Induction	Prednisone (1 mg/kg PO q 12–24h) and MMF (10 mg/kg PO q 12h) administered in combination. The dosage of prednisone is tapered every 2 weeks, while MMF is continued at the same dosage	Prednisone (0.5 mg/kg PO q 12–24h) and levamisole (5 mg/kg PO q 48h—a maximum dose of 150 mg/dog is used) administered in combination. The dosage of prednisone is tapered every 2 weeks, while levamisole is continued at the same dosage
Maintenance	MMF alone. If remission is obtained on MMF alone for 2 months, the dosage is halved for an additional 2 months, and then discontinued	Levamisole is given continuously for 4 months and then stopped
Relapse	MMF is reinduced with a short course of prednisone, and MMF (10 mg/kg PO q 12–24h) is then continued for life	Levamisole alone is reinstituted for a further 4-month period.
Side effects	Side effects of MMF are generally mild (diarrhea) and dosage-related; hematologic side effects are uncommon	Side effects of long-term levamisole treatment are rare in dogs (neutropenia, aggressiveness, excited behavior)

evaluation of cellular immunity (e.g., enumeration of the circulating CD8+ lymphocytes, CD4:CD8 ratio, degree of lymphocyte activation).[7]

Therapy

Owing to the wide spectrum of clinical manifestations, treatment of SLE should be tailored to the severity and extent of disease in individual patients. Medications are used to control the disease, prevent recurrence of symptoms, and reduce their severity and duration. Sunlight should be avoided if photosensitization occurs.

Traditional Immunosuppressive Drugs

The standard primary therapeutic approach in veterinary medicine involves the use of tapered high-dose corticosteroid therapy. Prednisone or prednisolone at doses of 2–2.2 mg/kg/day is recommended in most instances. Full doses are administered until remission is attained, and then tapered slowly. Remission is usually brief and permanent corticosteroid therapy at the lowest effective dose is generally required. Dexamethasone has been used in treatment of equine SLE, but treatment of reported equine cases has been unsuccessful so far.

Additional immunosuppressive drugs, such as cyclophosphamide or azathioprine in dogs or cyclophosphamide or chlorambucil in cats, are used in refractory cases or to reduce the corticosteroid dosage because of unacceptable side effects.

Nowadays, standard treatment for active lupus nephritis in humans is mycophenolate mofetil (MMF) or cyclophosphamide combined with high-dose corticosteroids, while calcineurin inhibitors (including cyclosporine) are promising agents for the treatment of refractory cases. Studies in lupus nephritis have established the equivalence of MMF to intravenous cyclophosphamide and its equivalence or superiority to azathioprine in the maintenance phase of treatment.[10] The clinical utility of MMF is increasingly being explored in companion animals,[20] and its use in canine SLE as an adjunctive immunosuppressive agent with corticosteroids can be recommended (Table 52.4).[35] In our experience, we also use cyclosporine (5 mg/kg PO q 12h) for canine SLE in cases refractory to levamisole, with pharmacodynamics testing to adjust the dosage.

Levamisole

Levamisole is an anthelmintic drug, also used as an immunoadjuvant that stimulates T cell responses. It probably enhances suppressor T cell function. Levamisole has been used with success in canine SLE.[7,12] This regimen (Table 52.4) is reported to produce long-term remission in over 50% of dogs with SLE.

Other Alternatives

In human SLE, antimalarial agents (hydroxychloroquine) remain as first-line treatment for patient with mild SLE along with nonsteroidal anti-inflammatory drugs. Hydroxychloroquine is used to control skin and joint symptoms and protect against the development of systemic disease. Its use has not been reported in dogs and cats.

According to the expansion of knowledge and understanding of disease mechanisms over the past two decades, biologic therapies have been proposed for human SLE. These targeted therapies in use or under evaluation (Table 52.5) are designed to block pathways involved in disease pathogenesis and re-establish self-tolerance.[10] The use of CTLA-4-Ig is one of the targeted therapeutic approaches in SLE and has been used in the canine SLE experimental model.[9] CTLA-4 (CD152) fusion protein outcompetes the CD28 receptor for binding to CD80 (B7-1) and CD86 (B7-2) ligands expressed by antigen-presenting myeloid cells, including B cells (Figure 52.3). CD28 is a key costimulatory molecule that delivers the second signal required for antigen-induced T cell activation. The CTLA-4-Ig blocks the

TABLE 52.5 Examples of targeted therapies for SLE.

Target	Agent type	Effect
B cell	Anti-CD20 mAb	B-cell depletion
	Anti-CD19 mAb	B-cell and plasma cell depletion
	Anti-CD22 mAb	Inhibition of B-cell activation and proliferation
Cytokine	Anti-CD257 (BAFF) mAb	Inhibition of B-cell survival and differentiation
	Anti-IFN□	Blocking of inflammation induced by type I IFNγ
	Anti-IL-6R	Blocking of IL-6 binding to the IL-6R to decrease inflammation
	Anti-IL-6	Neutralization of IL-6 to decrease inflammation
Treg	Recombinant IL-2 (low-dose)	Induction and expansion of Tregs
Costimulators	CTLA-4-Fc fusion protein	Blocking of CD28 binding to CD80/86, blocking of T- and B-cell costimulation
	Anti-CD275 mAb	Blocking of T follicular helper cell activation/differentiation
	Anti-CXCR5 mAb	Blocking of CXCR5 binding to CXCL13 and cell migration to lymph nodes and target organs
	Anti-C5 mAb	Blocking of C5, preventing of C5a, membrane attack complex formation (C5b–C9)

Note: BAFF, B-cell-activating factor of the TNF family; CD, cluster of differentiation; CTLA-4, cytotoxic T lymphocyte-associated protein 4; CXCL, chemokine ligand; CXCR, chemokine receptor; IFN, interferon; IL, interleukin; mAb, monoclonal antibody; Tregs, Regulatory T cells.

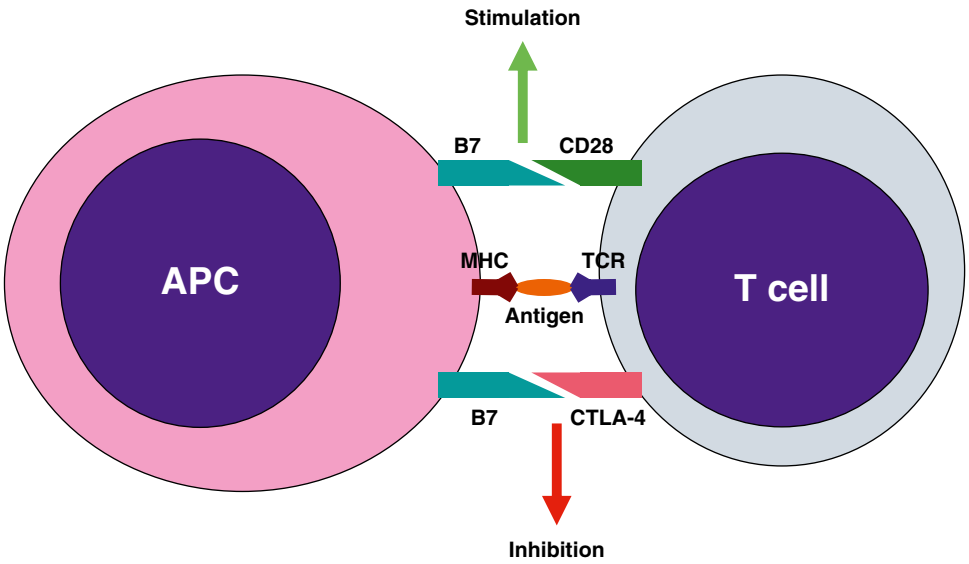

FIGURE 52.3 Interaction between a T cell and an antigen-presenting cell. The antigen-presenting cell (APC) binds antigen in a complex with a molecule from the MHC on its surface. This complex interacts with the T-cell receptor (TCR). The effect on the T cells depends on the interaction between other molecules on the surfaces of the two cells. Two alternative interactions are shown: B7 with CD28, which is stimulatory, and B7 with cytotoxic T lymphocyte-associated protein 4 (CTLA-4), which is inhibitory. If the positive signal caused by the CD28–B7 interaction dominates, the T cell is activated, leading to cytokine release, B cell help, and inflammation. If the negative signal caused by the CTLA-4–B7 interaction dominates, activation is suppressed.

CD28–B7 interaction and thus directly targets the interaction between T cells and antigen-presenting cells by inhibiting costimulation. The CTLA-4-Ig treatment can result in diminished T cell responses and T-dependent B-cell antibody production.

Acronyms and Abbreviations

3TC, 2′,3′-dideoxy-3′-thiacytidine; AIDS, acquired immunodeficiency syndrome; AZT, azidothymidine; CNS, central nervous system; CRD2, cysteine-rich domain-2; ELISA, enzyme-linked immunosorbent assay; FCV, feline calicivirus; FCoV, feline coronavirus; FHV-1, feline herpesvirus-1; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; FPV, feline panleukopenia virus; HIV, human immunodeficiency virus; IFN-α, interferon-α; MDA, maternally derived antibodies; PBMC, peripheral blood mononuclear cells; PCR, polymerase chain reaction; PMEA, 9-(2-phosphonomethoxyethyl)adenine; rHuEPO, recombinant human erythropoietin; rHuGM-CSF, recombinant human granulocyte macrophage colony-stimulating factor; TM, transmembrane.

Feline immunodeficiency virus (FIV), discovered in 1987,[36] shares a similar structure, genetic organization, lymphocyte tropism, and pathogenesis to the human immunodeficiency virus (HIV).[26] Species-specific FIV strains have been isolated from many species of non-domestic Felidae, including the puma, lion, leopard, and Pallas cat.[35] FIV is a lentivirus, containing accessory genes in addition to gag, pol, and env. The FIV gag gene encodes, among others, the capsid protein p24; the pol gene encodes the protease, integrase, and reverse transcriptase and additional enzymes important to virulence of FIV. Both gag and pol are relatively conserved between strains. The env gene encodes the viral surface glycoprotein (gp120) and the transmembrane (TM) protein (gp41), with the gp120 carrying the major determinants of viral diversity among isolates. Six genetically distinct subtypes or clades (designated A to F) have been defined, which exhibit considerable sequence diversity within the env genes. The majority of viruses identified so far belong to either subtype A or B. Although multiple subtypes have been documented in cats from the same continent, there tends to be geographic clustering of subtypes.

PREVALENCE AND EPIDEMIOLOGY

FIV is endemic in domestic cats worldwide; the seroprevalence varies between regions, with estimates of 1–14% in cats with no clinical signs and up to 44% in sick cats. Sick adults, males, and free-roaming cats are most likely to be infected. The major route of natural transmission occurs via the inoculation of saliva during fighting.[55] Vertical transmission and transmission between socially well-adapted cats are relatively uncommon. Transmission from mother to kittens can occur; the proportion of kittens infected depends on the viral load of the queen during pregnancy and birth.[9] If the queen

became infected at the time of mating (being bitten by an FIV-infected tom cat), the viral load may be high and up to 70% of the kittens may become infected at birth or via milk.[11–13] By contrast, if the queen was infected before conception and was clinically healthy during gestation, her viral load would be low and kittens would generally not become infected.

PATHOGENESIS

FIV gp120 binds CD134 expressed on activated CD4+ T lymphocytes resulting in a conformational change occurring in gp120 that leads to binding to the viral co-receptor, CXCR4.[44] These steps mediate fusion of viral and cell membranes (Figure 53.1) and viral entry. The viral reverse transcriptase enzyme synthesizes a DNA strand, complementary to the viral RNA, which is inserted into the host DNA to form the provirus. As reverse transcriptase lacks a proofreading function, its fidelity is low, and, as a consequence, FIV has a tendency to mutate. This, together with the development of the immune reaction, is the basis for genetic diversity, resulting in the generation of variants and immune evasion.

In the first days after infection, FIV replicates in dendritic cells, macrophages, and CD4+ T lymphocytes. Within 1–2 weeks, a low-level viremia develops.[3] The loads of viral RNA in plasma and provirus present in blood mononuclear cells increase with time, with the highest loads found between 8 and 12 weeks post infection.[8] This "acute phase" of infection is overcome by a functioning immune system, giving rise usually to a long asymptomatic phase during which plasma viral loads are stable at low levels (Figure 53.2). As infection progresses, the number of CD4+ T lymphocytes gradually decreases, resulting in a decreased CD4:CD8 T lymphocyte ratio and immune deficiency.[25] Immunodeficiency with high viral loads is accompanied by the clinical signs of acquired immunodeficiency syndrome (AIDS) and death.[28] FIV strains isolated during the early or primary stage of infection display a distinct receptor usage phenotype, requiring the CRD2 domain of the CD134 molecule for infection; the CRD2 domain is not required by strains isolated during the terminal/AIDS phase.[53] The switch in phenotype from CRD2-dependent to CRD2-independent strains coincides with the onset of immunodeficiency[6,7] and can be used to stage the infection (Figure 53.2).

CLINICAL DISEASE

During the acute phase of infection in experimentally infected cats, lymphadenopathy, pyrexia, anorexia, and lethargy can be observed. Lymphadenopathy may persist for many weeks or months and is associated with increased number and size of germinal centers. A decrease in plasma viral load marks the beginning of the "asymptomatic" phase that can last for many years or can be lifelong.[5] Progression to immunosuppression probably depends on the virulence of the infecting strain and cat age at the time of infection.[28,47] In addition, the higher genetic stability of FIV compared to HIV could explain why many cats naturally infected with FIV do not show evidence of disease progression.

Immunosuppression usually manifests as stomatitis/gingivitis, chronic rhinitis, skin disease, lymphadenopathy, or weight loss and infected cats are prone to secondary or opportunistic infections and neoplasia. B cell lymphosarcomas, myeloproliferative disease, and squamous cell carcinomas have been reported, as well as many concurrent viral, bacterial, fungal, and protozoal infections, although

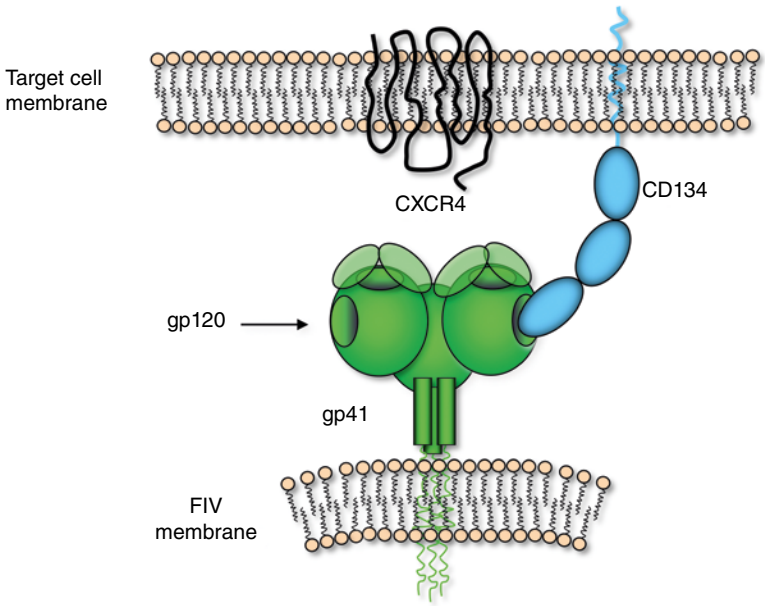

FIGURE 53.1 Schematic representation of the two-receptor mechanism for FIV infection, showing the interaction between FIV gp120 and the primary receptor molecule CD134 and the co-receptor CXCR4. (**Source:** Provided by Prof. B. Willett, MRC-University of Glasgow Centre for Virus Research, Glasgow, UK)

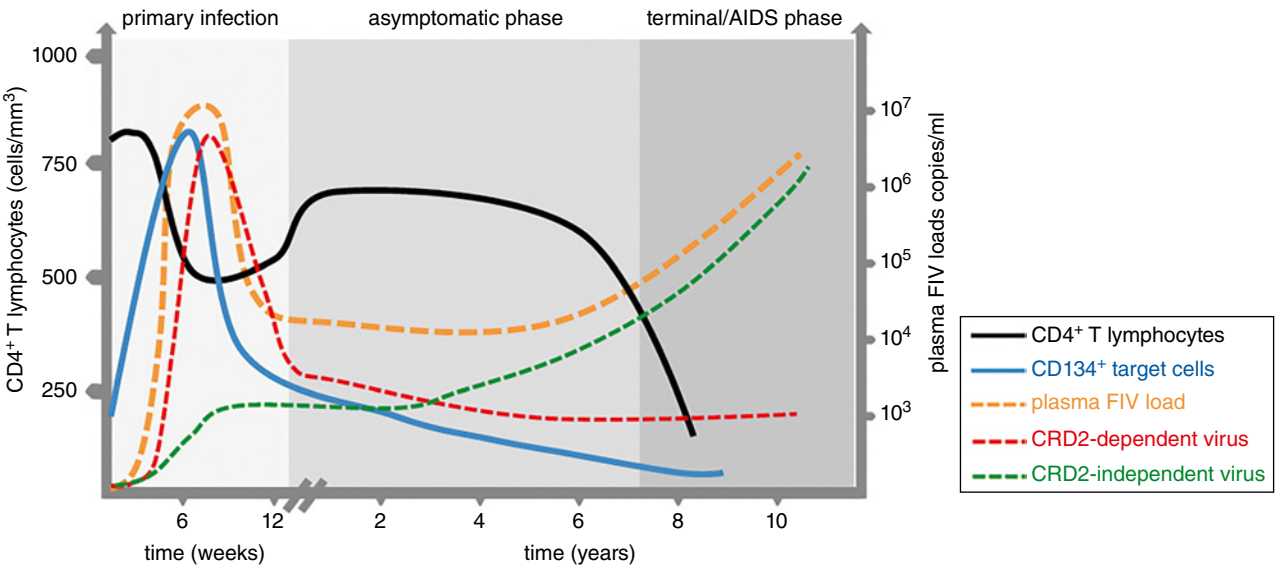

FIGURE 53.2 The course of FIV infection, showing CD4+ T lymphocytes, CD134+ activated T cells, plasma virus load, and levels of CRD2-dependent and CRD2-independent variants of FIV during the primary, asymptomatic, and terminal phases of infection. (**Source:** Provided by Dr. N. Techakriengkrai, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand)

some studies have found no significant association between FIV infection and *Cryptococcus*, *Cryptosporidium*, or *Mycoplasma haemofelis / Mycoplasma haemominutum*.[10,27,45,50]

FIV also infects the central nervous system (CNS),[14] which can lead to unnatural behavior.[38] Disrupted reproduction has been reported in FIV-infected cats when placental and fetal tissues are affected.[51] Also, an association between FIV infection and glomerular and tubulointerstitial lesions combined with proteinuria has been documented.[39] However, many of these reported outcomes were observed for cats that had been infected experimentally with FIV, often using specific strains of the virus. By contrast, clinical signs in cats with naturally acquired FIV infection are often mild or inapparent. Cats housed in single-cat households remained free of clinical signs during a 22-month study period, while cats kept in crowded shelter conditions developed clinical signs, showed more pronounced declines in CD4+ T lymphocyte numbers, and were more likely to die during the follow-up period.[5]

HEMATOLOGIC DISORDERS

During the acute phase of experimental FIV infection, mild lymphopenia and later lymphopenia and severe neutropenia have been described.[22] The most frequent hematologic abnormalities include anemia, neutropenia, lymphopenia, and monocytosis.[28,31,43]

IMMUNE REACTION

After infection, cats readily develop high titers of antibodies recognizing different FIV components. Antibodies can be detected by immunofluorescence assays, ELISAs, or immunochromatography tests.[32,36] Antibody specificity is usually determined by western blots or radioimmunoprecipitation.[16] Anti-FIV antibodies are detectable from 2–4 weeks post infection, or later if cats are exposed to low doses of virus.[24] Antibodies recognizing gp41 appear first, within a few weeks after infection, whereas those recognizing gag and gp120 appear later.[11] Virus-neutralizing antibodies develop a few weeks after infection. However, cats cannot clear FIV infection, even if high titers of virus neutralizing antibodies are present, suggesting that cellular immunity might have a role in suppressing FIV replication in cats displaying low viral loads.[6] FIV-specific CD8+ T cells were detected as early as 2 weeks after infection.[4] A population of CD8+ T cells termed CD8low was observed in early FIV infection, which act as a marker of immune activation by more virulent strains of FIV and might contribute functionally to the noncytolytic CD8+ T cell activity against FIV.[17]

DIAGNOSIS

FIV infection can be diagnosed either directly, by detecting the virus, or indirectly, by demonstrating the presence of antibodies.

Direct Detection of FIV

Virus Isolation

Isolation of FIV in cell culture was the first method used to demonstrate FIV infection in infected cats.[36] Peripheral blood lymphocytes are prepared from fresh samples of heparinized blood and are co-cultivated with primary feline T cells for up to 4 weeks. The presence of virus in culture fluids can be confirmed by measuring the levels

of FIV core proteins in the culture fluids or by quantitation of provirus or FIV RNA using real-time PCR or RT-PCR.[30] Virus isolation in culture is laborious and tends not to be used routinely.

Polymerase Chain Reaction

PCR-based assays that detect viral RNA or proviral DNA[42,49] led to use of real-time PCR to quantify FIV-DNA and RNA.[30] PCR-based FIV detection is sensitive, but false negatives occur. Seropositive results in PCR-negative cats can also occur following vaccination. In addition, false positive results have been described in cats living in close contact with FIV-infected seropositive cats. It is suspected that such cats have become infected at low levels and will seroconvert when viral loads have increased sufficiently to induce antibody production.

Detection of Antibodies to FIV

During FIV infection cats develop antibodies to all components of FIV.[6,11,34] Antibodies to the TM protein gp41 appear first, followed by antibodies to gag and gp120.[11] For routine detection of antibodies to FIV, purified whole FIV, FIV-infected cells, and purified proteins produced by recombinant DNA technology have been described.[41] Serological tests used in diagnostic laboratories are mostly based on a combination of p24 and TM peptides, while immunochromatography tests usually contain synthetically produced peptides from the TM region. Western blots are considered the "gold standard" for FIV serology and are used to confirm inconclusive results.[34] ELISA and immunochromatography tests are widely used under practice conditions, but false positive results can occur. This is especially important in populations with low prevalence, such as in many countries in Central Europe. Therefore, any positive result in a cat without risk factors (e.g., young, healthy, indoor, purebred cats) must be confirmed. A positive result in a cat from a high-risk group (e.g., free roaming, aged, male with scratch wounds) is more likely to be a true positive as the frequency of true positives will exceed the frequency of false positives in this population. Negative results in low-prevalence populations are generally very accurate, but false negative results may be obtained early in infection because cats remain seronegative for weeks to months. False negative results may be also obtained in the terminal stages of disease due to immunosuppression and when high viral titers may lead to sequestration of anti-FIV antibodies in virus–antibody complexes.

Kittens born to FIV-infected queens can test seropositive as a result of passively acquired maternally derived antibodies (MDA) and should be retested after approximately 16 weeks of age, when MDA will have declined to undetectable levels. However, in rare cases, antibodies may persist up to 6 months. If an earlier result is required, virus isolation or PCR could be used; however, the queen should be tested in parallel to ensure that the PCR can detect the strain of virus causing the seropositive reaction.

Vaccination of cats against FIV infection with an inactivated, whole virus vaccine results in rapid and persistent production of antibodies that are indistinguishable from those used for diagnosis of FIV infection. This vaccine is available in Australia, New Zealand, and Japan, but is not licensed in Europe and has been withdrawn from use in the USA. Vaccinated cats may be imported from a country where the vaccine is (or was) used and will test positive for antibodies to FIV. Antibodies can usually be detected within a few weeks after vaccination, and they can persist for more than 7 years. In such cases, a positive antibody test cannot distinguish between infection and vaccination.

TREATMENT

Supportive Treatment

Symptomatic treatment of infected cats should be directed at the clinical signs that arise from secondary infections. During the early phase of FIV infection, cats usually respond, as well as FIV-negative cats to appropriate medications, although a longer or more aggressive course of therapy (e.g., antibiotics) may be required. There are reports of clinical benefits using corticosteroids and other immune suppressive drugs in FIV-infected cats with chronic stomatitis, but their use is controversial.

Antiretroviral Drugs

There is no treatment of FIV infection that leads to complete clearance of the virus. Several drugs have proven antiretroviral activity against FIV, their modes of action and efficacies being similar for FIV and HIV.

Azidothymidine (AZT) or zidovudine, 3′-azido-2′,3′-dideoxythymidine, is a nucleoside analog reverse transcriptase inhibitor that inhibits the replication of both HIV and FIV. Treatment with AZT led to significant clinical improvements in FIV-infected cats.[2,21] Side effects of AZT (nonregenerative anemia) are seen in some cats, especially at higher doses.

Other nucleoside analogs with a similar mode of action to AZT have been used to treat FIV. Stampidine, 2′,3′-didehydro-3′-deoxy-5′-thymidylyl-L-alanine methyl ester, inhibited FIV replication in vitro and was well tolerated by cats.[48] Lamivudine (2′,3′-dideoxy-3′-thiacytidine), 3TC, was evaluated in vitro and in vivo and inhibited FIV replication. The combination of 3TC and AZT was highly effective for prophylaxis; however, the combination was only marginally effective in chronically infected cats.[2] The acyclic purine nucleoside analog 9-(2-phosphonomethoxyethyl)adenine (PMEA) efficiently inhibited FIV replication and improved the clinical signs of FIV infection, but with strong side effects, especially at higher doses, precluding its use in clinical cases. Enfuvirtide or T20 is a fusion inhibitor that binds gp41 and prevents fusion between the virus and the host cell, thereby blocking infection. Similarly, an analog to the FIV TM protein was shown to inhibit

FIV infection in vitro and to lead to a reduced viral load in vivo.[18] Although well tolerated by cats, its use is limited as it must be administered by subcutaneous injection because of its short half-life.

Bicyclams inhibit FIV as well as HIV infection,[15] blocking the primary receptor molecule CXCR4 molecule.[52] Plerixafor (1,1′-(1,4-phenylenebismethylene)-bis(1,4,8,11-tetraazacyclotetradecane)-octachloride dehydrate, AMD3100) is the prototype bicyclam drug and is active against FIV in vitro 90 when administered to cats at 0.5 mg/kg q12h. Magnesium and calcium levels should be monitored during treatment. In a placebo-controlled double-blind clinical trial of naturally FIV-infected cats, treatment with plerixafor resulted in a significant decrease in provirus load, but also a decrease in serum magnesium levels, although the latter was not clinically significant.

Immune Modulators

The use of recombinant human granulocyte macrophage colony-stimulating factor (rHuGM-CSF) in FIV infection is not advised because the peripheral blood mononuclear cells (PBMC)-associated FIV load in some treated cats increased by one to two logs.[1] In trials, significant increases in neutrophils and myeloid:erythroid ratios of the bone marrow cells were observed without increased stimulation of FIV expression, but 14–21 days after initiation of treatment, anti-rHuGM-CSF antibodies were induced in some cats, neutralizing its effect.[37] Recombinant human erythropoietin (rHuEPO) led to a gradual increase in red and white blood cell counts in FIV-infected cats and no increase in virus load was observed.[1] Insulin-like growth factor-1 (IGF-1) is available as recombinant human product (rHuIGF-1). Besides other actions, it has the ability to induce thymic growth and to stimulate T-cell function. In cats experimentally infected with FIV, the use of rHuIGF-1 resulted in increased thymus size and thymic cortical regeneration, leading to an increase in peripheral T cell counts.[54] Therefore, rHuIGF-1 could be considered as a supportive treatment in younger cats with FIV infection.

Interferon-α (IFN-α) is active against FIV in vitro[46] and has been used to treat FIV-infected cats.[12,20] In a placebo-controlled double-blind study, low-dose human IFN-α treatment significantly prolonged the survival of FIV-infected cats and improved their clinical signs compared to cats in a placebo group. Feline interferon-ω (IFN-ω) is licensed for use in veterinary medicine in some European countries and Japan, as it inhibits FIV replication in vitro[46] and does not stimulate the development of antibodies. In a placebo-controlled multicenter trial treating 62 naturally FIV-infected cats (106 IU/kg SC q24h on 5 consecutive days), there was no difference in survival of IFN-ω-treated cats compared to the placebo group, although some clinical improvements were noted.[12] In naturally FIV-infected cats housed in a shelter, clinical improvement was observed, but there was no control group. Oral administration of a lower dose of rfIFN-ω (105 U/cat PO q24h for 90 days) to clinically affected, naturally FIV-infected cats was associated with improvement of clinical scores.[20] The improvement was similar to that observed in a historical control group treated with SC rfIFN-ω, suggesting that PO administration of the lower dose of rfIFN-ω could be used as an alternative to the licensed protocol at reduced cost. In a follow-up study of naturally FIV-infected cats treated either with PO or SC rfIFN-ω, there was no change in viremia and most cytokine concentrations measured,[29] raising questions about the efficacy noted in the previous trials that lacked placebo-treated controls; the clinical improvement observed might have resulted from an effect of rfIFN-ω on secondary bacterial infections rather than on the primary FIV infection. Indeed, 16 naturally FIV- and or FeLV-infected cats that were followed for 65 days during rfIFN-ω treatment had reduced excretion of co-infecting viruses (feline calicivirus (FCV), feline herpesvirus-1 (FHV-1), feline coronavirus (FCoV), feline panleukopenia virus (FPV)).[19] Additional randomized, placebo-controlled, and double-blinded studies are required to fully determine the efficacy of IFN-ω.

PROGNOSIS

Under natural conditions, clinical signs may take many months to years to develop and many FIV-infected cats have an apparently normal life expectancy.[40] Nevertheless, FIV-positive cats are more likely to develop clinical signs, often associated with secondary infections, immune-mediated disease, or neoplasia.[33] Therefore, surrogate markers are required to provide an objective assessment of FIV progression in individual cats. FIV strains that dominate in early infection display a distinct receptor usage phenotype[53] and the emergence of viruses with an altered receptor usage phenotype coincides with the onset of immunodeficiency.[7] Therefore, it might be possible to develop viral phenotyping tests to assist in the clinical staging of individual cats diagnosed with FIV infection.

The clinical course of FIV infection depends on the sex, age, roaming habits, and the immune status of the affected cat.[13] Co-infections, especially with feline leukemia virus, accelerate disease progression.[23] Prospective studies of FIV-infected cats kept in stable, single-cat households showed that disease progression was delayed or even prevented, whereas FIV-infected cats kept in overcrowded conditions were more likely to show signs of disease progression.[5]

IMMUNODEFICIENCY DISEASE

Immunodeficiency diseases, characterized by an increased susceptibility to infection, are a diverse group of diseases that result from abnormalities in one or more components of the immune system. Immunodeficiency diseases can be broadly divided into either primary or acquired immunodeficiencies. Primary immunodeficiencies are diseases in which the animal is born with a genetic defect involving the immune system and clinical disease is a direct consequence of the hereditary defect with the majority of affected patients being neonates or young animals. Acquired immunodeficiencies are diseases in which the animal is born with an intact immune system, but as a result of some underlying disease process, their immune system becomes transiently or permanently impaired. Conditions that may indicate immunodeficiency include chronic or recurrent infections, infection with usually nonpathogenic organisms (opportunistic infections), infections nonresponsive to appropriate antibiotic therapy, failure to respond to immunization, adverse reactions to modified live vaccines, and growth retardation.

Defects in the B cell (humoral immune) system usually result in increased susceptibility to bacterial infections. Animals with T cell (cell-mediated immune) deficiencies usually have an increased susceptibility to intracellular microorganisms such as fungal, protozoal, and viral infections. Since a humoral immune response is highly dependent on the T cell system, certain T cell deficiencies may also present as humoral immunodeficiencies. Complement deficiencies are usually associated with recurrent infections with pyogenic bacteria.

DIAGNOSIS OF AN IMMUNODEFICIENCY

Although many tests of immune function are available, the clinical immunologic tests listed in the following text are commonly used to initially determine the competence of the various components of the immune system. Once an immunodeficiency has been established,

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.

other more sophisticated tests can be performed to localize the defect more precisely.

1. B cell system
   - Quantitation of serum IgA, IgG, and IgM.
   - Phenotypic evaluation of B cells by flow cytometry (see Chapter 142).
2. T cell system
   - T cell proliferation assay.
   - Phenotypic evaluation of T cells by flow cytometry (see Chapter 142).
3. Complement system\
   - Quantitation of serum C3.

The most practical test for evaluating the humoral immune system is to quantitate the serum concentrations of IgG, IgM, and IgA. Since the only published normal values are from normal adult animals, it is important to compare the immunoglobulin concentrations of young animals with age-matched healthy animals. The T cell proliferation assay is the simplest and most widely accepted in vitro test to evaluate the competence of the T cell system. This test evaluates the capacity of T cells to proliferate after stimulation. Animals with T cell deficiencies have an absent or a significantly reduced response to stimulation.

DISEASES OF THE B CELL (HUMORAL) IMMUNE SYSTEM

Agammaglobulinemia

Agammaglobulinemia is a rare immunodeficiency that has been reported in Thoroughbreds, Quarter Horses, and Standardbreds.[4] In a study of 2516 horses, approximately 0.16% were diagnosed with agammaglobulinemia.[23] It has only been reported in males, suggesting an X-linked mode of inheritance with many similarities to X-linked agammaglobulinemia in humans.

Affected horses suffer from recurrent bacterial infections, such as pneumonia, enteritis, laminitis, and arthritis. Clinical signs begin between 2 and 6 months of age with most affected horses dying before 2 years of age from generalized infections. The two major laboratory findings are the absence of peripheral B cells and low or absent serum IgA, IgG, and IgM. Specific antibody responses also are severely depressed T cell function in these horses is normal. Treatment is symptomatic including antibiotic therapy. Although administration of plasma may temporarily control infections, the long-term prognosis is poor.

Selective IgM Deficiency

IgM deficiency is characterized by reduced or absent serum IgM with normal or elevated serum concentrations of other immunoglobulin classes. IgM deficiency has been reported in foals 2–8 months of age and adult horses.[3,24] Although it occurs in different breeds of horses, it is most frequent in Arabians and Quarter Horses. The mode of inheritance and genetic cause is unknown.

Affected foals are often small for their age, and they experience repeated episodes of bacterial infections including pneumonia, arthritis, enteritis, and possibly septicemia. The bacterial infections are frequently caused by *Klebsiella sp*. Most of these foals die before 10 months of age. IgM deficiency in adult horses has been associated with lymphoma/lymphosarcoma.

The only significant laboratory abnormality is an absent or low serum IgM and is the basis for the diagnosis of this disease. T cells in horses with IgM deficiency have normal T cell function. In contrast to equine agammaglobulinemia, the proportion and absolute numbers of both B cells and T cells are normal. Other than supportive care and antibiotic therapy, there is no effective treatment for IgM deficiency.

Selective IgA Deficiency

The function of serum IgA remains unclear, but a specialized form of IgA, secretory IgA (sIgA), that is produced locally in various mucosal organs is found in saliva, tears, colostrum, nasal and bronchial secretions, gastrointestinal fluids, and urine. A deficiency of IgA results in failure to mount a local immune response to bacteria and viruses, predisposing the individual to infections particularly of mucosal organs. IgA-deficient individuals also have an increased absorption of antigens, predisposing them to potential development of allergies and autoimmune diseases. IgA deficiency has only been documented in humans and dogs.

IgA deficiency (IgAD) is the most frequent primary immunodeficiency in humans with a reported prevalence of approximately 1/600 in Western populations based upon screening large populations of healthy adult blood donors.[30,31] IgADs consist of two main types—severe IgAD defined as undetectable IgA, and partial IgAD defined as low IgA. Although individuals with IgAD are frequently asymptomatic, reduced levels of IgA predispose to a variety of diseases, including upper respiratory infections, gastrointestinal infections including giardiasis, skin infections, allergies, and autoimmune diseases. Approximately 50% of symptomatic IgAD patients present with recurrent infections, particularly of the upper respiratory tract. Autoimmune diseases have been reported to occur in 25–30% of symptomatic IgAD patients, and atopic disease has been reported to occur in 10–15% of symptomatic IgAD patients.

The initial descriptions of IgAD in the dog were in the Beagle and Shar Pei.[13,21] The most frequent clinical problems in dogs with IgAD include recurrent upper respiratory infections due to *Bordetella bronchiseptica* and canine parainfluenza virus, otitis, staphylococcal dermatitis, and atopic dermatitis. The infections associated with IgAD in the dog begin in the first few months of life, but are usually not life-threatening. In a prospective

study of Beagle puppies diagnosed with IgAD, the incidence of upper respiratory disease was 2.4 times greater and infection with *Giardia* was three times greater in the IgAD dogs than in age-matched dogs with normal IgA concentrations.[14] A relative IgA deficiency has been reported in German Shepherd dogs, which is associated with gastrointestinal disorders.[5,29]

Screening of 829 clinically normal adult Beagles revealed the presence of IgAD in approximately 9% of the dogs, 1% with severe IgAD and 8% with partial IgAD.[14] A recent study of 1247 dogs, both healthy and diseased, representing 22 different breeds over 1 year of age from the United States and Europe revealed that 15% of the dogs were considered IgA-deficient.[22] This study also showed a strong association of canine IgAD and atopic dermatitis, and breed predilection for IgAD not only in the previously described Shar Pei and German Shepherd, but also Golden Retriever and Labrador Retriever.

The diagnosis of IgAD, both in humans and dogs, is based upon the quantitation of serum IgA. It is important to compare a young, potentially IgAD dog with values for age-matched normal dogs. Treatment of IgAD dogs is limited to symptomatic treatment of the various infections, allergies, and/or autoimmune diseases. No specific immunotherapy exists for the treatment of IgAD. Immune globulin is contraindicated because many IgAD patients may possess or produce anti-IgA antibodies that could result in anaphylactic reactions. In addition, it would not replace sIgA that is the cause of IgAD.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) in humans is a late-onset hypogammaglobulinemia with onset of symptoms between 20 and 30 years of age.[10,11] CVID patients suffer from recurrent upper respiratory and gastrointestinal infections and have an increased incidence of autoimmune disorders and malignancies, primarily lymphoma and gastrointestinal adenocarcinomas. The major immunologic finding is low concentrations of two or all three of the immunoglobulin isotypes, reduced or absent specific antibody production, and abnormal T cell function in approximately 40–50% of patients. CVID has been reported in dogs and horses.

CVID has been documented in two breeds of dogs with *Pneumocystis carinii* pneumonia. *Pneumocystis* pneumonia has been reported in a small number of human CVID patients. The first report was in seven Miniature Dachshunds.[19] The immunologic abnormalities in these dogs were low levels of serum IgG, IgM, and IgA, decreased T cell function as measured by the lymphocyte transformation test, and the absence of B cells with the presence of T cells in lymphoid tissues. The second report involved a Pomeranian with *Pneumocystis* pneumonia.[18] In this dog, serum IgG and IgA were low, but serum IgM was normal. Immunohistochemical examination of lymphoid tissue revealed markedly decreased numbers of B cells with abundant T cells. T cell function was not evaluated in this dog.

A late-onset immunodeficiency that has striking similarities to CVID has been described in Shar Pei dogs.[25] The disease in Shar Peis is characterized by intermittent fever and recurrent infection of skin, respiratory system, and gastrointestinal system, including ulcerative colitis. The mean age at clinical onset is 3 years. In several reported cases, death occurred as the result of intestinal adenocarcinoma and malignant lymphoma. The mean age of dogs with malignant tumors was 6 years. Although affected dogs have normal proportions of peripheral B and T cells, they do demonstrate abnormalities in B and T cell function. The major laboratory findings are low serum concentrations of one or more of the serum immunoglobulins. Most affected dogs had low serum concentrations of IgM and IgA, and some dogs also had low levels of serum IgG. Approximately half of affected dogs had depressed T cell proliferative responses following mitogenic stimulation that correlated, like human CVID patients, with decreased serum concentrations of IgG.

CVID has been reported in a total of 14 horses.[15] The average age of the affected horses was 10.7 years (range = 2–19 years) with essentially an equal number of males and females. The most common clinical signs are recurrent fever and respiratory infections, and meningitis in a large number of patients. The immunologic abnormalities included low serum IgG and IgM, low peripheral B cells and normal peripheral T cells, normal proliferative response of peripheral T cells to mitogenic stimulation, poor specific antibody response following immunization, and absence of B cells in lymphoid tissues. Although a few horses have been managed for 1–5 years on continuous or intermittent antibiotic therapy, in the absence of intensive therapy survival past 6 months after diagnosis is rare.

Transient Hypogammaglobulinemia of Infancy

Transient hypogammaglobulinemia of infancy is a self-limited immunoglobulin deficiency in dogs and horses resulting from a delayed onset of IgG and IgA production by the young puppy or foal.[12,20] Affected puppies and foals are clinically normal during the time they possess maternal antibody. However, when the maternal antibody disappears, they have increased susceptibility to infection, primarily chronic or recurrent bacterial infections of the respiratory tract. Spontaneous recovery occurs between 5 and 7 months of age when the animal's own humoral immune system begins to produce sufficient immunoglobulin. Symptomatic treatment may be needed during this period. The only significant laboratory finding is markedly reduced concentrations of serum immunoglobulin after the disappearance of maternal antibody, at around 2–3 months of age that persists until 5–7 months of age. It is essential to monitor the immunoglobulin concentrations of puppies and foals diagnosed as immunoglobulin-deficient to determine if the defect is permanent or transient.

Failure to Receive Colostrum

Although the immune system of the normal newborn is competent at the time of birth, they have never been exposed to antigens in the environment and any immune response they mount following their initial antigenic challenge has to be a primary immune response. This makes them vulnerable to infectious disease agents during the first weeks of life. Antibodies from the mother (maternal or passive immunity) help protect the newborn while they develop their own immune response to the antigens in their environment.

The newborn receives maternal antibody through either the colostrum or placenta that is directly influenced by the type of placenta in a particular species.[8] In humans, placental transfer is the primary source of maternal antibody in newborns. In dogs, only 5–10% of maternal antibody is transferred through the placenta, while most must be obtained through colostrum. Placental transfer of maternal antibody is prevented in most other domestic animals, including the horse, making the newborn entirely dependent upon colostrum for maternal immunity. It is important that newborns receive colostrum within the first 12–24 hours after birth, since the ability of the intestinal epithelium to absorb the maternal antibody ceases around 24 hours after birth. This phenomenon is referred to as "intestinal closure."

Newborns that fail to obtain colostrum have abnormally low levels of IgG for the first 2–3 months of life. They may have problems with bacterial infections during this time until their own humoral immune system has produced sufficient amounts of antibody to protect them. These animals may have to be maintained on supportive antibiotic therapy.

DISEASES OF THE T CELL (CELL-MEDIATED) IMMUNE SYSTEM

Diseases associated with isolated T cell defects are rare in domestic animals. The major T cell deficiencies in animals also involve the B cell system and are referred to as combined immunodeficiencies including X-linked severe combined immunodeficiency in dogs, severe combined immunodeficiency in Jack Russell Terriers, and severe combined immunodeficiency in Arabian foals. These diseases are discussed in Chapter 55.

Hypotrichosis with Thymic Aplasia (Nude Kittens)

An autosomal recessive disease has been described in Birman cats that appears to be the homolog of the T-cell-immunodeficient nude mouse and, more recently, T-cell-immunodeficient human nude patients.[9,16] The disease is characterized by lack of hair growth and thymic development, and severe immunodeficiency resulting in increased susceptibility to infections. Kittens are born with no hair and fail to thrive, which results in early death. Necropsy findings include lack of a thymus and severe depletion of lymphocytes in the paracortical (T-cell-dependent) regions of the lymphoid tissue in the spleen, Peyer's patches, and lymph nodes. The genetic defect in these kittens has recently been shown to be due to mutations in the FOXN1 gene, which is the same gene involved in T-cell-deficient nude mice and human patients.[1,16] FOXN1 encodes a transcription factor important in the development of keratinocytes in the skin and maturation of thymic epithelial cells that are important in the development of T cells.

T Cell Deficiency in Growth-Hormone-Deficient Dogs

A growth hormone deficiency has been reported in an inbred family of Weimaraner dogs that also had an associated T cell deficiency.[27] This is not surprising because there is increasing evidence that the thymus is a target organ for growth hormone.[27,28] Growth hormone is produced in the thymus by both thymic epithelial cells and thymocytes and appears to enhance secretion of cytokines by thymic epithelial cells, and proliferation and differentiation of thymocytes. This is most likely mediated by interleukin-7 secreted by thymic epithelial cells.

Affected puppies appear normal at birth, but at 6–7 weeks of age they develop a wasting syndrome that is characterized by anemia, emaciation, lethargy, growth failure, and persistent infections, resulting in death. The peripheral T cells from affected dogs fail to respond to mitogenic stimulation. Serum immunoglobulin concentrations in affected dogs are within the reference interval, and the dogs are capable of producing specific antibody following immunization. The thymus is small and lacks cellularity. This syndrome is similar to that seen in several strains of immunodeficient mice. Replacement therapy with growth hormone results in marked increase in size and cellularity of the thymus and marked clinical improvement.[26]

Lethal Acrodermatitis in Bull Terriers

An acquired T cell deficiency has been described in Bull Terriers secondary to an abnormality in absorption and metabolism of zinc.[17] The clinical signs include skin lesions (acrodermatitis, chronic pyoderma, and paronychia), hyperkeratosis of foot pads, poor growth, diarrhea, and recurrent respiratory infections. Affected dogs also have a lighter pigmentation at birth that becomes progressively more noticeable with age. Growth retardation is noticeable by 5–6 weeks of age when compared with their unaffected littermates. Affected dogs rarely survive past 1–2 years of age with bronchopneumonia as the major cause of death. Immunological evaluation of affected dogs reveals normal serum IgM and IgG, low normal serum IgA, and severely depressed T cell response after mitogenic stimulation. Pathologic findings, in addition to skin pathology, include a small, frequently unidentifiable thymus, severe depletion of lymphocytes in the T cell areas of the lymph nodes and spleen, and dilatation of the cerebral ventricles. Unlike other zinc deficiencies, affected dogs show little clinical

improvement after zinc supplementation. The mode of inheritance is autosomal recessive. A recent study has reported a mutation in the MKLN1 (muskelin 1) gene in 46 Bull Terriers with the disease that was not present in 191 normal Bull Terriers.[6]

Viral Infections

Many viral infections are capable of producing an acquired immunodeficiency in dogs and cats, especially those that affect the lymphoid tissue. The viruses include canine distemper virus, canine parvovirus, feline leukemia virus, feline immunodeficiency virus, and feline panleukopenia virus. These viral infections cause primarily a T cell deficiency as the result of a direct lytic effect on lymphocytes or disruption in the normal immunoregulatory cytokine network.

DISEASES OF THE COMPLEMENT SYSTEM

C3 Deficiency

C3 is a component of the complement system important in the opsonization of bacteria. A C3 deficiency, with an autosomal recessive mode of inheritance, has been reported in Brittany Spaniels.[7] Dogs that are homozygous for the trait have no detectable C3, whereas dogs that are heterozygous have C3 concentrations that are approximately 50% of normal and are clinically normal. The genetic defect is a deletion of cytosine at position 2136 causing a frameshift and generation of a premature stop codon resulting in a truncated protein <40% of the wild-type protein.[2] Clinical signs are observed only in dogs that are homozygous for the C3 deficiency and are related to an increased susceptibility to bacterial infections, including septicemia, and renal disease. Older C3-deficient dogs may develop type 1 glomerulonephritis and amyloidosis. The major immunologic abnormality is the absence of serum C3.

Acronyms and abbreviations

ADA, adenosine deaminase; BCR, B cell receptors; DNA-PK$_{CS}$ IL2RG, DNA-dependent protein kinase; FPS, Fell pony syndrome; JAK3, Janus kinas 3; MHC, major histocompatibility; RAG, recombination activating gene; SCID, severe combined immunodeficiency; SLC, sodium/myo-inositol cotransporter; XSCID, X-linked severe combined immunodeficiency.

Severe combined immunodeficiency (SCID) disorders are a rare (approximately 1/100,000 live births) heterogeneous group of at least 11 congenital genetic conditions in humans characterized by profound defects in both humoral and cell-mediated immune responses, most often leading to infantile death.[4,8,16] SCID classification is based on four main disease mechanisms: (1) Premature cell death due to accumulation of purine metabolites, seen in adenosine deaminase (ADA) deficiency. (2) Defective cytokine-dependent survival signaling in T cell precursors, seen in common gamma (γ_c) chain or janus kinas 3 (JAK3) mutations. (3) Defective V(D)J rearrangements of T cell (TCR) and B cell receptors (BCR), seen in recombination activating gene (RAG)1 or RAG2 mutations. (4) Defective pre-TCR and TCR signaling, seen in CD3δ or CD45 mutations.

Regardless of the mechanism, affected individuals are characterized by: (1) severely reduced numbers and functional capacities of T cells and, in some cases, B cells and natural killer (NK) cells; (2) failure to thrive; and (3) presentation with diarrhea and chronic infections after 2 months of age as protective maternal antibody titers decline. Most forms of SCID exhibit autosomal recessive inheritance with the X-linked recessive form of SCID (XSCID) being the most common (approximately 50%). Both SCID and XSCID have been reported in the veterinary literature.

SEVERE COMBINED IMMUNODEFICIENCY IN ARABIAN FOALS

Severe combined immunodeficiency in Arabian foals, a uniformly fatal disease first reported in 1973,[19] is an autosomal recessive disorder limited to foals in which both dam and sire are descendants of Arabian horses.[22] SCID foals appear deceptively normal at birth, but they cannot generate antigen-specific immune responses,[7] since they lack mature B and T cells. They have profound lymphopenia and hypoplasia of their lymphoid organs.[17,18,33]

Molecular Basis of Disease

SCID in Arabian foals is caused by a mutation in a gene located on chromosome 9 encoding the catalytic subunit of DNA-dependent protein kinase (DNA-PK_{CS}),[1] leading to a complete lack of expression of an active version of this enzyme.[26] DNA-PK_{CS} is an integral enzyme involved in the V(D)J recombination events of B and T lymphocyte antigen receptor rearrangements. A lack of V(D)J recombination results in B cells lacking expression of cell surface IgM and T cells lacking cell surface expression of antigen-specific receptors. These defective progenitors, which are unable to complete the maturation process, are eliminated resulting in profound lymphopenia. Therefore, this disease is similar mechanistically to human RAG1- or RAG2-deficient SCID where both B and T cells are affected with sparing of NK cells.

Sequence analysis revealed the same five base pair deletion in all cases.[26] The deletion causes a frameshift mutation at codon 3155 and formation of a premature stop codon at amino acid position 3160 (of 4127 amino acids). The resulting 967 amino acid loss eliminates the protein kinase active sites, which renders the enzyme functionally inactive.

Clinical Features

Most affected foals remain free of infections and grow well for 3–8 weeks if adequate colostrum is ingested. As maternal antibodies wane, respiratory infections become increasingly evident. Although initially responsive to antimicrobial therapy, the respiratory infections tend to increase in severity and frequency. Affected foals lose body condition and inevitably die between 2 and 5 months of age.

A number of opportunistic infectious agents have been isolated from SCID foals, with equine adenovirus being the most common and important. Infection usually starts in the upper respiratory tract or intestinal epithelial cells with spread to other sites including bronchiolar, renal, and pancreatic duct epithelium. The pancreas from a SCID foal infected with adenovirus exhibits marked reduction in exocrine tissue and an increase in fibrous connective tissue. Notable opportunistic respiratory bacteria cultured from SCID foals include *Pneumocystis carinii* and *Rhodococcus equi*. *Cryptosporidium parvum* infection can cause severe, life-threatening diarrhea. Because SCID foals have normal NK cell numbers and activity, equine herpesviruses rarely cause serious infections.

Diagnosis

Foals with selective IgM deficiency (see Chapter 54) or failure to absorb adequate maternal immunoglobulin from colostrum can exhibit clinical signs similar to SCID foals, although profound lymphopenia (<1000 lymphocytes/μL of blood) and lymphoid tissue hypoplasia are not seen. Therefore, before 1997, a definitive diagnosis of SCID required demonstration of (1) profound lymphopenia,[27] (2) absence of IgM in serum, and (3) hypoplasia of the thymus and spleen. A definitive diagnosis could not be confirmed until postmortem histologic examination of the spleen and lymphoid tissue revealed marked hypoplasia.

The definitive molecular criteria of SCID diagnosis in Arabian foals were published in 1997.[27] DNA isolated from blood or buccal swabs from horses of any age is subjected to PCR using primers that produce a product that spans the area of the five base pair deletion. DNA from a normal horse produces a 130 bp amplicon, while DNA from a SCID horse produces a 125 bp amplicon. Horses heterozygous for the disease will produce amplicons of both sizes (Figure 55.1). Importantly, this test can be used to unequivocally determine the definitive genotype of any horse and rule in or out SCID in foals exhibiting clinical signs such as recurrent infections or failure to thrive. The diagnostic test for SCID is available from VetGen, Inc. (www.vetgen.com). SCID test kits can be ordered from the Arabian Foal Association (www.foal.org/TestKitsandForms.html).

Treatment

Unfortunately, SCID is uniformly fatal, with all foals incapable of generating antigen-specific immune responses to prevent or recover from opportunistic bacterial and or viral infections. Although the clinical course of the disease can be prolonged with plasma transfusions as a source of antibodies in conjunction with antimicrobial therapy, SCID foals do not survive past 5 months of age.

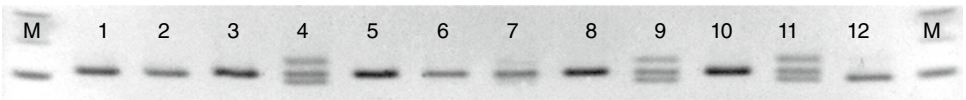

FIGURE 55.1 Genomic DNA PCR analysis for normal and SCID DNA-PK_{cs} sequences. Lanes 1–9 represent clinical blood samples; lane 10, known uninfected foal; lane 11, known heterozygous foal; lane 12, known SCID foal; M is a DNA marker. The foals in lanes 4 and 9 are heterozygous SCID carriers.

Bone marrow transplantation of a 32-day-old SCID foal using histocompatible, mixed-leukocyte-culture-nonreactive, sex-matched, full sibling marrow cells resulted in successful engraftment and reversal of the SCID phenotype.[21] Peripheral blood lymphocyte counts increased within 2 weeks of transplantation and, although a full year was required for normalization of immune functions, the foal developed the ability to respond to vaccine antigens and resist infections, indirectly implying normal B and T cell function. The horse survived for 5 years before succumbing to an unrelated intestinal disorder. Similar to human and canine XSCID, this experiment demonstrated that hematopoietic precursors in the donor marrow with a normal copy of the DNA-PK_{CS} gene enjoy a selective advantage in the SCID recipient with a rapid expansion of functional, mature B and T cells within the bone marrow, thymus, and peripheral lymphoid organs.

Control of SCID in the Arabian Horse Population

SCID in Arabian horses could be completely eliminated through careful genetic screening and selective breeding based on these results. Since only SCID foals can be produced when both the sire and dam are heterozygous for the mutant DNA-PK_{CS} gene, breeding programs can be structured to ensure that heterozygous stallions are never mated to heterozygous mares. Therefore, Arabian mares and stallions should be tested and classified as homozygous, heterozygous, or normal for the DNA-PK_{CS} gene. Theoretically, barring any new spontaneous mutations, Arabian SCID could be completely eliminated from the population within a few generations. Canine XSCID was eliminated from the canine breeding population using this strategy.

Although not recommended, an alternative to breeding only homozygous normal horses would be the continued use of known heterozygous horses under carefully controlled conditions based on genetic screening. For example, a heterozygous SCID stallion could breed with a homozygous normal mare with subsequent testing of all the foals to determine the genotype. The homozygous normal foals could be selected for future breeding programs, while the heterozygous colts could be gelded and all heterozygous offspring be used for nonreproductive activities. Indeed, the finding that the carrier prevalence of SCID in Arabian foals in South Africa was reduced from 6.4% in 2004/2005 to 3.4% in 2009/2010 is suggested to be the result of genetic screening followed by selective breeding.[31]

FELL PONY SYNDROME

Fell pony syndrome (FPS), also called foal immunodeficiency syndrome (FIS), first described in 1998 in an ancient breed of ponies bred mainly in upland areas of the UK,[25] is a uniformly fatal disease seen in Europe[3] and the USA.[11] Similar to other primary immunodeficiencies, affected foals are usually normal at birth, but then fail to thrive as maternal antibodies begin to wane. Unpublished genealogical studies have suggested a possible autosomal recessive mode of inheritance, which has been confirmed with the recent identification of a recessive mutation associated with the disease.

