the endothelium, (2) roll along the endothelium, (3) arrest and spread on endothelium, (4) crawl along the endothelium, (5) transmigrate into tissues, and (6) activate and then phagocytose and/or kill pathogens via production of ROS, degranulation, and generation of NETs.[24]

NEUTROPHIL ROLLING

Rolling of neutrophils on the endothelium is mediated by selectins, which are type I integral membrane proteins that recognize specific glycan structures. L-selectin (CD62L) is expressed by leukocytes, E-selectin (CD62E) is expressed by endothelial cells, and P-selectin (CD62P) is expressed by platelets and endothelial cells. P-selectin glycoprotein ligand-1 (PSGL-1) is the main glycoprotein ligand on neutrophils for endothelial and platelet P-selectin, and also is the primary ligand on endothelium for neutrophil L-selectin.[24,50]

Rolling is initiated by inflammatory mediators that induce endothelial surface expression of P-selectin and E-selectin. Endothelial selectins tether or capture free-flowing neutrophils by binding to their respective neutrophil ligands. To reach target tissues, neutrophils must roll along the vascular endothelium during high shear stress which they accomplish with a system of tethers

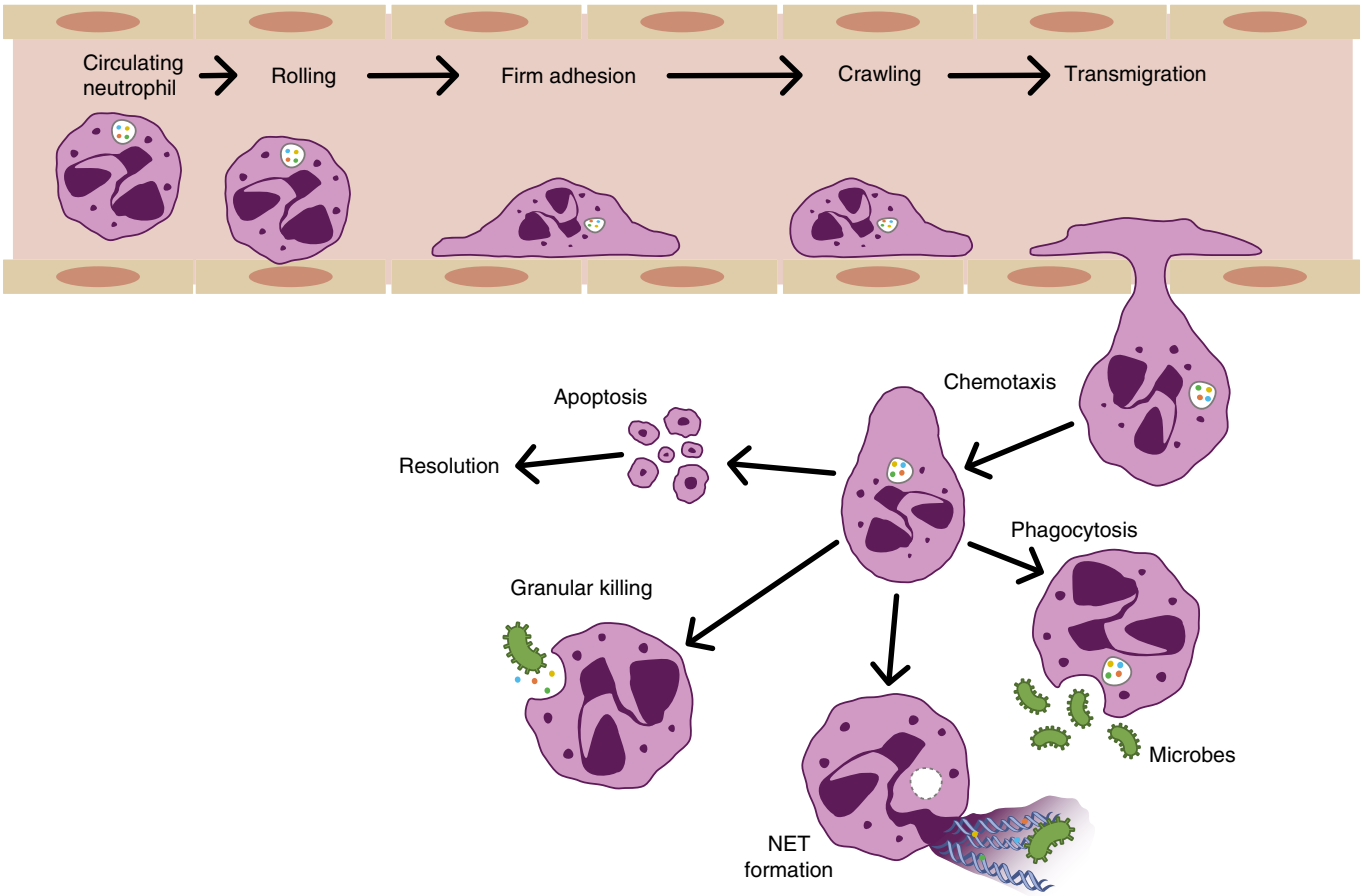

FIGURE 43.1 Antimicrobial activity of neutrophils is a multistep process. Neutrophils in flowing blood accumulate first by direct capture. The tethered neutrophils then roll utilizing slings to slow their rolling and become activated by chemokines. This leads to firm adhesion, crawling, and paracellular or transcellular endothelial migration. Rolling is mostly selectin-dependent, while adhesion, crawling, and transmigration are integrin-mediated. Upon entering tissues, neutrophils migrate toward chemotactic gradients and eliminate pathogens via phagocytosis, release of granular enzymes into phagosomes or extracellularly, or by release of neutrophil extracellular traps (NETs). Pathogen killing inside the phagosome occurs by reactive oxygen species generated by NADPH oxidase and by enzymes released from intracellular granules. Phagocytosis induces neutrophil apoptosis and subsequent clearance by macrophages and ultimately resolution of inflammation. (**Source:** Courtesy of Andrew Kingsbury, Center for Food Security and Public Health, Iowa State University)

and slings. Neutrophils form PSGL-1-mediated temporary tethers behind them that slow rolling, which then pull off the endothelium and sling to the front of the neutrophil, further slowing rolling.[24,47]

Neutrophil Adhesion and Crawling

Following rolling, integrins mediate neutrophil firm adhesion to the endothelium. During rolling, neutrophils are exposed to endothelial chemokines that activate neutrophils and cause integrin conformational changes. These integrin changes enable neutrophils to bind their endothelial ligands.[24] Integrins consist of noncovalent heterodimers (α and β subunits) of transmembrane glycoproteins with subfamilies organized around a particular subunit.[16] β_2 integrins are expressed in an inactive form on neutrophils and other leukocytes. These integrins undergo rapid affinity changes when stimulated by chemoattractants. Four known α (CD11) subunits combine with one common β (CD18) subunit to form unique β_2 integrins; CD11a, b, c, and d. $\alpha_M\beta_2$ (CD11b/CD18, Mac-1, complement receptor 3) is the most abundant integrin on neutrophils, and also is expressed on monocytes, macrophages, natural killer (NK) cells, and lymphocytes.[1] Mac-1 functions include (1) interacting with intercellular adhesion molecules (ICAMs) expressed on resting endothelium and induced on many cell types by inflammatory cytokines, (2) binding to denatured proteins to serve as a scavenger receptor, and (3) binding to iC3b on microbial surfaces with resulting phagocytosis of opsonized pathogens.[1] Following neutrophil activation, intracellular stores of Mac-1 relocalize to the cell surface and Mac-1 changes conformation enabling firm adhesion to endothelial ligands.[24]

The other important neutrophil β2 integrin is $\alpha_L\beta_2$ (CD11a/CD18, lymphocyte function-associated antigen-1 (LFA-1)). Although predominately expressed on lymphocytes, neutrophil LFA-1 binding to endothelial ICAM-1 enables firm adhesion.[24]

Following adhesion, neutrophils elongate and send out pseudopods, probing for endothelial junctions through which they can transmigrate. Neutrophils then crawl toward these junctions, releasing some of their bonds to move forward and form new endothelial adhesions. Active crawling depends on the interaction of neutrophil Mac-1 with endothelial ICAM-1.[24] Crawling also is a shear-driven process involving a complicated interplay of signaling molecules and actin-binding proteins.[24]

Neutrophil Extravasation

Neutrophils leave the vasculature by moving between endothelial cells (paracellular transmigration) and through endothelial cells (transcellular transmigration).[32] During paracellular endothelial transmigration, extensions of the endothelium rich in adhesion molecules (ICAM-1 and vascular cell adhesion molecule-1 (VCAM-1)) form domes around neutrophils (via neutrophil integrins LFA-1 and very late antigen 4) to limit vascular leakage as neutrophils leave the vasculature.[24,32] Although paracellular migration is the prime means of neutrophil egress, transcellular migration may be preferred when endothelial junctions are especially tight, such as at the blood–brain barrier.[32]

CHEMOTAXIS

Once extravasated, neutrophils respond and bind to chemotactic molecules in a hierarchal manner (chemotaxis) to reach inflammatory sites, and find their ultimate target through complex signaling. Neutrophils become less sensitive to initial chemokines, and continue to migrate toward end target chemoattractants, such as bacterial peptide N-formyl-methionyl-leucyl-phenylalanine (fMLP) and/or complement components (C5a and C3a), which override other chemotactic signals such as those released by endothelium.[12,24] In addition to fMLP and complement, potent chemoattractants for neutrophils include interleukin (IL)-8 (CXCL8), platelet-activating factor, and leukotrienes (LTs).[18]

The chemokine system involves greater than 50 distinct chemokines, produced constitutively or in response to inflammatory stimuli by a variety of cells, and over 20 G-protein-coupled chemokine receptors.[36] Chemokines have been classified into four subfamilies based on the presence and placement of cysteine (C) residues at the amino terminus: (1) α subfamily (CXC), (2) β subfamily (CC), (3) γ subfamily (C), and (4) δ subfamily (CX_3C) where X represents noncysteine amino acids. Chemokines in subfamilies are named with the letter L (ligand) and given a number (e.g., CXCL8 = IL-8).[43] Each family of chemokines interacts with a reciprocal family of G-protein-coupled receptors, expression of which varies depending on the stage of leukocyte differentiation and stimuli.[17] When chemokines bind to their receptors on leukocytes, they induce conformational changes in cell-surface integrins such as Mac-1 and LFA-1, enabling neutrophil adhesion and locomotion.[24]

PHAGOCYTOSIS

After neutrophil entry into the tissues, neutrophil activation allows for rapid acquisition of phagocytic functions, ROS generation, release of granule proteins, and production of NETs. Neutrophil priming by lipopolysaccharide (LPS), tumor necrosis factor-alpha (TNF-α), and chemokines precedes neutrophil activation. Priming helps limit tissue damage by preventing premature neutrophil activation and granule release. However, misdirected neutrophil activation does occur in autoimmune and chronic inflammatory diseases.[32]

Neutrophils recognize pathogens via cell-surface and intracellular receptors. Neutrophil recognition receptors consist of (1) pattern-recognition receptors (PRR), such as toll-like receptors, engaged by pathogen-associated molecular patterns (PAMPs) or, during sterile inflammation, damage-associated molecular patterns (DAMPs),

(2) opsonic receptors such as complement receptors and FcγRs that detect C3 complement products and IgG, respectively, and (3) G-protein-coupled receptors that detect bacterial fMLP, chemokines, and endogenous inflammatory molecules.[32] The C-type lectin receptor PRRs recognize fungal β-glucan, allowing neutrophils to endocytose fungal pathogens. Although toll-like receptors are nonphagocytic, they prime neutrophil responses to other stimuli and increase their phagocytic capacity.[32] As detailed in the following text, the resulting phagocytic vesicle becomes a site for granular and oxidative microbial killing.

ANTIMICROBIAL MECHANISMS

Intracellular antimicrobial mechanisms within the neutrophil phagosome have generally been divided into oxygen-dependent and oxygen-independent mechanisms, but it is now known that these mechanisms are complexly integrated. Microbial killing is accomplished by lethal reactive oxygen species, granular enzymes, and NETosis.

Respiratory Burst and Generation of Reactive Oxygen Species

Oxygen-dependent mechanisms rely on membrane-bound NADPH oxidase.[2] The NADPH oxidase membrane-associated component, flavocytochrome b_{558}, is found in the cell and granule membranes, and becomes part of the phagosome membrane. Flavocytochrome b_{558}, a heterodimer of $gp91^{phox}$ and $p22^{phox}$, provides the conduit for pumping electrons from the cytosol to oxygen in the vacuole. When stimulated, the cytosolic *phox* components of NADPH oxidase are translocated to the membrane to join the flavocytochrome.[38] The NADPH oxidase complex catalyzes the reduction of molecular oxygen to the superoxide anion ($NADPH + 2O_2 \rightarrow NADP^+ + H^+ + 2O_2^{\bullet-}$), and the associated rapid consumption of oxygen is the "respiratory burst."

Neutrophils produce large amounts of $O_2^{\bullet-}$ that can combine with H_2O_2 to generate the highly reactive hydroxyl radical $OH^{\bullet}$ via the Haber–Weiss reaction ($O_2^{\bullet-} + H_2O_2 \rightarrow OH^{\bullet} + O_2 + OH^-$), which is preceded by the Fenton reaction: $Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH^{\bullet}$.[44] Myeloperoxidase (MPO) catalyzes the conversion of H_2O_2 and halide ions to hypohalous acids, primarily hypochlorous acid. Also, H_2O_2 interacts with hypohalous acids to produce high-energy singlet oxygen ($^1O_2$) that attacks double bonds. These ROS intermediates have a critical role in pathogen killing by targeting organism unsaturated lipids, carbon bonds, sulfhydryl and amino groups, nucleic acids, pyrimidine nucleotides, and enzymes.

Products of the respiratory burst also are toxic to host cells. Endogenous antioxidant systems protect cells from harmful oxidants and include cytosolic superoxide dismutase, glutathione peroxidase, glutathione reductase, and catalase, which can convert oxygen radicals to water and oxygen.[39]

Granular Killing

Antibacterial proteins are released from neutrophil granules into phagosomes or extracellularly, thereby enabling neutrophils to kill intracellular or extracellular pathogens.[24] In the phagosome, the NADPH oxidase system provides the ideal environment for granular proteases to achieve enzymatic digestion and microbial killing, which may actually be more important for neutrophil killing than its ROS generation.[44] Electrons pumped into the phagocytic vacuole by NADPH oxidase increase vacuolar pH, making it ideal for protease activity. Influx of potassium ions stimulates release of granular proteins from matrix proteins into a soluble, activated form. That granular enzymes require specific hypertonicity and alkaline pH for maximum activity limits their toxicity and damage to host tissues.[44]

The cationic antimicrobial peptides α-defensin and cathelicidin are major components of neutrophil primary (azurophilic) granules.[10] Defensins (1) mediate killing bacteria, mycobacteria, fungi, parasites, and viruses by forming transmembrane pores, (2) enhance antigen uptake and processing, and (3) stimulate chemotaxis of monocytes, macrophages, and mast cells.[33]

Bacteria permeability-enhancing factor (BPI) is a microbicidal protein in neutrophil primary granules with a high affinity for LPS and neutralizes LPS, thereby limiting inflammatory responses to gram-negative bacteria.[33]

Neutrophil granules contain serine proteases and acid hydrolases with microbicidal activity and different substrate specificities. Some proteases also assist with neutrophil migration by degrading extracellular matrix and cleaving adhesion molecules.[25,40] Serine proteases also modulate chemokine and cytokine activity and thereby inflammatory responses.[40]

Granule lactoferrin inhibits bacterial growth directly by microbicidal activity, indirectly by sequestering iron, an important microbial nutrient, and also reduces inflammation by binding LPS.[45]

Neutrophil Extracellular Traps

During NETosis, neutrophils release their nuclear material in a meshwork consisting of granular-derived antimicrobial proteins, enzymes, and histones.[5] Therefore, NETs are defined by the colocalization of chromatin with histones and granular proteins such as MPO and elastase. Since NETs ensnare pathogens in their meshwork of chromatin and expose them to high concentrations of antimicrobial peptides and enzymes, NETs are recognized as an important mechanism of extracellular microbial killing. Proteins confirmed to be present on NETs include antimicrobials (lactoferrin, defensins, and BPI), proteases (elastase), and enzymes required for ROS generation (MPO).[24] Histones themselves are antimicrobial. NETs have been confirmed to trap bacteria, viruses, fungi, and protozoan parasites.[24] Some bacteria increase their virulence by producing nucleases to escape the NET immune

response by degrading chromatin.[49] Animal models in which NETosis is inhibited have increased susceptibility to pathogens. NETs have been described in dogs, cats, horses, zebrafish, chickens, mice, rabbits, cattle, and humans.[6,8,19,28,37,42,51] NETosis occurs in response to numerous inflammatory stimuli, including combinations of inflammatory cytokines (e.g., IL-8), pathogens (bacteria, fungi, protozoa), and PAMPs.

NEUTROPHIL FATE

Neutrophils are short-lived cells due to constitutive apoptosis of senescent cells shortly after maturation.[35] After stimulation by pathogens or inflammatory mediators, neutrophils undergo apoptosis, necroptosis, or NET release. Extravasated neutrophils also may survive and undergo reverse migration, re-entering the vasculature, where they return to the bone marrow and likely die of apoptosis.[7,24]

Apoptosis

Following phagocytosis and intracellular killing of pathogens, neutrophils often die by apoptosis. During apoptosis, the cell forms apoptotic bodies which are cleared by phagocytic cells. Because intracellular contents are not released, the process is noninflammatory and is associated with wound healing and tissue repair.[32,35]

Necroptosis

Necroptosis is programed neutrophil necrosis that results in chromatin condensation and fragmentation, cell and organelle swelling, and plasma membrane rupture. Extracellular spillage of cell contents occurs inducing inflammation.[35]

NETosis

NETosis is a distinct form of cell death, and the process varies depending on the stimulus.[35] "Suicidal" or "lytic" NETosis induced by phorbol myristate acetate is a slow, NADH-oxidase-dependent process that ruptures the cell membrane leading to cell death.[7,35] "Vital" or "nonlytic" NET release, a rapid, ROS-independent process, often induced by bacteria or fungi, occurs by vesicular trafficking without membrane rupture leaving neutrophils viable.[35] Following vital NETosis, neutrophils can still perform chemotaxis and phagocytosis.[7] Both vital and suicidal NETosis depend on citrullination of histones to enable chromatin decondensation and NET formation. NET release is prevented by phagocytosis, so neutrophils containing phagocytosed bacteria do not subsequently release the bacteria during NETosis.[7] Details of NET clearance are unknown. Endogenous DNAse is speculated to degrade NETs, but macrophages may also phagocytose NETs.[7]

IMMUNOMODULATORY FUNCTION OF NEUTROPHILS

Neutrophils in the Adaptive Immune Response

In addition to their role in innate immunity, neutrophils also modulate the adaptive immune response by signaling other immune cells via soluble or surface molecules. Additionally, neutrophil microparticles can activate platelets and endothelial cells and suppress macrophage function.[32]

In inflammation, neutrophils recruit dendritic cells (DCs) via release of chemokines, lactoferrin, and defensins.[32] When DCs directly bind neutrophils, the neutrophils provide DCs access to their captured pathogens and stimulate DCs to become more effective antigen-presenting cells.[32] Stimulated neutrophils can serve as antigen-presenting cells by expressing low levels of major histocompatibility complex class II and costimulatory molecules.[32] Neutrophils can transport antigens to lymph nodes via lymphatics and present antigen to T cells or DCs. Neutrophils can activate splenic B cells via B-cell-activating factor (BAFF). Neutrophils also have immunosuppressive effects by releasing arginase which depletes L-arginine needed for T-cell proliferation.[32] Neutrophils regulate NK maturation in steady-state conditions, and neutrophil cytokine release during inflammation directly activates NK cells. Many NK-cell-derived cytokines prolong the life of neutrophils to further enhance the inflammatory process.

Neutrophil-Mediated Regulation of Inflammation

Neutrophils are active partners in the overall amplification and resolution of inflammation. Indeed, both pro- and anti-inflammatory subsets of neutrophils exist, but it is unknown if these subsets have different lineages or have adapted different capacities.[24] For example, only about a quarter of neutrophils produce NETs in response to *Staphylococcus aureus* stimulation.[7]

Neutrophils propagate inflammation by secreting inflammatory mediators such as LTs, prostaglandins, cytokines, and chemokines.[24] Neutrophils synthesize LTB4 that (1) primes and directly activates neutrophils, (2) is chemotactic for neutrophils, monocytes, and eosinophils, and (3) stimulates neutrophil aggregation, superoxide production, and integrin expression. Activated neutrophils secrete cytokines that amplify inflammation, including TNF-α, IL-1β, and IL-6 and produce interferon-gamma (IFN-γ), IL-10, and transforming growth factor-β, known to affect adaptive immunity.[14,18,48] Also, neutrophils secrete CC and CXC chemokines.[48]

In later stages of inflammation, neutrophils can be anti-inflammatory and promote tissue healing via growth factors that promote angiogenesis. The neutrophil lipid profile changes so that neutrophils produce lipoxin A4, which inhibits neutrophil migration and recruits monocytes to phagocytose neutrophils.[24] Neutrophils also recruit monocytes to inflamed tissues via release of cytokines.[24] Macrophage phagocytosis of apoptotic neutrophils yields decreased macrophage

IL-23 production, which ultimately leads to decreased granulocyte colony stimulating factor (G-CSF) and decreased marrow neutrophil production.[32] Macrophage phagocytosis of apoptotic neutrophils also results in macrophage production of IL-10, which promotes tissue repair.[32]

NEUTROPHILS IN DISEASE

Not only do they participate in infection control, but neutrophils play a central role in many inflammatory and autoimmune diseases due to their capacity to cause host tissue damage and promote thrombosis. Uncontrolled release of neutrophil granules or oxidative products during phagocytosis is a major cause of tissue damage. Neutrophil granules may fuse with the phagosome before it is completely sealed, releasing cytosolic contents and oxidative products into tissues.[32] Neutrophil phagocytic receptors may detect immune complexes or complement along large surfaces, such as endothelial cells, and subsequently fail to completely engulf these complexes.[32] The subsequent release of neutrophil granules and oxidative products can lead to endothelial damage, vasculitis, and thrombosis. While NETs serve important antimicrobial functions, they have the potential to cause significant host tissue damage, autoimmunity, and thrombosis.

Neutrophils in Acute Inflammatory Disease

In veterinary medicine, localized neutrophil-mediated lung injury occurs due to *Mannheimia haemolytica*. Cattle studies have documented rapid neutrophil recruitment into the lungs within 2 hours, and associated fibrinopurulent pneumonia, endothelial disruption, and alveolar epithelial swelling.[46] Neutrophil depletion before inoculation of *M. haemolytica* into the lungs markedly attenuates alveolar capillary endothelial injury, supporting the role of neutrophil-mediated tissue damage.[46]

Similarly, activated neutrophils create much of the microvascular injury in acute respiratory distress syndrome (ARDS).[26,53] Neutrophils in the pulmonary microvasculature exceed those in circulation by up to fivefold making them ideally poised to respond to insult, but also to cause bystander damage.[53] Neutrophils lodge in extensive pulmonary capillary beds, becoming activated and releasing oxygen radicals and granule contents onto the endothelial surface. Subsequent endothelial injury results in (1) massive leakage of plasma into alveoli, (2) maldistribution of blood flow, and (3) disturbances of oxygen transport and utilization, leading to dyspnea and hypoxemia.[53] Increased production and decreased clearance of NETs likely contribute to pathogenesis of ARDS in people as well.[15]

In mice during early sepsis, NETs provide protective antimicrobial effects by preventing bacterial dissemination; however, later NET-induced host tissue damage outweighs their protective effects.[30,49] Canine and equine neutrophils release NETs in response to LPS, and NETs have been documented in the lungs and in abdominal and pleural effusion samples from septic dogs.[27]

Neutrophils in Thromboembolic Disease

Neutrophils play a central role in immunothrombosis, which can be protective by trapping bacteria, but can result in excessive clot formation. Neutrophilia is associated with increased thrombotic risk and thrombosis causes significant morbidity and mortality in human and veterinary patients.[35] Local and disseminated activation of coagulation frequently accompanies sepsis.[52] Neutrophils can trigger microvascular thrombosis by causing endothelial injury via degranulation, which converts the endothelial surface to a procoagulant surface that binds and activates platelets. Activated neutrophils and activated endothelial cells express a potent platelet agonist, platelet-activating factor.[34] Activated platelets expose their surface P-selectin that interacts with neutrophil surface PSGL-1 forming platelet–neutrophil aggregates. Platelet–neutrophil aggregates are rigid, lodge in capillary beds, and initiate microvascular thrombotic events.[35] Platelet–neutrophil interactions and activated platelet mediator release stimulate nearby neutrophils to generate NETs, which are prothrombotic.[32,35]

NET histones activate platelets and increase thrombin generation. Also, NETs bind factor XII and activate the contact coagulation pathway, increasing the rate of clot formation and stabilizing clots by inhibiting fibrinolysis.[20,31] NET-associated elastase further promotes clot formation by degrading anticoagulants such as tissue factor pathway inhibitor.[31] Additionally, NETs directly inhibit intravascular blood flow and provide a binding site for circulating hemostatic cells and factors.[35] Many animal models of thrombosis depend on NET formation, and NETs are implicated in thrombosis in a multitude of diseases including thrombotic microangiopathies, disseminated intravascular coagulation, and deep vein thrombosis in people.[22,23,31] NETs are present in dogs with immune-mediated hemolytic anemia (IMHA) and may play a role in thrombotic outcomes in this disease.[21]

Neutrophils in Immune-Mediated Diseases

Neutrophils are implicated in autoimmune diseases as direct effector cells that induce tissue injury and as immune-modulating cells. Autoantibodies such as antineutrophil cytoplasmic antibodies (ANCAs) can directly activate neutrophils.[32] ANCA-activated neutrophils can initiate a cascade of increasing inflammation and autoantibody production by releasing NETs, damaging endothelium, and promoting B-cell differentiation via release of BAFF.[32] In systemic lupus erythematosus (SLE) and rheumatoid arthritis, neutrophil recognition of immune-complexes can result in neutrophil activation to establish a self-amplifying loop of inflammation.[32] Neutrophils also promote autoimmunity via NETosis, since NETs expose autoantigen like proteins and nucleic acids in an inflammatory environment.[3] In SLE, there is increased NET formation and decreased NET clearance

due to reduced DNase activity and inhibition of DNase access to NETs by antibodies.[3]

Neutrophils in Inflammatory Bowel Disease

Neutrophils have a role in inflammatory bowel disease (IBD) including Crohn's disease and ulcerative colitis in people and in enteropathies in dogs.[32] In IBD, the degree of intestinal neutrophil infiltration correlates with disease severity. Based on animal models, the IBD pathogenesis appears due to neutrophil transepithelial migration resulting in mucosal barrier breakdown and ROS damage to epithelial integrity.[32] ANCAs are found in human IBD patients and likely contribute to disease pathogenesis. ANCAs are reported in canine chronic enteropathies and correlate with a positive response to strict elimination diets.[11,29]

Neutrophils in Cancer

The relationship between neutrophils and cancer cells is complex with both neutrophil protumorigenic and antitumorigenic effects. Neutrophil chemoattractant chemokines are produced by tumor cells, and increased tissue neutrophils have been associated with increased tumor growth and a poor prognosis.[13,32] Neutrophil tumor-promoting aspects include (1) neutrophil proteinase basement membrane degradation enabling tumor growth and metastasis and 2) neutrophil suppression of other immune effector cells.[32] By contrast, neutrophil antitumor effects include (1) direct killing of tumor cells via ROS, (2) neutrophil-induced apoptosis of tumor cells, and (3) neutrophil presentation of tumor antigens to T cells.[32] The balance between these opposing functions varies in individual patients and cancers. Animal cancer models and studies in human patients suggest a role for NETs in cancer progression. NET-associated elastase may directly induce tumor cell proliferation, NETs may provide a scaffold for metastasizing tumors, and NETs are involved in tumor-associated thrombosis.[9]

Acronyms and abbreviations

ACTH, adrenocorticotropic hormone; BLAD, bovine leukocyte adhesion deficiency; BVDV, bovine viral diarrhea virus; CGD, chronic granulomatous disease; CLAD, canine leukocyte adhesion deficiency; FeLV, feline leukemia virus; G-CSF, granulocyte colony stimulating factor; LAD, leukocyte adhesion deficiency; FLAD, feline leukocyte adhesion deficiency; IBRV, infectious bovine rhinotracheitis virus; MPS, mucopolysaccharidosis; NEFA, non-esterified fatty acid; P–H, Pelger–Huët.

Because neutrophilic phagocytosis is a complex multistep mechanism, several steps may be influenced by inherited or acquired defects. This ultimately leads to an overall decrease of neutrophilic phagocytic activity with increased susceptibility to bacterial infections. For some inherited diseases, the precise molecular mechanisms have been clearly identified. In others, multiple steps of the phagocytic process are influenced and tendency toward infection may be uncommon or less severe.

INHERITED DISORDERS

Inherited diseases impairing steps of phagocytosis are summarized in Figure 44.1.

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency (LAD) syndrome is a group of inherited diseases characterized by a failure of extravasation due to disfunction in selectin- or integrin-mediated adhesion to endothelial cells. This frequently leads to persistent neutrophilia, beginning at an early age that is associated with granulocytic hyperplasia in bone marrow. The syndrome is rare, but symptoms may be severe including recurrent bacterial infections, sepsis, and impaired wound repair.

In humans, three monogenic diseases have been identified and designated as type I to III. These mutations have been identified in animals, thus providing possible models of the human conditions.[34]

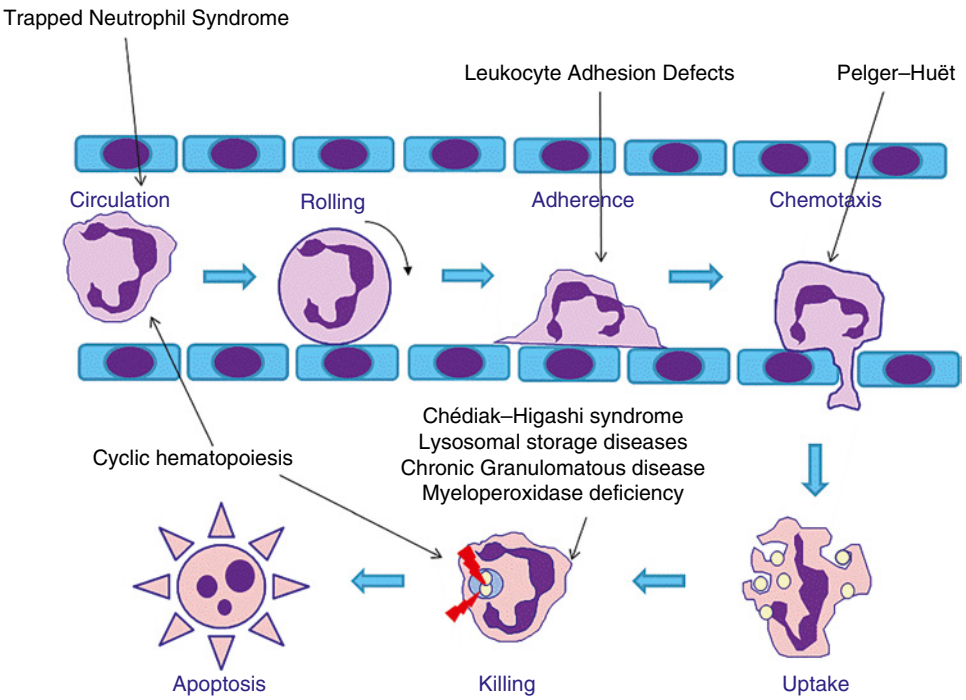

FIGURE 44.1 Summary of most relevant inherited disorders affecting different steps of neutrophil phagocytosis.

Leukocyte Adhesion Deficiency, Type I

Leukocyte adhesion deficiency, type I is the most common in humans and animals and it is linked to a biallelic mutation in the gene ITGB2, coding for the integrin protein CD18. Disease transmission is autosomal recessive, and, in humans, a germline point mutation has been identified leading to an aspartic acid to glycine substitution at amino acid 128 of CD18 polypeptide. All CD18 subfamilies are affected preventing the formation of functional CD11/CD18 complexes. As a consequence, neither the CD18 integrin subunit nor its three subunit partners CD11 come to the cell surface adversely affecting neutrophil adhesion and chemotaxis.

Spontaneous LAD type I has been identified in cows, dogs, and cats, and several mouse models have been generated.[34]

Canine leukocyte adhesion deficiency (CLAD) has been identified in Irish Setter dogs and cross-bred dogs and in one unrelated mixed-breed dog.[16,40] Affected dogs fail to express CD11/CD18 molecules on their surface similar to humans, but the point mutation responsible for CLAD causes a cysteine at amino acid 36 to be substituted for a serine.

Dogs with CLAD have persistent neutrophilia, myeloid hyperplasia in bone marrow, and suffer from recurrent bacterial or mycotic infections without pus formation. Oral cavity and lungs are most frequently affected, and dogs also suffer from fever, poor wound healing, and poor growth. A PCR test for CLAD has been developed and successfully applied in Irish Setters and mixed-breed dogs.

Gene therapy using foamy viruses or lentiviral vectors has been tested in vitro for CLAD resulting in a reversal of CLAD phenotype with long-term correction of the symptoms and neutrophil adhesion defects. This opens interesting perspectives for possible use of gene therapy to treat children with LAD-1.

Bovine leukocyte adhesion deficiency (BLAD), first reported in 1983 in a Holstein heifer with recurrent infections, periodontitis, oral ulcers, and marked, persistent neutrophilia, was initially termed bovine granulocytopathy syndrome. The term BLAD was introduced in 1990 when the lack of CD18 was demonstrated.[22] BLAD has been identified worldwide as an autosomal recessive trait in Holstein cows, thanks to the development of a rapid and economical PCR test useful in identifying carriers. Carriers are reported to range from 5% to 20% of the Holstein population in the USA, Japan, and Europe.

The molecular basis of BLAD is a single point mutation identical to that identified in humans leading to a 56–90% decrease in expression of CD18 in heterozygous calves. Affected cows show a severe decrease of both adherence and chemotaxis, but carriers show no detectable decrease in neutrophil function despite decreased expression of the CD18 molecule.[36] Currently, the most used approach to control in clinical practice is identification and elimination of carrier bulls from mating.

Feline leukocyte adhesion deficiency (FLAD) has been reported in a domestic longhair adult cat with recurrent infections and neutrophilia.[3] Laboratory tests revealed a lack of CD18 expression in all leukocytes and a severe decrease of unstimulated neutrophil adhesion. Genetic analysis showed a mutation in the ITGB2 gene, due to a 24 bp deletion causing a truncated gene product. In contrast with dogs and cattle, FLAD mutation appears extremely rare, although associated with a less severe phenotype probably associated with a CD18-independent T-cell activation pattern.

Leukocyte Adhesion Deficiency, Type II

Leukocyte adhesion deficiency, type II is a severe disease also associated with poor growth. In humans, a biallelic mutation of SLC35C1 gene, encoding for a fucose-transporter protein, has been reported. In spite of the lack of association between fucose metabolism and adhesion molecules, the disease is associated with a severe decrease in neutrophil rolling. Engineered mice with an analogous mutation have no spontaneous diseases consistent with the LAD II phenotype.

Leukocyte Adhesion Deficiency, Type III

Leukocyte adhesion deficiency, type III is a severe deficiency associated with reduced neutrophil adhesion and chemotaxis and platelets dysfunction (Glanzmann-like) causing severe bleeding. A biallelic mutation in FERMET3 gene, encoding for the protein kindlin 3, has been identified. Kindlin 3 is an intracellular protein linked to the cytoskeleton and binds CD18.

FERMET knockout mice show a similar phenotype to human LAD III. In addition, spontaneous diseases mimicking LAD III have been reported in one German Shepherd dog and in a mixed-breed dog.[4,19]

Leukocyte Granule Abnormalities

Leukocyte granule abnormalities may involve either oxygen-independent or oxygen-dependent mechanisms, affecting killing ability and, in some cases, are accompanied by alterations in steps in the phagocytic process or other cell types. The appearance of granules in the cytoplasm of neutrophils in blood smears may be helpful in differentiating some types of leukocyte granule abnormalities.

Defects in Oxygen-Independent Killing

Chédiak–Higashi Syndrome Chédiak–Higashi Syndrome is a rare inherited disorder reported in humans, cattle, Persian cats, Aleutian mink, Arctic foxes, killer whales and some strains of mice. In humans, the disorder is inherited in an autosomal recessive manner. Abnormal lysosome granule formation leads to giant lysosomes in leukocytes, platelets, and melanocytes (Figure 44.2). Decreased neutrophil chemotaxis, and oxygen-independent killing, mild to moderate bleeding, and oculocutaneous partial albinism are frequently seen in affected animals, but the severity of symptoms is quite variable among species, being generally more severe in cattle and mice than in cats. In humans and mice, a defect in LYST (CHS1) gene has been identified encoding for a protein involved in regulating vesicular size and trafficking. In Japanese Black cattle, a similar mutation has been identified and a PCR test to identify carriers has been developed. Stained blood smears commonly show pink to magenta staining granules due to the fusion of primary and secondary granules, which may stain positive with myeloperoxidase stain.

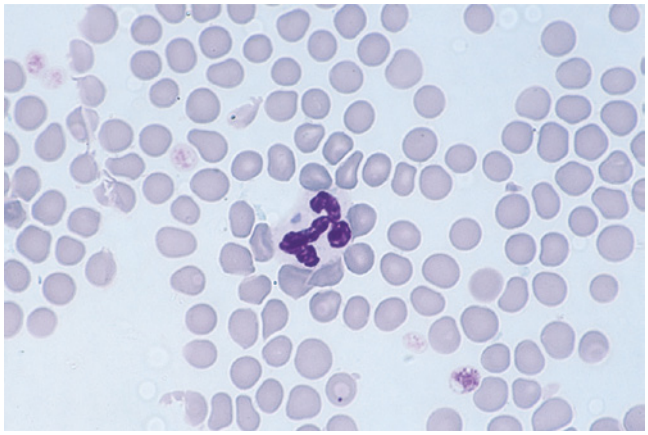

FIGURE 44.2 Giant lysosomes in the neutrophil cytoplasm of a cat that has Chédiak–Higashi.

Lysosomal Storage Diseases

Lysosomal storage diseases are a group of rare inherited enzyme deficiencies leading to accumulation of metabolic by-products within leukocyte granules and variable impairment of killing ability of neutrophils (see Chapter 49). Among these, mucopolysaccharidosis (MPS) is associated with altered mucopolysaccharide (glycosaminoglycan) catabolism and classified into different types according to genes involved and consequent enzymes affected. Several MPS have been described in humans, with recognized counterparts in dogs and cats: MPS type I (Hurler's syndrome), due to deficiency of alpha-L-hyaluronidase; MPS type II (Hunter syndrome), due to deficiency of hyaluronate sulfatase; MPS type III (Sanfilippo syndrome), due to various enzyme deficiencies leading to heparan sulfate accumulation; MPS IV (Morquio syndrome), due to deficiency of galactose-6-sulfatase and beta-galactosidase; MPS VI (Maroteaux–Lamy syndrome), due to deficiency of arylsulfatase; and MPS VII (Sly syndrome), due to deficiency in beta-glucuronidase. Other lysosomal storage diseases involving leukocytes include GM1 gangliosidosis (reported in Friesian cattle, Siamese and Korat cats, English Springer Spaniels, Beagles, Portuguese Water dogs, and Shiba Inus), GM2 gangliosidosis (in Yorkshire piglets, German Shorthaired Pointers, Golden Retrievers, and cats), and fucosidosis (in English Springer Spaniels). Pink to purple small granules are often visible in leukocytes stained with Wright's or Toluidine blue dyes, but the overall neutrophil function may be minimally affected. Type and severity of clinical signs are variable and more related to other tissues affected.

Birman Cat Neutrophil Granulation Anomaly

Birman cat neutrophil granulation anomaly is a rare hereditary trait affecting purebred Birman cats characterized by red azurophilic granules in the cytoplasm of neutrophils stained with Wright's stains. The color of these granules resembles that of promyelocytes, and it is

probably attributable to a different affinity for dyes. The trait is not associated with clinical signs or recurrent infections, and neutrophil functions do not appear impaired. The granules have normal electron microscopic morphology and do not stain for acid mucopolysaccharide, thus differentiating this condition from mucopolysaccharidosis types VI and VII.[17]

Defects in Oxygen-Dependent Killing

Chronic Granulomatous Disease Chronic granulomatous disease (CGD) is a group of heterogeneous inherited defects caused in humans by more than 40 different mutations in genes encoding components of NADPH oxidase. The majority of cases are transmitted as a mutation on the X-chromosome (X-linked trait), but some autosomal recessive diseases have been described. Affected children have recurrent, but rarely fatal, infections due to bacterial (mainly catalase-positive) or fungal microorganisms. Neutrophil inability to activate a respiratory burst is demonstrable by the nitroblue tetrazolium test, dihydrorhodamine (DHR) test, or cytochrome C reduction assays (see Chapter 45).

Five phenotypically different CGDs have been described, and knockout mouse models but no spontaneous animal models of human CGD have been demonstrated. Impairment of oxygen-dependent killing, partly resembling human CGD, has been reported in eight closely related Doberman Pinscher dogs with chronic recurrent bronchopneumonia and rhinitis that tended to relapse when antibiotic therapy was discontinued. Neutrophil chemotaxis and ingestion were normal, but the ability to kill *Staphylococcus aureus* in vitro, reduce of nitroblue tetrazolium, and produce superoxide was impaired, thus supporting decreased oxygen radical generation.[6]

A group of Weimaraner puppies with recurrent fevers, diarrhea, pneumonia, pyoderma, lymphadenopathy, stomatitis, and osteomyelitis have been described.[11] A defect in chemiluminescence response to phorbol ester, leading to impaired oxygen-dependent killing, was the major neutrophil alteration. Serum IgG and IgM concentrations also were decreased, but this finding was not associated with any decrease in humoral or cellular immune responses.

Myeloperoxidase Deficiency

Myeloperoxidase deficiency is the most common inherited defect of neutrophils in humans, generally leading to mild clinical signs. Myeloperoxidase deficiency is rare in animals, but has been reported in cyclic hematopoiesis of Gray Collies and is associated with a decrease in oxygen-dependent killing.[18]

Other Defects

Although not directly correlated with a severe decrease of neutrophil function, some inherited disorders may be considered among neutrophil function abnormalities.

Cyclic Hematopoiesis of Gray Collies

Cyclic hematopoiesis of Gray Collies is an inherited autosomal recessive disease due to a mutation in the beta subunit of adaptor protein complex-3 (AP3B1).[13] The mutation results from an insertion of an extra adenine residue in exon 21 of the canine AP3B1 gene leading to a frameshift with premature termination. Paradoxically, heterozygous carrier puppies show a normal AP3B1 transcript and protein, while homozygous puppies have a heterogeneous population of AP3B1 mRNA containing both mutant and wild-type transcripts. This paradox is probably attributable to transcription errors. AP3B1 protein is a membrane cargo protein involved in transport of several proteins, including neutrophil elastase, from Golgi to lysosomes. Therefore, cyclic hematopoiesis of Gray Collie is considered analogous to a hereditary mutation of the human elastase gene (ELANE). Accumulation of elastase on neutrophil membranes likely induces an increased degradation of important signaling protein promoting hematopoiesis leading to decreased hematopoiesis. Decreased neutrophil elastase allows a temporary boost in hematopoiesis. This hypothesis is supported by the asynchronous fluctuations of platelet and reticulocytes that tend to increase during the neutropenic phase.

Affected puppies die in the first weeks or show stunted growth, recurrent bacterial infections (enteric, respiratory, buccal, cutaneous), bleeding, and shortened life span. Affected dogs often have dilution of skin pigmentation and ocular lesions. Diagnosis is generally confirmed by recurrent neutropenia, every 11–14 days, lasting for about 3–4 days, followed by neutrophilia, thrombocytopenia, and reticulocytosis. Neutrophils have mildly reduced myeloperoxidase activity and platelet function may also be impaired.

Several treatment options have been proposed including antibiotics to manage bacterial infections, endotoxin, and lithium carbonate to stimulate hematopoiesis, granulocyte colony stimulating factor (G-CSF) subcutaneously or delivered using lentiviral vectors. Bone marrow transplantation may also be effective.

Autosomal Recessive Hereditary Neutropenia

Autosomal recessive hereditary neutropenia, also termed trapped neutrophil syndrome, has been described in Border Collies accompanied by recurrent infections, fever, and lameness due to lytic bone lesions.[1] The causative mutation has been identified in the canine VPS13B gene and is similar to human Cohen syndrome.[35] Neutropenia is associated with accumulation of mature and immature neutrophils in bone marrow which are unable to escape. A PCR test is available to reveal carriers and affected animals.

Pelger–Huët (P–H) Anomaly

Pelger–Huët (P–H) anomaly is a hereditary disorder described in several breeds of dogs, domestic shorthair cats, rabbits, and Arabian horses. The anomaly is an

autosomal dominant trait and heterozygous animals express the typical phenotype, although generally do not show clinical symptoms. Neutrophils with P–H anomaly may show decreased chemotaxis due to a more rigid nucleus, but other studies contradicted this hypothesis. Homozygous cats and rabbits have been associated with skeletal deformities and recurrent infections leading to death.

Pelger–Huët anomaly is characterized by failure of neutrophil nuclei to segment (Figure 44.3). They show round or hypolobulated nuclei, chromatin pattern is more clumped than those of band neutrophils and no toxic changes are identified (Figure 44.4). The features of persistent left shift without any clinical signs of infection are highly suggested of P–H anomaly. Other leukocytes and megakaryocytes in bone marrow may also show hypolobulation.

The underlying mutation likely involves the gene encoding for lamin B receptor, which is an inner nuclear membrane protein participating in nuclear segmentation and the trafficking of heterochromatin to the nuclear membrane. The mutation has been identified in human and mice, but not in domestic animals. The anomaly should be differentiated from transient acquired conditions due to inflammation or myelodysplasia (pseudo-Pelger–Huët) with asynchronous neutrophil maturation.

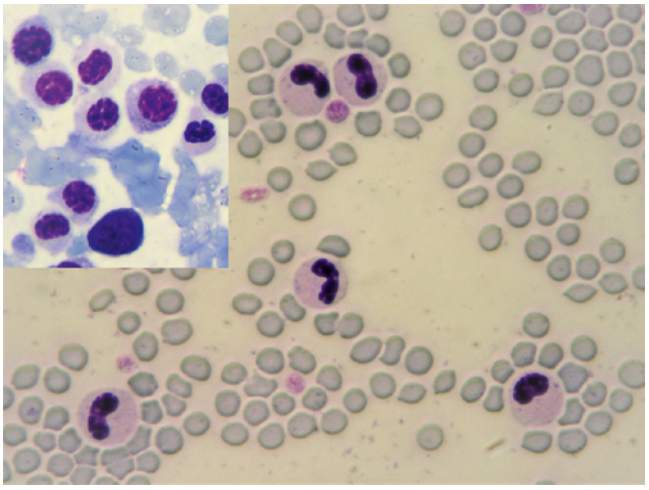

FIGURE 44.3 Peripheral blood and bone marrow (inset) from a cat with Pelger–Huët anomaly. Note hyposegmented neutrophils with a clumped chromatin pattern.

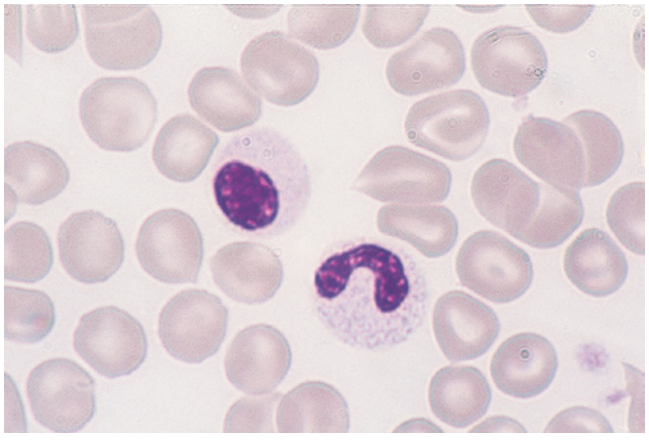

FIGURE 44.4 Band and myelocyte neutrophils from a Border Collie that has Pelger–Huët anomaly. (**Source:** Courtesy of Dr. K. S. Latimer, University of Georgia, Athens, Georgia)

ACQUIRED DISORDERS

Several physiological and pathological conditions have been reported to potentially influence neutrophil function. In contrast with congenital disorders, these conditions are quite frequent, but phagocytosis impairment is generally mild. A majority of reports are inconsistent and focused on in vitro effects on neutrophil function that do not necessarily reflect an in vivo impairment of the phagocytic process.

Stress

Immunosuppression due to prolonged stress is a well-recognized factor potentially increasing susceptibility to infections and both innate and specific immunity may be affected. Endogenous cortisol, released in stressful conditions, increases neutrophil counts by recruiting neutrophils from the marginal pool, following decreased selectin expression on endothelial cell and neutrophil membranes. However, data on the direct effects of cortisol on single steps in the phagocytic process are inconsistent among studies. Some authors reported increased adherence of sheep neutrophils 2 hours after mimicking acute stress by administration of adrenocorticotropic hormone (ACTH). Bovine neutrophils exposed to multiple corticoid treatments, mimicking chronic stress, showed decreased oxidative burst. Bovine neutrophils exposed to glucocorticoids have been described to show differential expression of genes involved in immune function, apoptosis, and tissue remodeling, and a downregulation of L-selectin which impaired neutrophil rolling.[8]

After 30 minutes of transportation, 4–6-month-old Friesian calves showed an increase in neutrophil superoxide production and decreased neutrophil apoptosis associated to increased cortisol, suggesting a possible pro-inflammatory effect. Other authors reported that transport stress may induce decreased expression of surface selectins and integrins, but increased chemotaxis. Transport stress may modulate peripheral blood neutrophil function, enhancing migration into the udder, thus contributing to increased milk somatic cell counts.

Neutrophils from neonatal calves exposed to cold stress showed no effects on killing ability. In addition, cold exposure seemed to restore ACTH-induced reduction in neutrophil chemiluminescence in Japanese Black steers.

Stress due to weaning was associated with decreased particle uptake and expression of L-selectin but not bactericidal activity in beef calves. This was associated

with circulating neutrophilia and impaired rolling and adherence.

Effect of stress due to exercise on circulating neutrophils has been investigated in horses. Endurance rides reduced oxidative burst in equine neutrophils.[12] Similarly, chemotaxis and chemiluminescence were decreased by a single bout of intense exercise. Untrained horses subjected to moderately intense exercise showed increased oxidative burst and phagocytosis; by contrast, high-intensity training caused an impairment of oxidative burst and phagocytosis.[29] These reports suggest a suppressive effect on equine neutrophil function of high-intensity or long-duration exercise; however, these effects are mild.[14]

Neonatal Animal

Impaired neutrophil activity in neonatal animals may predispose to a greater susceptibility to infectious diseases; however, studies in foals and calves are inconsistent. In studying neonatal calves, some researchers reported decreased phagocytosis, killing, and respiratory burst, while others reported increased superoxide production and increased chemotaxis and shape change.

Transition Period

Transition period is defined as the interval from 3 weeks before to 3 weeks after calving. Transition period is characterized by several concurrent conditions potentially predisposing to infectious diseases including reduced leukocyte function, negative energy balance, hypocalcemia, systemic inflammatory response, and oxidative stress.[38] Decreased neutrophil function, particularly in the ability of neutrophils to migrate into udder, has been recognized as an important predisposing factor for bovine mastitis.[21,28] A few weeks after calving, neutrophils have been reported to show reduced myeloperoxidase activity, antibody-dependent bacterial killing, diapedesis, chemotaxis, and phagocytosis. This impairment has been partly attributed to both direct alterations in neutrophils and to soluble mediators in serum.[2] Although stress due to parturition may be involved in depressing neutrophil function, proteomic studies showed that more than 70 genes are differentially expressed in neutrophils from transition cows and from cows inoculated with steroids. This implies that stress-related modifications are not the only factors impairing neutrophil function.[25] Other authors suggest that impairment of neutrophil function in the dry period might anticipate the onset of infectious diseases including mastitis and metritis. Myeloperoxidase activity is decreased before calving in cows that developed metritis, and myeloperoxidase and chemotaxis are affected in cows that developed retained placenta. Neutrophil chemotaxis is reduced in cows that subsequently developed mastitis.[9] The hypothesis is that pre-parturition impairment of neutrophil phagocytosis contributes to the onset of infectious disease after calving, even if other factors (ketosis, hypocalcemia, selenium concentration, and lypomobilization) might play a determinant role at the onset of infections.[38]

Metabolic Diseases

Metabolic diseases associated with the peripartum period in dairy cattle have been widely investigated to better elucidate the role of ketosis, increased non-esterified fatty acid (NEFA), and hypocalcemia on increased susceptibility to infections in the first week after calving.

Ketone bodies have been reported to impair bovine neutrophil function in vitro with decreases in chemotaxis, phagocytosis, and respiratory burst while bacterial killing capacity appears unaffected. In sheep, phagocytosis, chemotaxis, and bactericidal activity have been reported to be decreased in vitro by a concentration of ketone bodies similar to those seen in moderate to severe ketosis, while adherence appears unaffected.

The direct effect of NEFA due to lypomobilization on neutrophil activities is more controversial. Some authors reported a dramatic increase of respiratory burst, and necrosis of bovine neutrophils incubated with NEFA while phagocytosis was not affected.[33] Other authors have variously showed a reduced myeloperoxidase activity ex vivo, decreased respiratory burst activity, or increased chemotaxis and phagocytosis.

Cows with experimentally induced postpartum hypocalcemia exhibited severe impairment of immune cell function. Additionally, neutrophils from hypocalcemic cows had reduced phagocytosis and oxidative burst.[20,26]

All these data describe multifactorial effect of metabolic imbalances occurring after calving in dairy cows. This imbalance may increase susceptibility to infections mainly mastitis and endometritis.

Effects of diabetes mellitus and hyperglycemia have been investigated in cats and dogs. Neutrophil adherence, chemotaxis, and chemokinesis were reported to be decreased in poorly controlled diabetic dogs, but not in well-controlled ones.[24] Neutrophil adherence is decreased in whole blood with increased blood glucose, but no difference was observed when isolated cells were evaluated.[37] This implies that plasma factors may be responsible for decreasing phagocytic activities, thus predisposing to infections. Neutrophils from diabetic cats were reported to show an exaggerated oxidative burst that may contribute to diabetes-associated microvascular damages.[15] However, other authors found no evidence of increased oxidative stress or decreased neutrophil function in feline diabetes mellitus.[39]

Among nutritional factors, malnutrition has been associated with impaired neutrophil chemotaxis, respiratory burst, the release of lysosomal enzymes, and impaired microbicidal activity. Selenium and vitamin E are known to potentially improve neutrophil function, while copper deficiency has been reported to decrease the neutrophil's ability to kill yeast.[5,10] In cats, taurine deficiency has been associated with decreased neutrophil respiratory burst.

Infectious Diseases

Impairments of neutrophil function, possibly increasing susceptibility to bacterial infections (such as respiratory diseases) or comorbidities, have been described for some viral and parasitic diseases.

In cattle, the bovine viral diarrhea virus (BVDV) may induce impaired iodination capacity, random migration, phagocytosis, killing, and respiratory burst activity.[7] Similarly, altered neutrophil function was observed after vaccination with modified live BVDV vaccines.[32] Infectious bovine rhinotracheitis virus (IBRV), parainfluenza 3 virus, bovine herpes virus-1, and bovine immunodeficiency virus-1 may induce decreased neutrophil random migration and chemotaxis predisposing to bacterial pneumonia.[27] Neutrophils from cats affected by feline leukemia virus (FeLV) showed decreased chemotaxis and chemiluminescence.[23] Among parasites, decreased neutrophil functions were described in a dog infected by *Prototheca zopfi* and in cattle infected with *Eimeria spp*.[30,31]

Acronyms and abbreviations

BAL, bronchoalveolar lavage; CV, coefficient of variation; DCF, 2,7-dichlorofluorescein; DHE, dihydroethidium; DNA, deoxyribonucleic acid; DPI, diphenyleneiodonium chloride; FMLP, formylmethionine-leucyl-phenylalanine; H2-DCFDA, dichlorodihydrofluorescein diacetate; LPS, Lipopolysaccharide; MCLA, methyl cypridina luciferin analog; NBD, N-(7-nitrobenzofurazan-4-yl); NBT, nitroblue tetrazolium salt; NET, neutrophil extracellular traps; PAF, platelet-activating factor; PMA, phorbol myristate acetate; ROS, reactive oxygen species; TdT, terminal deoxyribonucleotidyl transferase; TUNEL, terminal-deoxynucleotidyl-transferase-mediated dUTP nick-end-labeling; ZAS, zymosan-activated serum.

Neutrophils play an important role in innate immunity as the first defense against microbes, mainly bacteria and fungi.

In vivo, innate immunity response is the result of neutrophil function and localized or systemic conditions including vessel permeabilization, priming, and opsonization, cytokines, complement fractions, and soluble mediator secretion, the interaction between polymorphonuclear leukocytes (PMN) and extracellular matrix, or other inflammatory and endothelial cells. However, testing neutrophil function in vivo is complex and does not permit discrimination between direct and indirect alterations. Thus, in vitro assays, which can be standardized, are more useful in pathological conditions and allow testing the effects of different substances, drugs, and activators on neutrophils.

SPECIMEN, STORAGE, AND NEUTROPHIL ISOLATION

Theoretically, a purified population of cells supplies more correct information about functional abnormalities. However, isolation techniques may activate cells; thus, using techniques requiring whole blood (such as flow cytometry or chemiluminescence) may be preferable in order to limit activation of cells.

Neutrophils from peripheral blood, milk, exudates, and bronchoalveolar lavage (BAL) have been tested. Peripheral blood or fluids must be collected in anticoagulated tubes. Definitive studies on the influence of anticoagulants on neutrophil function in animals are not available, but heparin is generally preferred, since

ionized calcium, which is necessary for phagocytic activity and cell movement, is not chelated. However, EDTA and acid–citrate–dextrose are often used as good alternative choices in dog, pig, and ruminants. The samples should ideally be processed within 4 hours, but, in some studies, analysis has been delayed up to 24 hours after collection. Samples should be stored at room temperature. In order to avoid neutrophil activation, plastic instead of glass tubes should be used and sterility of all solutions should be carefully maintained.

Neutrophil Isolation by Lysis

The simplest method of preparation of blood leukocytes is osmotic lysis of RBCs, by adding distilled water to an aliquot of whole blood followed by restoring isotonicity with a hypertonic solution. Red blood cells are ruptured while leukocytes are more resistant, and RBC membranes debris is removed by washing steps. This technique is very simple, but it does not allow isolation of leukocyte subpopulations and purity of neutrophils is similar to that of whole blood. On the other hand, the method induces only minimal activation of neutrophils. A modification of this technique is the method described by Carlson and Kaneko[1] and widely used in ruminants. It involves osmotic lysis after the removal of buffy coat that contains most of the mononuclear cells. The method yields a high percentage of granulocytes, but eosinophils cannot be separated from neutrophils. The method does not provide good purity and recovery in non-ruminant species.

Red blood cell lysis can also be performed by means of chemical solutions such as tris-buffered ammonium chloride. Unfortunately, this technique frequently interferes with some neutrophil functions or induces apoptosis; therefore, it should be limited to flow cytometric evaluation of membrane antigens.

Sedimentation Techniques

Neutrophils can be enriched by adding an equal volume of dextran solution to whole blood. Dextran is a polysaccharide solution that induces rouleaux formation by increasing sedimentation of erythrocytes and mononuclear cells. After 30 min, the granulocyte-rich supernatant is collected, centrifuged, and washed. This method has been described in humans and dogs as a single step or followed by gradient centrifugation, and it requires a minimal amount of blood.[21] However, isolated cells are characterized by low purity and dextran can partially influence neutrophil function.

Gradient Centrifugation Techniques

Several isolation techniques use colloidal suspension at different densities to concentrate cells according to their specific gravity. Discontinuous gradients are more feasible and adaptable in routine isolation of cell populations than continuous gradients. However, continuous gradient may help to set up isolation conditions for specific cell subpopulations compared with density-labeled beads. The most frequently used technique in veterinary medicine is separation using a discontinuous gradient of Percoll®, silica particles coated with polyvinylpyrrolidone. For canine neutrophils, two different densities (1.092 and 1.071 by using 74% and 55% of Percoll, respectively, in saline solution) are layered and leukocyte suspensions are put in top of the tube. After centrifugation, a neutrophil-rich band is easily recognizable at the interface between two densities (Figure 45.1). This layer can be removed and after washing provides a very pure population of neutrophils. The method can be adapted to different species by adjusting densities of Percoll (swine 65% and 55%; bovine 70% and 50%; horse 75% and 60%). The main advantage of this technique is the high purity and yield of neutrophils, mainly in healthy animals. However, cell densities often vary with physiological and disease conditions, which could lead to failure to isolate atypical or activated cells.

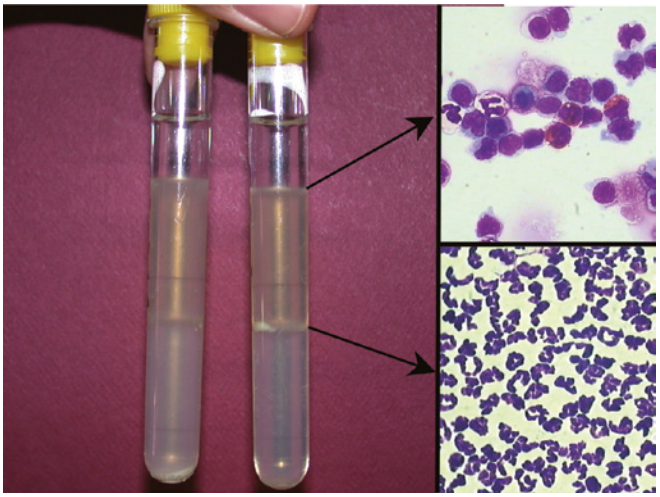

FIGURE 45.1 Isolation of blood neutrophils using a discontinuous Percoll gradient. After centrifugation, a neutrophil-rich band is located at the interface between the two Percoll densities. (**Source:** Courtesy of V. Spagnolo)

A similar technique uses another commercially available polymer, Ficoll-Paque®, which is able to separate mononuclear cells and platelets (top of the tube) from granulocytes and erythrocytes (bottom of the tube). This method is generally more reserved to concentrate peripheral blood mononuclear cells.

Finally, an interesting method using discontinuous metrizamide gradient has been developed to isolate bovine neutrophils.[3] This technique is reported to provide neutrophils with high purity and yield and minimal interference with function tests, but it has not been widely used.

Immunological Separation Techniques

Increase in availability of lineage-specific monoclonal antibodies has permitted separation of leukocyte subpopulation with a high percentage of purity. Fluorescence-activated cell sorting (FACS) is widely used for isolating lymphocyte subpopulations, but is of

limited use for myeloid cells, due to the paucity of specific antigens, the difficulty in maintaining sterility, and possible activation due to manipulation. Separation methods using magnetic beads have been developed for cattle.[17] Briefly, magnetic beads are labeled with anti-neutrophil-specific monoclonal antibodies and then incubated with leukocyte suspensions. Leukocytes bound to the beads are then captured using the magnetic system, while unbound cells (mononuclear and other granulocytes) are eluted and discarded. After removal of the magnetic field, collected neutrophils are collected in high percentage, purity, and yield. However, this technique requires neutrophil-specific antibodies that do not recognize other polymorphonuclear leukocytes. Moreover, incubation with antibodies may induce activation of neutrophils, thus influencing function tests. For these reasons, antibodies should be chosen carefully. A possible solution is the enrichment of neutrophil by depleting other cell populations, using a mixture of lymphocyte- and monocyte-specific antibodies labeled with magnetic beads. Magnetic negative methods may provide neutrophils with high yield, but purity may be low.

CLASSICAL TECHNIQUES FOR EVALUATION OF PHAGOCYTIC PROCESS

Different techniques are described, some of which are able to evaluate the whole phagocytic process, while others are used to discriminate single steps of phagocytosis. Tests for specific steps of phagocytosis are useful because some diseases or conditions lead to alterations in a single function without perturbing the whole phagocytic process. In this case, a panel of tests for simultaneous evaluation of different steps of phagocytosis is strongly recommended in order to correctly assess neutrophil function. Alternatively, tests for the whole phagocytic process are easier to perform and provide a complete picture of interactions with nonspecific immunity, but are less informative regarding disease pathogenesis.

Cellular Movement and Chemotaxis

The simplest technique to evaluate increased cellular movement is microscopic detection of conformational changes of neutrophils after activation. Activated neutrophils show a bipolar configuration within a few minutes after exposure to activating agents with a gradual return to spheric shape. However, this method is difficult to standardize and does not distinguish spontaneous motility, random migration (chemokinesis), and directional migration of the cell toward an activator substance (i.e., chemotaxis). Many chemoattractant substances have been recognized, but some of them (interleukin-8, zymosan-activated serum (ZAS), casein, LTB4, C5a, TNF-α, platelet-activating factor (PAF), and formylated peptides such as N-formylmethionine-leucyl-phenylalanine (FMLP) are more commonly used in chemotactic tests. However, some species differences have been recognized. Neutrophils from cows, pigs, and cats do not respond to formylated peptides and those from dogs require a priming agent in order to express enough receptors for such substances.

A frequently used method to test chemokinesis and chemotaxis is evaluation of neutrophil migration using a modified Boyden chamber.[23] Briefly, suspensions of isolated neutrophils are put into the upper wells of the migration chamber, while chemoattractant is added in the lower well. For evaluating random migration, chemoattractant is omitted from the lower well.

Two different methods have been described according to the type of filter used between the two wells:[20]

Method 1: In the leading front method (Figure 45.2), a 150 μm-thick cellulose nitrate filter is used. The chamber is incubated for 30 min at 37 °C in humidified, 5% CO_2 atmosphere, and then the filter is removed, fixed, stained, dehydrated, clarified in xylene, and mounted on a glass slide. Cellular movement is evaluated using the fine adjustment and micrometer of a microscope. The distance between the top of the filter and the leading front, where the two last cells are in focus, is determined.

Method 2: In the lower surface count method, a thin (12 μm) polycarbonate filter with a pore size of 2 μm diameter is used. After incubation, the filter is removed and the number of cells that pass through the filter is enumerated in the lower well, using a cell counter or a spectrophotometric method.[5] Cells attached to the lower surface of the filter are counted after wiping the upper surface of the filter and staining with the Wright method.

These two techniques provide different data on neutrophil chemotaxis, but, according to some investigators, both methods are strongly influenced by the degree of adherence and gravity.

Thus, assays to evaluate chemotaxis in a collagen gel matrix or under-agarose have been developed.[11] The collagen gel matrix assay consists of a visual assay obtained by two capillary tubes with their ends covered by a dialysis membrane and connected by a polyethylene tubing sleeve. The compartment formed between the ends of the two tubes is filled with a solution of monomeric collagen and put under a microscope. Cell movements are recorded microscopically after the addition of cell suspension and chemoattractant. This technique is quite complex, but it allows the study of neutrophil movement step-by-step in a microenvironment similar to an "in vivo" system.

The under-agarose technique is a simple, inexpensive, and widely used method based on the preparation of a gel matrix in a Teflon chamber. Wells are cut in the gel, and cell suspensions are added to the wells. Different chemoattractants can be put in separate wells, and in some cases chemoattractant is omitted in order to evaluate spontaneous motility. After incubation, agarose is flooded with methanol, followed by 35% formaldehyde in order to harden the gel, and, after staining, the migration distance of neutrophils toward chemoattractant wells is evaluated by microscopy.

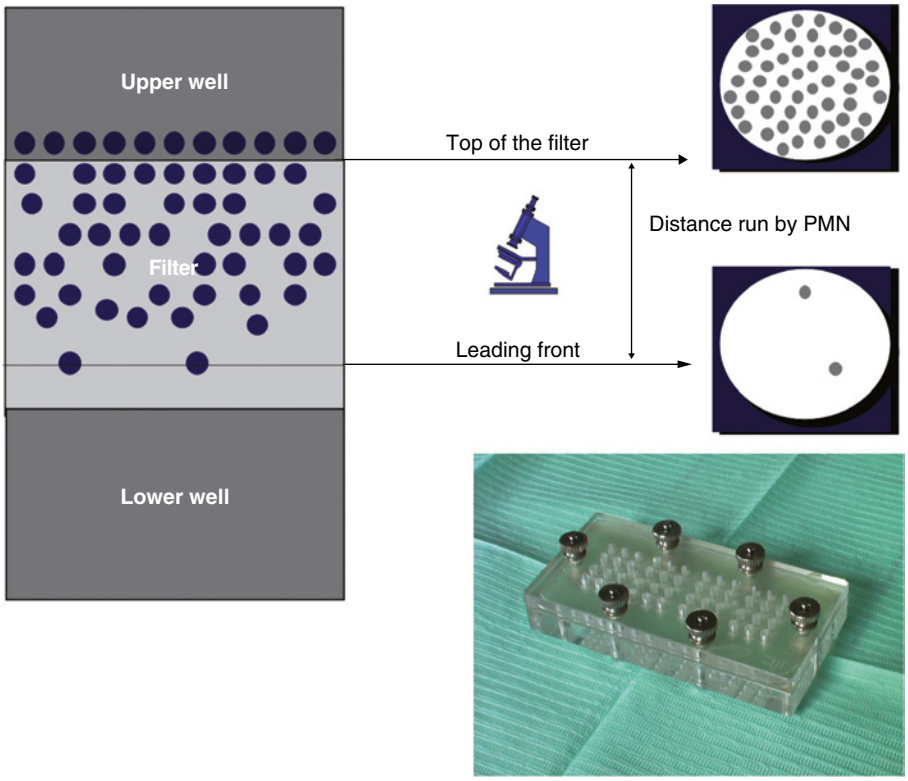

FIGURE 45.2 Evaluation of chemotaxis in a Boyden chamber, using the leading front method. Neutrophils migrate from the upper to the lower well (toward a chemoattractant) through a cellulose nitrate filter. The distance traveled by the cells is evaluated after staining the filter, using the fine adjustment on the microscope.

Recently, some authors developed a real-time cell migration assay based on a microfluidic device and a dedicated application for smartphone. To date, no applications to veterinary medicine have been described.[22]

Finally, some authors suggested a more complex method that requires a culture system made of successive layers of collagen, fibroblasts, and a confluent monolayer of epithelial cells coated on a porous membrane.[16] Cells are put at the basal side of the membrane, and cells passing over the epithelial layer toward a chemoattractant stimuli are counted. This technique is particularly useful for studying chemotaxis and diapedesis of neutrophils during infection in the mammary gland, but it is quite difficult to perform and standardize.

Adherence

Assays for evaluation of adhesive capability of neutrophils could be schematically divided into two groups: (1) those evaluating adherence to inert substances, such as polysaccharides, nylon fibers, glass, or plastic, and (2) those that study adhesiveness to biological structures, such as endothelial cells, monolayers, or cell culture systems. The latter assays reproduce interactions between neutrophils and biological barriers in a more complex way, similar to that which occurs in vivo. However, they are strongly influenced by extragranulocytic factors; thus, most of these techniques are difficult to standardize and lack reproducibility.

Techniques that evaluate adherence to inorganic substances have been developed using column or microtiter plates. Briefly, borosilicate glass column can be filled with packed Sephadex or nylon fibers and neutrophils suspension is percolated through the column. The percentage of adhered cells is then calculated by counting the percentage of recovered cells. Different stimulators or substances can be used.

All these methods lack precision; thus, it is strongly recommended that these tests be run in triplicate. Assays in microtiter plates are performed by adding a suspension of PMN in flat bottom wells together with different activators or inhibitors and they may also be useful to test the influence of different substances on neutrophil adhesiveness. Nonspecific adherence to plastic wells or adherence after activation with an activation agent (e.g., phorbol myristate acetate (PMA) or ZAS) can be evaluated. In order to remove nonspecific activation due to contact with plastic wells, some wells can be precoating with gelatin. After incubation and washing to remove nonadherent cells, the percentage of adhered cells is evaluated by microscopic count using an inverted microscope or neutrophils can be lysed and indirectly evaluated by means of chemical or fluorometric methods. Fluorometric labeling with calcein[10] or colorimetric methods to quantify myeloperoxidase or acid phosphatase is commonly used.[15] Results should be reported as the number of adhered cells compared to a standard curve obtained by different dilutions of neutrophils from the same animal. Assays in microtiter plates are more reproducible in comparison with those in columns and require a smaller amount of blood; thus, they are more applicable for use in small animals.

Many assays have been reported to test adhesive capability of neutrophils to cell layers or tissues. The simplest methods use cultured endothelial cells packed into an adherence column instead of nylon fibers or

Sephadex. Other techniques using monolayer of cultured cells of different origin (endothelial, fibroblasts, myocytes) have been reported. Target cells may be isolated from fresh tissues and cultured on a glass coverslip until confluent. An adhesion assay chamber is obtained by adding a second coverslip separated from the monolayer by a rubber O-ring. Neutrophils are added in this incubation chamber and adhesion is evaluated by a visual method, using an inverted microscope equipped with phase-contrast optics. The number of neutrophils remaining on the slide after washing off the nonadherent cells is enumerated. This technique reproduces the complex interactions between neutrophils and tissue cells and is very useful for studying the production of cytokines by endothelial or mesenchymal cells or the mechanism of interaction between neutrophil adhesion molecules and their ligands. However, the technique is difficult to perform, lacks reproducibility, and is very influenced by extraneutrophilic factors.

Particle Uptake

Although there are several methods to evaluate neutrophil capability to uptake particles, the basic concept is measuring the amount of labeled foreign material engulfed after incubation with or without activating substances. Particles can be evaluated by visual, spectrophotometric, or flow cytometric assays. Various particles can be used including latex beads, yeasts (e.g., *Saccharomyces* or *Candida*), or bacteria (e.g., *Escherichia coli*, *Staphylococcus aureus*, or *Streptococcus spp*.). Particles may be incubated directly on a glass slide with a suspension of isolated neutrophils, then ingestion is stopped adding an ice-cold isotonic solution, and phagocytosis is evaluated by fluorescence microscopy. The simplest method is microscopic evaluation of the percentage of cells that have phagocytized particles, after staining adherent cells. In other assays, particles can be prelabeled with a fluorescent dye (fluorescein isothiocyanate or acridine orange) and the mean number of ingested particles per neutrophil is determined using a fluorescence microscope. Fluorescence of noningested particles is inactivated by treating cellular suspension with trypan blue solution.[21] The main issue with this technique is that results are strongly affected by adherence to the glass slide; therefore, assays using neutrophil suspensions in tubes or flasks have been developed.[18]

Another interesting technique uses polystyrene latex beads (1.09 μm diameter).[14] After incubation, noningested particles are removed by centrifugation and the supernatant is discarded; then neutrophils are ruptured and ingested latex particles are solubilized with 1,4-dioxan. The amount of latex is indirectly determined in a spectrophotometer at 255 nm. This method is very simple, inexpensive, and rapid, but it does not permit determination of the percentage of neutrophils phagocytizing particles.

Finally, ingestion can be evaluated after labeling bacteria with radioactive materials followed by measuring the quantity of radioactivity in cell suspensions.[13] However, this technique is complex and expensive and requires handling of radioactive materials.

Killing

Many assays have been developed to evaluate bactericidal activity of neutrophils. These may be divided in three groups:

Group 1: This group includes techniques that evaluate residual viability of bacteria incubated with neutrophil suspensions. These assays are easy to perform and can be applied to whole blood providing an overall evaluation of innate immunity. The method consists of incubation of a suspension of live bacteria with neutrophil suspensions and serum in order to allow opsonization. After incubation, bactericidal activity is determined by counting colony-forming units, after cultivation on blood agar plates, or by enumerating live bacteria using a spectrophotometric assay (at 560 nm) after addition of tetrazolium compound.[19] Live bacteria reduce tetrazolium to red-purple formazan. Results are compared with a standard curve obtained with a known number of live bacteria.

Group 2: This group includes techniques that quantify neutrophil lysosomal enzymes. Many assays have been developed to quantify the activity of lysosomal enzymes (myeloperoxidase, lysozyme, lactoferrin, cationic proteins, neutral proteases, acid hydrolases, and proteases) after neutrophil lysis. Most of them utilize colorimetric or ELISA methods that can be performed using a spectrophotometer or a microtiter plate reader. In horses, microtiter ELISA tests were used to evaluate myeloperoxidase and elastase activities and an automated laser hematology system (ADVIA 2120) has been proposed to evaluate changes in myeloperoxidase content of neutrophils associated with experimental endotoxemia.[8]

Group 3: This group includes techniques that quantify the production of oxygen compounds produced by the respiratory burst. Neutrophils generate reactive oxygen species (ROS) that play an important role in bactericidal activity. Many ROS are involved, but superoxide anion is the precursor. Several assays have been developed to test the oxidative burst of neutrophil. Most of them are performed in multiwell microplates. Neutrophil suspensions are incubated in the presence of activators and, after incubation, several methods to measure ROS production can be used. The differential between intracellular and extracellular ROS production can be quantified by pretreating cell suspension with a NADPH-oxidase inhibitor (diphenyleneiodonium chloride or DPI) or with superoxide dismutase or catalase, which are superoxide and hydrogen peroxide scavengers, respectively. These substances do not cross cell membranes; therefore, they inhibit only extracellular ROS.

A rapid assay to detect respiratory burst activity evaluates the capability of neutrophils to reduce nitroblue tetrazolium salt (NBT) to formazan with the production of a red-purple color that can be evaluated using an ELISA reader.[9] Also, chemiluminescence assays have been described.[12] In the cytochrome C reduction assay,

ferricytochrome C is added to wells and it is reduced by superoxide. Changes in absorbance at 550 nm are spectrophotometrically evaluated at 10-min intervals. This assay is reported to be a specific indicator of extracellular superoxide production. Chemiluminescence can be evaluated by adding methyl cypridina luciferin analog (MCLA). After addition of MCLA, the decrease in chemiluminescence is measured at 10-min intervals using a microplate luminometer. A commercially available test (Amplex-Red-dependent fluorescence) consists of a reaction mixture (resorufin and horseradish peroxidase) that is added to neutrophils. Samples are evaluated in a fluorimeter at an excitation wavelength of 530 nm and an emission wavelength of 590 nm every 15 min. The test detects extracellular hydrogen peroxide. Other fluorescent assays include the dihydroethidium (DHE)/dichlorodihydrofluorescein diacetate (H2-DCFDA) fluorescence assay and the luminol/isoluminol chemiluminescence assay.

All these assays are suitable for detection of neutrophil burst in bovine. Intra-assay repeatability is good; however, interassay variability is high. The luminol assay has the lowest interassay coefficient of variation (CV), while other tests such as cytochrome C reduction, Amplex Red, and DHE have high interassay variability (CV > 30%). In dogs, studies using evaluation of ROS production using cytochrome C reduction, luminol chemiluminescence, H2-DCFDA, and NBT reduction have been reported.

FLOW CYTOMETRIC TESTS FOR NEUTROPHIL FUNCTION

The previously described measurement of neutrophil function, using physical, microscopic, or chemical methods, remains time-consuming. Moreover, because phagocytosis is due to sequential activation of multiple steps (rearrangement of cytoskeleton, chemotaxis and adherence, degranulation and production of oxygen radicals) and alteration in any single step can influence the whole process, a panel of assays is usually applied. This requires large numbers of neutrophils that are difficult to obtain from small or diseased animals. Flow cytometric assays for testing neutrophil function have significant advantages compared to classical ones: they are very rapid to perform, require small amounts of cells (at least 50–100 times less than conventional assays), and can be applied on heterogeneous populations of cells such as whole blood, avoiding neutrophil isolation that could induce significant activation of cells. Flow cytometry measures fluorescence and light scatter signals through a laser source (see Chapter 142). Using the gating technique, the neutrophil population can be isolated from a mixed population of cells. Resolution may be further increased using a multicolor approach and lineage-specific monoclonal antibodies labeled with different fluorochromes. In some cases, subsets of neutrophils (e.g., immature neutrophils or activated neutrophils) may be distinguished and their activities separately interrogated and compared. Many different flow cytometric assays have been described in human medicine, but only a limited number have been validated and used in veterinary medicine.

Cytoskeletal Activity

Actin is a major cytoskeletal protein of neutrophils and it can be found in a globular monomeric form (G-actin) and in a filamentous polymeric form (F-actin). During activation, G-actin changes into F-actin and accumulates at the periphery of cells. This process is involved in adhesion, deformability, and cell movement. Dysfunction in actin dynamic polymerization has been linked to susceptibility to infectious diseases. Flow cytometric detection of F-actin can be assessed using the fluorochrome N-(7-nitrobenzofurazan-4-yl) (NBD)-phallacidin. Whole blood cells are activated, then cells are fixed with 3% paraformaldehyde and RBCs are lysed. Leukocytes are permeabilized and stained with fluorochromes. In the flow cytometer, fluorochromes within neutrophils are excited with standard (488 nm) laser light and the amount of emitted green fluorescence is correlated with F-actin content. The technique has been used in bovine in which great increases of F-actin were found after neutrophil activation.