Clinical Presentation

At 4–8 weeks of age, affected foals begin to lose body condition and develop multiple, chronic infections that do not respond appropriately to antimicrobial therapy. Weight loss, diarrhea, bilateral nasal or oculonasal mucopurulent discharge, hypersalivation, coughing, and bronchopneumonia are the most common clinical signs. Other notable abnormalities include pyrexia, frequent chewing movements, halitosis, and a pale, friable, pseudomembranous and hyperkeratotic lingual coating. Severe, normocytic, normochromic anemia and lymphopenia are the most common blood dyscrasias. The bone marrow typically has a reduction in erythrocyte precursors. The foals deteriorate progressively and die or are euthanized, usually between 1 and 3 months of age.

Postmortem examination invariably reveals multisystemic necrotizing and inflammatory lesions associated with opportunistic infections with a wide variety of bacteria.[24] Rhinitis, sinusitis, bronchitis, pneumonia, and glossal hyperkeratosis are the most common respiratory abnormalities. The most common gastrointestinal abnormalities include hepatitis, typhlocolitis, adenovirus-induced pancreatitis, and enteritis. Most ponies also have inconspicuous lymphoid tissue including small thymuses, a lack of lymph node follicles and germinal centers, and a paucity of splenic corpuscular tissue. Peripheral gangliopathy, characterized by neuronal chromatolysis and nuclear pyknosis of dorsal root ganglia, has also been documented.[25]

Immunologic Abnormalities

FPS foals have low IgM and IgA immunoglobulin levels,[25] while IgG levels can be variable, most likely reflecting the presence of maternally derived IgG antibodies from colostrum. Importantly, FPS foals have significantly reduced peripheral B cell numbers (<10%) when compared to age-matched normal Fell ponies. This correlates with immunohistochemical data showing a severe reduction of CD79a+ B cells in the lymph nodes, spleen, and bone marrow from FPS foals.[25] Lymphocyte function tests and the distribution of CD4+ or CD8+ T cells are typically normal, although depressed mitogenic responses have been described.[25] Lymphocyte cell surface expression of major histocompatibility (MHC) class II is variable.

Diagnosis

The genetic mutation associated with FPS in Fell and Dales ponies has been reported.[9] A point mutation in a single exon of the sodium/myo-inositol cotransporter (SLC5A3) gene leads to a Pro446 to Leu446 amino acid

change in the protein. To date, the altered phenotype in affected foals is thought to be the result of either alteration or loss of SLC5A3 activity that is deleterious to B cell and erythroid development. Using a DNA-based carrier test, approximately 18% of Dales ponies and approximately 38% of Fells ponies were carriers of the mutation.[10] No alterations of gene expression relating to B cell development, signaling, and maturation have been identified.[30]

Treatment

As with most primary immunodeficiencies in animals, there is no treatment for FPS. This disease is most likely the result of a severe defect in B cell development at the level of the bone marrow, which contributes to the failure of B cell expansion in the periphery. Similar to SCID in Arabian foals, implementation of appropriate breeding programs to reduce the incidence of FPS can now be considered in light of an available DNA-based carrier test (http://www.fellponysociety.org.uk/health.htm).

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY

XSCID, the most common SCID in humans,[4] has also been reported in dogs.[15,23] Both species share common immunologic abnormalities including: peripheral T cell lymphopenia with variable numbers of phenotypically normal B cells that do not undergo isotype class-switching to IgG in vivo peripheral T cells that do not proliferate in response to mitogens; and reduced production of NK cells. Human and canine XSCID patients exhibit a reduced ability to prevent or combat opportunistic infections resulting in infantile death.

Incidence of Canine XSCID

Canine XSCID was first reported in a litter of Basset Hounds in 1989.[15] Breeding studies confirmed the disease was X-linked. Additional cases of XSCID in the general Basset Hound population have not been reported. Canine XSCID was again recognized in 1997 in closely related Cardigan Welsh Corgi dogs.[23] Pedigree analysis of this family was consistent with X-linked inheritance, and the definitive diagnosis of XSCID was confirmed with DNA analysis. Subsequent pedigree DNA analysis identified the gene mutation in the affected male dog and related obligate carrier females and grandmother of the affected dog. Genetic testing identified carrier females so they could be removed from the breeding population.

It is believed that the genetic mutations responsible for XSCID in Basset Hounds and Cardigan Welsh Corgis were due to random chance. Since genetic testing followed by controlled breeding has eliminated the disease from the Corgi and Basset populations, XSCID is no more likely to occur in these two breeds than in any other breed.

Molecular Basis of Canine XSCID

Similar to XSCID-affected boys, canine XSCID is caused by mutations in the gene encoding the third or gamma chain of the interleukin-2 (IL-2) receptor.[14] The IL-2 receptor gamma chain is also a component of additional cytokine receptors, including the receptors for IL-4, IL-7, IL-9, and IL-15. The normal canine γc protein, which is 373 amino acids in length and 84% and 71% identical to the human and mouse protein sequences, respectively,[14] is composed of several evolutionarily conserved potential functional domains. Unlike human XSCID where hundreds of different γc mutations have been identified, only two mutations have been identified in dogs. Basset hounds have a four base pair deletion in the signal peptide region of the γc gene, which causes a shift in the translation reading frame and premature truncation of the γc protein during its synthesis. The mutant, nonfunctional protein is only 21 amino acids in length.[14] Cardigan Welsh Corgi dogs have a single nucleotide insertion following nucleotide 582 that also causes a shift in the translation reading frame and premature truncation of the γc protein at amino acid 196.[23] This effectively eliminates the transmembrane and the Src homology domains, resulting in a nonfunctional protein.

Clinical Presentation

Similar to XSCID boys, canine XSCID is characterized by a failure to thrive and an increased susceptibility to bacterial and viral infections at a young age.[5] Puppies appear normal at birth and are presumably protected by maternal antibodies for several weeks. As maternal antibodies wane, XSCID puppies fail to thrive and infections begin to develop. These infections include bacterial pyoderma, otitis, and cystitis, as well as diarrhea. Affected puppies lack palpable peripheral lymph nodes and no thymic shadow is visible on thoracic radiographs. Antimicrobial therapy is generally ineffective in combating these recurrent infections and puppies die or are euthanized by 5–6 months of age.

The thymuses of XSCID puppies are often less than 10% of the weight of age-matched normal littermates and are usually obscured by adipose tissue. Histologically, thymuses from XSCID puppies can range from simple dysplasia with no Hassall's corpuscles to relatively normal looking with many Hassall's corpuscles, although total thymocyte numbers are always severely reduced.

Immunologic Abnormalities

The most significant immunologic problem in XSCID is the defect in T cell function and development.[28] XSCID puppies are variably lymphopenic, with normal or increased percentages of B cells, and usually decreased percentages of peripheral T cells. XSCID dogs can develop variable numbers of phenotypically mature peripheral T cells; their ability to proliferate in response to mitogenic stimulation or IL-2 binding is negligible due to a dysfunctional IL-2 receptor.

Treatment of XSCID

In humans, bone marrow transplantation is the only treatment for XSCID, with success ranging from 50% to nearly 100%. Gene therapy using retroviral vectors harboring a normal copy of the γc cDNA has cured a number of affected boys, although two patients later developed leukemia, most likely the result of insertional mutagenesis.[12]

XSCID puppies have received bone marrow transplants using unfractionated whole marrow collected from both normal and carrier littermates.[6] The transplanted dogs, none of which received pretransplant cytoablative therapy, developed completely engrafted donor T cells, partially engrafted donor B cells, and were maintained in a conventional environment. XSCID puppies have also been transplanted with highly purified populations of CD34+ hematopoietic progenitor cells harvested from dog leukocyte antigen (DLA)-matched littermates.[13] All six dogs in this study went on to develop completely engrafted donor T cells from 1 to 3 months after transplantation, variable engrafted donor B cells, and were maintained in a conventional environment for over 6 months.

Retroviral gene therapy has also been used successfully to treat canine XSCID. In an initial study, a murine retroviral expression vector harboring enhanced green fluorescent protein (EGFP) and γc cDNAs was used for the ex vivo transduction of normal DLA-matched CD34+ cells followed by transplantation into XSCID-affected littermates.[29] Three of the five transplanted puppies went on to develop durable immune reconstitution with up to 28% of peripheral blood T cells expressing EGFP. A more recent study used in vivo retroviral gene therapy whereby XSCID puppies were directly injected with a retroviral vector encoding a normal copy of the γc cDNA.[32] Three of the four injected dogs attained normal numbers of gene-corrected peripheral T cells by 8 weeks following treatment.

SEVERE COMBINED IMMUNODEFICIENCY IN JACK RUSSELL TERRIERS

SCID has also been reported in a single family of Jack Russell Terriers. Twelve of 32 siblings from this single pair breeding succumbed to opportunistic infections within 8–14 weeks of age.[3] Additional breedings allowed the elucidation of the underlying genetic defect responsible for the immunodeficiency.

Molecular Basis of Disease

Jack Russell Terriers SCID, which is inherited as an autosomal recessive trait, is a non-B/non-T SCID most likely caused by a genetic DNA-PK_{CS} deficiency, similar to Arabian foal SCID.[20] A single nucleotide polymorphic transition (A/G) at position 95 of intron 5 results in a stop codon at nucleotide 10,828 and a premature termination at amino acid 517. This functionally null allele is responsible for lack of DNA-PK_{CS} activity and subsequent defective V(D)J recombination. The carrier frequency of the Jack Russell Terriers SCID allele is less than 1.1%.

Clinical Features

The clinical features of SCID in Jack Russell Terriers mirror those seen in most other SCID-affected animals.[2] Puppies typically appear normal until maternal antibodies begin to wane, with most succumbing to a wide variety of opportunistic infections between 8 and 14 weeks of age. Extreme lymphopenia and agammaglobulinemia are seen, while thymic dysplasia and peripheral lymphoid aplasia are the most common findings at necropsy.

Diagnosis

A DNA-based carrier test is available to screen Jack Russell Terriers whose matings produce offspring with an unusually high puppy mortality rate (http://www.animalabs.com/shop/dogs/severe-combined-immunodeficiency-terrier-type/).

Treatment

There are no published reports of Jack Russell Terriers SCID treatment, although bone marrow transplantation using DLA-matched siblings is, at least theoretically, a possibility.

FNA, fine needle aspiration biopsy.

LYMPH NODE ANATOMY

The focus of this chapter is on lymphadenopathy not caused by lymphoma and other hematopoietic neoplasia, which is described in Section V and elsewhere. The functional anatomy and histology of the lymph node are well described in Chapter 9.

LYMPHADENOPATHY

The term lymphadenopathy means an abnormal process (disease) has occurred in one or more lymph nodes. Lymphadenopathy is usually interpreted to mean enlargement of lymph nodes. A distinction, not in common use, is to restrict the term lymphadenopathy for changes without an infectious cause. This relates to the difference in the two suffixes: *opathy* and *itis*. Lymphadenitis denotes infiltration of inflammatory cells into the node rather than identifying an infectious agent. It is frequently not possible with cytologic or histologic examination to identify an infectious agent. Solitary lymphadenopathy refers to enlargement of a single lymph node. Regional lymphadenopathy describes the enlargement of lymph nodes draining a specific anatomic region. Generalized lymphadenopathy refers to enlargement of lymph nodes in more than one anatomic area. The distribution of lymphadenopathy aides in diagnosis. Solitary or regional lymphadenopathy suggests a lesion in the area drained by the lymph node. By contrast, generalized lymphadenopathy suggests systemic infections or hematopoietic neoplasia.

The type of animal affected, anamneses, and frequency of different diseases in a geographical area affect the diagnosis. For descriptions of changes seen with the many diseases of lymph nodes and other lymphoid organs, use references such as *Veterinary Comparative Hematopathology*.[9] Bacterial and viral infections may initially cause edema and swelling of lymph nodes early, and later cause variable patterns of necrosis, atrophy, hemorrhage, or infarction with or without lymphoid hyperplasia. Chronic stress may cause atrophy of lymph nodes.

CYTOLOGICAL EVALUATION

Abnormal lymph nodes are usually initially evaluated by cytologic evaluation of fine needle aspiration (FNA) biopsies as a minimally invasive test with rapidly available interpretations.[1] Impression smears may also be made from the cut surface of excised lymph nodes. FNA should indicate the relative numbers of different cell

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

types found in the node if adequate numbers of cells with good morphology are obtained. Lymphoid cells are fragile and are easily and often damaged beyond recognition. Take great care to be gentle with collection of a FNA and with spreading of the sample into a thin monolayer.

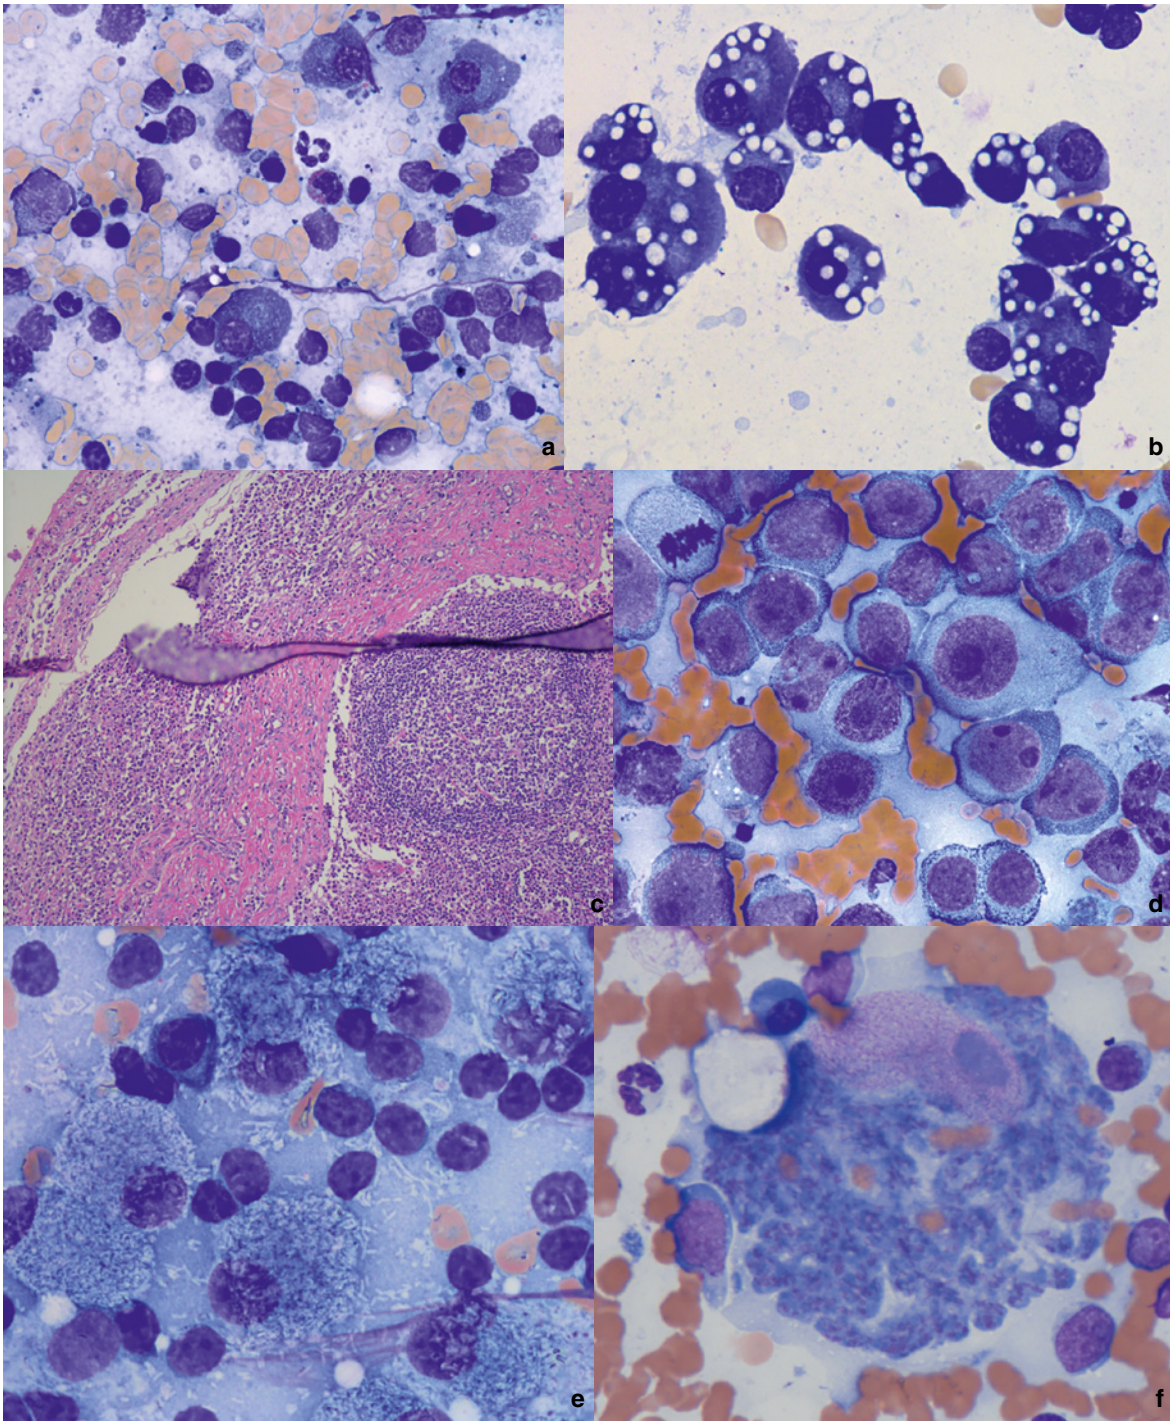
The cells found normally are mainly small to medium lymphocytes (75–95%) with few plasma cells (0–3%), and a small number of large lymphoid cells and blast cells (3–15%). Occasional other cells are present and include macrophages, neutrophils, eosinophils, and mast cells (Figure 56.1a). The percentages of different cell types are given to help describe expected populations, but should not be used as absolutes when making cytological diagnoses. The author usually combines the larger lymphoid cells (with a more open chromatin pattern) and lymphoblasts (with a nucleolus) together as "immature cells" in a differential cell count when both are few in number, but will add different categories to a differential cell count, such as intermediate cells, hand-mirror cells, plasmacytoid cells, etc., when they represent a dominant cell type.

Younger, more actively dividing cells have more euchromatin. Euchromatin is not stained. The increased area of unstained euchromatin gives the nucleus a more "open" appearance. Heterochromatin is the resting DNA that appears as stained granules of different sizes. The expected cell populations will vary among different lymph nodes. For example, "normal" intestinal, submandibular, and popliteal lymph nodes often look more reactive with a higher percentage of plasma cells or more immature-appearing lymphoid cells.

If the FNA indicates a similar population of cells to those normally seen in a lymph node and the lymph node is enlarged, a diagnosis of hyperplasia is appropriate. A prominent increase in plasma cells indicates a B cell response, while mainly small lymphocytes may suggest a T cell response. The numbers of lymphoblasts and larger lymphoid cells are often increased in hyperplastic lymph nodes and may be so greatly increased that differentiation of hyperplasia from lymphoma cannot be made with certainty. A cutoff of more than 50% immature lymphoid cells/lymphoblasts is usually used to indicate lymphoma. Similarly, a prominent increase in plasma cells in some infections may be difficult to distinguish from plasma cell neoplasia. Fortunately, the most common type of canine lymphoma has clearly over 50% large blast cells with large nucleoli, many mitotic figures, and tingible body macrophages to allow a definitive lymphoma diagnosis. However, nuclei in many types of lymphoma lack nucleoli and may be small to medium in size, which makes cytological diagnosis more difficult and uncertain. When lymphoid cells are very similar in appearance (monomorphic), lymphoid neoplasia is more likely. With hyperplasia, the appearance of lymphoid cells is typically more diverse.

An increase in nonlymphoid leukocytes indicates inflammation (lymphadenitis). The predominant cell type is used to classify the inflammation. A prominent increase in neutrophils (>15–25%) indicates neutrophilic inflammation (purulent or suppurative lymphadenitis). A predominance of neutrophils indicates severe purulent inflammation or even abscess formation. The amount of blood contamination should be considered because of the contribution of neutrophils and other leukocytes found in blood to the FNA sample especially in patients with leukocytosis. A small number of neutrophils (3–8%) may be normal or only indicate blood contamination especially in samples with a small number of nucleated cells.

This author uses the "reactive lymph node" classification as a more general diagnosis to include changes too mild to consider as lymphadenitis. This includes mild increases in neutrophils (10–15%), eosinophils (2–7%), and macrophages (3–8%). These increases are inflammatory changes, but mild. Hyperplasia of normal-appearing lymphoid cells is a reactive change, but suggests no increase in other types of leukocytes.



Macrophages occur normally in medullary sinuses and other areas of lymph nodes. A mild increase (3–8%) in macrophages or finding focal accumulations of macrophages may indicate a hyperplastic change due to some stimulus such with sinus histiocytosis. Moderate to large numbers (10–80%) of macrophages should indicate macrophage (granulomatous) inflammation (Figure 56.1e). Macrophages should be evaluated for phagocytosis and the phagocytic material may indicate the cause. Erythrophagocytosis and hemosiderin indicate pathological hemorrhage in the drainage field. Melanin may be seen in macrophages in lymph nodes draining an area with dermatitis.

If both neutrophils and macrophages are increased in number, the term pyogranulomatous lymphadenitis is used. Neutrophils are less fixed in the tissue, which allows relatively more neutrophils to be taken up in a FNA so the percentage of neutrophils usually exceeds that of macrophages. Larger numbers of macrophages may be seen in histological sections.

Organisms, when found, clearly indicate the diagnosis (Figure 56.1e,f). Organisms include various bacteria (e.g., *Mycobacterium*), fungi (including the classical dimorphic *Histoplasma*, *Blastomyces*, *Cryptococcus*, and *Coccidioides*), protozoa (e.g., *Leishmania*, *Cytauxzoon*), and even parasites (*Demodex*).[4]

Eosinophilic inflammation is fairly common.[2] The percentage of eosinophils required to classify the change as eosinophilic inflammation is less (>10–20 %) than that needed for neutrophils. Eosinophils may accompany neoplasia including mast cell tumors and lymphosarcoma. Basophilic inflammation is rare. The cytological pattern seen in lesions in the draining field may aid in diagnosis (e.g., allergic dermatitis).

Metastatic neoplasia in a lymph node sample is a common consideration/question. Metastasis can be early with only occasional neoplastic cells in a FNA or the entire lymph node can be replaced by neoplastic cells. Diagnosis is easier if the abnormal cells in a FNA are different from those normally seen in lymph nodes (Figure 56.1d). Occasional mast cells may be seen normally. Alternatively, large numbers of mast cells in a FNA indicate mast cell neoplasia. Mast cell hyperplasia is usually mild with few mast cells, but even a few mast

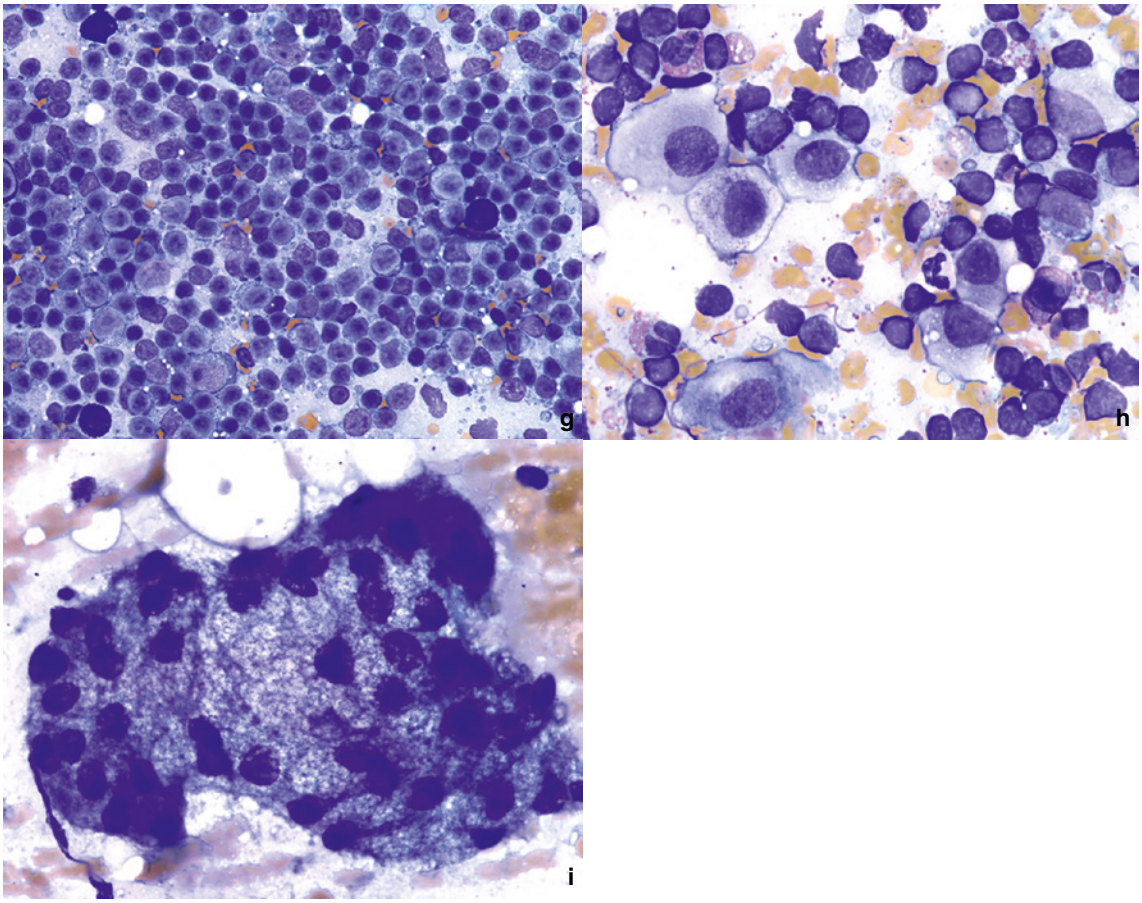

FIGURE 56.1 Lymph node aspirates and histological sections. (a) Reactive lymph node illustrating the types of cells seen in a normal lymph node aspirate. There are three plasma cells with abundant dark blue cytoplasm and a perinuclear halo. Three plasma cells on one field could suggest plasma cell hyperplasia. Most of the cells are small lymphocytes. One lymphoblast on the left side has a nucleus that is about 2.5 times the diameter of an RBC and has an open chromatin pattern with several nucleoli (light blue color). Lymphoblasts have larger nuclei, more euchromatin, and usually have one or more nucleoli. There is also a neutrophil and an eosinophil (Giemsa stain, original magnification 600×); (b) A lymph node aspirate with 15 plasma cells containing Russell bodies. Russell bodies are clear vacuoles in the cytoplasm representing excessive antibody in the endoplasmic reticulum. It is unusual to see this many plasma cells containing Russell bodies and a monomorphic population can suggest a lymphoproliferative disorder (Giemsa stain; original magnification 600×); (c) A histological section of an intestinal lymph node from a cat with gastrointestinal eosinophilic sclerosing fibroplasia. The purpose of the photo is to illustrate the architectural information available from histology that is not appreciated with cytology. A round germinal center is present on the center right. A bit of the capsule is at the upper left. Between these is of fibroplasia and an infiltrate of eosinophils and other leukocytes. (H&E stain; original magnification 100×); (d) An abdominal lymph node aspirate illustrates that not all large round, blast cells in a lymph node indicate lymphoma. This dog had metastatic testicular seminoma. The cells are often round with large round nuclei and very large nucleoli. One normal-appearing mitotic figure is present in the upper left (Giemsa stain; original magnification 1000×); (e) A lymph node aspirate from a Miniature Schnauzer with a *Mycobacterium* infection. There are six to seven large macrophages filled with negatively staining, white rods, which are also seen in the background. This indicates a granulomatous lymphadenitis with *Mycobacterium*-type bacteria (Giemsa stain; original magnification 600×); (f) Lymph node aspirate from a cat with *Cytauxzoon* infection. There is a huge macrophage (schizont) filled with many developing merozoites. (Giemsa stain; original magnification 600×); (g) A lymph node aspirate from a cat illustrate three well-granulated mast cells seen as individual cells widely separated from each other. Low numbers of mast cells are present within normal and inflamed lymph node aspirates and do not necessarily indicate the presence of a mast cell tumor. (Giemsa stain; original magnification 100×); (h) Mandibular lymph node aspirate from a dog illustrating metastasis of a mast cell tumor. Most cells are lymphocytes. There are six or more large mononuclear cells which are malignant mast cells. One of these cells to the upper left has a small number of granules that indicate it is of mast cell origin. The presence of increased numbers of eosinophils supports a conclusion that these undifferentiated cells are mast cells (Giemsa stain; original magnification 600×); (i) A salivary gland aspirate. Cells consist of an acinus of mature salivary gland cells with abundant foamy cytoplasm. The salivary gland is fairly often sampled with FNA when it is mistaken for an enlarge lymph node (Giemsa stain; original magnification 600×).

cells can cause difficulty in ruling out metastasis of mast cell tumors to a lymph node. The pattern seen with mast cell hyperplasia in a FNA smear or fragments of lymph node tissue in a FNA smear is the presence of individual mast cells separated from each other (Figure 56.1g). Aggregates of mast cells are more consistent with mast cell neoplasia. The presence of poorly differentiated mast cells is a stronger indication of mast cell tumor metastasis (Figure 56.1h). Cytologic diagnosis of histiocytic neoplasia provides similar challenges. Macrophage inflammation and hyperplasia are frequently associated with large and immature macrophages which may resemble histiocytic sarcoma.

Increased size of a lymph node can be due to noncellular elements such as edema or other causes of increased lymph. There is normally fat around a lymph node which can be a prominent part of the FNA. FNA of nonneoplastic, noninflamed submandibular salivary glands are relatively commonly seen in cytological practice (Figure 56.1i). Tattoo ink may be found in lymph nodes. Calcium oxalate crystals may be seen rarely in lymph nodes with pyogranulomatous inflammation.

Lymph Node Histopathology

Histopathology reveals abundant information not available from cytology.[8] Architectural patterns are important in differential diagnosis of hyperplasia from neoplasia (Figure 56.1c). There are often more special stains available to histopathologists than to cytologists to more precisely identify various cell types.

SELECTED DISORDERS ASSOCIATED WITH NONMALIGNANT LYMPHADENOPATHY IN DOGS AND CATS

Bacterial Lymphadenitis

Two syndromes presumptively associated with pyogenic bacterial infections and lymphadenitis, contagious streptococcal lymphadenitis of cats and puppy strangles, have been described in small animals.[3] Also, localized streptococcal and staphylococcal infections may result in solitary or regional lymphadenopathy in these species.

Contagious streptococcal lymphadenitis was described in several kittens and one adult cat in a cat colony.[3] The kittens developed diarrhea and fever at 4 weeks of age and cervical lymphadenopathy 2 weeks later. The lymph nodes in these cats were significantly enlarged and developed draining purulent lesions. All the cats tested negative for circulating feline leukemia virus (FeLV) p27 antigen. Lancefield group G beta-hemolytic streptococci were isolated from abscessed lymph nodes and from heart blood in one kitten that died of septicemia. Most cats responded to treatment with penicillin.

Puppy strangles (i.e., juvenile cellulitis) is a disorder associated with cutaneous cellulitis of the head and neck, and mandibular and cervical lymphadenopathy in 4–12-week-old puppies. Pups usually present with fever and facial skin lesions including edema, pustules, and crusts on the chin or muzzle, or in the ears, along with lymphadenopathy. Sometimes the lymphadenopathy is not associated with skin lesions. More than one pup in the litter is frequently affected. Fine needle aspiration of affected lymph nodes reveals purulent lymphadenitis, and staphylococcal or streptococcal organisms may be cultured. However, due to lack of response to antibiotic therapy in a high proportion of cases, the absence of bacteria in most cultures obtained from affected areas, and the subsequent response to immunosuppressive doses of corticosteroids, a hypersensitivity reaction to staphylococcal antigens is suspected.

Idiopathic Lymphadenopathies

A syndrome, called idiopathic lymphadenopathy, has been described in the cat.[6,7] Some cats are clinically normal on initial physical examination, except for the presence of lymphadenopathy; clinical signs in the other cats included fever, lethargy, anorexia, pallor, hematuria, eczema, vomiting, and mastitis. In one study, six of nine cats evaluated for FeLV antigens in peripheral blood were positive, while in another study they were negative.[7]

In one study, histologic changes in affected lymph nodes included distortion of the architecture; proliferation of histiocytes, lymphocytes, plasma cells, and lymphoblasts in paracortical regions; and numerous prominent postcapillary venules.[7] Histological features in the FeLV-negative cats were suggestive of lymphoma and included loss of normal lymph node architecture, presence of a uniform population of lymphoid cells in the paracortical areas, capsular and perinodal infiltration, and presence of large follicular structures without germinal centers.[6] However, other features were not compatible with lymphoma. Resolution of the lymphadenopathy occurred in the FeLV-negative cats within 5–120 days and all cats were alive 12–84 months after initial diagnosis.

The clinical and pathologic features in cats that have idiopathic reactive lymphadenopathy are similar to those observed in cats naturally or experimentally infected with feline immunodeficiency virus (FIV). It is improbable that all cats that have idiopathic reactive lymphadenopathy are infected with FIV; more likely, FIV represents one of the agents that can induce these changes in lymph nodes of domestic cats.

A clinical syndrome characterized by solitary cervical or inguinal lymphadenopathy in cats ranging in ages from 3 to 14 years, and referred to as plexiform vascularization of lymph nodes has been described.[5] The lesions were unilateral in seven of nine cats studied. Most cats were asymptomatic and the FeLV status was

not reported. Surgical removal of the affected nodes resulted in uneventful recovery in most cats. Histologically, the nodes showed replacement of the interfollicular pulp by a plexiform proliferation of small capillary-sized vascular channels and lymphoid atrophy.

Mineral-Associated Lymphadenopathy

A primary lymph node disease termed mineral-associated lymphadenopathy was described in the 1980s and has been reported since exclusively in dogs in the United Kingdom.[1] Affected dogs have nonspecific clinical signs (e.g., malaise, pyrexia, inappetence) in combination with generalized lymphadenopathy. Histologic examination of lymph nodes reveals a granulomatous lymphadenitis with accumulation of large quantities of crystalline-appearing, mineral material in the node. Electron microprobe analysis of this mineral reveals it consists of a complex mixture of elements including aluminum, silicon, titanium, and nickel, suggesting an environmental origin. In affected lymph nodes, inflammatory cytokines (IL-1, TNF-α) are produced causing the clinical symptoms. In several cases, concurrent diseases, like lymphosarcoma and immune-mediated diseases, are present.

APC, anaphase-promoting complex; CAK, CDK-activating kinase; CDK, cyclin-dependent kinase; CDKI, CDK inhibitor; DNA, deoxyribonucleic acid; G(0), gap (0) phase; HDAC, histone deacetylase; IL, interleukin; MHC, major histocompatibility complex; MPF, maturation-promoting factor; ORC, origin of replication complex; TGF-β, transforming growth factor-β.

In the late 1980s, there was a confluence of several fields of research. Scientists studying cell division in budding yeast (*Saccharomyces cerevisiae*), in fission yeast (*Schizosaccharomyces pombe*), and in frog eggs (*Xenopus laevis*) discovered a group of proteins that were responsible for cell-cycle oscillation.[4,8,16] Because the proteins were expressed cyclically, they were named cyclins. In short order, a "cell-cycle engine" that functions in all eukaryotic organisms was defined. This mechanism consists of cyclin-regulated cell-cycle kinases that provide the crucial checkpoints and feedback controls that regulate cell division.

THE CELL-CYCLE ENGINE

To simplify its study, the cell cycle has been subdivided into various steps (Figure 57.1). These steps include gap (G0), or the phase at which cells are in a resting or nonproliferative phase; G1, which defines entry into the cell cycle and is characterized by increased cellular metabolism and growth; synthesis (S), in which the whole genetic complement of the cell is replicated; G2, where the cell finishes the growth processes necessary for division; and finally mitosis (M), where division of one cell into two daughter cells finally takes place.[9] In normal cells, transitions among these states are defined functionally and are exquisitely fine-tuned. The balanced action of proliferative and antiproliferative signals ultimately determines whether cells enter the cell cycle, exit the cell cycle, or undergo programed cell death (i.e., apoptosis).[7]

The cell-cycle engine defines a regulatory network whose key components include proteins from two unrelated gene families, the cyclins and the cyclin-dependent kinases (CDKs). These proteins control phase transition and are regulated transcriptionally and post-transcriptionally. In this chapter, we will use T cells to

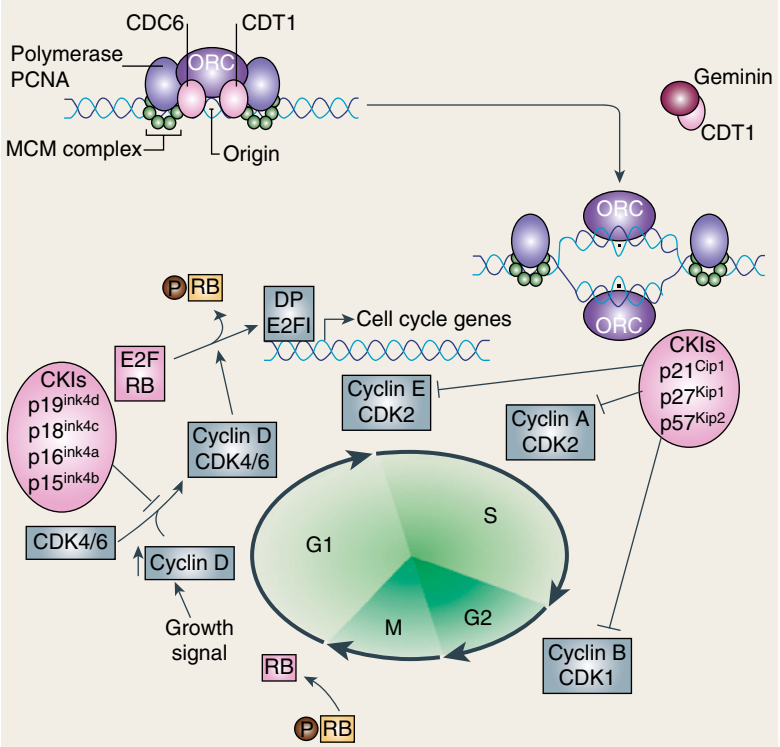

FIGURE 57.1 A schematic representation of the cell cycle. Cells enter the cell cycle in the G1 phase. G0 is a specialized form of G1 (highly differentiated cells, which are unlikely to divide unless provoked, remain in G0). During late G1, the cell commits to divide, typically marked by phosphorylation of Rb, and activation of E2F, which in association with DP-1 binds to the promoters of various cell-cycle genes. The process of replication of the entire genome is completed during the S phase, resulting in doubling of DNA content of the cell. The mechanical components that will organize chromosomes and physically divide the cell are assembled during the G2 phase, and a complex cytological event that accurately divides the duplicated sets of chromosomes and coordinates the events of fission to produce two cells from one is executed during the M phase. Many events take place during M phase, including dephosphorylation of RB. Upon completion of M phase, both daughter cells re-enter G1 and a new cell cycle is set to begin. Proteins that drive or inhibit the cell cycle are shown in gray or pink boxes, respectively. Cyclins are activator proteins that are upregulated or downregulated depending on the phase of the cell cycle. CDKs are serine/threonine kinases that require the binding of a cyclin (or related protein) for full activity. Their range of substrates is not fully defined, but interfering with their activity arrests or slows the cycle. CDKIs are small peptides that block cyclin/CDK activity either by forming an inactive complex or by acting as a competitive CDK ligand. DNA polymerases, proliferating cell nuclear antigen (PCNA), and minichromosome maintenance (MCM) proteins initiate replication only once per cycle. The checkpoint proteins are members of a network of proteins that monitor DNA integrity and arrest the cell cycle until DNA damage can be repaired. (**Source:** Reproduced from Herrup and Yang[9] with permission. ©Macmillan)

illustrate the transition steps that regulate cell-cycle entry, progression, and exit.

Cyclins

Cyclins are highly conserved in all eukaryotic species studied. More than 12 mammalian cyclin homolog genes have been characterized, but here we will focus only on those genes that control cell-cycle transitions. Cyclins function as regulatory subunits for the CDKs because monomeric CDKs have essentially no catalytic function.[19] However, the association of a CDK and a cyclin into a complex is only one regulatory step in the activation of these protein kinases. The cyclins are divided into groups according to the phase of the cell cycle in which they are expressed. Examples include the mitotic cyclins (B-type cyclins), S-phase cyclins (cyclins A and E), and G1 cyclins (cyclins D1–D3, cyclin E). Cyclin H is part of an enzyme complex called CDK-activating kinase (CAK). The nucleotide and amino acid sequence homology among cyclin proteins is limited (<30% at the amino acid level) and is restricted to a highly conserved region called the cyclin box. This cyclin box is required for association with a CDK, along with an independent, protein-specific sequence that mediates binding to small molecules called cyclin-dependent kinase inhibitors (CDKIs) that facilitate assembly of the cyclin–CDK complex.[11]

Cyclin-Dependent Kinases

In higher eukaryotes, the CDKs comprise a family of more than 12 proline-directed, serine and threonine protein kinases that share a PSTAIRE motif. Those members of the CDK family that control cell-cycle transitions are subdivided into proteins closely related to CDK1 (the mammalian Cdc2 homolog) that include CDK2, CDK3, CDK 4, CDK5, and CDK6.

Cyclin-Dependent Kinase Inhibitors

The CDKIs are products from various distinct gene families, the prototypes of which are p16 (CDKN2A), and the closely related p21 (CDKN1A) and p27 (CDKN1B).[17,20] Proteins in the p16 family (p15, p16, p18, p19) are specific inhibitors of CDK4 and CDK6, and their expression and function are dependent on a functional *RB*1 gene product (Rb). Indeed, the absence of Rb appears to make these CDKIs, as well as CDK4 and CDK6, inconsequential in their cell-cycle regulatory function. In normal cells, the upregulation of p16-related proteins is inducible by transforming growth factor-β (TGF-β). The expression of p21 is closely regulated by another unrelated tumor suppressor gene called p53. The p21 gene may be inducible as an effector of growth arrest before S-phase entry if the cell must undergo DNA repair. The function of members of the p27 family (p27, p57) appears to be regulated by various signaling pathways that affect cell-cycle progression, including those that are mediated by TGF-β or by cyclic AMP.

Regulation of Cyclin-Dependent Kinase Activity

Each CDK can associate with multiple cyclins: among the G1 CDKs (CDK2, CDK4, CDK6), CDK2 associates with A, E, and D-type cyclins, whereas CDK4 and CDK6 form complexes only with D-type cyclins. The cyclin partner is required for activation of the kinase, it confers substrate specificity, and it regulates the interactions of the complex with other proteins.

Inactivation of the kinases occurs in part due to the proteolytic degradation of the cyclin partner. CDK activity also is controlled by other kinases and phosphatases. Phosphorylation and dephosphorylation reactions occur at defined residues that are highly conserved throughout the CDK family; e.g., phosphorylation of a distal threonine residue (T160/T172 in CDK2 and CDK4, respectively) by CAK is an important activating event for all CDKs. Another critical event is dephosphorylation of N-terminal threonine (T14) and tyrosine (Y15/17) residues near the ATP-binding site by a bifunctional protein phosphatase of the Cdc25 family. Conversely, phosphorylation of T14 and Y15/Y17 by the Wee1 bifunctional protein kinase and dephosphorylation of T161/T172 by a protein like protein phosphatase 1 are important to inactivate the CDKs. The kinases and phosphatases that carry out this phase of CDK regulation provide additional links between environmental signals and activation of the cell-cycle machinery.

MAINTENANCE OF G0

Cell growth and proliferation are integral parts of the immune response. Mature peripheral T cells generally maintain homeostasis in a true resting (G0) state where the cell-cycle kinases (CDK1, CDK2, CDK4, or CDK6) and their cyclin partners (cyclin D2, cyclin D3, cyclin E, cyclin A, or cyclin B) are not expressed.[15]

Negative Regulation of Cell-Cycle Entry

The process of thymic education dictates that naïve T cells must interact with self-peptides presented by major histocompatibility complex (MHC) (i.e., potential autoantigens) to survive. Naïve T cells express high levels of T cell receptors, so the avidity for self-MHC might trigger their activation and result in autoimmunity. To prevent such activation, several interrelated negative regulatory pathways in lymphocytes enforce quiescence. Regulatory molecules in these pathways include those that dampen signaling such as IAN5 and negative transcriptional regulators such as the transducer of ErbB2-1 (Tob-1), nuclear factor of activated T cells-c2 (NFATc2), and Smad3, which is primarily responsible for integrating antiproliferative and prosurvival signals delivered through the TGF-β receptor.[12,23] Mutations in these genes result in T cells that survive poorly (IAN5 knockout), fulminant autoimmunity (TGF-β receptor dominant-negative), or cells that show cell-cycle dysregulation with eventual tumor formation (Tob-1 and NFATc2 knockouts). Intriguingly, the tumor phenotypes for Tob-1 and NFATc2 deficiency are B-cell lymphomas, and a recent study suggests that these proteins contribute to this subtype of lymphoma in dogs.[6]

THE G0 TO G1 TRANSITION AND G1-PHASE PROGRESSION

Antigen binding to the T-cell receptor complex triggers a series of events that give rise to several interactive, nonlinear biochemical cascades that disengage negative regulation and activate the cell-cycle machinery. Events during the G1 phase are essential to integrate environmental signals with cellular responses. In some instances, cell proliferation may be separated from other biological responses. For example, stimuli that incite production of interleukins can promote lymphocyte maturation and differentiation, immunoglobulin production, or enhanced cytotoxic or antigen-presenting functions, and may not lead to cell division. Conversely, exogenously provided cytokines may promote proliferation of receptive lymphocytes in a paracrine or endocrine fashion.

Unlike embryonic cells where the length of the cell cycle is temporally fixed, transit time through the G1 phase is variable in adult somatic cells. Potentially transforming events can significantly shorten the G1 phase. In most cases, this prompts activation of checkpoints that prevent transition to the S phase or leads to apoptosis. Cancer cells must, therefore, acquire mutations that allow them to overcome these safeguards.[20]

The G1 Restriction Point

Cell-cycle entry, defined as the transition from G0 to G1, is reversible. This transition point can be defined by partial activation of the CDK4/cyclin D2 holoenzyme complex and phosphorylation of the retinoblastoma susceptibility protein Rb. Transition into G1 also requires activation of CDK6 and CDK2. The CDKI p27 protein

may be especially important in control of G1 progression. At least part of the observed increase in CDK2 activity in activated T cells may be due to IL2-induced dissociation of p27 from CDK2 kinase complexes, and T cells from p27-knockout mice have exaggerated T-cell responses.[5] Cells that reach this stage of activation acquire the capability to respond to proliferative signals, but are not committed to continue transit into the S phase until they cross the restriction point, R.[15] This occurs at least in part by activation of CDK4/cyclin D3 and CDK2/cyclin E complexes.

Regulation of the G1 to S Transition by Rb

The proteins of the Rb family promote (or suppress) the expression of genes that control the G1 to S transition, including members of the E2F family of transcription factors and histone deacetylases (HDACs). In the hypophosphorylated state, modulation of these proteins by Rb acts as a cell-cycle brake. Phosphorylation of Rb by the CDKs leads to functional collapse of the pocket, releasing latent transcription factors and allowing their activation. It appears that phosphorylation by CDK4 releases HDACs, relieving transcriptional repression for some genes such as cyclin E, and opens the conformation of Rb, making it permissive for phosphorylation by CDK2. Subsequent Rb phosphorylation by CDK2/cyclin E releases E2F transcription factors. The activation of E2F factors requires their association with DP-1 or DP-2 to form heterodimers that orchestrate transcription of genes necessary for DNA synthesis (Figure 57.2). In lymphocytes, activation of Aurora B in conjunction with Survivin and mTOR is an essential step to complete the transition from G1 to the S phase.

S-PHASE PROGRESSION

In mammalian cells, an important control element in the process of DNA replication is assembly and activation of pre-replication complexes. Initiation sites (the replication origin) interact with a group of proteins called the origin of replication complex (ORC).[23] This allows helicases and other enzymes to unwind the double strand and recruit polymerases. Replication forks then move away from the origin in either direction (Figure 57.1).

As is true with abnormal G1 transit, partial re-replication triggers checkpoints that arrest cell-cycle progression or promote apoptosis. Re-replication is in some ways unavoidable and may be a driver of evolution. Indeed, it is now clear that subtle differences in DNA copy number exist among individuals within a species, and in dogs these might be conserved within members of the same breed, similarly to microsatellites and single-nucleotide polymorphisms.[3,13]

Checkpoint Transit

The S-phase checkpoint relies on detection of stalled replication forks (usually due to insufficient trinucleotide building blocks) or DNA damage. Members of the ataxia-telangiectasia-mutated and Rad3-related (ATM/ATR) kinase families act as sensor kinases, which in turn activate the effector kinase Chk2. Chk2 activation delays or arrests S-phase progression. Persistent stalled forks or DNA damage that cannot be repaired triggers apoptosis of normal cells.

Regulation of the Origin or Replication

Cells must avoid extensive re-replication during DNA synthesis. The ORC contains six stable subunits that bind to DNA in the transition from mitosis to G1 (or G0), followed by additional proteins, such as minichromosome maintenance (MCM) helicases, that are synthesized or stabilized at or near the G1 to S transition to form the pre-replicative complexes. CDK2/cyclin E (and other S-phase kinases) primes these pre-replicative complexes to form preinitiation complexes that are necessary for activation of DNA polymerases. Progression through S phase requires transition from CDK2/cyclin E to CDK2/cyclin A complexes, which are followed by the appearance of CDK1 complexed to cyclin A and cyclin B. Substrate specificity is probably important to prevent re-replication and to maintain the fidelity of DNA polymerases.

G2-PHASE PROGRESSION

Transition from S to the G2 phase occurs upon completion of DNA replication. At this point, somatic cells are tetraploid (i.e., have four copies of DNA) and are destined to divide.

DNA Damage Checkpoint

The S-phase checkpoint is fallible, so a partially redundant checkpoint exists during the G2 phase. ATM/ATR kinases also act as G2-DNA damage sensors. Lymphocytes that undergo physiologic DNA double strand breaks during antigen receptor gene rearrangement are particularly susceptible to chromosomal instability, which is why patients with ataxia telangiectasia have hypofunctional adaptive immune responses and a significantly higher risk of developing cancer.[2] The primary G2-DNA damage effector kinase is Chk1, which controls G2-phase progression and M-phase entry, primarily by phosphorylating the CDK-regulatory Cdc25 phosphatases.

Preparation for Mitosis

Proper chromatid alignment and association are necessary for normal separation during mitosis. Spindle assembly and the spindle checkpoint are regulated by CDK1 in conjunction with the Aurora A and Aurora B kinases, respectively. Aurora C kinase controls chromosomal segregation in mitosis.

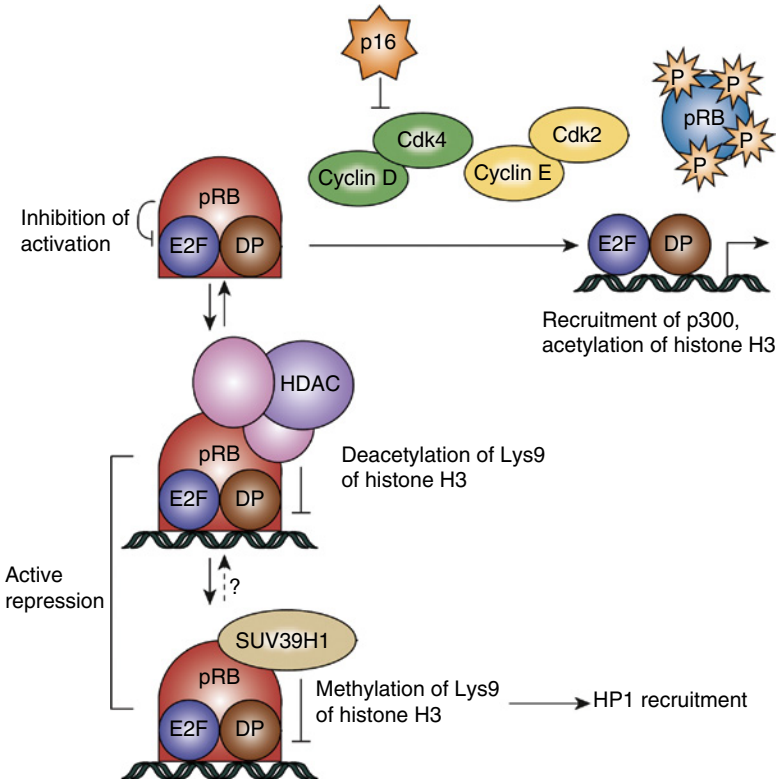

FIGURE 57.2 General mechanisms that control the repressive activity of E2F. The retinoblastoma protein binds to an E2F–DP complex in G0/G1 cells and this leads to repression of E2F-responsive genes through two possible mechanisms. First, phosphorylated RB (pRB) inhibits E2F from activating transcription by binding to its transactivation domain and preventing its interaction with the core transcriptional machinery. Second, the resulting complex binds to the promoters of E2F-responsive genes and enforces their "active repression" through recruitment of either histone deacetylases (HDACs), which remove the acetyl group from lysine 9 (Lys9) of the histone H3 tail and thereby facilitate nucleosome packing, or SUV39H1, which methylates the same lysine residue to create binding sites for HP1, leading to transcriptional silencing. Cell-cycle entry is dependent on the sequential activation of the cell-cycle-dependent kinases, CDK4/CDK6–cyclin D and CDK2–cyclin E, which phosphorylate RB and cause it to release E2F. The resultant activation of E2F-responsive genes seems to be at least partially dependent on the ability of E2F to recruit p300, leading to the acetylation of Lys9 of histone H3. Several key components of the pRB regulatory pathway are known to be tumor suppressors (pRB, p16) or oncogenes (cyclin D, CDK4). DP, differentiation-regulated transcription factor (DRTF) protein; pRB, retinoblastoma protein. (**Source:** Reproduced from Trimarchi and Lees[21] with permission. ©Macmillan)

M-PHASE PROGRESSION

Chromatin condensation occurs throughout the cell cycle until the onset of mitosis, when the chromatin is packaged into species-specific units called chromosomes. M-phase progression begins with the dissolution of the nuclear membrane, continues with the assembly of the mitotic spindle, and culminates with division into two daughter cells, each with a diploid complement of DNA.

Prophase

Breakdown of the nuclear envelope proceeds at the end stage of chromosome condensation by phosphorylation of lamins. This precedes spindle formation, which is mediated by complex interactions of microtubules and kinetochores. Centromeres allow chromosomes to attach to the spindle, a process that also may be controlled through Aurora B kinase and Survivin.[1]

Metaphase

As cells approach metaphase, chromosomes align along the spindle at equal distance from each pole to form the traditional metaphase plate in a process called *congression*.

Anaphase

Cyclin B is rapidly degraded by the anaphase-promoting complex (APC), which functions as an E3 ubiquitin ligase; this is followed by separation of sister chromatids. Anaphase-promoting complex activity is restrained by the spindle checkpoint until kinetochore alignment is complete. Sister chromatid separation is itself a complex process and is controlled at least in part by DNA topoisomerase II. The importance of this enzyme in mitosis is underscored by the exacting sensitivity of cancer cells to camptothecin and other topoisomerase II inhibitors.

After the separation of sister chromatids, there is little resistance for chromosome segregation toward the

poles. Vesicles on the chromosomes promote reformation of the nuclear envelope and cytokinesis ensues as CDK1/cyclin B activity subsides. Each daughter cell can then resume its normal function or re-enter the cell cycle.

THE CELL CYCLE AND CANCER

Cancer is a condition where cells divide uncontrollably, making it easy to see how it can be linked to abnormal cell-cycle function. Common abnormalities include inactivation of CDKIs through mutation or deletion, inappropriate expression of D-type cyclins, inactivation of Rb, and malfunction of DNA damage checkpoints, among others.[10] Not surprisingly, these gross abnormalities are prognostic, but even subtle quantitative differences in cyclin expression, Rb phosphorylation, etc., can influence tumor progression and serve as useful indicators of prognosis for hematopoietic tumors.[14] Indeed, studies from our laboratory suggest that gene expression signatures that are indicative of aberrant cell-cycle regulation are hallmarks of canine high-grade B-cell malignancies and canine osteosarcomas that respond poorly to conventional therapy.[6,18]

Acronyms and Abbreviations

2,4-D, 2,4-dichlorophenoxyacetic acid; BLV, bovine leukemia virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; VDL, Veterinary Diagnostic Laboratory.