Recently, an interesting method to quantify receptor clustering via flow cytometry has been described. Receptor clustering is mediated by cytoskeletal protein and is highly suggestive of cell activation and polarization. In flow cytometry, receptor clustering may be evaluated measuring in real time the decrease in the ratio between fluorescence/forward scatter time of flights and the increase in the ratio between height/area fluorescence signals.[2] No application of such technique is available at the moment in veterinary medicine.

Surface Adhesion Molecules

Flow cytometric assays for neutrophil adhesion are mainly based on the detection of adhesion molecules on the cellular surface. Adhesion molecules may be divided into two groups: the selectin family, which establishes a weak association of neutrophils with endothelial cells, and the integrin family, which interacts with the immunoglobulin superfamily on endothelial cells, resulting in a firm bound that allows neutrophil diapedesis. The expression of adhesion molecules can be easily quantified using specific monoclonal antibodies. Whole blood is preferable to avoid neutrophil activation during the isolation procedure. After labeling cells with fluorochrome-conjugated antibodies, the expression of membrane surface molecules is evaluated on gated neutrophils and expressed as mean (or median) fluorescence channel units. Integrins increase on neutrophil cell membranes after activation due to the externalization of adhesion molecules from cytoplasmic granules (Figure 45.3). Expression of selectins on the membrane of activated cells is controversial.

This assay is very simple and rapid, but it requires careful standardization of procedures, number of cells, and antibody titration in order to work with a large excess of antibody.

In veterinary medicine, several studies using this technique have been reported with particular attention given to canine and bovine adhesion molecules. Some studies in dogs investigated the expression of integrins

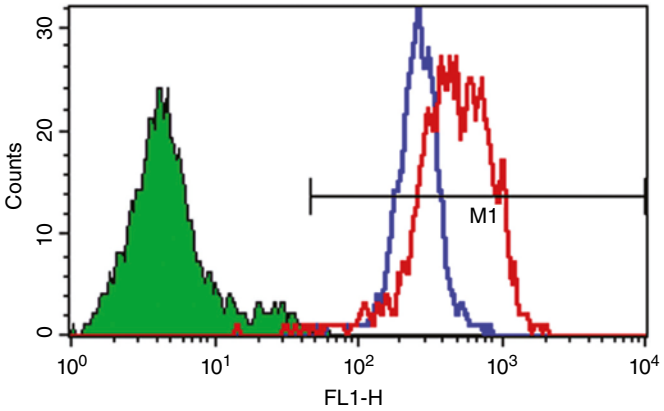

FIGURE 45.3 Flow cytometric evaluation of membrane integrin CD11b in bovine neutrophils. Lipopolysaccharide (LPS)-activated neutrophils (red line) express increased fluorescence compared to nonactivated neutrophils (blue line). Shaded line indicates isotypic control.

(CD35, CD18, CD11b, CD11c) and Fc receptors (CD16). In cattle, CD11b, CD11a, CD11c, CD18, L-selectin, CD47, and CD44 have been studied on neutrophils from peripheral blood and milk.

Phagocytosis

Many different assays to quantify neutrophil phagocytic capabilities have been described. These methods entail incubating whole blood with fluorescent-conjugated particles of different origin (inorganic beads, bacteria, yeast). The amount of fluorescence is taken as an indicator of phagocytic activity (Figure 45.4).

Heparinized whole blood is the preferred sample because other anticoagulants chelate Ca^{2+} that is necessary for phagocytosis. A major limitation is that nonspecific adherence to the neutrophil membrane can induce an overestimation of phagocytosis. This aspect could be partially limited by quenching the fluorescence of nonphagocytized particles using trypan blue or crystal violet solution. Alternatively, a control sample can be incubated at 4 °C, thus, inhibiting phagocytosis and allowing quantification of nonspecific adherence.

An interesting variant of this method allowing simultaneous evaluation of phagocytosis and oxidative burst has been described in cows, dogs, cats, and horses. The technique couples evaluation of ROS production using fluorescent dyes (dihydrorhodamine 123 or 2,7-dichlorofluorescein (DCF)) with ingestion of propidium-conjugated bacteria that emit a red fluorescence. Two-color analysis allows easy measurement of particle uptake and oxidative burst activity simultaneously. Recently, commercially available flow cytometric assays have been validated for the bovine species, and show a good agreement with other classic methods.[6]

Reactive Oxygen Species Production

Many flow cytometric tests to measure ROS production have been developed and applied in cows, dogs, and horses. One of the most frequently used is the DCF assay.

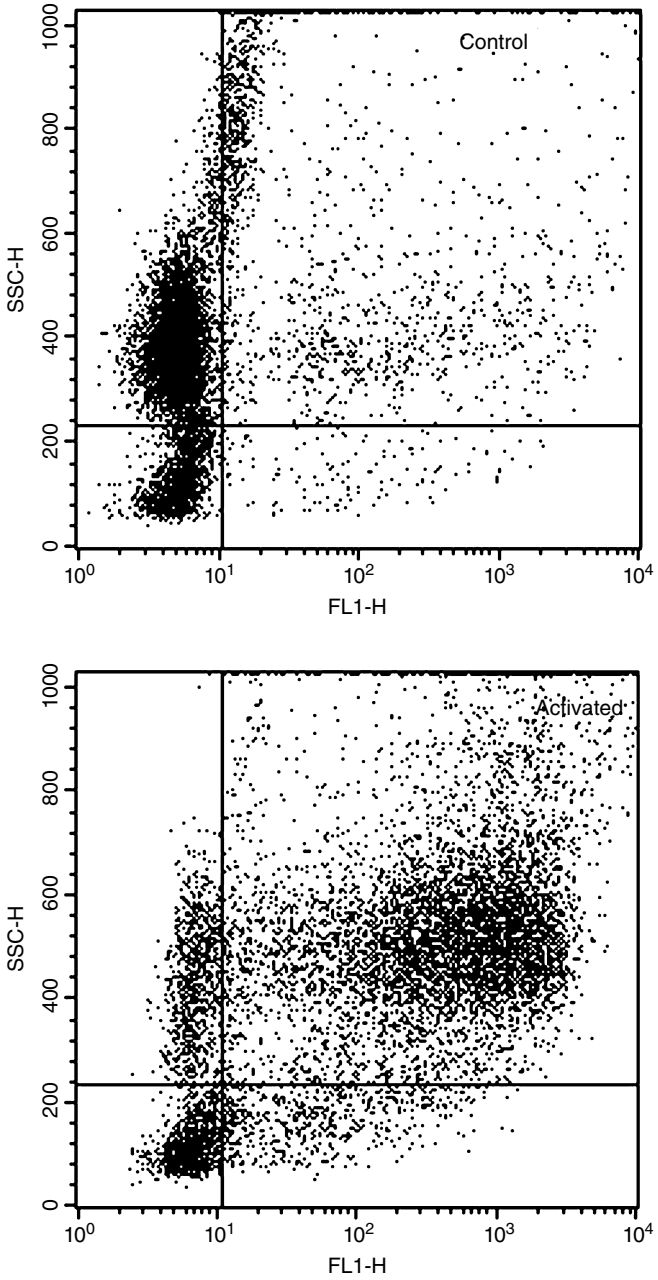

FIGURE 45.4 Flow cytometric evaluation of phagocytosis of fluorescein-labeled *Escherichia coli*. A high percentage of neutrophils shows fluorescence due to bacterial ingestion. In the control sample, phagocytosis is inhibited by incubating cells at 4 °C.

The acetate form enters the cells and is oxidized mainly by hydrogen peroxide resulting in green fluorescence. Similar techniques use dihydrorhodamine 123, which is converted to the fluorescent rhodamine 123, or hydroethidine, which is converted to the fluorescent ethidium bromide. These three techniques are useful to assess neutrophil phagocytosis, but they react differently with different oxygen compound produced during the respiratory burst. The choice of probe depends on the ROS of interest, while a combination of techniques can provide a more accurate and specific evaluation.

Eosinophils, which are not differentiated based on scatter properties, are capable of an oxidative burst. Thus, results in whole blood must be carefully evaluated in animals with hypereosinophilia.

EVALUATION OF NEUTROPHIL DEATH

The study of neutrophil death, occurring by apoptosis (programed cell death) or necrosis, is another challenging area of neutrophil function. Neutrophils are normally characterized by a very short life span that can vary in physiological or pathological conditions. Evaluation of neutrophil death by apoptosis and/or necrosis is interesting because many different cytokines and substances produced by pathogens can influence the rate at which neutrophils undergo apoptosis and/or necrosis.

Many assays using conventional and flow cytometric techniques have been developed to test cell death. Conventional techniques use mainly cytochemical stains (terminal-deoxynucleotidyl-transferase-mediated dUTP nick-end-labeling (TUNEL)) or colorimetric evaluation of proteases involved in the apoptosis process (e.g., caspase-3).

Flow cytometric techniques have the advantage of differentiating apoptosis versus necrosis in a large number of cells and are rapid and easy to perform. Many different assays have been developed that can evaluate the following:

1. *Scatter properties:* Apoptotic cells lose water and decrease granularity. This aspect can be easily identified by decreases in both forward and side scatter. However, this method cannot distinguish between apoptotic and necrotic cells.
2. *DNA content:* The content of DNA can be evaluated using fluorescent dye propidium iodide (or other dyes such as acridine orange, ethidium bromide, Hoechst 33342, or actinomycin D) after cell permeabilization. Apoptosis results in DNA fragmentation; thus, the detection of cells with less DNA content than normal diploid neutrophils is suggestive of apoptosis or necrotic cells.
3. *Combined test for evaluating cell death:* Many tests to evaluate cell viability are commercially available. Each of them focuses on a specific stage on the death process; Annexin V is a polypeptide that exhibits a strong affinity for phosphatidylserine molecules that are present only on the inner layer of the cell membrane in viable cells. During early apoptosis, phosphatidylserine residues are exposed on the cell membrane. Early apoptotic neutrophils and necrotic cells can be easily detected by double labeling cells with fluorescent-conjugated annexin V and propidium iodide that enters only necrotic cells. Modifications of this technique use other fluorescent dyes instead of annexin V to evaluate membrane integrity (SYBR-14) or mitochondrial function (rhodamine 123).
4. *TUNEL:* The principle of this assay is that, during apoptosis, terminal deoxynucleotidyl transferase (TdT) adds nucleosides to free 3′-ends produced from DNA cleavage. Neutrophils are permeabilized and incubated with biotinylated nucleosides and TdT; after washing, fluorescent-conjugated streptavidin, which binds to the biotin, is added and the number of cells in apoptosis is detected using a fluorescent microscope or flow cytometer. This assay is one of the more widely used methods to detect apoptosis. However, nonspecific positivity in necrotic cells is reported; thus, it should be combined with one or more other techniques.

EVALUATION OF NEUTROPHIL EXTRACELLULAR TRAPS

Neutrophil extracellular traps (NETs) are networks of DNA, nuclear material, and proteins released in response to many inflammatory or infectious stimuli (see Chapter 43). NETs are components of innate immunity that entraps and kills pathogens. However, excessive NET formation may enhance tissue damage, thrombosis, and autoimmunity. The evaluation of NET formation has recently been reported in several species, mainly in dogs. Isolated cells are incubated in multiwell plates with activator substances. DNA release is quantified by adding a cell-impermeable nucleic-acid dye and reading absorbance using a spectrophotometer.[4] Alternatively, two nucleic-acid dyes, one that stains cells with intact membranes (SYTOX green) and one that stains cells with permeable membranes (SYTOX orange), may be used and NET formation is evaluated using a fluorescence microscope equipped with an image analyzer.[7]

Acronyms and Abbreviations

CLCP, Charcot–Leyden crystal protein; EBP, eosinophilic bronchopneumopathy; ECF-A, eosinophil chemotactic factor of anaphylaxis; ECP, eosinophil cationic protein; EDN, eosinophil-derived neurotoxin; EoSV, eosinophil sombrero vesicle; EPO, eosinophil peroxidase; Gal-10, galectin-10; HES, hypereosinophilic syndrome; HETE, hydroxyeicosatetraenoic acid; HHT, hydroxyheptadecatrienoic acid; GI, gastrointestinal; GM-CSF, granulocyte macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MBP, major basic protein; MCP-3, monocyte chemotactic peptide-3; MIP-1α, macrophage inflammatory protein-1α; PAF, platelet-activating factor; PGE, prostaglandin E; RER, rough endoplasmic reticulum; Siglec, sialic-acid-binding Ig-like lectin; SNARE, soluble *N*-ethylmaleimide-sensitive factor attachment receptor; TGF, transforming growth factor; TNF-α, tumor necrosis factor-α.

Eosinophils, named by Ehrlich based on their affinity for anionic dyes such as eosin,[34] defend against helminthic parasites, are bidirectional partners in basophil- or mast-cell-mediated inflammation, and may damage host tissues. Eosinophils participate in innate, acquired, and adaptive immunity, tissue remodeling, and developmental biology, and are pleotrophic multifunctional cells that serve complex physiologic roles. This chapter emphasizes structure–function relationships to elucidate the varying roles of eosinophils in many complex processes. The reader is referred to several recent comprehensive reviews.[5,29,43,46,61,66]

REGULATION, PRODUCTION, AND RELEASE

Eosinophils develop in bone marrow and to a lesser extent in thymus, spleen, lung, and lymph nodes in some laboratory species.[21,36,78] Type-2 helper T (TH_2) cells secrete interleukin (IL)-5 and IL-13 and are important regulators of all aspects of eosinophil development and function, including increased production by bone marrow, mediated by IL-5, and recruitment to tissues by eotaxins, regulated by IL-13. IL-3 and granulocyte macrophage colony-stimulating factor (GM-CSF) also play roles in production but are less lineage-specific (see Chapter 41).

Produced in bone marrow over 2–6 days, eosinophils comprise <10% of marrow nucleated cells; the marrow-to-blood eosinophil ratio varies between 300:1 in guinea pigs and 3.4:1 in humans. The half-life of circulating eosinophils varies from <1 hour in dogs to 18–24 hours in humans. Eosinophils migrate into tissues, especially the gastrointestinal (GI) tract and lungs, and live for about 2 days unless anti-apoptotic factors, such as IL-5, prolong their survival for up to 2 weeks. Under pathologic conditions, generation and emergence times can be altered, and eosinophils may re-enter circulation.[17,76]

TISSUE DISTRIBUTION AND METABOLISM

Eosinophils reside mainly in the skin, respiratory tract, and GI tract. Their location and number vary with species, stage of estrous cycle, diet, and histamine content of the tissue; most eosinophils are found in the GI tract where they are recruited by the chemokine eotaxin-1 (CCL11).[50,53]

STRUCTURE AND MORPHOLOGY

Eosinophils are polymorphonuclear leukocytes that become recognizable with the appearance of specific (secondary) granules at the progranulocyte/myelocyte stage (Figure 46.1). Myelocytes have numerous immature specific granules, an extensive Golgi complex, and abundant rough endoplasmic reticulum (RER).[29] The nucleus undergoes segmentation, and granules continue to mature in band and segmented forms. Eosinophils contain three types of granules—specific granules, primary granules, and small dense granules—as well as eosinophil sombrero vesicles (EoSVs),[52] lipid bodies, mitochondria, free ribosomes, sparse RER, a small Golgi, and glycogen.[2,19]

Specific granules containing potent cytotoxic proteins and comprising the majority of the granule population have a bicompartmental structure in many species, including humans, rhesus monkeys, cats, goats, rabbits, opossums, guinea pigs, rats, and mice,[2,40,51] with a distinctive electron-dense core (crystalloid) characterized by both longitudinal and cross-sectional periodicity and surrounded by more lucent matrix (Figure 46.2a–d). Cores vary in density, size, and shape among species; variation is especially wide in cats. Approximately 10% of canine granules have distinct cores[37]; approximately 50% of sighthounds and individuals of other canine breeds can have eosinophils with poorly staining granules, termed gray eosinophils. This staining difference appears due to eosinophil peroxidase (EPO) deficiency; other deficiencies may also be present. Using Romanowsky stains, gray eosinophils from Greyhounds are similar to murine eosinophils deficient in both EPO and major basic protein (MBP).[4,27,38,39] Equine eosinophil granules contain dense cores that lack crystalline patterns, are often located eccentrically, and are surrounded by less-dense matrix.[65]

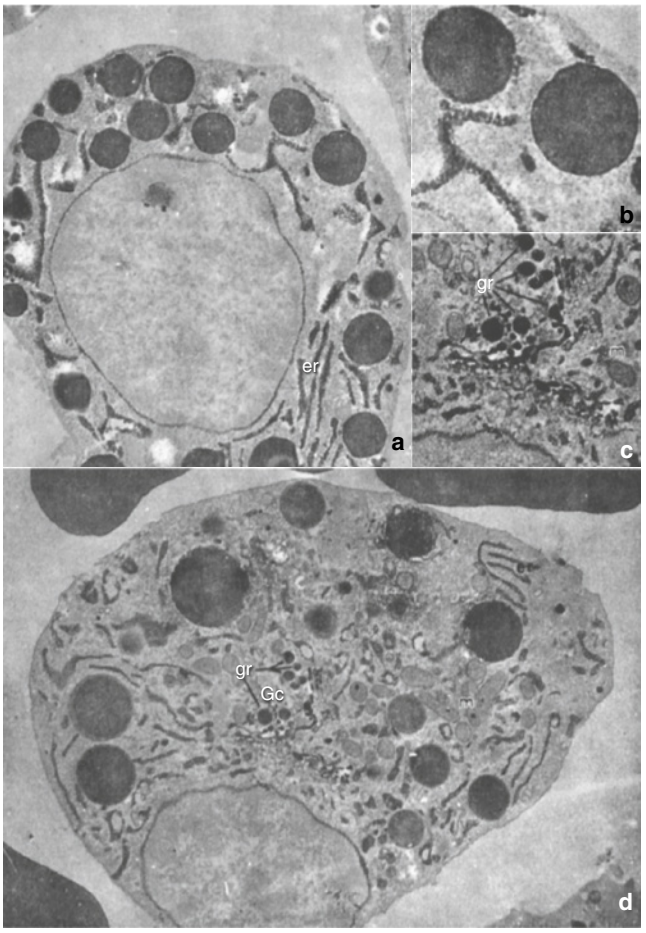

FIGURE 46.1 Eosinophil progranulocyte and myelocyte from canine bone marrow stained for eosinophil peroxidase (EPO) activity. (a) A progranulocyte contains dense, homogeneous granules and cisternae of rough endoplasmic reticulum (er), highlighted in (b). The myelocyte shown in (d) contains condensing granules of varying morphology, an active Golgi complex (Gc) producing granules (gr), profiles of rough endoplasmic reticulum, and numerous mitochondria. (c) An enlargement of the Golgi area from the cell in (d). Eosinophil peroxidase activity is characterized by the electron-dense material in the perinuclear cisterna, rough endoplasmic reticulum, Golgi complex, and specific granules. (a) 10 080×. (b) 18 900×. (c) 14 280×. (d) 10 080×.

Homogeneous granules are found in eosinophils from cattle, mink, and gorillas.[40,51]

Features of the four major proteins are described in Table 48.1. Major basic protein, located in the core, comprises >50% of the granule protein content. Deposits of MBP can be found at sites of eosinophilic inflammation. The other proteins are found in the matrix. Eosinophil peroxidase is found in progranulocytes and myelocytes in the RER, perinuclear cisterna, Golgi, and specific granules. Thereafter, EPO is located solely in specific granules.[2,19] Eosinophil peroxidase is distinct from and more potent than myeloperoxidase.[2] Different sources conclude that EPO is involved in bacterial killing and has activities against parasites and viruses.[59,72] This enzyme has been widely reported to be absent from feline

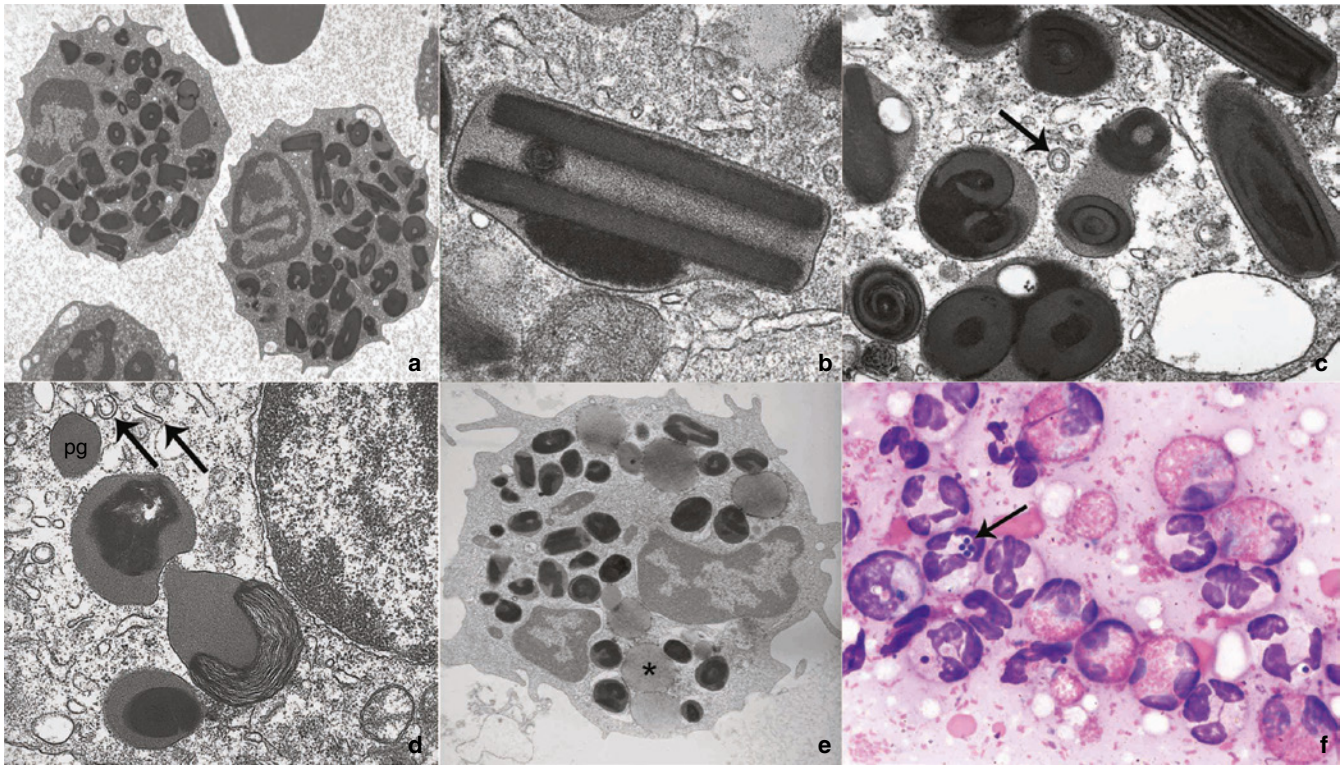

FIGURE 46.2 (a)–(e) Transmission electron micrographs and (f) cytologic preparation of feline eosinophils in blood and tissue. (a) Two blood eosinophils containing numerous heterogeneous bicompartmental granules; 34 500×; (b) A rod-shaped specific granule with electron-dense cores (which may be disassembling) and lucent matrix; 340 000×; (c) Multiple specific granules with disassembling electron-dense cores surrounded by more lucent matrix. Wright's stain; 1000×.

eosinophils; however, protein peaks separated from feline eosinophil granules are most compatible with EPO, eosinophil cationic protein (ECP), and MBP.[25] ECP constitutes approximately 30% of the granule protein and damages membranes by a colloidal osmotic process, causing formation of transmembrane non-ion-selective pores; this protein promotes mast cell degranulation and is bactericidal. Two isoforms have been identified by chromatography.[29] Eosinophil-derived neurotoxin (EDN) is also expressed in mononuclear cells and possibly neutrophils; it damages myelinated nerve fibers and is implicated in activity against respiratory viruses.[59] Other granule constituents include catalase, peroxisomal lipid β-oxidation enzymes (enoyl-CoA hydratase, 3-ketoacyl-CoA thiolase), flavoprotein (acyl-CoA oxidase), β-glucuronidase, cathepsin D, serine:pyruvate aminotransferase, and zinc.[19,40] Acid phosphatase and arylsulfatase activities may be unmasked in the matrix in activated eosinophils.[19] Four basic proteins have been isolated from equine eosinophils, but could not be correlated definitively to human proteins, although one is likely the analog of human MBP.[56]

Membrane-bound primary granules are most numerous in progranulocytes and can be found in all stages of eosinophils in some species (Figure 46.2d). Their lysophospholipase activity has been reported to reside in Charcot–Leyden crystal protein (CLCP), but is now believed to be due to other eosinophil lysophospholipases.[11,35,45] CLCP, renamed galectin-10 (Gal-10) based on homology with other members of that protein family and its presence in regulatory T cells,[11,45] comprises 7–10% of total eosinophil protein in humans and other primates.[11,19,20,45] This protein polymerizes to form hexagonal crystals deposited in tissues with eosinophilic inflammation even when intact eosinophils are no longer visible; its function in humans remains obscure, and CLCP/Gal-10 does not appear to be present in species of veterinary importance.[11,35,45] Lysophospholipase dampens inflammation by impeding generation of arachidonic acid metabolites and may inactivate cell-damaging lysophosphatides produced during degranulation.[29] A third type of eosinophil granule, the small dense granule, contains acid phosphatase, arylsulfatase, and perhaps ECP, catalase, and peroxidase.

Lipid bodies store arachidonic acid used in the generation of lipid mediators such as leukotrienes and prostaglandins.[19] Eosinophils also synthesize cytokines, proteoglycans, vitamin-B-binding proteins, and numerous enzymes, including collagenase, histaminase, phospholipase D, and nonspecific esterases. At least

TABLE 46.1 Summary of major preformed proteins released from specific granules of eosinophils.

Protein	Location	Characteristics	Actions
Major basic protein (MBP)	Specific granule core (also found in basophils)	Cationic protein, 14 kDa, pI 10.9, 117 amino acid (aa) single polypeptide rich in arginine; premolecule (207 aa) has a pI of 6.2 owing to a 90 aa acidic portion thought to protect cell from toxic effects of MBP during transport	Cytotoxic to parasites, protozoa, bacteria, normal mammalian epithelial cells, murine tumor cells; stimulates signaling pathways and mediator release from mast cells, neutrophils, and basophils; neutralizes heparin; activates platelets, basophils, mast cells, and neutrophils; induces bronchospasm; activates complement via classical and alternative pathways; activates remodeling factors from epithelial cells; increases cutaneous vasopermeability; adversely affects smooth muscle contraction responses; implicated in regulating peripheral nerve plasticity by inhibiting apoptosis; no enzymatic activity
Eosinophil peroxidase (EPO)	Specific granule matrix	Heavy (58 kDa) and light (14 kDa) subunits; pI 10.8; genetically and biochemically distinct from myeloperoxidase	In presence of H_2O_2 and halide, generates oxygen radicals toxic to helminths, bacteria, mycoplasmas, fungi, protozoa, viruses, and tumor cells; in absence of H_2O_2 acts as cationic toxin; toxic to host respiratory epithelium; induces release of granules, histamine from mast cells; inactivates leukotrienes
Eosinophil cationic protein (ECP)	Specific granule matrix	Cationic protein, 18–21 kDa, pI 10.8, 133 aa; secreted and stored forms differ; ribonuclease gene superfamily; 66% sequence homology with EDN	Toxic to helminths, protozoa, bacteria, and tracheal epithelium; neurotoxic; neutralizes heparin; promotes mast cell degranulation
Eosinophil-derived neurotoxin (EDN, also called eosinophil protein X [EPX])	Specific granule matrix	Cationic protein, 18–19 kDa, pI 8.9, 134 aa; ribonuclease gene superfamily; 66% sequence homology with ECP	Toxic to myelinated nerve fibers; significant ribonuclease activity; antiviral activity in respiratory infection

35 cytokines, chemokines, and growth factors are produced by eosinophils.[35] Eosinophils are the chief producers of cytokines such as transforming growth factor (TGF)-β in a variety of eosinophil-associated diseases such as asthma.

The plasma membrane contains NADPH oxidase to generate an oxidative burst and alkaline phosphatase in some species (cattle, horses, dogs, and cats).[40] Eosinophils lack bactericidal lysozyme, lactoferrin, and phagocytin.[18]

SURFACE MOLECULES

By scanning electron microscopy, surfaces of eosinophils have short blunt processes and sparse microvilli. Their many cell surface receptors include receptors for cytokines, chemokines, complement proteins, immunoglobulins (Ig), adhesion molecules, lipid mediators, enzymes, and signaling and apoptotic factors.[81] Adhesion receptors link eosinophils with endothelial cells or extracellular matrix, allowing their emigration and directing their movement in tissues and extracellular spaces. Chemotactic factors and chemokines recruit eosinophils to sites of inflammation. Many factors, including lipid mediators, Igs, and complement components, act through receptors to activate eosinophils to perform effector functions and connect them with their targets.[40,46]

Other surface molecules have been identified on eosinophils and include toll-like receptors and inhibitory receptors, such as sialic-acid-binding Ig-like lectin (Siglec-8).[46,60] Activation of inhibitory receptors suppresses eosinophil activation and induces negative signaling in murine eosinophils; cross-binding Siglec-8 induces apoptosis of eosinophils.[35]

SIGNS OF ACTIVATION

Eosinophil activation results in changes in morphology, surface characteristics, and functional activities.[7,19,46] These changes are acquired after leaving the circulation, but may be found in circulating eosinophils of patients with allergic disease and hypereosinophilic syndrome (HES). Activated eosinophils are typically hypodense and have fewer specific granules and increased numbers of lipid bodies (Figure 46.2e) and vesiculotubular structures. Lipid bodies are repositories of arachidonate-containing lipids for oxidative metabolism and synthesis of lipid mediators; vesiculotubular structures, now termed EoSVs, store and transport granule products.

Upon activation, EoSVs move to the plasma membrane and fuse with it to rapidly release mediators. In a canine model of asthma, eosinophils in bronchoalveolar lavage fluid had either a typical polymorphonuclear appearance or the appearance of a globule leukocyte. Other changes noted in human activated eosinophils are increased primary granules and small dense granules. Functionally, cytotoxicity to parasites and mammalian cells is increased, generation of reactive oxygen species is enhanced, and enzymes, such as acid phosphatase, are activated.

INVOLVEMENT IN HOMEOSTASIS AND THE IMMUNE SYSTEM

Eosinophils participate in homeostatic functions and mucosal immunity in the GI tract. Under homeostatic conditions, eosinophils traffic into the thymus, mammary gland, uterus, and the GI tract.[60] They are recruited by eotaxin-1 to the thymus during the neonatal period and are associated with thymocyte deletion.[68] They participate in T-cell-mediated immunity through recognition and presentation of microbial, viral, and parasitic antigens, as well as superantigens. Their immunologic roles may be related to their location at surfaces in contact with the outside environment, their capacity to respond to particulate antigens (inhaled, ingested, or granuloma-encapsulated antigens), and their expression of Fc receptors for IgG, IgE, and IgA.[75] Eosinophils can prime B cells for IgM production and regulate T-cell polarization and proliferation of effector T cells.[60,71] Eosinophils appear to play regulatory roles in development of the postpubertal mammary gland, onset of estrous cycling, and blastocyst implantation.[30,58,60]

TRAFFICKING IN EOSINOPHILIC INFLAMMATION

Trafficking of eosinophils into tissues is directed by cytokines produced by TH_2 cells and endothelial cells; these include IL-4, IL-5, and IL-13, adhesion molecules (β1-, β2-, and β7-integrins), chemokines (CCL5 and the eotaxins), and many other molecules, including acidic mammalian chitinase.[79] Eotaxins-1, -2, and -3 (CCL11, CCL24, and CCL26, respectively)[42,64] are produced by respiratory epithelium and skin fibroblasts in human hypersensitivity disorders; CCL11 appears at the earliest stages, followed by CCL24 and then CCL26.[35]

Circulating eosinophils participate in inflammation through the following sequence of events:

1. Quiescent circulating eosinophils express L-selectin, permitting the eosinophil to roll along the vessel wall.[46]

2. Eosinophils meet a priming stimulus, such as IL-3, GM-CSF, IL-5, IgG, and IgA, released from perivascular immune cells, endothelial cells, and local inflammatory sites.[44] IL-4 mediates ε isotype switching and brisk production of IgE.[26] IL-5 initiates signal transduction in eosinophils resulting in expression of genes for surface receptors, structural and secreted proteins, and transcription factors.[44,69] Priming leads to adhesion, chemotaxis, degranulation, release of lipid mediators, and oxidative burst.

3. One priming function of IL-5 is to increase the number of responsive eosinophils.[14,55] Primed eosinophils express β1- (very late activation [VLA]-4), β2- (Mac-1 and leukocyte-function-associated antigen [LFA]-1), and β7-integrins that mediate secure adhesion to endothelial ligands (vascular-cell-adhesion molecule [VCAM]-1 and intercellular adhesion molecule [ICAM]-1) induced by IL-1.[6,7] The VLA-4/VCAM-1 pathway is selective for eosinophils and basophils.[6] Expression of tissue factor by eosinophils may play a role in migration from blood.[54] Adhesion further primes eosinophils to respond to chemoattractants and lipid mediators.

4. Recruited by various chemotactic factors, primed eosinophils migrate between endothelial cells into interstitial spaces. Depending on the target organ, eosinophils migrate into tissues by a regulated process involving coordinated interaction between networks involving CCL11, eosinophil adhesion molecules (α4β1, α4β7, αmβ2, αLβ2), and adhesion receptors on the endothelium (MAdCAM-1, VCAM-1, and ICAM-1).

5. Eosinophils approach their final destination guided by interactions with adhesion molecules in the extracellular matrix (fibronectin, laminin, and fibrinogen) and a concentration gradient of chemoattractants, including C5a, *N*-formyl-methionyl peptides, leukotrienes, platelet-activating factor (PAF), hydroxyeicosatetraenoicacids(HETEs),hydroxyheptadecatrienoic acids (HHTs), monocyte chemotactic peptide-3 (MCP-3), macrophage inflammatory protein-1α (MIP-1α), eosinophil chemotactic factor of anaphylaxis (ECF-A), histamine, parasite-derived factors, and chemokines such as CCL5.[15,46]

6. Eosinophils are activated by cytokines, lipid mediators, chemoattractants, and Igs to release granule proteins, lipid mediators, and oxygen radicals.

7. Eosinophil survival is enhanced through exposure to inflammatory cytokines, such as IL-5.[33]

8. Eosinophils contribute to wound healing, or sclerosis, by secretion of TGF-β, procoagulation through activation of factor XII by ECP, and fibrinolysis by activation of plasminogen.[9,16,70,73]

Eosinophilic predominance in certain disorders, such as parasitic disease and asthma, is likely mediated by several eosinophil-selective molecules, including

adhesion molecules, primers, chemoattractants, and anti-apoptotic agents. Finally, a major consequence of chronic eosinophilic inflammation is tissue damage. Injury to airway epithelium mediated by MBP appears to be reversible, but myocardial fibrosis, perhaps induced by granule proteins or TGF, is permanent in hypereosinophilic syndrome.[7,29,46]

EFFECTOR FUNCTIONS

Defense Against Helminthic Parasites

Eosinophils are capable of phagocytosis, but helminths are too large, and eosinophils secrete mediators directly onto the target rather than engulfing them and, working in concert with T-cell-derived perforins, bind to larvae opsonized with IgG, IgE, or complement, flatten against the integument, release basic toxins and hydrolytic enzymes directly onto the target, and migrate under the damaged larval skin.[8,10,46,51] Oxidative burst may contribute to anti-helminthic action, but the cytotoxic effect of MBP to schistosomula of *Schistosoma mansoni* occurs independently of oxygen metabolites.[46] Eosinophils contribute to host defense by dampening immediate pathologic responses and participating in tissue remodeling and immunomodulation. IL-5 may play a role in the effectiveness of parasite vaccines in mice.[49]

The role of eosinophils in helminthic cytotoxicity in vivo remains uncertain. Some human studies suggest that eosinophils may prevent reinfection rather than clear an initial infection.[31] Studies of transgenic mice that overproduce IL-5 or mice deficient in IL-5, eotaxin, or the eotaxin receptor yield conflicting results about the role of eosinophils and their mediators in helminthic infections. Parasitized mice in which eosinophil and IgE responses were ablated by anti-IL-5 antibody had no changes in parasite burden or resistance to infection.[32,63] Interpretation of findings is confounded by use of parasites for which the mouse is not the natural host, equating murine and human eosinophils, which have functional differences, and lack of ability to ascertain that eosinophils are degranulating in response to parasitic infection. Horses with insect-bite hypersensitivity treated with an anti-IL-5 vaccine that reduced tissue, but not peripheral blood, eosinophils did not have greater intestinal parasite counts compared with placebo-treated horses.[24] After many years, the beneficial role of eosinophils in control of parasite infection remains poorly understood.

Effector Cells in Asthma and Allergic Disease

The definitive contributions of eosinophils in hypersensitivity disorders are still being determined. Asthma is characterized by inflammation, hyperresponsiveness, mucus secretion, and remodeling with smooth muscle hyperplasia, collagen deposition, neovascularization, and metaplasia of goblet cells.[3,9] Studies in animals and people suggest an important role for eosinophils in airway remodeling and in acute exacerbations in asthma, but uncertainties remain.[57]

Eosinophils promote damage and dysfunction through elaboration of proinflammatory mediators, such as leukotriene C4, PAF, and eicosanoids, and release of granule proteins.[80] Eosinophils recruited into tissues by cytokines then recruit CD4+ cells into tissues by releasing IL-16. IgE-mediated mast cell degranulation, induced upon re-exposure to allergens and parasite antigens, plays a role in eosinophil recruitment in hypersensitivity disorders (Figure 46.2f).[46] Eosinophil granule products, reactive oxygen species, and lipid mediators cause damage to airway mucosa and nerves and bronchoconstriction. Major basic protein is toxic to airway epithelium and triggers degranulation of mast cells and basophils.[60] Eosinophils from asthmatic patients are hyperadhesive and have increased collagen receptor expression. TGF-β from eosinophils may play a role in airway remodeling. Leukotrienes secreted by eosinophils mediate vascular permeability, secretion of mucus, and constriction of smooth muscle. Cytokines involved in recruitment enhance effector functions and prolong survival of eosinophils by delaying apoptosis.

Modulation of Inflammation

Eosinophils suppress immediate hypersensitivity reactions.[46] They phagocytose immune complexes, peroxidize mast cell granule debris, and release histaminase to neutralize histamine, phospholipase B to inactivate mast cell PAF, MBP to inactivate mast cell heparin, plasminogen to reduce local thrombin activity, arylsulfatase B and hypochlorous acid to inactivate leukotrienes, prostaglandin E1 (PGE1) and PGE2 to inhibit degranulation of basophils and mast cells, and lysophospholipase to prevent generation of arachidonic acid metabolites.

Phagocytosis

Eosinophils have the capacity to phagocytose immune complexes, antibody-coated RBCs, mast cell granules, inert particles, yeast, and bacteria, including *Mycoplasma*. They are less efficient at killing bacteria than neutrophils despite having higher levels of peroxidase activity, oxidative responses, and hydrogen peroxide (H_2O_2) production.[18,40] Eosinophils lack several bactericidal substances and have a lower density of complement receptors than neutrophils.

Antitumor Effect

Eosinophil products are cytotoxic to or induce apoptosis of tumor cells in vitro,[41] and antitumor roles for IL-5 and eosinophils are suggested in murine models of increased expression of IL-5 and eotaxin deficiency, respectively. In some neoplasms, local infiltration by eosinophils in the absence of peripheral eosinophilia improves prognosis.[48] In human colorectal carcinomas, improved prognosis associated with eosinophil infiltration was independent of staging, vascularization, p53 expression, and histologic grade.[23] However, in other studies, eosinophilic infiltrates in tumors have been associated with a poorer prognosis or had no impact on prognosis.[1,47]

MECHANISMS OF EOSINOPHIL EFFECTOR FUNCTION

Release of Granule Proteins

Granule products are released through exocytosis, piecemeal degranulation, or cell lysis.[52,62] In piecemeal degranulation, transport vesicles carry granule products to the plasma membrane. Unique to eosinophils is a dynamic system of vesicular compartments, termed EoSVs, generated by specific granules. Using electron tomography, EoSVs are demonstrated to be highly pleomorphic curved tubular structures that are round, C-shaped, or elongated (Figure 46.2c,d). They change shape to accommodate transport of membrane-bound proteins over long distances in the cell and store certain proteins for quick release upon stimulation.[52] EoSV "dock" and then fuse with the plasma membrane, releasing proteins. The docking complex consists of soluble *N*-ethylmaleimide-sensitive factor attachment receptors (SNARE) located on the plasma membrane and the vesicle. Piecemeal degranulation is selective and tightly regulated so that only specific proteins are released after receiving a distinctive stimulus: IgE induces release of EPO and IgA binding can cause release of ECP and EPO, whereas IgG binding results in release of ECP and EDN.[43,46,51] Equine eosinophils degranulate through a complex process of compound exocytosis and cumulative fusion of multiple granules, resulting in a degranulation sac and focal release of granule proteins.[62]

Release of Lipid Mediators

Eosinophils respond to PAF and also produce and secrete it on activation. Platelet-activating factor enhances many eosinophil activities, including adherence to endothelium, chemotaxis, binding of IgE, production and release of oxygen radicals, release of granule proteins, and synthesis of prostanoids. Other lipid mediators released by eosinophils include leukotrienes (e.g., LTB4 and LTC4), thromboxane A2, and prostaglandins.[46] With the exception of PGE, which may downregulate eosinophil effector functions, lipid mediators contribute to host dysfunction, such as bronchial hyperreactivity.[46]

Cytokine Release

Eosinophils exhibit paracrine regulation of other inflammatory cells, endothelial cells, and fibroblasts through release of IL-1, IL-2, tumor necrosis factor-α (TNF-α), TNF-β, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-13, IL-16, IL-18, TGF-α/-β, eotaxin, and CCL5. Autocrine control results from elaboration of IL-3, IL-5, and GM-CSF by eosinophils.[7,75]

MECHANISMS OF EOSINOPHILIA AND EOSINOPENIA

The number of eosinophils in circulation is influenced by diurnal variation related to cortisol levels, age, exercise, and exposure to environmental stimuli. The least accurate method to quantify blood eosinophils is the differential leukocyte count performed on a stained blood film, but this method is useful in most situations. Eosinophil counting chambers can be used, but automated methods that stain peroxidase provide the most accurate counts. Eosinophil peroxidase is not detected by this method in all animal species, especially cats. Reference intervals for eosinophils vary among species and geographic regions. Eosinophilia is not always present in the face of eosinophilic inflammation in tissues where eosinophil survival is increased.

Eosinophilia

Eosinophilia results from elaboration of eosinophilopoietic factors, principally IL-5, by T cells sensitized by parasite antigens or allergens.[28,32] IL-5 primes eosinophils, enhances their function, and prolongs their survival.[77] Eosinophilia associated with parasitism occurs when parasites are located in tissues rather than in the intestinal lumen. In eosinophilic bronchopneumopathy (EBP), previously termed pulmonary infiltrates with eosinophilia, eosinophilic infiltrates are found in the bronchial mucosa and interstitium[12,13]; hypersensitivity may be initiated by heartworm infection, migration of larval parasites, and antigens associated with chronic infections. Chronic eosinophilia is associated with inflammatory disorders of mast cell-rich organs, namely, skin, lung, GI tract, and uterus. Other conditions include eosinophilic dermatitis, previously termed eosinophilic plaque/granuloma/indolent ulcer, and eosinophilic inflammatory bowel disease in cats and eosinophilic myositis, eosinophilic panosteitis, and eosinophilic gastroenteritis in dogs. Paraneoplastic eosinophilia is caused by tumors, such as lymphoma, mast cell tumor, and solid tumors, that produce IL-5 and other cytokines.[67] Eosinophilic leukemia is a rare disease, and the diagnosis depends on ruling out other causes (see Chapter 66). In HES, characterized by persistent eosinophilia of unknown origin, increased survival of eosinophils in circulation, tissue infiltrates, and organ dysfunction, one proposed mechanism is clonal expansion of T cells generating eosinophilopoietic factors.[74] Increased levels of IL-5 in some patients may override the apoptotic effects of corticosteroids. In a subset of people with HES, constitutive expression of tyrosine kinases leads to production of eosinophils independent of growth factors.[60] Eosinophilia is sometimes recognized in animals with hypoadrenocorticism owing to decreased or absent cortisol.

Eosinopenia

Detection of low numbers of eosinophils has limited significance, and underlying mechanisms of eosinopenia are unclear. Corticosteroids cause eosinopenia, perhaps by neutralization of circulating histamine and inhibition of mast cell degranulation. The lympholytic effect of corticosteroids may attract eosinophils into lymphoid tissues after release of cytokines; alternatively, production of cytokines promoting growth and function of

eosinophils may be diminished. Corticosteroids inhibit cytokine-dependent eosinophil survival. Thus, eosinopenia may occur in hyperadrenocorticism or after exogenous administration of corticosteroids. Catecholamines may induce eosinopenia through a β-adrenergic effect, as the effect is eliminated by β-blockers. Eosinopenia present in acute inflammation or infection may result from release of corticosteroids and catecholamines.

THERAPEUTIC APPROACHES

Novel therapeutic interventions based on molecular and cellular mechanisms of eosinophilic inflammation may transform medical management of patients with eosinophilic inflammation.[7,22,24,35,46,60] Glucocorticoids have been the therapeutic mainstay and act by destabilizing eotaxin mRNA, suppressing transcription of IL-4, IL-5, and eotaxin genes, and inhibiting survival of eosinophils.[61] Not all patients respond or maintain a response to glucocorticoids. Other approaches include reduction of eosinophil production by myelosuppressive drugs (e.g., hydroxyurea), inhibition of eosinophil degranulation and effector functions by interferon (IFN)-α, and interference with transcription of cytokines, such as IL-5 and GM-CSF, by cyclosporin A. Novel approaches include anti-IL-5 antibodies such as mepolizumab, used in eosinophilic asthma; therapeutic recombinant vaccination against IL-5; antagonists to leukotrienes or their receptors; tyrosine kinase inhibitors, such as imatinib, that may be effective in patients with HES caused by constitutive production of tyrosine kinases; lidocaine, demonstrated to shorten eosinophil survival; third-generation antihistamines; blockers of eosinophil adhesion; inhibitors of the eotaxin/CCR3 pathway; anti-human IL-13 antibody; and induction of eosinophil apoptosis by antibody cross-linking of Siglec-8.

Basophils and mast cells are often referred to as sister cells due to similarities in their chemical compositions and biologic functions. Both cells are well known for their involvement in T-helper lymphocyte type 2 (Th2)-mediated immunity and hypersensitivity reactions. However, these cells are distinct with unique maturation pathways, tissue localizations, and chemokine-signaling responses. Additionally, basophils and mast cells function independently in their protective and immunologic roles. Therefore, laboratory abnormalities of basophils and mast cells have distinctive differential diagnoses.

ORIGIN, DEVELOPMENT, AND TISSUE DISTRIBUTION

Basophils and mast cells arise from shared early progenitor cells in bone marrow and spleen via separate maturation pathways.[5] In the few reported cases of defective basophilopoiesis or basophil function, patients lacked concurrent mast cell defects providing clinical evidence for separate maturation pathways.[9]

Common Origin of Basophils and Mast Cells

Within the bone marrow, hematopoietic stem cells develop into common myeloid progenitor cells which, in turn, differentiate into granulocyte–monocyte precursors (GMPs).[5] GMPs are agranular, lineage negative (Lin^-), cluster of differentiation (CD)34^+, receptor tyrosine kinase KIT (c-KIT^+), CD16/32^+ cells, which have the potential to differentiate into mast cells, basophils, eosinophils, neutrophils, or macrophages.[5] The final maturation pathway selected by these multipotent bone marrow GMPs is influenced by specific chemokines, interleukins (ILs), and activated transcription factors. IL-3 signaling via the janus kinase (JAK)2/signal transducer and activator of transcription 5 (STAT5) pathway is crucial for development of both basophils and mast cells.[29]

The majority of GMPs within bone marrow express FcεRI, the high-affinity receptor for the fragment crystallizable (Fc) region of IgE, which is important for basophil and mast cell function.[5] These $FcεRI^+$ GMPs are also referred to as pre-basophil and mast cell progenitors (pre-BMPs).[5] Both pre-BMPs and $FcεRI^-$ GMPs are capable of differentiating into either basophil progenitors (BaP) or mast cell progenitors (MCP).[5] In murine bone marrow, the differentiation of pre-BMPs into either BaPs or MCPs depends upon the relative expression of the transcription factors GATA-binding protein 2 (GATA2), CCAAT-enhancer-binding protein alpha (C/EBPα), and melanogenesis-associated transcription factor (MITF).[25] MITF expression is necessary for mast cell development and is disrupted by high concentrations of C/EBPα expression.[29] Thus, MCPs have high MITF and low C/EBPα gene expression; BaPs have low MITF and high C/EBPα gene expression.[29]

Using the murine animal model, the common origin of basophils and mast cells within the spleen follows a slightly different pathway than that described in bone marrow. The murine spleen contains Lin^-, $CD34^+$, c-KIT^+, $FcεRI^-$ multipotent GMP-like cells analogous to bone marrow $FcεRI^-$ GMPs.[25] However, splenic GMP-like cells are capable of promoting enhanced type-2 cytokine responses (i.e., IL-4, IL-5, IL-9, and IL-13 production).[25] GMP-like cells develop into a bipotent basophil–mast cell progenitor (BMCP), which is immunophenotypically distinct from the murine bone marrow pre-BMP.[4,25] Splenic BMCPs are believed to be capable of further differentiation into both BaPs and MCPs.[4,25]

Basophil Development and Tissue Distribution

Under the influences of IL-3 and thymic stromal lymphopoietin (TSLP), BaPs within bone marrow or spleen develop into mature basophils which are released into circulation.[25] In health, basophil maturation within bone marrow is completed in about 2.5 days.[27] Once in blood, basophils have a brief circulating half-life of approximately 6 hours and constitute about 0.5% of blood leukocytes.[27] From the blood, basophils are recruited into tissues in response to inflammatory stimuli where they may live as long as 2 weeks.[27] Within tissue, basophils retain their unique morphologic features, but are not routinely identified in H&E-stained tissue sections.

IL-3 is the major basophil growth factor and promoter of basophil production, differentiation, and survival;[25] it upregulates essentially all basophil immune responses. IL-3-induced basophils arise primarily from bone marrow as part of immunoglobulin E (IgE)-dependent, Th2-mediated immunologic responses.[25] IL-3 activates GATA1, GATA2, and STAT5 transcription factor pathways in multipotent GMPs resulting in amplified basophiloiesis, bone marrow basophil hyperplasia, and increased peripheral basophil concentration.[25] Additional growth factors that contribute to basophil production and differentiation include TSLP, granulocyte macrophage colony-stimulating factor (GM-CSF), IL-4, IL-5, and stem cell factor (SCF).[25,27]

Basophils emigrate from blood to tissues along chemotactic gradients in order to participate in inflammatory responses. After stimulation, basophils release cytokines, including tumor necrosis factor-alpha (TNF-α) and IL-4, which increase expression of adhesion molecules on endothelial cells, thereby initiating emigration. Rolling of basophils along endothelium is mediated by basophil selectins, which act to tether the cells loosely to their carbohydrate counter ligands on endothelial cells. Adherence of basophils to the vascular endothelium involves intercellular adhesion molecule (ICAM)-1, endothelial-cell–leukocyte adhesion molecule (ELAM)-1, and vascular cell adhesion molecule (VCAM)-1, which are expressed on the surface of activated endothelial cells. Basophil integrins act to establish firm adhesion. Transendothelial migration and movement through the extracellular matrix are mediated by similar mechanisms. In addition to directing basophils to inflammatory sites, chemotactic cytokines enhance basophil degranulation.[27]

Mast Cell Development and Tissue Distribution

Unlike other leukocyte lineages, most mast cells do not complete maturation within the bone marrow or spleen. Instead, immature poorly granulated MCPs are released into circulation and migrate into perivascular, subendothelial, and perineuronal areas within connective and mucosal tissues.[5] There, they proliferate, differentiate, and mature into well-granulated mast cells under the influence of a variety of interleukins including IL-3, IL-4, IL-9, and IL-10.[27] Mature mast cells are resident tissue cells capable of surviving for weeks to months, even after degranulation and subsequent cytoplasmic granule regeneration.[5]

Mast cell survival, growth, and differentiation are dependent upon normal interactions between SCF and its cell-surface receptor c-KIT (CD117).[39] SCF is produced by endothelial cells, epithelial cells, fibroblasts, and other cell lines in culture. Mast cells deprived of SCF undergo apoptosis. KIT is a transmembrane receptor tyrosine kinase which uses the mitogen-activated protein kinase (MAPK) signaling cascade and is encoded by the c-KIT proto-oncogene.[39] Mutations in the c-KIT proto-oncogene can result in mastocytosis and mast cell neoplasia (see Chapter 73).[39] The effects of SCF on tissue mast cells are antagonized by GM-CSF, interferon-gamma (IFN)-γ, and transforming growth factor-beta (TGF)-β. Mast cell differentiation and proliferation are also supported by IgE, IL-6, IL-9, C-C motif chemokine ligand (CCL)11, CCL24, CCL26, and neuronal growth factor.[5,7]

Mast cells are distributed within tissues commonly associated with clinical symptoms of allergic disease: gastrointestinal tract, lungs, and skin. Rodents, and potentially other mammals, have a large pool of MCPs and mast cells within the peritoneum and associated adipose tissues.[5] Migration of MCPs into the gastrointestinal tract is primarily mediated by C-X-C chemokine receptor (CXCR)2 and α4β7 integrin, which binds to mucosal vascular addressin cell adhesion molecule-1 (MAdCAM-1) and VCAM-1 on endothelial surfaces.[8,12] Similar MCP homing mechanisms have been described in the lungs utilizing CXCR2, C-C chemokine receptor (CCR)2, and CCL2.[5] The MCP integrins, α4β7 and α4β1, interface with VCAM-1 on pulmonary endothelial cells and thereby facilitate MCP migration into the pulmonary parenchyma.[5] The primary chemotactants for mast cells in the skin are leukotriene (LT)B_4, IgE, and CCL2/CCR2.[5] Once in tissue, mast cells participate in protective and pathologic processes.

OVERVIEW OF BASOPHIL AND MAST CELL BIOLOGIC FUNCTIONS

In addition to participating in allergic responses, mast cells and basophils also perform protective roles in innate immunity, host defense, and inflammation.[36] In response to microbial invasion, microbial products, and tissue damage, basophils and mast cells release potent inflammatory mediators, such as histamine, proteases, chemotactic factors, cytokines, and arachidonic acid metabolites.[31] Both cells may also be activated by other inflammatory molecules, such as defensins, neuropeptides, adenosine, and endothelins.[4]

Basophils

Basophils participate in type 2 immunity and allergic inflammation. Type 2 immunity defends the host from helminths and ticks and is achieved by the stimulation of a Th2-mediated response. Basophils are critical in the development of IgE-mediated chronic allergic inflammation and recruit neutrophils and eosinophils to inflammatory sites.[36] Circulating basophils enter inflamed tissues during the late phase of IgE-mediated immediate type I hypersensitivity reactions where, like mast cells, they have deleterious effects. The importance of basophils in type I hypersensitivity responses is demonstrated by the ability of genetically engineered mast-cell-deficient mice to mount an IgE-mediated anaphylactic response.[13] Basophils are also crucial players in many other allergic conditions such as allergic rhinitis, hives (e.g., urticaria), asthma, allergic conjunctivitis, allergic gastritis, drug-induced or insect-bite-induced anaphylaxis, and inflammatory bowel disease.[25] Basophils may also antagonize or promote hemostasis by means of the anticoagulant actions of secreted heparin and the procoagulant effects of kallikrein.[27]

Mast Cells

Mast cells have critical roles in type 1 hypersensitivity reactions, but their other immunologic functions are vast. Mast cells protect hosts against a wide range of parasitic and bacterial infections, degrade venom toxins, mediate tolerance to skin transplants, contribute to tumor rejection, and exacerbate autoimmunity.[36]

Mast cells promote hypersensitivity reactions characterized by vasodilation, increased vascular permeability, bronchoconstriction, mucus secretion, and nerve stimulation. They modulate the immune response by stimulating T cells; play a role in host defense against tissue parasites; and promote acute and chronic inflammatory responses by stimulating leukocyte migration, endothelial–leukocyte adhesion, angiogenesis, fibrin deposition, fibroblast proliferation, and fibrosis.[11,36] Mast cells also play a protective role in innate immune responses to invading bacteria by releasing mediators that promote clearing infection.[36]

Mast cells are central mediators of wound healing and fibrosis; they release fibroblast-activating factors and cytokines, such as basic fibroblast growth factor, vascular endothelial growth factor, macrophage inflammatory protein-1, TGF-β, and IL-4.[11] Mast cells contribute to pathologic fibrotic disorders. For instance, after cardiac infarcts, mast-cell-mediated fibrosis and angiogenesis result in the replacement of injured cardiomyocytes with granulation tissue, thus, perpetuating cardiac insufficiency.[8]

MAJOR PRODUCTS OF BASOPHILS AND MAST CELLS

Many of the immediate effectors of basophils and mast cells are preformed and stored within their cytoplasmic granules. Basophils and mast cells also synthesize de novo products following activation. After degranulation, basophils and mast cells are capable of regenerating both their granules and granular contents.[5]

Stored Products

The primary substances stored in mast cell and basophil granules include proteoglycans, biogenic amines, enzymes, and, in basophils, major basic protein.[37] Stored products enhance localized innate immune responses following activation and degranulation.

The chemical composition of stored proteoglycans, such as heparin, serglycin, and chondroitin sulfate, is responsible for the characteristic metachromatic staining of basophil and mast cell cytoplasmic granules.[37] Among stored biogenic amines, histamine is arguably the most important due to its effects on local blood flow, vascular permeability, and smooth muscle contractility in inflammatory reactions. Other stored amines, which vary between species, include serotonin, adenosine, and dopamine.[37]

The collections of stored enzymes within mast cell and basophil granules are notably different. In addition, the enzymes within mast cell granules vary somewhat between mucosal (i.e., contain tryptase) and connective tissue (i.e., contain tryptase and chymase) mast cell populations.[37] Mast cell granules typically contain tryptase and sometimes chymase along with β-hexosaminidase, carboxypeptidase, cathepsin G, phospholipase A_2 (PLA_2), acid hydrolases, and chitinase.[37] By contrast, basophil granules contain bradykinin-generating neutral peptidases, elastase, β-glucuronidase, tryptase, and cathepsin-G-like enzyme.[27] Mast cells also store small quantities of various growth factors and cytokines, particularly TNF-α.[31]

De Novo Products

Because of their active roles in immediate inflammatory responses, basophils and mast cells are capable of de novo synthesis of various lipid-derived inflammatory mediators, cytokines, and interleukins. Basophils and mast cells preferentially utilize different arachidonic acid metabolism pathways in the production of their respective repertoires of lipid-derived products. Basophils tend to favor the lipoxygenase pathway with production of leukotrienes such as LTC_4, LTD_4, and LTE_4.[31] Mast cells utilize both the cyclooxygenase (COX) and lipoxygenase pathways to synthesize prostaglandin D_2 (PGD_2), PGE_2, LTC_4, LTB_4, LTE_4, and thromboxane B_2 (TXB_2).[31] Basophils and mast cells produce lipid-derived platelet-activating factor.[31] The dominant interleukins and cytokines produced by these cells are those important in type 2 immune responses, specifically IL-4, IL-3, IL-8, IL-13, TNF-α, and CCL3. Basophils, in particular, produce abundant IL-4, which recruits eosinophils and helps drive immunoglobulin class switching to IgE.[31] Mast cells also produce IL-1, IL-6, and GM-CSF, known for their roles in systemic acute inflammatory responses, as well as IL-5, a potent mediator of eosinophil proliferation.[31] Additionally, mast cells synthesize several growth factors and chemokines involved in mast cell proliferation, wound healing, fibrosis, and vascular dynamics including SCF, vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), nerve growth factor, and endothelin.[31,37]

ROLE OF BASOPHILS AND MAST CELLS IN TYPE 2 IMMUNE RESPONSES

Basophils and mast cells participate in type 2 immune responses.[36] Adaptive type 2 immunity protects the host from large multicellular invaders, such as helminths and ticks, and is characterized by activation of Th2 lymphocytes and antibody class switching to IgE.[36] The ultimate goal of a type 2 immune response is to create an inhospitable environment culminating in the expulsion of invading pathogens from the host's body. If pathogen expulsion cannot be achieved, type 2 immune responses will encapsulate the invader within a granuloma which shields local tissues from further damage.[36]

Activation of Basophils and Mast Cells

There are numerous initiators of basophil and mast cell activation and degranulation including IgE-mediated FcεRI cross-linking, cytokines, chemokines, chemical agents (e.g., radiocontrast solutions, narcotics, muscle relaxants, calcium ionophores), physical stimuli (e.g., cold), peptides (e.g., neutrophil lysosomal proteins, venoms, bacteria, and bacterial products), and viruses.[27] Basophils and mast cells also express their own unique sets of toll-like receptors (TLR), which facilitate activation during innate immune responses. Basophils of various mammalian species may express TLR1, TLR2, TLR4, and TLR6.[17] The TLR complement of mast cells is much broader, potentially due to their role as tissue sentinel cells, and includes TLR1, TLR2, TLR3, TLR4, TLR6, TLR7, and TLR9.[17]

Mast cell degranulation is also controlled by surface catecholamine receptors (α- and β-adrenoceptors) with opposing effects. Stimulation of α-receptors (e.g., norepinephrine and phenylephrine) or blockade of β-receptors (e.g., propranolol) induces mast cell degranulation. β-blockade, resulting in increased mast cell degranulation and tissue inflammation, can be caused by some respiratory pathogens such as *Bordetella pertussis* or *Haemophilus influenza*.[27] Animals with these infections are also predisposed to development of respiratory allergies.[27] Conversely, mast cell degranulation is inhibited by molecules that block α-receptors or stimulate β-receptors such as isoproterenol, epinephrine, and salbutamol. Thus, these medications may be employed in treatment of type I hypersensitivity reactions.[27]

Additional pharmacologic inhibitors of mast cell and basophil activation include corticosteroids, cyclosporine A, and theophylline.[15]

Degranulation and Production of Mediators by Basophils and Mast Cells

Following activation, basophils and mast cells release preformed inflammatory mediators stored within their cytoplasmic granules. The preformed contents have immediate local and, in some cases, systemic effects. Histamine, a major constituent of basophil and mast cell granules, is a short-lived vasoactive amine that causes an immediate increase in local blood flow and vessel permeability. Enzymes, such as chymase, tryptase, and serine esterases, activate matrix metalloproteases. Matrix metalloproteases, in turn, cause tissue destruction by breaking down tissue matrix proteins.

In addition to releasing preformed mediators, activated basophils and mast cells synthesize additional effector molecules. Synthesis and secretion of lipid mediators are induced via the activation of the cytoplasmic enzyme PLA_2. Activation of PLA_2 results in hydrolysis of mast cell membrane phospholipids and the production of arachidonic acid and subsequent prostaglandins and leukotrienes by the actions of cyclooxygenase or lipoxygenase.[27] The major arachidonic-acid-derived mediators produced by mast cells are PGD_2, LTC_4, LTD_4, and LTE_4. Basophils produce predominantly LTC_4.[27] Platelet-activating factor causes bronchoconstriction, retraction of endothelial cells, and relaxation of vascular smooth muscle.

Production and Action of IgE

After antigen exposure, B cells within lymph nodes undergo antibody class-switching to IgE via IL-4- and IL-13-mediated interactions with Th2 lymphocytes.[36] Upon subsequent exposures, preformed IgE is readily available to rapidly activate basophils and mast cells via IgE-mediated FcεRI cross-linking.[36]

IgE-mediated mast cell and basophil responses are critical in defense against parasitic infections. IgE-dependent mast cell activation in the gastrointestinal tract and lungs promotes the physical expulsion of parasites by initiating mucus release and triggering gastrointestinal peristalsis. Mast cells may also reduce the reproductive capability of gastrointestinal parasites, thereby reducing parasitic load.[14]

IgE-mediated mast cell and basophil responses are also protective against blood-sucking ticks. Upon initial exposure, skin at the site of a tick bite contains degranulated mast cells, basophils, and eosinophils. With subsequent tick-feedings, basophil-dependent resistance to the tick bite develops.[36] Basophils may confer this resistance via activation of the basophil cell-surface receptors, FcεRI, and Fc region of the IgG receptor IIIa (FcγRIIIa).[36] This resistance to subsequent tick feedings reduces transmission of *Borrelia burgdorferi* in mice.[36,42]

Interactions of Basophils and Mast Cells with Eosinophils

Mast cells, basophils, and eosinophils interact with each other at sites of inflammation in protective and pathologic roles. Mast cells produce IL-5 and CCL11, CCL24, and CCL26 that stimulate the release of eosinophils from the bone marrow.[27] Molecules such as CCL11, CCL24, and CCL26, histamine, LTB_4, 5-hydroxytryptamine, and platelet-activating factor attract eosinophils to a site of inflammation.[23] Basophil influx occurs in the late-phase of an allergic response. Eosinophil degranulation releases major basic protein and platelet-activating factor causing additional mast cells and basophils to degranulate. This effect is augmented by mast cells, which further synthesize and secrete IL-3, IL-5, and GM-CSF, thereby enhancing eosinophil and basophil growth, differentiation, and activation.[27]

ROLE OF BASOPHILS AND MAST CELLS IN TYPE I HYPERSENSITIVITY REACTIONS

Most of our knowledge of mast cell- and basophil-mediated responses stems from the investigation of hypersensitivity diseases. Type 1 hypersensitivities are characterized by: (1) Th2 cell activation, (2) high concentrations of IgE, and (3) eosinophilia. Mast cells, basophils, and their granular contents are the central effectors of IgE-mediated immediate type I hypersensitivity reactions and allergic diseases.[27] The clinical and pathologic manifestations of type I hypersensitivity disorders depend upon (1) the tissue location, (2) the degree of previous antigen sensitization, (3) the quantity of antigen to which the animal is exposed, (4) the route of antigen administration, and (5) the chronicity of the resulting inflammatory process.[27]

Exposure to environmental antigens occurs routinely. Yet, most animals show no obvious clinical consequences because they produce primarily IgG or IgA antibodies. However, some animals develop an exaggerated Th2 response to such commonplace antigens. Basophils are believed to be key players in this exaggerated Th2 response by releasing the IL-4 required to initially activate CD4+ T cells and induce immunoglobulin class-switching to IgE production.[31]

IgE antibodies attach to the $\alpha\beta\gamma_2$ form of the FcεRI, the high-affinity surface Fc receptor specific for IgE ε-heavy-chains, on basophils and mast cells. Upon subsequent antigen exposure, the cell-surface-bound IgE molecules immediately join with their complimentary antigen. When antigen concurrently binds to two adjacent cell-surface-bound IgE molecules, it induces aggregation of the IgE molecules and associated FcεRI receptors. This cross-linking of FcεRI by IgE–antigen complexes initiates a signaling cascade resulting in three types of biological responses: (1) secretion of the preformed granule contents, (2) synthesis and secretion of lipid mediators, and (3) synthesis and secretion of cytokines, all of which work together to initiate a local inflammatory response.[27]

Degranulation and release of stored inflammatory mediators, such as histamine, are responsible for the clinical signs of immediate hypersensitivity reactions observed within minutes of allergen exposure. IgE-mediated cross-linking of FcεRI activates protein kinases to induce gene transcription factors, such as nuclear factor of activated T cells (NFAT), nuclear factor κβ (NF-κβ), and activator protein-1 (AP-1). These transcription factors initiate the production of IL-4, IL-5, IL-6, IL-13, and TNF among others. Newly synthesized inflammatory mediators are responsible for the clinically observed late-phase of type I hypersensitivity reactions 2–12 hours after allergen exposure.[27]

LABORATORY EVALUATION OF BASOPHILS

Staining Characteristics

For a description of morphologic features, see section IX.

Basophil Activation Tests

The majority of histamine within peripheral blood is contained within basophil granules. In an attempt to assess hypersensitivity states in several species, including horses and sheep, basophil histamine release assays have been developed. In people, flow cytometric assays are available to assess basophil activation.[20]

Basophil Concentrations in Blood

Due to the low concentration of circulating basophils in most mammals, manual 100-cell differentials are imprecise estimates of the true basophil concentration. Regardless, manual differential counts are often considered the most reliable method of basophil enumeration.

Further complicating basophil enumeration, automated hematology analyzers are fraught with error in basophil identification in veterinary species. Current automated methods are based upon the unique ability of human basophils to resist lysis by a strong surfactant known to lyse nonbasophil leukocytes. Thus, in theory, cells that remain intact after exposure to the surfactant are either basophils or atypical lysis-resistant circulating cells. However, this method does not appear to work well for dogs and cats. For example, the Technicon H1®, Advia 2120®, Sysmex XT-2000iV®, CELL-DYN 3500®, and likely the LaserCyte® do not accurately detect canine basophils even in the presence of pronounced basophilia.[18,19,27,33–35,41] Feline basophils have been identified on the Sysmex XT-2000iV WBC/DIFF scattergram via fluorescence-activated flow cytometry as a distinct population of cells between the neutrophil, eosinophil, and lymphocyte clusters.[32] However, these cells were not detected in the Sysmex XT-2000iv® basophil channel, further confirming the inadequacy of basophil detection via the basophil channel in feline patients.[32] Although the Sysmex XT-2000iV® basophil channel fails to detect canine and feline basophils, mast cells of both species appear to be lysis-resistant and have been detected within the Sysmex XT-2000iV® basophil channel.[18] Interestingly, the Advia 2120® can accurately enumerate lysis-resistant rabbit basophils.[19] The Technicon H1®, Advia 2120®, and Sysmex XT-2000iV® have indicated the presence of basophilia when basophilia was not detected by blood smear inspection.[27,34] Therefore, an increased automated concentration of basophils should be confirmed via blood film evaluation.

Basophilia

Basophilia in mammals is relatively rare. For domestic mammals, only marked or persistent increases in basophil concentrations >200–300 basophils/μL should be considered abnormal.[27] When observed, basophilia is typically associated with an IgE-mediated disorder and often accompanied by eosinophilia. Therefore, primary considerations should be given to allergic diseases and parasitism. Parasites documented to cause basophilia include ectoparasites, gastrointestinal parasites, and vascular parasites.[27]

If parasites and allergic inflammation are ruled out, neoplastic and other nonallergic inflammatory conditions should be considered. Basophilic leukemia is rare, but has been reported in dogs.[22] Basophilia may also occur secondary to other neoplastic disorders such as mast cell neoplasia, lymphomatoid granulomatosis, myeloid leukemias, polycythemia vera, essential thrombocytosis, or idiopathic canine myelofibrosis.[6,7,28,40]

Basopenia

Circulating basophils are in very low concentrations in healthy animals, often resulting in the inclusion of 0 cells/μL within basophil reference intervals. Therefore, basopenia is not recognized in most species. Nevertheless, decreased concentrations of circulating basophils have been reported in people with disorders such as urticaria and anaphylaxis, some inflammatory and immunologic conditions, corticosteroid administration, neoplasia, and hemorrhage.[10]

LABORATORY EVALUATION OF MAST CELLS

Structure, Morphology, and Staining Characteristics

Mast cells are round cells with a moderate volume of pale cytoplasm that contains numerous coarse, metachromatic granules which may stain various shades of red to deep purple. Mast cell nuclei are frequently obscured or faintly stained amid their abundant mass of deeply staining, purple, cytoplasmic granules. When visible, nuclei are usually round and centrally located. Chromatin patterns can range from coarsely granular to finely stippled, depending on cellular maturity. Prominent nucleoli are not typically seen in normal mast cells, but may be seen in mast cell neoplasia. In some species, highly granulated basophils can be confused with mast cells.

When stained with methanolic Romanowsky stains, mast cell granules are easily recognizable. However, mast cell granules may stain poorly or not at all when aqueous-based Romanowsky-type quick stains are used.[1] The exact reason for this phenomenon is unknown. Prolonging the fixation time in order to prevent the theorized dissolution of mast cell granules within the aqueous stain solutions was recently proven ineffective at improving mast cell granule-staining intensity.[16]

Mastocythemia and Marrow Mastocytosis

Because mast cells are normal tissue residents, occasional mast cells (i.e., 0–1/1000 nucleated cells) are present in healthy bone marrow.[2] Bone marrow mastocytosis has been reported in dogs with myelofibrosis, lymphoma, myelosuppressive chronic monocytic ehrlichiosis, aplastic anemia, systemic mastocytosis, and mast cell leukemia.[24,38] Mast cell leukemia is rare in dogs.[6]

Mastocythemia (aka mastocytemia) is the presence of circulating mast cells within peripheral blood. In the past, mastocythemia in dogs was considered highly suggestive of mast cell neoplasia; however, in one study, 95.5% of canine patients with circulating mast cells had no concurrent evidence of mast cell neoplasia.[21] Furthermore, mastocythemia may be observed in animals with inflammatory disease, regenerative anemia, tissue injury, neoplasia other than mast cell tumors, and necrosis.[3,21,30] In addition, mastocythemia of high magnitude is not always indicative of underlying mast cell neoplasia and may occur with inflammatory conditions.[21,30] If other concurrent disease states have been ruled out and/or circulating mast cells have atypical cytologic features, evaluation for visceral, cutaneous, or bone marrow mast cell neoplasia should be performed. In contrast to canines, feline mastocythemia, although rare, is most commonly associated with visceral or cutaneous mast cell neoplasia.[26] Feline mastocythemia has also been reported in feline patients with lymphoid neoplasia, hemangiosarcoma, and chronic kidney disease.[26]

CHAPTER 48

Monocytes, Macrophages, and Dendritic Cell Production

CLEVERSON D. SOUZA and DOUGLAS J. WEISS

Monocyte Production
Macrophages Production
Dendritic Cell Production
Summary

Acronyms and Abbreviations

AP-1, activator protein-1; BATF3, basic leucine zipper ATF-like transcription factor 3; C/EBP-α, CCAAT/enhancer-binding protein-alpha; CCL2, C-C motif chemokine ligand 2; cDCs, conventional DCs; c-KIT, tyrosine-protein kinase kit; cMoPs, common monocyte progenitors; CMP, common myeloid progenitor; DCs, dendritic cells; FLT3, fms-related tyrosine kinase 3; EMPs, erythro-myeloid progenitors; GMP, granulocyte/monocyte progenitors; HSC, hematopoietic stem cells; IL, interleukin; IRF8, interferon-γ-responsive transcription factor; M-CSF, macrophage colony-stimulating factor; MDP, macrophage/dendritic cell progenitors; miRNAs, microRNA; MPS, mononuclear phagocyte system; pDCs, plasmacytoid DCs; PU.1, hematopoietic transcription factor; SCF, stem cell factor; TLR, toll-like receptor.

The mononuclear phagocyte system (MPS) is organized as a complex structure of ontogenetically and functionally distinct cells, that have been best described in mouse and human and to a lesser extent in other species.[8,15,25] These cells consist of multiple subsets of monocytes, macrophages, and dendritic cells (DCs) traditionally defined by their expression of various surface markers, morphologic characteristics, and biological function.[8] Recent studies have challenged previous models of MPS ontogenesis.[7,8] Monocytes and macrophages protect the body against bacterial infections through production of microbicidal compounds including reactive nitrogen intermediates and proinflammatory cytokines. These cells also function to preserve tissue homeostasis through scavenger activity and production of molecules to aid tissue repair.[12] Dendritic cells are highly efficient antigen-presenting cells with key roles in regulation of tolerance and immune defense against pathogens and tumors.[17] This chapter aims to describe the ontogenesis, transcriptome profiles, and features of the MPS, particularly in mice and human. This area is incompletely understood and will undoubtedly continue to undergo redefinition and modification.

MONOCYTE PRODUCTION

Monocytes represent approximately 3–10% of all nucleated blood cells with a marginal pool of considerable size in the spleen and lungs that can be mobilized on demand.[2,4] These cells are defined morphologically as well as by their characteristic cell-surface markers, and gene and microRNA expression signatures. Recent studies indicated that monocytes initiate inflammation, patrol the vasculature, transport antigen to lymphoid tissue, and participate in tumor cell destruction.[3,4]

Monocyte development in adult mice, and likely most species, depends on macrophage colony-stimulating factor (M-CSF). Monocytes arise from myeloid precursor cells in the fetal liver and bone marrow, during both embryonic and adult hematopoiesis (Figure 48.1).[3,4] In contrast to adult monocytes, fetal liver monocytes proliferate independent of M-CSF.[3,4] However, in-depth information on these cells is lacking. Monocyte ontogeny gained considerable attention in the last decade with the identification of dedicated clonotypic precursor cells, termed *macrophage/dendritic cell progenitors* (MDPs), in mouse bone marrow.[5,7,10] MDPs

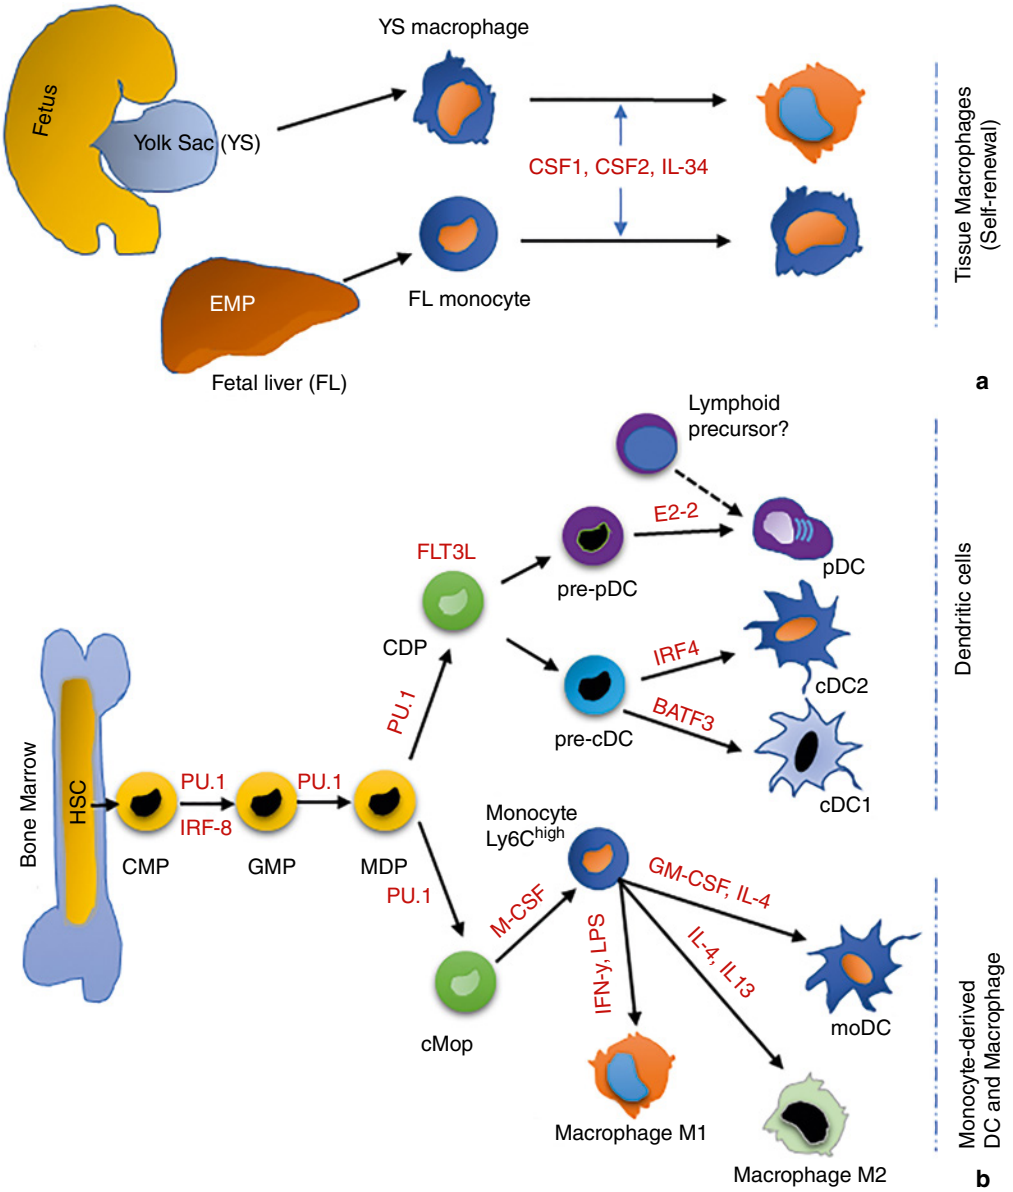

FIGURE 48.1 Current understanding of embryonic and hematopoietic development of mononuclear phagocytes (MNPs) in mice. (a) Some tissue macrophages have an embryonic origin, from yolk sac macrophages and fetal liver monocytes; (b) In bone marrow, monocytes, macrophages, and dendritic cells (DCs) originate from distinctive cell lines. DCs and monocytes originate from bone marrow committed DC progenitors (CDP) and common monocyte progenitors (cMoPs), respectively. Dendritic cells express diverse transcription factors important for its development. Examples include basic leucine zipper ATF-like transcription factor 3 (BATF3) for cDC1s, interferon regulatory factor 4 (IRF4) for cDC2s, and E2-2 for plasmacytoid DCs (pDCs). These cells are also dependent on various growth factors such as fms-related tyrosine kinase 3 (FLT3) ligand for DCs, M-CSF for monocytes, and immunomodulatory cytokines for macrophages and monocyte-derived dendritic cells.

are defined as lineage-negative cells that express tyrosine-protein kinase kit (c-KIT), fms-related tyrosine kinase 3 (FLT3), and M-CSF receptor.[3,18] MDPs lack the potential to produce neutrophils, but can give rise to monocytes, plasmacytoid dendritic cells (pDCs), and conventional dendritic cells (cDCs).[3,5,10,11,16] MDP differentiation toward monocytes includes a defined transient intermediate, the common monocyte progenitor (cMoP).[3,11,16] cMoPs differ from MDPs by their lack of FLT3 expression, as well as by inability to differentiate in cDC or pDC. cMoPs have been shown to give rise to both Ly6C+ and Ly6C− monocyte subsets. In mice, the spleen is a major source of Ly6C+ and Ly6C− monocytes that are mobilized to the peripheral blood in response to tissue damage.[18] This response often results in an acute monocytosis that facilitates tissue repair.