The simplest definition of epidemiology is the study of factors which define a population's risk of susceptibility to a given disease. Both genetic and environmental influences are usually important, particularly when identifying risk factors for neoplasia. Epidemiology data have inherent uncertainty, as they seek to identify the probability that disease will develop within a given population or the risk of one population to develop a particular disease as compared to another population without that risk. The predominant statistical terms used in cancer epidemiology are relative risk and absolute risk. Relative risk is the comparison between two groups: one group has a given risk factor and the other group does not. Absolute risk is the probability that cancer will develop within a defined period of time. If the period of time is from birth to death, it is referred to as lifetime risk (Figure 58.1). In order to establish risk factors, data from a test population are compared to a reference population. Replication of the data is required for validation. The ultimate goal is to have the most representative group to which other populations can be objectively compared. There are vast amounts of information of this type available for neoplasia in human beings; however, it is significantly lacking for other species.

Epidemiology of hematopoietic neoplasia in domestic animals is an understudied area. By far, the most information available is for dogs. Yet, even in dogs, the most current database regarding a reference population is 40 years old. The reference population itself has changed considerably and needs to be updated to reflect: (1) breed popularity changes; (2) changes in breeding practices to produce different desirable traits; (3) changes in production management and husbandry practices; (4) popular sire effects; (5) development of new breeds, and breeds from narrow gene pools; (6)

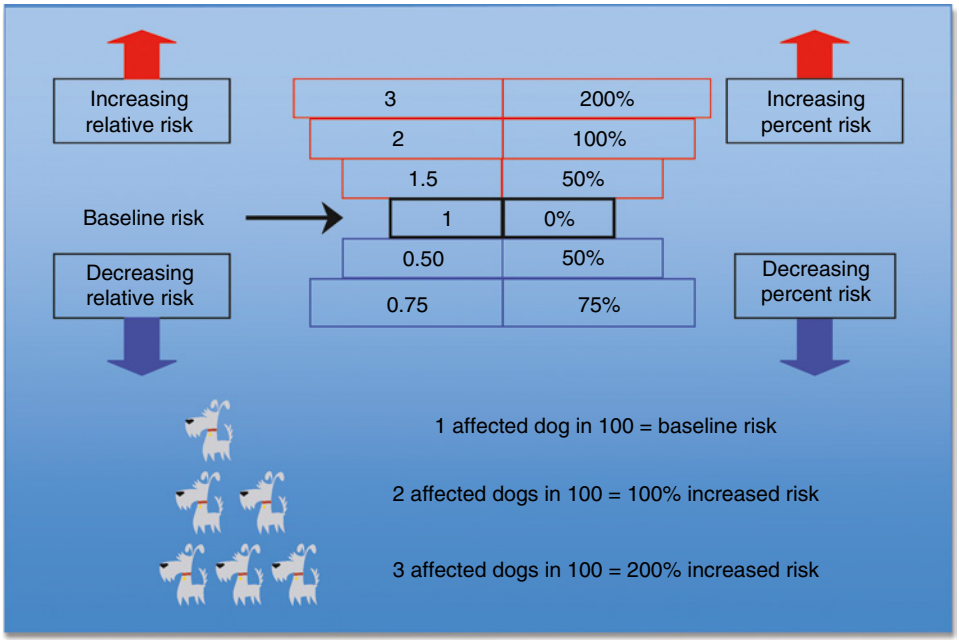

FIGURE 58.1 Two different ways of looking at cancer risk. In the upper portion of the figure, baseline relative risk is equivalent to 1% or 0% risk in the population. When risk increases to 50%, relative risk increases by 1.5× the baseline. When the overall risk decreases by 50%, relative risk decreases to 0.5× the baseline. In the bottom portion of the figure, this is represented by the example of a baseline risk of one affected dog in a given population of 100 dogs: when two dogs are affected, the risk increases by 100%; when three dogs are affected, the risk increases by 200%.

geographical changes; and (7) changing infectious disease influences. More recent studies generally have involved significantly smaller numbers of animals and have not been based on reference populations. This means many specific risk factors will be difficult to identify.

HEMATOPOIETIC NEOPLASIA EPIDEMIOLOGY BASED ON A REFERENCE POPULATION

A pioneering study on cancer epidemiology in dogs and cats was the first of its kind to investigate the implications of sex and age in a defined population in 1968.[4] Although the data encompassed a limited geographical region, this paper was among the first to describe a higher incidence of cancer in purebred dogs compared to mixed breeds. Above all, this paper underscored the need for a more geographically comprehensive reference regarding the susceptibilities and risks of domestic animals for developing neoplasia. A much broader study and the only animal cancer reference population still available today comes from a compilation of data from 15 veterinary schools in the USA and Canada through the years 1964–1977.[22] The geographical bias is somewhat minimized, however, by comparing animals from schools from a diverse group of geographic locations.

Reference Population Information for Dogs

In dogs with hematopoietic neoplasms, lymphoma represented the most cases (1324), followed distantly by hemangiosarcoma of the spleen (referred to as angiosarcoma) with 165 cases, and leukemia (subclassifications not defined) at 151 cases. Breeds that represented the highest risk for lymphoma, leukemia, and hemangiosarcoma (spleen) included Boxers, Basset Hounds, and St. Bernards, which were three to four times as likely as all breeds combined (reference population) to develop these cancers. Breeds twice as likely to develop lymphoma, hemangiosarcoma, and leukemia included Scottish Terriers, Bulldogs, Airedales, Weimaraners, Golden Retrievers, Doberman Pinschers, Labrador Retrievers, English Setters, and Great Danes. Dogs considered less likely to develop these tumors (relative risk <1) were mixed breeds, Miniature and Toy Poodles, Pomeranians, Chihuahuas, Boston Terriers, Cocker Spaniels, and Dachshunds.

When hemangiosarcoma was evaluated separately from leukemia and lymphoma, breeds with the highest risk (two to three times greater) included: Boxers, Great Danes, German Shepherds, English Setters, Golden Retrievers, Pointers, and German Shorthaired Pointers. Breeds with decreased risk included Miniature Schnauzers, Brittany Spaniels, Cocker Spaniels, Beagles, Boston Terriers, Miniature and Toy Poodles, Dachshunds, and Pekingese, with Chihuahuas showing the lowest risk.

There were 202 cases of mast cell tumors in the skin and 162 cases of cutaneous hemangiosarcoma in the database. The relative risk was similar to hematopoietic and lymphatic neoplasms; however, spayed females were 1.3 times more likely to develop these tumors. Also, it should be noted that the incidence of mast cell tumors was only reported in dogs.

Hematopoietic tumors not considered in this study included plasma cell tumors and histiocytic sarcomas (with the exception of histiocytomas which were considered along with benign neoplasia). Histiocytomas were by far more prevalent in dogs than cats.

An independent study that reviewed the database of the Veterinary Medical Data Program from 1964 to 1989 to determine the incidence of neoplasia in dogs of 6 months of age or younger showed that cancers of the hematopoietic system were most frequent in this population.[13]

Reference Population Information for Cats

Lymphoma was reported in 657 cats. Manx cats were 4.6 times more likely than non-Manx cats, and Burmese were 3.1 times more likely than non-Burmese to develop lymphoma. Females, neutered and intact, had slightly lower relative risk than males. Four-hundred-and-seventeen cases of leukemia were identified. Mixed breed cats were 1.3 times as likely to develop leukemia as purebred cats, and Persians were 1.2 times as likely as non-Persians to develop leukemia. Siamese cats had a lower relative risk than the average for the reference population. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) status was not evaluated.

Reference Population Information for Horses

Forty-eight cases of equine lymphoma were recorded, as were five cases of leukemia. Appaloosas, mixed breeds, and Standardbreds were 1.7, 1.5, and 1.2 times as likely to develop lymphoma, respectively. Mares were 1.6 times as likely as geldings and stallions to develop lymphoma.

Reference Population Information for Cattle

There were 332 cases of bovine lymphoma and 56 cases of bovine leukemia recorded in the database. Gender was found to be the most significant risk factor. Steers were 3.8 times as likely as bulls, and cows were twice as likely as bulls to develop lymphoma. Bovine leukemia virus (BLV) status was not evaluated. Breeds at highest risk for lymphoma included Angus and Ayrshire (1.6×), Jerseys (1.5×), mixed-breed dairy and shorthorns (1.3×), mixed-breed beef and Holsteins (1.2×), while Guernseys, Herefords, and Charolais had lower relative risk.

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN DOGS

Lymphoma

Environmental Risk Factors

Because it is one of the most common malignant neoplasms affecting domestic dogs, lymphoma has been very extensively studied in dogs (see Chapters 62, 67, and 70). Many attempts have been made to associate lymphoma with environmental risk factors; however, none has been conclusively verified. One environmental risk factor evaluated was exposure to the lawn herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). Although one study found a relationship, a subsequent re-evaluation was unable to confirm the association.[10,12] An association between exposure to electromagnetic fields and the subsequent development of lymphoma in dogs was published, but follow-up studies have not been performed to validate that connection.[24]

A study retrospectively performed in the Tuscany region of Italy evaluated dogs with residential exposure to environmental pollutants from 1996 to 1998.[6] The results of this study suggested that there might be an increased risk of lymphoma in dogs living in or near industrial areas and dogs that may have had environmental exposure to household paints and solvents. However, the study's findings were subject to bias recall on the part of the dogs' owners (information obtained by questionnaires and telephone interviews), and specific information regarding types of chemical exposure and amount of exposure was not investigated. The authors of this study affirm that additional investigation is warranted to validate these potential associations.

Genetic/Heritable Risks

It has been postulated that perhaps no other species shows more variability and flexibility of its genome than the domestic dog.[20] *Canis familiaris* has, through selective breeding practices by humans, had its gene pool manipulated to produce more than 400 distinct breeds ranging in size from 2 kg to over 100 kg. Life expectancy, hair coat, skull and skeletal conformation, and behaviors all have been diversified in just 2800 years.[20] There is abundant evidence that humans also have altered dogs' susceptibility to cancer. Epidemiologic evidence for genetic risk factors for lymphoma in domestic dogs is currently limited to breed associations. The occurrence of tumors is sporadic; however, their development is affected to an extent by heritability. The prevalence of lymphoid neoplasms in dogs differs among breeds as does the frequency of B-cell and T-cell neoplasms; however, heritable risk factors have not been identified.

More recent information regarding hematopoietic cancers in dogs can be obtained from health surveys privately commissioned by specific American Kennel Club National Breed Clubs. This information is collected via voluntary recruitment of members of the national breed clubs who complete a written survey. The data are then compiled by statisticians and are presented as a health report for the specific breed club. These surveys are not normalized to a reference population and may contain considerable bias. Diagnoses are unable to be directly confirmed by the investigators and sometimes by a veterinarian, so there is considerable variation in the numbers of responses obtained. Nevertheless, taken within the context of their limitations, breed health surveys can provide further insight into the epidemiology of hematopoietic neoplasms in dogs.

Based on analysis of data for Golden Retrievers, Irish Setters, Rottweilers, Portuguese Water Dogs, English

Cocker Spaniels, and Gordon Setters, the risks for hematopoietic neoplasia were combined to include lymphoma, mast cell tumors, and hemangiosarcoma.[7,8,27–30] A meta-analysis of the available data, using the chi-squared test, indicates Golden Retrievers have the highest risk of the three hematopoietic tumors combined, followed distantly by Gordon Setters, which, in turn, were at higher risk than Portuguese Water Dogs, Rottweilers, and Irish Setters.[27–30] The last three breeds were roughly equivalent in prevalence for these hematopoietic tumors. When the prevalence of lymphoma was considered separately from mast cell tumors and hemangiosarcoma, the rank order of apparent breed risk did not change. When a nonhematopoietic neoplasia such as osteosarcoma was evaluated using the same breed survey information, the rank order of breed risk changed considerably. Irish Setters had the highest absolute number of affected dogs followed by Golden Retrievers, Rottweilers, Gordon Setters, and, more distantly, by Portuguese Water Dogs. English Cocker Spaniels had an insignificant risk for osteosarcoma.

Geographic Risk Factors

There may be geographic risk factors; however, data are regionalized and sporadic. For example, Jagielski et al. found in a study of dogs admitted to the Warsaw Veterinary College between 1998 and 2000 that the odds ratio for Rottweilers to be diagnosed with multicentric lymphoma was sixfold greater than dogs from other breeds.[11] However, the study populations may not accurately reflect the general dog population in Poland or elsewhere. This information certainly is a valuable starting point for more thorough and controlled epidemiological studies; however, one must guard against overinterpretation of this type of data.

Similarly, a study comparing the lifetime occurrence of neoplasia in German Shepherd dogs and Belgian Malinois military working dogs (United States Department of Defense) during the year 1992 reported that more Belgian Malinois were diagnosed with lymphoma than were German Shepherd dogs and that more German Shepherd dogs were diagnosed with hemangiosarcoma.[21] The authors remind the readers that the study's limitations include that these dogs spend a proportion of their lives outside of the USA in various regions around the world, and that these dogs have a standard high-nutritional plane and level of fitness as well as handlers that are extremely vigilant over their welfare. Thus, these groups are being evaluated, as they relate to each other and the study's findings should not necessarily be generalized to the Belgian Malinois and German Shepherd dog breeds as a whole.

Investigators in Austria[9] classified subtypes of canine lymphoma and then compared their results with findings in other countries in Western Europe and found no difference in morphology and immunophenotype of lymphomas. They concluded from this information that Austrian dogs are unlikely to have significantly different risk factors than other canine populations in Western Europe.

Leukemia

Leukemia appears to be less common than lymphoma in the canine population and, although leukemia may be underdiagnosed, there is no new information on the specific epidemiology of this neoplasm since the study by Priester and McKay (see Chapters 63 and 65).[22]

Histiocytic Sarcomas

Cutaneous histiocytomas are associated with young dogs (<6 years of age) and are typically benign in nature. Breeds historically associated with a higher incidence of cutaneous histiocytoma include Boxer dogs and Bulldogs. Scottish Terriers, Doberman Pinschers, and Cocker Spaniels also have been suggested as breeds with higher risk to develop this neoplasm.[5]

The malignant counterparts of cutaneous histiocytic sarcoma are collectively known as the histiocytic sarcoma complex, which comprises a spectrum of malignancy rather than a static neoplastic process (see Chapter 71). The histiocytic sarcoma complex includes both localized and disseminated forms. Breeds at highest risk are reported to be Bernese Mountain Dogs, Golden and Flat-coated Retrievers, and Rottweilers.[5] It should be noted that histiocytic sarcomas are not related to malignant fibrous histiocytomas, which are classified with the tumor group of soft-tissue sarcoma.

Plasma Cell Tumors

An increased frequency of lingual plasma cell tumors was found in Cocker Spaniels.[3] This study evaluated 1196 cases of lingual lesions that were submitted to the Colorado State University Veterinary Diagnostic Laboratory (VDL) during the years 1995–2004. Previously, Cocker Spaniels were suspected of an increased risk to develop mucocutaneous plasmacytomas in a study of 75 cases published in 1989.[23]

Mast Cell Tumors

Mast cell tumors can occur in any breed of dog and mixed-breed dogs; however, there have been associations made with specific dog breeds that seem to have increased susceptibility (see Chapter 66). A study from Sydney, Australia considering data from 1989 to 2001 at the University Veterinary Center found that Boxers, Australian Cattle Dogs, and Staffordshire Bull Terriers were at a significantly higher risk for mast cell tumors.[1] Pugs, Boston Terriers, and other brachycephalic breeds also have been present in statistically significant numbers in other studies.

Hemangiosarcomas

Hemangiosarcoma has recently been suggested to originate from progenitor cells in the bone marrow rather than from endothelial lining cells of the organs in which the solid tumors have originated (see Chapter 72).[15] Recent evidence suggests that these tumors may merit

reclassification from the soft-tissue sarcoma group into the hematopoietic neoplasms. Interestingly, Priester and McKay also categorized lymphoma, leukemia, and hemangiosarcoma together in their publication in the late 1970s.[22]

Hemangiosarcoma is more common in dogs than any other species. Data from six consecutive years were used to evaluate the prevalence of canine hemangiosarcoma. Two-hundred-and-twenty-two canine samples of nonvisceral hemangiosarcoma (mostly cutaneous) received by the VDL at Colorado State University in 1996, 1997, and 2002 revealed equal numbers of male and female dogs affected. The most common breeds, when corrected for popularity bias, included Pit Bull Terriers (most common), and sighthounds (Whippets, Greyhounds, and Italian Greyhounds, specifically). The largest number of submissions came from Golden Retrievers and German Shepherd dogs. Lingual hemangiosarcoma risk was shown to be increased in Border Collies, while Beagles were shown to have an increased risk for concurrent lingual and cutaneous hemangiosarcoma.[3] Three-hundred-and-eight tissue samples of canine visceral hemangiosarcoma evaluated exclusively from year 6 of the VDL study showed an approximately equal sex distribution. However, the most common breeds affected were Golden Retriever (56 cases), Labrador Retrievers (45 cases), and then German Shepherd dogs (30 cases).[25]

Srebernik and Appleby[31] reported a retrospective study of 4535 cases of canine vascular tumors evaluated from 1968 to 1989 at the Royal Veterinary College (UK). This study showed a significantly higher risk among German Shepherd dogs for hemangiomas and hemangiosarcomas with roughly 66% of those cases being hemangiosarcomas. They also found that the spleen was the most frequent site in German Shepherd dogs with males being overrepresented. German Shepherd dogs had a lower frequency of cutaneous and subcutaneous hemangioma and hemangiosarcoma.

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN CATS

Lymphoma/Leukemia (Lymphoid Neoplasms)

Environmental

A recent questionnaire-based study suggested that cats with exposure of 5 years or longer to secondhand household tobacco smoke were 3.2 times more likely to develop lymphoma than cats from nonsmoking households.[2] Although some recall bias is inevitable in this type of study, it is more limited here, as the study focused on only one parameter of which the owners would have a firsthand knowledge. Nevertheless, this study needs to be further validated.

Infectious Diseases

Feline retroviruses as risk factors have had a significant impact on the development of lymphoid neoplasms in the cat. The so-called "feline leukemia virus infection era" comprises the late 1970s through 1983.[17] This period of time showed a high incidence of lymphoma, in particular, associated with FeLV infection. A retrospective study from 1968–1988 of 53 cats from the Pacific Northwest region with matched controls showed that cats infected with the FeLV virus had a 62.1 times greater risk of developing leukemia or lymphoma than cats that were uninfected.[26] Cats infected with both FeLV and FIV had an increased risk of 77.3 times greater than the control population for these neoplasms, and cats infected with FIV alone had a 5.6 times greater risk than uninfected cats.[26] After 1983, the impact of vaccination against FeLV and culling of infected animals determined by FeLV testing resulted in a significant reduction in FeLV infection. Cases of non-FeLV-associated lymphoma (i.e., thymic and alimentary lymphomas) began to rise in the feline population.[26]

Genetic/Heritable

Siamese cats and other related Oriental breeds have demonstrated an increased risk for development of mediastinal lymphoma at younger than 4 years of age in multiple studies.[17,26] Some cats were infected with FeLV.[26] Nevertheless, this information indicates a potential shift in breed risk in feline lymphoma compared to the reference population evaluated 40 years ago.[22] In that population, Siamese cats had a lower-than-average risk of developing lymphoma.

Mast Cell Tumors

Siamese cats are predisposed to mast cell tumors compared with other breeds.[19] In an assessment of 41 cats with mast cell tumors published in 2006, young Siamese cats were shown to be more likely to present with a military histiocytic form of cutaneous mast cell tumors.[16] It appears that visceral mast cell tumors (majority in the spleen) are more common in cats. Currently, there is no known association of infectious disease with mast cell tumor development.

Hemangiosarcoma

Hemangiosarcoma continues to be a rare tumor in cats and no specific risk factors have yet been identified in this species. Evaluation of 72 histopathological samples of hemangiosarcomas in cats submitted to the VDL at Colorado State University over a 6-year period showed that the majority of these tumors were cutaneous (59 out of 72), there was no noted sex predilection, and the average cat age was 10 years.[25]

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN HORSES

The only current information on epidemiology of lymphoma suggests that T-cell multicentric lymphomas are

more common than B-cell multicentric lymphomas in horses.[18] Hemangiosarcoma in horses is rare and no specific risk factors have yet been identified. A total of 11 samples of equine hemangiosarcoma were identified in the previously mentioned study by Schultheiss through the VDL at Colorado State University in a 6-year period.[25]

HEMATOPOIETIC NEOPLASIA RISK ASSESSMENT IN CATTLE

Lymphoma

The only hematopoietic neoplasia of clinical importance in cows, based on the literature to date, is lymphoma. One risk factor identified in cows for lymphoma is infection with BLV. It is estimated that 2–5% of BLV cows develop lymphoma, representing about 5200 cows/year in the state of California alone.[14]

CONCLUSIONS

The paucity of specific data based on an updated reference population regarding hematopoietic neoplasia in domestic animals underscores the need to define specific risk factors for these diseases. By linking large databases with updated communication technology, and by addressing factors affecting populations of domestic animals that have relevance to development of hematopoietic cancer, more accurate perceptions of risk can be ascertained. Changes in breeding practices and husbandry based on better-defined risk factors can then be implemented to help reduce the incidence of hematopoietic neoplasia for those animals that are significantly threatened. In the big picture, by deepening our understanding of susceptibility to cancer, we also come to understand its nature more profoundly, which will lead us to earlier diagnosis and, ultimately, more effective therapy.

Acronyms and Abbreviations

DNA, deoxyribonucleic acid; HIF, hypoxia-inducible factor; IL, interleukin; LOH, loss of heterozygosity; LTR, long terminal repeat; mRNA, messenger RNA; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; RCND, renal carcinoma and nodular dermatofibrosis; VEGF, vascular endothelial growth factor-A; VEGFR, vascular endothelial growth factor receptor; VHL, von Hippel–Lindau (tumor suppressor gene).

It is now clear that cancer is a disease driven by the accumulation of genetic abnormalities.[41] Hundreds of genetic abnormalities that are peculiarly associated with specific cancers have been identified. In fact, technological advances, such as high-throughput methods, have allowed full sequencing of tumor genomes.[28] During the past decade, a vast amount of sequencing data has been generated. Consequently, the process of statistically integrating diverse sources of information arising from the genome, such as genetic, epigenetic, and transcriptomic data, is becoming increasingly prevalent. The information from these experiments has reinforced current concepts and provided insight into new areas of research. This chapter will focus on how interactions between genes and environment impact the origin, progression, and response to therapy of hematopoietic tumors.

GENES AND CANCER RISK

To understand cancer, one must first realize this is neither a single nor a simple disease. Rather, the term cancer describes a large number of diseases whose only common feature is uncontrolled cell growth and proliferation. An important and universally accepted concept is that cancer is a genetic disease, although it is not always heritable. Tumors arise from the accumulation of mutations that eliminate normal constraints of proliferation and genetic integrity in a somatic cell. Among other causes, mutations can arise due to the inherent error rate of enzymes that control DNA replication, which introduces from one in ten million to one in a million mutations for each base that is replicated during each round of cell division. Most mammalian genomes comprise two to three billion base pairs, so every time a cell divides, each daughter cell is likely to carry at least a few hundred mutations in its DNA. Most of these mutations are silent; i.e., they do not hinder the cell's ability to function. However, others can disable tumor suppressor genes or activate protooncogenes that respectively inhibit or promote cell division and survival.

Heritable Cancer Syndromes

The existence of genetic predisposition to cancer is illustrated by well-defined heritable cancer syndromes.[11] Even though they account for fewer than 5% of all

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

human cancers, studies of families with these syndromes provided many of the initial clues to understand the genetic basis of sporadic (nonheritable) cancers. Although inheritance is recessive, these familial cancer syndromes show dominant patterns of inheritance and have high penetrance. All but two of the known familial cancer syndromes are due to mutations that inactivate tumor suppressor genes. As originally proposed by Knudson in his "two-hit" hypothesis from studies in children with retinoblastoma,[24] individuals at risk are obligate heterozygotes (they inherit a mutant allele and a wild-type allele). As it happens, homozygous mutations in critical growth-regulatory genes usually cause embryonic lethality; but in the case where a single allele is affected, the mutation is present in every cell in the body. Given the rate of spontaneous mutation described in the earlier text, the probability that the second, wild-type allele will be inactivated in at least one cell is extremely high, therefore facilitating tumorigenesis. This process is called loss of heterozygosity (LOH).

A mutation in a single gene can predispose individuals to distinct cancer syndromes, while independent, single mutations of different genes can result in virtually the same disease.[11] This is not surprising when we consider that commonly affected genes are multifunctional and are parts of complex interactive networks or circuits, so a mutation may only alter gene function along one biochemical pathway, leaving its interactions with other pathways intact. Moreover, mutations that contribute to most sporadic cancers are restricted to a small subset of genes, many of which also are associated with heritable cancer syndromes.

At least one heritable cancer syndrome (renal carcinoma and nodular dermatofibrosis [RCND]) has been described in German Shepherd dogs.[29] The heritable factor (or *RCND* gene) for this syndrome maps to dog chromosome 5 (CFA 5), and specifically to the folliculin gene, which was recently described as corresponding to the human disease (Birt–Hogg–Dubé syndrome).[37]

Genetic Influence in Sporadic Cancers

Both the environment and the individual's peculiar genetic background influence cancer risk and the natural history of tumors. This is especially clear in mice, where the relative rate of spontaneous cancers and the susceptibility to chemically induced cancers differ according to the genetic background of various inbred strains. Similar evidence exists for humans; for example, the risk of habitual smokers to develop lung cancer is tightly linked to a unique allele encoding the alpha-3 subunit of the high-affinity nicotinic receptor.[1] There also is evidence to suggest that in some cases mutations are "directed" due to the presence of a "mutator phenotype," where the factors that control DNA replication and repair are prone to more errors than would be expected by simple random events. This leads to different rates of cancer predisposition, which would be higher than the mean in individuals bearing this mutator phenotype, and might explain why not all people or animals exposed to similar environmental carcinogens develop the same forms of cancer at the same rate.[30]

In dogs and other domestic animals, the coexistence of genetic isolates in closed populations we call breeds, along with animals of mixed breeding, lends itself to study how a relatively homogeneous background influences cancer in outbred populations. Published data from whole genome association studies suggest there are distinct heritable traits that segregate with common cancer phenotypes in dogs.[22,40,53] Some of these traits are shared between closely related breeds, whereas others seem to contribute to risk independently in different breeds. Perhaps more importantly, dogs are the first species where genetic background has been shown to mold tumor genomes and tumor gene expression profiles.[33,50,52] Together with the demonstration that causal, pathognomonic genetic abnormalities are conserved in homologous human and canine cancers, this opens up a new area to identify the precise contribution of heritable traits to sporadic cancers using comparative systems approaches.

THE HALLMARKS OF CANCER

Six essential, acquired characteristics are necessary for cellular transformation (Figure 59.1).[17] These characteristics are: (1) the ability to sustain proliferative signaling; (2) the evasion of growth suppression; (3) the ability to resist cell death; (4) the capacity to enable reproductive immortality; (5) the ability to induce angiogenesis; and (6) the capacity to invade tissues and metastasize. Some of the important concepts that are clarified by this list include: no single gene is universally responsible for transformation; five or six mutations are the minimum probable number required to endow the cancer phenotype; each step is regulated by multiple interactive biochemical pathways; thus, mutations of different genes along a pathway can result in equivalent phenotypes, and, conversely, mutations of the same gene can result in different cancers with distinct biology; tumors behave as tissues, and the interactions between the tumor and its microenvironment are major drivers of cancer behavior.

Sustaining Proliferative Signaling

The production and release of growth-promoting signals that lead to entrance into and progression through the cell-growth-and-division cycle are accurately controlled by normal tissues, thereby ensuring a homeostasis of number and thus maintenance of normal tissue architecture and function. Cells communicate with each other and integrate environmental signals by sensing cues and gradients. For example, migration, metabolism, and proliferation of mature hematopoietic cells are regulated in autocrine and paracrine fashions by locally secreted cytokines. The same cytokines may travel systemically and act in an endocrine fashion. Generally,

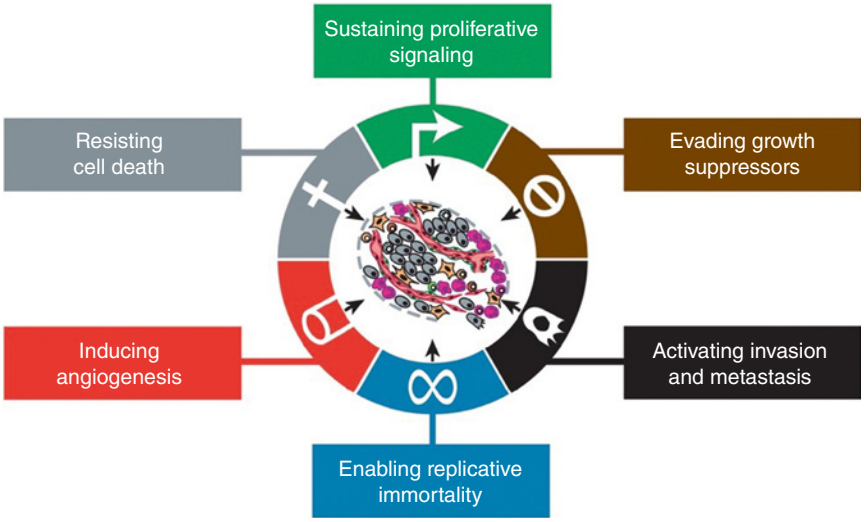

FIGURE 59.1 Acquired capabilities of cancer. Most, if not all, cancers acquire the same set of functional capabilities during their development, albeit through multiple mechanistic strategies. (**Source:** Reproduced from Hanahan and Weinberg[17] with permission. ©Elsevier.)

the cytokines work by binding transmembrane receptors, which in turn initiate signaling cascades that culminate in transcriptional changes. The activities of these cytokines, their receptors, and the corresponding signaling molecules are finely tuned. The system can be shut down when the concentration of the cytokine falls below a threshold that can stably bind the receptor, when the receptor ceases to be expressed, or when signaling molecules are downregulated or otherwise inactivated. High-throughput DNA sequencing analyses of cancer cell genomes have revealed somatic mutations in human and companion animal tumors that predict constitutive activation of signaling circuits, usually triggered by activated growth factor receptors. This capability to sustain chronic proliferation is the most fundamental trait of cancer cells. Among many examples, there is a translocation between chromosome 2 and chromosome 5 (t(2;5)) that is present in almost half of human anaplastic lymphomas. The translocation creates a fusion protein between the nucleophosmin gene (*NPM1*) and the anaplastic lymphoma kinase gene (*ALK*), which aberrantly activates the JAK2/STAT5 signaling pathway[47] that is normally responsive to various interleukins (IL) including IL-2, IL-3, and IL-6. The genes that encode the normal growth-promoting proteins (such as *ALK*, JAK2, and STAT5) are called *protooncogenes*; the mutated versions that allow cells to gain self-sufficiency from the environmental signals are called oncogenes. It is important to note that not all growth-promoting genes have the capacity to become oncogenes and that the outcome of oncogenic activation is most commonly apoptosis, unless there are additional events that promote stable transformation and survival.

Evading Growth Suppressors

To maintain homeostasis, cells also must integrate antigrowth signals from the environment. As noted in the previous section, quiescence in nonhematopoietic cells is enforced by signals delivered by contact inhibition. Hematopoietic cells, on the other hand, utilize cell–cell contacts to maintain interactions within the niche and to regulate the timing and intensity of hematopoiesis, inflammation, and immunity.[35] Stop signals are usually delivered and integrated by the products of tumor suppressor genes, which derive their name largely from the observation that their inactivation facilitates tumor formation. Tumor suppressor genes balance the activity of growth-promoting protooncogenes and tend to act in tandem with these in most biochemical pathways. Loss of function of one or more tumor suppressor genes occurs in virtually every cancer, with inactivation of *p53*, *RB-1*, *PTEN*, or *CDKN2A* each seen in >50% of all tumors. Each of these pathways may contribute to the pathogenesis of bone-marrow-derived tumors in companion animals, and their dysfunction also may be predictive for outcomes.[9,26,27,34]

Resisting Cell Death

Apoptosis, or programed cell death, is the imprinted outcome for every cell in multicellular organisms. Survival requires support from extrinsic (environmental) factors, as well as precise balance of cellular energetics and metabolism. Bone-marrow-derived cells normally undergo apoptosis when concentrations of survival factors (stem cell factor, IL-3, IL-7, etc.) or nutrients are limiting, or when there are severe disruptions to cellular bioenergetics. Evasion of apoptosis is an essential acquired feature of all cancers, and it can result from loss of pro-apoptotic tumor suppressor genes such as *p53* or *PTEN*, or by gain of function of anti-apoptotic genes such as *BCL2*.

Enabling Reproductive Immortality

Immortalization is another essential feature of cancer. The genetic program limits the number of times a cell is

able to replicate, the so-called Hayflick limit, that when reached induces replicative senescence. Induction of replicative senescence does not induce death; cells maintain energetic homeostasis and remain functional, but they undergo significant genetic changes characterized by telomere erosion. Cells that are able to replicate must maintain the integrity of telomeres, "caps" made of repetitive DNA sequence that protect chromosomes from destruction. Solid tumors acquire immortalization predominantly by activation of the telomerase enzyme system and the consequent maintenance of telomere integrity. In hematopoietic cells, telomerase activity seems to be retained longer than in other somatic cells, probably facilitating immortalization in lymphoma and leukemia.[39] Indeed, critically shortened telomeres, telomerase enzyme activation, and altered expression of telomere-associated proteins are common features in hematopoietic malignancies and are related with progression or chemotherapy drug resistance in these diseases.[55]

Inducing Angiogenesis

The process of angiogenesis requires the coordinated action of a variety of growth factors and cell-adhesion molecules in endothelial and stromal cells. So far, vascular endothelial growth factor-A (VEGF) and its receptors comprise the best-characterized signaling pathway in tumor angiogenesis.[12] VEGF binds two receptor tyrosine kinases, VEGFR-1 (Flt-1) and VEGFR-2 (KDR, Flk-1). VEGFR-2 is the major mediator of the angiogenic effects of VEGF. However, VEGFR-1 is expressed by some tumor cells and may mediate chemotactic signals, thus potentially having a role in cancer growth. The expression of VEGF is upregulated by hypoxia and inflammation. The transcription factor hypoxia-inducible factor-1 (HIF-1), which is part of a pathway that also includes regulation by the von Hippel–Lindau (VHL) tumor suppressor gene, is a major regulator of VEGF expression. Under conditions or normal oxygen tension, VHL protein targets HIF for degradation; under low oxygen conditions, HIF increases and VHL-mediated degradation is reduced, permitting upregulation of VEGF. Other signaling molecules that contribute to angiogenesis include platelet-derived growth factor-β (PDGF-β) and its receptor (PDGFR), and the angiopoietins. PDGF-β is required for recruitment of pericytes and maturation of new capillaries. Recent studies also document the importance of tumor-derived PDGF in recruitment of stroma that produces VEGF and other angiogenic factors (Figure 59.2).

Angiogenesis appears to be important in hematopoietic tumors. Patients with chronic lymphocytic leukemia responded to treatment with anti-angiogenic compounds,[36] followed by similar success for some patients with multiple myeloma.[11] Furthermore, different histologic types of human non-Hodgkin lymphoma show different patterns of angiogenesis, and these can predict outcomes.[46] Plasma VEGF levels have proved to be significantly higher in B- and T-cell lymphoma compared with healthy controls.[2] Notably, high-grade T-cell lymphomas, that usually harbor a poor prognosis, and high-stages B-cell lymphomas revealed higher VEGF mRNA and protein expression levels compared to low-grade T-cell lymphomas and low-stages B-cell lymphomas, respectively.[4] One study has shown that microvessel density is similarly correlated with aggressive behavior of canine lymphoma,[44] and similar findings have been reported for other blood-derived and solid tumors of dogs such as mast cell cancer and mammary cancer.[43,45]

Invasion and Metastasis

The role of genetic events in invasion and metastasis is still incompletely understood. The classical model of metastasis proposed by Fidler[14] suggests a stepwise acquisition of assets that enables cells to leave the primary tumor site, travel through blood or lymph, invade stroma in favorable locations, and thus become re-established at distant sites. More recent work suggests that most tumors possess the ability to dislodge cells that travel to distant sites, and the ability of such cells to survive in capillary beds may be the most important step in the metastatic process.[23]

Bone-marrow-derived cells have intrinsic properties that allow them to travel throughout the body, traffic through all major organs, and home to areas of inflammation. Thus, bone-marrow-derived tumors are inherently metastatic. Nevertheless, hematopoietic tumors that are cytologically indistinguishable can have distinct and preferential tissue distribution. We do not fully understand what events make leukemic cells stay in the circulation, while cells from corresponding lymphomas (or myeloid sarcomas) with virtually identical molecular signatures stay confined to lymphoid or visceral organs.

MOLECULAR EVENTS IN CARCINOGENESIS

Various models have been proposed to explain how cells acquire the features that lead to neoplastic transformation and eventually to clinical cancer. One model describes the process as stepwise accumulation of mutations that reduce constraints on growth and eventually promote transformation. Although this model is overly simplistic and technically flawed, it is nevertheless useful to convey the events that lead to carcinogenesis.

Initiation, Promotion, Progression

Unlike diseases due to single-gene defects, cancer is a complex, multigenic disease. The initiation, promotion, and progression model was among the first to propose a sequential progression of mutations that could account for cancer.[54] In this model, a genetic event would endow a somatic cell with limitless replicative potential or another growth or survival advantage from other cells in its environment (initiation). Alone, this would not be sufficient to give rise to a tumor, as the cell would remain

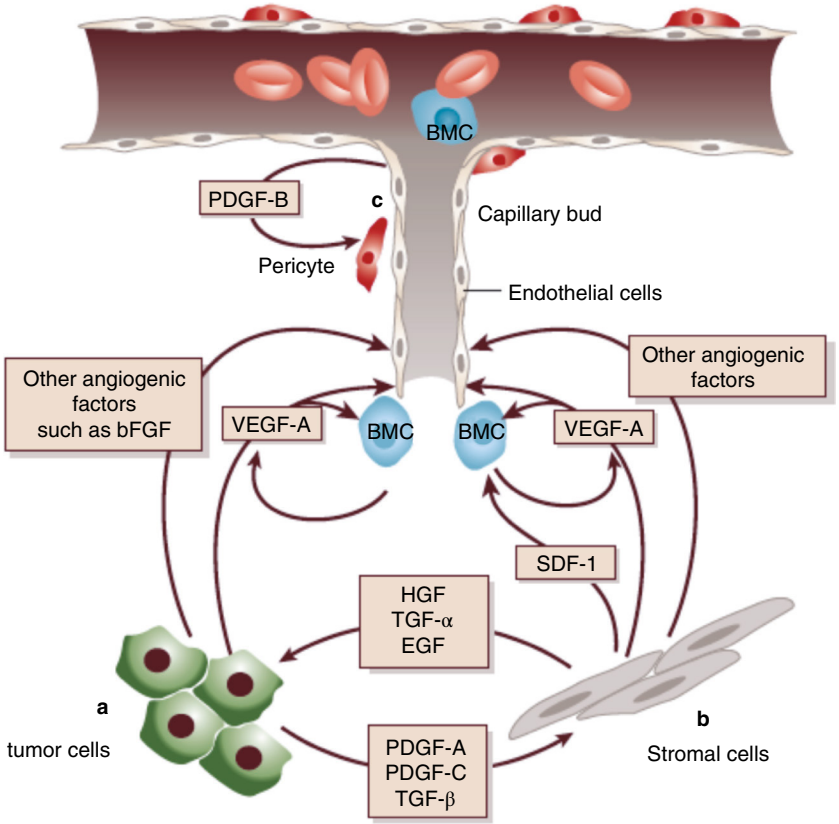

FIGURE 59.2 Molecular and cellular components of the tumor microvascular environment. (a) Tumor cells produce VEGF and other angiogenic factors such as basic fibroblast growth factor (bFGF), angiopoietins, and interleukin-8. These stimulate resident endothelial cells to proliferate and migrate; (b) An additional source of angiogenic factors is the stroma. This is a heterogeneous compartment, comprising fibroblastic, inflammatory, and immune cells. Recent studies indicate that VEGF, as well as chemokines produced by tumor-associated fibroblasts, recruit bone-marrow-derived angiogenic cells (BMC). A well-established function of tumor-associated fibroblasts is the production of growth/survival factor for tumor cells such as epidermal growth factor (EGF), transforming growth factor-α (TGF-α), hepatocyte growth factor (HGF), and heregulin; (c) Endothelial cells produce PDGF-β, which promotes recruitment of pericytes in the microvasculature after activation of PDGFR. Tumor cell death will lead to dissolution of blood vessels and release of endothelial cells into the circulation. (**Source:** Reproduced from Ferrara and Kerbel[12] with permission. ©Macmillan.)

constrained by environmental factors. A second event would further add to the cell's ability to outcompete its neighbors in this environment, leading to its potential expansion into a recognizable tumor mass (promotion). Finally, a third event would reinforce the cell's malignant potential (invasion, tissue destruction, and metastasis), leading to clinical disease (progression). It is important to note that an "event" is not equivalent to a single mutation, but rather is more likely to represent a series of mutations that act in concert to alter the cell's functional and morphological phenotype.

In recent years, mimicking human studies, significant efforts have been directed at identifying key mutations in canine osteosarcoma,[15] melanoma,[19] ameloblastoma,[41] hemangiosarcoma,[32] and lymphoma,[7,10] also assessing the evolution of the mutational pattern from initiation to progression and metastasis.[15,16,57] Two studies investigated somatic mutations by exome sequencing in canine lymphoma. The first study[7] identified TRAF3 gene as being commonly mutated in both dog and human B-cell lymphomas. The second study[10] detected the presence of recurrent mutations on TRAF3–MAP3K14, FBXW7, and POT1 gene loci in Cocker Spaniels and Golden Retrievers, highlighting the crucial role of breed predisposition and genetic risk factors.

Genetic Instability

The stepwise model of clonal evolution is satisfying because it can be correlated with discrete pathological changes in tumor progression, especially for epithelial tumors where such progression can be seen in lesions that go through stages of hyperplasia, atypical hyperplasia (dysplasia), adenoma, carcinoma in situ, invasive carcinoma, and metastatic carcinoma. However, analysis of tumor genomes even in early stages usually shows aneuploidy (abnormal DNA copy number) as well as chaotic changes indicative of multiple numerical and structural DNA abnormalities. Similar abnormalities first noticed by Boveri more than 100 years ago in studies of sea urchin cells, which are described in a recently reprinted, annotated version of the original 1914 article translated into English,[6] led him to formulate the aneuploidy theory of cancer. We know now that

aneuploidy is especially evident in solid tumors; based on this, Loeb proposed the existence of a "mutator phenotype" where cells are predisposed to undergo multiple mutations, some of which inevitably lead to cancer.[30] Some tenets of his hypothesis appear to be correct; however, direct measurements of mutation rates of sporadic tumors are much lower than those predicted if a "mutator phenotype" was operative in these tumors.

Still, genetic instability is a hallmark of most tumors, and while it can be partly explained by increased errors in DNA replication and chromosomal segregation in cells that are rapidly dividing, other mechanisms are clearly operative, involving telomeres and telomerase, as well as mechanisms of DNA replication and repair and chromosomal segregation. Although many of these changes are not recurrent and appear to be random products of instability, some may in fact contribute to proliferative crisis.[31] It is possible that the initiation events for many tumors occur early in life during highly proliferative stages of tissue growth and remodeling, but they become evident late in life when a last series of mutations allows the transformed cell to reach this crisis stage. As we inferred in the earlier text, human hematopoietic tumors seem to avoid the chaotic chromosomal instability associated with solid tumors: the same trend has also been observed in canine non-Hodgkin lymphomas.[3,51] We do not fully understand the reasons for this, although it may be partly due to intrinsic protective mechanisms associated with the proliferative rate of bone marrow precursor cells.

Epigenetic Events

Another observation is that events leading to cancer need not necessarily be caused by mutational events, and advances in epigenetic analysis of tumor genomes using high-throughput DNA sequencing have provided the compelling demonstration that cancer cells harbor global epigenetic abnormalities, in addition to numerous genetic alterations. Epigenetic events are those that can alter phenotype without changing the genotype. Two well-characterized epigenetic mechanisms regulate gene expression. Gene silencing can occur by methylation of CpG residues in promoter regions, as well as by histone deacetylation. Both of these events interfere with the transcriptional machinery and repress gene expression. Silencing specific genes by methylation is implicated in numerous cancers of humans and animals.[42] One important observation is that most (or all) genes that are subject to silencing by methylation in specific cancers (e.g., *CDKN2A* in T-cell leukemia) are commonly inactivated by mutation or deletion in other cancers (e.g., *CDKN2A* in melanoma). DNA methylation profiling studies in canine diffuse large B-cell lymphomas have revealed tumorigenic and stem-cell-like signatures, highlighting the presence of putative subgroups with prognostic relevance.[3,13]

Genomic imprinting presents a unique example where heritable epigenetic changes influence cancer predisposition. Genomic imprinting refers to a pattern of gene expression that is determined by the parental origin of the gene; in other words, unlike most genes where both parental alleles are expressed, only one allele of an imprinted gene is expressed and the other one is permanently repressed. Epigenetic changes in Wilms' tumor and in heritable colon cancer (among others) alter the expression of the imprinted allele, leading to loss of imprinting that causes overexpression of the insulin growth factor-2 (*IGF2*) gene.[42]

CANCER STEM CELLS

Unlike diseases that arise from single-gene defects, cancer is a complex, multigenic disease. In fact, a sequential progression of mutations is required to produce a tumor cell. We can think of many genes contributing to, rather than causing, the origin and progression of cancer. This model is consistent with many aspects of the natural behavior of tumors, and, to some extent, it can predict risk and outcome.

A competing theory now exists whose main tenet is that self-renewal is limited to a small population of cancer stem cells.[5,8,20] The existence of cancer stem cells is documented; they are characterized both by peculiar phenotypes and by defined sets of mutations of a small number of genes.[20] Other mutations then endow their progeny with limited or extensive capacity to undergo programed differentiation, hence resulting in distinct clinical phenotypes such as acute and chronic leukemias or high-grade and low-grade solid tumors. The strongest evidence for cancer stem cells comes from hematopoietic tumors, but cancer stem cells also have been identified in various solid tumors.[48] The origin of cancer stem cells is among the most important contemporary topics of cancer investigation. Cancer stem cells may arise from mutations that occur in bona fide stem cells, they may arise by de-differentiation of somatic cells that acquire mutations endowing them with stem-cell-like properties, or they may develop by fusion of a transformed cell and a bone-marrow-derived stem cell. In companion animals, putative cancer stem cells have been identified in hemangiosarcoma,[25] osteosarcoma,[56] brain tumors,[49] and lymphoma.[18]

ADAPTIVE EVOLUTION IN THE TUMOR MICROENVIRONMENT

The clonal evolution theory[38] addresses the significance of sequential genetic changes providing growth and survival advantages, but to this we must add the fact that, in addition to these self-sufficient events that influence growth and survival, tumor cells must also evade predators, such as inflammation and the immune system. Tumors have the capacity to modulate stromal cells to support their own growth by providing a suitable matrix and an abundance of nutrients, while maintaining antitumor responses at bay. In addition, the immune inflammatory cells can also be recruited by the tumor and act as tumor-promoting agents. Tumors that

outgrow the capability of their immediate surroundings to support their growth will seek to become established in other favorable locations. Thus, adaptive evolution likely contributes to the anatomic distribution of hematopoietic tumors much as it does to the metastatic spread of solid tumors.

Acronyms and Abbreviations

ALSV, avian leukosis and sarcoma viruses; ALV, avian leukosis virus; ASV, avian sarcoma virus; ATL, adult T-cell leukemia; BLV, bovine leukemia virus; CAEV, caprine arthritis encephalitis virus; CIS, common insertion or integration site; DNA, deoxyribonucleic acid; EIAV, equine infectious anemia virus; ENTV, enzootic nasal tumor virus; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; GALV, gibbon ape leukemia virus; HAM/TSP, HTLV-associated myelopathy/tropical spastic paraparesis; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; IL, interleukin; JSRV, jaagsiekte sheep retrovirus; LRT, long terminal repeats; MHC, major histocompatibility complex; MMTV, mouse mammary tumor virus; MPMV, Mason-Pfizer monkey virus; MuLV, murine leukemia virus; RSV, Rous sarcoma virus; Sag, superantigen; SIV, simian immunodeficiency virus; STLV, simian T-cell lymphotropic virus; WDSV, Walleye dermal sarcoma virus.

Oncogenic retroviruses were first identified near the beginning of the 20th century when Rous and colleagues discovered that certain cancers could be transmitted between animals by the inoculation of cell-free extracts. Studies of these agents have resulted in many critical breakthroughs in the field of oncogenesis.

RETROVIRIDAE

Retroviruses are enveloped RNA viruses that replicate via a DNA intermediate that becomes integrated into the host genome. Seven genera of retroviruses are currently recognized.[5] Retroviruses exist both as exogenous

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

(nonintegrated) and endogenous forms (integrated provirus). Endogenous retroviruses integrated into the host DNA comprise 5–8% of the human genome, and perhaps more than 10% of the genome in other mammals.

General Retroviral Structure

Retroviruses are single-stranded, linear, positive-sense RNA viruses with 7–13 kb genomes.[2,5] All retroviruses contain *gag*, *env*, *pol*, and *pro* genes, while complex retroviruses also encode a variety of regulatory proteins. Viral RNA is characterized by the presence of R (repeated) and U (unique) regions at both ends of the genome that, once transcribed, result in identical copies being placed at each end of the newly produced DNA in a U3–R–U5 sequence to create long terminal repeats (LTRs). Long terminal repeats are used for integration into the host genome and serve as regulatory sequences for virus production.

Virions are approximately 100 nm in diameter. At the center is a highly condensed form of the genomic RNA in association with the nucleocapsid protein. The virion core also contains viral enzymes such as reverse transcriptase, integrase, and protease. The core is contained within a structural icosahedral capsid and then a matrix shell, both encoded by gag. The virion is enveloped by a lipid bilayer, encoded by env, which also produces distinctive glycoprotein cell-surface spikes that are critical for virus binding and entry.

RETROVIRAL LIFE CYCLE

The retroviral life cycle is complex and includes variations between different retroviruses; however, the basic template is similar.[2] Virus binds via a specific cell-surface receptor. Retroviral receptors are diverse and include ion transporters, cell differentiation markers, chemokine receptors, the transferrin receptor, and Fas-like receptors. Internalization and uncoating occur through fusion of the viral and plasma membrane or via endocytosis.

Reverse transcription of the RNA genome into double-stranded DNA uniquely defines the retroviridae. Reverse transcription is a complex, multistep process initiated by the creation of a negative-sense DNA strand. Following degradation of the viral RNA by RNase H, the negative strand serves as a template to create a double-stranded linear DNA. The double-stranded linear DNA is then transported to the cell nucleus and integrated into the host DNA as a provirus.

Viral RNA and protein are expressed from the integrated provirus using the normal cellular processes of transcription and translation. Transcription by the RNA polymerase II system results in a complete unspliced viral genomic RNA that can serve as the genetic material to be packaged into progeny virions or as the template for production of viral proteins. The latter may require RNA splicing and processing of precursor proteins.

RNA packaging into developing virions is driven through Gag interactions. Gag also controls the assembly of the viral protein products whether it occurs at the plasma membrane or in the cytoplasm. Virions assembled in the cytoplasm are then transported to the membrane for envelopment and release. During the process of release, host membrane proteins are frequently incorporated into the virion envelope and several have been shown to be functionally significant.

CLASSIFICATION OF THE FAMILY RETROVIRIDAE

The current classification by the International Committee on Taxonomy of Viruses uses physical and morphologic properties of the virion, organization and replication of the genome, and biologic properties such as host range to classify viruses.[5] The family Retroviridae contains two subfamilies. The Orthoretroviruses contain six of the seven genera, while Spumaretroviruses comprise only the spumaviruses.

Alpharetroviruses

Alpharetroviruses are simple retroviruses that encode only *gag*, *pro*, *pol*, and *env*. The *pro* and *gag* genes utilize the same reading frame. These C-type virions are assembled at the plasma membrane and do not appear to produce intermediate-stage cytoplasmic particles. The virion has a centrally located, condensed, spherical core and surface projections of intermediate prominence. Key examples of this genera include avian leukosis virus (ALV), Rous sarcoma virus (RSV), and avian sarcoma virus (ASV).

Betaretroviruses

Betaretroviruses are also simple retroviruses but have a B- or D-type virus morphology; they are assembled within the cytoplasm, transported to the plasma membrane, and become enveloped during budding. B-type virions are characterized by a condensed, eccentric core and have prominent surface envelope projections. The *gag*, *pro*, *pol*, and *env* genes are found in different reading frames. Viruses of significance include mouse mammary tumor virus (MMTV), Mason-Pfizer monkey virus (MPMV), jaagsiekte sheep retrovirus (JSRV), and enzootic nasal tumor virus (ENTV) of sheep.

Gammaretroviruses

Gammaretroviruses are also simple C-type retroviruses; however, the *pol*, *gag*, and *pro* sequences share a reading frame. Gammaretroviruses comprise the largest number of species and infect mammalian, avian, and reptilian hosts. This genus also contains a number of replication-defective endogenous viruses. Key gammaretroviruses include feline leukemia virus (FeLV), the murine leukemia viruses (MuLV), and the avian reticuloendotheliosis virus (REV) group.

Deltaretroviruses

Deltaretroviruses are complex C-type retroviruses that contain *tax* and *rex* regulatory genes in addition to *gag*, *pro*, *pol*, and *env*. Protein expression requires frame shifts over several different reading frames. Bovine leukemia virus (BLV) and human T-cell lymphotropic virus (HTLV) are the best-known examples.

Epsilonretroviruses

Epsilonretroviruses are complex C-type retroviruses that contain one or more additional open reading frames. The prototype virus is walleye dermal sarcoma virus (WDSV). Two other walleye viruses are included in the genus and two additional fish viruses are proposed for inclusion.

Lentiviruses

Lentiviruses are complex retroviruses that are further categorized into five groups based on the host species they infect: primates, cats (domestic and nondomestic), horses, cattle, and sheep/goats. Virions have a distinctive conical morphology. Genomes contain a variable number of accessory genes that regulate viral replication. This genus includes several well-studied viruses including human immunodeficiency virus (HIV), simian immunodeficiency virus (SIV), feline immunodeficiency virus (FIV), equine infectious anemia virus (EIAV), caprine arthritis encephalitis virus (CAEV), and Maedi-visna virus. Lentiviruses are characterized by the relatively long period between infection and disease development.

Spumaviruses (Foamy Viruses or Syncytial Viruses)

Spumaviruses are complex retroviruses with immature C-like virions that have a less-condensed core and more prominent surface spikes. Virions are assembled in the cytoplasm and then bud through the endoplasmic reticulum as well as the plasma membrane. Newly formed virions uniquely contain large amounts of reverse transcribed DNA. While spumaviruses establish persistent infection in a number of species including humans, nonhuman primates, cattle, horses, and cats, they are not typically associated with clinical disease.

OVERVIEW OF RETROVIRUS-INDUCED DISEASE

Immunodeficiency

Modification of the immune system by viral proteins can enhance carcinogenesis through several mechanisms including disruption of tumor surveillance, atypical stimulation of the immune system, and alteration of the microenvironment (see Chapter 55). The association of lentivirus-induced immunodeficiency and cancer has been well established in several systems such as HIV infection and the development of Kaposi sarcomas and B-cell lymphomas.

Leukemogenesis

One of the most common mechanisms of retroviral-induced leukemogenesis is through insertional activation, which is the activation of proto-oncogenes following proviral integration.

Direct Cytopathicity

Several viruses produce gene products that are directly cytopathic to the host. Examples include the neurologic damage induced by the Env SU subunit of some MuLVs, wasting syndrome induced by many of the avian viruses, and induction of cytopathicity by FeLVs with mutation in the Env SU subunit.

Host Determinants of Pathogenicity

Alterations in host genes can influence the progression of retroviral infection, particularly those that control the target cell availability through cell cycling, tumor suppression genes, and growth factors. Similarly, mutations within the genes responsible for the immune response can alter pathogenicity.

Stimulation of Host Cell Proliferation

While the primary means of inducing host cell proliferation is through insertional activation, some oncogenic retroviruses use other mechanisms. One of the best understood is the superantigen (Sag) protein of MMTV that binds and activates T cells through common (nonantigen-specific) areas on major histocompatibility complex (MHCII) molecules. Alternatively, the spleen focus-forming viruses and the Env helper protein of MuLV activate erythroid proliferations through binding of the erythropoietin receptor.

Oncogenic Transformation

Retroviruses can induce oncogenic transformation through a number of mechanisms covered in detail in the next section.

RETROVIRUS-INDUCED ONCOGENES

Oncogenes are genes whose products contribute to the formation of cancer. Oncogenes arise as mutated forms of normal cellular genes (i.e., proto-oncogenes) coding for key proteins involved in growth control, development, and differentiation.