Variable phenotypic changes and expression of transcription factors are involved in defining monocyte lineage commitment.[2,11,28] A multitude of factors, including chronic stress, inflammation, and infection, have been shown to effect myeloid differentiation. For example, diabetic mice have increased proliferation of both

common myeloid progenitor (CMP) and granulocyte/monocyte progenitors (GMP), resulting in increased levels of peripheral blood monocytes and neutrophils.[28] In addition, bacterial infections increase monopoiesis, through toll-like receptor (TLR) signaling, which increases C-C motif chemokine ligand 2 (CCL2) signaling in bone marrow and causes rapid monocyte emigration. Most of these signals have been shown to modify peripheral blood monocytes by stimulating the proliferation of progenitor cells and regulating the release of cytokines.[28] Moreover, it is likely that epigenetic changes occur within myeloid progenitors during disease, which can trigger transcriptional reprograming of monocytes.

Monocyte differentiation is regulated by lineage-specific transcription factors that are turned on or off during different phases of hematopoiesis.[2,11] Hematopoietic transcription factor (PU.1) is a key transcription factor important in the early phases of myeloid and lymphoid development. PU.1-deficient mice lack monocytes as well as granulocytes, and some subsets of lymphocytes.[2,28] Proteins of the CCAAT/enhancer-binding protein (C/EBP) family are crucially important in the development and maintenance of myeloid cell subsets. Analysis of C/EBPβ knockout mice shows a selective reduction in peripheral blood monocytes, but not of other lineages. How C/EBP regulates commitment of monopoiesis is poorly understood.[2,11,28]

Interferon-γ-responsive transcription factor (IRF8) is critical for monocyte development in bone marrow.[2,11,28] IRF8 promotes monocyte differentiation and inhibits granulocyte production. IRF8 expression persists in differentiated monocytes and macrophages, but declines in neutrophils. Other transcription factors thought to be involved in the production of monocytes have been reviewed.[28] MicroRNAs (miRNAs) can suppress target protein production by inducing RNA degradation and by hindering protein translation. How miRNAs regulate myelopoiesis is poorly understood.[28] miR-146a is differentially regulated in human and murine monocyte subsets and appears to control Ly6C+ monocyte propagation during inflammation, but has no effect on Ly6C– monocytes.[28] Interestingly, miRNAs have been shown to participate in macrophage polarization to M1 or M2 subsets.[23] The intricacies of transcription factor regulation and function during monocyte development are incompletely understood. Understanding how these transcription factors are controlled by noncoding RNAs, miRNAs, and metabolic and epigenetic changes that occur in response to environmental cues may aid the development of novel therapeutic targets to assist in controlling the inflammatory response.

MACROPHAGES PRODUCTION

Macrophages are rarely present in blood. These cells occur as phenotypically heterogeneous forms depending on the tissue of residence. Some examples include alveolar macrophages, Küpffer cells, Langerhans cells, osteoclasts, and microglia. These mononuclear phagocytes (MNPs) play critical roles in many fundamental biological processes such as host defense against pathogens and tissue homeostasis.[6]

For many years, the overall assumption was that macrophage populations were derived from blood monocytes.[15,26] Current murine and human studies challenge this assumption and have shown that the majority of tissue-resident macrophages develop during embryogenesis independently of hematopoietic stem cells (HSC).[7,10,23] These macrophages are characterized by the ability to self-renew and to self-maintain in adult tissues without the need for replenishment by monocytes. The two main sources of tissue-resident macrophages are most likely from yolk-sac macrophages (contributing to microglia production) and yolk-sac endothelium (which produce erythro-myeloid progenitors (EMPs); Figure 48.1). EMPs migrate, proliferate, and differentiate into monocytes or premacrophages in the fetal liver.[10,23] Subsequently, monocytes or premacrophages colonize various fetal tissues where they differentiate into long-lived macrophages. Interestingly, murine EMPs seem to be the source of most tissue-resident macrophages.[7] Hematopoietic-stem-cell-derived monocytes originate from the aorta–gonad mesonephros, proliferate in the fetal liver, and colonize the bone marrow before birth.[7,10,23] Bone marrow hematopoietic stem cells produce Ly6C+ monocytes.[10,23] During tissue damage, Ly6C+ monocytes quickly travel into inflamed tissues and differentiate into inflammatory macrophages and DCs.[1,4,12] Some tissue-resident macrophage populations, including intestinal macrophages and skin dermal macrophages, are derived from Ly6C+ monocytes and not from embryonic, self-renewable macrophages.[1,4,10] Thus, during times of need, there will be variability in the origin of populations of mononuclear phagocytes in tissue.

PU.1 is the most important transcription factor in macrophage development.[2,11,28] Studies have shown the majority of monocytes, macrophages, and mature B cells are absent in PU.1 knockout mice. Moreover, fetal progenitor cells containing macrophage precursors are also decreased in PU.1 knockout mice. PU.1 works in harmony with other transcription factors including C/EBPs, activator protein-1 (AP-1), and IRFs.[28] M-CSF signaling is required for the proliferation, survival, and differentiation of macrophages, as shown in M-CSF receptor (M-CSFR)-knockout mice studies.[2,11,28] Two ligands have been described for the M-CSFR. One is M-CSF and the other interleukin (IL)-34. The interaction of these factors with the M-CSF receptor activates tyrosine signaling pathways, thus, regulating cell proliferation and survival.[28] As discussed in the earlier text, most tissue-resident macrophages are self-renewing and long-lived; however, the molecular mechanisms involved in these processes remain undefined.

DENDRITIC CELL PRODUCTION

One of the most important functions of macrophages and DCs is detection of danger through recognition of damage-associated and pathogen-associated molecular

patterns. In addition, DCs have greater ability to prime and sensitize immune cells compared to macrophages. Hence, DCs play a key role in organized and effective immune responses.[20] Recent studies advanced our understanding on the ontogeny of DCs in the murine system through the recognition of adult, bone-marrow-derived, monocyte-independent DC lineages.[9,17] This is of central importance for DC distinctiveness as highlighted by the discovery of conserved transcription factors involved in the DC development and by the documentation of a unique, well-conserved, transcriptomic profile in DCs that is distinct from monocytes and macrophages.[14,17,19,20,22,24]

Murine ontogenic studies have identified the committed DC progenitors (CDPs) with a select ability to differentiate solely into DC.[14] CDPs differentiated in cDC1, cDC2, and pDC with very specific transcription factor dependency.[7] This pathway is distinct from DC originated from monocyte-derived dendritic cells (MoDCs). MoDCs are ontogenetically and functionally distinct, which represent a steady-state DC in the mucosa and dermis, which is vital for tissue homeostasis.[17,20] In addition, MoDC plays a key role as inflammatory DC.[17,20]

Several recent studies, mostly in the murine model, have identified cell-lineage-defined hematopoietic factors required for differentiation of DC and MoDC.[7,14,17,18] FLT3 represents a key growth factor for development of cDC1, cDC2, and pDC, whereas M-CSF is critical for MoDC development.[14,17,18] DC differentiation and proliferation are driven by a plethora of well-defined transcription factors. In the murine model, the crucial factors for DC production are E2-2 for pDC, basic leucine zipper ATF-like transcription factor 3 (BATF3) for cDC1, and IRF4 for cDC2.[7,14,17] Given the degree of conservation, it can be expected that similar transcription factors will control DC development in veterinary species.

The analysis of DC uniqueness through transcriptomic profiling in murine and human DCs has shown that this approach is powerful for differentiating macrophages from DC.[27] In addition, transcriptomic analysis represents a novel and elegant tool to determine the phylogenetic relationship between immune system cell types, including monocytes, macrophages, DCs, and lymphocytes.[13,27] In this regard, studies have shown that many differentially expressed genes on DC subsets are conserved between human and mice.[14,21] A similar approach should be productive in veterinary medicine.

SUMMARY

Until recently, the MPS provided an effective framework for understanding the development of mononuclear phagocytes. This model, in which monocytes were the common precursor to macrophages and DC, has given way to a system where long-lived macrophages and pure DC lineages contribute to tissue cell populations. Mouse models have been crucial for the analysis of hematopoiesis and continue to provide insights into the pathways of monocytes, macrophages, and DC development in humans and veterinary species. While in vivo and in vitro studies of monocyte-derived macrophages and DCs have provided many stimulating experimental results, the real physiological context of this body of work remains incompletely understood. In the future, single-cell-RNA-sequencing analysis technologies, immunophenotypic assessment using mass cytometry, epigenetic programing, and more classical immunophenotype techniques will be instrumental to assessment of functional aspects of these cells, particularly at sites of inflammation. It will be possible to identify previously unknown cell subsets and to identify interactions with other cells of the immune system. Understanding the ontogeny of the monocytes, macrophages, and DC more fully offers the potential for the discovery of novel cell-mediated therapies. In this regard, complementary research in veterinary species is essential.

Acronyms and Abbreviations

ADCC, antibody-dependent cellular cytotoxicity; AIDS, acquired immunodeficiency syndrome; APC, antigen-presenting cells; CD, cluster of differentiation; CDP, common dendritic cell precursor; CLEC 9A, C-type lectin domain containing 9A; CPV, canine parvovirus; CSF, colony-stimulating factor; DAMPs, danger-associated molecular patterns; DCs, dendritic cells; DCIR2, dendritic cell inhibitory receptor-2; DTH, delayed-type hypersensitivity; EHV, equine herpesvirus; ETs, extracellular traps; FGF, fibroblast growth factor; FIV, feline immunodeficiency virus; HIV, human immunodeficiency virus; HPS, hemophagocytic syndrome; IFN, interferon; IL, interleukin; IMHA, immune-mediated hemolytic anemia; IRF, interferon regulatory transcription factor; ISGD, idiopathic systemic granulomatous disease; LPS, lipopolysaccharide; LSDs, lysosomal storage diseases; MARCO, macrophage receptor with collagenous structure; M-CSF, macrophage-colony stimulating factor; MCP-1, monocyte chemoattractant protein-1; MDP, macrophage/DC precursor; MDSCs, myeloid-derived suppressor cells; METs, macrophage extracellular traps; MHC, major histocompatibility complex; MIP-1α, macrophage inflammatory protein-1α; mTOR, mammalian target of rapamycin; MMP9, matrix metallopeptidase 9; NADPH, nicotinamide adenine dinucleotide phosphate; NF-κB, nuclear factor-kappa B; NLRs, nucleotide-binding domains and leucine-rich repeat containing receptors; NO, nitric oxide; PAMPs, pathogen-associated molecular patterns; PAS, periodic acid–Schiff; PRRs, pattern recognition receptors; RANTES, regulated upon activation, normal T cell expressed and presumably secreted; RLRs, retinoic-acid-inducible gene-I-like receptors; ROS, reactive oxygen species; RTX, repeats in toxin; SNPs, single-nucleotide polymorphisms; STAT, signal transducer and activator of transcription; TAMs, tumor-associated macrophages; TEM, transmission electron microscopy; TLRs, toll-like receptors; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor; WC1, workshop cluster-1.

Formerly known as the reticuloendothelial system, the mononuclear phagocyte system is composed of blood, bone marrow, and tissue-derived monocytes, macrophages, dendritic cells (DCs), and osteoclasts.[17] The mononuclear phagocyte system plays an important role in innate and adaptive immunity, interacting with

lymphoid cells to mediate the body's immune response to pathogens, vaccines, tumors, and other sources of self- and non-self-antigens.[15,17] These cells also contribute significantly to tissue repair, including angiogenesis, collagen deposition, and matrix remodeling.[32] Although there are shared phenotypic and functional traits among the cells of the mononuclear phagocyte system, there is also considerable heterogeneity, which derives from their surrounding microenvironment.[6,24]

MONOCYTES

Once released into circulation, monocytes have a half-life of 1–2 days, after which time, they migrate into various tissues, where they differentiate into macrophages and dendritic cells.[51] Similar to neutrophils, they are frequently separated into a circulating pool and a marginating pool to help conceptualize their distribution and kinetics within the vasculature.[49] Although rabbits and mice have large marginating pools of monocytes, their presence has not been documented in other veterinary species.[49] Monocyte reservoirs exist within the bone marrow and spleen, specifically within the subcapsular red pulp.[37]

Subsets and Functions

Two distinct subsets of monocytes have been identified in mice, based on surface expression of the molecule Ly6C.[6,32,37] Using the monoclonal antibody *Gr1*, murine monocytes can be separated into Ly6C^{high} (inflammatory monocytes) and Ly6C^{low} (patrolling or resident monocytes), which correspond with the human subtypes CD16– and CD16+, respectively.[37] Although expression of Ly6C has garnered the most attention, expressions of CD11a, CD11b, CD16, CD62L (L-selectin), CD43, and lymphocyte function-associated antigen-1 (LFA-1) have also been shown to differ significantly between these two populations.[15,37,50] Ly6C^{high} monocytes, due to expression of C-C chemokine receptor type 2 (CCR2), respond to monocyte chemoattractant protein-1 (MCP-1 or CCL2), MCP-3 (CCL7), and MCP-5, and are recruited to sites of tissue injury to participate in inflammatory and phagocytic functions.[22] in vitro experiments in mice have shown that Ly6C^{high} monocytes are the predominant subtype in wound infiltrates up to 6 hours after muscle injury or tissue trauma.[32,37] These inflammatory monocytes ultimately differentiate into classically activated, M1-like macrophages and various DC subtypes, as shown in infectious disease models involving *Listeria monocytogenes* and *Toxoplasma gondii*.[15] In addition, Ly6C^{high} monocytes may contribute to myeloid-derived suppressor cells (MDSCs)—a group of myeloid cells shown to aggregate in the lymphoid tissues of mice with bacterial and parasitic infections, autoimmune diseases, traumatic lesions, neoplasia, and other causes of chronic inflammation.[13,50] MDSCs are capable of suppressing T-cell function, and enhancing tumor growth and metastasis by promoting angiogenesis via production of factors such as vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), and matrix metallopeptidase 9 (MMP9).[13] Carcinomas (i.e., mammary, colon) demonstrate the most significant expansion in response to MDSCs.[50] MDSCs are phenotypically distinct from tumor-associated macrophages (TAMs), as the former demonstrate relatively increased expression of F4/80 and the macrophage-colony stimulating factor (M-CSF) receptor (CD115).[13]

By contrast, Ly6C^{low} monocytes, which express CX_3CR_1 (the chemokine receptor for fractalkine) and CCR5 (the receptor for macrophage inflammatory protein- 1α (MIP-1α), MIP-1β, and regulated upon activation, normal T cell expressed and presumably secreted (RANTES)), are suspected to play more of an anti-inflammatory role and contribute to reparative functions within damaged tissues.[22] Also termed patrolling or resident monocytes, Ly6C^{low} monocytes have been shown to slowly crawl along the luminal aspect of vascular endothelial cells, surveying for potential damage or infection.[15,37] This stands in stark contrast to the "rolling" demonstrated by inflammatory monocytes and granulocytic cells preparing for diapedesis. Influx of Ly6C^{low} monocytes occurs during the later phase of tissue injury, and they serve as the predominant subset during repair. The method of influx, however, appears to differ depending on the site of injury. While studies involving myocardial infarction reveal recruitment of a distinct population of Ly6C^{low} monocytes 4 days after injury, similar studies involving skeletal muscle are more suggestive of in situ conversion of inflammatory Ly6C^{high} monocytes.[15,32] In addition to promoting angiogenesis and collagen deposition, Ly6C^{low} monocytes differentiate into alternative, M2-like macrophages and CD103^{-} pulmonary DCs.[15,22]

Phenotypic Appearance and Ultrastructure

Monocytes are cytologically similar across species (see Section IX). They are large leukocytes (approximately 15–20 μm in diameter) with a variably shaped (ovoid, reniform, or convoluted) nucleus, granular to lacy chromatin, and abundant amounts of blue-gray cytoplasm that is variably vacuolated, depending on degree of activation or reactivity.[5,36] They have large Golgi complexes and surface filopodia, which can be appreciated using transmission electron microscopy (TEM).[5] After activation with interferon-γ (IFN-γ), cytoplasmic volume increases due to increased numbers of free ribosomes, mitochondria, and lysosomal granules.[5,49]

Monocytes in reptilian species are different in that they may display azurophilic (pink/purple), fine to coarse, intracytoplasmic granules.[45] While azurophils are considered a variation of the monocyte in non-squamate reptiles, they are a distinct type of leukocyte in snakes, and demonstrate functional similarities to the neutrophil.[1,45] Azurophils of snakes have round nuclei, while those in other reptiles have lobulated nuclei.[1,45]

MACROPHAGES

Unlike other myeloid cells, macrophages are long-lived, persisting in tissues for several months to more than a year in some species, except for those responding to inflammatory stimuli, or those derived from the differentiation of monocytes.[42,49]

Subsets and Functions

Although macrophages perform several conserved functions that are crucial to the orchestration of innate and adaptive immune responses, they represent a heterogeneous population of cells whose differences are governed by origin, activating stimuli, and microenvironment. While blood monocytes contribute to resident populations of macrophages within the gastrointestinal tract and dermis, those in the bone marrow, central nervous system (CNS), liver, and lung originate from precursors that derive from the yolk sac and fetal liver.[6,17] Function is intricately linked with tissue distribution. For example, macrophages within the splenic red pulp contribute to heme catabolism, while macrophages in the splenic white pulp contribute to clearance of apoptotic lymphocytes.[17] Shared functions include the phagocytosis of antigens and pathogens, which occurs via phagocytosis, and the recognition of specific moieties and organic ligands by pattern recognition receptors (PRRs). PRRs, which include toll-like receptors (TLRs), nucleotide-binding domains and leucine-rich repeat containing receptors (NLRs), and retinoic-acid-inducible gene-I-like receptors (RLRs), are expressed both intracellularly and extracellularly, and require coreceptors (i.e., CD14, CD36) for binding and signaling.[17] Recognition of pathogen-associated and danger-associated molecular patterns (PAMPs and DAMPs, respectively) results in the activation of an intracellular signaling cascade involving the adaptor protein MyD88. After the translocation of nuclear factor-kappa B (NF-κB) or IRF3/IRF7 into the nucleus, synthesis of specific cytokines (i.e., interleukin (IL)-1β) or interferons ensues, resulting in continued leukocyte recruitment and activation.[24]

Pathogen inactivation can also occur through a programed cell death pathway ("ETosis") that involves the production of extracellular traps (ETs). Similar to granulocytes and mast cells, macrophages are capable of releasing a web-like complex (macrophage extracellular traps, METs) of nuclear material, histones, and cellular proteins, which entrap and eliminate some microorganisms.[8] This process, which can occur in less than 30 minutes, has not been consistently observed during different experimental conditions, and it is therefore suspected that certain macrophage subtypes may be more prone to ETosis. ET release may be intrinsically linked to certain pathogenic proteins and toxins, as ETosis has been shown to occur in a leukotoxin-dependent and repeats-in-toxin (RTX)-dependent manner during in vitro studies involving macrophages and the bacterial pathogens *Mannheimia hemolytica* and *Escherichia coli*, respectively.[3,8] Similar to neutrophils, ET formation by macrophages is also dependent on NADPH-oxidase activity.[3] Further studies are necessary to determine what role METs or their overproduction may play in disease pathology, including thrombosis, coagulation disorders, and metastatic disease.[3,27]

Despite the phenotypic and functional heterogeneity of macrophages, they are commonly subdivided into two distinct classes (M1 and M2), which were derived based on in vitro studies (Table 49.1). Commitment to these subtypes has been shown to occur within an hour of exposure to stimulatory cytokines in vitro and is dependent on mammalian target of rapamycin (mTOR).[37] The macrophages, however, can transition in vivo during stages of inflammation and repair. Although convenient, the subsets fail to capture the heterogeneity of the macrophage population and overlook macrophages that exhibit characteristics from both the M1 and M2 phenotypes, or do not correspond to either.[32,37]

M1 macrophages are considered "classically activated," as their differentiation is triggered after exposure to cytokines (i.e., IFN-γ, tumor necrosis factor (TNF)-α) and TLR agonists (i.e., lipopolysaccharide (LPS)).[6,24] These macrophages are proinflammatory and release high levels of IL-12 and IL-23, contributing to a Th1 response, which further supports microbicidal activity and pathogen killing.[6,39] The high levels of reactive oxygen intermediates and nitric oxide released by M1 macrophages also promote tumoricidal activity.[39] M1 macrophages can be further divided into M1a and M1b subtypes, which primarily differ based on receptor expression. M1a macrophages express high levels of major histocompatibility complex (MHC), costimulatory molecules (CD40, CD80, and CD86), and complement receptors (CD35, CD11a/CD18, CD11b/CD18, and CD11c/CD18), which enhance their phagocytic abilities and function as antigen-presenting cells (APCs).[24,37,49] Alternatively, M1b macrophages express high levels of Fc receptors and scavenger receptors workshop cluster-1(WC1), the latter of which recognizes negatively charged macromolecules, and is concurrently expressed on gamma delta T cells.[37,49] Fc receptors (i.e., FcγR, FcεRI), which are also expressed on the cell surface of monocytes, neutrophils, and mast cells, enhance phagocytosis and antibody-dependent cellular cytotoxicity (ADCC) by allowing for the recognition of immunoglobulin-coated cells or pathogens, and opsonins of innate immunity (i.e., C-reactive protein).[25]

M2 macrophages, which have been broadly classified as anti-inflammatory, or "alternatively activated" macrophages, secrete anti-inflammatory IL-10, chemokine (C-C motif) ligands, support a Th2 response, and play an important role in tissue repair.[24,39,49] They have enhanced endocytic capability due to the increased expression of mannose receptor (CD206) and dectin-1, which allow for the recognition of mannosyl residues, fucosyl residues, and other carbohydrate signatures,

TABLE 49.1 Characterization of macrophage subtypes.

Phenotype	Stimulus	Increased expression/production	Biological function
M1a$^{mTOR\ low}$	IFN-γ + LPS or TNF-α	Complement receptors MHC-I and MHC-II CD80/CD86 IL-1β, IL-12, IL-6, TNF-α CXCL9, CXCL10, CXCL11 CCL2, CCL3, CCL5 CCL2, CCL3, CCL5 Reactive oxygen species (ROS), nitric oxide (NO)	Classically activated Th1 responses; type I inflammation; delayed-type hypersensitivity (DTH); killing of intracellular pathogens; tumor resistance
M1b$^{mTOR\ low}$	LPS	Fcγ receptors Scavenger receptors Co-stimulatory signals IFN-β, IL-1β, IL-6, TNF-α CXCL9, CXCL10, CXCL11 CCL2, CCL3, CCL5 ROS Macrophage receptor with collagenous structure (MARCO)	Innate activated macrophages Share many of the proinflammatory properties with M1a macrophages, but they do not secrete biologically active IL-12, and therefore do not directly drive Th1 responses
M2a$^{mTOR\ high}$	IL-4 and IL-13	Fcγ receptors Scavenger receptors MHC-II CD80/CD86 IL-1RA, IL-10, TGF-β CCL2, CCL13, CCL17 Macrophage fusion Autophagy	Th2 responses; type II inflammation; allergy; killing and encapsulation of parasites
M2b$^{mTOR\ high}$	Immune complexes and TLR/IL-1R ligands	MHC-II CD80/CD86 IL-10 CCL1, CCL20 CXCL3	Th2 activation; immunoregulation
M2c$^{mTOR\ high}$	IL-10, TGF-β, glucocorticoids	Fcγ receptors Scavenger receptors IL-1RA, IL-10, TGF-β CXCL4, CXCL13, CXCL23 CCL18	Immunoregulation; matrix deposition and tissue remodeling

and permit the binding of parasitic organisms, bacteria, and yeast.[24,32,39,49] Due to decreased production of nitric oxide, M2 macrophages have a reduced ability to eliminate intracellular pathogens.[24] M2 macrophages can be divided into three subtypes, which differ based on activating stimuli from the surrounding environment. M2a macrophages are stimulated by IL-4 or IL-13, which interact with the common receptor IL-4Rα, subsequently activating signal transducer and activator of transcription 6 (STAT6).[32,37,39] M2b are activated following exposure to LPS, immune complexes, and CD40 ligand, while M2c macrophages differentiate following exposure to IL-10, transforming growth factor (TGF)-β, and glucocorticoids.[37,39] M2a and M2c macrophages have been shown to increase fibroblast collagen production and myofibroblast differentiation in culture, which likely occurs through the production of TGF-β.[32]

Phenotypic Appearance and Ultrastructure

Macrophages share similar cytologic features and ultrastructural characteristics to monocytes, particularly when unstimulated (Figure 49.1). In addition to large Golgi complexes, they possess many primary lysosomes, which contain acid hydrolases, lysozyme, collagenase, elastase, and other enzymes important for the elimination of intracellular and extracellular pathogens.[5,49] After activation, macrophages generally display enlarged Golgi complexes, along with increased numbers of lysosomes, mitochondria, and pinocytic vesicles.[49] The heterogeneity of their phenotypic appearance, however, is reflected in their ultrastructural appearance, with significant variation noted on TEM. Fusion of macrophages, which can occur secondary to antigenic stimulation or cytokine stimulation from T lymphocytes, results in the

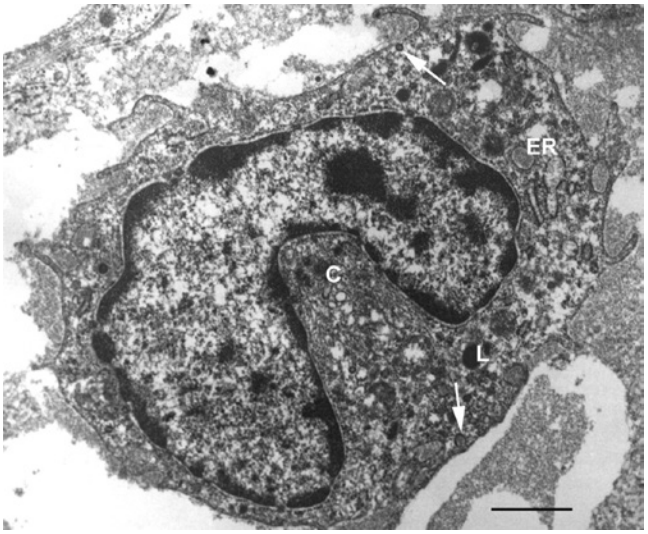

FIGURE 49.1 Porcine tissue macrophage from the skin. Endoplasmic reticulum (ER), primary lysosomes (L), clathrin-coated pits (arrows). Bar, 2 μm. (**Source:** Courtesy of W. L. Steffens III, University of Georgia)

formation of multinucleated giant cells.[5] These cells, which are components of granulomatous inflammation, have extensive, undulating membranes that form from the interdigitation of individual cells. Although cytokinesis is inhibited in these cells, karyokinesis is not.[5]

A specific group of pigmented macrophages has been defined in most fish, amphibians, and reptiles.[7] Melanomacrophages are found in lymphoid and nonlymphoid tissues, including kidney, spleen, and intestines, and are occasionally observed in circulation, particularly during inflammatory conditions.[18,46] The size and number of melanomacrophage centers in amphibians and reptiles have been reported to increase with season and age, respectively.[20,43] Despite their designation, melanomacrophage pigments consist predominantly of lipofuscin and hemosiderin, with smaller amounts of melanin.[18] Functions of these cells include phagocytosis of effete erythrocytes, iron storage, neutralization of free radicals, and phagocytosis of pathogens. It has been suggested that melanomacrophages are the primary defenders against infection during hibernation because they have been shown to retain their effectiveness at near-freezing temperatures in turtles.[18] Due to their role in antigen storage and processing, their close association with plasma cells, and their 5′-nucleotidase profile, melanomacrophages are speculated to function similarly to follicular dendritic cells, which supports the theory that melanomacrophage centers represent primitive germinal centers.[18,46]

DENDRITIC CELLS

Dendritic cells are MHC-II+, CD11C+ APCs that serve as essential conduits between the innate and adaptive immune responses. DCs are the APCs mainly responsible for the cross-presentation of exogenous antigens to the MHC class I pathway, which enables activation of cytotoxic CD8+ T cells in vivo.[19] Although much regarding their origin remains to be elucidated, it has been shown that DC subsets arise from both the MDP, a common progenitor cell for monocytes, macrophages, and DCs, as well as a common dendritic cell precursor (CDP), which does not respond to colony-stimulating factor-1 (CSF-1).[2,28] It is suspected that the MDP pathway is involved in DC generation during inflammation, while the CDP pathway maintains stable populations of DCs during homeostasis.[2]

Subsets and Functions

DCs are generally classified into two categories—plasmacytoid (pDCs) and classical (cDCs), the latter of which constitute all DCs other than pDCs.[28] Present within blood and lymphoid tissues, pDCs have a plasma-cell-like morphology and express a narrow range of PRRs, including TLR7 and TLR9. They produce high levels of type I interferons after exposure to viral antigens or TLR ligation.[6] They can also serve as antigen-presenting cells and mediate T-cell responses, despite their relatively low expression of MHC class II and CD11c.[2,28]

Classical DCs, which reside within most lymphoid and nonlymphoid tissues, are highly phagocytic cells that express high levels of MHC class II and costimulatory molecules (CD80/CD86) following activation.[2,5,28] They can migrate from tissues to the T- and B-cell zones of lymphoid organs via CCR7 in order to regulate lymphocyte responses to antigens during the steady state, as well as during inflammation. When circulating in lymph, DCs are referred to as veiled cells.[5] Within nonlymphoid tissues, DCs comprise between 1% and 5% of tissue cells, and are divided into two major subsets—CD103+CD11b− and CD103+CD11b+, which differ based on origin, expression of FcγRI, FLT3, and responsiveness to FLT3 ligand.[28] Within lymphoid tissues, DCs are divided into two subsets, CD8+ and CD11b+, and are colloquially referred to as interdigitating or follicular DCs based on location within the lymph node, and preference for T-cell activation versus B-cell-activation.[5,28] CD8+ DC function and origin are shared with the previously described CD103+CD11b− DCs. Therefore, this subset expresses high FLT3 levels and lectin receptors, including CD205, C-type lectin domain containing 9A (CLEC9A), and langerin.[28] CD11b+ DCs, which exclusively express dendritic cell inhibitory receptor-2 (DCIR2), are the predominant cDCs in lymphoid tissues, apart from the thymus. This subset can potentially be further divided based on the expression of endothelial cell-specific adhesion molecule (ESAM), particularly within the spleen.[28]

Langerhans cells are a specific type of DC that primarily reside within the suprabasal epidermis, where they serve to process and transport cutaneous antigens to draining lymph nodes for T-cell activation. They also have been documented within the gingiva, epithelium of the gastrointestinal tract, and lymphoid tissues, such

as lymph nodes, thymus, and tonsils.[5] Langerhans cells express lower levels of MHC class II than other DC subsets. They are characterized by expression of E-cadherin and high levels of CD207 (a calcium-dependent C-type lectin).[28]

Phenotypic Appearance and Ultrastructure

Dendritic cells are characterized by the presence of surface dendrites, which transform from filiform to beaded dendrites after activation.[5] Ultrastructural studies have identified nodose enlargements of the beaded dendrites that are responsible for the entrapment of antigen–antibody complexes.[5] Langerhans cells can be identified ultrastructurally by the presence of intracytoplasmic Birbeck granules, which are rod- or racquet-shaped granules, that appear as electron-dense striations. Langerin (CD207) is involved in their formation.[5,28]

MONOCYTE DISORDERS

Monocytopenia

Although monocytopenia is generally not considered to be of clinical significance, it can be observed secondary to a variety of infectious and non-infectious disorders (i.e., estrogen toxicity, chemotherapy). Common infectious causes include parvovirus (canine parvovirus-1 (CPV-1), CPV-2a, CPV-2b) and chronic canine monocytic ehrlichiosis, both of which can result in bone marrow hypoplasia and the destruction of leukocyte precursors.[16] Monocytopenia can occur in up to 53% of cases of dogs with chronic monocytic ehrlichiosis caused by *Ehrlichia canis*.[29] Acute cases, alternatively, can result in a monocytosis. In addition to affecting absolute numbers, infection with CPV-1 has been shown to impair monocyte function, resulting in decreased phagocytic ability and impaired pathogen killing, which likely predisposes to comorbidities.[16] Monitoring the monocyte count may be useful for predicting recovery from bone marrow suppression, since monocytes and neutrophils share a common progenitor cell, and the time taken for monocyte production (3 days) is shorter than the time necessary for neutropoiesis (6 days).[16,49]

Monocytosis

Monocytosis is a common, reactive response to inflammatory disorders that typically reflects a need for macrophages in diseased blood or tissues.[44] It is commonly observed in infectious disorders (e.g., acute and chronic bacterial, fungal infections, rickettsial infections, protozoal infections), immune-mediated diseases (e.g., immune-mediated hemolytic anemia (IMHA)), tissue necrosis (e.g., infarction, trauma), and neoplasia. A reactive monocytosis rarely exceeds 10,000 cells/μL.[49] A neutrophilia often occurs concurrently, since monocytes and neutrophils share a common progenitor cell. A monocytosis can also be observed secondary to the effects of corticosteroids (primarily in dogs and cats), and in obesity. In the latter, adipose tissue macrophages and inflammasome-dependent IL-1β production can directly stimulate the proliferation and expansion of bone marrow myeloid progenitors, thereby resulting in a neutrophilia and monocytosis.[30,41]

Malignant proliferations of monocytes can also occur. Disease processes, including acute and chronic monocytic leukemia and myelomonocytic leukemia, are discussed in Chapters 66 and 68.

Monocyte Dysfunction

Monocyte dysfunction, without a concurrent or consistent alteration in absolute number, can occur secondary to multiple metabolic and systemic diseases, including liver failure, renal failure, diabetes mellitus, and obesity.[12] Monocytes in human patients with end-stage cirrhosis, for example, have lower MHC class II and CCR2 surface expression, decreased phagocytic and oxidative function, and decreased inflammatory cytokine (i.e., TNF) production, thereby resulting in secondary infection and increased mortality.[14] Experimental studies in mice and nonhuman primates involving high-fat and high-cholesterol diets have demonstrated increased MCP-1-mediated chemotaxis, and a skewed expression of Ly6C^{high} monocytes, resulting in a proinflammatory state.[4,41] Continual secretion of proinflammatory cytokines (TNF-α, IL-6) and monocyte "priming" have subsequently been shown to contribute to insulin resistance, diabetes mellitus, kidney disease, and cardiovascular disease.[4]

Several infectious diseases can also result in monocyte dysfunction, particularly those viruses (i.e., lentivirus, herpesvirus, influenza A virus) with a tropism for peripheral blood mononuclear cells. Lentiviruses (of the retrovirus family) are of particular interest, since they affect multiple species, including nonhuman primates (simian immunodeficiency virus), equids (equine infectious anemia virus), bovine (bovine immunodeficiency virus), sheep (maedi–visna virus), goats (caprine arthritis encephalitis virus), and felids (feline immunodeficiency virus). Lentiviruses can serve as translational, comparative models for human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS).[10] Infected monocytes in sheep experimentally infected with maedi–visna virus, for example, demonstrate decreased surface expression of CD80 (B7-1), which is a costimulatory ligand that is crucial for T-cell activation and survival.[38] It is important to note, however, that not all lentiviruses are associated with monocyte dysfunction and disease. Although more virulent strains have been isolated, bovine immunodeficiency virus generally causes mild symptoms, including lymphocytosis, in affected cattle.[10,49] Certain viruses (i.e., porcine reproductive and respiratory syndrome virus) show a restricted tropism for macrophage subsets, as opposed to their circulating counterparts.

MACROPHAGE DISORDERS

Malignant proliferation of macrophages can be difficult to differentiate from reactive processes, particularly if the neoplastic population does not display overt criteria

of malignancy. A thorough review of localized and systemic histiocytic sarcoma and cutaneous and systemic histiocytosis is provided in Chapter 74.

Acquired Defects in Macrophage Activation and Function

Although macrophages play a crucial role in defense against a variety of infectious organisms, including *Mycobacterium*, *Leishmania*, *Rhodococcus*, *Toxoplasma*, *Listeria*, *Brucella*, *Salmonella*, *Yersinia*, and *Rickettsia*, certain pathogens are adept at suppressing macrophage activation or neutralizing their mechanisms of killing. Yeast forms of *Cryptococcus neoformans* and *Cryptococcus gattii*, for example, can prevent phagocytosis and subsequent activation of macrophages by blocking dectin-1 and CD11b.[23] Other pathogens, such as *Rhodococcus*, are able to decrease surface expression of key glycoproteins involved in antigen-presentation (i.e., CD1b), while *Mycobacterium avium* subsp. *paratuberculosis* can interfere with the acidification and fusion of intracellular lysosomes.[33,49] Such interference results in the persistence of the pathogen, resulting in patient morbidity and mortality.

Hemophagocytic Syndrome

Hemophagocytic syndrome (HPS), which is also known as hemophagocytic lymphohistiocytosis, is a reactive proliferation of macrophages that label positive with monoclonal antibodies against CD14, CD18, MHC class II, and Thy-1.[47] Although in humans it can either be inherited as a genetic (primary or familial HPS) or acquired (secondary or reactive HPS) disorder, only acquired cases arising secondary to infectious (*Trypanosoma congolense*, African swine fever virus, simian retrovirus, ehrlichiosis, parvovirus, blastomycosis), IMHA, and neoplastic (lymphoma, multiple myeloma) diseases have been documented in dogs, cats, cattle, swine, and a rhesus macaque.[31] Idiopathic cases have also been reported. In humans, primary or familial HPS is an autosomal recessive disorder that has been linked to reduced perforin function and subsequent defects in cell-mediated cytotoxicity.[31,49] Perforin monomers are calcium-dependent, channel-forming proteins that result in the osmotic lysis of, and allow for, the introduction of apoptosis-inducing granzymes into target cells.[31] Although more investigation is required, preliminary studies in Bernese Mountain Dogs with and without histiocytic diseases concluded that single-nucleotide polymorphisms (SNPs) within the perforin gene were unrelated to the expression of disease, since the SNPs did not result in alteration of amino acid coding sequences.[31]

Due to its similar presentation to other disease processes, including bacterial sepsis and the systemic inflammatory response syndrome, HPS can be difficult to document both clinically and cytologically.[49] Documented cases, which require bicytopenia or pancytopenia in peripheral blood, and >2% hemophagocytic macrophages in a cellular bone marrow, can present with vague clinical signs including pyrexia and diarrhea, as well as hepatosplenomegaly.[31,48,49] Abnormalities that can be observed on serum biochemical panels include hypoalbuminemia and hypocholesterolemia.[9] In canines, a strong breed predilection has been documented in Bernese Mountain Dogs, Flat-Coated Retrievers, Rottweilers, and Tibetan Terriers.[31,48] Mortality rates reportedly range from 22% to 62%, but overall, canines with HPS secondary to infection have better survival rates than cases arising from immune-mediated, neoplastic, or idiopathic causes.[48,49]

When evaluating bone marrow samples, HPS must be distinguished from malignant histiocytosis (also known as disseminated histiocytic sarcoma), and other causes of macrophagic proliferation within the bone marrow (i.e., necrosis, IMHA). Criteria that can be used to differentiate malignant histiocytosis from HPS include highly anaplastic nuclear features (i.e., multinucleated giant cells, karyomegaly, bizarre mitotic figures) and >30% neoplastic cells in a normocellular or hypercellular bone marrow.[9,48] An expansion of well-differentiated macrophages can also be seen on aspirates of the liver and spleen in cases of HPS. However, since cytologically malignant features can be observed in cases of HPS, flow cytometry scatter plots or immunophenotyping may be necessary to differentiate HPS from malignant histiocytosis.[9,47,48]

Lysosomal Storage Diseases

Lysosomal storage diseases (LSDs) are a relatively uncommon, broad category of inherited, autosomal recessive, and X-linked disorders that result in atypical lysosomal function, and subsequent accumulation of incompletely degraded macromolecules, including sphingolipids, cholesterol esters, glycoproteins, and mucopolysaccharides.[11,21] Such accumulation affects the function of cells, tissues, and organs, resulting primarily in central nervous system dysfunction and neurodegenerative disease. Signs associated with LSDs, however, can be multisystemic, resulting in musculoskeletal, cardiovascular, and ocular disorders.[11] Electron microscopy of affected tissues reveals membranous cytoplasmic bodies or zebra bodies, which represent concentric and stacked membranous material, respectively.[21] Natural cases of LSDs, which include GM1 and GM2 gangliosidosis, mucopolysaccharidosis, glucocerebrosidosis (Gaucher disease), sphingomyelinosis (Neimann–Pick disease), β- galactocerebrosidosis (globoid cell leukodystrophy or Krabbe disease), α- and β-mannosidosis, and α-l-fucosidosis, have been documented in dogs, cats, ruminants (cattle, goats, sheep), guinea pigs, rodents (mice and rats), pigs, Japanese quail, emus, and flamingos.[11,21,49] Breed predispositions and specific inherited mutations are documented elsewhere.[21] Genetic testing for canines and felines is currently offered through the University of Pennsylvania's PennGen Laboratories.