Role in Cancer

Carcinogenesis is a multistage process. Oncogenes may have direct or indirect roles at several stages in this

process. Direct transformation occurs when a viral gene product interacts with a cellular gene or gene product resulting in loss of internal regulation of normal proliferation, cell cycle, or cell death and neoplastic transformation in that cell. Indirect transformation occurs when the virus alters cells other than the tumor cell resulting in loss of external regulation. The oncogene may transform only a specific cell type or it may have more global effects.

Nonacute

Nonacute transforming retroviruses are replication-competent viruses that induce neoplasia after a latent period. These viruses do not typically induce morphologic transformation in culture. Oncogenesis is often initiated, as proto-oncogenes are activated after viral integration. There are two general mechanisms by which this occurs. In promoter insertion, viral transcription "reads through" to the proto-oncogene each time the virus is replicated resulting in overexpression of the host gene. The second mechanism is enhancer activation in which the proto-oncogene promoter is activated by a viral enhancer.

Acute

Acute transforming retroviruses derive from nonacute retroviruses but have acquired an altered host proto-oncogene. Because they carry oncogenes, these viruses induce rapid transformation and tumor growth. Most acute transforming retroviruses are replication-defective and require replication-competent viruses for propagation. These host-derived oncogenes include growth factors, tyrosine and serine/threonine kinases, transcription proteins, and G-protein signaling proteins.

Mechanisms of Action

The primary mechanisms of oncogenic transformation are through transduction, cis-activation, and trans-activation. Less commonly, viral proteins such as Env may directly stimulate cell proliferation, interfere with cell cycle checkpoints, or inhibit surveillance for tumor cells.

Transduction

During replication, retroviruses can acquire host sequences through recombination errors. These viruses are usually defective and require helper viruses for replication. The transforming power of recombinant viruses depends on the cellular gene they have acquired, but many viruses with rapid transformative ability utilize this mechanism.[11] In general, transduction is uncommon in natural infections, but is a useful research tool for studying oncogenesis in the laboratory.

Cis-Activation

Cis-activation occurs when a provirus inserts near a proto-oncogene. Activation of the proto-oncogene occurs by promoters or enhancer elements in the viral LTR. Cis-activation is commonly used by simple retroviruses.

Trans-Activation

Trans-activation occurs as a virally encoded protein such as Tax interacts with host transcriptional factors, thereby altering expression of normal cellular genes.

PROTOTYPICAL AND WELL-CHARACTERIZED ONCORETROVIRUSES

Avian Leukosis and Sarcoma Viruses

The avian leukosis and sarcoma viruses (ALSVs) cause tumors in a variety of avian species. ALVs are simple retroviruses that are transmitted both horizontally and vertically. However, while a large percentage of the flock may be infected, neoplasia develops in only a small percentage. Vaccination strategies have not been successful, making eradication of ALV from the breeding stock a critical control step. In the early 1980s, eradication of the five primary envelope subgroups had been reasonably successful. However, in the mid-1980s, a highly pathogenic myeloid tumor-inducing subgroup J virus emerged to become one of the major infectious diseases facing the poultry industry.

Exogenous ALVs are transmitted as infectious virions, while endogenous ALVs are incorporated into the host genome and transmitted genetically. The number of endogenous viruses varies among avian species and the biological significance of endogenous viruses is not entirely clear. Some forms appear to protect the host from infection by newly acquired ALV infection through receptor interference. However, endogenous viruses may also have a negative effect on the host.

ALVs are well-described oncogenic viruses. Both nonacute and acute transforming forms are recognized. Nonacute transforming viruses induce tumors that appear late in the period of infection. Typically, oncogenesis is induced through the insertion of the ALV genome near a proto-oncogene resulting in cis-activation. Lymphoid leukosis is one of the best-described examples. In lymphoid leukosis, the B-cell c-*myc* gene is activated resulting in a multistage lymphomagenesis that produces neoplastic lymphoblasts resistant to apoptosis. Because multiple follicles can be affected nearly simultaneously, the disease can appear to be polyclonal.

By contrast, acute transforming ALVs contain one or more viral oncogenes. These ALVs tend to be replication-incompetent due to mutations (usually deletions) within the structural genes and require coinfection with a nondefective helper virus. Several ALV strains carry the *myc* oncogene that tends to induce myelomonocytic neoplasia. Avian sarcoma viruses also tend to be acutely transforming. The best characterized is Rous sarcoma virus which encodes a protein kinase through *src* viral oncogene.

In addition to their known neoplastic induction, certain ALVs serve as a model of viral-associated obesity. For example, the Rous-associated virus type 7 ALV induces a syndrome of hypertriglyceridemia and hypercholesterolemia.

Bovine Leukemia Virus

BLV is a type-C deltaretrovirus that infects cattle and sheep. Bovine leukemia virus replication is primarily dependent on cell proliferation and mitotic division. Virus infection stimulates a polyclonal expansion of B cells, called persistent lymphocytosis, in approximately one-third of infected animals. In cattle, only a small percentage of infected animals develop bovine enzootic leukosis, a polyclonal, but neoplastic, B-cell expansion. A higher rate of neoplasia is seen in experimentally infected sheep. Transmission is primarily horizontal through the transfer of infected cells by direct contact and possibly through blood-sucking insects. Vertical transmission is less common, but may occur in utero, at parturition, or through milk ingestion.

Bovine leukemia virus is related to the primate lymphotropic viruses, but has over 40% phylogenetic divergence. While the primate viruses infect T cells, BLV primarily infects B cells, particularly those expressing surface IgM, but also can infect monocytes and macrophages. Bovine leukemia virus encodes both Rex and Tax proteins, Tax being the primary oncogenic protein. Transmission by cell-free virus is inefficient, and cell-to-cell transmission by cell fusion predominates. After infection of a new cell, BLV integrates randomly into the host genome. Virus replication is primarily through the production of daughter cells via mitotic division.

Feline Leukemia Virus

FeLV is a simple retrovirus that infects domestic cats as well as nondomestic felids. FeLV has high sequence homology with MuLV, supporting the hypothesis that infection of cats resulted from MuLV cross-species transmission. Three genotypes of FeLV have been described: types A, B, and C. Type A FeLV is the dominant virus in nature. This exogenously transmitted retrovirus is ubiquitous, readily transmitted, and highly conserved. Types B and C result from mutation and recombination of type A FeLV with endogenous retroviral sequences. The variability in viral recombination corresponds with variability in the pathogenesis and disease outcomes including aplastic anemia, T-cell lymphoma/leukemia, myeloid leukemia, and immunosuppression.

Feline leukemia virus is transmitted horizontally, primarily through saliva, biting, and other close contact. Vertical transmission occurs both in utero and by ingestion of infected milk. Susceptibility is inversely correlated with age; thus, the highest potential for transmission and infection occurs during the first 4–6 months of age. Approximately 30% of infected cats develop persistent viremia and secondary diseases including immunodeficiency, hematopoietic and other neoplasia, and opportunistic infections. The majority (60–65%) of all infected cats rapidly or eventually clear the virus after infection due to a robust immune response, minimal virus exposure, or a combination of the two, and remain antigen-negative by ELISA. A small percentage of cats develop a transient antigen-positive viremia, but then become persistently aviremic and antigen-negative. Finally, 5–10% of all infected cats may develop an "atypical" infection due to localized or sequestered infection and have mixed or inconsistent test results. These cats may maintain a lifelong latent infection, but may progress to outright viremia or viral clearance. Latent FeLV may be reactivated through secondary diseases or treatments that result in impairment of the immune system.

Gibbon Ape Leukemia Virus

Gibbon ape leukemia virus (GALV) is genetically related to simian-sarcoma-associated virus, murine leukemia virus, and feline leukemia virus. Gibbon ape leukemia virus is a highly oncogenic C-type retrovirus that induces myeloproliferative disorders, particularly in juvenile animals. To date, four strains of GALV have been identified from captive gibbons. Because the virus has not been identified in wild animals, it is uncertain if GALV is of simian origin or represents an endogenous retrovirus transferred between species. Because GALV infects a wide variety of cell types from different species, several GALV-based retroviral vectors have been developed for gene transfer.

Human T-Cell Lymphotropic Viruses

Type 1 and type 2 HTLVs are closely related viruses that share significant nucleotide similarly, but also have important differences. Recently, additional members of the HTLV family, HTLV-3 and HTLV-4, have been identified.[6] The HTLVs are complex retroviruses with several regulatory and accessory genes. The HTLVs are genetically stable viruses whose replication is limited by the immune response. HTLV replication primarily occurs through clonal replication of infected cells. HTLV-1 is endemic in Southeast Asia including Japan, the Caribbean, Melanesia, as well as parts of South America, Central Africa, and the Middle East. HTLV-1 infection can result in adult T-cell leukemia (ATL) and HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP); however, only a small percentage of infected individuals develop clinical disease.

Jaagsiekte Sheep Retrovirus and Enzootic Nasal Tumor Virus

JSRV is the causative agent of pulmonary adenomatosis in sheep. Pulmonary adenomatosis serves as a transmissible model of human bronchioloalveolar carcinoma. It is a simple retrovirus, but includes an additional gene, *orf-x*. The mechanism of JSRV-induced oncogenesis is not well defined, but both *orf-x* and *env* have been proposed to play a role. The virus spreads

horizontally through infection of type II pneumocytes and Clara cells in the lower respiratory tract. The time to tumorigenesis ranges from months to years, but disease progresses rapidly once clinical signs develop.

ENTV has >95% genetic similarity with JSRV. While JSRV induces tumors in the lower respiratory tract, ENTV causes tumors in the nasal cavity.

Mouse Mammary Tumor Virus

MMTV induces mammary adenocarcinomas and, less commonly, T-cell lymphoma. MMTV is transmitted genetically through the germ line and via infected breast milk. MMTV has been classified as a simple betaretrovirus, but encodes Rem, a self-regulatory mRNA export protein related to the Rev protein of HIV.[3,7] MMTV also encodes *sag*, a superantigen that uniquely stimulates viral replication. B cells in the gut are the initial target for viral infection. B-cell expression of the superantigen activates bystander CD4+ T cells that, in turn, induce clonal expansion of Sag expressing B cells responsible for trafficking to the mammary gland and infecting mammary epithelial cells.

Mouse mammary tumor virus tumorigenesis occurs primarily through viral insertion near a proto-oncogene and subsequent activation. Endogenous viruses are frequently truncated or defective; however, those mice with a functional *sag* gene have some degree of protection against infection with exogenous MMTV because the T cells that would normally react against the superantigen have been deleted during thymic maturation.

Recently, several sequences have been detected within the human genome and human cancers that have very high sequence homology with MMTV. Although somewhat controversial, this has led to speculation that these elements may play a role in human breast cancer and lymphoma as well as other diseases such as primary biliary cirrhosis.[1,4,8,9,10,12] While additional work is necessary to establish a causative link between MMTV-like sequences and these diseases, current studies are shifting our understanding of the role of endogenous retroviruses and retroelements.

MURINE LEUKEMIA VIRUSES

There are several strains of well-characterized MuLVs including Friend, Moloney, and Rauscher viruses. MuLVs induce a wide spectrum of malignancies including T-cell lymphoma/leukemia, myeloid leukemia, and erythroleukemia. These viruses can also affect the nervous system. The tumorigenic effects are driven by the LTR U3 region, while neuropathicity is mediated by the Env SU. These simple retroviruses are further classified by host range and replication capacity. Ecotropic viruses replicate only in their natural host. Amphotropic or polytropic viruses replicate in both rodent and nonrodent species. Xenotropic viruses infect only nonmurine cells. Wild rodents frequently harbor non-ecotropic viruses. Because these non-ecotropic viruses efficiently infect human cells, they make efficient gene delivery vectors.

Reticuloendotheliosis Virus

REV is a simple gammaretrovirus that infects a number of avian species. Serologic studies suggest that the virus is prevalent in both chickens and turkeys, and appears to be transmitted vertically and horizontally. The name reticuloendotheliosis virus arises from the acute reticulum cell neoplasia seen in chickens experimentally inoculated with a unique replication-defective laboratory strain containing the *rel* oncogene. However, most clinical isolates lack oncogenes and are replication-competent. Reticuloendotheliosis virus induces three distinct clinical syndromes including a non-neoplastic runting syndrome associated with bursal and thymic atrophy, a variety of acute neoplastic diseases involving multiple organs, and chronic B- and T-cell lymphomas.

Simian T-Cell Lymphotropic Virus

The simian T-cell lymphotropic viruses (STLVs) are complex deltaretroviruses closely related to HTLV. The genetic relatedness between STLV-1 and HTLV-1 supports the hypothesis that HTLV-1 originated from cross-species STLV transmission. STLV-1 infects over 20 species of Old World primate species, while STLV-2 has a much more limited species range. Clinical disease is uncommon in STLV-infected primates and, when seen, tends to occur following chronic infection.

Walleye Dermal Sarcoma Virus

WDSV is the best-characterized piscine retrovirus and is endemic in walleye throughout North America. It is a complex retrovirus with at least three accessory genes. Walleye dermal sarcoma virus replication and the induced dermal sarcomas have a unique cyclical pattern. Walleye-dermal-sarcoma-virus-induced dermal sarcomas are benign tumors that develop in the fall when virus production is low. In the spring, virus replication increases and these tumors concurrently regress. These findings suggest that virus replication is dependent on host endocrine or immunologic changes associated with spawning and/or changes in water temperature.

Acronyms and Abbreviations

ACH, acetylcholinesterase; ACP, acid phosphatase; ALL, acute lymphoblastic leukemia; ANAE, alpha-naphthyl acetate esterase; ANBE, alpha-naphthyl butyrate esterase; βG, β-glucuronidase; CAE, chloroacetate esterase; IHC, immunohistochemistry; LAP, leukocyte alkaline phosphatase; NK, natural killer; NSE, nonspecific esterase; OEN, omega-exonuclease; PAS, periodic acid–Schiff; PER, peroxidase; SBB, Sudan Black B; TB, toluidine blue.

GENERAL PRINCIPLES OF CYTOCHEMISTRY

Cytochemistry is the use of special stains for the microscopic detection of cellular constituents such as lipids, carbohydrates, and enzymes.[97] These stains may detect differences between normal cell types and identify the lineage of poorly differentiated blast cells. Cytochemistry is valuable because it involves minimal cost and is readily performed at diagnostic referral centers. This technique may be used with hemolymphatic tissues (blood, bone marrow, lymph nodes, spleen, and thymus) or with liver.[82] These specimens may include fresh imprints or aspirates, frozen tissues, or plastic-embedded tissues.[15,136] Notably, cytochemistry can also detect substrates that may be lost during the preparation of paraffin-embedded tissues (e.g., nonspecific esterase (NSE) activity) because the enzyme is unstable during tissue processing. In addition to light microscopic preparations, cytochemical staining also has been applied to electron microscopic specimens.[9,85]

To ensure proper sample handling, submitters should contact the laboratory prior to sample collection.

Multiple unfixed slides usually are preferred, so a panel of stains can be performed. During cytochemical staining, appropriate control slides are used as positive and negative controls to assure quality control for the procedure(s). Although cytochemistry is applicable to the cells of various species, it is noteworthy that incubation times, staining patterns, and the presence of substrates may differ, even among the various avian, reptile, and fish species.

GENERAL CONSIDERATIONS FOR STAINING NEOPLASTIC HEMATOPOIETIC CELLS

The first step in the identification and classification of hematopoietic neoplasia is the morphologic characterization of the blast cell population. This may be followed by special tests to better define the cell of origin (e.g., cytochemistry, immunocytochemistry (ICC), and flow cytometry). Poorly differentiated cells are indistinguishable by morphology alone, but may be better identified by their cytochemical characteristics. This is critical for acute leukemias and especially useful in domestic animals like the dog, cat, and horse. The use of cytochemical staining can improve the diagnosis and sometimes change the initial morphologic interpretation.[53,67]

The general premise of cytochemistry is that the neoplastic cells contain the same enzymes or cellular products as cells from healthy individuals. However, occasional irregularities may occur related to the altered development of neoplastic or dysplastic cells. Cytochemical staining is best interpreted when a panel rather than one or two stains is performed, since discrepancies may occur with neoplastic cells.

In general, lymphoid cells do not stain with many cytochemical stains; however, negative staining does not automatically indicate a lymphoid neoplasm. Stain intensity is often very weak or absent in the most undifferentiated cells because they contain few of the necessary enzymes or cellular constituents. By contrast, some enzymes (e.g., myeloperoxidase (MPO)) are highly expressed in the immature cells. In cytochemistry, it is best to interpret the results of positive staining rather than the lack of staining.

In addition to stain intensity, the pattern of staining may be helpful. For example, T-lymphocytes containing focal lysosomal granules often produce a focal localization of NSE enzyme activity compared with the diffuse or granular nature found in some nonlymphoid cells. Lymphoid cells are best classified using immunologic markers, but lineage- and species-specific monoclonal antibodies may be limited in availability or by cost. Therefore, particularly for unique species, cytochemical staining can be very helpful for T-cell identification.[9]

In the interpretation of cytochemical staining data, it is important to note that reactions seen within one species cannot be extended to other species. For example, feline eosinophils do not stain with either peroxidase (PER) or Sudan Black B (SBB), but such staining can be seen in other species. It is also important to note the extent of staining within the sample. For example, the percentage of PER- or SBB-positive blast cells in the bone marrow should be greater than 3% to identify human myeloblastic leukemia (without maturation).[16] It is best to count a minimum of 200 bone marrow cells when calculating this figure to avoid an overestimation or underestimation.[79] A simplified classification of acute leukemias using cytochemical staining is shown in Figure 61.1.

REACTIONS OF NORMAL HEMATOPOIETIC CELLS

A summary of cytochemical staining profiles for selected stains and leukocytes in several domestic and exotic animal species is provided in Tables 61.1 and 61.2.

Neutrophils/Heterophils

Primary or azurophilic lysosomal granules contain myeloperoxidase. PER activity is readily demonstrated from the promyelocyte stage through mature segmented forms (Figure 61.2a,b). In electron microscopic preparations, PER activity also may be found in the nuclear membrane, rough endoplasmic reticulum, and Golgi apparatus of myeloblasts. PER reactivity generally is absent in heterophils of rabbits, certain birds, and reptiles.[88,3,178] Iguana heterophils, in contrast to many reptiles, have a significant positive PER reactivity as do two species of frog.[27,28] Neutrophils with eosinophilic prominence, such as those of the manatee, demonstrate intense PER staining.[64]

SBB intensely stains the lipids of secondary or specific granules (Figure 61.3a), but can also be found to a lesser extent within primary granules (Figure 61.3b). As such, all stages of neutrophil maturation are detected. Primary and secondary neutrophilic granules also contain chloroacetate esterase (CAE) activity (Figure 61.4a–c), which results in moderate to strong reactions in all neutrophil maturation stages (Figure 61.5a–c). Notably, in frogs and cod, CAE is found in monocytes.[27,148]

Leukocyte alkaline phosphatase (LAP) is found predominantly in the secondary granules of most species including humans, horses, rabbits, and ruminants (Figures 61.5 and 61.6). However, LAP staining is absent in the mature neutrophils of dogs and cats, is variable in the neutrophils of horses and goats, and is absent from the neutrophils from most other species.[169] Acid phosphatase (ACP) activity of modest staining intensity is present in the primary granules of neutrophils. The highest ACP activity is detected in immature neutrophils as opposed to bands and segmented forms.

Eosinophils

The PER in eosinophils differs both structurally and biochemically from that found in neutrophils and megakaryocytes. In eosinophils, PER is present in the matrix of large eosinophilic granules, but not within the crystalloid core (Figure 61.2a). Notably, and unlike most species, feline eosinophils do not stain with either PER or SBB techniques. However, PER and SBB reactivity may be observed in avian and reptilian eosinophils.[3,6,104] In general, eosinophils do not stain with

CAE technique; however, reactivity has been observed in these cells from the green turtle, yellow-bellied slider, and koi.[69,168,178] NSE activity is absent in canine and feline eosinophils, but may be observed in equine and ruminant eosinophils. Both alpha-naphthyl butyrate esterase (ANBE) and alpha-naphthyl acetate esterase (ANAE) activities are noted to be strong in elephant eosinophils. Eosinophils, especially those of the cat, stain strongly for ACP activity within the intergranular areas and is tartrate-resistant.[53,54] LAP activity

is found intracellularly between the specific granules of eosinophils (Figures 61.5 and 61.6) with the strongest reactivity seen in the horse, whereas feline eosinophils may lack or have weak reactivity.[82] Specific eosinophil stains, such as luna and luxol fast blue, may also be helpful in eosinophil identification.[183]

Basophils

Basophils are negative for SBB and PER reactivity. Feline and opossum basophils may demonstrate occasional positive LAP staining.[39] Canine and feline basophils demonstrate moderate CAE staining, whereas bovine and equine basophils are weakly positive. Basophils of the dog, cat, horse, and cow are negative for NSE activity. Tartrate-resistant ACP activity may be observed in canine and feline basophils.[53,54] Alcian blue stains the sulfated mucosubstances in the basophil granules of many species.[135] Omega-exonuclease (OEN) activity is present in basophils and mast cells of dogs and cats (Figure 61.7a,b), but it is absent in both equine and bovine basophils.[81,135] Toluidine blue (TB) staining may be metachromatic (purple) for basophil granules of domestic animals under acidic conditions, but this characteristic is not observed at neutral pH. TB staining also has been demonstrated in basophils from several reptiles.[3,69,104] Basophils from Asian elephants are strongly positive to β-glucuronidase (βG).

Monocytes/Azurophils

Monocytes and azurophils of some species show diffuse, weakly positive reactivity for SBB and PER (Figure 61.5).[2,4,24] PER activity may be more evident when copper nitrate is used to intensify the enzymatic reaction within the lysosomes. Generally, monocytes do not contain CAE activity; however, trace positive reactivity may be observed in bovine, equine, ovine, caprine monocytes, as well as the bilobed monocyte of elephants. NSE is present in cells of monocytic origin, resulting in diffuse, finely granular reactivity (Figure 61.5) that is most intense in macrophages.[76,180] NSE reactivity (Figure 61.8) is inhibited with sodium fluoride due to the presence of the enzymes on the plasma membrane.[26,47] ACP reactivity is present in a diffuse manner, similar to that observed for NSE. ACP reactivity is of moderate intensity in monocytes and increases with

maturity into macrophages. LAP may be found in canine monocytes and monoblasts (Figures 61.5 and 61.9). Koi monocytes are noted to have naphthyl butyrate esterase (NBE), as well as beta-glucuronidase activities.[168]

Lymphocytes

Traditionally, lymphocytes lack reactivity to many of the cytochemical stains used to identify granulocytes and monocytes. PER activity is absent, although rare PER expression detected by molecular studies has been documented in humans.[74] LAP activity, present as a fine and diffusely granular pattern involving the plasma membrane, may be observed in a B-cell subtype associated with the mantle zone of lymph nodes in dogs.[136] CAE reactivity is rare in lymphocytes (Figure 61.4b), but weak staining has been reported in bovine and equine lymphocytes, as well as elephants. Occasional punctate staining has been associated with non-T-cell large granular lymphocytes in people.[71] NSE activity can be seen as a focal, discrete staining reaction within the intracellular organelles of normal and neoplastic T-lymphocytes from humans, dogs, cats, cattle, horses, sheep, elephants, and chickens.[9,47,53,54,71,130,136,175,179,181] Weak periodic acid–Schiff (PAS) staining has been demonstrated in lymphocytes from cattle, dogs, horses, and sheep. Positive reactivity for ACP has been observed in canine natural killer (NK) cells with and without tartrate incubation (Figure 61.10).[90]

Platelets, Thrombocytes, and Megakaryocytes

Platelets and their precursors contain, in the endoplasmic reticulum and nuclear membrane of megakaryocytes and in the tubular system of the platelets, a specific PER which is only apparent in ultrastructural preparations. Slight CAE reactivity in canine and feline megakaryocytes has been reported, similar to that observed in human cells.[53,54] PAS staining is often apparent within platelets and megakaryocytes of many animal species, including thrombocytes of birds and reptiles (Figure 61.11), but not in some fish.[69,104,148,159] Although megakaryocytes and platelets may exhibit reactivity for

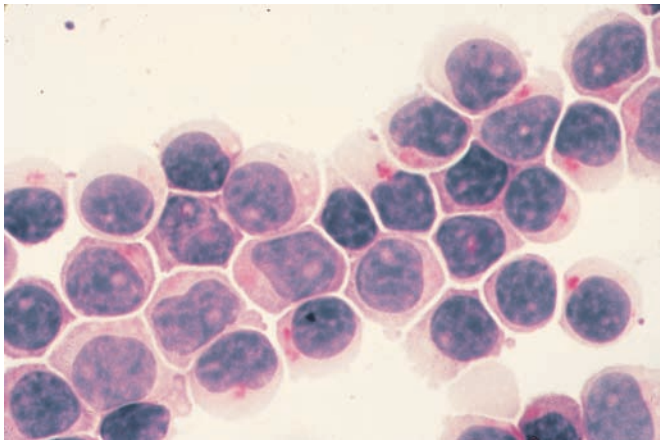

FIGURE 61.10 Focal stain reaction with ACP in canine lymphocytes having NK-cell activity. 100× objective.

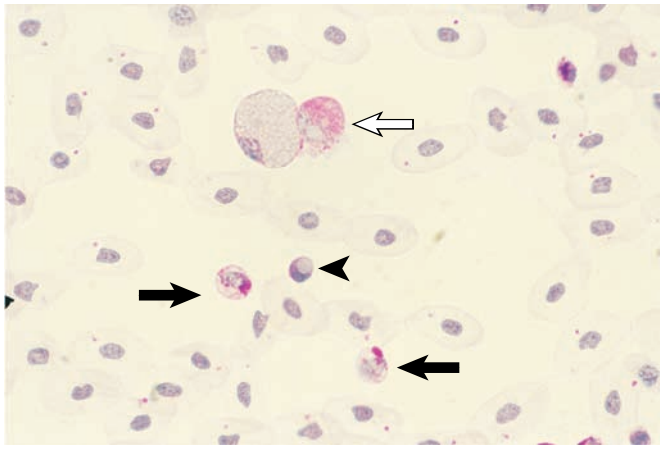

FIGURE 61.11 PAS reaction in boa snake blood cells showing strong reaction in thrombocytes (black arrows), moderate reaction in an azurophil (white arrow), trace reaction in a heterophil, and punctate reaction in erythrocytes. Note lymphocyte with inclusion body (arrowhead). 100× objective.

NSE, these reactions are mildly to totally inhibited with sodium fluoride.[67] Both megakaryocytes and platelets are strongly reactive for ACP activity. Synacril black AN, a textile dye, yields selectively metachromatic staining of the acid mucopolysaccharides in megakaryocyte cytoplasm (Figure 61.12a,b).[87] Acetylcholinesterase (ACH) is another marker that primarily identifies megakaryocytes and platelets in dogs, cats, and rats.[84] Platelets are negative for LAP and SBB.

Erythroid Cells

Reactivity of erythroid cells to routine cytochemical stains is observed infrequently. Examples include a diffuse blush of positive reactivity to PER and SBB techniques. ACP, beta-glucuronidase, PAS (Figure 61.11), and alpha-naphthyl butyrate esterase techniques may result in diffuse granular staining of various stages of erythroid precursors.[53,54,170]

Mast Cells

Canine and feline mast cells exhibit variable reactivity with CAE, PAS, Alcian blue, TB, and OEN (Figure 61.7b).[81] Mast cells, like basophils, are negative for PER and SBB reactivity. LAP activity is not present in canine and feline mast cells, whereas ACP reactivity results only in weak staining. NSE reactivity may have variable intensity in mast cells from some species like the pig, dog, and cat.

CYTOCHEMICAL STAINING PRINCIPLES AND DIAGNOSTIC APPLICATION

A listing of selected cytochemical stains and their methodologies can be found in the 5th edition (2000). Notably, other methods and kits may be used to obtain similar results, including double staining techniques (Figure 61.5). The cytochemical principle and diagnostic

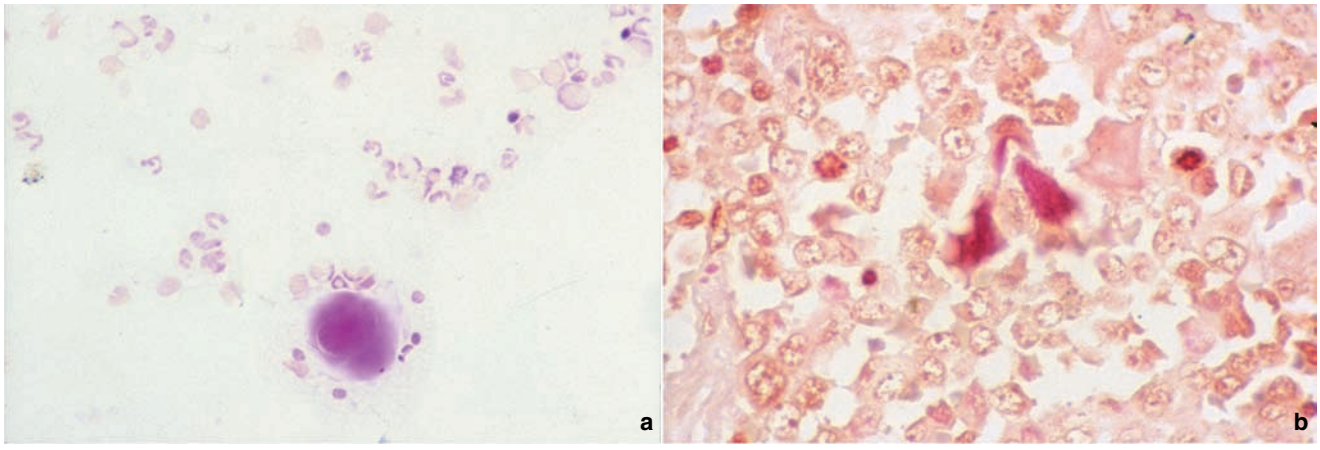

FIGURE 61.12 (a) Feline megakaryocyte with magenta reaction stained with Synacril black AN (Megacolor). Bone marrow histopathology. 100× objective.

application for each staining target are described in the following text and summarized in Table 61.3.

Myeloperoxidase

Peroxidase staining is used to identify myeloid cells, particularly neutrophils, eosinophils, and monocytes in most mammals (Figure 61.2a). The PER enzymes are sensitive to tissue processing; therefore, enzymatic reactivity is demonstrable only in fresh tissues and not in paraffin-embedded tissues. PER reactivity diminishes over time, especially in samples older than 2 weeks of age. PER reactivity may be less intense if smears are over 3 days old.[66] The most sensitive method to detect PER activity involves benzidine compounds that are potentially carcinogenic.(39) Copper salts enhance the benzidine reaction producing a gray-black product rather than an orange-brown result. An acceptable alternative substrate to diaminobenzidine tetrahydrochloride is 3-amino-9-ethylcarbazole.[80]

[a]PER = peroxidase; SBB = Sudan Black B; CAE = chloroacetate esterase; LAP = leukocyte alkaline phosphatase; NAE = naphthyl acetate esterase; NBE = naphthyl butyrate esterase; ACP = acid phosphatase; ACP/T = acid phosphatase with tartrate; BG = beta-glucuronidase; PAS = periodic acid–Schiff; ET = essential thrombocythemia; neg = no reaction; pos = easily detectable; pos/neg = weak or occasional reactivity.

The blast cells within the bone marrow may stain positive with PER for myeloblastic leukemia (with or without maturation), myelomonocytic leukemia, and erythroleukemia. Rare positive staining in monoblastic leukemia (without maturation) is possible. In humans, PER activity may be used as a monitoring tool during the treatment for myeloid leukemia. In a subset of human patients, neutrophil MPO activity can be used as a surrogate for MPO activity in neoplastic myeloblasts, and, in these patients, an increase in neutrophil MPO activity may presage emergence from remission.

Lymphoid malignancies traditionally lack PER reactivity; however, occasional reports in human medicine have identified molecular expression of the enzyme.[74] There are limited reports of PER activity in veterinary hematopoietic neoplasia. One case detected myeloperoxidase positivity in a dog with acute megakaryoblastic leukemia.[55] PER staining was helpful in the diagnosis of several canine, feline, equine, and porcine cases of myeloblastic leukemia (Figure 61.2a) and myelomonocytic leukemia (Figure 61.5).[28,37,65-67,86,116,138]

Sudan Black B

Lipids (including phospholipids, neutral fats, and sterols) within neutrophils/heterophils, eosinophils, and occasional monocytes/azurophils are identified by a gray-black reaction using SBB dye (Figure 61.3a). The mechanism of cellular staining may involve an enzymatic reaction because eosinophils from human and feline patients that have eosinophil PER deficiency do not stain after SBB application. The sudanophilic material within cells is stable with heat or storage. SBB activity has been demonstrated in cases of canine, feline, equine, and bovine leukemia, including eosinophilic leukemia, monocytic leukemia, myelomonocytic leukemia, and erythroleukemia.[28,53,54,64,100,117,134,138,177] It is also expected that the blast cells in myeloblastic leukemia (with or without maturation) should stain positively with SBB (Figure 61.3b). Lymphoid malignancies are traditionally negative for SBB staining; however, one case of canine acute lymphoblastic leukemia displayed slight sudanophilia.[54] One case of canine malignant histiocytosis (now termed disseminated histiocytic sarcoma) had positive SBB reactivity.[54]

Chloroacetate Esterase

Referred to as specific esterase, the CAE reaction is likely produced by a group of enzymes. This reaction is considered more specific for neutrophils than PER or SBB, although the CAE technique is less sensitive (Figure 61.4b). CAE reactivity is strongest from the promyelocyte to the segmented stage with weaker reactivity observed in myeloblasts (Figure 61.4a). This enzyme is found within the primary and secondary granules of neutrophils and within the specific granules of basophils. Although CAE is generally specific for neutrophils, other cell types have weak reactions. For example, CAE activity is found in mast cells and basophils and mild positivity may be seen within the monocytes of horses and ruminants. CAE positivity is described in the monocytes, heterophils, eosinophils, and basophils of the yellow-bellied slider, and mild reactions are described in normal canine and feline megakaryocytes.[53,54]

In disease, CAE activity can be detected in myeloblastic leukemia (with or without maturation), myelomonocytic leukemia (Figures 61.4a and 61.5), erythroleukemia, basophilic leukemia, and mast cell tumors. One case of feline eosinophilic leukemia was positive for CAE, and occasional weak to moderate staining was noted in three cases of canine megakaryoblastic leukemia.[40,53,109] One case of weak CAE staining occurred in a horse with monocytic leukemia.[31] Moreover, CAE activity was helpful in the diagnosis of several canine, feline, bovine, equine, porcine, camelid, and saurian cases of myeloblastic leukemia, basophilic leukemia, myelogenous leukemia, myelomonocytic leukemia, malignant histiocytosis, mast cell tumor, and erythroleukemia.[12,14,19,25,28,53,54,64,106,116,134,135,138,150,154,161,165,176] Although lymphoid malignancies generally lack positive reactions with CAE, one case each of canine and feline acute lymphoblastic leukemia (ALL), similar to human ALL, displayed a slight reaction.[53] In addition, CAE staining was noted in several feline lymphoma cases, many of which involved large granular lymphocytes.[141,175]

The enzymatic reactivity detected during the CAE staining results from proteases such as chymotrypsin and elastase. During staining, these enzymes hydrolyze esters linked to the substrate (naphthol AS-D chloroacetate) which then complex with a diazonium salt to produce an insoluble, colored product.[113] The CAE esterase group can be distinguished from NSE using gel electrophoresis and is considered specific due to its resistance to sodium fluoride inhibition. CAE may be performed together with a nonspecific esterase to simultaneously detect neutrophils (CAE-positive) and monocytes (NSE-positive) (Figure 61.5).[180] The CAE cytochemical reaction is very stable and may be used in paraffin-embedded tissues.

Leukocyte Alkaline Phosphatase

Enzymes with LAP activity hydrolyze naphthol AS-BI phosphate at an alkaline pH, releasing naphthol to complex with a diazonium salt, forming an insoluble, colored product. This group of enzymes is present in granulocytes (Figure 61.5), heterophils, osteoblasts, histiocytes, vascular endothelial cells, and a subset of lymphocytes.[11,51,120,148] The extent and distribution of LAP reactivity in neutrophils vary with the species. In human neutrophils, LAP activity is present in a subset of plasma-membrane-associated granules and is detectable only in mature cells. In humans, LAP reactivity can be increased in leukocytosis or leukemoid reaction, but decreased in neoplastic neutrophils. Similar LAP reactivity is found in rabbits, rats, guinea pigs, horses, cattle, sheep, goats, and monkeys. In dogs and cats, mature neutrophils are devoid of LAP activity, whereas enzymatic activity is present in myeloblast and promyelocyte stages. LAP activity is absent in human eosinophils,

but is strong in equine eosinophils, moderate in bovine eosinophils, and negative to moderate in canine and feline eosinophils (Figure 61.5). In each instance, enzymatic activity is usually observed in the cytoplasm between the specific granules. A subset of B-lymphocytes, present in the mantle zone of lymph nodes and spleen, exhibits cellular membrane staining with LAP technique in people, dogs, rats, and mice.[120,136,156]

Although LAP may be found in neutrophil precursors, it is not considered lineage-specific in the characterization of canine and feline hematopoietic neoplasia. LAP activity has been described in myeloblastic leukemia (with or without maturation), myelomonocytic leukemia, erythroleukemia, eosinophilic leukemia, and basophilic leukemia (Figure 61.9).[25,53,54,64–66,101,156,160] Additionally, LAP staining has been described in CD34+ canine acute lymphoblastic leukemia, (presumed monoblastic) myeloid leukemia, canine monocytic leukemia, and equine monocytic leukemia.[31,79,156(47)] Lymphoid malignancies generally lack LAP activity; however, rare positive reactions have been described in both B-cell and T-cell lymphoid malignancies from dogs and pigs.[54,136,156,161,174] In summary, LAP activity is not lineage-specific and other diagnostic methods, including morphology, cytochemistry, and flow cytometry, are necessary for lineage assignment.

Periodic Acid–Schiff

In the PAS technique, periodic acid oxidizes carbohydrates to form aldehydes that react with Schiff's reagent to produce a dye product. The bright red or magenta reaction product is focal, diffuse, or granular. Within cells, stainable substrates include glycoproteins, mucoproteins, glycolipids, and high-molecular-weight carbohydrates. By including a diastase digestion step, glycogen staining can be eliminated, which indicates that a positive reaction reflects the presence of mucoproteins or other materials. Depending on the species, PAS may be found within neutrophils, heterophils, eosinophils, basophils, monocytes, azurophils, lymphocytes, platelets, thrombocytes, and erythrocytes (Figure 61.11). In circulating cells, glycogen is the most stained substance. Mature forms of neutrophils, platelets, and megakaryocytes stain the most intense, whereas monocytes, eosinophils, and basophils produce a weak positive reaction. Myeloblasts and promyelocytes are PAS-negative and PAS-weakly positive, respectively.[53,54] Lymphocytes usually do not stain positive.

Diagnostically, PAS staining is used to differentiate granulocytic or megakaryocytic precursors from lymphoid precursors. Specific subtypes of PAS-positive myeloid leukemia include myeloblastic leukemia, myelomonocytic leukemia, monocytic leukemia, eosinophilic leukemia, basophilic leukemia, erythroleukemia or erythroleukemia with erythroid predominance, and megakaryoblastic leukemia.[40,53,54,67,106,134,138,143] Mast cell neoplasia in the dog, cat, goat, pig, and gecko are PAS-positive.[14,135,150] Infrequent or weak PAS staining has occurred with some feline and equine lymphoid malignancies.[53,175] Positive staining has been documented in canine histiocytic sarcoma.[54]

Nonspecific Esterases

NSE comprises a group of enzymes capable of hydrolyzing esters to liberate naphthol products that bind with a coupler dye. These esterases demonstrate a wide range of substrate specificity and stain pH environment for various blood cells. Therefore, they are termed nonspecific. However, many of the esterases, as determined by polyacrylamide gel electrophoresis, are cell-specific. Monocytes, granulocytes, and a subset of lymphocytes exhibit unique patterns of reactivity. A coupler-dependent, red to pink-brown diffusely granular pattern is reported in monocytes (Figure 61.5) and macrophages, whereas focal to punctate staining is seen in T-lymphocytes.[9,179,181] The NSE activity in monocytes, histiocytes, macrophages, megakaryocytes, platelets, and plasma cells is inhibited by the addition of sodium fluoride, whereas T-lymphocytes remain stained.[47,67] The difference in inhibition relates to the location of the enzyme in these cells.[26,46,71,174] The activity of these enzymes is unstable and sensitive to heat, fixatives, and storage. Accordingly, fresh blood smears or tissue imprints are preferred to paraffin-embedded tissues.

Cell specificity for naphthyl acetate esterase (NAE) activity may be demonstrated by altering the pH of the medium, the staining temperature, or the length of incubation.[26,97] For example, monocytes are best stained in an acidic medium, although both granulocytes and monocytes may stain in a neutral medium. Lymphocytes stain best in acid conditions with prolonged incubation. Compared with NBE, NAE is more sensitive and less specific in identifying mammalian monocytes, macrophages, and T-lymphocytes. For example, in Murray cod, NAE was positive in heterophils, basophils, lymphocytes, and monocytes, while NBE was negative for all blood cells.[148] Sodium fluoride inhibition is necessary to differentiate the cell types when using NAE in mammals; however, it is rarely used with NBE owing to the latter's greater specificity for monocytes. Notably, in the case of heterophils, basophils, and thrombocytes from yellow-bellied sliders, these cells remained positive following fluoride inhibition with NBE.[69] Caution should be used with interpretation of nonmammalian blood cells, as the presence of enzymes does not necessarily relate to cell function or identification.

Specific subtypes of myeloid leukemia that demonstrate NSE activity include myelomonocytic leukemia, monoblastic leukemia, megakaryoblastic leukemia, basophilic leukemia (using ANAE), eosinophilic leukemia (using NBE), undifferentiated leukemia, and erythroleukemia (using NBE).[25,53,61,106] In addition, occasional positive NBE reactions have been documented in canine, feline, and porcine mast cell tumors.[14,53,135] Positive staining has been documented in cases of canine, feline, and equine histiocytic neoplasia.[42,79,96,176] Positive staining is occasionally reported in lymphoid neoplasms from dogs, cats, cattle, and sheep.[30,53,54,62,66,130,136,141,161,174,175] In summary, NAE has been helpful in diagnosing mammalian myelomonocytic leukemia, monocytic leukemia (Figure 61.8), megakaryoblastic leukemia, blast cells of essential

thrombocythemia, and histiocytic neoplasia, whereas NBE has been helpful in diagnosing myelomonocytic leukemia, monocytic leukemia, and histiocytic neoplasia.[19,28,31,33,37,42,53,54,64,66,67,72,96,112,116,127,134,136,171,176,177]

Acid Phosphatase

ACP comprises a group of enzymes that hydrolyze phosphate esters in an acidic environment. Many cell types stain in the ACP reaction, including lymphocytes, monocytes, histiocytes, granulocytes (particularly eosinophils), platelets, megakaryocytes, plasma cells, and erythroid precursors.[15,54] The reaction product is diffuse in monocytes, whereas histiocytes stain more intensely. A single focal or punctate reaction product in the Golgi area occurs in canine T-lymphocytes and lymphocytes with NK-cell activity (Figure 61.10).[181] Tartrate-resistant acid phosphatase was found in eosinophils and basophils from normal dogs and cats.[53,54] As all ACP isoenzymes are sensitive to tissue processing and heat, the ACP technique is recommended only for fresh cytologic or plastic-embedded materials (Figure 61.13) and not for paraffin-embedded tissues.

Specific subtypes of myeloid leukemia that display ACP positivity include myeloblastic leukemia, myelomonocytic leukemia, eosinophilic leukemia, basophilic leukemia, erythroleukemia, megakaryoblastic leukemia, and undifferentiated leukemia(37).[53,54,109,138] Additionally, occasional positive ACP reactions have been documented in canine, feline, and porcine mast cell tumors and histiocytic neoplasia.[14,42,53,54,135,175] Positive ACP staining may also be found in lymphoid malignancies from dogs, cats, cattle, sheep, and pigs.[30,53,54,130,136,141,151,161,175,182]

Beta-Glucuronidase

βG is a hydrolytic enzyme with a mechanism and staining pattern similar to the esterases. βG hydrolyzes the staining substrate and liberates naphthol compounds which subsequently bind to a colored dye. Enzymatic activity is found in blood lymphocytes, monocytes, and granulocytes (Figure 61.14). Both monocytes and neutrophils display weak, diffuse, cytoplasmic reactivity, whereas T-lymphocytes produce a focal or distinct granular reaction.[99] In cats, βG activity appears in monocytes (which demonstrate the strongest staining), granulocytes, lymphocytes, and platelets.[170] Weak positive reactivity has been observed in neutrophils/heterophils of channel catfish and Murray cod.[148,185] Murray cod fish demonstrate βG reactivity in lymphocytes, monocytes, and basophils.[148] In disease, βG staining has been documented in a case of feline acute undifferentiated leukemia and in cats with large granular lymphocyte lymphoma.[30,61,175]

Miscellaneous Stains

Toluidine Blue

This common histologic stain is helpful for the evaluation of basophil and mast cells from many species.[69,81] TB is a basic dye that reacts with the acid mucopolysaccharides to form metachromatic complexes that appear red-purple. Basophils stain readily in an acidic TB, but not in a neutral TB.

In disease, TB staining aided in the diagnosis of two cases of canine basophilic leukemia, a case of basophilic leukemia in a snake, and for the diagnosis of mast cell tumors from the dog, cat, goat, cow, pig, and horse.[14,29,102,105,106,135,143,147,150] Several cases of large granular lymphoma and leukemia, including in the dog, cat, horse,

and ferret, were evaluated with TB, but only feline case demonstrated a positive reaction.[23,30,174,175]

Omega-Exonuclease

OEN is an alkaline phosphodiesterase found within the cytoplasm of basophils and mast cells and their precursors in several species, particularly humans, dogs, cats (Figure 61.7a), and primates. Positive OEN reactivity produces diffuse, red-brown, granular cytoplasmic deposits, but does not stain the specific granules; therefore, it is said that OEN activity is more helpful than TB in identifying poorly differentiated or degranulated mast cells. OEN staining has been used to determine the extent of involvement in one case of basophilia leukemia in the dog.[106] Also, OEN was used to identify mast cells in tumors (Figure 61.7a) from a dog and cat.[135] OEN staining is not found in normal basophils of the horse, cow, goat, pig, or alpaca.[81](17)

Synacril Black AN

Synacril black AN, which was originally a commercial textile dye (Megacolor from Cytocolor, Inc.), stains the acid mucopolysaccharides found in megakaryocytic cytoplasm.[87](35) After fixation with formaldehyde acetic acid ethanol, specimens are pretreated with ribonuclease A (bovine pancreas type III-A) to remove ribonucleic acid. The dye stains the cytoplasm of mature and immature megakaryocytes with a red to violet, metachromatic reaction product (Figure 61.12a). All other cells are pale yellow to brown except eosinophils whose granules appear pink. In one report, normal equine megakaryocytes along with normal and neoplastic canine megakaryocytes (Figure 61.12b) stained magenta.[96]

Immunohistochemical staining using antibodies against human von Willebrand factor (Factor VIII-related antigen) and human platelet glycoprotein (GP IIIa) helped support the characterization of the neoplastic cells in several cases of canine and feline megakaryoblastic leukemia.[32,40,109,128]

Acetylcholinesterase

The enzymatic detection of ACH can be used to identify mature megakaryocytes and platelets from dogs, cats, and rats.[78,84] In addition, ACH is found in human and murine erythroid precursors.[91] ACH staining is accomplished using acetylthiocholine iodide as a substrate and the subsequent reaction product is brown. ACH staining was helpful in the identification of megakaryocytic precursors in canine megakaryoblastic leukemia and essential thrombocythemia.[33,72]

Luna

Luna is a specific stain for eosinophil granules used to identify atypical granulocytes or blast cells with eosinophilic differentiation. It was helpful in confirming the presence of eosinophilic precursors in a case of equine eosinophilic leukemia.[117]

GENERAL PRINCIPLES OF IMMUNOCYTOCHEMISTRY

As with cytochemistry, ICC is a useful ancillary tool to assist with: (1) identifying cell(s) of origin in ambiguous cases of suspected neoplasia; (2) assessing prognostic features of tumor populations; and (3) defining cellular characteristics that may aid in treatment selection. Like other antibody-based immunostaining techniques, ICC is rooted in the detection of specific antigens of interest using natural or synthetic antibodies via chromogenic or fluorescent markers. Detection of these epitopes can occur individually (single-plexed ICC) or in combination (multiplexed ICC) as part of a panel of antibodies.

compared to immunohistochemistry (IHC), advantages of ICC include: (1) collection of samples via minimally invasive fine-needle aspiration (FNA); (2) resampling is easier than biopsy in the case of nondiagnostic results; (3) shorter turnaround time offers the opportunity for near-bedside results; and (4) recognition that certain antibodies, such as some T-lymphocyte and histiocytic markers, are only effective in cytologic preparations.[8,34,57,146,172] As compared to flow cytometry, ICC allows for the simultaneous visualization of cell morphology and pattern of immunostaining (which can be helpful if the cells of interest are scant) and does not require viable cells (allowing slides for ICC to be stored at room temperature or frozen).[73,152]

In clinical scenarios, ICC is often performed on samples collected by FNA (e.g., direct smears, cytospins, and cell blocks) or biopsy impression smears.[49,58,63,89,140,152,163,173,184] Chromogenic ICC can be performed multiple times on decolorized smears, as well as samples previously visualized with Romanowsky-type stains or Papanicolaou.[1,111,119,149,157] However, previously stained slides are subject to autofluorescence, making them unsuitable for fluorescent ICC. In cases with limited slides, single samples can be divided into multiple zones or the smear can be divided using tissue-transfer techniques.[157]

While the technical details and troubleshooting steps of ICC are beyond the scope of this chapter, it is important to note that specific ICC techniques are dictated by: (1) the subcellular location of the epitope of interest; (2) whether antigen retrieval is necessary; (3) whether direct or indirect methods are employed; and (4) whether chromogenic versus fluorescent detection is utilized. Regardless of staining protocol, positive and negative controls must be included to allow for proper interpretation. Negative controls comprise cells that are not expected to show immunoreactivity when incubated with the specific antibody. If staining is seen on the negative control, it is interpreted as nonspecific antibody cross-reactivity and must be considered in the interpretation of any staining on the patient sample. Positive controls are tissues that are expected to show positive immunoreactivity to the antibody of interest. Positive controls affirm that the assay was performed correctly and allow for the comparison of staining intensity

between the positive control and test sample. Laboratories often maintain a bank of positive and negative controls to facilitate their usage. Formalin-fixed paraffin-embedded sections are considered inappropriate ICC control specimens.[58]

The most common disadvantages of ICC include preanalytical variations in sample quality and inadequate slides to complete a full ICC panel.[58,125,131] While the former is challenging to resolve once the sample has arrived at the laboratory, cytospin and cell block techniques offer a valuable solution to the latter scenario.[58,172] For these techniques, cells are collected into transport media and shipped for slide or block preparation (fluid samples may not require transport media). Liquid transport media also allows for the concentration of low cellular samples and enables the removal of problematic, background-causing substances (e.g., protein, carbohydrate, and lipid).

It is strongly recommended that ICC be utilized only as an adjunct to corresponding cytologic and clinicopathologic data.[125,131] As such, one representative Romanowsky-stained slide should be reserved for comparison with ICC slides. If this is not possible, representative images (photomicrographs or whole slide scanning) should be retained. The interpretation of ICC also requires a strict definition of positive or negative immunostaining, which is reliant on the use of appropriate controls. When reporting ICC findings, the interpreting pathologist should define and record the staining intensity and percentage of positive cells.[131] Finally, it is recommended that a standardized panel of antibodies be used to avoid confirmation bias toward a preliminary diagnosis.[58,125]

REACTIONS OF NORMAL HEMATOPOIETIC CELLS

As described in the cytochemistry section, it is important to be aware of the pattern of marker expression in non-neoplastic hematopoietic cells when interpreting their potentially neoplastic counterparts. This information is provided for five common domestic species seen frequently in clinics or utilized for research purposes: canine (Table 61.4), feline (Table 61.5), equine (Table 61.6), bovine (Table 61.7), and porcine (Table 61.8). As can be inferred from these tables, protocols and antibodies for ICC are most commonly validated in dogs and cats. Further studies are needed to expand ICC options into other veterinary species.

GENERAL CONSIDERATIONS FOR DIAGNOSING NEOPLASTIC HEMATOPOIETIC CELLS

Morphologic assessment, via cytology or histology, is key in the complete characterization of neoplastic hematopoietic cells. This morphologic assessment is complemented by tumor cell immunophenotyping, which can supply important diagnostic and/or prognostic information. Antibody-based assays for the immunophenotyping of hematopoietic neoplasms include IHC, ICC, and flow cytometry. Flow cytometry is generally considered the preferred method to diagnose and immunophenotype hematopoietic neoplasms. The non-antibody-based PCR for antigen receptor rearrangements (PARR) assay distinguishes a monoclonal expansion of lymphocytes from a polyclonal population while also providing a T- or B-cell phenotype. Currently, there are no known antibodies available against erythroid progenitor cells in veterinary medicine.

When only cytology slides are available, ICC can be used to immunophenotype neoplastic hematopoietic cells. Like flow cytometry, ICC utilizes antibody panels, including those directed at surface and intracellular lymphoid and myeloid markers (Tables 61.4–61.8) to assign lineage. According to the American Society for Veterinary Clinical Pathology (ASVCP) Quality Assurance Guidelines, institutions offering ICC are expected to validate their staining protocols for each intended species. Such validation, and the adoption of panel-based staining approach (instead of using a single marker), is particularly important when interpreting results for neoplastic cases. One antigen is rarely sufficient to accurately define cell lineage, and aberrant epitope expression can occur with malignant transformation.[44,156] Comprehensive lineage classification in some cases of hematopoietic neoplasia (such as myeloid versus lymphoid) often requires a combination of morphological, flow cytometric, and cytochemical interpretations.

Beyond determining cell of origin, ICC can be used to provide novel biologic and prognostic information for certain types of canine neoplasia. In dogs with lymphoma, there was a small, but statistically significant relationship between tobacco smoke exposure and ICC-detectable Ki-67.[122] Additionally, ICC has shown that paranuclear CD117 (c-kit) staining pattern was significantly increased in high-grade canine mast cell tumors.[145] Several articles have used a variety of molecular techniques to look at markers of proliferation, multidrug resistance, and apoptotic pathways in dogs with lymphoma to aid with prognostic information.[17,114,158] Although many prognostic indicators have been established for ICC use in human samples, the clinical significance and utility of these antigens with ICC are still in their infancy for our veterinary patients.

Summary

Cytochemical staining can be an inexpensive and convenient tool to identify the chemical constituents of blood cells and characterize poorly differentiated forms of myeloid neoplasia. Given the sparse number of cell-specific antibodies, cytochemistry is particularly useful in nondomestic animal species including birds, reptiles, amphibians, fish, and invertebrates. ICC is also a complimentary diagnostic tool that assists with cell identification, prognostication, and selection of treatment options. In the future, cytological diagnosis of hematopoietic

Acronyms and Abbreviations

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; AR, androgen receptor; CDR3, complementarity-determining region 3; CIAR, corrected inactive allele ratio; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; DLBCL, diffuse large B-cell lymphoma; EATL, enteropathy-associated T-cell lymphoma; ET, essential thrombocythemia; FCM, flow cytometry; FeLV, feline leukemia virus; FFPE, formalin-fixed paraffin-embedded; FNA, fine-needle aspiration; HUMARA, human androgen receptor gene assay; IGH, immunoglobulin heavy chain; IGK, immunoglobulin kappa light chain; IGL, immunoglobulin lambda light chain; IHC, immunohistochemistry; Kde, kappa-deleting element; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; NK, natural killer; PARR, polymerase chain reaction for antigen receptor rearrangement; PCR, polymerase chain reaction; PV, polycythemia vera; TCRG, T-cell receptor gamma chain; WHO, World Health Organization; XCIP, X-chromosome inactivation pattern.

INTRODUCTION

Clonal cell proliferation is a fundamental characteristic of neoplasms. Neoplastic cells are essentially derived from a single transformed cell, whereas normal or reactive tissues are generally composed of polyclonal cell populations. Assessment of clonality can provide information that may be useful for diagnosis and management of proliferative disorders.