Cases of acquired LSDs have also been documented, particularly in herbivores following exposure to toxic agents, such as *Swainsona*, *Oxytropis*, and *Astragalus* spp. Also known as locoweeds, the plants of these genera can cause disease similar to α-mannosidosis in horses, cattle,

and sheep due to the inhibition of α-mannosidase within lysosomes and the Golgi complex by swainsonine.[21] Similar clinical signs and histological lesions have been documented in horses, deer, and goats, following ingestion of *Sida carpinifolia*, a swainsonine-containing wireweed.[26] Ingestion of *Trachyandra divaricata*, *Phalaris* spp., and *Solanum* has also been associated with acquired LSDs.

Idiopathic Systemic Granulomatous Disease in Horses and Cattle

Idiopathic systemic granulomatous disease (ISGD) is an uncommon, multisystemic, non-caseating granulomatous disease that is characterized by the presence of fibrinoid necrosis, perivascular infiltrates composed of lymphocytes, macrophages, plasma cells, and multinucleated giant cells.[34,35,40] Closely resembling human sarcoidosis, this disease process has no age, breed, or sex predilection, and is suspected to originate from a dysregulated immune response. Unlike the human disease, however, ISGD is not associated with hypercalcemic states or soft-tissue mineralization.[35] A similar disease process has been documented in cattle and horses after ingestion of *Vicia villosa* (hairy vetch).[34,35,40] The granulomatous lesions that develop secondary to ingestion of this legume are suspected to represent either a type IV hypersensitivity reaction against the plant constituents or direct activation of T cells by lectin.[34] ISGD is currently a diagnosis of exclusion, and requires that bacterial (i.e., *Mycobacterium spp.*), viral (i.e., equine herpesvirus-2 (EHV-2)), and fungal (i.e., *Coccidioides immitis*) causes of granulomatous disease be ruled out.

Acronyms and Abbreviations

αβ, alphabeta; AID, activation-induced deaminase; AIRE, autoimmune regulatory gene; BCR, B cell receptor; Blimp-1, B lymphocyte-induced maturation protein-1; C, constant; CCR, chemokine receptor; CD, cluster of differentiation; CDR, complementarity determining region; c-Kit, mast/stem cell growth factor receptor or CD117; CLP, common lymphoid progenitor; D, diversity; DN, double negative; DNA-PK, DNA-dependent protein kinase; DP, double positive; FLT3, FMS-like tyrosine kinase 3 (CD135); G, guanine; γδ, gammadelta; GATA3, GATA-binding protein 3; HSC, hematopoietic stem cell; Ig, immunoglobulin; IFNγ, interferon gamma; IGF1, insulin-like growth factor 1; IL, interleukin; J, junctional; KLRG1, killer cell lectin-like receptor G1; MALT, mucosa-associated lymphoid tissue; MHC, major histocompatibility antigens; MPP, multipotent progenitor; NK, natural killer (cell); NKT, natural killer T (cell); RAG, recombination-activating gene; RSS, recombination signal sequences; sca-1; stem cell antigen-1; SCID, severe combined immunodeficiency; TCR, T cell receptor; TdT, terminal deoxynucleotidyl transferase; TGF-β, transforming growth factor-beta; U, uracil; V, variable.

Lymphocytes develop from bone-marrow-derived pluripotent hematopoietic stem cells (HSCs). Pluripotent stem cells have the capacity either to self-renew or to differentiate into all blood cell types.[11] HSCs initially give rise to multipotent progenitors (MPPs) that retain the ability to differentiate into all cell lineages, but lack the ability to self-renew (see Chapter 41). MPPs differentiate into oligopotent progenitors—the common myeloid progenitors and the common lymphoid progenitors (CLP). CLPs give rise to the three lymphocytic lineages: B cell progenitors, T cell progenitors and natural killer (NK) cell progenitors.[6] As hematopoietic cells mature, they express different cell surface markers, forming the basis of identification of cells by flow cytometry. CLPs are characterized by the expression of interleukin (IL)-7, as well as mast/stem cell growth factor receptor (c-Kit or CD117), stem cell antigen-1 (sca-1), and FMS-like tyrosine kinase 3 (FLT3 or CD135).

The writing and compilation of the chapter greatly benefitted from the contributions of Mary J. Burkhard's Chapter 10 in the 6th edition of Schalm's Veterinary Hematology.

IMMUNOLOGIC DIVERSITY

Lymphocytes are unique in their ability to recognize and bind to an almost unlimited array of antigens through their T-cell receptors (TCR) and B-cell receptors/immunoglobulin (BCR, Ig). The process by which this diversity is achieved is similar in both T and B cells and involves combinatorial diversity and junctional diversity. A third

process in B cells, somatic hypermutation, further diversifies Ig after T-helper-cell stimulation.

Combinatorial Diversity

Unlike many genes, there is not a single contiguous segment of the genome that encodes TCRs and Igs. Instead, in germline DNA, there are multiple segments, named variable (V), diversity (D), and junctional (J) segments, with multiple copies of each of these. Combinatorial diversity occurs through random joining of different V, D, and J segments, during V(D)J rearrangement to create millions of V(D)J permutations. Specific gene segments called recombination signal sequences (RSS) and recombination-activating gene (RAG) enzyme complexes are crucial for V(D)J rearrangement. RSS flank Ig and TCR V, D, and J gene segments and are composed of a conserved heptamer, a non-conserved spacer of 12 or 23 base pairs and a conserved nonamer. The orientation of RSS and the size of the non-conserved spacer region (12 vs. 23) ensure orderly recombination of V, D, and J segments, and prevent the recombination of similar gene segments (e.g., V–V). RAG-1 and RAG-2 proteins are nuclear recombination enzymes unique to developing lymphocytes that recognize and bind to RSSs adjacent to different V, D, and J gene segments. In general, RAG enzyme production ceases at the end of V(D)J rearrangement. RAG enzymes and other more universally expressed DNA-repair enzymes including DNA-dependent protein kinase (DNA-PK), artemis nuclease, terminal deoxynucleotidyl transferase (TdT), and DNA ligase IV form complexes that bind, excise, and repair V, D, and J segments to form a unique V(D)J sequence. This occurs in a multistep process where first RAG-1 and RAG-2 enzymes recognize and bind to two RSSs on different D and J regions, creating a nick in one strand of the DNA. The intervening DNA forms a hairpin between the selected D and J segments. Nucleotides can then be added or deleted to create blunt-ended double-stranded DNA breaks (see junctional diversity). The cut ends of the DNA are held in place by RAG enzymes that are then reannealed by a complex of artemis nuclease, DNA-PK, and DNA ligase IV. V(D)J rearrangement is initiated by joining of one D region with one J region. A V region is then added and the intervening DNA is deleted, resulting in a single recombined V(D)J genomic sequence (see Figure 50.1).

There are differences in the BCR (Ig) and TCR components as to whether all three V, D, and J segments are incorporated. TCR α-chain and BCR (Ig) light chain use only V and J rearrangement, whereas TCR β-chain and BCR (Ig) heavy chain use V, D, and J rearrangements. There is reduced diversity in the number of V-segments encoding for γδ TCR, accounting for some of the decreased antigenic diversity of this receptor.

V(D)J rearrangement defines specific stages of B- and T-cell development. In B cells, successful heavy-chain rearrangement is required before light-chain rearrangement can begin. In T cells, rearrangement of the TCR loci follows a specific order starting with delta, then proceeding through the gamma, beta, and finally alpha genes. Two distinct subpopulations of TCR expressing cells are formed from these chains: αβ and γδ T cells. To underscore the importance of V(D)J rearrangement, foals that genetically lack DNA-PK die early in life due to severe combined immunodeficiency (see Chapter 55).

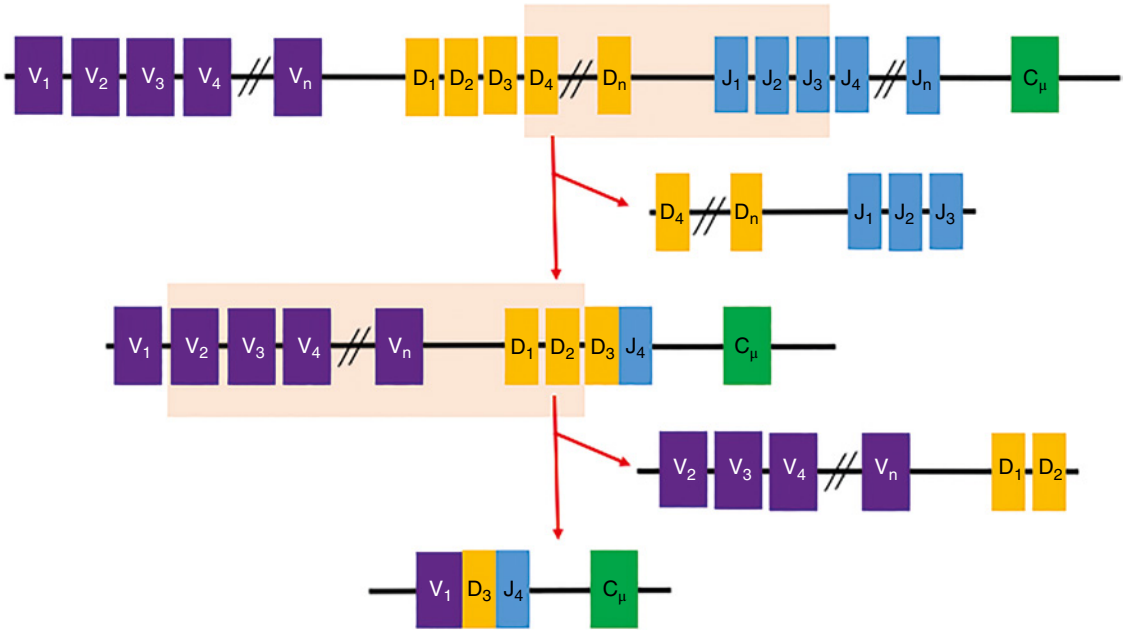

FIGURE 50.1 V(D)J rearrangement. RAG enzyme complexes bind to RSS sequences adjacent to V, D, and J segments, excising the intervening DNA and binding cut ends. D and J segments recombine first, excising the intervening DNA. Thereafter, V segments produce a final rearranged product containing one V, D, and J segment.

Junctional Diversity

Junctional diversity is created by the random addition of nucleotides to DNA ends that are cleaved during recombination. TdT is a DNA polymerase that adds variable numbers of nucleotides to the V, D, and J exons during rearrangement. These additional nucleotides at the V(D)J junctions are called N regions and provide additional diversity of the Ig heavy chain and the TCR. As the addition or subtraction of nucleotides by TdT is random, there is also the possibility that during this process, a frameshift or nonsense mutation is introduced, resulting in nonfunctional TCR or Ig open reading frames. This necessitates a quality-control step in both T- and B-cell maturation to ensure proper formation of TCR and Ig chains. Combinatorial gene rearrangement and junctional diversity are initiated first in one paired chromosome and move to the second chromosome if a functional chain fails to form. Failure of both chromosome rearrangements to form a functional chain results in apoptosis of the cell. TdT expression declines as B cells mature and does not increase light-chain diversity.

Somatic Hypermutation

In activated, proliferating follicular B cells, additional immunoglobulin diversity is achieved through programed somatic hypermutation within the Ig genes. Although this occurs after lymphopoiesis, it is an essential component of B-cell maturation and markedly hones the specificity of the acquired immune response. Somatic hypermutation occurs in proliferating B cells that have been activated by antigen-bearing T-helper cells. It is restricted to the BCR genes predominantly in the complementarity determining regions (CDR), the area of the BCR that binds antigen. Hypermutation in this region occurs at approximately 10^5–10^6 times higher than in other regions and consists mostly of single nucleotide replacements. Activation-induced deaminase (AID) mediates somatic hypermutation by deaminating cytosine residues in CDRs to uracil, resulting in a uracil–guanine (U:G) mismatch. Base-excision-repair enzymes remove these, which are then repaired by error-prone DNA polymerases that create mutations in one to a few nucleotides surrounding the U:G mismatch. As B cells are proliferating at a high rate when somatic hypermutation occurs, this results in thousands of variations of antigen-recognizing B cells, some of which will have enhanced recognition of the antigen. The B cells with the highest affinity for the antigen have a selective advantage to receive signals to clonally expand and eventually to differentiate into plasma cells and memory B cells.

B CELL DEVELOPMENT

B cell lymphopoiesis is a lifelong process in mammals that begins in the fetal liver and transitions to bone marrow after birth. In birds, B-cell maturation occurs in the bursa of Fabricius, in fish it occurs in the kidneys and in amphibians in the spleen, bone marrow, and kidney.[3] Mature B cells form the cornerstone of humoral immunity, producing and secreting highly antigen-specific antibodies. Mammalian BCR are comprised of two heavy chains and two light chains, bound together by disulfide bonds. Each paired N-terminus of the heavy and light chain forms an antigen-binding domain—the location of the highest amount of variability which is divided into three regions of hypervariability, CDR1, CDR2, and CDR3.[5] The paired C-terminuses of the heavy chains are relatively constant and can be attached to a membrane through a membrane-binding domain (BCR) or are free in solution (Ig). A B cell can, throughout its life, express different BCR forms. These forms maintain their antigen specificity, but vary in the C-terminus of the heavy chain, creating different antibody isotypes (e.g., IgG, IgM, IgA, etc.) with the IgM isotype the initial BCR expressed by all developing mammalian B cells.

B-2 B Cells

There are several different types of B cells: B-2, B-1, and marginal zone B cells. B-2 are the more conventional type of B cell that on maturation reside in secondary lymphoid tissue follicles and differentiate after activation into memory B cells and plasma cells. Much of what is understood about B cell lymphopoiesis pertains to B-2 B cells.

IL-7 is important in the initial proliferation of committed B cell progenitors. Later stages of developing B cells require only soluble factors for development. IL-1α, IL-3, IL-4, IL-11, transforming growth factor-beta (TGF-β), interferon gamma (IFNγ), insulin-like growth factor (IGF1), c-Kit ligand, FLT3 ligand, and estrogen are known to play a role in B cell proliferation, differentiation, and regulation.

The sequential V(D)J rearrangement of BCR gene closely follows the sequence of B-cell maturation. Heavy-chain rearrangement occurs first in pre-/pro-B cells where D and J gene segments recombine. This is followed in pro-B cells where variable segments are recombined to the rearranged (D)J segments. This completed V(D)J forms the heavy chain and is the first quality assurance step in B-cell maturation. To test if the recombined heavy chain can bind to a light chain and be expressed on the surface of the cell, the cell binds the heavy chain to a surrogate light chain to produce a pre-BCR. If the cell fails to produce a pre-BCR, genetic recombination of the heavy chain occurs again on the paired chromosome. The second checkpoint in BCR production assesses the pre-BCR for heavy-chain self-reactivity. Expression of a functional pre-BCR inhibits further heavy-chain rearrangement, stimulates cell replication, and is necessary for the survival and positive selection of pre-B cells after which recombination of the light chain commences.

Light-chain rearrangement occurs in late pre-B cells. Kappa rearrangement proceeds first. Lambda rearrangement will occur only if kappa rearrangement is unsuccessful. After successful production of the light chain, the newly formed BCR forms and is expressed on the cell surface. If the light chain produced is unable to bind to the heavy chain, the other parental chromosome is

rearranged, and if the light-chain production fails for a second time, the cell undergoes apoptosis. Light-chain and heavy-chain proteins combine to produce a BCR. The third checkpoint occurs at this stage where the newly formed BCR is exposed to self-antigen and those with high affinity are deleted.[12] As cytoplasmic IgM is exported to the surface membrane, cells transition into immature B cells that express CD21. Surviving immature B-2 B cells migrate to peripheral lymphoid tissues where they begin to express surface IgD as well as IgM. As these cells interact with antigen and T cells, they undergo the fourth checkpoint: the process of class switching, somatic hypermutation, and affinity maturation (see Figure 50.2).

Further, functional diversity in immunoglobulins and BCR comes from varying isotypes (IgM, IgA, IgD, IgG, IgE, etc.). These different isotypes are determined by multiple gene encodings for different constant regions—Cμ, Cδ, Cγ, Cε, and Cα corresponding to IgM, IgD, IgG, IgE, and IgA. During isotype switching, different constant regions are expressed, while the variable region (the antigen-binding region) remains the same. The Cμ gene is adjacent to the V(D)J region in the genome, and as such, B cells initially express IgM isotype and some IgD, switching later after antigen and T-helper activation in the periphery to IgE, IgA, and IgG.

B-1 B Cells

B-1 B cells play more of a role in innate than acquired immunity. It is currently thought that most B-1 B cells are produced in the yolk sac, fetal liver, and bone marrow, with a lesser number produced in the adult bone marrow. Most agree that B-1 B cells are derived from a different, parallel lineage to B-2 B cells, arising from a B-1 CLP.[13] After maturation in the fetal liver, B-1 cells mostly localize to pleural and peritoneal cavities where they establish self-renewing populations. Most B-1 B cells express cell surface CD5 and produce predominantly IgM antibodies. While they are the minority population in humans and rodents, they form the majority of B cells in ruminants and rabbits. There is much less BCR diversity in B-1 B cells as they lack the enzyme TdT required for junctional diversity, they do not undergo somatic hypermutation, and there are many fewer possible DJ and V(D)J permutations. Their antigenic repertoire, while narrower, is honed to bacterial polysaccharides and lipids, the predominant pathogen in peritoneal and pleural cavities. B-1 B cells are capable of activation independent of Th-cells.[9] Their capacity to quickly respond to bacterial antigens gives them unique advantages over B-2 B cells.

Marginal Zone B Cells

A second subset of less common B cells is the marginal zone B cells that are localized to the marginal zone of the spleen–the primary site of blood antigen monitoring in the body. Like B-1 B cells, marginal B cells are able to respond to antigen in a T-helper-independent manner and tend to have higher responsiveness to non-protein

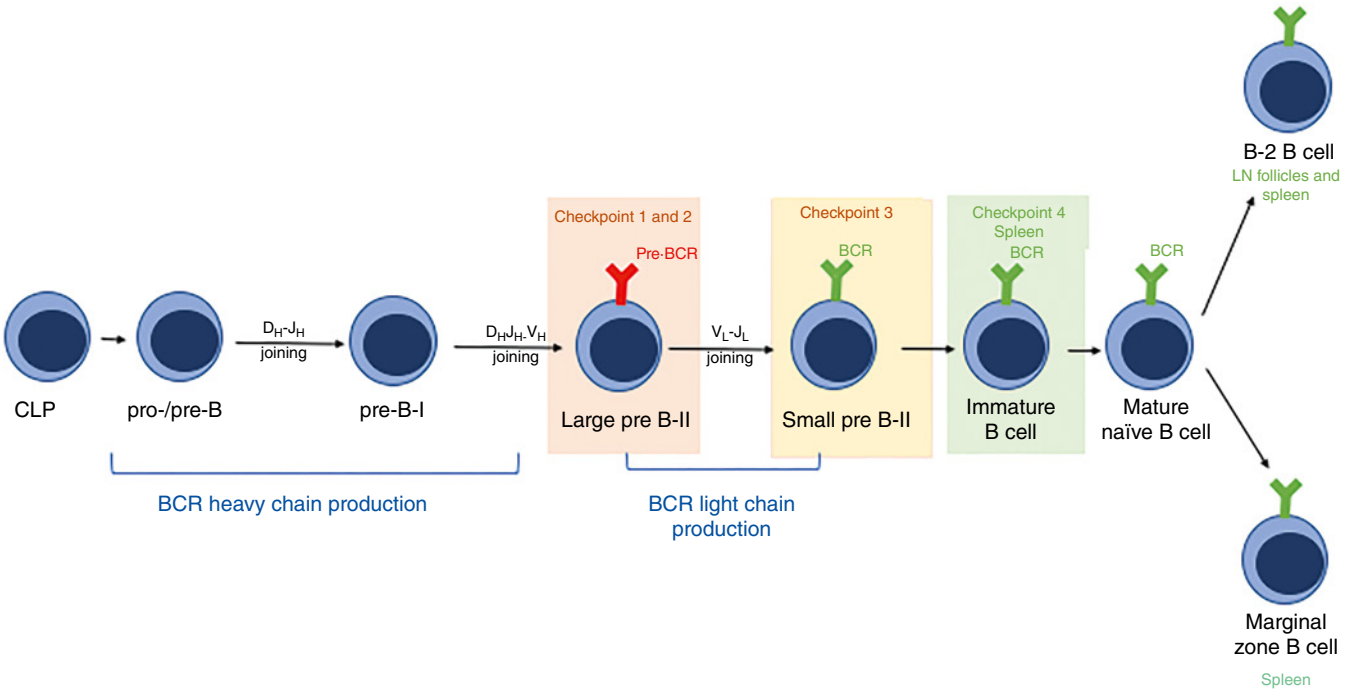

FIGURE 50.2 B cell development. BCR heavy-chain rearrangement begins in pro-/pre-B cells and ends in large pre-B-II cells. After production of a heavy chain, a pre-BCR is produced and the first two checkpoints of the heavy chain's ability to bind to the surrogate light chain and not react with self is interrogated. Light-chain production follows with expression of fully formed BCR and the third checkpoint to eliminate self-reactivity of the formed BCR. Immature B cells are thought then to migrate to the spleen where a fourth checkpoint for self-reactivity is believed to occur. (Source: Modified from Melchers[12])

antigen than B-2 B cells. Similar to B-1 B cells, they are only able to produce IgM antibodies, and compared to B-2 B cells, they have reduced BCR diversity. Our understanding of marginal B cell lymphopoiesis is still emerging. The current belief is that marginal B cells are derived from bone marrow, but develop into marginal B cells in the spleen in response to a combination of BCR antigen affinity strength and Notch2 signaling.[8]

T CELL DEVELOPMENT

Similar to B cells, T cells are characterized by enormous TCR diversity. The derivation of the TCR closely follows T-cell development and maturation. Initial T cell precursors are produced in bone marrow from CLP cells. These cells migrate to the thymus for maturation and are termed "thymocytes." The thymic stroma is a uniquely organized epithelial network on a mesenchymal cell backbone with interspersed dendritic cells and macrophages (see Chapter 51). This cellular network provides the extracellular matrix ligands and growth factors critical for T-cell selection and development. Thymic precursors enter at the corticomedullary junction via molecules such as CD44, CD62P, and chemokine receptor 9 (CCR9), and migrate initially to the outer cortex, then later to the medulla. Initial T-cell development in the thymus is driven by notch expression by thymic stromal cells that interacts with the notch receptors on thymocytes. Notch signaling is essential for T versus B cell fate decision and promotes αβ T-cell development over γδ T cells.[16] Notch1 with GATA3 is important for the transition from the T/NK progenitor to sole T-cell commitment.[15] Notch1 alone directs cells toward γδ TCR development, but HEB (one of the basic helix–loop–helix E-box-binding proteins) directs cells toward αβ TCR.[14] IL-7 is also necessary for T cell development. Defects in the IL-7/IL-7 receptor complex and signaling pathway are responsible for several reported T cell defects. B lymphocyte-induced maturation protein (Blimp-1) has been shown to be essential for terminal differentiation of T cells.[10]

T cell development proceeds down two primary pathways as defined by expression of different TCR types: αβ and γδ. In most species, approximately 90% of immature cells develop into αβ T cells through thymic selection, while the remaining cells develop into γδ T cells. αβ TCRs are only capable of recognizing antigen when it is complexed to either major histocompatibility antigens (MHC)-I or MHC-II molecules and have a much wider range of TCR diversity, compared to γδ TCR. γδ TCRs can recognize unprocessed antigen, not associated with MHC, and the narrow range of antigen they are capable of binding to includes lipid antigens (including those produced by mycobacteria), phosphorylated ligands, and heat shock proteins.[4] The narrow range of variability in γδ T cells relates to a lower number of V-gene segments. αβ T cells are CD3+ and the majority also express either CD4 or CD8.

TCR Production

The earliest progenitors of T cells in the thymus are the double negative (DN) cells, so called because they lack expression of either CD4 or CD8. As DN cells mature, they undergo variable expression of CD44 and CD25. The earliest DN1 cells are CD44+/CD25−. DN2 cells are CD44+/CD25+, followed by decreased CD44 expression in DN3 cells (CD44−/CD25+) to the dropping of both markers in DN4 cells (CD44−/CD25−). TCR production accompanies this maturation. TCR β-chain rearrangement occurs first in DN3 (CD44−/CD25+) cells. DN4 (CD44−/CD25−) cells produce a pre-TCR by combining the newly formed β-chain with a surrogate TCRα chain to express a pre-TCR that complexes with CD3 on the cell surface. This is termed beta-selection, a quality assurance checkpoint. Successful formation of the pre-TCR leads to survival, proliferation, and upregulation of CD4 and CD8. Cells that fail beta-selection undergo apoptosis. TCRα rearrangement and expression then commence in CD4+/CD8+ double positive cells to produce rearranged αβTCRs.

Positive Selection

After a functional TCR is produced, double positive cells undergo positive selection. This is to ensure that the TCR–CD3 complex is able to interact with MHC class I and II molecules. Positive selection occurs in the cortex of the thymus where double positive thymocytes interact with low- to moderate-affinity MHC peptide ligands on cortical epithelial cells to receive a survival signal. Although the basis of positive selection is the TCR–MHC interaction, CD4 and CD8 are also required for selection. Double positive cells that select MHC-II molecules will become CD4 T cells, while those that select MHC-I molecules will become CD8 T cells, forming the basis for lineage commitment. Positive and negative selection occurs during interaction with dendritic cells and other antigen-presenting cells at the corticomedullary junction. Differential downregulation of either CD4 or CD8 occurs in the thymic medulla.[16] CD4+ T cells can become T-helper cells including Th1, Th2, Th17, and likely T-regulatory cells, and CD8+ T cells can become T-cytotoxic cells.

Negative Selection

As a diverse population of TCRs is produced, the next stage removes self-reacting T cells. Thymocytes that survive positive selection upregulate cell-surface expression of the chemokine receptor CCR7 and migrate to the thymic medulla for elimination of autoreactive T cells. Medullary epithelial and dendritic cells are induced to express peripheral antigens (e.g., those expressed by the pancreas, liver, etc.) through the autoimmune regulatory gene called AIRE. In the medulla, thymocytes interact with high-affinity self-ligands on the medullary epithelium. Cells that react strongly receive an apoptotic signal. Surviving cells undergo final maturation and then exit the thymus. Greater than 95% of developing lymphocytes fail one of these selection processes (see Figure 50.3).

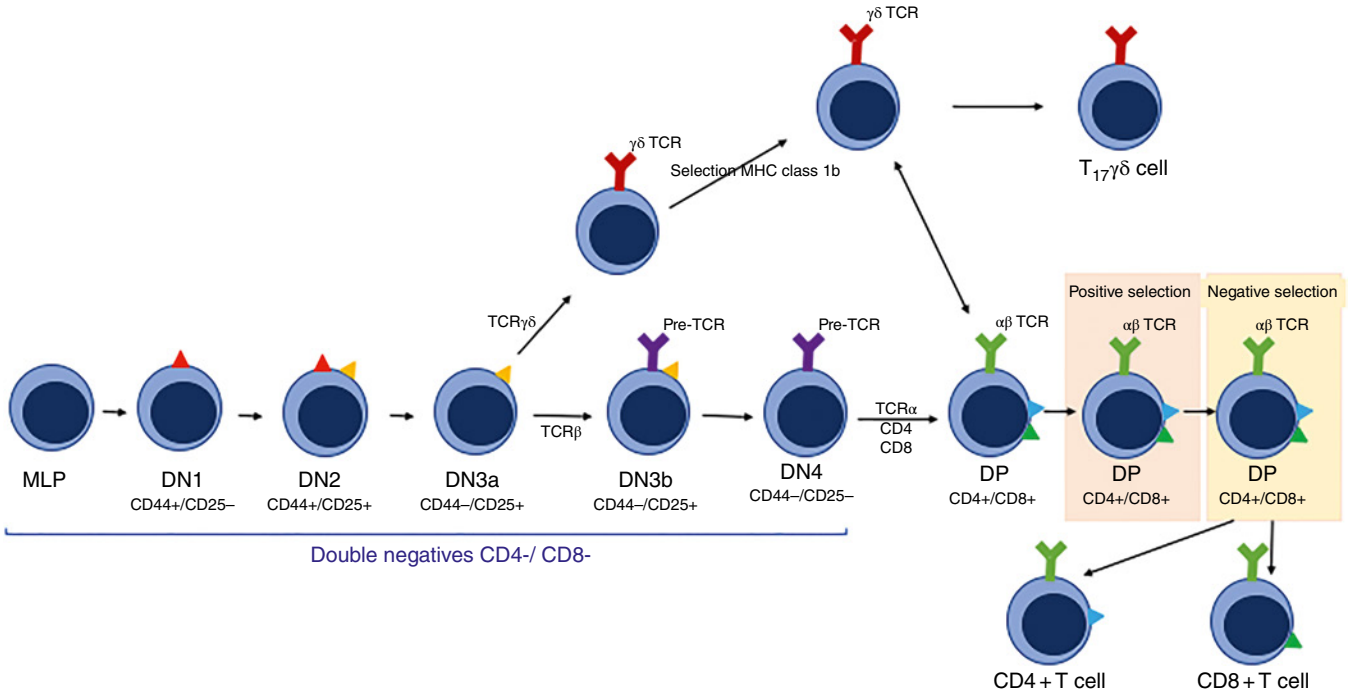

FIGURE 50.3 T cell development. CLPs migrate from bone marrow to the thymus where thymocytes are termed double negative (DN) cells lacking CD4 or CD8 expression. In the thymic cortex, DN cells mature through several stages with differential expression of CD44 and CD25 that results in TCR β-chain rearrangement, production of pre-TCR, and beta selection checkpoint. TCRα chain production and expression of both CD4 and CD8 follow, producing double positive (DP) cells. The functional TCR undergoes both positive and negative selection in the medulla of the thymus after which differential reduction in either CD4 or CD8 expression occurs producing functional CD4+ and CD8+ cells that exit the thymus. (**Source:** Modified from Gerondakis et al.[7])

Natural Killer T Cells

Natural killer T (NKT) or NK1.1 T cells are a unique subpopulation of αβ T cells that functionally bridge the innate and adaptive immune systems. NKT cells express NK1.1, a marker typically found on NK cells, can be CD4 and CD8 positive or negative and express CD16, CD56, and produce granzyme. Unlike conventional T cells, NKT cells recognize antigen presented in CD1d molecules, rather than MHC, a consequence of which is their enhanced ability to recognize lipid and glycolipid antigen (e.g., mycobacteria). NKT cells undergo selection via interactions with CD1 ligands in the cortical region of the thymus after they reach the double positive stage of development. TCR development in NKT cells can progress in a manner similar to conventional T cells; however, a subset of NKT cells (invariant iNKT cells) produces an invariant α-chain and have limited β-chain diversity.[2]

NATURAL KILLER CELL DEVELOPMENT

NK cells are cytotoxic innate lymphocytes that kill altered host cells. NK cells are thought to be activated by alterations in the balance between activating and inhibitory signals expressed on the surface of host cells. Activating signals are often normal cell surface proteins whose structure is modified by increased intracellular stress, as can happen with viral infection. Normal MHC-I expression can inhibit cell killing, and altered MHC-I expression can induce killing. NK cells lack TCR, CD3, and BCR expression and NK-receptors do not undergo recombinatorial events, but instead are constitutively expressed. NK development occurs in the fetal liver and thymus, and after birth in the bone marrow and peripheral lymphoid tissues.[1] Like other lymphocytes, NK cells develop from CLP cells with the expression of IL-15 receptor β-chain (CD122) identifying the earliest committed pre-NK cell progenitors. Three stages of NK development are currently recognized: lineage commitment, NK receptor selection, and functional maturation. NKG2D expression occurs initially, followed by NK1.1 and NCR1 expression. Mature NK cells are characterized by the expression of CD51, CD49, CD43, CD11b (Mac-1), and finally Ly49. Maturing NK cells then migrate to secondary lymphoid organs to complete maturation characterized by the expression of killer cell lectin-like receptor G1 (KLRG1). The transition from CLP to T/NK precursor is mediated, at least in part, by Notch1 and the T-box transcription factors, T-bet and Eomesodermin. IL-1, IL-7, and IL-15 are required for NK growth and maturation. The process by which NK cells are educated to not self-react is not fully understood, but may involve mechanisms similar I to T cell or B cell anergy or binding through self-MHC-I-specific inhibitory receptor interactions.

Acronyms and Abbreviations

APC, antigen-presenting cell; BALT, bronchus-associated lymphoid tissue; BLV, bovine leukemia virus; BVDV, bovine viral diarrhea virus; CD, cluster of differentiation; D, diversity; FeLV, feline leukemia virus; GALT, gut-associated lymphoid tissue; H&E, hematoxylin & eosin; HEV, high endothelial venules; HSC, hematopoietic stem cell; Ig, immunoglobulin; J, joining; MALT, mucosa-associated lymphoid tissue; MHC, major histocompatibility complex; NK cell, natural killer cell; PALS, periarteriolar lymphoid sheath; PCB, polychlorinated biphenyls; PCV2, porcine circovirus type 2; RBC, red blood cell; SCID, severe combined immunodeficiency; TCR, T cell receptor; Th2 cell, T-helper 2 cell; V, variable; VALT, vulvovaginal-associated lymphoid tissue.

The lymphoid system consists of primary and secondary lymphoid tissues. Primary tissues, including the bone marrow and thymus, are sites of lymphocyte production, development, and maturation. Secondary lymphoid tissues are the sites where lymphocytes interact with each other as well as antigen-presenting cells (APC) in the orchestration of the adaptive immune response. Subsets of lymphocytes develop and mature in different ways and in different tissues. T cells are formed in the bone marrow but migrate to the thymus for maturation and selection. B cells are formed and primarily mature in the bone marrow, though there is some evidence that B cell maturation and education may also occur in the spleen and peri-intestinal lymphoid tissues. NK cells, the only known innate lymphoid cell, develop and mature in bone marrow and then are released into and spend much of their time circulating in the blood and lymphatic systems.

Other highly specialized structures support the hematopoietic system. These include the epithelial cells of the thymus that sheath the blood vessels and form the saccular structures of the thymic cortex that are important for T cell maturation and selection. The fibrovascular supporting framework of the lymph node and spleen plays crucial roles in antigen-presenting cell and lymphocyte migration, orchestrating their interactions during adaptive immune responses. The vascular endothelium of the hematopoietic system includes the regionally undifferentiated cells lining the lymphatics as well as the regionally differentiated

The writing and compilation of this chapter greatly benefitted from the contributions in Chapter 52 by V. E. Ted Valli and Robert M. Jacob in the 6th edition of *Schalm's Veterinary Hematology*.

endothelial cells of the blood vascular system, which include the high endothelial venules of the lymph node paracortex with specific cell surface markers permitting the adhesion of lymphocytes in transit and their transmural migration to enter the node paracortex. The specialized circulating blood cells and their conducting and supporting structures are uniquely packaged in a series of organs of either separate design like the thymus, lymph nodes, and spleen or are incorporated into other organs like the bone marrow. These also include the free and fixed tissue macrophages and dendritic cells. These cells and organs of the blood vascular system constitute remarkably interrelated and integrated systems.

STRUCTURE, FUNCTION, AND DISORDERS OF PRIMARY LYMPHOID TISSUE

Bone Marrow

In mature animals, the bone marrow is the primary site of lymphocyte production, arising from common lymphoid progenitor cells, which in turn differentiate from common hematopoietic stem cells (HSC) (see Chapter 50). During embryogenesis, hematopoiesis occurs predominantly in the liver and migrates to bone marrow by the time an animal is born.

Lymphocyte production starts in the intersinusoidal spaces with initial differentiation to early lymphoid progenitors that later differentiate into the T cell, B cell, and NK cell lineages.[5,6,10,12,16]

Due to the rapidly dividing nature of hematopoietic cells, including lymphopoietic cells, the marrow is particularly susceptible to toxic and infectious agent injury as well as radiation and chemotherapeutic drugs. Disorders of the bone marrow are wide-ranging and encompass primary and secondary infections, neoplastic, developmental, toxic, and nutritional diseases (see Chapters 12 and 16).

Thymus

The thymus, the primary site of T cell maturation, is located in the cranial mediastinum in most species, as well as the ventral portion of the neck in young calves and pigs, and occasionally in kittens and foals. It is comprised of maturing T cells, termed thymocytes while in the thymus, and epithelial cells arranged in lobules with a distinct cortex and medulla (Figures 51.1 and 51.2). The cortex stains darker than the medulla on H&E stain due to a higher density of smaller, more basophilic lymphocytes in this area. An intricate network of epithelial cells and blood vessels form the structural basis of the thymus. Unlike other lymphoid organs, the normal thymus contains no afferent lymphatics or B cells. The thymus reaches maximal development at puberty and regresses in adulthood, but thymic remnants remain through the animal's life. Thymic function does not necessarily correlate to thymic size.

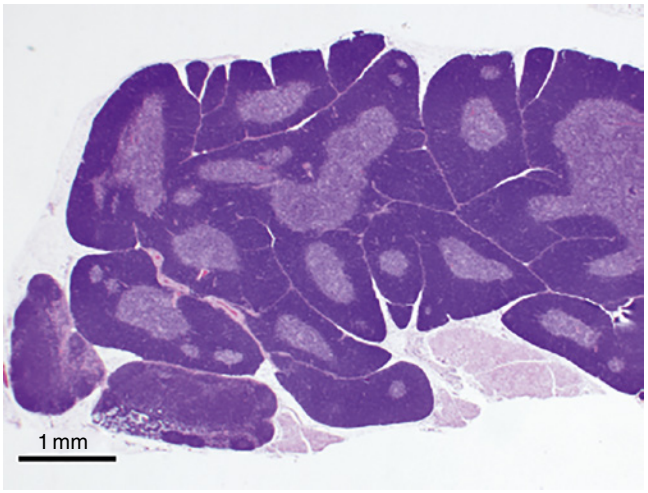

FIGURE 51.1 Thymus from a young adult male rat. The organ is composed of closely faceted lobules with a sharp distinction between the darker cortex and the lighter medullary areas of each lobule. H&E stain; bar = 1 mm.

The epithelial cells of the thymus are derived from the third and fourth pharyngeal pouches. This migration occurs very early in embryologic development and is immediately followed by seeding of the thymus with progenitor cells from the blood islands of the yolk sac. The first stream of embryonal epithelial migration forms the isolated reticular epithelial cells of the cortex and medulla of the adult thymic lobule, which forms the scaffold through which maturing lymphocytes migrate. The second epithelial migration forms the thymic duct epithelium and later the Hassall's corpuscles of the thymic medulla (Figure 51.3). Early reticular epithelial cells form loose cuffs around small vessels that persist in adult life and become obvious in conditions of lymphoid atrophy. Also in early development, the ductular component of epithelium forms the branching system that communicates between the lobules of a single thymic lobe.

The epithelial cells surrounding thymic vessels, as well as continuous endothelium of the capillaries and cuffs of macrophages, form a barrier to blood-borne antigens in the thymic cortex. This provides a sequestered environment for naïve T cell maturation, such that they receive their immunologic training solely from the reticular epithelial cells. Lymphoid germinal centers occurring in the thymus are not necessarily pathologic or an indication of autoimmune disease if they occur near a blood vessel and lie within the vascular epithelial sheath, as in those areas they are immunologically outside of the thymus. Detection of the epithelial sheath can require the application of a cytokeratin stain. The cortical and medullary epithelium produces trophic hormones that assist lymphocytic colonization and are the source of nonpathogenic cysts lined by ciliated epithelium that frequently develops in adult life. An additional cellular component to the thymus is myoid cells. They surround the Hassall's corpuscles and are important in the pathogenesis of myasthenia gravis. In young animals, particularly rabbits,

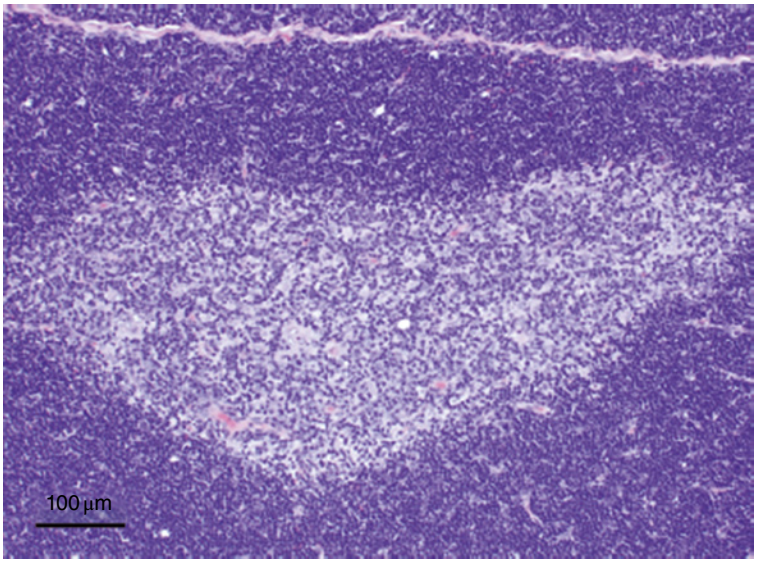

FIGURE 51.2 Mammalian thymus. In mammals, the medulla and cortex are sharply delineated in young healthy animals with the widths of the cortices and medulla approximately equal to one-third the width of the lobe. H&E stain; bar = 100 µm.

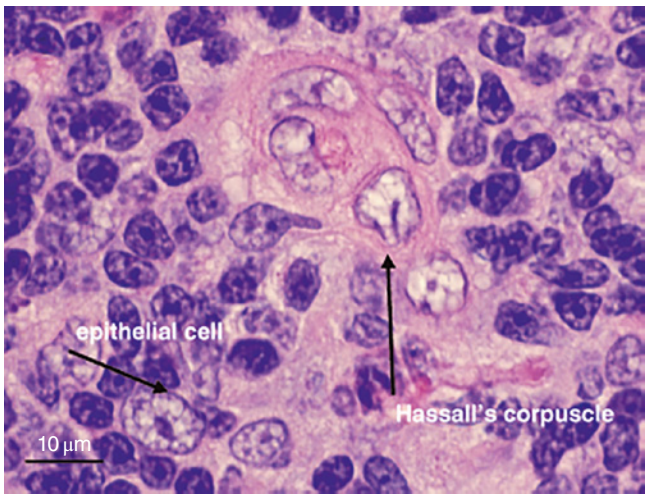

FIGURE 51.3 Hassall's corpuscle in the thymic medullary area consisting of concentric laminations of squamous epithelial cells. The surrounding lymphocytes are characteristically a mixture of small and medium cells and epithelial cells with large pale nuclei (arrow). These cells with moderately abundant cytoplasm separating the nuclei give the medulla a less dense appearance than the cortex on histological examination. H&E stain; bar = 10 µm.

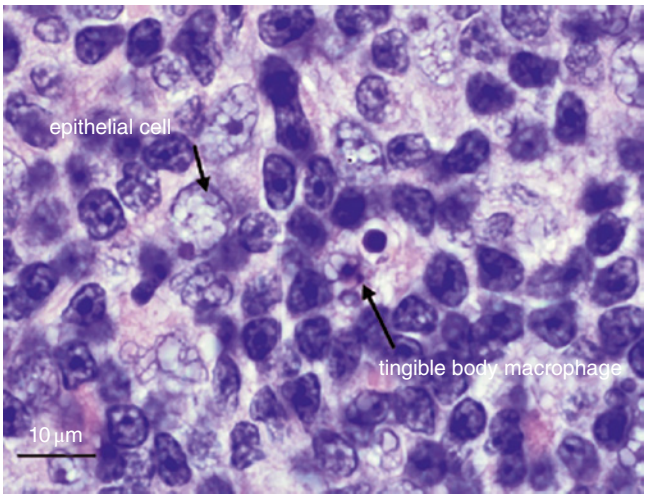

FIGURE 51.4 Thymic cortex composed of densely packed small lymphocytes. A macrophage in the center has cytoplasm that contains several pyknotic nuclear fragments (tingible bodies) of apoptotic cortical thymocytes. The larger vesicular nuclei above and to the left of the macrophage are probably epithelial cells involved in the self-recognition selection process of developing T cells. H&E stain; bar = 10 µm.

heterophils are frequently found in the thymus, particularly in lobular connective tissue. Eosinophils may occasionally be found in the thymic connective tissues and mast cells are present in the thymic capsules in most species and are particularly frequent in rats.

After production in the bone marrow, immature CD4−/CD8− T cells (prothymocytes) home to the cortex of the thymus for T cell receptor (TCR) rearrangement, maturation, and immunological selection for tolerance to self-antigens. Here, they proliferate in niches created by thin-walled pouches (caveolae) consisting of reticular epithelial cells. In caveolae, maturing T cells undergo negative selection by epithelial nurse cells in the outer cortex and dendritic cells in the inner cortex for reactivity to self-antigens, of which only about 1% will survive. Physiologic development continues when lymphocytes enter the medullary areas with exposure to self-antigen expressed by medullary epithelial cells. During this stage, cells also acquire CD3, CD4, and CD8 as they adopt the potential for differentiating into helper T cell, cytotoxic T cell, and suppressor T cell roles (see Chapter 50). The cells that are not selected undergo apoptosis and are removed by thymic macrophages, termed tingible body macrophages owing to the hematoxylin-stained apoptotic cell remnants in their phagolysosomes (Figure 51.4). During times of stress or atrophy, there is an increase in the proportion of tingible body macrophages and epithelial cells, resulting in lighter staining and a punched-out appearance to the cortex. in H&E stained sections.

Thymic involution and atrophy are histologically indistinguishable, characterized by a reduced size in thymic lobules and blurring of the corticomedullary junction. Involution is a natural, physiologic process, whereas atrophy occurring in young animals can be secondary to a variety of disease states. This can include atrophy secondary to poor nutrition and chronic high levels of glucocorticoids (usually due to chronic stress) as well as toxic insult (dioxin, polychlorinated biphenyls (PCB), lead, fumonisin B1 and B2) and viral infection (canine parvovirus, canine distemper virus, feline leukemia virus, feline panleukopenia virus, feline immunodeficiency virus, equine herpesvirus-1, classical swine fever, porcine reproductive and respiratory syndrome virus, and bovine viral diarrhea virus [BVDV]). The thymus can also be severely hypoplastic or absent in developmental diseases that either congenitally or genetically inhibit lymphocyte development, such as seen in severe combined immunodeficiency (SCID) and nude mice. Thymic hyperplasia occurs largely through an increase in number of lobules rather than increased lobule size, and is typically a nonspecific adaptive response to chronic antigenic stimulation. This can include the formation of functional B-cell follicles, termed follicular hyperplasia. Thymic hemorrhage and hematomas are found in young dogs, secondary to trauma, overstretching of the neck, rupture of aneurysms, hemorrhage from a thymic neoplasm, or secondary to anticoagulant (e.g., rodenticide) ingestion. An idiopathic form of spontaneous thymic hemorrhage is thought to occur due to the fragility of thymic blood vessels during thymic involution. Thymitis is seen in epizootic bovine abortion and salmon poisoning (*Neorickettsia helminthoeca*). Thymic cysts, often nonclinical, occur in the remnants of the brachial cyst ducts, and are lined by a single layer of ciliated epithelial cells.

Primary thymic neoplasia occurs in two forms: thymoma, derived from the thymic epithelial cells, and thymic lymphoma, derived from the thymic T cells. Thymomas are often benign, found in older animals as expansile mediastinal masses. A variety of autoimmune diseases have been associated with thymomas including myasthenia gravis and exfoliative dermatitis in cats.[11] Thymic lymphoma is more often seen in young animals, particularly young cats and cattle, and is often a lymphoblastic lymphoma.

Bursa of Fabricius

The bursa of Fabricius is a specialized lymphoid organ unique to birds. It is located in the dorsal diverticulum of the cloaca, and, like the thymus, is comprised of epithelial and lymphoid components. It is most active in young birds, reaching maximal size at around 6 months of age and progressively atrophying during adulthood. The bursa of Fabricius is the site of B cell maturation in birds, which in mammals generally occurs in the bone marrow. The bursal lymphoid follicles are located immediately subjacent to the folded epithelium of the dorsal cloaca in a similar structure to the Peyer's patches. Bursal lymphoid follicles contain lymphocytes, macrophages, dendritic cells, and plasma cells. Immature B cells are thought to migrate to the bursal mesenchyma where they interact with dendritic cells, and undergo V(D)J rearrangements and selection (see Chapter 50). After V(D)J rearrangement, B cells migrate to the bursal epithelium where they proliferate and generate bursal follicles. The epithelium overlying the bursal follicles has phagocytic abilities, sampling cloacal luminal antigens for presentation to dendritic cells and follicular lymphocytes, akin to the function of mammalian mucosa-associated lymphoid tissue (MALT) M cells.

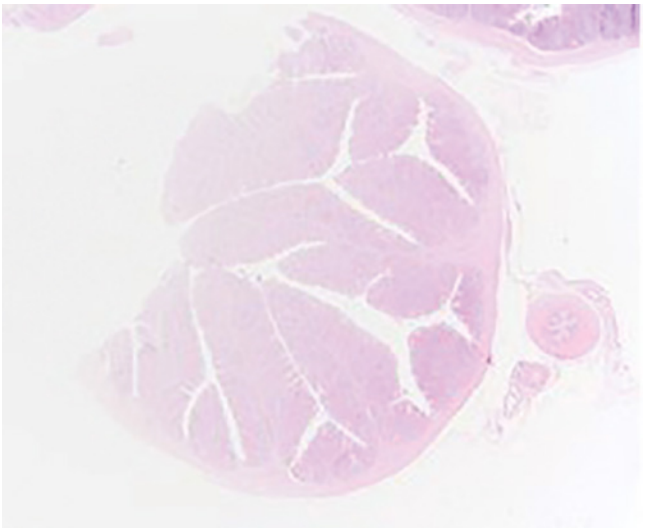

FIGURE 51.5 Bursa of Fabricius from a chicken infected with infectious bursal disease virus. There is severe diffuse atrophy of the bursa secondary to marked depletion of B cells H&E stain.

Infectious bursal disease, caused by infectious bursal disease virus (a birnavirus), specifically targets and kills maturing, IgM-producing, B cells in the bursa of Fabricius, the MALT, and in circulation, resulting in severe immunosuppression (Figure 51.5).

STRUCTURE, FUNCTION, AND DISORDERS OF SECONDARY LYMPHOID TISSUE

Lymph Nodes

The lymph node is the primary site of the adaptive immune response to antigens, bringing together antigen, APC, and lymphocytes. Lymph nodes are situated at multiple points of lymphatic vessel convergence and interface with vascular supply throughout the body. The anatomical location and number of nodes vary depending on the species. The lymph node architecture is critical to its function, as it dictates the spatial organization of lymphocytes and dendritic cells, orchestrating their interactions and performing a key role in which direction an immune response will develop (CD4+ vs. CD8+ vs. TH fate).[7] The lymph node is comprised of multiple repeating subunits—the lymphoid lobules. Lymphoid lobules can be singular in smaller lymph nodes, but in larger lymph nodes are arranged adjacent to each other,

radiating from the hilus and their vascular supply.[18] Lymphoid lobules are divided into the cortex, paracortex, and medulla. This arrangement is consistent in all domestic species, with the exception of the pig, where the organization of the medulla and the cortex are reversed. In the pig, afferent lymphatics enter the center of the node where the germinal centers are located first, such that functional delivery of antigen to the node is similar to other mammals.

The lymph node is surrounded by a peripheral capsule that is thin and taut in conditions in which there has been rapid enlargement of a lymph node. By contrast, lymph node atrophy results in relative thickening of the capsule that on H&E stained slides is thickened and wavy, with widening of the peripheral sinuses. In cattle and likely in other species, the lymph node capsule is contractile and under neural control, thus assisting lymph flow.[8]

The structure of the lymph node is centered on two circulatory systems—the lymphatic and vascular systems—and supported by a fine meshwork of supportive reticular cells. Lymph enters the capsule of the lymph node through afferent vessels that drain into subcapsular sinuses of the cortex (Figure 51.6). In lymph nodes draining areas of inflammation, the subcapsular sinus is a common area for the relevant inflammatory cells (neutrophils, macrophages, and eosinophils) as well as infectious agents to accumulate. Cortical, paracortical, and transverse sinuses percolate through the cortex and paracortex connecting lymph flow to the medullary sinuses in an intricate meshwork. The medullary sinuses converge near the hilus of the lymph node, eventually forming the efferent lymphatic that exits the node. Entering the hilus is the lymph node arteriole. This arborizes in the medulla, following medullary cords, dividing into small arterioles and a capillary network that supplies the cortex and paracortex. Postcapillary high endothelial venules (HEV) in the paracortex are important sites of T cell migration. As the venules enlarge and re-enter the medulla, they converge, leaving the hilus again as a single lymph node vein. The reticular network is comprised of stellate and spindled fibroblastic reticular cells that form a delicate network through which APCs and lymphocytes migrate. The vascular, lymphatic, and reticular network of the lymph node forms the basis of lymphocyte colonization during embryogenesis and later, after colonization, the lymphoid lobule.

The cortex of the lymph node is comprised of follicular and interfollicular regions. Cortical follicles contain mostly B cells and are the location of germinal centers following immune stimulation. Germinal centers are the site of B cell clonal expansion, somatic hypermutation, and affinity maturation (see Chapter 50). In unstimulated lymph nodes, B cells form dense follicles in the superficial cortex. After stimulation, germinal centers develop; displacing naïve B cells that then form the mantle zone. The mantle zone is eccentrically thickened near the capsule and forms a thinner rim closer to the paracortex. The naïve B cells in the mantle zone have small dense nuclei, staining darker on H&E. The proliferating germinal center is divided into two compartments: the dense zone (deep pole), adjacent to the T cell parafollicular zone, and the light zone (superficial pole), nearest the capsule. The dense zone is comprised almost exclusively of B cells with a high nucleus: cytoplasm ratio and dense chromatin, producing a darker basophilic stain on H&E. The light zone contains a mix of cells, which includes B cells, follicular dendritic cells, T cells, and migrating naïve B cells.[17] Tingible body macrophages are found throughout both zones of the germinal center, phagocytozing B cells that become apoptotic during B cell selection (see Figures 51.7 and 51.8). Previous work has suggested two different types of B cells present in dense and light zones: centroblasts and centrocytes, respectively. It was thought that centroblasts in the dense zone underwent clonal expansion and antigen receptor

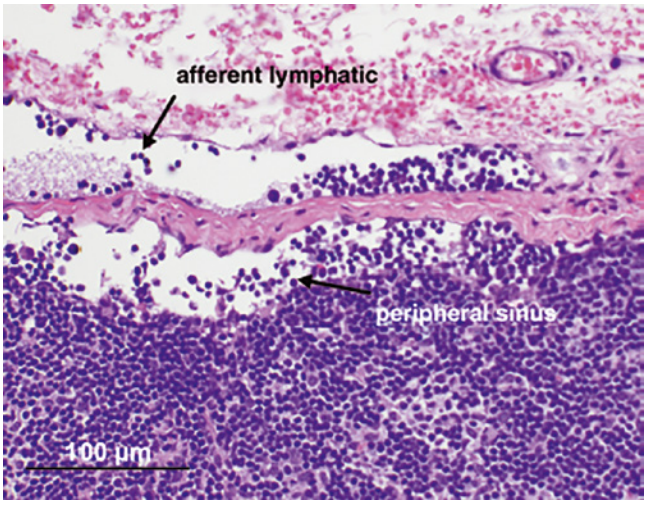

FIGURE 51.6 Lymph node outer cortex from a healthy dog. An afferent lymphatic (arrow) leads into the peripheral sinus beneath the node capsule. The sinus is open and contains a few cells in transit, whereas to the left and right, the sinus is compressed by developing germinal centers. H&E stain; bar = 100 µm.

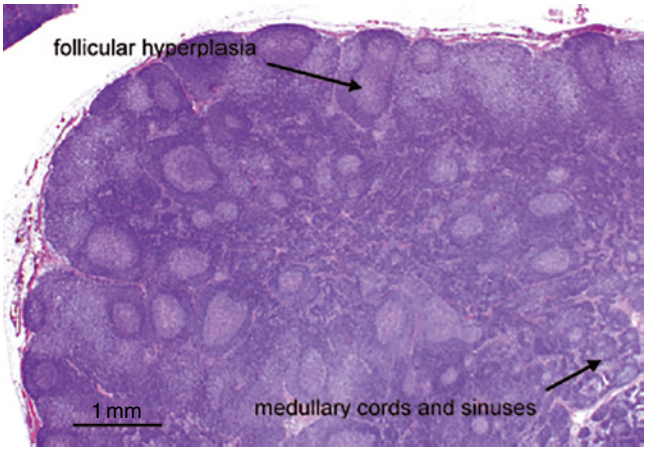

FIGURE 51.7 Architecture of the lymph node in Figure 51.6 showing follicular hyperplasia and densely cellular medullary cords and sinuses (arrows). H&E stain; bar = 1 mm.

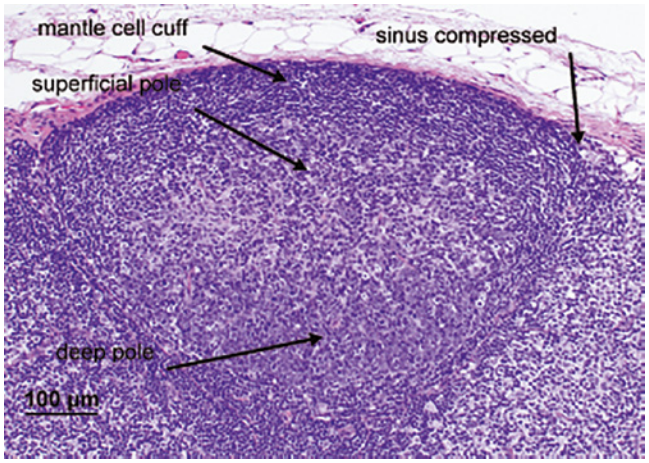

FIGURE 51.8 Lymph node cortex of Figure 51.6 with subcapsular germinal center having a polarity directed toward the antigens being delivered from the peripheral sinus into the superficial pole of small lymphocytes. In the middle of the germinal center, there are small and large lymphocytes with macrophages removing apoptotic lymphocyte nuclei. Near the bottom of the picture, the deep pole area consists of lymphocytes with large nuclei and a narrow rim of highly basophilic cytoplasm. H&E stain; bar = 100 µm.

diversification that matured to centrocytes that unidirectionally migrated to the light zone where B cell selection and antigen binding occurred. Numerous recent studies have challenged the centroblast/centrocyte model with no differences in B cells in the zones with respect to size, morphology, gene expression, or dynamic behavior and B cells seem to move back and forth between the zones during the immune reaction.[1,2,14] Instead, it is thought that B cells cycle between the dense and light zones, with proliferation occurring in the dense zone and selection occurring in the light zone, in repetitive iterations of selection of high-affinity clones, proliferation, mutation, and further selection–leading to affinity maturation of the B cell response.[17] Proliferation, hypermutation, and selection of B cells in germinal centers produce both memory B cells and plasma cells. Plasma cells can remain in the lymph node or can migrate to the medullary cords, or bone marrow. B cells that are stimulated in a T-cell-independent manner (by foreign polysaccharides or CpG DNA) proliferate outside of the follicles and do not produce germinal centers.[7]

T cells home to the deep cortex (also called the *paracortex*) and interfollicular region of the cortex, entering through HEVs where they migrate and survey dendritic cells.[13] HEVs are sophisticated structures with pockets between endothelial cells and the basement membrane that have the capacity to store circulating lymphocytes, prior to entry into the lymph node, regulating lymphocyte entry. A reticular framework supports the interfollicular cortex and paracortex, similar to the rest of the node, within which are dendritic cells. The fibroblastic reticular cells that form the framework are believed to produce cytokines that establish the spatial segregation of T and B cells in the lymph node and induce and aid in T cell migration through these areas. The deep cortex is comprised of semi-ovoid aggregations of T cells that center on lymphatic openings. With stimulation, proliferating T cells form dense nodular aggregates, termed deep cortical units. Unlike germinal centers, the distribution of cells in proliferating deep cortical units is more homogenous (Figure 51.9). Central areas of deep cortical units can have a mottled appearance histologically, due to varying proportions of large and small lymphocytes with some macrophages and HEVs (Figure 51.10). The edges of the deep cortical units gradually meld with the surrounding medullary cords and sinuses.

The medulla of the lymph node is comprised of medullary cords and sinuses. The medullary cords are centered on centrifugally radiating medullary arterioles and medullary veins that are returning to the hilus centripetally. Surrounding the blood vessels is a meshwork

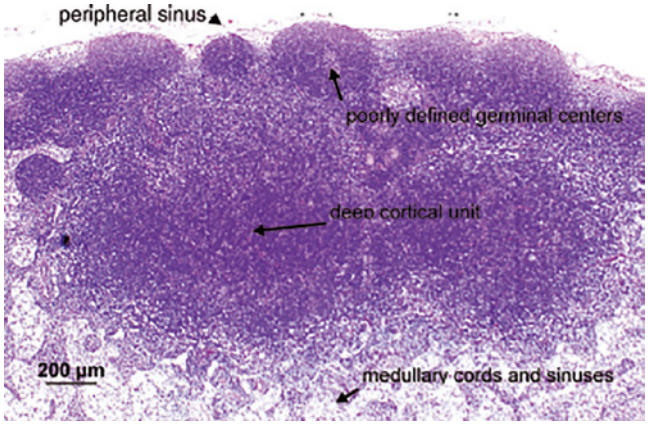

FIGURE 51.9 Cross-section of rat mesenteric lymph node. The upper area of the node is occupied by typically poorly defined germinal centers. The medullary cords and sinuses lie along the bottom of the image and abut a large uniformly dense oval deep cortical unit that lies across the cut surface of the node. A rim of less-dense cellularity lightly outlines the unit. H&E stain; bar = 200 µm.

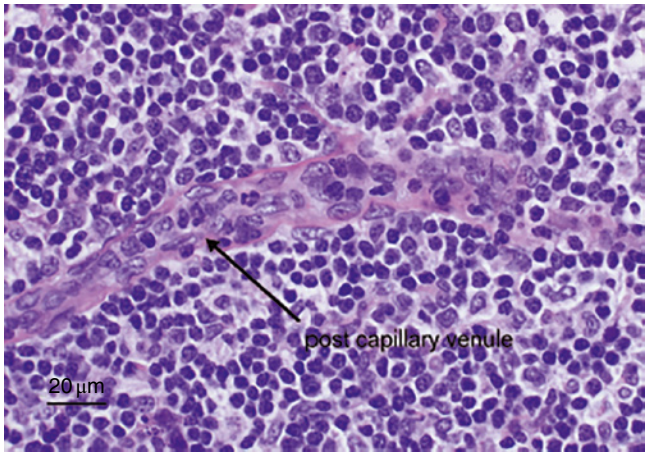

FIGURE 51.10 Paracortex (deep cortex) of rat mesenteric lymph node with a high endothelial postcapillary venule crossing the center. Several lymphocytes within the wall of the venule can be seen to be in transmural transit exiting the blood to enter the node cortex (near arrow). H&E stain; bar = 20 µm.

of pericytic reticular cells within which are migrating, recirculating lymphocytes.[18] Stimulated B cells forming precursor plasma cells migrate to the medullary cords where they mature to plasma cells. Interdigitating between the medullary cords are the medullary sinuses that drain lymph from the cortical and paracortical sinuses to the efferent lymphatic at the lymph node hilus. In the medullary sinuses, macrophages adhere to reticular cells phagocytozing debris, bacteria, RBCs, and infectious agents in the circulating lymph (Figure 51.11). Proliferation of medullary macrophages in response to increased draining debris is termed "sinus histiocytosis." This can be seen in lymph nodes draining areas of tissue necrosis, infection, or hemorrhage, and in the case of hemorrhage often contain large amounts of cytoplasmic hemosiderin, pigmenting the center of the node. In lymph nodes draining areas of chronic dermatitis, melanin pigment can be found phagocytosed in macrophages. The fine reticular network of the medullary cords forms a fertile microenvironment for extramedullary hematopoiesis. In myeloid leukemias, the malignant cells also colonize the medullary cords, and under these circumstances, there may be both tumor and benign extramedullary hematopoiesis coexisting.

Developmental diseases of lymphocytes can result in lymph node atrophy in a manner similar to that seen in the thymus. Foals with SCID have small lymph nodes that lack germinal centers and have poorly populated paracortical zones (see Figure 51.12). Severe T cell deficiencies have developed cortical follicles, but a poorly developed paracortex, and severe B cell deficiencies have the opposite, developed paracortex, but virtually absent cortex. In adulthood, severe cachexia and advanced age can result in lymph node atrophy, commonly associated with relative thickening of the capsule and the medullary trabeculae. Cachectic atrophy is more common in old sheep and goats and senile atrophy is more frequently seen in aged dogs, cats, and primates.

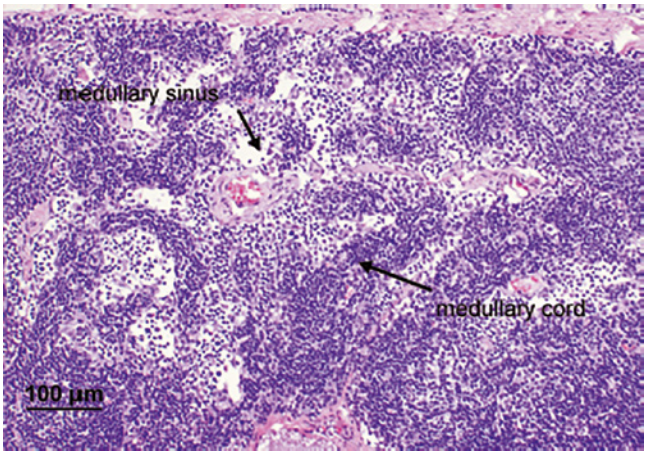

FIGURE 51.11 Medulla of a lymph node from a dog with normal cords and sinuses. The cords are densely cellular and surrounded by a thin endothelial membrane with the sinuses containing a few fixed macrophages and cells in transit in a background of lymph. H&E stain; bar = 100 µm.

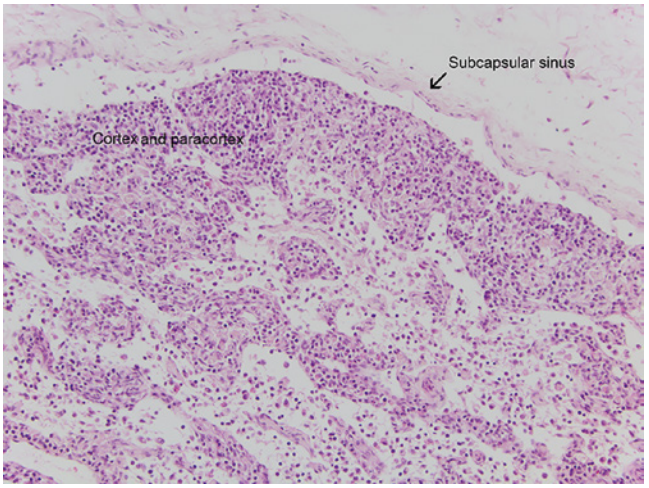

FIGURE 51.12 Hypoplastic lymph node from a 4-month-old Arabian foal with SCID. Marked hypoplasia of the cortex and paracortex, populated mostly with dendritic cells, reticular cells, and macrophages. H&E stain.

Lymph node atrophy can also occur secondary to a chronic infection with a lympholytic virus, e.g., BVDV.

Lymphadenitis occurs when an infectious or inflammatory agent specifically inflames lymphoid tissue, as opposed to benign hyperplasia, a reactive immunologic response to inflammation in the draining field. In acute lymphadenitis, typical features of acute inflammation (vasodilation, hyperemia, and edema) are present in the lymph node, as well as an increased proportion (typically >25% on cytology) of the relevant inflammatory cells. As with most infectious processes, neutrophilic lymphadenitis occurs in response to bacterial agents, including *Streptococcus* species, *Brucella* species, *Trueperella pyogenes*, *Salmonella* species, and *Toxoplasma* species. *Francisella tularensis* and *Yersinia pestis* frequently cause severe liquefactive necrosis of the lymph node, as well as suppuration. Chronic lymphadenitis can produce fibrosis around the node that fixes them in the surrounding connective tissue. Typically, the capsule and trabeculae are also thickened and sclerotic. Chronic inflammation can be mixed or granulomatous. It can be seen nonspecifically with chronic bacterial infections (usually mixed inflammation), as well as with specific agents including *Corynebacterium pseudotuberculosis* (also called caseous lymphadenitis), *Mycobacterial* agents (granulomatous inflammation), *Rhodococcus equi* (granulomatous inflammation), and fungi (granulomatous inflammation) (Figure 51.13). Porcine circovirus type 2 (PCV2)-associated diseases can also cause granulomatous lymphadenitis with characteristic botryoid, intracytoplasmic, viral inclusion bodies in macrophages. Eosinophilic lymphadenitis occurs in response to parasitic infections of the node (e.g., demodex lymphadenitis) or hypersensitivity reactions.

Lymphadenopathy (better termed lymphadenomegaly) is a generalized term used for enlargement of the lymph node due to nonspecific lymphoid hyperplasia. Lymphoid hyperplasia can be skewed to a predominantly

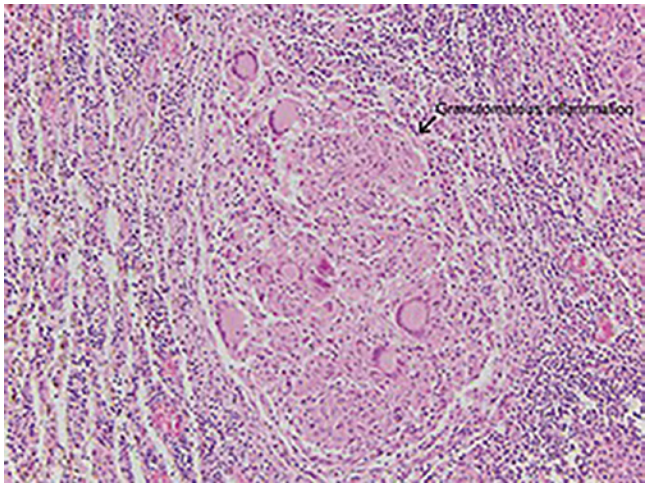

FIGURE 51.13 Granulomatous lymphadenitis in an adult cow infected with *Mycobacterium bovis*. The granuloma is located in the paracortex and consists of epithelioid and multinucleated Langhans-type macrophages. Increased numbers of hemosiderin-laden macrophages are present in the medullary sinuses on the left producing brown pigmentation of the lymph node. This is consistent with the lymph node draining hemorrhage in the local area.

B cell response in which follicular hyperplasia and cortical expansion are prominent, or a predominantly T cell response in which hyperplastic deep cortical units in the parafollicular or deep cortical area are predominant (Figure 51.8). Increased proportions of plasma cells in medullary cords and sinus histiocytosis are other features of a reactive immune-driven hyperplasia. When the lymph node is draining an area of active inflammation, there are increased numbers of often innate immune cells that drain into the subcapsular sinuses.

Differentiation of marked lymphoid hyperplasia from lymphoma can be difficult. Key, commonly used features are the disruption of the normal lymphoid architecture and the homogeneity of the lymphocyte population in lymphoma. Disruption of the outer sinuses and invasion of the capsule are features seen in lymphoma, but not in lymphoid hyperplasia. While some lymphomas can have two types of neoplastic lymphoid cells histologically (e.g., a T-cell-rich B cell lymphoma), there are no known neoplastic processes with three different lymphoid types. Chromatin and cytoplasmic homogeneity is generally expected in lymphoma. Follicular hyperplasia can be differentiated from follicular lymphoma based on the architecture of the follicles, as well as by the preservation of an intact mantle cell corona in a hyperplastic process. The polarity of germinal centers is important to distinguish benign and atypical follicular hyperplasia from follicular lymphomas. In follicular lymphoma, the mantle is often effaced, there is often concurrent paracortical atrophy, and the follicles themselves lack the lymphocytic heterogeneity expected in a reactive follicle.[15] Follicular lymphoma have few or no tingible body macrophages, as the tumor cells, unlike the benign cell selection process, are not undergoing apoptosis. A further distinction between true follicular lesions, whether benign or malignant, and pseudofollicular lesions is that the postcapillary venules are between the follicular or nodular proliferations and never within them.[15]

As lymph nodes are the hub of lymphatic drainage and surveillance, they are also a common site for metastatic disease, particularly from primary neoplasms in their draining area. Following the route of drainage, metastatic neoplastic cells are frequently found at the periphery of the node in subcapsular sinuses and in the medullary sinuses as single or clusters of neoplastic cells (Figure 51.14). In non-lymphoma metastatic disease, the lymph node is generally atrophied. Myeloid leukemias tend to home to medullary cords, which are also sites of extramedullary hematopoiesis. Spread of neoplastic lymphoma cells to lymph nodes tends to reflect the cell type and homing receptors of the neoplastic cells such that B cell lymphoma will tend to spread to B cell areas in the cortex and T cell lymphoma spread to T cell areas in the paracortex.

Tertiary Lymphoid Centers

Where lymph nodes, the spleen, and MALT comprise the secondary lymphoid centers with the anatomic localization of these organs similar between individuals of a species, tertiary lymphoid centers with similar structure to lymph nodes develop ectopically in response to chronic inflammation or neoplasia. Similar to lymph node development, tertiary centers are believed to be induced by chemokine secretion by stromal cells localized to the site of chronic inflammation. A similar structure to a lymph node develops including T cell zones with high endothelial blood vessels, B cell follicles, and germinal centers of proliferating B cells.

Spleen

The spleen is the primary blood-filtering organ of the immune system. Analogous to the role of lymph nodes in surveilling antigen in the lymph, the spleen's primary

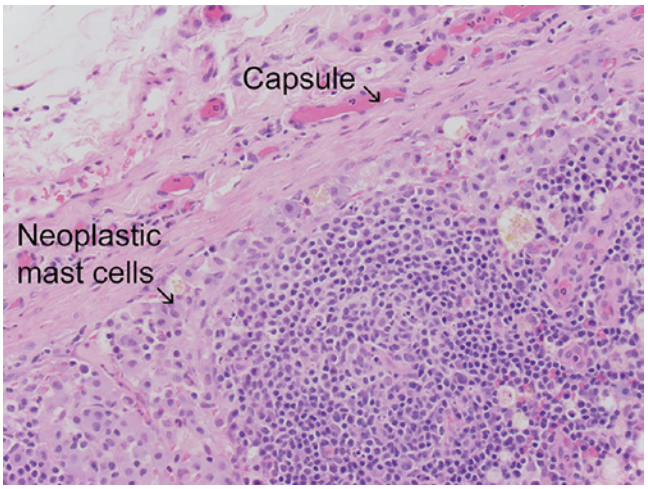

FIGURE 51.14 Lymph node from an adult dog. Neoplastic mast cells infiltrate the subcapsular sinus of a draining lymph node.

immunologic function is surveillance of antigens in the blood, as well as removal of effete or defective erythrocytes or white blood cells. The anatomy of the spleen reflects this blood-filtering role: it is comprised of a complex arborizing network of arteries and arterioles that drain into porous venous sinuses of the red pulp where lymphocytes, dendritic cells, macrophages, and other immune cells can be maximally exposed to circulating cells and pathogens. The venous system similarly arborizes into increasingly sized veins that eventually merge to form the splenic vein. Both the major arterial supply and venous outflow enter through the hilus of the spleen. While the spleen contains efferent lymphatics, no afferent lymphatics are present. The spleen has additional functions in lymphopoiesis and extramedullary hematopoiesis. The spleen forms early in embryonic life and is a site of active hematopoiesis during the fetal period, and recolonization of these sites occurs at times of increased demand during adulthood.

The vascular anatomy of the spleen is critical to its function. It contains arborizing arterioles that, as they become smaller, are surrounded by a lymphoid sheath, termed the periarteriolar lymphoid sheaths (PALS). The PALS is formed by a cuff of densely packed T cells which, at points along the length of the artery, dilate eccentrically with B cell follicles, located to the periphery of and surrounded by the T cell cuff (Figure 51.15). At the periphery of both the PALS and the follicles is a looser arrangement of mixed T and B cells called the marginal zone. Together, the periarteriolar sheath, B cell follicles, and marginal zone lymphocytes form the white pulp.

Similar to the lymph node, the PALS form a distinct T cell zone, and the follicles form distinct B cell zones. The PALS is comprised centrally of dense accumulations of darkly staining T cells, most of which are CD4+ T cells interacting with interdigitating dendritic cells and lesser numbers of CD8+ T cells. B cells in follicles function similarly to the lymph node, where, once activated, B cells migrate to the follicle, proliferate, and undergo clonal expansion, isotype switching, and somatic hypermutation (see Chapter 50). The marginal zone forms a key transit area for lymphocytes leaving the blood stream and entering the white pulp, in contrast to the lymph node, where lymphocytes mostly enter through afferent lymphatics or HEVs. At the periphery of both the PALS and B cell follicles is the marginal zone, a complex, highly organized zone with key functions in cell migration. The marginal cell zone layer is more loosely arranged and is comprised of T cells, B cells, marginal zone macrophages, and marginal metallophilic macrophages whose scavenging properties play a key role in antigen presentation (Figure 51.16). While the B and T cell zones of the white pulp are almost exclusively involved in adaptive immune responses, the marginal zone is involved in both innate and adaptive responses. Marginal zone B cells are specialized to detect blood-borne pathogens, can differentiate into plasma cells producing high levels of IgM, and can function as antigen-presenting cells. They can migrate to the B cell follicles, initiating T-cell-independent humoral immunity. Marginal zone B cells acting as APC can also migrate to the T cell zone where they activate naïve CD4 T cells. Lymphocytes exit the white pulp either through the efferent lymphatics or back into the blood stream through the marginal zone.[9]

B cell follicles are supplied by very small arterioles that branch off the larger sheathed arteriole. In some species, these small arterioles end in the marginal sinus (the area between the white pulp and the marginal zone), whereas in others, the arterioles transverse the marginal zone and directly drain into venous systems of the red pulp.[9] These areas receive some of the more recently arrived cells to the spleen, and in cases of

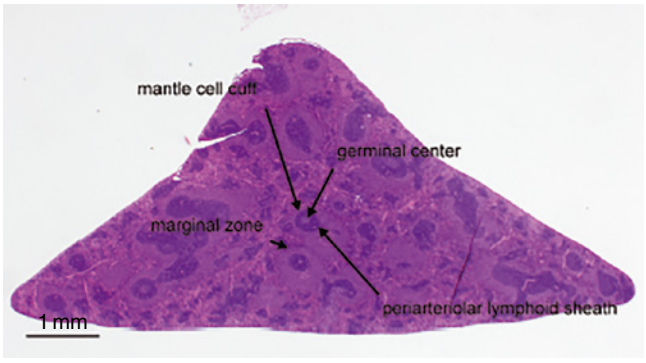

FIGURE 51.15 Cross-section of spleen from a young adult male rat. At the architectural level, the spleen is occupied by multiple, dispersed round dark areas representing lymphoid nodules with the intervening lighter areas consisting of sinuses. The lymphoid or white pulp areas may have a germinal center in the middle of the mantle cell cuff (arrows). The lighter mantle and marginal zone areas surround these areas. H&E stain; bar = 1 mm.