Several types of molecular analytical systems have been developed for assessment of cell clonality in human neoplastic diseases. When a specific karyotype aberration (resulting in fusion gene synthesis, etc.) or gene mutation fundamentally associated with the tumorigenesis is identified in a neoplasm, detection of such an aberration provides a precise tool with which its clonal origin may be demonstrated. The Philadelphia chromosome carries the *BCR–ABL1* fusion gene, a representative genetic aberration typical of chronic myeloid leukemia (CML) and several other hematologic malignancies in humans, and is utilized for the diagnoses as well as the marker of progression/regression.[33] Genetic aberrations in each subtype of lymphoid and hematopoietic neoplasms in humans have been extensively explored and integrated into the World Health Organization (WHO) classification system.[74]

Similar genetic mutations have been identified in veterinary hematopoietic neoplasms. *TP53*, which is the most commonly mutated gene in human malignancies, has been described as a target of mutations in canine lymphoma.[41] Deletion or mutation of *p16* has also been reported in a large proportion of canine lymphomas.[18] Moreover, recent studies using RNA-seq and exome sequencing have revealed mutations in *TRAF3*, *FBXW7*,

POT1, and *PTEN* in dogs affected with lymphoma.[6,15] Meanwhile, several other studies have reported the presence of karyotype aberrations[3,4,12] and gene mutations[83] in a variable proportion of dogs with hematopoietic tumors. However, specific genetic aberrations that may be used as diagnostic tools have not yet been identified in lymphoid and hematopoietic tumors in dogs. Studies related to genetic changes in these tumors in cats are scant.

Based on the abovementioned research background, molecular clonality assessments in dogs and cats have been conducted using PCR for antigen receptor rearrangement (PARR) and X-chromosome inactivation pattern (XCIP) analyses, because knowledge of specific genetic aberrations is not required to perform these tests. In this chapter, clinical utility of PARR and XCIP analyses in the determination of cell clonality in lymphoid and hematopoietic neoplasms of dogs and cats is described.

POLYMERASE CHAIN REACTION FOR ANTIGEN RECEPTOR REARRANGEMENT (PARR)

Principles of PARR

The PARR assay determines the clonal or heterogeneous (polyclonal) nature of lymphoid cell populations. It is based on the detection of V–D–J rearrangement of antigen receptor genes such as T-cell receptor gamma chain (*TCRG*) and immunoglobulin heavy chain (*IGH*), which results in the generation of a unique sequence with the ability to bind numerous antigens (Figure 62.1).[35]

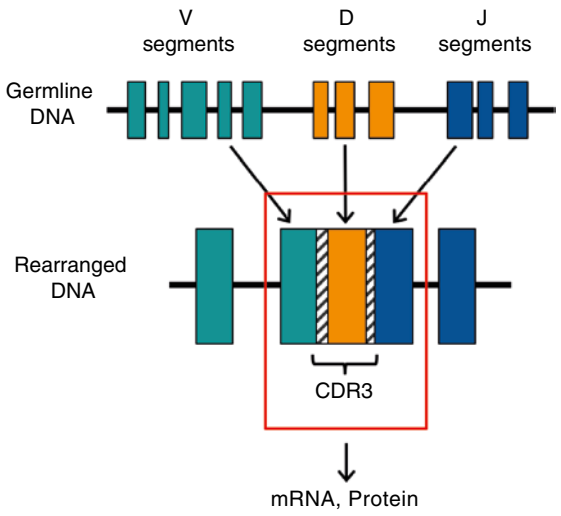

FIGURE 62.1 Schema of antigen receptor (*IGH*) gene rearrangement. *IGH* locus on germline DNA contains multiple different variable (V), diversity (D), and joining (J) segments. The sequences of randomly selected V, D, and J segments are rearranged. At the junction site of each segment, deletion and random insertion of nucleotide(s) occurs during rearrangement, leading to the development of the complementarity-determining region 3 (CDR3). The rearranged antigen receptor gene (e.g., *IGH*) is transcribed and translated to the protein as an antigen receptor.

Diagnoses of lymphoproliferative diseases are traditionally based on histopathology supported by immunohistochemistry (IHC). Cytology, preferentially used in a clinical environment, is useful for diagnosing typical subtypes of lymphoma. However, in a certain number of cases, resection biopsy of the lymph node or other lesions to obtain the histopathological finding is needed for a definitive diagnosis and subtype classification. Flow cytometry (FCM) is increasingly demonstrating utility for both the diagnosis and immunophenotyping of certain lymphoid neoplasms.

PARR combined with conventional examination tools, such as cytology or histopathology, provides information regarding cell morphology, tumor architecture, cell clonality, and lymphocyte lineage (e.g., T or B). PARR has been used as a supporting analytical tool, in the diagnosis of lymphoid malignancies in humans, when the abovementioned examination results are ambiguous. PARR is especially useful for demonstrating the clonal nature of small lymphoid cells in indolent lymphomas of the lymph nodes, spleen, and intestine, as well as chronic lymphocytic leukemia (CLL).

PARR can provide information regarding lymphoid cell lineage (e.g., T, B) from a rearranged gene, such as *IGH* or *TCRG*. However, it should be noted that discrepancies between protein expression evaluated by IHC or FCM and gene rearrangement evaluated by PARR have been reported often.[79,87,88] Furthermore, cross-lineage rearrangement suggested from the rearrangements of both *IGH* and *TCRG* has been observed on occasion in lymphoid malignancies.[39,87,88]

Procedures for PARR

Evaluation of the rearrangement of *TCRG* and *IGH* in canine and feline lymphoid tumors by Southern blot hybridization has been reported previously.[16,59] Southern blot is an authentic method which is useful for investigating gene rearrangement. However, a negative aspect of this method is that it requires a relatively large amount of sample DNA. Following the introduction of PCR techniques for the assessment of antigen receptor gene rearrangement in the veterinary field,[5,14,85] PARR is commonly used to support the diagnosis of lymphoid tumors in dogs and cats.

Primers are designed at variable (V) and joining (J) segments for fragment amplification including complementarity-determining region 3 (CDR3) within antigen receptor genes. Differing lengths of V, diversity (D), and J segments, as well as random insertions and deletions of a few nucleotides occurring in the CDR3 region, lead to the generation of numerous amplicons of different sizes in polyclonal samples (Figure 62.2). On the contrary, since lymphoid neoplasms are fundamentally composed of clonally expanded cells, amplicons of a uniform size are generated by monoclonal samples in PARR (Figure 62.2).

IGH and *TCRG* are the most commonly used targets of PARR analysis. During the differentiation of B cells, rearrangement of *IGH* is followed by the rearrangement of immunoglobulin light chains (kappa and lambda

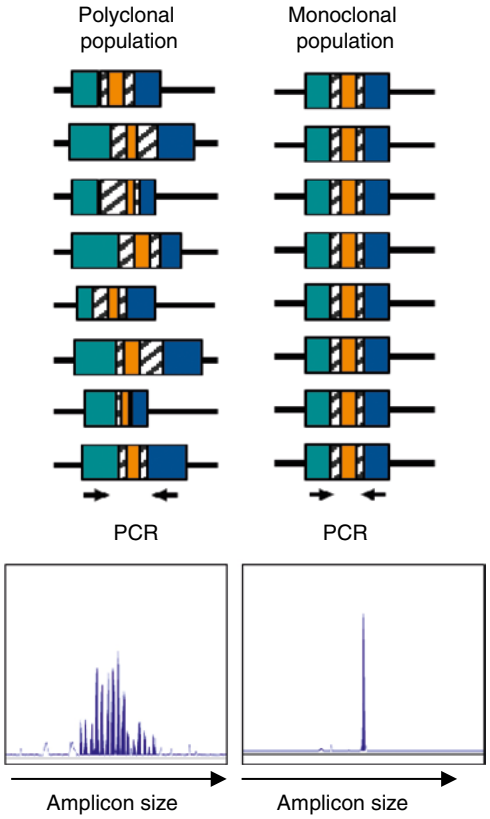

FIGURE 62.2 Schema of PARR analysis results. Forward and reverse primers for PCR are designed within the V and J regions, respectively. (Left) Many differently sized PCR products are amplified from a polyclonal sample resulting in Gaussian distributed multiple peaks. (Right) On the contrary, a single PCR product is amplified from a monoclonal sample resulting in a single peak. Representative results of GeneScan analysis are shown.

chains).[35] During T-cell differentiation, the *TCRG* locus is rearranged early in the differentiation stage and retained throughout the life span of both αβ and γδ T cells.[80] In order to amplify the CDR3 region, forward primers are designed within the V region, while reverse primers are set within the J region, in both *IGH* and *TCRG* loci. In order to improve the sensitivity and specificity of PARR analytical systems, many types of primer sets have been designed in various laboratories for dogs[5,9,22,23,37,38,78,84,85,91] and cats.[28,57,58,62,88,90] In addition to PARR evaluating complete *IGH–VDJ* rearrangement, use of PARR for incomplete *IGH–DJ*, kappa-deleting element *(Kde)*, and immunoglobulin lambda light chain *(IGL)* gene rearrangement was recently reported for detecting clonality in feline B-cell neoplasms.[70]

Three types of analytical procedures have been developed for PARR. These are gel electrophoresis, melting curve analysis, and GeneScan. Gel electrophoresis is a standard procedure which is commonly used for the analysis of PCR products. Polyacrylamide gel electrophoresis is usually performed following heteroduplex procedures.[77]

Melting curve analysis is another method used to analyze PARR products in dogs and cats. Real-time PCR systems enable the separation of contiguous PCR products via melting temperatures. Since this method does not utilize electrophoresis, rapid analysis with a reduced risk of cross-contamination is made possible.[29,44]

GeneScan was introduced for PARR tests in dogs and cats.[22,23,57,58] DNA fragments amplified using fluorochrome-labeled primers are analyzed in denatured condition using a capillary-sequencing polymer. Since the GeneScan method possesses high-resolution capabilities, it is suited for the detection of clonal peak(s) in a polyclonal background. Furthermore, the exact sizes of PCR products can be determined using this method. GeneScan analysis followed by DNA sequencing was used to demonstrate the identity of lymphocyte clone during the progression from nodal marginal zone lymphoma to diffuse large B-cell lymphoma in a dog.[71]

Samples for PARR

Any genomic DNA sample extracted from cells/tissues may be used for PARR analysis. Samples that are commonly used for PARR include fine-needle aspiration (FNA) samples of lymph node/mass/organ, endoscopic biopsied tissues, peripheral blood, bone marrow, biopsied samples of skin/tissue/organ, and abdominal/thoracic/cerebrospinal fluid. Freshly isolated or rapidly frozen tissues/cells can be a source of ideal samples. Meanwhile, cells smeared on glass slides (stained or not) or formalin-fixed paraffin-embedded (FFPE) tissues can also be used for PARR. However, since DNA fragmentation may occur due to storage on glass slides at room temperature for a long time, or due to formalin fixation,[25,45] amplification of control gene(s) should be concurrently performed to ensure the integrity of DNA extracted from these samples.

Interpretation of the Results of PARR

Since one somatic cell contains a pair of chromosomes, amplification of one or two distinct band(s)/peak(s) is usually interpreted as clonal.[22,57,84,90] Although normal mature lymphocytes possess only one rearranged *IGH* or *TCRG* allele following differentiation, as described in the allelic exclusion theory,[35] two distinct bands (or peaks) are often observed in lymphoid malignancies. Furthermore, the presence of multiple rearrangements in the *TCRG* locus (4.6 rearrangements per lymphoma in average) has been detected in canine T-cell malignancies.[37] Recent reports have revealed that a canine *TCRG* locus includes seven complete V–J–C cassettes,[37,48] enabling multiple rearrangements in each allele, which is topologically different from that of human genomes. The topology of the feline *TCRG* locus is not known. However, three to five distinct bands (or peaks) are frequently amplified in feline T-cell lymphomas.[62]

As for the rearrangement of *IGH*, amplification of one or two distinct bands (or peaks) is usually interpreted as an indication of clonal rearrangement. On the other hand, the criteria for clonal rearrangement of *TCRG*

differ between studies, wherein some studies define one or two distinct bands (or peaks) as clonal,[20,32,63,84,91] whereas others may consider samples with three or more bands (or peaks) as clonal.[9,22,38,61]

Clonal results indicate the proliferation of a particular lymphocyte clone. Clonally expanded lymphocytes would be most likely indicative of a neoplastic disease, such as lymphoma, lymphoid leukemia, or plasma cell tumors. However, clonal results may also be a result of reactive proliferation against a specific antigen.[5,52] Lymphocyte populations that infiltrated regressing histiocytomas were also shown to be clonal by PARR.[39]

When a clonal pattern is not detected via PARR analysis, the lymphoid cell population in the sample is generally assumed to be normal, or one generated by reactive proliferation. However, irrespective of the actual presence of a neoplastic cell population, if the rate of tumor cells in the sample is below the detection limit of PARR (approximately 10% in lymphoid tissues),[5] a clonal result cannot be confirmed. Moreover, because the rearrangement process of antigen receptor genes is quite complex and variable, any of the primers designed in many laboratories do not have a 100% ability to amplify a rearranged antigen receptor gene, such as *IGH* or *TCRG*. Therefore, even when a clonal pattern is not indicated by PARR analysis, a diagnosis of lymphoma, or other form of lymphoid malignancy, cannot be excluded.

Sensitivity and Specificity of PARR

The overall sensitivity of PARR analysis for detection of lymphoid tumors is reported to be in the range of 60–100% for dogs[5,22,23,38,43,44,79,87] and 30–90% for cats.[26,28,29,57,58,61,62,88,90] Specificity is reported to exceed 90% in both dogs and cats. Sensitivity and specificity of PARR vary with the type of malignancy.

Of these PARR analyses in dogs and cats, sensitivity for detecting *IGH* rearrangement among feline B-cell neoplasms has been low, with sensitivity values ranging from 30% to 50% in several studies.[26,29,61] In addition to the PARR evaluating complete *IGH–VDJ* rearrangement, use of PARR for incomplete *IGH–DJ*, *Kde*, and *IGL* rearrangement was shown to increase the sensitivity (up to 87%) for detecting clonality in feline B-cell neoplasms.[70]

Application of PARR for Diagnosis

A large proportion of dogs with multicentric lymphoma are afflicted with high-grade B-cell lymphoma, histologically classified as DLBCL. FNA of enlarged lymph nodes of a dog with DLBCL usually shows a uniform population of large lymphoid cells (centroblasts, immunoblasts, etc.). In such cases, diagnosis of lymphoma may be made via cytology. However, when cytological examinations show the lymphoid cells to be small, or not typical of centroblasts, resection biopsy followed by histological examination may be indicated. Although PARR does not provide the scope of information provided by histopathology, PARR analysis of FNA samples may detect clonality and define T- or B-cell lineage. Demonstration of cell clonality via PARR has been helpful for the diagnosis of several subtypes of lymphoma with a relatively indolent biologic behavior, such as nodal and lingual T-zone lymphomas (Figure 62.3a),[27,54,84] splenic marginal zone lymphoma,[64,73,84] and colorectal follicular lymphoma.[68]

Various types of lymphomas are observed in cats, including alimentary, nasal, mediastinal, peripheral nodal, laryngeal/tracheal, renal, central nervous system, cutaneous, and hepatic forms. Histopathology is a standard procedure used for diagnosis. However, sufficient tissue samples cannot be obtained in some cats suspected of having lymphoma. In such cases, findings of PARR combined with those of cytological examinations of FNA specimens or body cavity fluids may be utilized to support the diagnosis.

PARR analysis using endoscopically biopsied specimens has been utilized for the assessment of gastrointestinal diseases in cats. In feline gastrointestinal lymphoma, its sensitivity was shown to be 80–90% for T-cell lymphoma,[24,61,62] and 50% for B-cell lymphoma.[61] A stepwise diagnosis algorithm, integrating the results of immunohistochemistry and PARR with those of histopathological findings, was proposed to differentiate between intestinal lymphoma (especially small cell lymphoma) and inflammatory bowel disease in cats.[40]

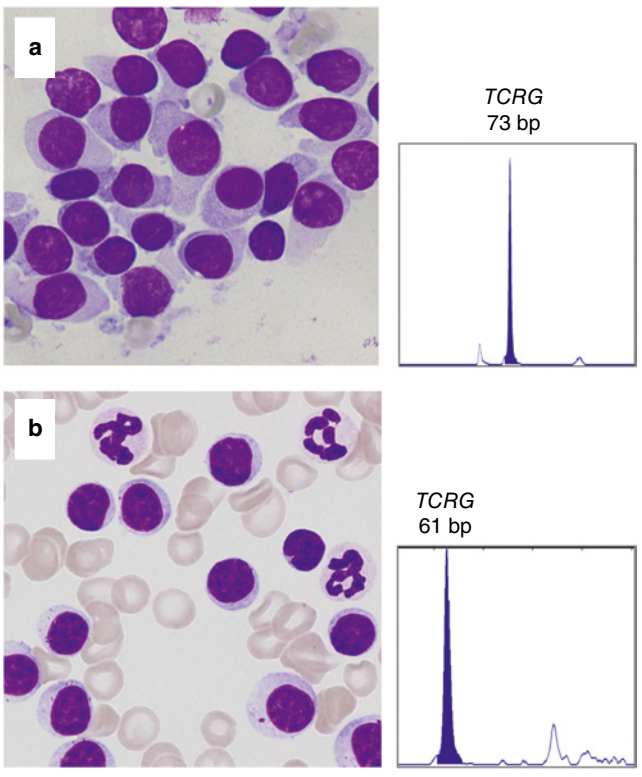

FIGURE 62.3 Examples of the results of PARR analysis for (a) a lymph node tissue sample from a dog with T-zone lymphoma and (b) a peripheral blood sample from a dog with T-cell chronic lymphocytic leukemia (T-CLL). Sizes of the monoclonal peaks are indicated above the charts.

In canine gastrointestinal lymphoma, detection sensitivity of PARR is reported to be 65–85%.[20,23,32,66,75] Canine gastrointestinal T-cell lymphoma is divided into two major subtypes: large cell lymphoma resembling human enteropathy-associated T-cell lymphoma (EATL) type I; and small cell lymphoma resembling human EATL type II.[7,11,49,50,51] Distinguishing between small cell lymphoma and chronic enteritis via histopathology alone is problematic. Moreover, 20–50% of tissue samples diagnosed as chronic enteritis via histologic findings were found to show clonal patterns by PARR analysis,[32,50,63,67] making differential diagnosis of small cell lymphoma and chronic enteritis even more difficult. Caution is required when interpreting PARR results of biopsied gastrointestinal tissue samples. Some studies have indicated an association between clonality and prognosis for canine small cell lymphoma and chronic enteritis.[63,65,67] Further studies may be needed to disclose the relationship between chronic enteritis and small cell lymphoma.

PARR of canine epitheliotropic cutaneous T-cell lymphoma using skin biopsy samples resulted in a sensitivity as high as 95%.[9] On the other hand, PARR of feline cutaneous lymphoma at vaccine injection sites including T, B, and natural killer (NK) types resulted in 60% sensitivity.[69] PARR was also used to indicate clonality in acute lymphoblastic leukemia (ALL) and CLL in dogs, resulting in a sensitivity higher than 80%.[5,91] When an increase in the number of small lymphocytes occurs in peripheral blood in the absence of a possible cause of lymphocytosis, a differential diagnosis of CLL is considered. In such cases, PARR using a sample of peripheral blood or bone marrow may be helpful for identification of clonality and cell lineage (Figure 62.3b). The sensitivity of PARR seems to be lower for leukemias in cats, although the reason for this is not well understood due to the limited case numbers.[57,82] Clonal rearrangement of *IGH* was shown in a large proportion of canine and feline cases with plasmacytoma and myeloma;[5,57,87] however, a low sensitivity (41%) for canine cutaneous plasmacytoma was reported.[76] PARR may also be helpful in the diagnosis of nonlymphoid neoplastic diseases such as thymoma, where polyclonal results were detected in 92% of canine thymoma tissues.[86]

X-CHROMOSOME INACTIVATION PATTERN (XCIP) ANALYSIS

Principles of XCIP Analysis

In mammalian females, either the paternal or maternal X-chromosome generally undergoes random inactivation in each cell by way of epigenetic changes during embryogenesis. This is stably inherited by the daughter progeny of each cell, resulting in a theoretical expectation of an approximately 1:1 inactivation ratio between paternally and maternally derived X-chromosomes in normal or reactive tissues. By contrast, most neoplastic tissues are composed of a cell population clonally derived from a single cell, generally exhibiting a uniform XCIP and a significant deviation from the 1:1 inactivation ratio (Figure 62.4). Therefore, demonstration of a nonrandom XCIP (skewed XCIP) is indicative of a clonal origin of the cells concerned. A widely used method for determining clonality in humans via the X-chromosome inactivation principle is known as the human androgen receptor (AR) gene assay (HUMARA).[10,17]

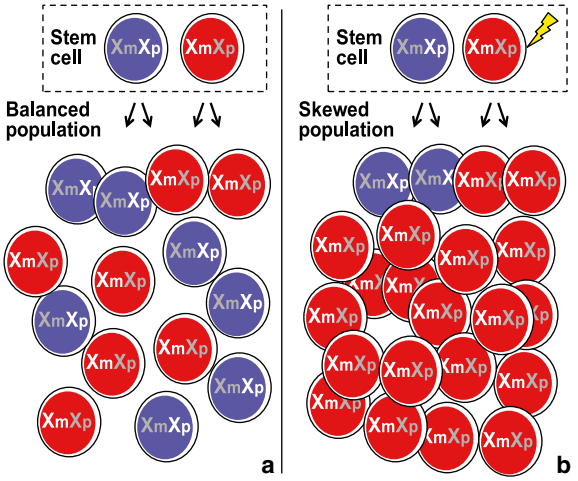

FIGURE 62.4 Principles of XCIP analysis for the clonality assessment. Xm or Xp (characters indicated in the nucleus) indicates maternal or paternal X-chromosome, respectively. White-colored or grey-colored character indicates active or inactive X-chromosome, respectively. (a) In non-neoplastic condition, cells in some organ (e.g., bone marrow) are composed of a balanced population of blue cells (harboring inactive maternal and active paternal X-chromosomes) and red cells (harboring active maternal and inactive paternal X-chromosomes); (b) By contrast, in neoplastic condition, cells in some organ are composed of a skewed population with respect to XCIP because of the clonal expansion originated from a single transformed cell (e.g., red cells harboring active maternal and inactive paternal X-chromosomes).

Procedures for XCIP Analysis

Transcription of human *AR* gene on the inactive X-chromosome is strictly inhibited by methylation of the CpG island in the promoter.[34] Methylation status is revealed whether the restriction site is cleaved by some methylation-sensitive restriction endonuclease. Because of the difference in methylation status between inactive (methylated) and active (nonmethylated) X-chromosomes, DNA from only inactive X-chromosomes can be amplified after digestion with a methylation-sensitive endonuclease (e.g., HpaII). A difference in the number of polymorphic repetitive sequence (e.g., CAG repeat) between two X-chromosomes enables distinguishing one from the other.[1,55,56]

The degree of skewness (imbalanced inactivation) is determined by comparing the amplified DNA amount for each allele of digested and undigested samples, using results of the GeneScan analysis. The corrected inactive allele ratio (CIAR) is defined as the allele ratio of the digested sample divided by the allele ratio of the undigested sample.[55,56] The sample population is judged

as clonal when CIAR exceeds approximately 3 in several reports.[46,53]

To apply the XCIP analysis using *AR* gene for the assessment of clonal origin of cells, at least one of the two CAG tandem repeats should be heterozygous for the repeat number. The frequency of heterozygosity of CAG repeats in feline *AR* gene was shown to be 68%,[55] indicating its availability in more than two thirds of female cat individuals. On the other hand, the frequency of heterozygosity of CAG repeats in canine *AR* gene was found to be lower, 49%.[56] In a recent study, utility of XCIP analysis was improved up to 83% of female individuals by incorporating the examination of AC repeats in *SLIT* and *NTRK-like family member 4* (*SLITRK4*) gene into the previously reported CAG repeats examination of *AR* gene in dogs.[81]

A low tumor-cell purity in the sample (theoretically less than 50%) may lead to false negative results. Therefore, for XCIP analysis to be effective, more than 50% of the cell population should be the cells of interest (i.e., suspected tumor cells).

Application of XCIP Analysis for Diagnosis

XCIP analysis has been used for assessing cell clonality in various neoplastic and preneoplastic conditions of hematopoietic cells in humans such as CML,[53] acute myeloid leukemia (AML),[21] and myelodysplastic syndrome (MDS).[8] Although XCIP analysis is applicable only for females, a major advantage of this analysis is its possible application to any type of neoplastic diseases in which a tumor-specific genetic or phenotypic marker has not been identified.

In myeloproliferative neoplasms (MPNs) (formerly termed chronic myeloproliferative disorders), the morphology of proliferating cells differs little from that of normal blood cells, which makes the differentiation between neoplastic and non-neoplastic cells difficult. This class of diseases includes CML, polycythemia vera (PV), and essential thrombocythemia (ET).[36] Diagnosis of MPNs can be made primarily by excluding other causes via thorough clinical examinations. However, it is sometimes difficult to reach a definitive diagnosis. Although reciprocal chromosomal translocations have been identified in a proportion of canine neoplasms,[3,4,12] their frequency in specific disease is not known. Skewness in XCIP analysis has been shown to be useful for the diagnosis of CML in dogs.[56]

MDSs are a group of clonal hematopoietic stem cell diseases characterized by ineffective hematopoiesis resulting in cytopenia(s) and dysplasia in one or more blood cell lineages. Feline leukemia virus (FeLV) infection has been shown to be associated with the development of MDS in cats;[31] however, MDS is also found in FeLV antigen-negative cats.[36] In humans, MDS is considered to be caused by clonal expansion of bone marrow cells from aberrant pluripotent hematopoietic stem cells with a variety of somatic mutations.[42] Progression to acute myeloid leukemia from MDS has been reported in humans as well as in dogs[2,19,36,89] and cats.[30,31] Distinctly skewed XCIPs were found in bone marrow samples of cats hematologically diagnosed with MDS.[55] When findings based on peripheral blood and bone marrow examinations suggest a diagnosis of MDS, and other disorders are excluded, CIARs obtained via XCIP analysis may substantiate the clonality of cells, leading to a more reliable diagnosis of MDS.

Apart from the lymphoid and hematopoietic diseases, canine cutaneous histiocytoma was shown to be a disease of clonal origin by XCIP analysis.[13] There are several other disorders, such as splenic fibrohistiocytic nodules,[72] various histiocytic proliferative diseases,[13,60] and hypereosinophilic syndromes,[47] in which the neoplastic nature (clonal origin) of the diseases has been argued. XCIP analysis will provide objective data to demonstrate the clonality of the cells of interest, leading to more accurate diagnoses.

CHAPTER 63

Immunophenotyping

AUSTIN K. VIALL

Immunophenotyping
Indications
Sample Collection and Preparation
Blood and Bone Marrow
Aspirate Material and Cavity Fluids
Flow Cytometry Procedure
Antibody Panels
Reporting of Immunophenotyping Results
Interpretation of Immunophenotyping Results
Differentiating Reactive and Neoplastic Lymphocytes
Leukemia Lineage Determination
Differentiating Leukemia and Lymphoma

Acronyms and Abbreviations

ALL, acute lymphocytic leukemia; AML, acute myeloid leukemia; CML, chronic myeloid leukemia; CLL, chronic lymphocytic leukemia; ICC, immunocytochemistry; IHC, immunohistochemistry; MHC, major histocompatibility complex; TCR, T-cell receptor.

IMMUNOPHENOTYPING

In people, well over 80 distinct lymphomas and leukemias are recognized.[46] Historically, specific hematologic malignancies were defined by unique histological, cytological, and clinical features. The advent of diagnostic antibodies for detection of expressed surface and intracellular markers dramatically refined classification of human hematologic malignancies. Through this process of immunophenotyping, the vast majority of human lymphomas and leukemias may be identified by marker expression with concurrent cytological assessment.[4] For animals, there has been a similar expansion in the number of diagnostic antibodies available for tumor immunophenotyping, which has aided the process of diagnosing lymphoma and leukemia along with facilitating identification of novel types and subtypes of hematologic malignancies.

Immunophenotyping methodologies use the same fundamental approach. An antibody targeting a specific membrane or cytosolic protein marker is applied to the tumor cell population, with antibody binding detected either (1) directly through a conjugated fluorochrome or enzyme that facilitates a colorimetric reaction or (2) using a secondary reporting antibody targeting the bound primary antibody. Monoclonal antibodies are preferred over polyclonal antibodies due to variations in the target-binding motifs with polyclonal antibodies; polyclonal antibodies also have a higher tendency for nonspecific binding. Immunophenotyping may be performed on paraffin-embedded tissue specimens through immunohistochemistry (IHC) or on glass slide cytology samples with immunocytochemistry (ICC). IHC on lymph nodes and other tissues histologically suspected to contain lymphoid malignancies is an essential aspect of fully assessing such samples. However, formalin fixation may dramatically alter the physiochemical nature of antibody targets—specifically proteins—and subsequently reduce or nullify the binding capability of the antibody to the protein.[41] Consequently, the number of diagnostic antibodies available for performing IHC for animal lymphomas/leukemias is smaller than those available for immunophenotyping with flow cytometry. While most antibodies available for flow cytometric immunophenotyping also work for ICC, flow cytometry is considered a more flexible and technically forgiving analytic modality and provides a plethora of additional data concerning the target cell population (forward

scatter/side scatter for cell population differentiation, etc.) As such, immunophenotyping by flow cytometry will be the focus of this chapter.

Indications

For hematologic malignancies, flow cytometric immunophenotyping can be used to accomplish two general diagnostic objectives: (1) determine if a patient has lymphoma or leukemia and (2) determine the specific lymphoma or leukemia present. Furthermore, the presence or absence of certain cellular markers on a tumor population may be predictive of patient survival duration. While hematologic malignancies can manifest as a wide spectrum of clinical presentations, flow cytometric evaluation is most typically indicated when: (1) more cells of a specific type are present than normally expected (e.g., peripheral blood or bone marrow lymphocytosis) or (2) a round cell population has a cytologically malignant appearance. Table 63.1 provides more specific guidelines on scenarios when flow cytometry may be diagnostically beneficial or when the technique may provide no additionally useful information. Please note these are general guidelines and that flow cytometric immunophenotyping could be used diagnostically for a number of clinical scenarios as long as the diagnostician considers the findings in context of the limitations of this technique. Additionally, it is worthwhile to contact the laboratory performing the flow cytometry, as some groups may have additional or novel diagnostic capabilities that are not yet reported in scientific literature.

Sample Collection and Preparation

For flow cytometric immunophenotyping, it is critical that cells be viable during the analysis of their cell surface markers. Nonviable cells may have altered physical properties and decrease/loss of surface markers, which could potentially lead to incorrect or confounding flow cytometric results. Retaining cell viability is paramount and when cells are prepared for analysis measures should be taken to ensure and prolong viability. With refrigeration, peripheral blood and bone marrow samples may retain decent cellular viability for several days. Conversely, fluid preparations made from organs (e.g., lymph node or splenic aspirate material) and low-protein effusions have relatively poor cellular viability without addition of cellular-supportive reagents (e.g., serum or albumin). If not already performed, a concurrent CBC and blood smear review for peripheral blood or cytological/histological evaluation of lymph nodes or other organs is strongly recommended so as to provide complementary diagnostic information to the flow cytometry results. If samples are being submitted to another laboratory for flow cytometry, results for these diagnostic tests should be concurrently submitted with the flow cytometry samples.

The following are generally recommended guidelines for collecting and processing samples for flow cytometric immunophenotyping.

Blood and Bone Marrow

Peripheral blood and bone marrow aspirate samples should be immediately collected into an EDTA vacutainer to the appropriate volume for anticoagulation. 1 mL of whole blood or bone marrow is the minimum volume for analysis for most laboratories. Samples should be kept and/or shipped at 4 °C with cold packs; insulating the sample is recommended so as to prevent freezing. Samples being analyzed by another laboratory should be shipped overnight for analysis. Bone marrow samples usually retain adequate cell viability for 3 days postcollection, while peripheral blood samples may maintain adequate viability for 5 days postcollection. Utilization of commercially available vacutainers with stabilizing reagents, such as Cyto-Chex BCT vacutainers, may extend sample analysis viability out to 7 days postcollection, especially for certain markers (CD4, CD8, and CD21).[7,52]

Aspirate Material and Cavity Fluids

Tissue aspirate material and cavity fluid with a low-protein concentration (<5 mg/dL) should be placed in an aqueous medium with an added protein source (e.g., serum) to preserve cellular viability.[1,54] Tissue aspirate material could be expelled into 1–2 mL Roswell Park Memorial Institute (RPMI) medium, Dulbecco's modified Eagle's medium (DMEM), or other standard cell culture media with addition of fetal bovine serum (FBS) to 10% by volume. In a hospital setting, aspirate material could be placed into 1 mL of an isotonic IV-administered fluid (e.g., lactated Ringer's solution, Normosol-R, 0.9% NaCl) with addition of serum from the patient (or animal from the same species) to 10% by volume into a red-top vacutainer.[28] Cavity fluid should be placed into an EDTA vacutainer and serum similarly added to 10% by volume. The preparation should be immediately kept at 4 °C and if analyzed by another laboratory shipped overnight for evaluation. This stabilization procedure typically preserves cell viability for 2–3 days postcollection.

Flow Cytometry Procedure

Significant variation exists between laboratories for the protocols for preparing and analyzing samples for flow cytometry. That said, most protocols follow a similar procedure: (1) isolate leukocytes, (2) incubate with antibodies and a viability dye, (3) analyze samples with flow cytometer, and (4) evaluate flow cytometer data with flow cytometry standard (FCS) compatible software. Typically, leukocyte isolation, marker staining, and sample analysis by the cytometer are performed in immediate succession; this is the most common approach described by laboratories which report flow cytometric immunophenotyping.[3,19,23,28,47] The simplest method for isolating leukocytes is to treat samples with a hypotonic lysing solution to rupture erythrocytes, followed by centrifugation to generate a leukocyte pellet, and then leukocyte washing with an isotonic solution.[17]

TABLE 63.1 Indications and contraindications for flow cytometric immunophenotyping.

	Blood	Masses/lymph nodes	Bone marrow	Cavity fluids
Indicated	Lymphocytosis Cytologically abnormal cells Monocytosis	Lymphadenopathy Mediastinal masses Splenomegaly with cytologic suspicion of lymphoma	Cytologically abnormal cells Increased lymphocyte percentage	Increased lymphocytes Cells with aberrant morphology suggesting lymphoid or myeloid origin
Not indicated	Neutrophilia[a] Eosinophilia Thrombocytosis Polycythemia vera or cytopenias	Metastatic disease from nonlymphoid tumors[b] Primary tumors of nonhematologic origin Marked lymphoid reactivity	Increased plasma cells or monoclonal gammopathy[c] Loss of a specific lineage or myelofibrosis	Transudates with few cells Suspected septic process Suspect carcinoma/mesothelioma vs reactive mesothelial cells[b]

[a] Neutrophils from patients with chronic myeloid leukemia (CML) and non-neoplastic neutrophilia have identical immunophenotypes.
[b] The use of flow cytometry to detect nonlymphoid tumors in lymph nodes and cavity fluids (e.g., metastatic mast cell tumor or carcinoma) has been reported for certain tumor types. However, such flow cytometric assays are not widely commercially available. Diagnosticians are advised to consult with laboratory performing flow cytometric immunophenotyping to determine if available by the laboratory.
[c] A differentiating immunophenotype between malignant and reactive canine plasma cells has not yet been described. Flow cytometry will not be able to distinguish reactive from neoplastic plasma cells.

As an alternative, density gradient centrifugation to remove erythrocytes, platelets, and dead cells can be performed. However, this approach is more labor intensive, time consuming, and may cause selective loss of certain leukocyte populations. Isolated cells are then incubated with a panel of antibodies, often requiring multiple separate incubations with different antibody combinations designed to identify specific cell types while avoiding fluorochrome crossover. If the sample cannot be analyzed immediately after staining, then stained cells may be placed in a fixative buffer and stored at 4 °C; this can preserve the sample for up to three additional days for cytometer analysis.[22] However, the fixative buffer can potentially alter cell physical properties (e.g., forward scatter and side scatter) and antibody fluorochrome intensity.[17,22] As such, protocols utilizing fixative buffer should thoroughly vet the changes induced by the buffer in context of interpreting flow cytometric results. Specific details on flow cytometry procedural steps are beyond the scope of this chapter, but a number of protocols are reported.[9,11,27,28,37,39,47]

Antibody Panels

As laboratories which perform immunophenotyping use unique antibody combinations tailored to their respective protocols, the reported panels of diagnostic antibodies used for immunophenotyping are highly variable. The central goals of designing an antibody panel are to detect cells with an abnormal immunophenotype, which provides evidence for neoplasia when cytological or histological findings are unclear, and to determine the lineage origin of the malignant population. Currently, there are no standardized antibody panels for immunophenotyping in animals, so following consensus recommendations for immunophenotyping human hematologic malignancies is recommended.[12,43] While no consensus has been published for antibodies for veterinary immunophenotyping, the panel of antibodies for markers of lymphoid malignancies used in a multi-institutional proficiency study of canine immunophenotyping should be considered.[28] Each laboratory should also develop its antibody panel based upon the expertise of the laboratory group, available cytometer, recent literature on analytic antibodies, and commercial availability of antibodies. Furthermore, antibody panels will likely be different for the target species. Many more vetted antibodies are commercially available for dogs relative to cats, horses, ruminants, and other species.

A minimum panel for canine hematologic malignancies should include antibodies targeting surface markers for T lymphocytes (CD3, CD4, CD5, and CD8), B lymphocytes (CD21 or CD22), monocytes (CD14), stem cell antigen for acute leukemia (CD34), pan-leukocyte antigen (CD45), and major histocompatibility complex (MHC) II.[1,9,28] This panel identifies the most common lymphoproliferative disorders in the dog.[28] Addition of antibodies targeting T-cell receptor (TCR)αβ, TCRγδ, IgM, CD25, and CD90 may allow further subcharacterization of lymphoid malignancies along with prognostic information for certain lymphomas and leukemias.[16,23,36,54] Identification of myelomonocytic malignancies can be accomplished with antibodies targeting CD11b (neutrophil and monocyte marker), CD11c, CD11d, and CD1a/b/c (dendritic cell and macrophage markers), and CD18 (β integrin).[28,31,44] Detection of cytoplasmic markers CD3ε and CD79α requires a permeabilization step for staining, but these are essential for detecting the immunophenotype of acute leukemias, as such immature malignancies may not express expected surface antigens for their lineage.[49] The selection of antibodies available for immunophenotyping cats and other mammals is unfortunately limited. Monoclonal antibodies targeting and/or reacting to feline CD4, CD5, CD8, CD18, and CD21 are commercially available and reportedly used diagnostically.[39] For other species, antibodies used to detect CD3ε and CD79α along with the B lymphocyte nuclear transcription factor PAX5 react almost entirely across mammals and could be used to at least establish T or B lymphocyte origins.[24,29,30]

Concerning the source of analytic antibodies, commercially available fluorochrome-conjugated antibodies are generally preferred. A relatively small number of commercial sources provide analytic antibodies for veterinary diagnostics, and many vend the same antibody clones. As such, the production quality control of these antibodies, reagent preparation protocols, and antibody behavior become less variable between laboratories. Additionally, fluorochrome-conjugated primary antibodies permit multiparameter staining of cells, which is essential for identifying cells with aberrant immunophenotype. Concurrent incubation of the cells with a viability identification dye—such as propidium iodide, 7-amino-actinomycin D, or proprietary fixable dyes—is used to exclude dead cells from analysis.[28] Exclusion of nonviable cells is essential, as dead cells can stain falsely positive for markers due to either nonspecifically bind antibodies or being permeable enough for intracellular staining where cytosolic antigens may be present even in the absence of surface expression.[32]

Reporting of Immunophenotyping Results

A useful immunophenotyping report should contain both objective flow cytometric data along with a subjective interpretation of the results.[8,13] Recent consensus recommendations on reporting veterinary flow cytometric results advise the following information be provided: (1) laboratory identification, (2) patient identification, (3) sample type and quality (i.e., percentage of viable cells, (4) cell preparation and staining (i.e., antibodies used and reference intervals for expected positivities for sample type), (5) percentage of positive cells for each antibody (i.e., percentage of positive cells in gated population and/or whole population, absolute count of positive cells for peripheral blood samples), (6) descriptive report, (7) diagnosis and interpretation, (8) comments and references, and (9) pathologist's signature.[8] The consensus statement provides additional details on the specific information to be presented within each section of the report. Laboratories are advised to establish their own positivity reference intervals, either

percentage of lymphocyte subtypes for lymph node/bone marrow or absolute lymphocyte subtype counts for peripheral blood. If laboratory-specific reference intervals cannot be established, then reporting of published values for healthy animals for lymph node, bone marrow, or blood could be reported.[14,15,20,34,39,40,48]

Interpretation of Immunophenotyping Results

In most circumstance, flow cytometric results should be used to answer two key questions: (1) is a hematologic malignancy present? and (2) what is the lineage origin of the neoplastic population and/or the specific lymphoma/leukemia present? Two criteria classically used to determine if cellular population is malignant are (1) the presence of an abnormal phenotype or (2) an expanded population with a homogenous phenotype, especially for lymphocytes.[28] Lineage differentiation can subsequently be determined either by the expressed pattern of markers on the neoplastic population or, for lymphoid malignancies, lymphocyte clonality testing.[47] Furthermore, certain lymphomas and leukemias have phenotypic "calling cards" which permit subclassification using flow cytometric results alone (e.g., loss of CD45 expression in T-zone lymphoma or expression of CD34 for acute leukemias).

Differentiating Reactive and Neoplastic Lymphocytes

Flow cytometry is commonly performed in cases of peripheral blood lymphocytosis or lymphadenopathy when cytologic assessment cannot differentiate neoplastic or reactive processes. Unlike in human medicine, standardized criteria for differentiating lymphoid neoplasia from lymphoid reactivity with flow cytometry have not been reported.[46] That said, the following guidelines have been advocated for differentiating neoplastic lymphocytosis from non-neoplastic lymphocytosis in blood:[2,3]

Lymphocyte count is above the reference interval, and one of the following:

A. 80% of lymphocytes are a single phenotype, or
B. 60% of lymphocytes are a single phenotype with a monoclonal clonality assay result, or
C. presence of lymphocytes with an aberrant phenotype.

Similarly, consensus metrics for diagnosing lymphoma flow cytometrically has not been established, but the following criteria has been used:[9,47,54]

A. Expansion of specific lymphocyte subtype beyond >60% of all cells.
B. More than 1.5 times expansion of a specific lymphocyte subtype above the reference interval for the population.
C. Atypical dual staining phenotype (e.g., CD4+CD8+ or CD3+/CD5+ and CD21+/CD79a+).
D. Atypical null staining phenotype (e.g., CD3+ CD4− CD8−).

A well-documented exception to the idea that a homogenous expansion of lymphocytes is diagnostic for a lymphoid malignancy is that chronic *Ehrlichia canis* infections can induce a CD8+ T-cell lymphocytosis in small portion of infections.[21,35] Consequently, testing for *E. canis* infection should be considered for CD8+ lymphocytosis <30,000 cells/μL.

Cells may also be considered neoplastic if they have an aberrant phenotype, particularly if the antigens expressed are not typically found in normal or reactive lymphoid processes. Atypical phenotypes reported in lymphoid malignancies in the dog include: T-cell lymphomas and leukemias that have lost CD45 (e.g., T-zone lymphoma), CD3+ or CD5+ populations lacking CD4 and CD8, CD79α B-cell tumors with absent CD21 expression, and dual CD4 CD8 expression indicative of lymphoma in a lymph node, thymoma from an intrathoracic mass, or leukemia, or from peripheral blood.[6,25,42,55] The presence of such cells with aberrant immunophenotypes should be considered strong evidence for a lymphoid malignancy.

Less-reported information is present concerning the immunophenotypes of feline lymphomas and leukemias. A relatively homogenous lymphocytosis comprised of CD4+ lymphocytes, CD4− CD8− lymphocytes, or T cells with low CD5 expression is typically neoplastic.[39] Conversely, a peripheral lymphocytosis with B-lymphocyte expansion or heterogeneous population is more likely the result of reactive processes.[39] Cats with large granular lymphocyte alimentary lymphoma may be identified by CD3+ CD8+ population from the intestinal lesion or a peripheral lymphocytosis.[38] Conversely, a population of CD21 cells accounting >90% of lymphocytes in a feline intestinal lesion is strongly supportive of B-cell alimentary lymphoma.[18] The majority of feline nasal lymphomas are also B-cell immunophenotype.[26]

Leukemia Lineage Determination

While the cellular lineage of mature leukemias is relatively easy to identify due to cytomorphological features, leukemias of immature populations are notoriously challenging, if not impossible, to definitively differentiate cytologically.[50] Using flow cytometry, acute lymphocytic leukemia (ALL) may be identified by expression of extracellular/intracellular lymphoid markers along with co-expression of CD34. Historically, acute myeloid leukemia (AML) was diagnosed when a circulating CD34+ neoplastic population failed to express lymphoid markers along with cytomorphological features suggesting myelomonocytic origin.[50] The advent of antibodies targeting myelomonocytic cells (e.g., CD14, CD11b/c/d, CD18, neutrophil surface antibody, myeloperoxidase, and MAC387) has provided more definitive flow cytometric detection of AML.[28,51]

Select cytochemical stains may provide further support for myeloid origin acute leukemias.[44] Acute megakaryoblastic leukemias may express CD41, CD61, and von Willebrand factor in addition to CD34.[10,45]

The expression of CD34 is classically considered a diagnostic hallmark of acute leukemias. However, rare acute myeloid leukemias which meet other criteria for acute leukemia (e.g., >20% blastic cells in blood or bone marrow) have been reported to lack CD34 expression.[51] Furthermore, rarely B-cell lymphomas may express CD34 and could mimic ALL if presenting in advanced leukemic phase.[33] As such, the absence or expression of CD34 may be misleading in terms of establishing a diagnosis of acute leukemia in a minority of cases. MHC II expression may be situational helpful in differentiating such cases, as ALLs are typically MHC-II-negative while CD34+ B-cell lymphoma would likely be MHC-II-positive. Chronic myeloid leukemia (CML) and chronic lymphocytic leukemia (CLL) may be differentiated from their acute variants by the absence of CD34 expression along with cytomorphological features indicating a mature phenotype.

Differentiating Leukemia and Lymphoma

For patients presenting with a neoplastic lymphocytosis, a common diagnostic conundrum is distinguishing a true leukemia from a lymphoma in leukemic phase (e.g., canine stage V lymphoma). Presently, there are no consensus criteria for differentiating lymphoma and leukemia with immunophenotyping alone. As such, differentiating leukemia and lymphoma should be based upon a combination of immunophenotypic, cytologic, clinicopathologic, and clinical data from patients. Patterns suggesting a diagnosis of primary lymphocytic leukemia over leukemic-phase lymphoma in dogs include: CD34+ circulating population for ALL, circulating small cell population expressing CD21 for B-cell CLL, and circulating small cell population of CD8+ T lymphocytes with <30,000 lymphocytes/μL for T-cell CLL.[55] For canine B-cell CLL, alternate criteria includes: >5000 lymphocytes/μL with small cell phenotypes and >60% lymphocytes being CD21+.[5] Patients presenting with marked peripheral lymphadenopathy and lymphocytosis comprised of T or B cells with large lymphocytes suggest leukemic phase large cell lymphoma, although dogs with ALL may also have this clinical presentation. Indeed, the presence of lymphadenopathy—especially for dogs with small cell lymphocytosis—does not reliably differentiate lymphoma from a primary leukemia.[16,19,42] As for cats, criteria for CLL has been reported as >9000 lymphocytes/μL with a small mature phenotype, homogeneous immunophenotype, and concurrent cytopenia.[39] As the vast majority of feline CLLs are CD4+, the presence of such an immunophenotype on the neoplastic cells further supports this diagnosis.[39] Lymphocytosis accompanying lymphoma is relatively uncommon in cats, although low frequency of circulating neoplastic lymphocytes in cats with large granular lymphocyte alimentary lymphoma has been repeatedly reported.[38,53] For some patients presenting with advanced stages of either malignancy, it may be clinically impossible to truly differentiate a primary leukemia from leukemic phase lymphoma.

Acronyms and Abbreviations

ACK, ammonium-chloride-potassium; ALL, acute lymphocytic leukemia; AML, acute myeloid leukemia; AUL, acute undifferentiated leukemia; CBC, complete blood count; CD, cluster of differentiation; CLL, chronic lymphocytic leukemia; CSF, cerebrospinal fluid; DLBCL, diffuse large B-cell lymphoma; FNA, fine needle aspirate; FSC, forward scatter; IHC, immunohistochemistry; LGAL, low-grade alimentary lymphoma; LGL, large granular lymphocyte; LRS, lactated Ringer's solution; MCL, mantle cell lymphoma; MST, median survival time; MHCII, major histocompatibility complex II; MRD, minimal residual disease; NMZL, nodal marginal zone lymphoma; PARR, PCR for antigen receptor rearrangement; PTCL-NOS, peripheral T-cell lymphoma, not otherwise specified; T-LBL, T-cell lymphoblastic lymphoma; TZL, T-zone lymphoma/leukemia.

CLINICAL FLOW CYTOMETRY

The role of flow cytometry as an adjunctive tool for diagnosis and prognosis of hematologic neoplasia in veterinary medicine is rapidly expanding. Flow cytometry allows for the evaluation of thousands of cells in suspension based on light scatter properties and surface or internal protein expression to determine cell size, complexity, and immunophenotype.

There are over 20 recognized subtypes of lymphoma and leukemia in dogs and fewer in cats. Although these different subtypes were originally defined by histologic and/or cytologic appearance and clinical behavior, it is now possible to define some of the most common forms based on the array of proteins expressed on the cell surface using immunophenotyping. Immunophenotyping of hematopoietic cells by flow cytometry utilizes a panel of fluorescently labeled antibodies that bind to cell surface proteins, called cluster of differentiation (CD) markers, to identify cell lineage. Many monoclonal antibodies are now available for dogs, and a more limited number are available for cats.

INDICATIONS

In hematologic neoplasia, flow cytometry can be used to determine if a patient has lymphoma or leukemia, to

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

identify the type of lymphoma or leukemia, and to provide prognostic information. Flow cytometry is not a stand-alone diagnostic test. It is most often used in combination with other diagnostic modalities including cytology, CBC, and/or peripheral blood smear exam and less commonly following inconclusive histopathology results.

Hematologic neoplasia can present with a very wide range of clinical symptoms and flow cytometry is generally indicated when: (1) there are more leukocytes present than are expected, (2) there are cells with a cytologically atypical appearance, or (3) there is a cell type inappropriate for the given location. Flow cytometry is performed on peripheral blood, aspirates of lymph nodes, other organs or masses, body cavity fluids, and bone marrow. Flow cytometry may also be useful for evaluating minimal residual disease (MRD) in patients that have undergone chemotherapy.[4,16]

Flow cytometry of peripheral blood is indicated when there is a lymphocytosis, or the presence of cells concerning for neoplasia on blood smear examination. Flow cytometry is not indicated for neutrophilia, monocytosis, or eosinophilia. While persistent elevations in these cell lines may infrequently represent chronic leukemia, these conditions cannot be diagnosed by flow cytometry with currently available antibodies because the non-neoplastic cellular counterparts have the same immunophenotype as the leukemic cells.

Flow cytometry of bone marrow is indicated when increased numbers of blasts/immature cells or small lymphocytes are present, but not for lineage loss or myelofibrosis. Currently, no antibodies that definitively identify plasma cells in either dogs or cats are readily available for flow cytometry. If an expanded plasma cell population is present, and the clinician is trying to determine if it is neoplastic, the PCR for antigen receptor rearrangement (PARR) assay and serum protein electrophoresis/immunofixation would be the most useful tests to answer this question. If a population of clearly neoplastic cells is suspected to be plasma cells but the lineage is not clear, immunocytochemistry/histochemistry using antibodies to lineage-specific antigens (e.g., Mum1) would be appropriate.

Flow cytometry for patients with lymphadenopathy, organomegaly, masses and/or body cavity effusion is indicated if there is a histologic or cytologic interpretation of: (1) lymphoma or probable lymphoma, (2) uniform expansion of small lymphocytes, or (3) immature round cells suspicious for lymphoid or myeloid origin. Flow cytometry is also helpful to distinguish between lymphoma and thymoma for mediastinal masses. The use of flow cytometry to detect nonhematologic tumors in lymph nodes and cavity fluids (such as melanoma in a lymph node or carcinoma in a pleural effusion) is not utilized in veterinary medicine. As antibodies that detect these tumors become available and tested, however, flow cytometry may become an important application for this purpose.

It is also important to contact the laboratory to which you are submitting flow cytometry samples because some laboratories may have additional capabilities that have not yet been reported in the literature.

SAMPLE PREPARATION

Detection of cell surface antigens by flow cytometry requires viable cells. Therefore, when cells are prepared, steps must be taken to ensure they remain viable until they are processed. Peripheral blood and bone marrow samples can retain reasonable viability for several days when kept refrigerated, but samples from effusions, or aspirates of lymph nodes or masses, are less resilient. The following procedures are recommended when collecting samples for flow cytometry.

Blood and Bone Marrow

Collect samples in EDTA (a minimum of 0.5 mL for peripheral blood), store refrigerated, and ship overnight with a cold pack. Testing within 2–3 days of sample collection is preferred, but in some cases, blood samples can remain sufficiently viable for 5 days. A CBC performed within 2–3 days of sample acquisition for flow cytometry is required for interpretation of blood and bone marrow samples.

Aspirates and Body Cavity Fluid

It is essential that tissue aspirates be placed in medium with serum in order to preserve viability. Roswell Park Memorial Institute (RPMI) medium, Dulbecco's modified Eagle's medium (DMEM), and similar cell culture media with 10% fetal bovine serum are ideal. These reagents can usually be found in a university setting. In private practices where this is not readily available, 0.9% saline with 10% conspecific serum can be used. Typically, 1 mL of 0.9% saline lactated Ringer's solution (LRS, Norm R or Norm M may also be used) is added into an additive-free test tube or red-top tube (no serum separator) without anticoagulant, and serum from an animal of the same species (this can be from the patient, but it does not have to be) is added to constitute approximately 10% of the total fluid volume. Solid tissues should be collected using aspiration and gently flushed into the solution until it is cloudy, which requires aspirating about two to three times. For body cavity fluids, provide a minimum of 0.5 mL in an EDTA tube and if available an additional 0.5 mL in a red-top tube (no additive, no serum separator). If the total protein of body cavity fluid is <5 mg/dL or unknown, add two drops of serum (approximately 0.1 mL) from the same patient or another patient of the same species. Aspirates and body cavity fluids should be refrigerated and shipped with a cold pack overnight and tested as soon as possible. This method maintains viability for 2–3 days. Treatment with corticosteroids and/or other chemotherapy at the time of sample collection may alter cell viability or numbers.

The preparation of cells for flow cytometric analysis differs between laboratories. Generally, red blood cells are lysed with a hypotonic solution such as ammonium chloride or water and then stained immediately with fluorescently labeled antibodies.

ANTIBODY PANELS

Veterinary clinical flow cytometry utilizes monoclonal antibodies specific for cell surface (or less commonly cytosolic or nuclear) proteins. The antibodies are either directly conjugated to a fluorescent protein or detected using fluorescently labeled secondary antibodies specific for the monoclonal antibodies (Table 64.1). Each laboratory performing flow cytometry uses different combinations of antibodies and a different approach to immunophenotyping. The goal of designing an antibody panel is to be able to determine the lineage of neoplastic cells and to detect cells with an abnormal immunophenotype, suggesting neoplasia in cases where the diagnosis is not clear. Each laboratory should develop its own panels based on the experience of that laboratory, the most current literature, the technology available to that laboratory (e.g., the capability of the flow cytometer), and the array of antibodies available.

TABLE 64.1 Cell surface markers for immunophenotyping of hematologic neoplasia by flow cytometry.*

CD molecule	Primary cell type
Lymphocytes	
CD3	Pan-T cells
CD5	Pan-T cells
CD4	T helper cells
CD8	T cytotoxic cells
TCRαβ**	T cells
CD21, CD22	Mature B cells
IgM	B cells
Light-chain	Antibody-producing B cells, plasma cells (λ-light-chain expression is most common in cats and dogs)
Myeloid	
CD14	Mature monocytes
CD4	Canine neutrophils
CD1c	Monocytes, dendritic cells
CD11b	Neutrophils, monocytes, some macrophages
CD11c	Neutrophils, monocytes, dendritic cells
CD11d	Monocytes, macrophages, splenic T cells
CD90	Monocytes, dendritic cells, T cells, stem cells
Other	
CD45	All hematopoietic cells (except erythroid)
CD18	Neutrophils^{high}, monocytes^{intermediate}, lymphocytes^{dim}
MHCII	T cells, B cells, monocytes
CD34	Stem cells
CD25	Activated T cells, B cells
CD41, CD61	Platelets, megakaryocytes

* Most common target(s) in the absence of aberrant expression.
** Not commercially available.

It is the authors' opinion that commercially available, directly conjugated antibodies are preferable for several reasons. First, when a small number of commercial sources are used, quality control and reagent preparation (including conjugation) become less of a variable between laboratories. Second, the use of directly conjugated antibodies facilitates multiparameter analysis, which is essential for identifying cells with an abnormal immunophenotype (particularly when such cells are low in numbers). Last, use of directly conjugated antibodies reduces incubation time and nonspecific staining.

A minimum panel for canine hematologic neoplasia should include antibodies to cell surface proteins found on T cells (CD3, CD5, CD4, and CD8), B cells (CD21 or CD22), monocytes (CD14), precursor cells (CD34), and all mature leukocytes (CD18, CD45). An antibody to major histocompatibility complex II (MHCII) should also be included in a canine panel because decreased expression has diagnostic and prognostic utility for subtypes of canine B- and T-cell lymphoma.[6,58] Antibodies to cytoplasmic CD20, CD3e, and CD79a, which require cell permeabilization for staining,[79,86] may be needed to determine the immunophenotype of acute leukemias. Notably, caution is recommended when interpreting intracytoplasmic CD79a (clone HM57) staining for two reasons: (1) nonspecific nuclear staining has been reported that cannot be distinguished from cytoplasmic staining,[60] and (2) CD79a expression has been reported in non-B-cell neoplasms, including T-cell acute lymphoblastic leukemia (LBL) and acute myelogenous leukemia (AML) in people.[38,40] B-cell lineage-specific antigens such as CD20 or Pax5 are preferable to CD79a. The repertoire of monoclonal antibodies available for cats is limited. Directly conjugated antibodies to feline surface CD4, CD5, and CD8 and cytoplasmic CD3 are commercially available, and several additional antibodies react with feline cells, including anti-canine CD21 and CD18, and, possibly, antihuman CD14. The CD18 antibody is helpful to identify CD18 bright neutrophils and to exclude feline platelets, which can be quite large and do not express this antigen.

All flow cytometric panels should contain a cell viability stain (e.g., propidium iodide [PI] or 7-aminoactinomycin D [7-AAD]) to exclude dead cells. The omission of dead cells from analysis is vital, as they can bind antibodies nonspecifically or can inappropriately bind intracellular antigens in cells that lack surface expression of these antigens.[72] In addition, unstained cells and isotype antibodies matching the class and type of the primary antibodies should be included as controls. Fluorescence minus one (FMO) controls are used to identify fluorochrome spread and define gating strategies in a multicolor panel; however, the number of additional tubes required for these controls may be cost-prohibitive for a clinical assay.

TECHNICAL CONSIDERATIONS

As informed by the authors' experiences, there are a number of important, and as yet unpublished, technical considerations in the performance of canine and feline flow cytometry. First, the lysis of feline RBCs using standard ammonium chloride solutions (e.g., ammonium-chloride-potassium, ACK) often results in loss of neutrophils. Additionally, subsets of feline lymphocytes may be lost with water-based RBC lysis approaches. Commercial RBC lysis reagents, which have been reported to have variable success, are available and it is recommended that each laboratory optimize their lysis protocol to minimize nucleated cell loss. Second, anti-CD45 antibody-induced cell death has been observed in canine samples including potentially significant neutrophil loss and minor lymphocyte loss. The cause of the phenomenon has not been defined in dogs, but in mice; cross-linking of CD45 with monoclonal antibodies is reported to induce T-cell death.[28] To minimize this impact, the authors' recommend using the lowest possible concentration of anti-CD45 antibody. In light of this phenomenon, the authors recommend against incorporating this antibody in every tube, which is standard practice in human medicine. Third, autofluorescence from the 633 laser, detected in the 650–670 nm range (allophycocyanin, Alexa Fluor 647, Cy5 fluorochromes), has rarely, but repeatedly, been observed in aspirates of canine tissue or canine blood. Therefore, unstained controls should always be evaluated. Last, artifactual tumor cell binding of a commonly used anti-CD3 antibody (clone CA17.2A12 ST) has been observed in cases of canine B-cell lymphoma/leukemia.

REPORTING FLOW CYTOMETRY RESULTS

A 2017 publication from the European Canine Lymphoma Network provided consensus recommendations for the reporting of flow cytometric findings in canine hematopoietic neoplasms. According to the network, the following details should be reported: tissue and sample type, estimate of sample quality (cell preservation, proportion of viable cells) and method of assessment, proportion or numbers of positive cells, antibodies used, aberrant patterns, qualitative description of immunophenotype of cells of interest, commentary on quantitative expression of relevant markers, diagnosis of immunophenotype, lymphoma subtype (tentative), and party responsible for the service.[18] Any reported patient data should be accompanied by species-specific reference intervals (or ranges). Ideally, each laboratory will establish its own reference data, but flow cytometric reference ranges for hematopoietic cells in canine blood, bone marrow, cerebrospinal fluid (CSF), and lymph nodes have been published.[14,20,23,24,32,67,77,87,89] When size/forward scatter (FSC) of cells in a particular neoplastic population is reported in the literature, it is useful to provide the FSC of a benchmark non-neoplastic population, so that other laboratories can compare their data. To allow for comparisons across individual laboratories and instruments, multiple publications have advocated for using a patient's normal lymphocyte as an internal barometer of cell size. In this work, B cells classified as "large" had a median FSC that was >1.6 times the median FSC of the same patient's $CD5^+$ T cells.[27,58] In addition, the average FSC of neutrophils can be used for comparing the size of neoplastic cell populations between instruments. In one report of canine B-cell chronic lymphocytic leukemia (CLL), cells were categorized as small by flow cytometry if the ratio of the geometric mean of FSC of B cells to neutrophils was <0.55.[11]

Values are reported as percentages of different lymphocyte subpopulations for samples of bone marrow, organ or mass aspirates, and body cavity fluids. For peripheral blood samples it is strongly recommended to report absolute numbers (calculated using a current CBC). Although a similar consensus document has not been published, the chapter authors suggest a similar analytic and reporting approach be adopted for the reporting of feline flow cytometric findings.

DIAGNOSING HEMATOLOGIC NEOPLASIA BY FLOW CYTOMETRY

Objective criteria for defining the presence of a neoplastic cell population by flow cytometry have not been systematically defined within the veterinary community. However, general criteria include: (1) the identification of cells with an aberrant immunophenotype or (2) the identification of a marked expansion of single, immunophenotypically identical, lymphocyte population. The identification of a phenotypically normal lymphocyte population that demonstrates abnormal light scatter properties (e.g., increased FSC or side scatter) should increase suspicion for a neoplastic process. In canine peripheral blood samples, the authors suggest the following diagnostic criteria; namely, an elevated absolute lymphocyte concentration and at least one of the following: (1) >80% of the lymphocytes that share a single immunophenotype, or (2) a immunophenotypically homogeneous lymphocyte expansion of any magnitude and a positive clonality assay (PARR), or (3) the identification of an immunophenotypically aberrant lymphocyte population.[90]

There are important exceptions to these diagnostic criteria. One such is found with *Ehrlichia canis*, in which infected dogs can develop a disproportionate expansion of peripheral blood $CD8^+$ T cells with large granular lymphocyte (LGL) morphology. Young English Bulldogs are another exception to these guidelines with a small B-cell lymphocytosis. This condition was originally described as a unique presentation of B-cell CLL, in which affected dogs were younger and had different antigen expression when compared to the majority of cases.[11] However, further work by one of the authors has demonstrated that these dogs most likely have a non-neoplastic, nonclonal B-cell lymphocytosis (Rout et al., in review). Similar diagnostic criteria are recommended

for flow cytometric evaluation of solid tissues (lymph nodes, tissues, or masses).

Cells can be considered to have an aberrant immunophenotype if the detected phenotype is different from the phenotype expressed by the same cells in health or non-neoplastic disease. This is typified by the inappropriate gain or loss of characteristic antigens. In the dog, such aberrant phenotypes include: T-cell lymphomas/leukemias that lack expression of the pan-leukocyte marker CD45 (i.e., T-zone lymphoma/leukemia),[46,70] $CD3^+$ or $CD5^+$ T cells that lack expression of CD4 or CD8,[19,22,84,90] the coexpression of CD5 and CD21 on neoplastic B-cells,[58] the expression of CD34 on neoplastic B-cells,[89,91] the loss of MHCII expression on both neoplastic B and T cells,[6,22,58] or the loss of CD5 expression on neoplastic T cells.[6] The coexpression of CD4 and CD8 on a T cell can be considered phenotypically aberrant when such cells are found in large proportions in peripheral lymph node aspirates or peripheral blood[19,22,84,89], although a small number of these cells may be consistent with a reactive process.[57,63] $CD4^+/CD8^+$ T cells can be diagnostic for a thymoma when found in a mediastinal mass aspirate.[41] There is significantly less information available for feline leukemia/lymphoma assessed by flow cytometry. The finding of a large proportion of cells in peripheral blood or tissue aspirates that express CD18 but no other lineage antigens is highly suspicious for hematopoietic neoplasia, rather than a reactive process. If intracellular staining indicates that these cells express B- or T-cell antigens (CD3, CD20, Pax5), this could be considered diagnostic for neoplasia.

LYMPHOPROLIFERATIVE DISEASE

While "lymphoma" and "leukemia" are often referred to as separate diseases, the World Health Organization classification system for human lymphoproliferative disorders acknowledges that distinct tumor subtypes may reflect proliferation of an identical tumor cell population and differ only in tissue distribution.[75] For example, B-cell CLL and B-cell small lymphocytic lymphoma (SLL) are considered one disease with variable patterns of tissue distribution (i.e., blood and bone marrow in CLL and tissue in SLL). Neoplasms of precursor lymphocytes can present with either a dominant lymph node or blood/bone marrow disease burden and are referred to as either lymphoblastic lymphoma or leukemia, accordingly. The most defined example in veterinary medicine is canine T-zone lymphoma. In this condition, patients often present with simultaneous peripheral lymph node and peripheral blood involvement, but there is no clinical difference based on tissue of involvement.[25,46,70] Therefore, it is often more clinically useful to define a lymphoproliferative disease based on its phenotype and morphology rather than by the primary site of involvement.

The most common forms of lymphoproliferative disease in veterinary patients are multicentric, peripheral node lymphoma in dogs and intestinal lymphoma in cats.[43,52,56,80,85] Reported prevalence of canine lymphoma subtypes includes 52% diffuse large B-cell lymphoma (DLBCL), 15% peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS), 8% nodal marginal zone lymphoma (NMZL), 3–13% T-zone lymphoma (TZL), 7% other T-cell lymphoma, 6% other B-cell lymphoma, 3% T-cell lymphoblastic lymphoma (T-LBL), 2% mantle cell lymphoma (MCL), and 3% other lymphoma.[7,56,70,81,85] Of these, flow cytometry is most useful in the diagnosis of DLBCL, PTCL-NOS or T-LBL, and TZL (particularly when combined with fine needle aspirate (FNA) cytology). While the literature regarding the flow cytometric profiling of canine lymphoproliferative disease is expanding, limited information is published for cats (Table 64.2).

TABLE 64.2 Immunophenotype of hematologic neoplasia most commonly identified by flow cytometry in cats and dogs.

Neoplasm	Common immunophenotype	Additional considerations
Canine multicentric T-cell lymphoma (PTCL-NOS, T-LBL)	$CD3^+CD4^+CD45^+MHCII^-$	Often exhibit loss of CD5 expression[6]
Canine T-zone lymphoma/leukemia	$CD5^+CD45^-MHCII^{high}$, often $CD3^{dim}$ and $CD25^+$, variably $CD4/CD8^+$ or $^-$, variably $CD21^+$	Loss of CD45 expression and high MHCII expression are consistent features.[46,70] Cells are small to often intermediate (not large)
Canine multicentric B-cell lymphoma	$CD21^+CD45^+MHCII^+$	Low expression of MHCII and large cell size may be negative prognostic indicators[58]
Thymoma	$CD3^-CD5^+CD4^+CD8^+$	>10% of $CD4^+CD8^+$ lymphocytes[41]
Canine B-cell CLL	$CD21^+MHCII^+CD45^+$ often $CD25^+$	Solid tissue involvement is not uncommon[11]
Canine T-cell CLL	$CD3^+CD5^+CD8^+CD45^+$	
Feline T-cell CLL	$CD3^+CD5^+CD4^+$	
ALL	$CD34^+MHCII^-$	Up to 25% of canine ALL may be $CD34^{-}$[1,84,86] Stage V lymphoma may rarely be $CD34^{+}$[31,89]

Canine B-Cell Lymphoma

In dogs with multicentric lymphoma, a B-cell phenotype is more common than a T-cell phenotype, although there are breed-related exceptions.[44,45,50] Of the subtypes described in the earlier text, DLBCL is the most common form of canine multicentric BCL, with less common variants including NMZL, small B-cell lymphoma, Burkitt-like lymphoma, lymphoblastic lymphoma, and follicular lymphoma. Cytologically, canine DLBCL is reflected by a majority (>50%) of large lymphocytes (i.e., larger than a neutrophil). However, there is insufficient published information to broadly characterize the cytology of other subtypes of canine nodal lymphoma. Flow cytometrically, the neoplastic cells in canine BCL are CD21$^+$, CD45$^+$, and MHCII$^+$ (Figure 64.1 and Table 64.2). The size of the neoplastic cells as characterized by FSC is highly variably in canine BCL, including small and large cell variants.[45] Notably, in the authors' experience, cell size assessment by microscopy (particularly FNA cytology) tends to assign larger sizes than cell size assessment (via FSC evaluation) by flow cytometry. As such, although most cases of canine B-cell lymphoma are described as large cells by cytology, they are described as intermediate-sized cells by flow cytometry.[45,58] In light of the overlap in phenotype (and perhaps due to the

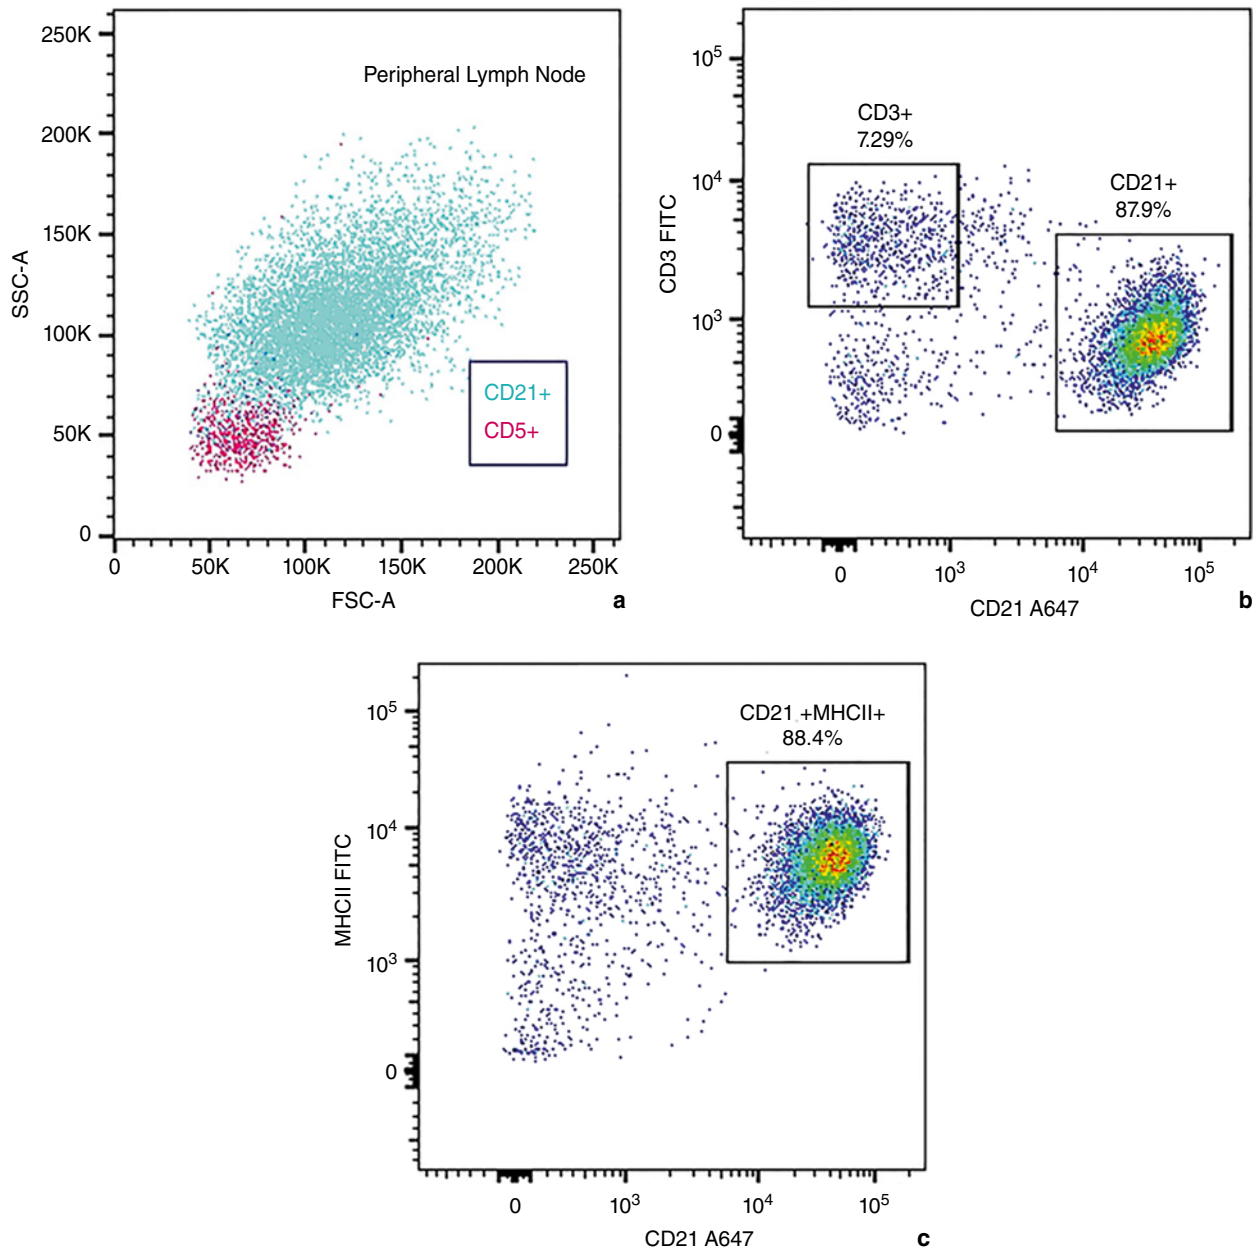

FIGURE 64.1 Flow cytometric analysis of a canine peripheral lymph node with multicentric B-cell lymphoma. (a) Increased light scatter shows an expansion of intermediate to large neoplastic B cells (aqua) with lower numbers of small non-neoplastic T cells (pink); (b) The neoplastic CD21$^+$ B cells comprise approximately 88% of the lymphocyte population and (c) express major histocompatibility complex II.

limited reagents), flow cytometry alone cannot be used to differentiate among the subtypes of BCL.[45]

In designing a flow cytometry panel, the authors recommend including a tube containing antibodies directed against CD21 and MHCII for potential prognostic purposes. In a study of 160 dogs with BCL, tumor cell immunophenotype and forward scatter were reported as independent predictors of outcome.[58] In this series, the majority of cases (93.1%) were composed of intermediate-sized $CD21^+$ B cells with high MHCII expression and a median survival time (MST) of 330 days. By contrast, BCL patients in which the neoplastic cells were defined as large cells or had low MHCII expression had MSTs of 155 days and 120 days, respectively.[58] Notably, expression of CD34 or CD5 in B-cell lymphomas was not correlated with outcome. Recent work focusing on DLBCL only does not demonstrate the prognostic significance of either MHCII expression or tumor cell size.[91] Flow cytometry has also been used to assess MRD in lymph node aspirates from dogs in complete remission following chemotherapy for DLBCL and predicted a shorter time to relapse when >0.5% large B cells were identified.[16]

Canine T-Cell Lymphoma

In the dog, although T-cell lymphoma occurs less frequently, immunophenotyping by flow cytometry is important to identify the two most common biologically distinct subtypes; namely, aggressive multicentric T-cell lymphoma and indolent TZL.

Multicentric T-Cell Lymphoma

Two of the most common forms of canine multicentric T-cell lymphoma (i.e., PTCL-NOS and T-LBL) are composed of $CD3^+$, $CD4^+$, $CD45^+$ lymphocytes that demonstrate variable expression of CD5 and frequent loss of MHCII (Figure 64.2).[6] To facilitate their detection by flow cytometry, the authors recommend combining CD3, CD4, CD8, and CD5 in one tube and CD4 and MHCII in a separate tube. The neoplastic cells are often intermediate to large by cytology, but variable in size by flow cytometry. In one study evaluating the clinical outcome of 61 dogs with multicentric $CD4^+/CD45^+/MHCII^-$ T-cell lymphoma, MST was 159 days.[6] Hypercalcemia and/or mediastinal masses are common findings in dogs with $CD4^+/CD45^+$ T-cell lymphoma; however, several studies have demonstrated that their presence is not a negative prognostic indicator.[6,10,58] An increased incidence of multicentric $CD4^+/CD45^+$ T-cell lymphoma has been reported in Golden Retriever and Boxer dogs as well as other pure breed dogs.[44,45,50]

T-Zone Lymphoma/Leukemia

Canine TZL has an indolent course in dogs and a unique flow cytometric immunophenotype. The neoplastic cells are small to intermediate in size, $CD5^+$ T cells that lack expression of the pan-leukocyte antigen CD45. In addition, the cells are $MHCII^{high}$, variably $CD4^+$ and/or $CD8^+$ ($CD4^+/CD8^-$, $CD4^-/CD8^+$, $CD4^+/CD8^+$, $CD4^-/CD8^-$), $CD3^{dim}$, and variably $CD25^+$ and $CD21^+$ (Figure 64.3).[46,70] To facilitate their identification, the authors recommend including a tube in a diagnostic canine panel containing CD5, CD21, and CD45. Identification of TZL by flow cytometry has resulted in increased recognition such that it represents 3–13% of all canine lymphomas and up to 60% of indolent canine lymphomas.[25,56,82] On cytology, cells are small with expanded cytoplasm that may have an extension creating a "mirror-handle" appearance.[5664,93] TZL is characterized by one or more enlarged lymph nodes and/or lymphocytosis that are often identified in asymptomatic older dogs.[49,70,82,83] Reported MSTs range from 637–1099 days.[25,46,70,83] Lymphocytosis is present in over half of cases and is not associated with a worse prognosis.[25,46,70] A higher incidence of TZL has been observed in Golden Retriever dogs and may be due to an increased frequency of TZ cells in this breed.[36,70] A unique lingual variant of TZL has been reported in 12 dogs with tongue masses, concurrent lymphocytosis and/or lymph node enlargement, and an indolent clinical course.[34] Notably, the lack of CD45 expression on T cells cannot alone be used as an absolute indicator of TZL. One case of suspected canine TZL, based on the flow cytometric identification of a $CD45^-$ T-cell population, was later classified as high-grade canine peripheral T-cell lymphoma by histopathology. Importantly, the neoplastic cells were, according to FSC, larger than those identified in typical TZL.[54] As such, although canine TZL has a unique immunophenotypic signature, if atypical features are identified, including increased cell size or variability in MHCII or CD5 expression, additional assessment using histopathology with immunohistochemistry (IHC) should be performed.

Thymoma and Mediastinal Lymphoma

Flow cytometry can help distinguish between two, cytologically similar mediastinal neoplasms, namely thymoma and mediastinal lymphoma. Thymomas contain thymocytes that express CD4, CD8, and CD5. In one study, the identification of >10% $CD4^+CD8^+$ cells from canine mediastinal mass samples correlated with histologic diagnosis of thymoma.[41] Similarly, a diagnosis of metastatic thymoma was supported by the identification of small $CD4^+CD8^+$ T cells in the liver of a dog.[88] By contrast, canine mediastinal T-cell lymphoma is reported as predominantly a $CD4^+/CD8^-/MHCII^-$, or $CD4^-/CD8^+/MHCII^-$ disease. In one report, a single case of $CD4^+/CD8^+/MHCII^-$ disease was identified, but, importantly, the neoplastic lymphocytes were significantly larger than the $CD4^+/CD8^+$ thymocytes in canine thymoma.[22,41] Paraneoplastic, polyclonal $CD4^-/CD8^-$ lymphocytosis has been reported in association with canine thymoma.[8,13]

Less-common subtypes of canine T-cell lymphoma include hepatosplenic and hepatocytotropic lymphoma. These are distinct and aggressive subtypes that require surgical histopathology for diagnosis. Reported IHC findings include $CD4^-/CD8^+$ or $CD4^-/CD8^-$, and either $CD3^+/TCR\alpha\beta^-/TCR\gamma\delta^+$ or $CD3^-/TCR\alpha\beta^-/TCR\gamma\delta^-$ with

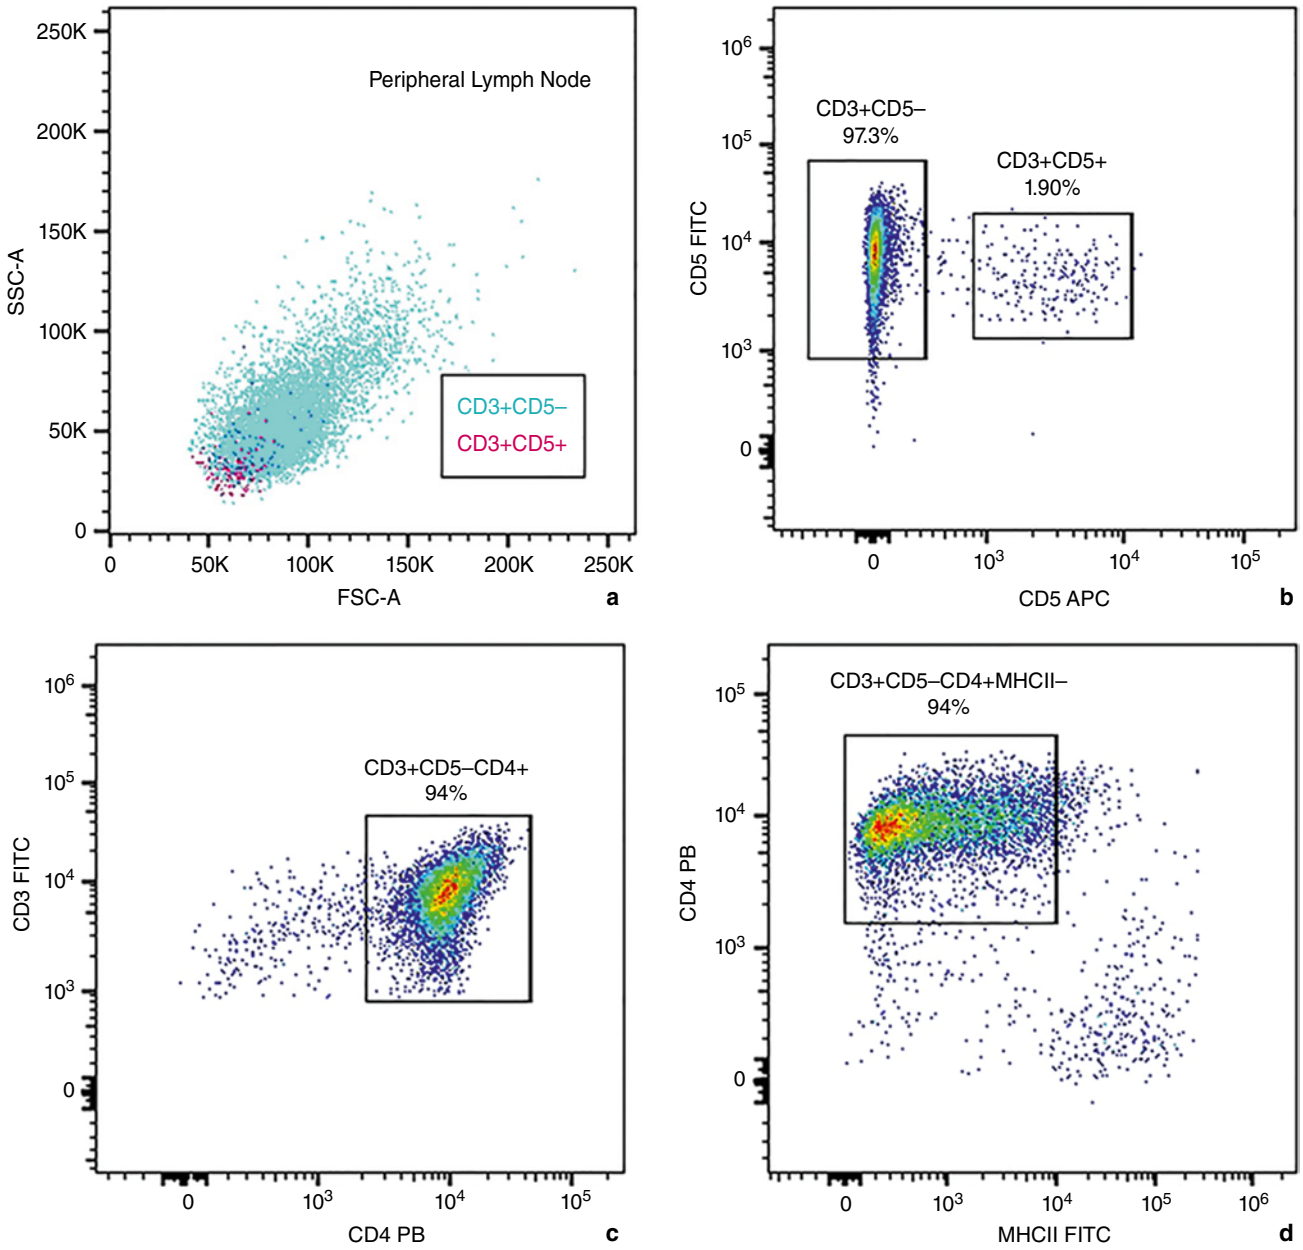

FIGURE 64.2 Flow cytometric analysis of a canine peripheral lymph node with multicentric T-cell lymphoma. (a) Increased light scatter shows an expansion of intermediate to large neoplastic T cells (aqua) with lower numbers of small non-neoplastic T cells (pink); (b) The neoplastic $CD3^+$ T cells comprise approximately 97% of the lymphocyte population and lack expression of CD5; (c) The population is $CD4^+$ and (d) lacks expression of major histocompatibility complex II.

CD11d expression in hepatosplenic types only.[37] Cutaneous epitheliotropic T-cell lymphoma (CETCL) is, according to both IHC and flow cytometry, a neoplasm of $CD4^-/CD8^+/MHCII^-$, $CD4^-/CD8^+/MHCII^+$, or $CD4^-/CD8^-/MHCII^-$ T cells.[22,27,51]

Feline Lymphoma

Little data are available characterizing the flow cytometric features of feline lymphoma. Intestinal lymphoma, which is the most common tissue type of feline lymphoma, is a low-grade, $CD3^+$ T-cell disease (low-grade alimentary lymphoma [LGAL]) and is more common than high-grade, large-cell, $CD21^+$ B-cell disease.[26,42,52,55,66] Differentiating LGAL from inflammatory bowel disease (IBD) can be a frustrating diagnostic dilemma. These diseases cannot be distinguished by cytology and may still be challenging with histopathology. Lymphoid clonality (PARR) testing is a sensitive means to support a diagnosis of feline LGAL, as well as being a predictor of biologic behavior and clinical outcome.[52,68] Flow cytometry may provide a useful adjunct to cytology and PARR, but it has not yet been thoroughly investigated. Large B-cell lymphoma can be diagnosed

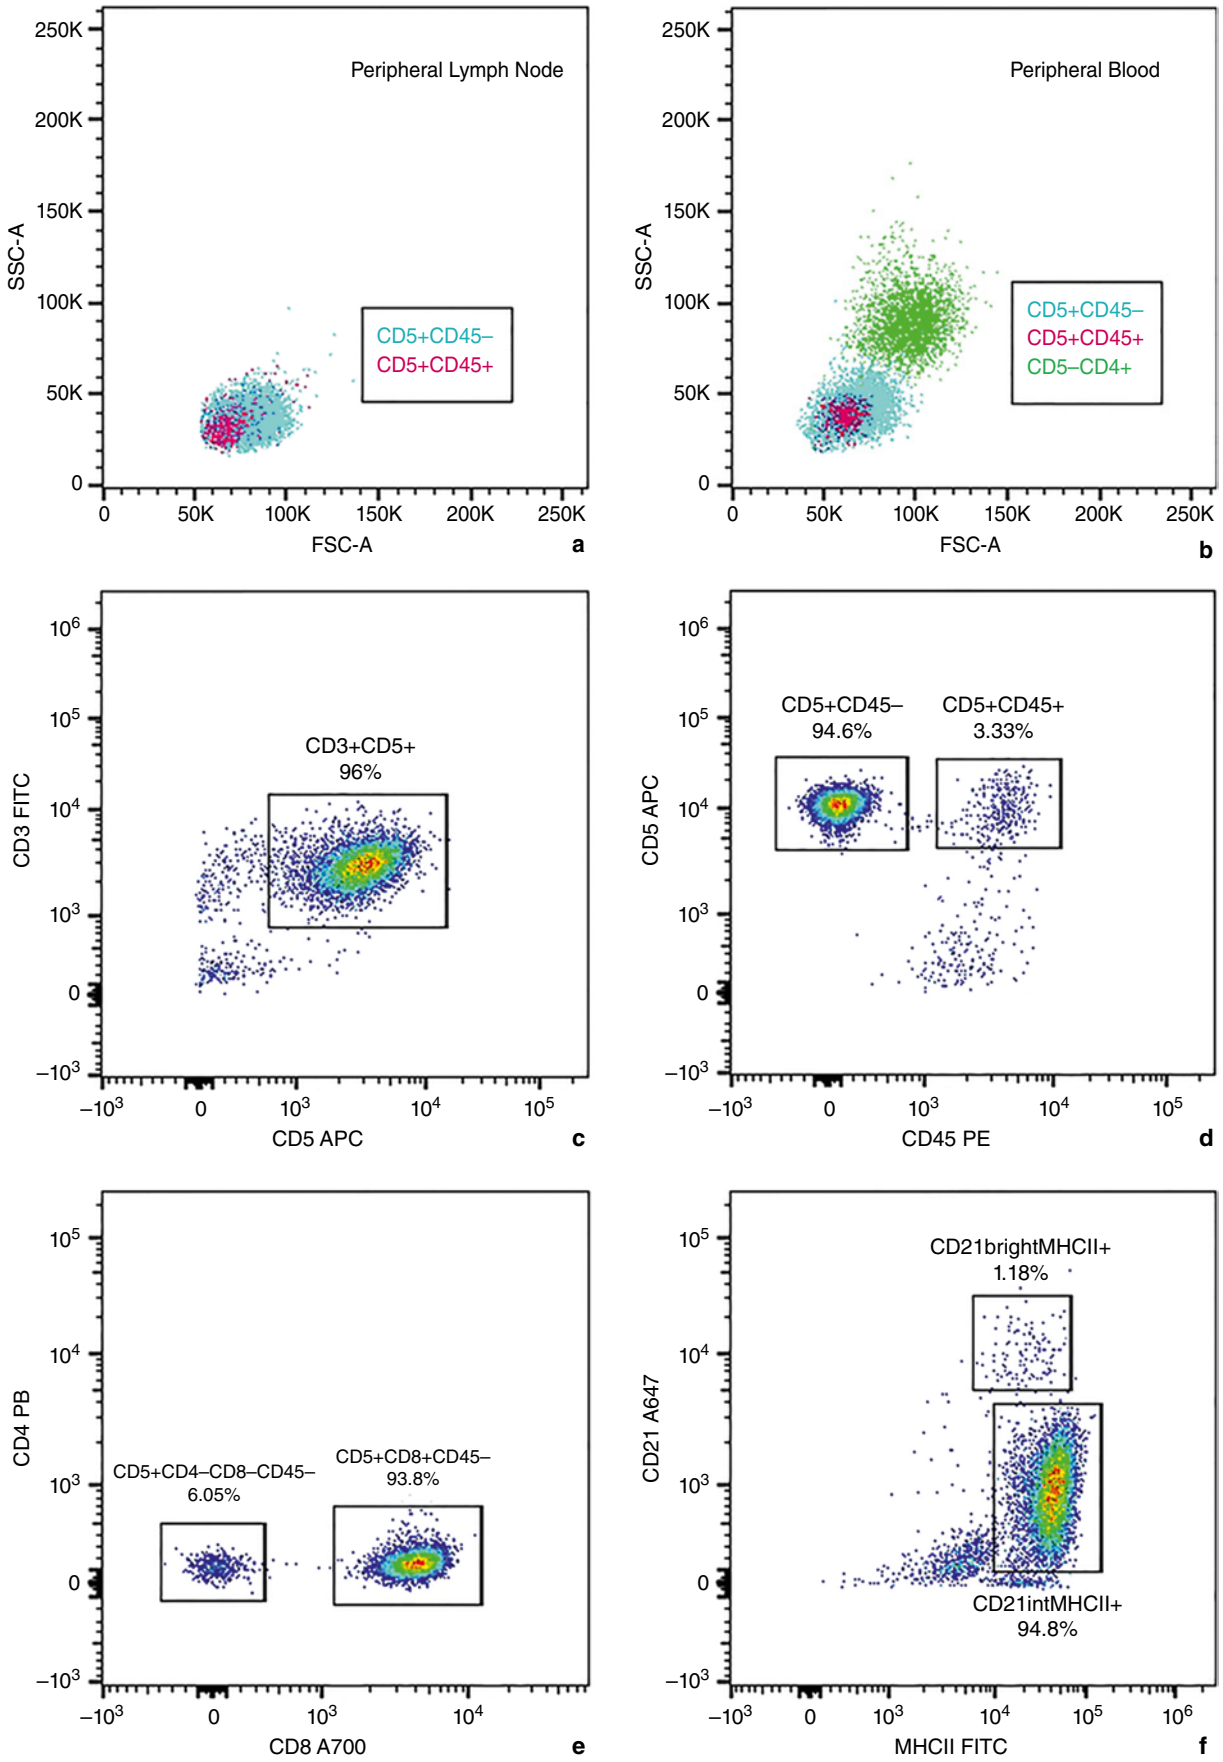

FIGURE 64.3 Flow cytometric analysis of a canine peripheral lymph node with T-zone lymphoma/leukemia (TZL). (a) Light scatter shows an expansion of intermediate neoplastic T cells (aqua) with lower numbers of small non-neoplastic T cells (pink); (b) A similar expansion of lymphocytes is seen in peripheral blood, $CD5^{-}CD4^{+}$ neutrophils are also shown; (c) The neoplastic $CD3^{+}CD5^{+}$ T cells comprise approximately 96% of the lymphocyte population and (d) lack expression of CD45; (e) the majority are $CD8^{+}$ with a lower percentage lacking expression of both CD4 and CD8; (f) The TZL population expresses a high level of major histocompatibility complex II and a lower level of CD21 than residual non-neoplastic B cells.

by cytology; however, immunophenotypic characterization may provide prognostic indicators. Feline intestinal large granular lymphoma is an aggressive, less-common form of intestinal lymphoma that may be diagnosed by cytology and is most often $CD3^+/CD8^+$.[61] As more reagents become available, the diagnostic and prognostic utility of flow cytometry for cats may increase.

LEUKEMIA

Chronic Leukemia

Canine B-Cell CLL

$CD21^+$ B-cell CLL (B-CLL) is one of the most common forms of canine CLL, occurring most often in older, small breed dogs. The disease is slowly progressive with a reported MST of 480 to >1000 days.[11,19,90] Although there are not widely agreed upon diagnostic criteria, one publication, which represents the largest study of canine B-cell CLL (491 cases), defined cases as dogs with: (1) an absolute peripheral blood lymphocyte count >5000 cells/μL and (2) >60% of lymphocytes comprising small $CD21^+$ B cells. Cells were categorized as small by flow cytometry if the ratio of the geometric mean of FSC of B cells to neutrophils was <0.55; cytomorphology was not included in this case definition.[11] Half of the cases in this study had lymphadenopathy and/or splenomegaly, which suggests frequent involvement of both solid tissue and peripheral blood. As noted in the earlier text, English Bulldogs are affected by a unique form of apparently reactive lymphocytosis that mimics B-cell CLL. However, in contrast to typical canine B-cell CLL, the B cells from affected English Bulldogs tended to have lower MHCII and CD25 expression as compared to non-English Bulldogs. Moreover, work by one of the authors has demonstrated that these dogs most likely have a non-neoplastic, nonclonal B-cell lymphocytosis (Rout et al., in review). Similar diagnostic criteria are recommended for flow cytometric evaluation of solid tissues (lymph nodes, tissues, or masses).

Although leukemic involvement of B-cell small lymphocytic lymphoma is a theoretical consideration in these patients, this is generally considered unlikely given the rarity of this lymphoma subtype in dogs.[33,82,83,85] In human medicine, the distinction between CLL and small lymphocytic lymphoma, in part, depends upon the distribution of neoplastic cells in the lymph node, but studies examining lymph node histology in cases of presumptive canine B-CLL are not available.

Canine T-Cell CLL

The entity historically referred to as "canine T-cell CLL (T-CLL)" likely represents at least three separate subtypes, namely, TZL, LGL CLL, and non-LGL CLL. The circulating neoplastic cells in canine TZL, which are reported present in up to 100% of nodal TZL cases, comprise a phenotypically aberrant population of $CD45^-CD5^+$ and/or $CD3^+$ T cells that demonstrate variable CD4 and CD8 expression.[70] LGL leukemia is characterized by an expansion of intermediate-sized $CD8^+$ T cells with fine intracytoplasmic granules, frequent splenomegaly, and minimal bone marrow involvement.[84,76] Canine LGL CLL has a higher prevalence in large breed dogs and has been shown to have an indolent course.[47] Other categories of T-CLL include non-LGL $CD8^+$ T-cell CLL and $CD4^-/CD8^-$ T-CLL.[71,77] The survival time of canine T-CLL is heterogeneous. In one study, dogs with $CD8^+$ T-CLL with absolute peripheral blood lymphocyte counts >30,000 lymphocytes/μL had a poor median survival time (131 days) compared with those presenting with <30,000 lymphocytes/μL (1098 days).[90] In another study, MST for 19 cases of T-cell CLL was 930 days and presence of anemia was associated with shorter survival time.[19] However, neither of these studies specifically excluded TZL.[19,90] A recently described form of aggressive T-cell leukemia that may be mistaken for T-cell CLL based on morphology and flow cytometry was identified in 118 dogs.[30] This disease is characterized by marked expansion of small, mature $CD5^+$ T cells that do not express CD4 or CD8 and express very low levels of MHCII. It is typically seen in young, primarily male dogs, and is most common in English Bulldogs; hepatic and splenic involvement is common and MST was 35 days.

It is important to note that the reactive $CD8^+$ lymphocytosis induced by *E. canis*, while typically <18,000 cells/μL, has been anecdotally reported to reach 30,000 cells/μL.[5,17,29,35,39,48] Notably, the $CD8^+$ T-cell response induced by *E. canis* infection may be clonal based on assessment using the PARR assay.[12]

Feline CLL

Most cases of feline CLL result from the expansion of T cells, namely, $CD4^+$, $CD4^+/CD8^+$, and $CD4^-/CD8^-$ cells.[15,65,92] The largest study of feline lymphocytosis (>6000 lymphocytes/μL) described five main flow cytometric immunophenotyes: (1) $CD21^+$ B cell, (2) $CD4^+$ T cell, (3) $CD4^-CD8^-$ T cell, (4) CD5 low T cells, and (5) heterogeneous (two or more lymphocyte lineages expanded).[65] The majority of B-cell and heterogeneous lymphocytoses demonstrated polyclonal PARR testing results and were considered non-neoplastic. Of the neoplastic lymphocytosis, $CD4^+$ T cell was most common and had a longer MST (752 days) than $CD4^-CD8^-$ (271 days) or CD5 low phenotypes (27.5 days). These results are similar to a prior study of 18 cats, in which the majority were $CD4^+$ T cell, with an overall MST of 14.4 months (range: 0.9–25.3 months), and a favorable response to treatment with oral chlorambucil and prednisolone.[15] By contrast, B-CLL appears to be uncommon in cats as clonality was identified in only two of 46 cases of $CD21^+$ lymphocytosis, including cats with B-cell counts as high as 26,000/μL.[65]

Acute Leukemia

Acute leukemia may be lymphoid (ALL), myeloid (AML, see Chapter 67), or undifferentiated (AUL). The flow cytometric detection of surface expression of the

stem cell marker CD34 and a corresponding lack of MHCII expression (i.e., $CD34^+/MHCII^-$) are characteristics of acute leukemia. Beyond this, lineage assignment of an acute leukemia into a myeloid or lymphoid origin can be challenging. Correspondingly, several studies assessing lineage of canine acute leukemia have reported variable frequencies of ALL, AML, and AUL likely due to variation in diagnostic methodology.[1,9,21,53,76,84] Further lineage assignment likely requires increase in usage of antibodies to cytoplasmic (intracellular) CD20 and CD3e[79,86]. Importantly, molecular clonality assessment (i.e., PARR testing) should not be used for lineage assignment in canine acute leukemia as T- and/or B-cell receptor rearrangements have been identified in up to 64% of canine AML cases.[12,73] The largest case series of canine $CD34^+/MHCII^-$ acute leukemia (194 cases) identified three immunophenotypes ($CD5^+$:ALL, $CD14^+$:AML, and AUL).[64] Golden Retriever and German Shepherd dogs were overrepresented in the ALL and AML groups, respectively.[64] Importantly, the clinical significance of lineage assignment in canine acute leukemia is uncertain, as all immunophenotypes shared a similarly poor clinical outcome. It is important to note that CD34 positivity should not be considered requisite in the diagnosis of acute leukemia as CD34-negative cases have been reported.[73,79,84,86,90] Moreover, CD34 expression should not be considered a specific marker of an acute neoplasm, as its expression has been described in a small subset of canine lymphomas.[31,58,89] In such cases, other flow cytometric, hematologic, and clinical data (e.g., MHCII expression, presence or absence of cytopenias, and clinical presentation) should be used to provide diagnostic context to the CD34 positivity. Cytochemistry can be useful for assigning a monocytic/myelomonocytic origin in acute leukemia and is discussed elsewhere (Chapters 61 and 67).[74] The flow cytometric detection of CD41, CD61, CD62P has been successfully used to diagnose acute megakaryocytic leuekmia.[3] Reports of acute leukemia in cats are rare and largely associated with FeLV infection.[71,78]

Histiocytic Neoplasia

There is limited published information on the role of flow cytometry in the diagnosis of canine histiocytic neoplasia. Flow cytometry has also been used to diagnose histiocytic neoplasia in dogs with peripheral blood involvement.[2,62] Dendritic cell leukemia was diagnosed in a Golden Retriever dog through the identification of a $CD1c^+/CD11c^+/CD18^+/MHCII^+/CD34^+/CD49d^+/CD54^+/CD45^+$ population that was negative for markers of macrophage (CD11d), granulocytic (CD4/11b), and of lymphoid (CD3/CD5/CD4/CD8/CD21/TCR) origin.[2] Disseminated histiocytic sarcoma with peripheral blood involvement was identified in a Bernese Mountain dog through the flow cytometric identification detection of a $CD1c^+/CD11c^+/CD18^+/CD45^+/CD14^+$ population.[62] In the authors' experience, histiocytic neoplasia of solid tissues can be diagnosed using flow cytometry from FNA samples based upon the identification of a large cell, $CD14^+$, $MHCII^+$, $CD45^+$ population.

Acronyms and Abbreviations

CLL, chronic lymphocytic leukemia; CNS, central nervous system; FeLV, feline leukemia virus; FC, flow cytometry; FIV, feline immunodeficiency virus; DLBCL, diffuse large B-cell lymphoma; ICC, immunocytochemistry; IHC, immunohistochemistry; LBL, lymphoblastic lymphoma; NCI, National Cancer Institute; NIH, National Institutes of Health; NMZL, nodal marginal zone lymphoma; MCL, mantle cell lymphoma; MI, mitotic index; MHC, major histocompatibility complex; PTCL NOS, peripheral T-cell lymphoma, not otherwise specified;; PTZL, peripheral T-zone lymphoma; REAL, revised European–American classification of lymphoid neoplasms; TCL, T-cell lymphoma; WHO, World Health Organization.

INTRODUCTION

As a complement to the preceding and following chapters, which provide subtype-specific clinical, diagnostic, to a limited degree, treatment information, this chapter will focus on: (1) the history and evolution of the classification of veterinary lymphoid neoplasms and (2) a general algorithmic approach toward the diagnosis of veterinary lymphoid neoplasms. For subtype-specific information, the reader is referred to Chapter 66 (Myeloproliferative Neoplasms), Chapter 68 (Acute Myeloid Leukemia), Chapter 69 (B-Cell Tumors), Chapter 70 (Plasma Cell Tumors), Chapter 71 (Hodgkin Lymphoma), and Chapter 72 (T-Cell Tumors).

CLASSIFICATION

Introduction to the Concepts of Classification

The development and implementation of lymphoid neoplasia classification schemes, both in human and veterinary pathology, have always been complex matters. This complexity results from a number of factors, including the inherently fluid nature of all classification schemes (which require iteration, as diagnostic and clinical knowledge expands), the persistent importance of cell morphology (which requires pathologist expertise), and the need to align geographically defined schemes (i.e., European vs. North American). One of the first

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

mentioned systems in the human field is from 1934, i.e., the "Classification of Lymphatic and Reticular Tumors" from the American Registry of Pathology.[8] All lymphoid neoplasm classification schemes were initially developed for humans, but their subsequent application in veterinary medicine has revealed an astonishing level of variation in animal leukemia and lymphoma.[113] Their application has also revealed a number of differences, including a higher proportion of high-grade lymphomas, a lower proportion of follicular neoplasms, and the rarity of Hodgkin-like neoplasms in animals.[64] With advances in veterinary diagnostics, including clonality assays and flow cytometry (FC), the diagnosis of "lymphoma" is no longer considered adequate.[115]

History of Classification

Any discussion of lymphoma classification requires an understanding of the evolution of its basic language. The first mentioning of "leukemia" was by Rudolf Virchow in 1845, the term "lymphoma" was introduced in 1863, and Theodor Billroth introduced the term "malignant lymphoma" in 1871.[43] Notably, the term "lymphosarcoma" defined by the National Dictionary of Cancer Terms of the National Institutes of Health (NIH) is an "obsolete term for a malignant tumor of lymphatic tissue" (https://www.cancer.gov/publications/dictionaries/cancer-terms/def/lymphosarcoma). Additionally, the designation of lymphoma as "malignant" should also be abandoned as it is redundant (all forms of lymphoma are malignant) and it is no longer used in any currently used classification system.[20] The fact that there are indolent forms, such as follicular, mantle cell, and marginal zone lymphomas of B-cell type, and T-zone lymphoma of T-cell type,[114] should not justify this name.

One of the earliest classification systems, published in 1934 in the American Registry of Pathology, divided neoplastic cells into three groups according to cell size, namely: lymphocytic (small cells), lymphosarcoma (medium-sized cells), and reticulum cell (large cells).[8] Coincident with this (1938), an English classification system created by Robb-Smith defined benign and malignant lymphoid disorders using the reticuloendothelial system.[88] In 1942, Gall and Mallory created a new system based on morphology and clinical outcome that, among other features, was the first to define Hodgkin's and non-Hodgkin's lymphoma as it is still now discriminated.[30] This system was the first to be accepted in the USA. In 1944, Jackson and Parker presented another system focusing on Hodgkin's disease, which was used unchanged until 1966.[39] In 1956, based on the Gall and Mallory system, Rappaport proposed an eponymous classification system that divided lymphoid neoplasms into diffuse or follicular according to their architecture pattern.[83,84] Although this system became the standard classification in North America, as a result of its overly dogmatic embrace of architecture, some previously known lymphoma subtypes were lost and, in retrospect, the Rappaport system is considered a regressive step in classification history.

During the 1960s and 1970s, the classification landscape was transformed by research allowing for the routine discrimination of the three distinct lymphocyte cell lineages, namely, B, T, and natural killer lymphocytes.[47] Simultaneous with this work, two new classification systems were published, namely, the Kiel and the Lukes and Collins systems.[50,55] As the latter required neoplastic cell immunophenotyping (either B or T cell), which was still not widespread in availability, it was never widely used. The Kiel classification was based on a hypothetical scheme of leukocyte differentiation, and the lymphomas were grouped into low or high grade according to cytological features. The Kiel system was updated in 1988, but was primarily utilized in Europe and never in the USA.[101] During this time, various other classification systems were proposed, including the "working classification,"[21] the British national lymphoma investigation classification[6] used in the UK, and the World Health Organization (WHO) classification.

In an attempt to simplify the expanding classification landscape, the National Cancer Institute (NCI) developed the "working formulation."[90] The scheme, which was primarily based on the Rappaport classification, but also included terminology from Lukes and Collins, was directed at predicting outcome and clinical behavior of each subtype. Two features were new in this system, namely, grading based on "patient survival" (rather than tumor cell morphology) and the discrimination of tumors into "low", "intermediate," and "high grades" (based on morphology). Although this system allowed oncologists to tailor grade-specific treatment, tumor cell morphology and phenotype were somewhat neglected. This system was widely adopted in Northern America, but, in Europe, the Kiel classification persisted.

During the 1980s and 1990s, many new entities were characterized and monoclonal antibodies became increasingly available for immunophenotyping (including in veterinary medicine).[74] In 1991, the first attempt to develop a unified classification by the International Lymphoma Study Group (ILSG) resulted in the European–American classification of lymphoid neoplasms. This system, for the first time, combined morphology, phenotype, genetic features, and clinical aspects. The classification system was presented in 1993[43] and an updated version, the revised European–American classification of lymphoid neoplasms (REAL), was presented in 1994.[36,43] The current and most widely used classification system is the WHO classification. This classification (the WHO classification of hematologic malignancies), originated in 1995 and presented in 1999, is developed by the European Association of Pathologists and the Society for Hematopathology.[35] The WHO system updated and revised the REAL classification and stratified hematologic neoplasms according to lineage as either myeloid neoplasms, lymphoid neoplasms, mast cell disorders, or histiocytic neoplasms. Like the REAL scheme, it incorporates tumor cell morphology, immunophenotype, and genetic and clinical features. Importantly, the WHO scheme is flexible, allowing for

the identification of new entities and subtypes. The current WHO classification of tumors of hematopoietic and lymphoid tissues represents a revised 4th edition.[106]

Classification of Lymphoma and Leukemia in Veterinary Medicine

The classification of veterinary lymphoid neoplasms directly results from the adoption of human-developed schemes. Notable highlights in this history include the adaptation of the Kiel classification for canine, feline, and bovine lymphoma in 1981.[112] Using the scheme, canine lymphomas were classified according to the proportion of small cells as either large-cell (<50% of small cells), mixed-cell (50–70% of small cells), or small-cell (>70% of small cells) lymphomas.[25,26,49] A second study assigned tumor grade by combining cell size with mitotic index (MI).[81] Specifically, cases with a majority of small cells and a low or medium MI were classified as low-grade lymphomas, whereas those showing a majority of medium and large cells and a moderate to high MI were classified as high-grade lymphomas.[97] Similar to human medicine, there were geographic differences in the adoption of veterinary classification schemes. The "working formulation" was used in the United States, whereas the updated Kiel classification was used in Europe.[11,27,31,107,110,119]

As in human medicine, veterinary experts also wanted to employ a uniformly used classification with the goal to improve diagnostics, to compare larger patient cohorts in multicenter studies, and to enhance comparative collaboration with the human field. They aimed at strengthening the canine patient as a spontaneous disease model for canine lymphoma and to promote a classification system containing morphology, immunophenotype, and genetic and clinical information.

For this purpose, the first Histological Classification of Hematopoietic Tumors of Domestic Animals was published in 2002.[115] This scheme drew directly from the 2001 REAL/WHO system and attempted to harmonize different expert groups, continents, and philosophies. The most recent version of this classification (2011) describes the six most common diagnoses (representing 80% of all canine cases)—diffuse large B-cell lymphoma (DLBCL), marginal zone lymphoma (MZL), peripheral T-cell lymphomas not otherwise specified (PTCL, NOS), T-zone lymphoma (PTZL) T-cell lymphoblastic lymphoma (T-LBL), and follicular lymphoma.[113] Notably, the classification of veterinary lymphoid neoplasms is based exclusively on morphology and immunophenotype, as other features (cytogenetic and other molecular changes) are still under investigation and not routinely applied.[77] This system has been used in various publications for different species.[2,22,24,28,42,67,68,123,124]

A recent review of veterinary classification schemes identified the updated Kiel and the WHO systems as the most valuable.[98] In light of its inherent adaptability, its reproducibility, its diagnostic precision, its provision of prognostic information, and its ability to allow for the worldwide comparison through the creation of large patient cohorts, the authors encourage and embrace increasing adoption of the WHO system.