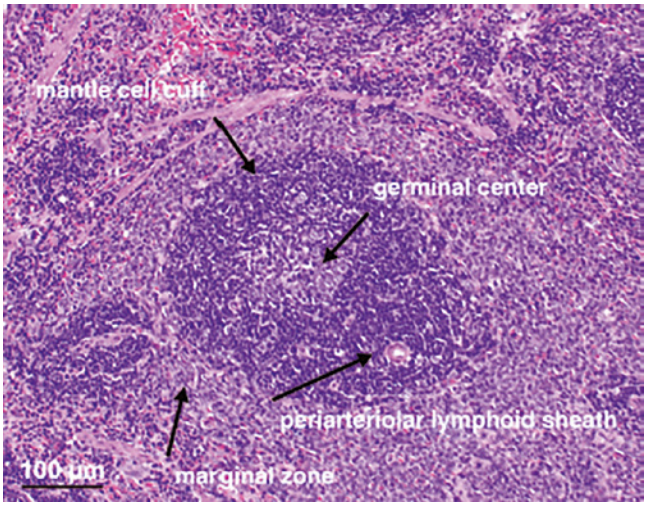

FIGURE 51.16 Details of Figure 51.5. Unlike larger mammals, rats tend not to have well-formed splenic germinal centers. In the middle of the image, a lighter zone constitutes the dendritic cell bed of an ill-defined germinal center eccentric to and abutting a small muscular arteriole at lower right (arrows). The germinal center is surrounded by a cuff of darker mantle lymphocytes that has an outer envelope of lighter-staining marginal zone cells that interface with the surrounding splenic red pulp. H&E stain; bar = 100 µm.

marked neutrophilia, neutrophils can form a cuff around the marginal zone. The splenic arterioles terminate in pencillary vessels that drain into large venous sinuses, which then drain into splenic veins. Ellipsoid reticular cells surround the pencillary vessels in some species, controlling the amount of blood flowing into the venus sinuses.

The red pulp is comprised of splenic cords and sinuses. Approximately 3% of the blood flow in the venous sinuses perfuses into the splenic cords (also called the *Billroth cords*) of the red pulp. The splenic cords are comprised of a network of reticular cells and fibers that are arranged such that cells exiting the macrophage-rich cords into the red pulp sinus have to squeeze through junctions formed by reticular cells. As erythrocytes age, or are damaged, they lose their deformability and their ability to squeeze effectively through reticular junctions. The cords are also rich in macrophages and the slowing of aged, less-deformable erythrocytes through reticular junctions allows for the phagocytosis and removal of senescent or deformed RBCs (including those with inclusion bodies or reticulocytes), senescent leukocytes, circulating foreign material, and iron breakdown products. The large venous sinuses of the red pulp are highly perforated, slowing blood as it flows through the red pulp. Macrophages, lymphocytes, and plasma cells are embedded in the Billroth cords and blood flow through this area is slow, such that there is maximum exposure of erythrocytes to surveilling cells. By this process, the entire blood volume passes through the filtering system of the spleen at least once each day.

Similar to the lymph node, after B cells proliferate and are selected in the germinal centers, they migrate as plasmablasts to the red pulp, often just outside the marginal zone, where they mature to plasma cells and produce antibodies.[9] The position of plasma cells in the red pulp allows rapid entry of antibodies into the blood stream.

The venous sinuses of the spleen constitute the expansile regions of the organ and thus may vary greatly in their content of blood, particularly in species with a high level of smooth muscle in the splenic capsule. In a muscular spleen in the contracted state, all of the blood would pass directly from the arteriole to the venous system in a "closed" circulation, permitting maximal utilization of blood cells in the systemic circulation. By contrast, any influence that causes the splenic capsule to dilate (e.g., anesthesia, portal hypertension due to hepatic fibrosis, or marked increase in extrasinusoidal macrophages) results in a greater proportion of blood passing through the filtering system.

A variety of changes occur in the spleen in response to systemic states, the most notable of which is reactive lymphoid hyperplasia of the PALS in an adaptive immune response to systemic infection. This is mostly in response to infections that involve the blood and can include systemic viremia (e.g., malignant catarrhal fever and equine infectious anemia), bacteremia/endotoxemia, blood cell parasitemia (e.g., malaria and trypanosomiasis), and immune-mediated diseases directed against circulating cells (most commonly, immune-mediated hemolytic anemia). In septicemia or cases of marked neutrophilia, aggregates of neutrophils can be seen in the marginal zone. Additionally, when acute infection is present, the spleen is often hyperemic and enlarged. This is most marked in anthrax, where the septicemic response is almost entirely vascular (Figure 51.17).[16] Acute toxic diseases, overwhelming infection, and certain viremias can result in lysis of lymphocytes in the germinal centers and replacement by residual proteinaceous debris referred to as follicular hyalinosis. Diagnosticians are aided by the fact that nuclear debris after acute lympholysis is cleared within 24 hours, but the hyalin debris may remain for many months. In systemic amyloidosis, the germinal centers may become sites of amyloid deposition, while atrophic changes due to starvation, aging, cancer, or chemotherapy may result in atrophy which impacts one or both of the thymic-dependent arteriolar sheaths or bone-marrow-dependent germinal center systems. In chronic hemolytic anemias, a marked increase in hemosiderin-bearing macrophages in sinus areas and iron deposition can occur in the connective tissue of the spleen, particularly in old dogs. Nodular hyperplasia is common in older dogs and occasionally old bulls. The nodules are comprised predominantly of proliferating large lymphocytes and differentiation from lymphoma can be difficult. Lymphoma and leukemias can localize to the spleen, resulting in splenomegaly. Hemangiosarcoma and hemangiomas are common vascular tumors of the spleen that can rupture, resulting in life-threatening hemoabdomen. Rupture of the spleen can also occur secondary to splenomegaly associated with lymphoma or as a result of abdominal trauma. As a blood-filtering organ, metastatic disease is also common. Splenic infarction occurs in focal areas of the spleen in dogs with hemangiosarcoma and is always of hemorrhagic type. Ischemic infarction can occur in dogs with myeloma due in part to the greater

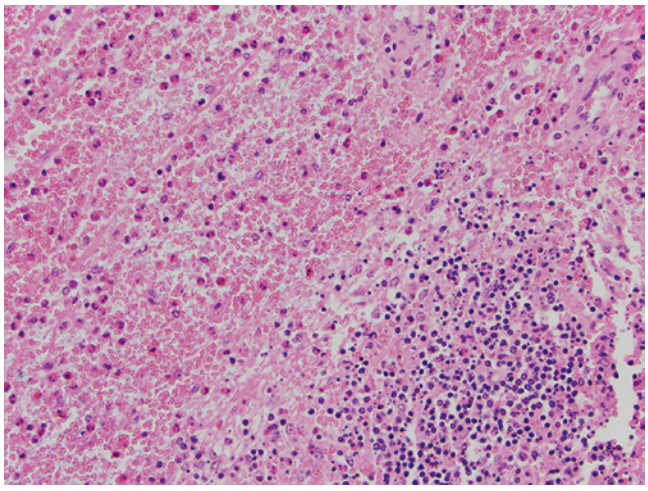

FIGURE 51.17 Spleen from a cow with anthrax. There is severe hyperemia of the red pulp with large number of neutrophils. Lymphocytolysis is present in the white pulp. Large numbers of faintly basophilic rod-shaped bacteria (*Bacillus anthracis*) are present in the background.

viscosity of blood secondary to hyperglobulinemia. Splenic torsion occurs primarily in dogs and rarely in adult pigs. In dogs, this is often secondary to gastric dilation and volvulus.

Hemal Nodes

Hemal nodes, found in ruminants and rats, have a similar structure to lymph nodes, but instead of draining and surveilling antigen in lymph, they drain and survey blood, a function more similar to the spleen. Arteries enter the hilus, similar to the lymph node, but arborize in the cortex, draining to veins. There are germinal centers in the cortex; however, the paracortex (T cell) is much diminished compared to a lymph node. Macrophages are present in trabecular areas and phagocytose efferent erythrocytes or defective erythrocytes.

Mucosa-Associated Lymphoid Tissue

The MALT is a system of small lymphoid aggregates located in the submucosa of most mucosal surfaces in the body including the respiratory, gastrointestinal, and reproductive tracts, as well as the skin, eye, excretory ducts, and mammary and salivary glands. MALT samples surface (mucosal) antigen, stimulating mucosal immunity. Although less familiar than lymph nodes and the spleen as sites of immunity, there are more immune cells in the intestinal mucosa than the any other site in the body.[3] MALT is key in regulating mucosal immunity, most commonly through Th2-driven IgA production and to a lesser degree Th1 and cytotoxic T cell reactions. The components of the MALT can be subdivided anatomically and as such, differentially named, e.g., gut-associated lymphoid tissue (GALT), bronchus-associated lymphoid tissue (BALT), vulvovaginal-associated lymphoid tissue (VALT), etc. (Figure 51.18). There is considerable species variation as to the prominence or even presence of the subsets of MALT. Generally, the anatomy and immunological function of the MALT are similar regardless of location.

Functionally, MALT serves as either inductive or effector sites. Inductive sites are areas where antigen is sampled from the mucosal surface and then presented to and stimulates cognate T and B cells. Follicles are present in inductive sites, forming germinal centers with activation that allows B cell proliferation and class switching, secondary to Th2 cell activation (see Chapter 50; Figure 51.19). The mucosa covering inductive sites contains specialized cells called "M cells" that phagocytose microbes and particles from the mucosal surface, transporting them through the epithelium to the underlying lymphoid tissue, exposing lymphocytes to antigens from the mucosal surface. Ultrastructurally, the subepithelial surface of M cells contains deep invaginations in which B and T cells as well as macrophages are located (Figure 51.20). Follicular areas mostly contain B cells embedded in a network of follicular dendritic cells with fewer CD4+ T cells and macrophages. Interfollicular areas are rich in T cells and recirculating lymphocytes can enter the MALT through HEVs. Efferent lymphatics connect MALT with regional lymph nodes, further inducing and augmenting an adaptive immune response. Effector sites are sites where effector cells, after stimulation, perform their immunologic function. Effector sites have more diffuse anatomy, spread along mucosal surfaces, most commonly in the lamina propriae.[4]

The GALT forms a relatively continuous chain from the oral cavity to the anus. There are generally few lymphocytes in the epithelium and mucosa of the esophagus. The Peyer's patches in the intestine and the tonsils form inductor sites for the GALT and can be the target of disease processes and pathogen portal of entry. *Mycobacteria*, *Salmonella*, *Yersinia*, and *Listeria* often gain entry to the body through M cells. Prion proteins have been isolated from the tonsillar tissue of sheep, cattle, elk, and deer. Aujeszky's disease in pigs targets tonsils causing a necrotizing tonsillitis. Many lymphotropic

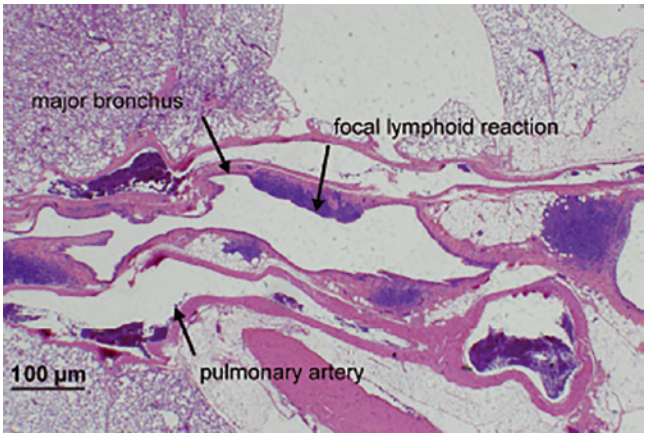

FIGURE 51.18 Lung from a normal rat with longitudinal section of a major bronchus. Note that the focal areas of lymphoid proliferation are both peribronchiolar and subepithelial. H&E stain; bar = 100 µm.

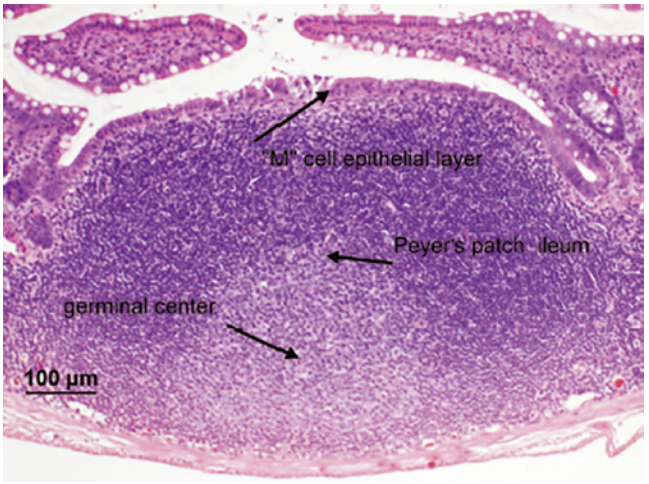

FIGURE 51.19 Lower small intestine of normal rat. A focal submucosal proliferation of lymphocytes in a dome area characterized by absent villi and modified epithelium to assist antigen recognition and sorting. H&E stain; bar = 100 µm.

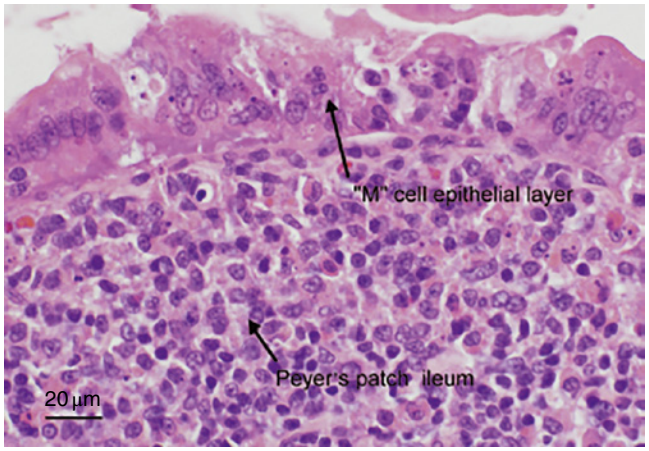

FIGURE 51.20 Details of Figure 51.15. The epithelium above the lymphoid follicle is modified to contain M cells that have deeply folded cellular membranes that enclose intraepithelial lymphocytes. The M cells are capable of uptake and of processing antigen from the intestinal lumen and providing immune instruction to maturing lymphocytes. In this area, there are lymphocytes in the epithelium undergoing apoptosis presumably similar to the selection process in node germinal centers. H&E stain; bar = 20 µm.

viruses, including feline panleukopenia virus, canine parvovirus, canine distemper, bovine viral diarrhea, rinderpest, and swine vesicular disease virus target Peyer's patches and tonsils with Peyer's patch necrosis particularly prominent in BVDV and rinderpest. Like the lymph node, PCV2 can cause granulomatous inflammation in Peyer's patches. The tonsils are also a site of viral persistence with feline calicivirus infection.

Intraepithelial lymphocytes (IEL) interdigitate between mucosal epithelial cells. Their unique expression of $\alpha_E\beta_7$ integrin interacts with E-cadherin on epithelial cells, allowing IELs to enter and remain within the epithelium. Unlike many lymphocytes, IELs do not circulate but remain as residents in the mucosal epithelium. In many species, the majority of intraepithelial lymphocytes express γδ TCR, as opposed to more common αβ TCR, and CD8αα as opposed to the more common CD8αβ. There is also a population of recently identified TCR-negative IELs. IELs play roles in both the innate (in a natural-killer-cell-like function) and adaptive immunity.

ANA, antinuclear antibody; ACR, American College of Rheumatology; CD, cluster of differentiation; CIC, circulating immune complex; DLA, dog leukocyte antigen; dsDNA, double-stranded DNA; ENA, extractable nuclear antigen; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; Ig, immunoglobulin; LE, lupus erythematosus; mAb, monoclonal antibody; MHC, major histocompatibility complex; MMF, mycophenolate mofetil; NSDTR, Nova Scotia Duck Tolling Retriever; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; SS-A, Sjögren syndrome antigen A.

Systemic lupus erythematosus (SLE) is a chronic inflammatory, multisystem, autoimmune disease with protean clinical manifestations and laboratory features. It is characterized by an autoantibody response and complement activation, immune complex formation, and immune dysregulation that cause damage to multiple organs and lead to a wide spectrum of clinical manifestations.

In animals, SLE has been described in monkeys, dogs, cats, and horses. A number of inbred strains of mice (e.g., the New Zealand black/white strain) spontaneously develop lupus-like syndromes, and this has allowed intensive study of disease mechanisms. SLE-like disorders have also been reported in poikilothermic species, such as snakes and iguanas. Considered as an infrequent disease in the dog, many studies have been published on canine SLE since its initial description in 1965,[22] while feline and equine SLE are rare. An experimental canine model of SLE has been developed, and could be interesting for a better understanding of this complex disease and evaluation of new therapeutic approaches.[8]

PATHOGENESIS

Autoimmunity

Systemic lupus erythematosus is the prototypic multisystem autoimmune disease in which immune dysregulation leads to failure of the mechanisms that normally prevent the development of self-response.[32]

Autoantibodies

SLE patients develop a wide variety of autoantibodies (Table 52.1).[26,28,35]

Antinuclear antibodies (ANAs) are the most significant autoantibodies found in SLE. One proposed mechanism for development of ANAs involves a defect in apoptosis that causes increased cell death. During apoptosis, blebs of cellular material form on the surface of dying cells. Antigens that are normally buried within the cell are exposed on the surface of these blebs and they may trigger an immune response (Figure 52.1). These exposed antigens include nucleosomes (DNA and histone proteins), extractable nuclear antigens (ENA, including ribonucleoproteins (RNP)), and anionic phospholipids. The clearance of apoptotic debris is abnormal in patients with lupus. Normally, apoptotic cells are removed by phagocytes without causing inflammation. However, macrophages from SLE patients show defective phagocytosis of apoptotic cells, which, as a result, accumulate in tissues.

Unlike humans, dogs do not develop ANAs against native DNA (double-stranded DNA (dsDNA)), and there is a restricted pattern of reactivity against the various individual histone antigens (H1, H2A, H3, and H4 polypeptides), while ANAs specific to nucleosome or histone–DNA complexes are rare.[26,28] Canine ANAs also appear to have additional reactivities not found with human SLE sera (e.g., for the glycoprotein hnRNP G).[34] By contrast, the pattern of reactivity of other ENAs found in dogs is similar to that found in humans; e.g., anti-Sm antibodies and anti-SS-A/Ro antibodies. Antibodies to the proliferating cell nuclear antigen have also been described in dogs.

ANAs mediate tissue inflammation and injury in SLE either by direct pathogenic effect (e.g., anti-SS-A/Ro activity against skin) or due to their association with antigens to form immune complexes either in situ or in circulation. Moreover, a wide range of abnormalities contribute to an impaired clearance of circulating immune complexes (CIC) in SLE (e.g., abnormal complement receptors, deficiency of complement components), and CICs are not effectively removed from the circulation. Thus, the net result is prolonged high levels of CIC, which become available for deposition in nonlymphoid sites such as kidneys, synovium, or skin. Inappropriate tissue deposition or formation in situ may result in complement activation, granulocyte chemotaxis, and release of inflammatory mediators leading to vascular injury (type III hypersensitivity) and tissue damage.

B and T Cell Response

Although ANAs are characteristics of SLE, many other autoantibodies are produced suggesting that affected patients have abnormalities in B cell function resulting in B cell hyperactivity. Abnormalities in T cell functions play a part in the induction and maintenance of B cell hyperactivity. T cell cytokines affect B cells by stimulating cell division, switching antibody production from IgM to IgG, and promoting a change in the molecular sequence of the secreted antibody so it binds more strongly to the driving antigen. Thus, T cells help make possible the production of high-affinity IgG autoantibodies. Defective suppressor T cell function also can fail to regulate B cells.

Data from canine studies have shown immunologic alterations involving T cells and support defective suppressor T cell function: (1) a rapid decline in the level of a soluble thymic factor in canine SLE sera; (2) resistance to induced tolerance in some cases of canine SLE; (3) deficient concanavalin-A-induced suppressor cell function; and (4) a decrease in the number of circulating CD8+ T cells.[7] The extent of this last abnormality is directly related to disease severity.

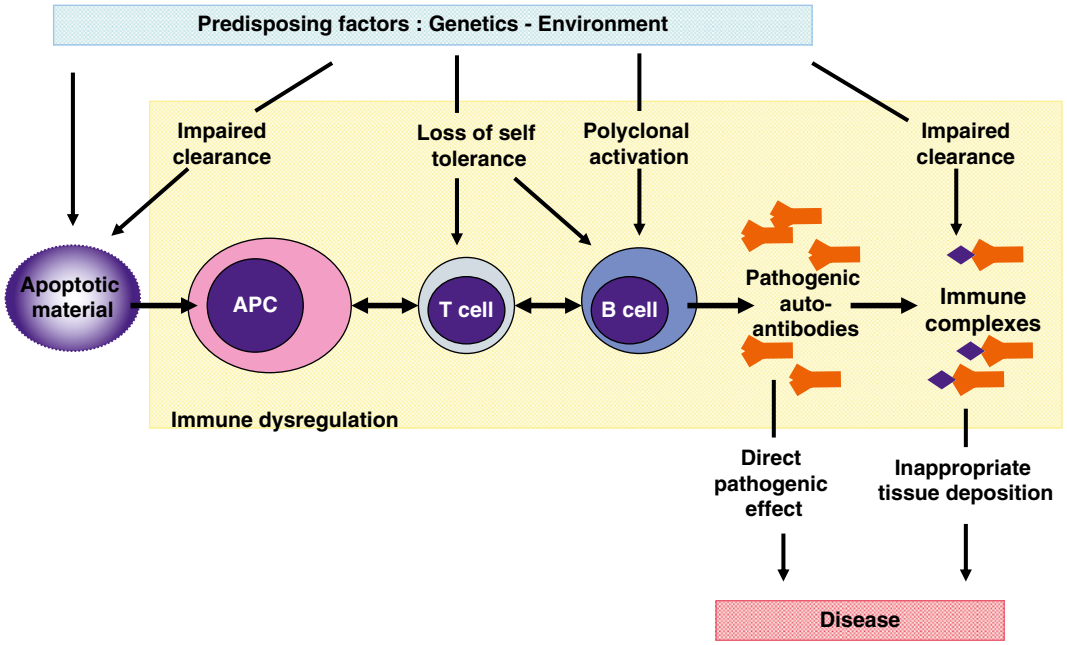

FIGURE 52.1 A simplified diagram of the immunologic events thought to occur in SLE leading to ANAs formation and immune complex deposition. Initiation of the disease involves a combination of predisposing factors that give rise to accumulation of apoptotic debris and immune dysregulation. Antigens that are normally buried within the cells are exposed on the surface of the dying cell, and may trigger an immune response. Loss of tolerance toward self-antigens combined with polyclonal stimulation perpetuates the autoantibody secretion. Autoantibodies may cause direct pathogenic effect or lead to immune complex formation and tissue damage. Impaired clearance by the mononuclear phagocyte system promotes immune complex deposition. APC, antigen-presenting cell. (**Source:** Modified from Rahman and Isenberg[32])

Genetic Factors, Breed, and Sex Predispositions

Genetic Factors

Susceptibility loci with confirmed linkage to SLE have been identified in humans and mice. These loci contain genes encoding molecules involved in immune response and apoptosis and most are associated with the major histocompatibility complex (MHC). The multitude of distinct genetic associations suggests a complex genetic predisposition for the disease, perhaps explaining the variable courses and organ system involvement.

The influence of genetic background in canine SLE is supported by studies of inbred lines and evidence of familial aggregation.[18,23,27,38] SLE is associated with the dog leukocyte antigen (DLA) system: the MHC class I DLA-A7 allele confers risk for disease expression, whereas dogs possessing the DLA-A1 and DLA-B5 (a MHC class II allele) are at decreased risk.[38] Dogs with a specific complement C4 allotype, a class III gene, may be predisposed to a lupus-like syndrome characterized by nonerosive polyarthritis, pyrexia, and ANAs.[11]

Nova Scotia Duck Tolling Retriever (NSDTR) dogs are at increased risk of autoimmune disorders, particularly for immune-mediated rheumatic disease,[16] which is considered to be an SLE-related disorder. In this breed, immune-mediated rheumatic disease is associated with the *DRB1* locus (DLA class II).[40] In addition to association to certain MHC alleles and haplotypes, a similarity between human and dog SLE at the genetic and functional levels is highlighted through an association with the *BANK1* gene (B-cell scaffold protein with ankyrin repeats 1). [41]

Feline SLE may occur more frequently in purebred cats, particularly those with a Siamese or Persian background. This suggests a genetic influence in this species.

Sex Hormones

Since 90% of human patients with lupus are women, an important role for female hormones seems probable. A protective role for male hormones or an effect of genes of the X chromosome is also possible. Such gender predisposition is not clearly seen in dogs.

Environmental and Exogenous Factors

A higher risk of developing ANA or SLE in pet dogs owned by human patients with SLE has been occasionally reported and supports the idea that a common environmental factor or zoonotic agent may have a role in causing SLE.

Light

Ultraviolet radiation is the most obvious environmental factor linked to SLE. Sunlight is known to be capable of triggering, or aggravating, SLE in humans, dogs, and cats. A photosensitive rash is a criterion of the American College of Rheumatology (ACR) for the diagnosis of the disease.[37]

Infectious Agents

While a microbial etiology for autoimmune diseases remains a popular theory, supportive evidence in SLE is limited. A role for viruses in the induction of canine SLE has been proposed. Antigens that cross-react with C-type retroviral particles have been identified on the cell membrane of blood lymphocytes from affected dogs, and cell-free extracts were able to transfer the serological abnormalities of SLE from affected to normal dogs.[31] However, these findings have not been widely corroborated and no direct virus isolation from canine tissues has been described. In cats, the retroviruses feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) can induce disease with similarities to SLE (e.g., immune-mediated hemolytic anemia), and ANAs develop in some cats infected with FeLV. However, most cases of feline SLE are seronegative for both viruses.[29]

Geographic Influence

Canine SLE is rarely diagnosed in the United States, Northern Europe, and Australia, but seems more frequently recognized in Mediterranean countries. This may reflect an association with different factors including breed distribution, regional gene pools, sun exposure, and prevalence of infectious diseases (e.g., leishmaniasis).

Drugs and Food

In humans, many drugs cause a variant of SLE called drug-induced lupus. The best known of these drugs are procainamide, hydralazine, and quinidine. Lupus-like syndromes have been induced by hydralazine in the dog,[3] and propylthiouracil in the cat.[2] Methimazole has been associated with the development of ANA in cats, but clinical signs of SLE have not been reported.[30]

Other possible factors implicated in humans include foods (celery, parsley) containing psoralens that could potentially increase photosensitivity, l-canavanine (found in alfalfa seeds, sprouts, and vegetables) that is structurally related to hydralazine, hair dyes, exposure to vinyl chloride, and implantation of silicone polymers.

Canine Experimental Model

An experimental model of canine SLE has been developed.[8] SLE was induced in mongrel and mixed-breed dogs by immunization with heparan sulfate, the major glycosaminoglycan of the glomerular basement membrane. The dogs developed a lupus-like syndrome with proteinuria, skin lesions, and ANAs. Gene therapy has been applied to this model using a nonviral peptide vector encoding canine CTLA-4-Ig gene.[9]

CLINICAL MANIFESTATIONS

SLE is a chronic, multifaceted inflammatory disease that can affect every organ system of the body. The symptoms of lupus can vary widely. They may come and go or stay constant; they can be mild, moderate, or severe; they may start suddenly or develop slowly over time.

Hematological Involvement

A history of multiple cytopenias such as leukopenia, lymphopenia, anemia, or thrombocytopenia may suggest SLE. Hemolytic anemia and thrombocytopenia were the main clinical signs together with nephritis cited in the initial description of canine SLE.[23] In more recent canine and feline studies, hemolytic anemia is a moderately frequent finding as it is in human SLE, whereas thrombocytopenia is rare. The Coombs test is positive in 17% of canine SLE cases, even occasionally in the absence of clinical signs of hemolysis. A mild nonregenerative, Coombs-negative anemia associated with chronic inflammation can also be present.

Leukopenia, due to lymphopenia, is not uncommon in SLE. During active disease, there is marked lymphopenia, presumably secondary to the presence of anti-T cell antibodies. An analysis of canine lymphocyte subsets in the peripheral blood reveals a striking decrease in the CD8+ population, which is directly related to disease severity. By contrast, although the percentage of CD4+ cells increases in SLE, the absolute number decreases. Consequently, the CD4:CD8 ratio may rise as high as 6 compared with a normal value of 2.3 in control dogs. Another important finding is the intense staining of T cells by activation markers.[7]

Abnormalities in coagulation pathways can be identified in some patients, resulting in prolongation of the partial thromboplastin time, which fails to be corrected with the addition of normal plasma.[24,36] These abnormalities are due to the presence of "lupus anticoagulant," an antibody directed against phospholipids. In human patients, it defines the phospholipid antibody syndrome, which is associated with a thrombotic disorder.

Overview of the Disease

Canine SLE

Systemic lupus erythematosus is mainly recognized in middle-aged dogs. The clinical expression of canine SLE encompasses a wide range of clinical features (Table 52.2).[12,14,35] Symptoms come and go unpredictably, and are observed successively rather than simultaneously as the disease evolves, except in advanced cases.

Constitutional manifestations such as loss of body mass, inappetence, fatigue, and fever are frequent when the disease is active. Musculoskeletal symptoms are the most frequent primary signs recognized in the dog, usually manifesting as polyarthritis, whereas polymyositis is occasionally identified. Joints most frequently involved are the distal joints (e.g., carpi, tarsi, elbows, and stifles). The vertebral articular facets could also be affected and, later in the course of the disease, the temporomandibular joints. The arthritis is usually symmetrical, nonerosive, and nondeforming. The arthritis/arthralgia may be evanescent, and recurrent. Synovial fluid analysis shows an increased nucleated cell count

TABLE 52.2 Clinical signs in canine SLE.

Signs	Percent positive
Fever	70–100
Nonerosive polyarthritis	80–90
Renal disorders	55–65
Mucocutaneous lesions	45–60
Lymphadenopathy and/or splenomegaly	40–50
Hemolytic anemia	15
Thrombocytopenia	5–15
Leukopenia	15–20
Myositis	5–10
Pleuropericarditis	<10
Central nervous system disorders	<5
Polyneuritis	<2

with predominance of neutrophils. Renal involvement is frequent, but can be asymptomatic initially. Proteinuria, or microhematuria, is the earliest manifestation and may be the only presenting renal symptom. Immune complex glomerulonephritis can range in severity from minor mesangial changes to diffuse proliferative lesions. Skin manifestations are highly variable and involve both cutaneous and mucous membranes. The lesions usually are characterized by photosensitization, with selective localization in areas exposed to sunlight (the dorsal region of the anterior limbs, the face with lips, nose pad, external ears in dogs with erect ears), and also in areas of thin skin poorly protected by the hair coat (axilla, inguinal region, ventral abdomen). Oral ulcers are infrequent, but palatal ulcers are highly suggestive of SLE. Subacute cutaneous lupus erythematosus in humans defines a subgroup of SLE patients characterized by photosensitivity, non-scarring dermatitis, mild systemic features, and a low prevalence of nephritis. These patients are frequently ANA-negative, but have antibodies to SS-A/Ro. Studies provide evidence supporting the hypothesis that vesicular cutaneous lupus erythematosus in the Rough Collie and Shetland dogs is a homolog of subacute cutaneous lupus erythematosus.[19] Lymphadenopathy or splenomegaly are common presenting signs (50%). In some cases, there is acute extensive facial or hemifacial edema. Cytological examination of enlarged lymph nodes shows plasma cell hyperplasia with an increase in small nucleolated cells or eosinophilic lymphadenitis. Cardiopulmonary involvement is not commonly documented in canine SLE.[4] Features include serositis (pleuritis, pericarditis), and myocarditis.[25] Although neurological manifestations are rare in canine SLE,[21] subtle behavioral disturbances may go unrecognized in the dog. NSDTR dogs predisposed to a SLE-like disease also show strong predisposition to another related immune-mediated disease, steroid-responsive meningitis-arteritis, with clinically relevant neurological signs.

Feline SLE

Systemic lupus erythematosus is a rare disease in the cat. Feline SLE involves the musculoskeletal, urinary, cutaneous, and hematopoietic systems with approximately equal frequency.[30,36,39] Fever is frequently reported in cats. Although the true prevalence of polyarthritis in feline SLE may be underestimated because it tends to be subclinical, articular symptoms seem to be common. Proteinuria or glomerulonephritis are frequently reported. Cutaneous manifestations include generalized alopecia, erythema, scaling, and crusting involving the face, ears, neck, ventrum, and limbs, and crusting of all digital pads. Neurological and behavioral disturbances may be not uncommon in feline SLE and include racing around the house; twitching of the ears, tail, or hind limbs; repeated licking; hyperesthesia along the dorsum; restless crying; disorientation; ataxia; and generalized seizures.[30,36]

Equine SLE

Equine lupus presents as generalized skin disease (alopecia, dermal ulceration, and crusting), accompanied by an antiglobulin-positive anemia. The disease is remarkable insofar as affected horses may be almost totally hairless. Affected horses may also have glomerulonephritis, synovitis, and lymphadenopathy.[13]

DIAGNOSIS

SLE must be diagnosed based on a proper constellation of clinical features and laboratory evidence.

Laboratory Investigations

Routine Laboratory Evaluation

Laboratory tests to diagnose possible SLE should include: a complete blood count to screen for leukopenia, lymphopenia, anemia, and thrombocytopenia; urinalysis to evaluate for proteinuria or hematuria; kidney and liver serum chemistry tests to monitor kidney disease activity and response to immunosuppressive and anti-inflammatory drugs; and inflammatory markers (e.g., c-reactive protein). The latter may be elevated in any inflammatory condition, including SLE, but level changes could be interesting for monitoring disease activity.[5,15]

Antinuclear Antibodies

ANAs are found in over 95% of dogs with SLE. The highest titers are seen in the most severe clinical cases, and diminish progressively with treatment. The decline consistently follows clinical remission, but with a certain time lag. ANAs can be encountered in other diseases,[33] and even in healthy animals (up to 15% of healthy dogs, and approximately 20% of dogs with various infectious diseases). In the majority of cases, their

titers are low, but titers higher than 1:1000 are occasionally found in healthy dogs, notably in German Shepherd dogs.[28] The most frequently observed staining pattern is homogeneous, followed by speckled. Among NSDTR dogs positive for ANA, 61% showed the speckled pattern, whereas 39% displayed homogeneous phenotype.[41] The significance of these staining patterns is currently unclear in animals. Although the ANA test is very sensitive, it has a low specificity, but is useful as a screening test. In NSDTR dogs with immune-mediated rheumatic disease, 30% displayed a negative ANA test.

In canine patients with high clinical suspicion or high ANA titer, additional testing is indicated for evaluation of ANA subtypes (such as histones, Sm, SS-A/Ro, hnRNP G). A number of methods are used to identify antibodies specific for the nuclear components (immunoprecipitation, ELISA, radioimmunoassay, western blotting). Unfortunately, these assays are rarely available outside the research setting. There are two categories of anti-ENA antibodies that, although their sensitivity is low, seem to be particularly interesting because of their high specificity for canine SLE. These categories are anti-Sm antibodies (found in 16% of patients) and anti-hnRNP G (found in 20% of patients).[28]

Healthy cats may have positive ANA (up to 30%): 10% had weak titers (1:40–1:80), but 20% had strong titers (1:160–1:320).[1] Titers greater than or equal to 1:1280 are occasionally found [personal observation].

Other Immunodiagnostic Tools

Formerly, the lupus erythematosus (LE) cell test was used for diagnosis of SLE. LE cells are neutrophils that have phagocytosed nuclei from dead and dying cells. Their presence may be detected in bone marrow and occasionally in buffy coat preparations. It is usually necessary to produce them in vitro using heparinized or clotted blood from patients. There is a high incidence of both false-positive and false-negative results. Because of this, the LE cell test is mostly of historic significance. LE cells rarely can be seen on smears of fluids (pericardial, pleural, or peritoneal effusions, bronchoalveolar lavage,[4] joint, cerebrospinal, and blister fluids) and, when present, are considered as highly suggestive of SLE.

A wide variety of autoantibodies can be detected in sera or tissue: rheumatoid factors (seen at low titers in 20% of patients);[6] antiphospholipid antibodies;[24,36] Coombs test to demonstrate anti-RBC antibodies; tests for antiplatelet antibodies (see Chapter 143).

A skin biopsy can help to diagnose SLE with histopathologic evidence of an interface dermatitis or vasculitis. The demonstration of immune deposits at the basement membrane zone (the "lupus band test") by immunofluorescence or immunohistochemistry in both affected and unaffected sites that have been exposed to sun, although not specific, is supportive of the diagnosis of SLE. A renal biopsy is useful in identifying the specific type of glomerulonephritis present.

CIC levels, serum complement function, and concentration of specific complement components can also be measured. CIC concentration will decrease and complement levels will rise to normal during clinical remission or after therapy. Reduced levels of complement in canine SLE are less likely to reflect inherited complement deficiency than utilization in immune complex clearance.

Diagnostic Criteria and Differential Diagnosis

Many diagnostic criteria have been proposed for SLE in veterinary medicine, and have been modified from those given for humans. The ACR established eleven criteria in 1982 that were updated in 1997.[17,37] These criteria summarize features necessary to diagnose SLE. However, more than diagnostic criteria, they were established for classification and use in scientific research (i.e., inclusion in randomized controlled trials); therefore, patients may have lupus but not meet all of the criteria.

In dogs and cats, the most frequently accepted and simplest diagnostic criteria include the presence of two separate manifestations of autoimmunity, together with significantly elevated titers of serum ANAs. For a more stringent diagnosis, it would be recommended to use the 1982 revised ACR criteria that have been proposed and adapted for dogs (Table 52.3).[35] A rigorous approach (Figure 52.2) is necessary for recognition of this complex disease and assessment of particular cases of SLE.

Systemic lupus erythematosus is a challenging disease whose wide variety of manifestations makes it part of the differential diagnosis for patients with many different presenting complaints (e.g., fever of unknown origin, polyarthritis, anemia, and nephritis). Infectious and neoplastic diseases must be excluded through imaging and appropriate biological testing, such as serology or polymerase chain reaction for vector-borne diseases (e.g., ehrlichiosis, leishmaniasis).

PROGNOSIS AND TREATMENT

Prognosis

The disease is progressive, so the severity of lesions and the number of organ systems involved increase gradually in untreated cases. Many patients die from renal failure. The earlier a diagnosis is made, the better the chance in-depth treatment will lead to a cure. Secondary infections are an ever-present risk in animals on immunosuppressive therapy.

Prognosis must take both disease activity and severity into account. A dog suffering from mild polyarthritis cannot be compared to one that is in critical condition, with a combination of severe anemia and renal failure. Various parameters have been suggested to evaluate disease severity and to monitor patients throughout therapy and during periods of remission: clinical criteria, as in the indices of activity defined for humans by the ACR; the ANA titer, which is in general proportional to the seriousness of the condition, but goes down slowly by comparison with clinical improvements; the serum levels of complement components, and

TABLE 52.3 Proposed criteria for the diagnosis of canine SLE.

1. **Arthritis:** nonerosive arthritis involving two or more peripheral joints, characterized mainly by pain during movement (progressive forced flexion–extension), where swelling or effusion is often not very marked
2. **Renal disorder**: persistent proteinuria in absence of urinary tract infection; or cellular casts (red blood cell, hemoglobin, granular, tubular, or mixed cellular casts)
3. **Cutaneous lesions**: depigmentation, erythema, erosions, ulcerations, crusts, and keratotic scaling which selectively affect the areas of thin skin, or skin poorly protected by the hair-coat (in particular, the face: nose pad, forehead, lips, and the periocular region)
4. **Oral ulcers**: oral or nasopharyngeal ulceration, usually painless
5. **Hematologic disorder**: hemolytic anemia; or leukopenia, <3.0 × 10^9/L on two or more occasions; or lymphopenia, <1.0 × 10^9/L on two or more occasions; or thrombocytopenia, <100 × 10^9/L in the absence of offending drugs
6. **Serositis:** presence of a nonseptic inflammatory cavity effusion (pleuritis or pericarditis)
7. **Neurologic disorders**: seizures or behavioral disturbances in the absence of offending drugs or known metabolic disorders (e.g., uremia, ketoacidosis, or electrolyte imbalances)
8. **Idiopathic inflammatory disease of the skeletal or cardiac muscles**: polymyositis or myocarditis
9. **Antinuclear antibody**: an abnormal ANA titer by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with their formation
10. **Immunologic disorder**: antibody to histone; or antibody to the Sm nuclear antigen; or antibody to the hnRNP G nuclear antigen; or decrease in the CD8 population, <0.2 × 10^9/L; or CD4/CD8 ratio higher than 4; or positive finding of anti-phospholipid antibody

Note: ANA, antinuclear antibody; RNP, ribonucleoprotein. Any combination of four or more of 10 criteria, well-documented at any time during a patient's history, makes it likely that the dog has SLE