Cytologic Classification of Lymphoma

All lymphoma classification systems rely upon tumor and tumor cell morphology. Currently, the gold standard for the diagnosis and classification of veterinary lymphoid neoplasms is histopathology (with immunophenotyping). However, the role of cytologic morphology (i.e., cytomorphology) in the process of classification is less certain. One Kiel-based study using cytology was published in 1997; however, no similar work has evaluated cytology in the comparison with the WHO scheme.[25] In light of its ease and high pet owner compliance, incorporating cytology in the classification of lymphoma is an attractive proposition.[97] However, within the veterinary clinical pathology community, although fine needle aspirate cytology is considered useful in the diagnosis of lymphoma, its role in classification requires further study.[4,91,111,113]

Lymphoma

Basic Biologic Aspects of Lymphoma

Lymphoma, first described in 1863 as lymphosarcoma, is a heterogeneous group of diseases that encompasses a number of subtypes of varying malignancy that occur as the result of neoplastic transformation of B and T lymphocytes at different stages of development.[43] Although a review of the basic oncogenic features of lymphoma is beyond the scope of this chapter, like other cancers, lymphoma is characterized by chromosomal modifications and genetic mutations that contribute to tumor initiation and progression.[3] The WHO classification lists more than 30 subtypes of canine lymphoma and there is significant overlap in subtype frequency and biology between dogs and humans.[113]

Incidence and Manifestation

The majority of the published information on veterinary lymphoma describes canine and feline forms of the disease.[87,77,38,32,14] The age-adjusted overall incidence of canine lymphoma is 1.5 and 84 per 100,000 dogs younger than 1 year and greater than 10 years of age, respectively.[60] The most common subtype of canine lymphoma is diffuse large B-cell lymphoma, and the frequency of acute and chronic leukemias has not been estimated (Figure 65.1).[81,116] In the cat, lymphoma is the most common hematopoietic neoplasm and is the highest for any veterinary species.[73] The overall frequency of equine lymphoma is less studied, but represents 1–14% of all equine tumors.[44,22,54,63,109,86]

Lymphoma has been described in a number of species, including the cheetah, fossa, panther, lion, goat, rabbit, dolphin, harbor seal, and parrot.[52,51,41,37,42,120,2,1,34,56]

In the dog, there are worldwide studies demonstrating the impact of breed on the development of lymphoma. In one European study, Dobermans, Rottweilers, Boxers, and Bernese Mountain Dogs showed a significant predisposition to lymphoma, including an increased frequency of T-cell lymphoma, B-cell lymphoma, and

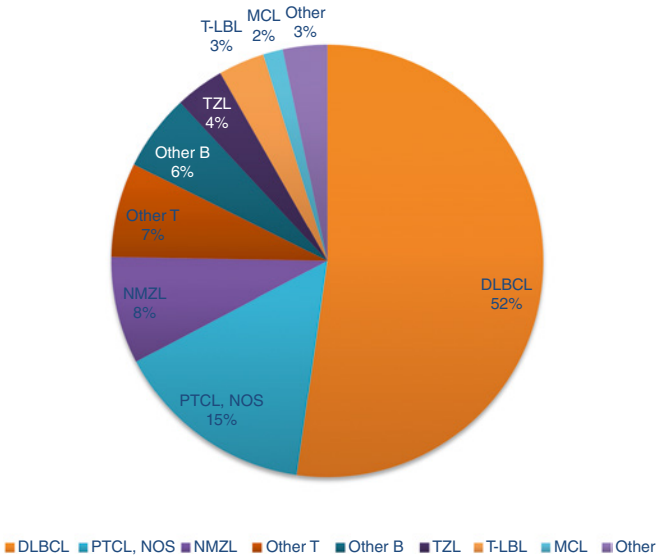

FIGURE 65.1 The frequency distribution of canine lymphoma as categorized by the WHO classification scheme.

high-grade T-cell lymphoma in Boxers, Rottweilers, and Labradors, respectively.[15] Similar results were reported in an Australian study while adding the Border Collie and Australian Cattle Dog.[125] In South Africa, the Labrador Retriever, Boerboel, Bull Terrier, Border Collie, Boxer, English Bulldog, Rhodesian Ridgeback, Basset Hound, Belgian Shepherd, Bullmastiff, Mastiff, Kerry Blue Terrier, and Schipperke were identified to be at an increased risk for lymphoma.[117] A US study identified geographic differences in the distribution of B-cell lymphoma and T-zone lymphoma in Golden Retrievers with T-zone lymphoma more likely to be diagnosed in dogs from the Northeast and East North Central regions as compared to dogs in the mountain region of the USA.[94] By contrast, European Golden Retrievers did not show any predisposition to lymphoma or T-zone lymphoma.[15] Limited information in the horse has shown that Quarter Horses almost exclusively develop T-cell-rich, large B-cell lymphoma and Thoroughbreds develop cutaneous lymphoma more commonly than other breeds.[67]

Causative Factors

There are limited studies defining the etiology of lymphoma in veterinary patients.[78,71] In humans, environmental agents, genetic predispositions, immune dysregulation, and infectious agents have been cited as potential causes.[117] In veterinary medicine, genetic abnormalities (e.g., chromosomal aberrations and epigenetic modifications) and environmental factors have been implicated.[17,71,78]

Twenty years ago, feline lymphoma was often affiliated with feline leukemia virus (FeLV) infection. Nowadays, FeLV is much less commonly associated with lymphoma. Cats with FeLV antigen and lymphoma are more likely to be younger and to have mediastinal lymphoma. A cat with FeLV antigenemia is less likely to have a long survival, possibly due to development of other diseases as well as lymphoma. However, FeLV is currently an uncommon disease, and the majority of cats with lymphoma are unaffected, so the clinical importance of this factor in contemporary veterinary oncology is comparatively low.[72]

Most forms of leukemia in veterinary medicine are believed to spontaneous in origin. Like lymphoma, given the association of specific leukemia subtypes with certain breeds of dogs, there is likely a heritable component to the development of canine lymphoma. In the cat, viral infection (e.g., FeLV and feline immunodeficiency virus (FIV), see Chapter 60) is well associated with both lymphoid and myeloid leukemias.

Clinical Presentations

The clinical presentation of lymphoid neoplasia is variable and related to location and extent of tumor involvement, tumor staging, and presence of paraneoplastic disease. In dogs, multicentric nodal lymphoma is most common (Figure 65.2a,b). The disease typically involves all peripheral lymph nodes and internal lymphoid tissues including tracheobronchial, sublumbar, and mesenteric lymph nodes. Tonsils, spleen, and liver are also frequently involved. Approximately 80–97% of dogs diagnosed show this form.[60] Less common anatomic variants include splenic,[96,102,104,118] hepatosplenic,[40] intestinal, cutaneous,[75,95,89] central nervous system (CNS) forms,[48] and ocular forms.[76,57] In the cat, alimentary lymphoma is most common.[79,73] By contrast, the multicentric form is hardly seen. In one study, alimentary lymphoma (47% of cases) was followed by cutaneous (17% of cases), nasal (13% of cases), laryngeal (10% of cases), nodal (7% of cases), ocular (3% of cases), and mixed (nodal and renal, 3% of cases).[124] Cats are affected by a unique form of nasal or nasopharyngeal lymphoma.[33,53]

In the horse, lymphoma is common and has a highly variable clinical presentation and course.[22] In the largest study (203 patients), affected patients had a mean age of 10.7 years and Quarter Horses, Thoroughbreds, and Standardbreds were the most commonly affected breeds. Multicentric lymphomas were common, as were skin and gastrointestinal tract. A total of 14 lymphoma subtypes were identified and T-cell-rich, large B-cell lymphoma, peripheral T-cell lymphoma, and diffuse large B-cell lymphoma were most frequent.[22] These findings mimic previous work.[54,67]

Like lymphoma, the leukemias are a heterogeneous group of diseases that are characterized by the proliferation of clonal lymphoid cells. In contrast to lymphoma, leukemia is defined by the accumulation of neoplastic cells in the peripheral blood and/or bone marrow. As exemplified by the most recent revision of the WHO classification of lymphoid tumors, it is important to note that the distinction between lymphoma and leukemia is based upon the tissue distribution of neoplastic cells rather than the biologic aspects of the neoplastic cells. For example, small cell lymphoma and chronic lymphocytic leukemia are considered tissue

FIGURE 65.2 Enlarged peripheral lymph nodes in two canine patients with multicentric lymphoma. (a) Mandibular lymph node; (b) Popliteal lymph node. (**Source:** Images courtesy of Birgitt Wolfesberger.)

variants of the same disease.[106] While this distinction is often less necessary in veterinary medicine, as there are fewer recognized subtypes and most patients present with advanced disease, there are specific diseases (e.g., T-zone lymphoma/leukemia) in which simultaneous significant tissue and peripheral blood involvement are common.[99]

Biological Behavior

Clinically, lymphoma and leukemia are heterogeneous diseases. The heterogeneity of lymphoma is best represented in the dog to include aggressive (e.g., diffuse large B-cell lymphoma and peripheral T-cell lymphoma) and indolent subtypes (e.g., T-zone lymphoma).[4,24,103] Specific lymphoma subtypes, and their clinical and pathologic findings, are discussed in the relevant B- and T-cell lymphoma chapters. Treatment and outcome differ widely between patients and it is beyond the scope of this chapter to detail subtype-specific biology. Broad clinical negative prognostic features include: illness at initial presentation, gastrointestinal or hepatosplenic lymphoma, and certain clinicopathologic features (e.g., thrombocytopenia, anemia, neutrophilia, increased neutrophil/lymphocyte ratio, cell size, hyperglobulinemia, hyperferritinemia, and increased serum lactate dehydrogenase activity).[13,61,18,12,16,4,59,66]

Considering the expanding diagnostic options, an increasing number of lymphoma prognostic features have been identified, including major histocompatibility complex (MHCII) status, CD25 expression, and Ki67 expression.[68,80,69,82] More importantly, it is increasingly evident that historical assertions, including that dogs with B-cell multicentric lymphoma have longer survival times than dogs with T-cell lymphoma, can no longer be claimed.[19,62,58,65,61] In canine leukemia, specific prognostic features include neoplastic cell size (in B-cell chronic lymphocytic leukemia, CLL) and neoplastic cell concentration (in T-cell CLL).[122] In feline leukemia, a number of different flow cytometric variants have been identified—each of which have distinct prognostic features. Based upon two studies, CD4+ T-cell leukemia, which is the most common feline immunophenotype, is a slowly progressive disease (medial survival time of 752 days) as compared to CD4−/CD8− T-cell leukemia (median survival time of 271 days) and $CD5^{low}$ T-cell leukemia (median survival time of 27.5 days).[93,9]

Regarding mutation analyses, overall survival time was significantly shorter in dogs with untreated high-grade lymphoma with p53 mutation than those with lymphoma retaining wild-type p53.[45] Another study demonstrated a higher Bcl-2/Bax ratio in dogs with T-cell lymphoma compared to B-cell lymphoma and normal dogs, respectively. This led to the theory that higher intrinsic resistance to apoptosis following cytotoxic treatment might contribute to the less favorable prognosis associated with multicentric T-cell lymphoma (TCL) in dogs. Nevertheless, genetic analyses are still less frequent and are so far most investigated in DLBCL.[3] One study revealed prognostically significant subtypes by molecular profiling.[29] Further discoveries are needed and will be key to clarifying subcellular pathologies that account for differences in clinical outcome.

PRESENTATION OF AN ALGORITHM FOR THE DIAGNOSIS/WORKUP OF LYMPHOMA AND LEUKEMIA

The diagnosis of lymphoid neoplasia begins with a thorough clinical history and physical examination followed by a clinicopathologic minimum database (CBC/Chem/Diff/UA) and medical imaging (Figure 65.3). Identification of peripheral or visceral lymphadenopathy, organomegaly, refractory cytopenias, unexplained hypercalcemia, and/or ambiguous clinical signs (i.e., inappetence,

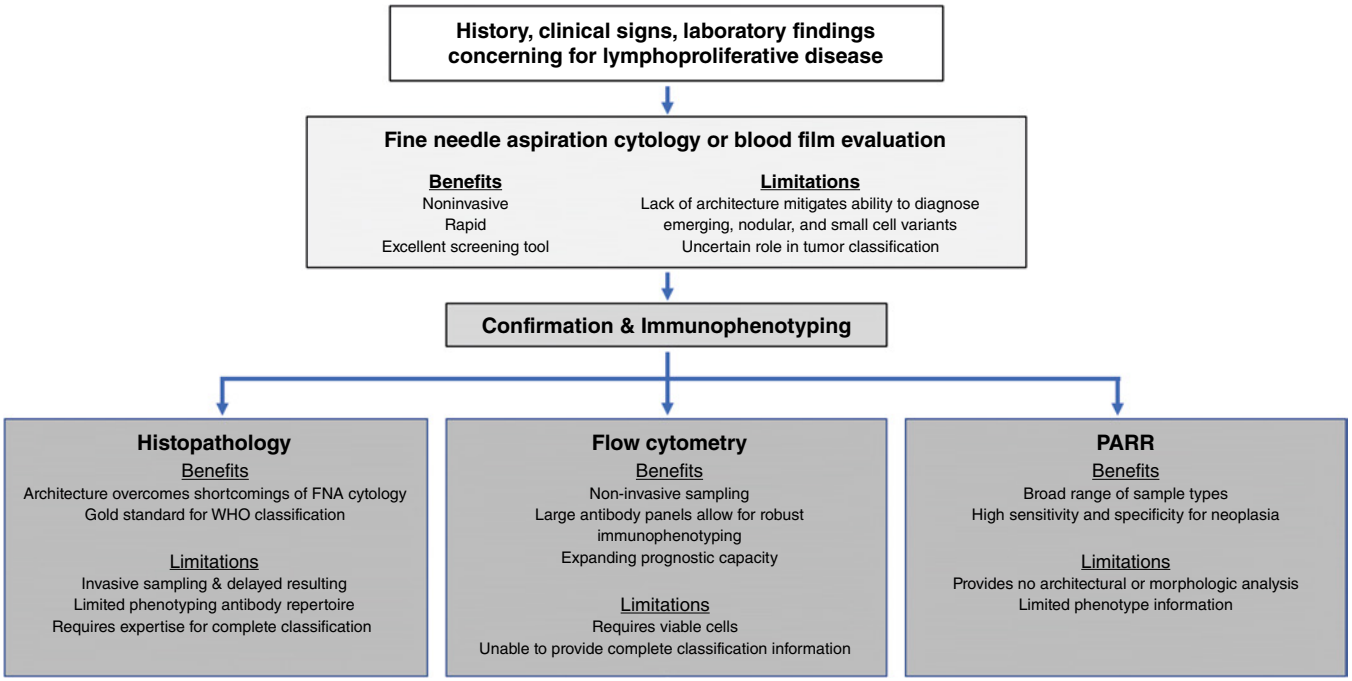

FIGURE 65.3 An algorithm for the diagnosis and classification of lymphoid neoplasms in veterinary medicine.

weight loss, gastrointestinal and respiratory signs) should prompt the diagnostician to consider more directed testing.[7]

Cytology and Hematology

Fine-needle aspirate cytology is a noninvasive, rapid, and frequently rewarding technique for the evaluation of lymphadenopathy and organomegaly.[7] Although there are tumor subtype-specific cytologic features (see T-cell and B-cell lymphoma chapters), the finding of a monomorphic population of large lymphocytes (1.5–2 times the diameter of a neutrophil) is consistent with the diagnosis of intermediate-to-large B-cell lymphoma. Neoplastic cells typically have a moderate amount of basophilic cytoplasm, a smooth chromatin pattern, and one or more visible nucleoli, although other morphologies (i.e., T-zone and large granular lymphomas) are also recognized.[92] Increased free cytoplasmic fragments, cytophagic (tingible-body) macrophages, and frequent mitotic figures are also common cytologic findings. Successful diagnosis is highly dependent on sample quality and location with decreased sensitivity reported for mesenteric lymph nodes and visceral organs.[46,100] Importantly, given the cytomorphologic and architectural heterogeneity of lymphoma (including nodular and small-/intermediate-cell-sized variants), additional diagnostics are often necessary.[7]

In leukemia, evaluation of the peripheral blood may reveal one or more cytopenias and the presence of circulating neoplastic cells. Diagnosis of leukemia may be made on evaluation of peripheral blood, but in cases where circulating neoplastic cells are rare or absent, bone marrow aspirate or core biopsy samples may be necessary. Assignment of lineage (i.e., lymphoid vs. myeloid) and maturation (i.e., acute vs. chronic) requires consideration of clinical and microscopic data as well as ancillary testing (cytochemical or immunocytochemical stains and/or flow cytometry).[92,105]

Confirmatory Tests and Immunophenotyping

Once a diagnosis of lymphoid neoplasia is established or if initial microscopy is equivocal, additional confirmatory and neoplastic cell phenotyping diagnostics are indicated. The used tools for this are immunocytochemistry (ICC), immunohistochemistry (IHC), and FC.[24,85,10] Phenotype, by facilitating subtyping and quantifying antigen expression, is considered one of the main prognostic indicators in lymphoma. Studies have highlighted the importance of immunophenotyping in treatment decisions with 31% of clinicians reportedly treating B- and T-cell lymphomas differently.[108] Furthermore, immunophenotyping leads to improved prognostication and a potentially more conservative and/or tailored treatment course.[23]

Histopathology and Immunohistochemistry

As noted in the earlier text, histology has been considered the gold standard for the diagnosis and classification of lymphoma. In addition to offering a standardized approach toward architectural and cytomorphologic assessment, histologic samples are readily repurposed for immunohistochemistry. Although histology is more invasive than cytology, requiring excisional, incisional, or tru-cut biopsy for diagnosis, it is superior to cytology in diagnosis of most cases of noneffacing, nonlarge cell

lymphoma. Importantly, as evident by evolving (and increasingly complex classification schemes), expertise in diagnostic hematopathology is increasingly important in establishing an accurate diagnosis.[116] Additional information on the histologic features of veterinary hematopathologic malignancies is available throughout this section.

Flow Cytometry

The role of flow cytometry in the diagnosis and immunophenotyping of lymphoid neoplasia is rapidly expanding. Indications for flow cytometry include peripheral blood or body fluid lymphocytosis, atypical circulating lymphocytes, and/or an expansion of monomorphic lymphocytes in lymph nodes, solid organs, or bone marrow.[7,108] There are limited studies examining the accuracy of hematologic malignancy diagnostics, but FC has a reported high sensitivity (98%) and specificity (100%) for the diagnosis of lymphoma in canine patients when compared to IHC.[108] Flow cytometry does not directly establish clonality; however, number, homogeneity, and/or phenotypic aberrancy of cells can be used to document a neoplastic population.[92] Specific information on flow cytometric methods and interpretation guidelines are available in Chapter 64.

Clonality Testing

PCR for antigen receptor rearrangement (PARR) is the most widely available and studied molecular assay used to detect clonality within lymphoid populations. PARR functions by amplifying the DNA encoding the variable regions of T- and B-cell receptors.[5] A more detailed discussion of clonality testing is presented in Chapter 62. In addition to defining the clonal nature of a cell population, clonality testing also provides limited phenotype information (i.e., B-cell vs. T-cell). From a practical perspective, samples for PARR testing can be derived from cytologic specimens (stained or unstained), fluids (including peripheral blood, cerebrospinal fluid, or body cavity effusion), formalin-fixed, or fresh frozen tissue. Importantly, owing to the phenomenon of "cross-lineage rearrangement", PARR may not accurately characterize phenotype and complete tumor classification requires additional morphologic and phenotyping diagnostics. Although PARR is highly specific (100% reported in one study), lower sensitivity was noted in identifying phenotype in contrast to flow cytometry in dogs (74% for PARR, 98% for flow cytometry) when compared to immunohistochemistry.[108,121] Finally, it is important to note that clonality is not equivalent to neoplastic, as benign clonal expansions have been described in some autoimmune disorders and certain infectious diseases (i.e., ehrlichiosis and leishmaniasis).[7] As a complement to PARR, additional clonality assays (i.e., X-linked inactivation pattern analysis) have yielded promising results and may become commonplace in the diagnosis and characterization of lymphoid neoplasia (see Chapter 62).[70]

CHAPTER 66

Myeloproliferative Neoplasms

ERIC J. FISH

Introduction
Classification System and Terminology
Molecular Pathogenesis
Chronic myeloid leukemia (CML)
Polycythemia Vera
Essential Thrombocythemia
Primary Myelofibrosis
Unclassifiable Myeloproliferative Neoplasms
Summary and Future Directions

Acronyms and Abbreviations

AML, acute myeloid leukemia; ABL, Abelson Murine Leukemia; BCR, breakpoint cluster region; FGFR, fibroblast growth factor receptor; FSC, forward scatter; GTP, guanosine triphosphates; MAPK/ERK, mitogen-activated protein kinase/extracellular signal-related kinases; MDS, myelodysplastic syndromes; MPN, myeloproliferative neoplasms; PI3K, 3-Kinase/protein kinase B; PLT, platelet concentration; PTEN, phosphatase and tensin homolog; STAT, signal transducer and activator of transcription; WHO, World Health Organization.

INTRODUCTION

Myeloproliferative neoplasms (MPN), formerly termed *chronic leukemias* or *myeloproliferative disorders*, are rare clonal expansions of bone marrow precursor cells that lead to overproduction of well-differentiated blood cells, including erythrocytes, leukocytes, or platelets. While myelodysplastic syndromes (MDS) are also clonal disorders of hematopoietic tissue, there are key distinctions between MPN and MDS, namely that MPN tend to result in a profound increase in the number of circulating cells, versus one or more cytopenias with MDS, and the degree of dysplasia and proportion of blasts are usually much higher in MDS (see Chapter 67 for more information on MDS).

This heterogeneous group of disorders shares some characteristics. In general, MPN are indolent and slowly progressive, though they can transform into more aggressive acute myeloid leukemias (AML).[48] There is often a marked increase in the concentration of the affected cell lineage (>100,000/μL for leukocytes, >1,000,000/μL for platelets, and PCV >65% for erythrocytes). Patients with MPN tend to be older (though patients can be any age), and they may be asymptomatic or have mild, nonspecific clinical signs. Splenomegaly, with or without hepatomegaly, is common.

MPN in humans and domestic animals can usually be diagnosed with reasonable certainty based on history, clinical signs, and serial CBCs.[1] Given that the excess cells in circulation and the bone marrow often appear morphologically normal or minimally dysplastic, MPN must be discriminated from hyperplastic or reactive proliferations. Diagnosis of MPN in human patients and experimental settings are aided by a wider array of tools to prove a clonal etiology, including fluorescence in situ hybridization (FISH) cytogenetics, X-linked clonality assay (see Chapter 62), and specific genetic assays for driver mutations.

Classification System and Terminology

Myeloid neoplasms in domestic animals were initially classified by the 1991 Animal Leukemia Study Group based on the human French–American–British (FAB) terminology of National Cancer Institute (NCI).[23] This system divided myeloid neoplasms into MDS and seven subtypes of AML, M1–M7 (see Chapter 68). AML and MDS were discriminated based on >30% blasts in blood

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

or bone marrow for acute leukemias and <30% blasts for MDS. At that time, chronic monocytic leukemia (CMoL) and chronic myelomonocytic leukemia (CMML) were considered subtypes of MDS, though the authors acknowledged several differences including the marked leukocytosis and minimal dysplasia. Veterinary medicine subsequently adopted the World Health Organization (WHO) human myeloid leukemia classification scheme. This scheme presents the parent category of MPN under which there are seven distinct entities, namely, chronic myeloid leukemia (CML), chronic neutrophilic leukemia (CNL), chronic eosinophilic leukemia (CEL), polycythemia vera (PV), chronic idiopathic myelofibrosis, essential thrombocythemia, and chronic myeloproliferative disease—unclassifiable.[31] Correlated with this adoption, the blast threshold between AML and MDS/MPN was lowered from 30% to 20%.[31]

The human WHO classification system was most recently revised in 2016 and recognizes the following subtypes of MPN: CML, CNL, PV, primary myelofibrosis (PMF), essential thrombocythemia (ET), chronic eosinophilic leukemia, and unclassifiable MPN (MPN-U).[1,3] The 2016 WHO criteria are complex and lay out specific diagnostic criteria for these entities based on clinical parameters, cell counts, and specific molecular lesions (Table 66.1).[1] Mastocytosis was previously included in this group, but is no longer considered to be a true MPN, and as such will not be discussed in this chapter. In human medicine, there is recognition of overlap between MDS and MPN, as well as some lymphoid neoplasms that have concurrent myeloid transformation that results in complex syndromes with similar characteristics.[3] In people, CMML and breakpoint cluster region–Abelson Murine Leukemia Viral Oncogene Homolog 1 (BCR–ABL)-negative atypical CML (aCML) are considered part of the MDS/MPN complex.[1] Juvenile myelomonocytic leukemia (JMML) is also included in this category and may be unique to people, as it has not been reported in domestic species.

The veterinary classification of MPN has not been independently updated since adoption of the 2016 WHO criteria and remains rudimentary and based on sporadic case reports rather than large studies. Furthermore, the latest WHO system increasingly relies on specific genetic markers, which are poorly defined in domestic species. However, in the spirit of comparative pathology, characteristics from the veterinary literature will be compared to the 2016 WHO classification system throughout this chapter.

Molecular Pathogenesis

The clonal nature of myeloid neoplasms has been known for over half a century. The first cytogenetic abnormality associated with a specific human cancer, the "Philadelphia chromosome" in patients with CML, was documented and characterized in the early 1960s, although its full significance would not be understood until decades later.[39] In the late 1980s, cats and dogs with myeloid leukemias were likewise shown to have karyotypic abnormalities such as aneuploidy, chromosomal deletions, and chromosome duplications.[16,17] However, it is only techniques such as whole genome sequencing, FISH, and chromosome immunoprecipitation (CHIP) that have allowed human oncologists and researchers to pinpoint the specific genes involved in MPN and other hematopoietic tumors.

MPN can be thought of as a warped version of normal hematopoiesis. In health, hematopoietic stem cells (HSCs) and subsequent lineage-specific progenitors and precursors are stimulated to survive and divide by cytokines such as erythropoietin (EPO), thrombopoietin (TPO), granulocyte colony-stimulating factor (G-CSF), interleukins, and many others (see Chapter 4 for more details on hematopoiesis).[25,49] The cytokines that normally regulate hematopoiesis bind to cell membrane receptors that activate one of the Janus kinases (JAK), which phosphorylate one or more transcription-regulating, signal transducer and activator of transcription (STAT) proteins (for more detail, see Chapter 4).[42] The JAK–STAT system can also interact with other key signaling pathways such as phosphoinositide 3-Kinase/protein kinase B (PI3K/AKT) and mitogen-activated protein kinase/extracellular signal-related kinases (MAPK/ERK). The downstream effects of JAK–STAT activation include cell survival and mitosis.

In MPN, HSCs acquire one or more somatic mutations that trigger constant proliferation even in the absence of growth-promoting cytokines or presence of cytostatic signals.[49] Eventually, these clonally transformed HSCs outcompete normal HSCs in the hematopoietic niche, replace a large portion of the bone marrow, and produce markedly increased peripheral blood concentrations of one or more blood cell lines. Though dozens of genetic mutations and epigenetic changes can promote clonal transformation of HSCs and early lineage-committed precursors, a relatively limited set of genes are involved in most cases of MPN.[32,33] Not surprisingly, most of the genes implicated in MPN are directly or indirectly involved in JAK–STAT signaling.[44] Some of these activating mutations affect cytokine receptors, such as colony-stimulating factor receptor 3 (CSFR3), which binds G-CSF, and myeloproliferative leukemia protein (MPL or CD110), which binds TPO. Other MPNs directly involve JAK mutations (such as the JAK2 V617F missense mutation in PV) or alterations that increase overall JAK–STAT signaling activity, such as the BCR–ABL1 fusion protein or calreticulin (CALR).

Nearly all cases of human CML, and some cases of acute lymphoid and myeloid leukemia, are caused by a chromosomal translocation resulting in fusion of the BCR and ABL1 genes (BCR–ABL1) and formation of the "Philadelphia chromosome."[1] The BCR gene encodes for a serine/threonine kinase that can activate guanosine triphosphates (GTP), and ABL encodes for a tyrosine kinase. The fusion product of this chromosomal translocation is constitutively active and results in constant cell signaling, particularly among hematopoietic cells. In addition to providing an explanation for the molecular pathogenesis, neoplasms with the BCR–ABL fusion gene may be targeted by specific tyrosine kinase inhibitors, such as imatinib mesylate, which has

TABLE 66.1 Comparative MPN classification in human and veterinary medicine.

Type of MPN	Human WHO criteria[1]	Reported characteristics in veterinary patients	Canonical genetic lesion(s)
1. Chronic myeloid leukemia (CML) (BCR–ABL$^+$)	Philadelphia chromosome-positive Accelerated phase (AP), one or more of the following: * Persistent or increasing leukocytosis (refractory to treatment) * Persistent or increasing splenomegaly (refractory to treatment) * Persistent thrombocytosis (refractory to treatment) * Persistent thrombocytopenia (refractory to treatment) * Basophilia (>20%) * 10–19% blasts (peripheral blood or marrow) * Additional genetic lesions besides BCR–ABL * New chromosomal abnormalities	BCR–ABL fusion gene documented in two dogs with CML and one with AML; marked monocytosis (>40,000/μL) with mature-appearing monocytes, blast percentage <20%, short survival times (4 weeks and 7 months)	BCR–ABL1 fusion gene‡
2. Chronic neutrophilic leukemia (CNL)	1. Leukocytosis >25,000/μL; >80% of WBCs are segmented neutrophils; myeloid precursors earlier than bands <10%; myeloblasts rare; monocytes <1000/μL; no dysplasia 2. Hypercellular marrow; myeloid hyperplasia; normal granulocyte maturation; <5% myeloblasts 3. Not compatible with CML or other MPN 4. Lacks PDGFRA, PDGFRB, or FGFR1, or PCM1–JAK2 rearrangement 5. Presence of canonical mutation OR neutrophilia >3 months with no obvious cause OR evidence of clonality	Dogs/cats: Neutrophilia 73,000–126,000/μL, variable presence of anemia, adequate platelets; Horse: Neutrophilia ranging from 8000–27,000/μL, moderate anemia, immature myeloid cells infiltrating and effacing lymph nodes, blasts <20% (single-case report)	CSF3R
3. Polycythemia vera (PV)	**Major criteria:** 1. Hgb > 16.5 g/dL (men) or 16 g/dL (women) OR Hct >49% (men) or 48% (women) 2. Hypercellular bone marrow, all lineages affected (panmyelosis), pleomorphic megakaryocytes 3. Documented canonical mutation **Minor criteria:** Low erythropoietin concentration *PV diagnosed by either all 3 major criteria OR major criteria 1+2 and minor criteria*	Hct >65%, may see reticulocytosis, rubricytosis; JAK2 (V617F) documented in one case report	JAK2‡

TABLE 66.1 (Continued)

Type of MPN	Human WHO criteria[1]	Reported characteristics in veterinary patients	Canonical genetic lesion(s)
4a. Primary myelofibrosis (PMF), early/ prefibrotic	**Major criteria:** 1. Megakaryocytic proliferation and atypia without reticulin fibrosis 2. Does not meet criteria for other MPN, MDS, MDS/MPN 3. Presence of canonical mutation OR demonstrated clonality **Minor criteria:** 1. Anemia without other cause 2. Palpable splenomegaly 3. Elevated LDH *Diagnosis requires 3 major criteria and ≥1 minor criteria*	Not clearly documented; may overlap with other case reports of animals with MPN/MDS	JAK2, CALR, MPL
4b. Primary myelofibrosis (PMF), overt	**Major criteria:** 1. Megakaryocytic proliferation and atypia with prominent reticulin and/or collagen fibrosis 2. Does not meet criteria for other MPN, MDS, MDS/MPN 3. Presence of canonical mutation OR demonstrated clonality **Minor criteria:** 1. Anemia without other cause 2. Leukocytosis >11,000/μL 3. Palpable splenomegaly 4. Elevated LDH 5. Leukoerythroblastosis *Diagnosis requires 3 major criteria and ≥1 minor criteria*	Marked thrombocytosis (>1,000,000/μL); splenomegaly; BM: megakaryocytic hyperplasia, increased dysplasia and blasts (single-case report)	JAK2, CALR, MPL
5. Essential thrombocythemia (ET)	**Major criteria:** 1. [PLT] > 450,000/μL 2. BM biopsy shows megakaryocytic hyperplasia and dysplasia with minimal erythroid/myeloid changes or fibrosis 3. Not compatible with BCR–ABL+ CML, MDS, or other MPN 4. Documented canonical mutation **Minor criteria:** Documented other clonal abnormality or exclusion of reactive cause *ET diagnosed by either all 4 major criteria OR major criteria 1–3 AND minor criteria*	Thrombocytosis ranging from 400,000/μL to 4,950,000/μL, moderate to marked nonregenerative anemia, leukocytosis with neutrophilia ± basophilia; increased PLT aggregation; megakaryocytic hyperplasia and myelofibrosis	JAK2, CALR, or MPL

(*Continued*)

TABLE 66.1 (Continued)

Type of MPN	Human WHO criteria[1]	Reported characteristics in veterinary patients	Canonical genetic lesion(s)
6. Chronic eosinophilic leukemia (CEL)-not otherwise specified[2]	1. Marked eosinophilia for >6 months (no cause identified) 2. Myeloblasts >2% blood OR <20% in bone marrow 3. Evidence of clonality 4. Does not meet criteria for MPN 1–5, MDS, MDS/MPN, 5. Does not have any of the following mutations: BCR–ABL fusion, PDGFRA, PDGFRB, or FGFR1; no PCM1/JAK2, ETV6/JAK2, or BCR/JAK2 fusion gene 6. Not compatible with AML	Marked eosinophilia (often >50,000–100,000/μL) without obvious cause, left-shift including blasts in blood and bone marrow; flow cytometry and cytochemistry compatible with normal eosinophils	N/a
7. Unclassifiable MPN	Does not meet WHO criteria for MPNs 1–6 mentioned above, MDS, MDS/MPN, or AML		N/a

[‡]= Mutation documented in veterinary patients.

transformed the prognosis for people with CML from grave to a manageable chronic long-term illness with a 10-year survival rate over 80%.[21]

Two case reports of dogs with CML documented a similar BCR–ABL fusion gene which researchers at North Carolina State University dubbed the "Raleigh chromosome."[7] In one report, the authors report a decline in the proportion of BCR–ABL-positive peripheral blood mononuclear cells from 17.3% to 3.3% after vincristine and prednisone treatment, suggesting that in addition to diagnostic uses, FISH could track cytogenetic response to treatment.[8] One of these dogs had simultaneous deletion of tumor suppressor gene phosphatase and tensin homolog (PTEN), illustrating that even in patients with a classic driver mutation, multiple genetic defects likely contribute to hematopoietic tumors.[7] An additional case report documented a dog with AML that had 34% circulating atypical CD34+ blast cells, and 32% of the peripheral blood mononuclear cells were positive for the BCR–ABL translocation.[12]

Nearly four in five people with CNL have activating mutations in the gene coding for CSFR3.[28] This mutation has not been identified in animals, although one report of a dog with CNL described a marked increase in phagocytic activity among leukemic neutrophils on an order of magnitude seen with exogenous G-CSF administration.[51] Since CSFR3 is the receptor for G-CSF, this could provide circumstantial evidence for a possible link.

Approximately 95% of cases of human MPN other than CML and CNL are caused by activating mutations in JAK2, CALR, or the thrombopoietin receptor (also known as MPL or CD110).[28,31] Multiple genetic lesions leading to clonal transformation of erythroid precursors have been documented in humans with PV. Approximately 90% of people with PV have mutations in the receptor tyrosine kinase JAK2 (primarily V617F) that leads to constitutive cell signaling and excessive erythropoiesis.[5]

PMF is primarily thought to arise from clonal transformation of HSCs rather than the fibroblasts themselves. However, experimental evidence from mice suggests that a nearly identical syndrome can be reproduced by deleting Rb or retinoic acid receptor gamma genes in myeloid-derived cells from the microenvironment and transplanting them into wild-type mice.[52,53]

Chronic Myeloid Leukemia (CML)

MPNs include several variants that overproduce leukocytes, including CNL, CML, and CEL. Cases of CNL and CML must be differentiated from mimics such as extreme, physiologic neutrophilic leukocytosis (aka "leukemoid reaction") secondary to marked inflammatory or paraneoplastic stimuli or marked leukocytosis because of the rare genetic disease leukocyte adhesion deficiency (LAD).[4,13,56]

CNL/CML has been uncommonly reported in dogs, and rarely in cats and horses.[24,26,32,35,48,51] The veterinary literature on CML is confounded by a lack of uniform terminology, with authors using varied labels such as "chronic granulocytic leukemia," "chronic myelogenous leukemia," "chronic myelomonocytic leukemia," and "chronic neutrophilic leukemia" to describe patients with similar leukogram patterns.

The leukocyte concentration of patients with CNL/CML often exceeds 100,000 cells/μL (Table 66.1 and Figure 66.1). Neutrophils in CNL and monocytes in CML often appear morphologically normal, but can show mild hypersegmentation or dysplasia (Figures 66.1 and 66.2). Leukocytes in CNL/CML do not appear to have impaired functional properties. The neutrophils in a dog with CNL were shown to have normal to increased

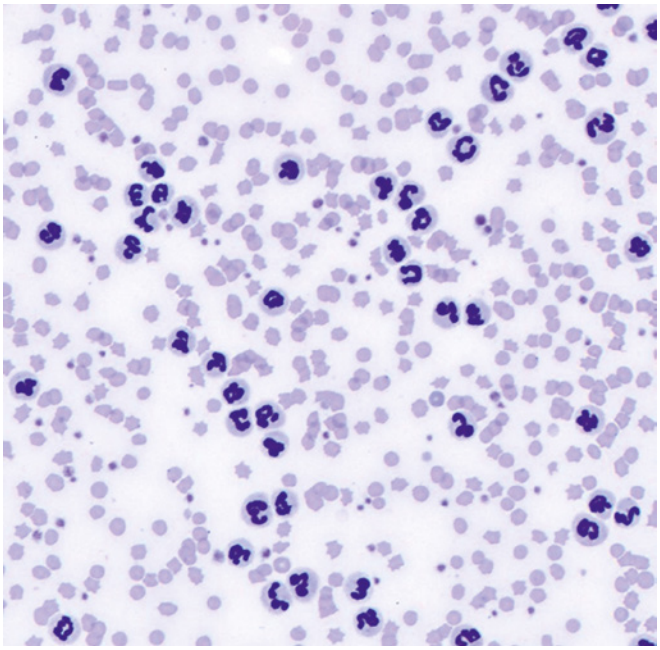

FIGURE 66.1 Chronic neutrophilic leukemia in a 19-year-old cat. The total leukocyte concentration was 342,870/μL. Virtually, all the leukocytes in this field are segmented neutrophils. They appear normal apart from a few hypersegmented types. Previous CBCs from this cat going back 4 years were unremarkable, excluding leukocyte adhesion deficiency (LAD), and the magnitude of this leukocytosis was considered far beyond the range for extreme neutrophilic leukocytosis ("leukemoid reaction"). Wright–Giemsa stain; original magnification 200×. (**Source:** Image courtesy of Laura Snyder, DVM, DACVP, IDEXX Laboratories)

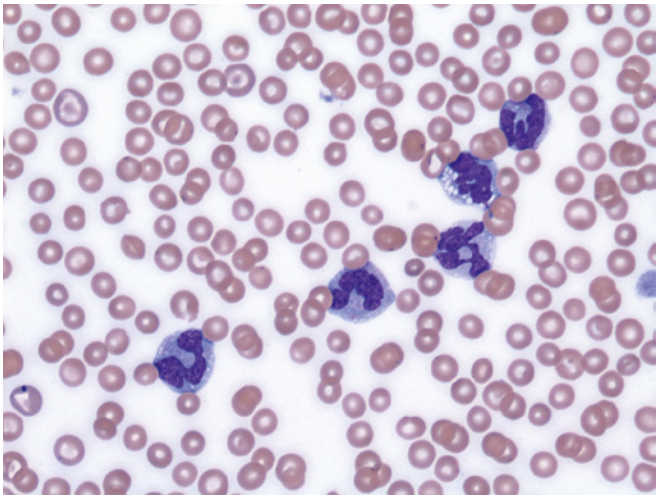

FIGURE 66.2 Chronic monocytic leukemia from an 8-year-old male castrated American Staffordshire Terrier. This patient presented with a leukocytosis of 36,700/μL, of which 80% were monocytes and 9% were immature blasts. All the leukocytes in this field are mature-appearing monocytes with medium blue cytoplasm, occasional clear vacuoles, and mildly pleomorphic nuclei with fine chromatin and absent nucleoli. One week later, the patient presented with a higher leukocytosis characterized by 67% circulating blasts and generalized lymphadenopathy with infiltration by these cells, indicating rapid transformation to acute monocytic leukemia (AML-M5). Wright–Giemsa stain; original magnification 200×.

phagocytic activity and normal migration and aggregation responses compared to healthy controls.[51] Anemia is a variable feature of CML/CNL and platelet concentrations are typically normal. CNL in the horse may have substantially lower peripheral neutrophil concentrations than in dogs or cats (Table 66.1).[24] One cat with CNL had concurrent eosinophilia and basophilia, illustrating that multiple cell lines can be stimulated to overproduce cells in MPN.[35] The variant aCML characterized by precursor tissue infiltrates, bone marrow dysplasia in erythroid, myeloid, and megakaryocytic cells, and negative BCR–ABL status has been diagnosed in one dog.[29]

Flow cytometry lacks many markers for myeloid neoplasms and there is no consensus on its role in the diagnosis of veterinary MPNs. However, certain antibodies (e.g., CD4 on canine neutrophils and CD14 on monocytes) can provide limited utility in some cases of MPN and AML (see Chapter 64 for more information on diagnostic flow cytometry).[36] One study identified increased neutrophil activation based on higher forward scatter (FSC) and decreased CD18 expression in immature granulocytes as subtle findings that differentiate CML from reactive neutrophilia.[6] Alkaline phosphatase cytochemistry has also been used to identify monocytic origin.[45]

Some cases in the literature document prolonged survival of 21 months (CML, dog) to 63 months (CNL, cat).[18,32] However, prognosis for these cases remains guarded, as they have been reported to progress to a blast crisis or acute myeloid leukemia in weeks to months after diagnosis.[8,48]

CEL is extremely rare, with two cases reported in the cat and one report of presumptive CEL in a dog.[14,37,43] These cases were characterized by marked eosinophilia (>50,000 cells/μL), dysplasia and/or immature eosinophils (including >1% to <20% blasts), and tissue infiltration. The marked eosinophilia with a left-shift can overlap with idiopathic hypereosinophilic syndrome (IHES), though IHES should not present with dysplastic changes or blasts/precursors. In one case of feline CEL, lineage assignment of poorly granulated and immature-appearing granulocytes was aided by cytochemistry, as the neoplastic cells were positive for alkaline phosphatase, but negative for myeloperoxidase, chloroacetate esterase, alpha-naphthyl acetate esterase, and toluidine blue (expected pattern for feline eosinophils; see Chapter 61 for more information on cytochemistry).[14] Increased serum IgE concentrations have been used to support a diagnosis of IHES as opposed to CEL in dogs.[46] Even in human oncology, it is considered quite difficult to definitively exclude CEL from IHES, myeloid/lymphoid neoplasms with fibroblast growth factor receptor 1 (FGFR1) mutations, or paraneoplastic hypereosinophilia.[2] For discussion of chronic basophilic leukemia, see the section entitled Unclassifiable Myeloproliferative Neoplasms.

Polycythemia Vera

PV is an uncommon MPN in dogs, cats, and calves characterized by overproduction of mature erythrocytes.[9,15,20,27,50]

These patients frequently have a chronic, progressive increase in measures of circulating red blood cell mass such as hematocrit, red blood cell concentration, and hemoglobin concentration. The magnitude of these changes in PV is often moderate to marked, with Hct values ranging from 65% to 80% (or more). Inappropriate reticulocytosis and/or rubricytosis may also be noted. Moderate to marked leukocytosis and/or thrombocytosis can also be present, as the transformed stem cell may be a pluripotent erythroid–myeloid precursor.

PV is a diagnosis of exclusion that must be differentiated from other causes of increased circulating red blood cell mass (erythrocytosis). Erythrocytosis can be subcategorized into relative and absolute causes. In relative erythrocytosis, the patient has a normal circulating red blood cell concentration, but splenic contraction or fluid shifting from the intravascular space to extravascular space due to severe dehydration, heatstroke, or hemorrhagic gastroenteritis increases the fraction of RBCs in proportion to the plasma volume. Relative erythrocytosis usually, but not always, results in less severe Hct changes than PV, and should resolve with correcting the underlying fluid deficits.

Absolute erythrocytosis is a true increase in circulating red blood cell mass. It may be a physiologically appropriate response secondary to increased erythropoietin production by renal interstitial sensing hypoxia as an adaptation to high-altitude climates or in pathologic conditions such as right-to-left cardiac shunts, chronic pulmonary disease, or renal infarcts. Inappropriate absolute erythrocytosis can be produced by PV and rarely by EPO-secreting renal tumors.[20] Erythropoietin levels may help differentiate between causes of erythrocytosis, although this assay is available on limited basis from commercial laboratories and there can be an overlap between presumed primary and secondary causes.[9]

Bone marrow evaluation in patients with PV reveals prominent erythroid hyperplasia, usually with a significantly decreased M:E ratio, and a relatively orderly maturation without dysplasia or an expanded population of rubriblasts.[54] Notably, marked erythrocytosis can, because red blood cells rely on glucose, result in artifactual hypoglycemia.[30]

PV may be asymptomatic and discovered incidentally on routine labwork. For patients with advanced disease, clinical signs are related to increased blood viscosity, including cardiac insufficiency, uveitis, seizures, or abnormal coagulation (including thromboemboli).[15,27] Treatment of PV patients is symptomatic and aimed at reducing signs of hyperviscosity. Clinicians have used a variety of approaches, including serial therapeutic phlebotomy and drugs such as hydroxyurea to decrease excess marrow production of red blood cells.

Essential Thrombocythemia

ET is an MPN characterized by megakaryocytic hyperplasia and marked thrombocytosis. The most recent WHO classification system for ET identifies several major criteria, including moderate to marked thrombocytosis with platelet concentration ([PLT] >450,000/μL), bone marrow biopsy showing marked fibrosis and megakaryocytic proliferation, not meeting criteria for other MPN, and identifying clonal genetic lesions or classic driver mutations (such as JAK2, CALR, or MPL) (see Table 66.1).[3] These mutations have not been documented in domestic animals and ET remains a diagnosis of exclusion in veterinary medicine. Differential diagnoses include other conditions resulting in a moderate to marked reactive thrombocytosis, particularly inflammatory/autoimmune disorders, hyperadrenocorticism, iron deficiency, administration of corticosteroids or vincristine, and a paraneoplastic response to nonmyeloid tumors.[38,57]

Probable ET has been reported in four dogs and one cat (Figure 66.3).[11,19,22,47] Features of these cases (see Table 66.1) include moderate to marked thrombocytosis, nonregenerative anemia, leukocytosis characterized by neutrophilia with or without basophilia, megakaryocytic hyperplasia, and myelofibrosis. Ultrastructural platelet and megakaryocyte abnormalities reported in one dog include platelets with large, asymmetric dilated open canalicular systems, megakaryoblasts with alpha granules, and dysplastic megakaryocytes that had poor cytoplasmic organization.[47] Humans with ET are hypercoagulable and prone to thromboembolic complications. This has not been conclusively demonstrated in animals, although in one case report, platelets from a dog with ET demonstrated increased aggregation responses.[11]

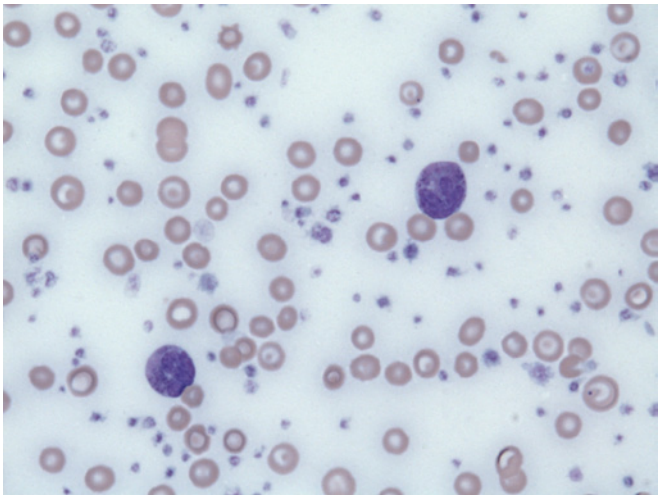

FIGURE 66.3 Marked thrombocytosis (1,552,000/μL) and basophilia (2577/μL) in a 6-year-old intact female Bulldog. The patient had a prior history of marked splenomegaly treated with splenectomy. This photomicrograph shows many hypergranulated platelets and two mature basophils. Core bone marrow biopsy was hypercellular with megakaryocytic hyperplasia, a markedly left-shifted myeloid series, and multifocal fibrosis. The differential diagnosis was ET with basophilia or unclassified MPN. Wright–Giemsa stain; original magnification 500×. (**Source:** Image courtesy of Cheryl A. Lawson, DVM, MS, DACVP, Iowa State University)

Primary Myelofibrosis

Myelofibrosis is the proliferation of stromal fibroblasts that produce reticulin and collagen fibrils. Myelofibrosis is classified as primary (i.e., neoplastic) or secondary (i.e., reactive). Secondary myelofibrosis may occur as a response to a wide variety of bone marrow insults such as myelitis, ischemia, necrosis, chronic overproduction of stimulating cytokines (such as with chronic hemolysis from pyruvate kinase deficiency or immune-mediated hemolytic anemia), or infiltration by nonmyeloid neoplastic cells.[40,55] Bone marrow aspirate cytology from patients with myelofibrosis is often unrewarding and results in poorly cellular "dry taps." Bone marrow core histopathology often reveals thin eosinophilic fibers that cause unusual cell bunching on H&E sections. Reticulin fibers seen in early myelofibrosis are visualized with silver stains, while the larger collagen fibrils seen later are identified with Masson's trichrome stain (Figure 66.4). Whether primary or secondary, myelofibrosis can contribute to one or more cytopenias.

PMF is an uncommon but well-defined entity in human medicine caused by clonal transformation of marrow HSCs. The major WHO criteria for PMF in people includes: megakaryocytic proliferation and atypia, presence of JAK2/CALR/MPL mutation or other clonal marker, and does not meet criteria for another MPN or MDS (Table 66.1). The degree of reticulin and collagen fibrosis can subdivide cases into prefibrotic and overt PMF.

In one retrospective study of 19 dogs with myelofibrosis, the vast majority (18/19) were classified as secondary.[55] In the one case of presumed PMF, the dog shared many characteristics of human PMF, including anemia, splenomegaly, marked thrombocytosis, and a bone marrow biopsy with prominent fibrosis, megakaryocytic hyperplasia, and multilineage dysplasia. It bears mentioning that while thrombocytosis is common with PMF, it is not a required diagnostic criterion and differentiating people with ET and early PMF can present a diagnostic dilemma, as many of the clinical and hematologic features overlap.[3,41]

Unclassifiable Myeloproliferative Neoplasms

Cases that do not fulfill the classification criteria for any of the specific MPNs are labeled MPN-U. In the veterinary literature, MPN-U includes several reports of "basophilic leukemia."[34] In addition to a marked basophilia, affected patients present with a marked thrombocytosis (sometimes between 2,000,000 and 3,000,000/μL) which can overlap with the case definition of ET. Notably, chronic basophilic leukemia is not currently recognized in the latest WHO classification of MPN, and could represent an entity unique to domestic animals. However, basophilia can accompany multiple other MPN in people and domestic animals, and may represent a negative prognostic marker of progression into AML.[10] For best concordance with human literature, this diagnostic entity should either be labeled MPN-U or considered a variable finding that can coexist with several of the MPN described in this chapter. Further research is needed in this area.

Summary and Future Directions

The classification, molecular understanding, and treatment of human MPN have advanced remarkably in the past 20 years. People with these disorders now benefit from targeted therapies that greatly increase life span with minimal adverse effects compared to traditional cytotoxic chemotherapy agents. By contrast, MPN in domestic species are less characterized, with much of what veterinary pathologists and oncologists "know" based on anecdotal opinion and personal experience. Larger studies and comparative research into driver mutations in veterinary patients with MPN are essential to align the classification system with the human scheme and provide revised diagnostic approaches and tailored molecular therapies that may improve the prognosis for these patients.

CHAPTER 67

Myelodysplastic Syndromes

DOUGLAS J. WEISS and RANCE K. SELLON

Introduction
Classification of Myelodysplastic Syndromes
Myelodysplastic Syndromes in Dogs
  MDS with Refractory Cytopenia
  Refractory Cytopenia with Multilineage Dysplasia
  MDS with Excessive Blasts
  Myelodysplastic Syndrome Unclassifiable
  Secondary Myelodysplastic Syndromes
Secondary Dysmyelopoiesis in Dogs
  Diseases/Drugs/Toxins
Myelodysplastic Syndromes in Cats
  Refractory Cytopenia with Multilineage Dysplasia
  Myelodysplastic Syndrome with Excessive Blasts
Secondary Dysmyelopoiesis in Cats
  Diseases/Drugs/Toxins
Myelodysplastic Syndrome in Horses

ACRONYMS AND ABBREVIATIONS

BM< bone marrow; DNA, deoxyribonucleic acid; IMHA, immune mediated hemolytic anemia; PRCA, pure red cell aplasia.

INTRODUCTION

Myelodysplastic syndromes (MDS) are a group of acquired clonal hematologic disorders, described in dogs, cats, horses, and humans, that originate from acquired genetic mutations in hematopoietic stem cells.[6,8,12,22,51] MDS are considered the most common reason for bone marrow (BM) failure syndromes in adult humans[5] and represent a diverse array of syndromes reflecting the underlying mutations. As in other neoplasms, clonal expansion is usually the result of one or more gene abnormalities including karyotypic abnormalities and mutations in genes with a variety of functions including tumor suppression, DNA repair, modification of histones, regulation of epigenetic events and apoptosis, intracellular signaling, and others.[2,16,32,35] A clonal origin has been documented in cats infected with feline leukemia virus (FeLV).[21] Myelodysplastic syndromes in dogs have been assumed to be clonal because of an absence of concurrent diseases or drug or toxin exposure, and because of the similarity of the MDS to those described in humans.[28,51] Compared to people, the genetic and molecular basis of MDS in veterinary species is poorly described and understood.

While the MDS are heterogeneous disorders, they are consistently characterized by peripheral blood (PB) cytopenias and dysplastic changes in one or more hematopoietic cell lineages. Some variants of MDS are associated with an increased risk of progression to acute myeloid leukemia. Cytopenias result from a combination of defects in growth and differentiation and increased apoptosis of hematopoietic cells. In people, some evidence supports defective immune system deletion of clones as contributing to the MDS, while other lines of evidence support a potential role of chronic inflammation and innate immune system signaling in the emergence of clonal expansion of hematopoietic cells.[2,4,35] These defects result in ineffective hematopoiesis.[9,29,37]

Major subtypes of MDS must be differentiated to better define appropriate treatment and establish a prognosis. While differentiation commonly relies on morphologic abnormalities noted on a blood smear or in a bone marrow sample, molecular testing plays an increasingly important role in the diagnosis of specific

types of MDS in people.[2] Myelodysplastic syndromes must also be differentiated from secondary dysmyelopoiesis due to diseases, drug and toxin exposure, robust hyperplasia, or congenital disorders.[1,20,42,43,45,49] The most reliable features that help differentiate MDS from secondary dysmyelopoiesis include increased numbers of myeloblasts or rubriblasts in bone marrow, a high percentage of dysplastic cells in bone marrow, and prominent megaloblastic changes in erythroid precursor cells.[9,45] However, clinical history and repeat peripheral blood and/or bone marrow analysis may be needed. Congenital dysmyelopoiesis is generally seen in juvenile animals and may be breed-restricted.

CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES

Although veterinary medicine utilizes similar terminology, the approach toward the diagnosis and classification of MDS has been defined by human medicine. Myelodysplastic syndromes were initially classified by the French–American–British (FAB) cooperative group (Table 67.1).[7] This system has been applied to both dogs and cats.[9,25,30] The FAB system categorized MDS into five categories primarily based on the distribution and type of dysplastic features and the percentage of myeloblasts present. These five categories included refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transition (i.e., 20–30% myeloblasts in bone marrow), and chronic myelomonocytic leukemia. Acute leukemia was defined as greater than 30% myeloblasts in bone marrow.[7]

The World Health Organization (WHO) modified the FAB classification system incorporating diagnostic information such as cytogenetics, immunologic markers, and molecular genetics.[18] The WHO classification system itself has undergone several revisions, most recently in 2016, with the current MDS classifications based not on specific cytopenias but the number of dysplastic cell lineages, the proportion of ring sideroblasts (RS) in bone marrow, and the proportion of blasts in BM and PB.[3] Sideroblasts are nucleated erythroid cells that contain many large iron deposits within mitochondria. Because mitochondria are distributed around the nucleus, iron deposits frequently form a perinuclear collar, and the cells are termed *ring sideroblasts* (Figure 67.1). Additional classification systems, notably an International Prognostic Scoring System (IPSS), a revised IPSS, and MD Anderson Global Prognostic Scoring System, exist; each was developed with the goal of improving clinical decision-making and prognosis, but with each having limitations.[26]

In the current WHO classification system of human MDS, the syndrome formerly referred to as RA is now MDS with single-lineage dysplasia (MDS-SLD) or multilineage dysplasia (MDS-MLD). MDS-SLD is characterized by one or two cytopenias (anemia, neutropenia, or thrombocytopenia) with a single dysplastic lineage, less than 15% ring sideroblasts in the bone marrow, less than 5% blasts in the BM, and less than 1% blasts in PB. MDS-MLD has the same BM and PB blast features as MDS-SLD, but MDS-MLD has two or three dysplastic lineages and is associated with one to three cytopenias (Figures 67.2 and 67.3). Refractory anemia with ring sideroblasts is now classified as MDS with RS and either SLD or MLD. Dysplastic lineages, cytopenias, and proportions of blasts in BM and PB in MDS-RS-SLD or MDS-RS-MLD are the same as for MDS-SLD or MDS-MLD, but the two MDS-RS entities have ≥15% RS in the BM. Refractory anemia with excess blasts in the FAB classification system is, in the WHO system, MDS with excessive blasts (EB)-1 or -2 depending on the number of blasts in PB and BM. MDS-EB-1 is characterized by cytopenias, SLD or

TABLE 67.1 Classification systems for myelodysplastic syndromes (MDS).

French–American–British	World Health Organization[3]	Dog/cat system[48]
Refractory anemia	MDS single-lineage or multilineage dysplasia (SLD or MLD)	MDS with refractory cytopenia
Refractory anemia with ring sideroblasts	MDS (either SLD or MLD) with ring sideroblasts	Refractory cytopenia with multilineage dysplasia with or without ring sideroblasts
Refractory anemia with excess blasts	MDS with excessive blasts-1	MDS with excess blasts (5–30% blasts)
Refractory anemia with excess blasts in transition	MDS with excessive blasts-2	
	MDS with isolated del(5q) chromosome abnormality	
	MDS unclassifiable	MDS unclassifiable
Chronic myelomonocytic leukemia		
Acute myeloid leukemia (>30% blasts)		Acute myeloid leukemia (>30% blasts)

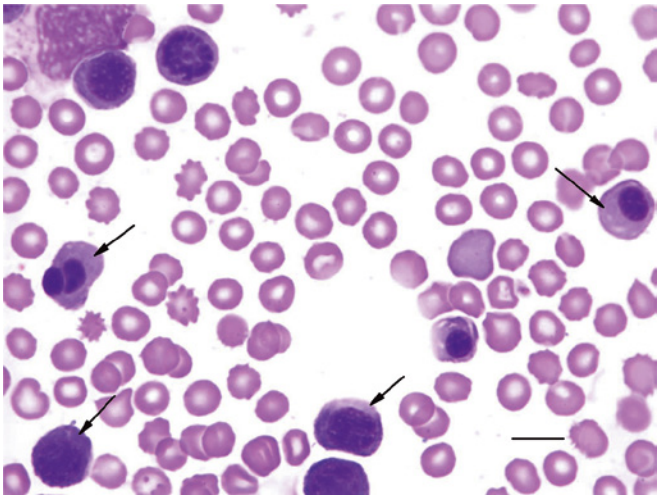

FIGURE 67.3 Mild megaloblastic dyserythropoiesis in a bone marrow aspirate from a dog with MDS with refractory cytopenia. Note the large size of nuclei in rubricytes relative to their maturity (arrows). Wright–Giemsa stain; bar = 10 µm.

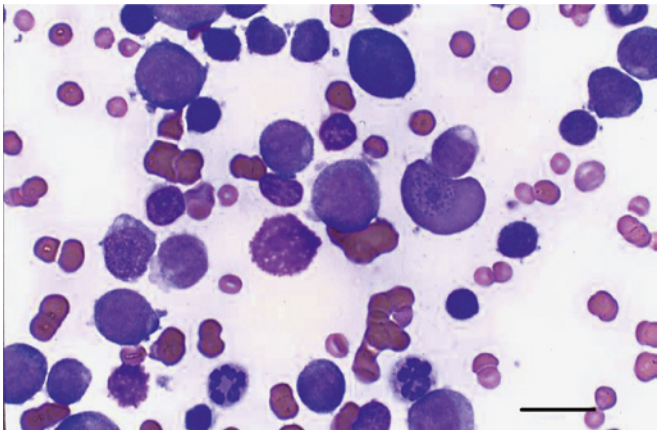

FIGURE 67.4 Increased numbers of myeloblasts and multilineage dysplasia in a bone marrow aspirate from a cat with MDS excess blasts. Note a large megaloblastic rubricyte and hypersegmented neutrophils. Wright–Giemsa stain; bar = 20 µm.

MLD, 2–4% blasts in PB, and/or 5–9% blasts in BM; MDS-EB-2 has 5–19% PB blasts and 10–19% BM blasts (Figure 67.4). In humans, MDS associated with isolated del(5q) chromosome abnormality has been shown to be sufficiently homogeneous to keep its own categorical classification. Acute myeloid leukemia is defined as greater than 20% myeloblasts in bone marrow. Neither acute nor chronic myelomonocytic leukemia is included in current WHO classifications of MDS.

A modified classification system (Table 67.1) has been described for dogs and cats,[48] but the proposed system has yet to be widely evaluated. Unfortunately, inconsistent use of a single system and variations in diagnostic criteria make it difficult to rely upon the published scientific literature for guidance. Nevertheless, in the system proposed in this chapter, major categories include: (1) MDS with refractory cytopenias, (2) refractory cytopenias with multilineage dysplasia, and (3) MDS with excess blasts. Myelodysplastic syndrome with refractory cytopenia is characterized by nonregenerative anemia, or occasionally multiple cytopenias, dysplastic features usually most prominent in the erythroid lineage, and less than 5% myeloblasts in bone marrow. Refractory cytopenias with multilineage dysplasia may occur without or with sideroblastic differentiation, the latter characterized in dogs by microcytic or hypochromic anemia and sideroblasts and ring sideroblasts in bone marrow.[46] MDS with excess blasts is typically characterized by bicytopenia or pancytopenia, bone marrow dysplasia in two or more cell lines, and greater than 5% bone marrow myeloblasts.

MYELODYSPLASTIC SYNDROMES IN DOGS

Retrospective studies have provided some insight into canine MDS. In a study of clinical bone marrow reports from a single veterinary teaching hospital, primary MDS was reported in 3.7% of sampled dogs.[46] MDS-EB was the most common, with MDS with refractory cytopenias and MDS-SD seen in fewer numbers. In another study, 12 dogs with primary MDS had features consistent with MDS with refractory cytopenia or MDS-EB based on the presence of pancytopenia and greater than 5% myeloblasts in bone marrow (Table 67.2).[52] Finally, another study found 13 of 267 dogs with bone marrow examinations had primary MDS with 4/13 having features of MDS with refractory cytopenias (n = 4) and the largest group having MDS-EB.[49] Collectively, these studies suggest that MDS-EB is the most common form of MDS observed in dogs.

MDS with Refractory Cytopenia

Dogs with MDS with refractory cytopenia (refractory anemia in older classification schemes) are typically older than 7 years with no breed predilection (Table 67.2).[49,52] Affected dogs have an insidious onset of lethargy and exercise intolerance. Frequent physical examination findings include pale mucous membranes, increased heart and respiratory rates, and anemia-related heart murmur. Hematologic alterations consist of moderate to severe, nonregenerative normocytic normochromic anemia. Total leukocyte and platelet concentrations are usually within reference ranges. Bone marrow is normocellular or hypercellular with a normal or decreased myeloid-to-erythroid ratio due to erythroid hyperplasia. Rubriblasts are frequently increased in number (5–30% of all nucleated bone marrow cells) and myeloblasts are consistently less than 5% of all nucleated bone marrow cells.[49,52] Dysplastic features, which are usually limited to the erythroid series, consist of binucleation, megaloblastosis, nuclear fragmentation, and asynchronous maturation.[49,52]

Treatment of dogs with MDS with refractory cytopenia has included prednisolone, cyclophosphamide, cytosine arabinoside, and erythropoietin.[10,40,52] Most dogs for which follow-up was available survived for months to years with no reports of progression to acute leukemia.[10,52] Of three dogs treated with recombinant erythropoietin, all had significant improvement in hematocrit and were nonanemic at last contact.[10,40,52] In the limited number of cases reported, response to treatment or survival did not appear to be dependent on the percentage of rubriblasts in bone marrow.

Refractory Cytopenia with Multilineage Dysplasia

Refractory cytopenia with multilineage dysplasia (RCMD) is characterized by prominent dysplastic features in two or more hematopoietic cell lineages, but no increase in bone marrow myeloblasts.[28,48] Dogs with RCMD include dogs with sideroblastic- and non-sideroblastic-types of anemia (Table 67.2).[15,28,43,46,48,50] Several dogs with non-sideroblastic anemia had normocytic normochromic nonregenerative anemia, thrombocytopenia, and dysplastic features in all hematopoietic cell lines.[15,28] Treatment of affected dogs has included low-dose aclarubicin, cytosine arabinoside, prednisolone, cyclosporine, and cytarabine ocfosfate, and has resulted in varied survival times.[15,23,28] Several cases of MDS with sideroblastic differentiation have been described.[46,49,50] However, because these conditions consistently had prominent dysplastic features in all cell lineages, it has been suggested that these are better categorized as RCMD.[46,48]

Dogs with sideroblastic-type RCMD demonstrate similar historical and physical exam findings as those with MDS with refractory cytopenias. Hematologic alterations consist of a microcytic or hypochromic nonregenerative anemia with many siderocytes in blood smears. The presence of siderocytes can be confirmed by staining the iron-containing granules with Prussian blue stain. Bone marrow is normocellular or hypercellular and usually contains increased amounts of hemosiderin. A characteristic feature is the presence of five or more

TABLE 67.2 Characteristics of myelodysplastic syndromes in dogs.[48]

Condition	Signalment	Clinical signs	Peripheral blood findings	Bone marrow findings
MDS with refractory cytopenias	Middle-aged to old	Lethargy, exercise intolerance	Normocytic normochromic nonregenerative anemia	Dyserythropoiesis, variable increase in rubriblasts, <5% myeloblasts
RCMD (without sideroblasts) RCMD (with sideroblasts)	Middle-aged to old	Uncertain Lethargy, exercise intolerance	Normocytic normochromic nonregenerative anemia Microcytic, hypochromic nonregenerative anemia	Dysplasia in multiple cell lineages, <5% myeloblasts
MDS with excessive blasts	Middle-aged to old	Lethargy, anorexia, fever, petechial hemorrhage	Bicytopenia or pancytopenia	Dyserythropoiesis, dysgranulopoiesis, dysmegakaryopoiesis, 5–20% myeloblasts

large iron deposits in rubricytes and metarubricytes (in contrast to the normal one to three small siderotic granules seen in the same cells from normal adult dogs).[13,43] Variable numbers of ring sideroblasts are also present. Although rubriblasts are frequently increased, myeloblasts are usually less than 5% of all nucleated cells. Too few cases of sideroblastic-type RCMD have been reported to establish treatment protocols or to evaluate outcome. However, among the few cases observed by one of the authors (DJW), both response to treatment and survival time appear to be less than that for MDS with refractory cytopenias. Cases of RCMD must be differentiated from sideroblastic anemia. Sideroblastic anemia has been associated with inflammatory diseases, myelofibrosis, and chloramphenicol therapy.[20,43]

MDS with Excessive Blasts

MDS-EB (refractory anemia with excess blasts in older classifications) is the most common form of primary myelodysplasia in dogs.[51,52] MDS-EB is a disease of middle-aged to old dogs (range 4–13 years) with no apparent breed or sex predilection (Table 67.2).[52] Dogs with MDS-EB usually appear more ill than those with MDS with refractory cytopenia. Signs of illness, which may appear acutely or progressively worsen over weeks to months, include lethargy, depression, anorexia, diarrhea, and fever.[52] Hematologic alterations include moderate to severe, normocytic normochromic nonregenerative anemia, neutropenia, and thrombocytopenia. Bone marrow is usually hypercellular with an increased myeloid-to-erythroid ratio. A hallmark feature of MDS-EB is increased numbers of myeloblasts (6–20% of all nucleated bone marrow cells).[52] Dysplastic features are typically present in all bone marrow cell lineages. Features of dysgranulopoiesis include small myeloblasts and promyelocytes, giant metamyelocytes and band cells, asynchronous maturation, and hypersegmentation.[6,49] Features of dyserythropoiesis include megaloblastic changes, asynchronous maturation, binucleation or trinucleation, nuclear fragmentation, and micrometarubricytes.[6,49] Features of dysmegakaryopoiesis include asynchronous maturation, large hypolobulated forms, dwarf megakaryocytes, and dispersed nuclei.[6,49]

Treatment of MDS-EB in dogs has been mostly supportive.[15,28,52] Broad spectrum antibiotics are indicated when severe neutropenia, fever, or sepsis is present. Red blood cell or whole blood transfusions are indicated to treat severe anemia. Erythropoietin and other hematopoietic growth factors have been given. Although these treatments may improve the cytopenias, they do not appear to significantly prolong survival. Administration of chemotherapeutic agents, including hydroxyurea, low-dose cytosine arabinoside, and low-dose aclarubicin, has been tried in individual cases; hydroxyurea has been used most frequently.[40] Survival times of dogs with MDS-EB are short, ranging from days to months.[15,52] Death or euthanasia is frequently associated with sepsis, organ failure, bleeding, or disseminated intravascular coagulopathy. Progression to acute myeloid leukemia has been documented in some cases.[52] In general, survival and progression to acute myeloid leukemia can be predicted by the percentage of myeloblasts present in bone marrow.

Myelodysplastic Syndrome Unclassifiable

Variant forms of MDS are occasionally seen. These probably result from different combinations of genetic mutations in hematopoietic stem cells. Primary dysmegakaryopoiesis is one variant form.[41] Affected dogs have a history of chronic moderate to severe thrombocytopenia unresponsive to immunosuppressive therapy. In bone marrow, dysplastic features of megakaryocytes include large hypolobulated or dwarf forms, asynchronous maturation, and discrete rather than lobulated nuclei. Causes of secondary dysmegakaryopoiesis, including immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, monocytic ehrlichiosis, and lymphosarcoma, should be ruled out before a diagnosis of MDS is made.[41] Affected dogs appear to have prolonged survival.

Secondary Myelodysplastic Syndromes

Secondary MDS is a clonal disorder of hematopoietic stem cells associated with drug or radiation treatment or toxin exposure.[34] In humans, secondary MDS has been associated with benzene exposure and treatment with alkylating agents and radiation. Secondary MDS frequently occurs months to years after exposure. Drug-associated MDS has not been reported in dogs, but dysmegakaryopoiesis has been reported as a preleukemic change in dogs after exposure to gamma radiation.[36] With ever increasing use of chemotherapeutic agents and radiation therapy in veterinary medicine, secondary MDS may become more frequently recognized.

SECONDARY DYSMYELOPOIESIS IN DOGS

Diseases/Drugs/Toxins

Secondary dysmyelopoiesis includes nonclonal dysplastic conditions that should not be classified as MDS. Secondary dysmyelopoiesis is associated with a variety of conditions including immune-mediated hemolytic anemia/immune-mediated thrombocytopenia, lymphosarcoma, myelofibrosis, administration of certain drugs, exposure to heavy metals, iron deficiency, and some congenital conditions.[19,41,43,49] Implicated drugs include antimetabolites (e.g., azathioprine, cytosine arabinoside, hydroxyurea), folate antagonists (e.g., methotrexate), plant alkaloids (e.g., vincristine), alkylating agents (e.g., cyclophosphamide), phenobarbital, estrogen, cephalosporins, chloramphenicol, and colchicine.[1,9,20,24,41] In the erythroid lineage, dysplastic findings include binucleation, fragmented nuclei, giant forms, atypical mitotic figures, and megaloblasts. Phenobarbital therapy has been associated with a severe normocytic

normochromic nonregenerative anemia and dyserythropoiesis.[24,27] Sideroblastic anemia was documented in a dog treated with chloramphenicol.[20]

Secondary dysmyelopoiesis has also been associated with iron deficiency, lead, zinc, and arsenic poisoning, and infection with *Leishmania infantum*, *Anaplasma platys*, and *Hepatozoon canis*.[9,11,14,17,19,38] Iron deficiency is characterized in its later stages by a microcytic hypochromic anemia.[39] Dysplastic features are restricted to the erythroid lineage and are characterized by rubricytes and metarubricytes with a ragged rim of cytoplasm and patchy areas of basophilia within the cytoplasm.[19] A late-stage maturation arrest in the erythroid series may be present in some dogs. Lead inhibits several enzymes in the heme synthesis pathway leading to iron accumulation in erythroid precursors and sideroblastic anemia.[17] Lead also inhibits a pyridine-specific 5′-nucleotidase involved in degradation of ribosomal ribonucleic acids. Retention of ribosomes may result in basophilic stippling. Arsenic poisoning causes marked dyserythropoiesis characterized by karyorrhexis, megaloblastosis, and multinuclearity. Infection with *Leishmania* and other vector-borne agents in dogs has been associated with dysgranulopoiesis, dysmegakaryopoiesis, and dyserythropoiesis.[11,14]

Other forms of secondary dysmyelopoiesis include selective dysmegakaryopoiesis and sideroblastic anemia.[41,43] Dysmegakaryopoiesis is associated with the same spectrum of disease conditions as other forms of secondary dysmyelopoiesis. Secondary dysmegakaryopoiesis must be differentiated from megakaryoblastic leukemia. Little or no increase in megakaryoblasts is seen in secondary dysmegakaryopoiesis, whereas megakaryoblastic leukemia is characterized by a moderate to marked increase in megakaryoblasts in blood or bone marrow.[41] Unlike other types of secondary dysmyelopoiesis, sideroblastic anemias are associated with inflammatory diseases and myelofibrosis.[43] Affected dogs have a moderate to severe microcytic or hypochromic anemia that may be confused with iron deficiency anemia. Dysplastic features are similar to those associated with RCMD with ring sideroblasts except that the percentage of rubriblasts in bone marrow is not increased. Dysplastic features are restricted to, or are most prominent in, the erythroid lineage. The role of pyridoxine deficiency as a cause of the sideroblastic changes has not been investigated.

Differentiating MDS from secondary dysmyelopoiesis on morphology alone can be challenging.[9,42] Generally, in secondary dysmyelopoiesis, the percentage of dysplastic cells is lower and the percentages of rubriblasts and myeloblasts are not increased. Exceptions include sepsis and bone marrow recovering from toxic injury. In the case of sepsis, a combination of increased myelopoiesis and rapid mobilization of mature myeloid cells into the blood results in a shift toward immaturity in the myeloid series. The presence of toxic changes in the myeloid cells is helpful in identifying sepsis-associated dysmyelopoiesis. In marrow recovering from toxic injury, a wave of immature cells may be seen, resulting in a high percentage of blasts cells.[31] Dysplastic features are usually more numerous in MDS compared to secondary dysmyelopoiesis and megaloblastic features are usually more prominent, but in individual cases, these differences may be insufficient to make a conclusive diagnosis. Therefore, diagnosis necessitates exclusion of diseases, drug treatments, or toxin exposures that are known to cause secondary dysmyelopoiesis, and, occasionally, serial data collection and assessment of response to therapy.[42,49]

MYELODYSPLASTIC SYNDROMES IN CATS

In a retrospective study of clinical bone marrow reports at a veterinary teaching hospital, 11.6% of sampled cats had a diagnosis of MDS. Of these, 4.3% had a diagnosis of RCMD, and 6.8% had a diagnosis of MDS-EB (Table 67.3).[45] Cytopenias in cats with MDS have been associated with decreased numbers of granulocyte–monocyte colony-forming units and erythroid colony-forming units in four of seven cats tested, and decreased size of granulocyte–monocyte colony-forming units in all seven cats tested.[29]

Refractory Cytopenia with Multilineage Dysplasia

Cats with RCMD include cats previously diagnosed with refractory anemia and MDS with refractory cytopenia.[48] Cats diagnosed with refractory anemia with ring sideroblasts also fit into this category because of the presence of multiple cytopenias, blood and bone marrow sideroctyes, variable numbers of ring sideroblasts, and multilineage dysplasia (Table 67.3).[22,33,47]

The age and FeLV status of cats with RCMD varied between studies. In some, the median age was approximately 3 years and 70–90% of the cats were FeLV-positive.[22,33] In another, 25% of cats were FeLV-positive and the median age was 8.7 years.[45] In

TABLE 67.3 Classification and characteristics of myelodysplastic syndromes in cats.[48]

Condition	Signalment	Clinical signs	Peripheral blood findings	Bone marrow findings
RCMD	Variable	Anorexia, depression, weight loss, weakness	Macrocytic normochromic nonregenerative anemia, bicytopenia or pancytopenia, metarubricytosis	Dysplasia in multiple cell lineages, <5% myeloblasts
MDS-EB	Variable	Lethargy, anorexia, fever, petechial hemorrhage	Normocytic or macrocytic nonregenerative anemia, bicytopenia or pancytopenia	Dyserythropoiesis, dysgranulopoiesis, dysmegakaryopoiesis, 5–20% myeloblasts

general, cats with RCMD are less severely ill than cats with MDS-EB. Frequently encountered clinical signs include anorexia, depression, weakness, and loss of body mass. Affected cats have a moderate to severe macrocytic normochromic nonregenerative anemia and frequently have metarubricytosis and autoagglutination. Unlike dogs, cats with RCMD with sideroblasts have a macrocytic normochromic anemia. Most cats are thrombocytopenic and some are leukopenic. Bone marrow is normocellular or hypercellular, myeloblasts are <5% of all nucleated cells, and rubriblasts are typically increased. Dysplastic features are present in the erythroid line of all cats and frequently present in granulocyte and megakaryocyte lineages. Features of dysgranulopoiesis include maturation arrest, hypersegmentation, hyposegmentation, giant band and segmented neutrophils, and asynchronous maturation of nucleus and cytoplasm. Features of dyserythropoiesis included asynchronous maturation of nucleus and cytoplasm, binucleation, fragmented or lobulated nuclei, and megaloblastosis. Features of dysmegakaryopoiesis included large megakaryocytes with mature-appearing granulated cytoplasm but poorly lobulated or multiple discrete nuclei, megakaryocytes with mature hyperlobulated nuclei but immature-appearing homogeneous blue cytoplasm, and many small megakaryocytes with single or multiple discrete round nuclei. Evaluation of bone marrow core biopsy specimens revealed myelonecrosis and myelofibrosis in one-third of cats with RCMD.[45]

Although prognosis is guarded, some cats with RCMD respond to supportive therapy and have prolonged survival.[45] Cats with RCMD appear to have less of a tendency to progress to acute myeloid leukemia and have a longer survival time compared to those with MDS-EB. However, this difference is difficult to prove statistically when small groups are compared.[22] Therapy has consisted of prednisolone, prednisolone and cytarabine, and cyclosporine A.[22]

Myelodysplastic Syndrome with Excessive Blasts

Cats with MDS-EB, alternatively known as refractory anemia with excessive blasts, are characterized by multiple cytopenias, multilineage dysplasia, and increased myeloblasts in bone marrow (Table 67.3). In studies in which most affected cats were FeLV-positive, the age of the cats was often less than 4 years, whereas in studies in which more affected cats were FeLV-negative, the age of affected cats skewed older.[22,33,45] Cats with MDS-EB tended to be severely ill with clinical signs including anorexia, weakness, depression, loss of body mass, fever, vomiting, diarrhea, and platelet-related bleeding. Affected cats have a moderate to severe nonregenerative anemia and some have metarubricytosis and autoagglutination. Most cats are thrombocytopenic, and some are leukopenic. Bone marrow is usually normocellular or hypercellular, but may be hypocellular. Erythroid hypoplasia is a relatively frequent finding in FeLV-positive cats. All cats had 6–20% myeloblasts in bone marrow with variable increases in rubriblasts. Dysplastic features are present in all cell lines. Features of dysgranulopoiesis, dyserythropoiesis, and dysmegakaryopoiesis are similar to those associated with RCMD. Myelonecrosis and myelofibrosis are present in bone marrow of some affected cats.[45] Presently, survival for cats with MDS-EB varies from days to a few months with progression to acute myeloid leukemia possible in some cats.[22,45]

SECONDARY DYSMYELOPOIESIS IN CATS

Diseases/Drugs/Toxins

In a retrospective study of clinical bone marrow reports in cats, 6.3% were categorized as secondary dysmyelopoiesis.[45] Diseases associated with secondary dysmyelopoiesis included immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, pure red cell aplasia, lymphosarcoma, glomerulonephritis, and feline infectious peritonitis.[45,47] Bone marrow had normal or increased cellularity, and dysplastic features were most prominent in the erythroid series, but could be found in granulocytes and megakaryocytes. In general, these changes were similar to those seen in MDS except that blast cells were not increased, the percentage of dysplastic changes was usually not as high, and megaloblasts were infrequently seen.

As in dogs, MDS can be difficult to differentiate from secondary dysmyelopoiesis using morphology alone, particularly in presumed immune-mediated anemia. Across all conditions, patients demonstrate a severe nonregenerative anemia, metarubricytosis, and possible agglutination.[45] Several factors are useful in differentiating these conditions. Marked macrocytosis (i.e., mean corpuscular volume (MCV) >65 fL) is a useful indicator RCMD. Additionally, >10% dysplastic changes in bone marrow are more consistent with MDS. Megaloblastic changes are prominent in MDS, but rare in secondary dysmyelopoiesis, and cats with MDS typically have increased rubriblasts or myeloblasts, while cats with secondary dysmyelopoiesis do not. An increased number of small lymphocytes in bone marrow is a consistent finding in immune mediated hemolytic anemia (IMHA) and pure red cell aplasia (PRCA).[44]

MYELODYSPLASTIC SYNDROME IN HORSES

Myelodysplastic syndrome, most consistent with MDS-EB, has been described in a Quarter Horse.[12] Peripheral blood findings consisted of a macrocytic nonregenerative anemia, leukopenia, and thrombocytopenia. Bone marrow evaluation revealed 9% myeloblasts, marked dyserythropoiesis, and increased plasma cells and eosinophils. Dyserythropoiesis was characterized by megaloblastic changes.

CHAPTER 68

Acute Myeloid Leukemia

TRACY STOKOL

Pathogenesis
Diagnosis
- Cytomorphology
- Immunophenotyping
- Cytochemical Staining
- Clonality Testing

Classification
Species Summary
- Acute Myeloid Leukemia in Dogs
- Acute Myeloid Leukemia in Cats
- Acute Myeloid Leukemia in Horses
- Acute Myeloid Leukemia in Other Species

Acronyms and Abbreviations

ALL, acute lymphoid leukemia; ALP, alkaline phosphatase; ANBE, alpha-naphthyl-butyrate esterase; AML, acute myeloid leukemia; AML-NOS, acute myeloid leukemia-not otherwise specified; CAE, chloroacetate esterase; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; DNMT, DNA methyltransferase; FAB, French–American–British; FeLV, feline leukemia virus; FLT3, FMS-like tyrosine kinase 3; FMS, feline McDonough Sarcoma MDS, myelodysplastic syndrome; MHC, major histocompatibility complex; MPx, myeloperoxidase; NPM, nucleophosmin SBB, Sudan Black B; WHO, World Health Organization.

Acute myeloid leukemia (AML) is an aggressive hematopoietic neoplasm that encompasses a myriad of subtypes, which differ in phenotypic and genetic characteristics and biologic behavior, including progression, response to therapy, and prognosis.[56] It is the most common type of leukemia in adult human beings,[72] and, even with advances in genetic testing and genetically tailored therapy, the prognosis remains poor.[19] Classification schemes in human medicine continue to evolve with the application of advanced technological tools, such as next-generation sequencing for genetic and epigenetic defects.[3,20,64] In veterinary medicine, we are behind our human counterparts in the tools available for diagnosis and classification of leukemia and treatment options. Our biggest challenge remains the initial diagnosis of AML, particularly distinguishing it from lymphoid tumors such as the leukemic phase of lymphoma or acute lymphoblastic leukemia. Challenges with AML facing human medicine, such as standardizing treatment protocols or outcomes, optimizing treatment strategies, prolonging life with individualized therapy, and identification and discrimination of minimal residual disease from clonal hematopoiesis of indeterminate potential,[7,20,52] are not even at play in animals. For this review, only selected individual case reports are referenced, with the summary of AML in certain species largely restricted to larger case series.

PATHOGENESIS

Acute myeloid leukemia involves the clonal expansion of myeloid stem cells, which can either minimally or partially differentiate down a particular myeloid lineage. The term myeloid can have several connotations, but in this case it means all nonlymphoid lineage cells, including granulocytes (neutrophil, eosinophil, basophil), megakaryocytes, erythrocytes, mast cells, and monocytes.[64] In rare cases of acute leukemia, there is evidence of mixed lineage differentiation (e.g., myeloid + B cell, myeloid + T cell) on the same or different cell populations,[36] but these mixed phenotype acute leukemias are not categorized as AML but rather as leukemia of ambiguous lineage

(similar to acute undifferentiated leukemia).[3,56,64] In acute leukemia, the neoplastic cells have a proliferative advantage, resulting in their accumulation in bone marrow, usually at the expense of normal hematopoiesis. They can spill over into blood or infiltrate extramedullary tissues. Rather than consisting of one neoplastic clone, AML is thought to consist of multiple subclones or leukemia stem cells, which are thought to arise from accumulating heterogeneous genetic mutations in a founding clone.[37,68] Leukemic stem cells have been identified in dogs with AML,[27] and these quiescent chemoresistant cells are likely responsible for disease recurrence or refractoriness to treatment. Partly differentiated myeloid cells can also revert to having "stem-like" properties.[38]

In human patients, AML is usually a de novo neoplasm, but it can emerge from a pre-existing myelodysplastic syndrome (MDS), mixed myelodysplastic/myeloproliferative disorder or myeloproliferative neoplasm (termed a blast crisis), or as a consequence of therapy for an unrelated hematopoietic or nonhematopoietic neoplasm (with alkylating agents, topoisomerase II inhibitors, antimetabolites, antitubulin agents, or ionizing radiation).[6,64] In animals, AML is usually a de novo neoplasm in most species except for domestic cats, in which MDS progression to AML occurs secondary to feline leukemia virus (FeLV) infection.[30,31,62] There have been rare individual reports of MDS-[41] and radiation-associated AML in dogs.[49,60]

Genetic defects, such as internal duplications, gene fusions, and point mutations, underlie the pathogenesis of AML. A large and diverse range of defects have been discovered (>5000 in one study),[46] with the most common involving cellular pathways of proliferation (e.g., activating mutations in feline McDonough sarcoma (FMS)-like tyrosine kinase 3 [FLT3]), differentiation (e.g., nucleophosmin or NPM1), and epigenetic control (e.g., the DNA methyltransferase [DNMT3A]) (Table 68.1).[24,46] The current consensus is that, similar to other cancers, leukemogenesis is a multistep pathway with more than one genetic defect being required for manifestation.[24,46] Although most human patients with AML have more than one abnormality, single-gene defects in signaling proteins (e.g., FLT3 or RAS), transcription factors (e.g., RUNX1), spliceosome proteins (which remove introns, e.g., U2AF1), and cohesins (protein complexes that control chromatid separation during mitosis or meiosis, e.g., STAG2) have been identified, some of which can initiate leukemia in murine models.[12] A study of 1524 human patients with AML provided genetic evidence for structured clonal evolution of AML. Defects in epigenetic (DNMT3A, TET2, and IDH) and chromatin (ASXL1) modifiers appeared to be early events and usually coexisted with other mutations, suggesting these mutations may "set the stage" for leukemogenesis, but do not result in AML alone.[46] However, mutations in these genes also occur in older patients with clonal hematopoiesis of indeterminate potential,[53] and may just reflect clonal hematopoiesis versus a preleukemic process. Defects in signaling genes, such as RAS, were later events and mutations in NPM1 were usually secondary. Some mutations frequently coexisted,[46] suggesting synergistic interactions between genes that promote the leukemia.[46,68]

TABLE 68.1 General categories (distinguished by cellular function) of identified genetic abnormalities, with example defects, in human patients with AML.[12]

Cellular function	Example defects
Transcription factors	
Fusions	PML–RARA, CBFB–MYH11, RUNX1–RUNX1T1
Mutations	RUNX1, CEBPA
Signaling molecules (gain of function)	
Fusions	BCR–ABL (rare)
Mutations/internal random duplications	FLT3, KIT*, KRAS*, NRAS, NF1
Tumor suppressor mutations (loss)	TP53, WT1
Epigenetic modifiers	
Fusions	MLL-multiple genes
Mutations	DNMT3*, TET, IDH
Chromatin modulator mutations	ASXL1, EZH2, NPM1**
Cohesin mutations	STAG2, RAD1
Spliceosome mutations	U2AF1, SF3B1

*Identified in dogs.[11,22,63]
**This nucleolar protein has multiple roles in cellular function, including chromatin remodeling, mRNA transport, and genetic stability.

Genetic defects are being used in newer classification schemes, to tailor individualized therapy and for prognostication.[3,19,20,46,55,64] In contrast to human medicine, little genetic analysis has been done in animals with AML and the few studies are restricted to dogs (Table 68.1).[11,22,63]

Aside from the leukemic cells themselves, there is growing awareness of the role of the microenvironment in tumor initiation, persistence, progression, and chemoresistance.[28] Less is known about how the microenvironment influences AML. The bone marrow microenvironment is complex, consisting of vascular, endosteal, and megakaryocyte niches and an array of cell types, including immune cells, fibroblasts, pluripotent mesenchymal cells, nerve cells, adipocytes, endothelial cells, osteoblasts, and osteoclasts. Through structural support, cell-to-cell adhesive interactions and release of soluble or extracellular vesicle-associated growth factors, cytokines (e.g., CXCL12, transforming growth factor-β), and microRNA, stromal cells play a vital role in normal hematopoiesis. The microenvironment provides homing signals to hematopoietic stem cells (e.g., CXCL12–CXCR4 interactions) and helps maintain stem cell quiescence and self-renewal, while inhibiting differentiation and apoptosis.[42,51] Studies are just beginning to elucidate the mechanisms by which the microenvironment promotes leukemogenesis, not only through the provision of a supportive and protective locale via tumor–stromal cross-talk, but also through genetic defects that may drive leukemogenesis.[42,51] For example,

deletion of the ribonuclease, Dicer1, in osteoprogenitor cells in mice results in MDS and secondary AML.[48] Targeting the microenvironment may prove to be a promising new strategy to treat patients with AML or reduce the high rate of relapse, which is attributed to the persistence of leukemic clones in bone marrow niches.[51]

DIAGNOSIS

Since AML usually arises in the marrow and the leukemia effaces the marrow or inhibits normal hematopoiesis, the hallmark laboratory findings are bicytopenia or pancytopenia with or without circulating blasts.[1,4,9,17,18,33,45,57,66] The neoplastic cells can also infiltrate extramedullary sites, often in a vascular-oriented distribution, including the liver, spleen, and lymph nodes and infrequently other organs, including the skin, gastrointestinal system, and brain.[4,17] In some human patients, AML can manifest as a solid extramedullary tumor, myeloid sarcoma, which can precede, occur concurrently with, or follow after a diagnosis of AML. Myeloid sarcomas are differentiated from standard leukemic organ infiltration patterns by the presence of a solid mass that effaces normal architecture.[56] Myeloid sarcomas have been reported rarely in animals.[21,43] The most common manifestation of myeloid sarcoma in dogs in the author's experience is a mediastinal mass, which can be large and mimic mediastinal lymphoma.[21] A diagnosis of acute leukemia (not categorized as lymphoid or myeloid) can be readily made when there are large numbers of circulating blasts and concurrent cytopenias. In the absence of circulating blasts, the diagnosis of AML requires a bone marrow aspirate to confirm an acute leukemia. However, lymphoma can infiltrate the bone marrow, and morphologic features alone are unreliable for determining the leukemic lineage (whether confined to marrow or in peripheral blood). Thus, the diagnosis of AML in animals relies upon combining cytomorphology and phenotype to ascribe a myeloid lineage to the tumor cells. The results of this testing may not be entirely declarative and often necessitates using a preponderance of evidence (i.e., do the tumor cells express more myeloid than lymphoid morphologic and phenotyping features?) for lineage assignment. In human medicine, cytomorphologic assessment and phenotyping are still essential components of diagnosis; however, genetic analysis has become commonplace and a required part of the diagnostic evaluation of AML.[3,20,56,64]

Cytomorphology

The basic requirement for the diagnosis of AML in humans is the presence of ≥20% myeloid blasts in blood or bone marrow. The World Health Organization (WHO) applies three exceptions to this rule: (1) Myeloid sarcoma, a solid proliferation of myeloid cells in extramedullary tissues, which can be diagnosed as a solitary entity; (2) Patients with specific gene fusions (RUNX1–RUNX1T1, CBFB–MYH11, PML–RARA); and (3) Pure erythroid leukemia, in which a cutoff of ≥30% proerythroblasts is used.[3] It is recommended to determine the blast percentage by morphologic assessment of a 200 or 500 count of nucleated cells on Romanowsky-stained smears of blood and bone marrow, respectively, versus expression of stem cell markers, like CD34, on flow cytometric analysis.[64] The rationale behind the latter recommendation is that some cases of AML may not express CD34 in human[64] and veterinary patients,[54,65,66] and methodologic issues, such as hemodilution and the clone of antibody used, can affect percentages. However, in cases where there are insufficient circulating blasts or a fibrotic marrow precludes aspiration, immunostaining for stem cell markers on histologic sections of bone marrow from human patients may be helpful. Notably, anti-CD34 antibodies have not been validated for the diagnosis of AML using bone marrow histologic specimens in animals.

The blast percentage encompasses myeloblasts, megakaryoblasts, and monoblasts (with promonocytes being included in the blast count for monocytic variants of AML).[56,64] Proerythroblasts (rubriblasts) are quantified for pure erythroid leukemia.[3] In contrast to humans, most publications in veterinary medicine have used a cutoff of ≥30% blasts for diagnosing AML,[1,9,33,34,57,66] with ≥30% rubriblasts in erythroid-dominant marrows.[33] More recently, the author and others have adopted the WHO cutoff of ≥20% myeloblasts for the diagnosis of AML.[4,17,54] In the author's experience, the diagnostic choice of 20% or 30% blasts does not seem to matter in most cases of AML because, by the time the disease is diagnosed, the blast percentage is much higher than either cutoff (often >60%). More commonly, at the time of presentation, the main diagnostic distinction in veterinary medicine is differentiating AML from acute lymphoid leukemia (ALL). In this author's experience, there are only infrequent patients that present with a lower blast percentage. In such cases, the diagnostic conundrum is principally differentiating AML from marrow-infiltrating lymphoma.

Since the blast percentage is key in diagnosing AML and distinguishing AML from MDS,[34,56,64] it is important to define what constitutes a blast. In human hematopathology, the WHO recommends criteria established by the International Working Group on Morphology of Myelodysplastic Syndrome[44] to define blasts.[64] Agranular blasts have variably shaped nuclei (round, oval to indented to rarely reniform) with usually fine chromatin and one or more nucleoli. Agranular blasts contain variably basophilic cytoplasm with a high nuclear to cytoplasmic ratio and no Golgi zone (with rare exceptions). By contrast, granular blasts contain azurophilic cytoplasmic granules and are distinguished from promyelocytes by the lack of a Golgi zone. Auer rods may be present in both types of blasts (but have not been reported in animals).[44] Monoblasts may have more cytoplasm than myeloblasts, with or without low numbers of cytoplasmic vacuoles or granules. By contrast, promonocytes have more irregular to deeply folded nuclei with fine chromatin. Nucleoli may or may not be apparent and the cytoplasm may contain fine or coarse granules.[56]

In 1991, the Animal Leukemia Study Group identified three types of blasts for classifying AML and MDS

in dogs and cats. Type 1 corresponded to an agranular blast (which could have a Golgi zone), whereas type II and III blasts were distinguished by the presence and number of cytoplasmic granules (<15 tiny granules in type II and many granules in type III).[34] The latter are now incorporated as granular blasts. The study group also defined monoblasts as cells containing round to irregular to folded nuclei (with fine chromatin and one or more nucleoli) and a moderate amount of blue cytoplasm with a prominent Golgi zone. They also defined promonocytes as cells containing cerebriform nuclei with prominent nuclear folds and stippled or lacy chromatin with no nucleoli. These cells are agranular with more abundant and less-blue cytoplasm than monoblasts. The definition of blasts or promonocytes has not been modified since in veterinary medicine, although it is likely that individual authors use their own criteria.

Even with these defined criteria, the morphologic identification of blasts in veterinary medicine remains subjective with high interindividual variability. It is also difficult to distinguish promyelocytes from granular blasts, promonocytes from more mature or dysplastic monocytes, and dysplastic megakaryocytes from megakaryoblasts (Figure 68.1), and blast identification ultimately ends up being a "matter of opinion." In addition to the challenges in distinguishing myeloid blasts from their slightly more mature progeny, such blasts may be erroneously assigned a lymphoid origin (i.e., called "lymphoblasts"). Based on the pitfalls of morphology-based lineage assignment, this author recommends that immature cells (fine chromatin, indicating mostly euchromatin, with or without nucleoli) in blood and bone marrow be given the generic term of "blasts" (when confident, such cells are not reactive lymphocytes), until further phenotyping or classification studies are performed. Morphologic features alone cannot be used to differentiate blasts of myeloid or lymphoid (including lymphoma or ALL) origin. Although features of myeloid differentiation are helpful in supporting a diagnosis of AML (Figures 68.1 and 68.2 and Table 68.2), these features can be subtle or subjective and there are many cases in which such features are lacking and the diagnosis relies on phenotyping to assign a myeloid lineage to the neoplastic cells.

Immunophenotyping

Immunophenotyping is the procedure by which cell lineage is ascertained using antibody-based staining on liquid (flow cytometry), cytologic (immunocytochemistry), or histologic (immunohistochemistry) specimens. The applied antibodies can detect cell surface proteins (e.g., CD45, CD3), intracytoplasmic proteins (e.g., MPx, CD79a, CD3-ε), or intranuclear proteins (e.g., Pax-5). The primary antibodies can be conjugated with a fluorophore (immunofluorescent microscopy or flow cytometry) or a chromogenic enzyme (immunocytochemical or histochemical staining). Alternately, antibodies can be identified using similarly conjugated-secondary antibodies raised against the host species in which the primary antibody was made. Some antigens are normally expressed in multiple cell types, whereas others are more lineage-restricted, which helps identify both normal cells and lineages of leukemic cells (Table 68.3). This section will concentrate on flow cytometry, the most commonly used method for phenotyping leukemias.

Flow cytometry is used on blood and aspirates of bone marrow or tissues and usually employs antibodies raised against surface antigens, which avoids the requirement for cell permeabilization. The latter can alter forward and side scatter features that are characteristic of different cell populations, making it difficult to

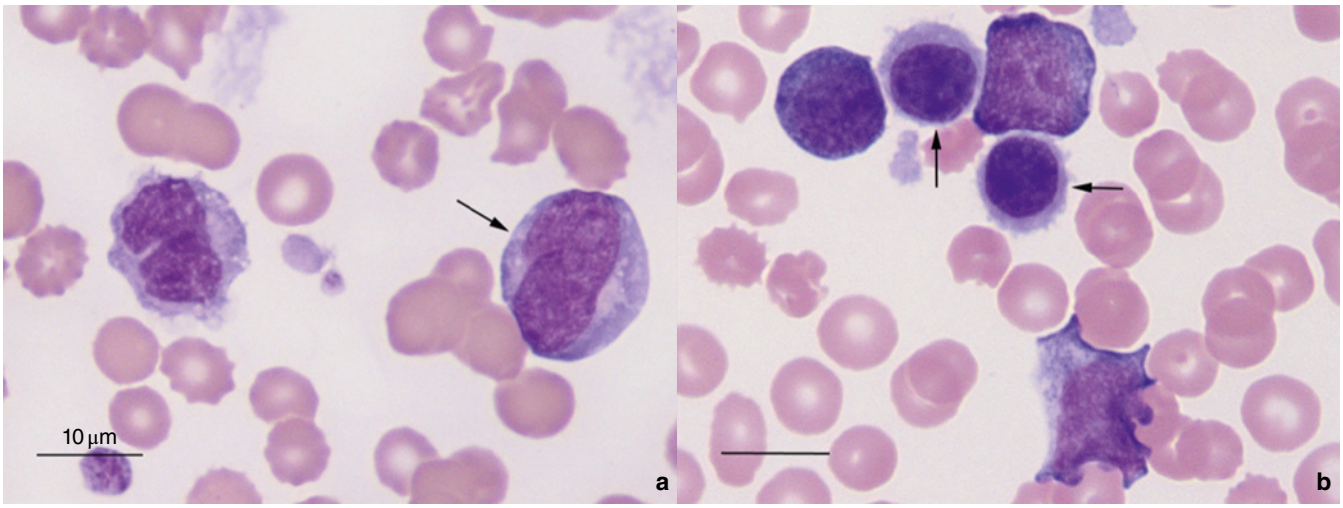

FIGURE 68.1 Distinguishing blasts in AML in modified Wright-stained smears. (a) A promonocyte (arrow) and monocyte in blood from a dog with AML-not otherwise specified (AML-NOS), subtype acute monoblastic/monocytic leukemia. The promonocyte has a deeply folded nucleus with fine chromatin. The promonocyte would have been included in the blast count; (b) Three blasts (presumptive, megakaryoblasts) and dwarf dysplastic megakaryocytes with light pink cytoplasm and ruffled borders (arrows) in blood from a dog with AML-NOS, acute megakaryoblastic leukemia (bar = 10 µm).

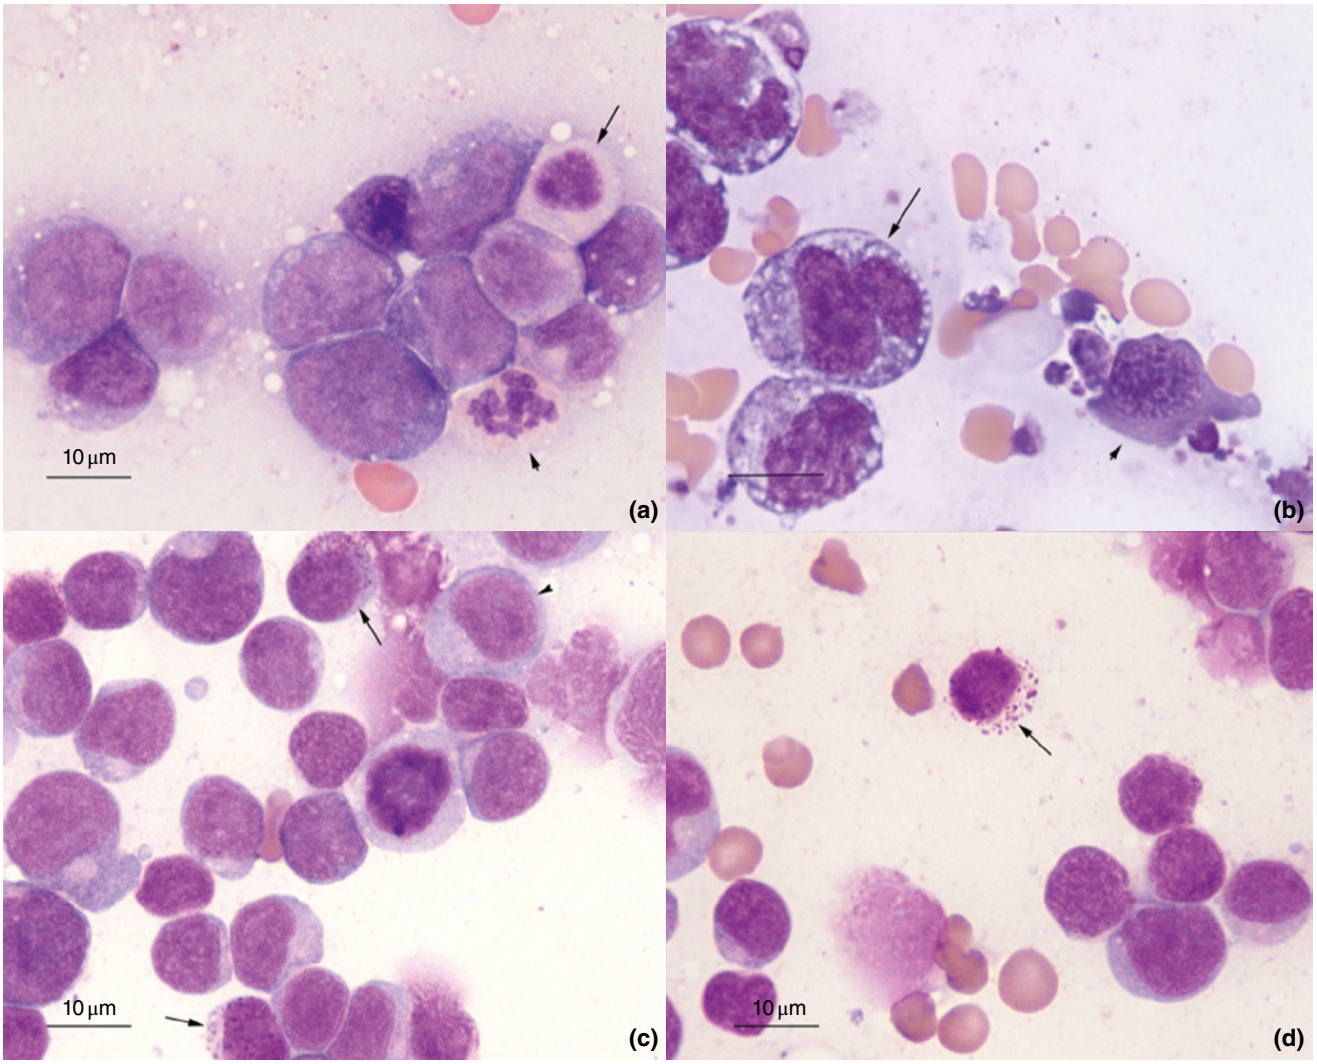

FIGURE 68.2 Features of myeloid differentiation in modified Wright-stained bone marrow smears from animals with AML. (a) A continuum between differentiated myeloid cells with moderate amounts of light blue to clear cytoplasm (arrow) and blasts is seen in the bone marrow of a dog with AML-NOS, acute myelomonocytic leukemia. A hypersegmented (dysplastic) neutrophil is also evident (arrowhead); (b) Dysplastic monocytes (arrow) and erythroid progenitors (arrowhead) are evident in a bone marrow aspirate from a horse with AML-NOS, acute monocytic leukemia (bar = 10 µm); (c) Granular blasts (arrows) and cells with increased amounts of light blue cytoplasm (arrowhead) are features of myeloid differentiation in the bone marrow of a dog with AML-NOS, acute monoblastic leukemia; (d) Blast with "mast-cell-like" chunky purple granules (arrow) in the bone marrow from the same dog as in image (c).

distinguish between cell types with certainty. In addition, with permeabilization, false positive reactions (e.g., nuclear staining with CD79a, which is normally expressed in the cytoplasm) cannot be avoided, unless additional steps are taken to confirm such positive reactions with immunocytochemical or histochemical staining, where the cellular location of the staining pattern can be identified. There are more commercially available flow cytometry antibodies directed against dog antigens (as compared to horses and cats) and more directed at T cell antigens, neutrophils, and monocytes (as compared to antigens of less-differentiated or stem cell antigens or B cells). Different laboratories use different staining methods, antibody clones, and analytical methods. As such, published results are not always comparable between labs (particularly if different clones are used).

Flow cytometry, when combined with cytomorphology, can often yield a definitive diagnosis of AML when there is expression of myeloid-associated antigens with concurrent lack of T and B cell markers. However, in both human and animal patients, cross-lineage expression of B and T cell markers occurs in AML[54,56] and subpopulations of monocytes in dogs can express antigens more typically associated with T cells (such as CD1c, CD11d, and CD90) (personal observations). This

TABLE 68.2 Morphologic, immunophenotypic, and cytochemical features of myeloid differentiation in acute leukemia.

Test	Supporting features*
Morphologic assessment of Romanowsky-stained blood or bone marrow smears	Differentiation (gradation between blasts and more mature identifiable myeloid cells), monocytoid nuclei, multinucleation or megakaryoblastoid nuclei, pink to red cytoplasmic granulation within a light to medium blue cytoplasm, chunky purple cytoplasmic granules ("mast-cell-like," Figure 68.2), dysplasia
Immunophenotypic testing modalities (flow cytometry, immunocytochemistry, immunohistochemistry)	Expression of myeloid antigens such as: myeloperoxidase (MPx), CD11b, CD11c, CD4 (with negative T cell markers), CD11d or CD1c (usually with negative T cell markers), CD14, unspecified neutrophil antigens, CD61 Expression of stem cell markers: CD34, CD90 with lack of MCHII expression Usually negative expression for T and B cell markers (cross-lineage expression can and does occur)
Cytochemical staining reactions	Positive for MPx, alkaline phosphatase (ALP), chloroacetate esterase (CAE), α-naphthyl butyrate esterase (ANBE, diffuse or chunky pattern), Sudan Black B (SBB)

*None of these features alone are diagnostic for AML, but should be used in combination with all the available findings.

complicates interpretation and makes it difficult to definitively distinguish T cell neoplasms from AML using flow cytometry. In the author's experience, the most useful myeloid differentiation markers are CD11b, CD11c, and CD14 (often with dual expression of CD4) for myelomonocytic, neutrophilic, and monocytic variants of AML. CD11b is rarely expressed on lymphoid neoplasms, whereas CD11c can be expressed on T cell neoplasms, particularly those of granular morphology. Double staining for MHCII major histocompatibility complex type II (MHCII) and CD34 is also useful, because CD34-expressing AMLs usually lack MHCII expression[54] in contrast to CD34-expressing lymphoid neoplasms (more commonly B[69] than T cell tumors), which co-express CD34 and MHCII (personal observations). CD34 expression, however, may not be detected in some dogs with AML,[54,65,66] particularly more-differentiated variants, such as AML-NOS, acute myelomonocytic leukemia, in dogs,[54,66] and CD34 is not reliably detected in horses with AML (personal observations). Similarly, CD11b, CD11c, and CD14 may not be detected on less-differentiated variants of AML, which may only express stem cell markers, such as CD34 and CD90.[54] If only flow-cytometric-based immunophenotyping (particularly with limited antibodies) is done on the latter cases, they could be diagnosed as acute undifferentiated leukemia. In this author's experience, many CD34-positive MHCII-negative acute leukemias have positive cytochemical staining reactions (particularly to ALP), which supports their myeloid origin.[54] In general, this author recommends a multiparameter approach for the flow cytometric diagnosis of AML and that flow cytometry data be interpreted against known patterns of marker expression in AML.[54] It also cannot be overemphasized that flow cytometry alone should not be used to diagnose AML, but should always be interpreted along with neoplastic cell morphology (in blood, bone marrow, or tissues), imaging studies, patient history, clinical signs, and physical examination findings.

In the absence of liquid specimens, immunophenotyping can be done on cytologic and histologic samples. Slides for immunocytochemistry can be acetone-fixed and stored at −70 °C for over a year with antigen retention.[47] Limitations of diagnostic immunocytochemistry include the often low numbers of available slides and a lack of preservation of cell morphology, which makes it difficult to conclusively identify blasts. Immunohistochemical staining is substantially limited by the number of antibodies that work in formalin-fixed tissue (Table 68.3). As such, the diagnosis of AML on such tissues is usually one of exclusion or based on lack of staining for standard lymphoid markers with morphologic features of myeloid differentation.[17] Of the available markers, staining for MPx (or megakaryocyte markers in the case of acute megakaryoblastic leukemia) may be helpful to confirm AML in dogs. However, in the author's experience, monocytic variants of AML may be negative for MPx and other monocytic/macrophage markers, including lysozyme and MAC387. Ionized calcium-binding adaptor molecule I (Iba-1) is considered a highly specific marker for macrophages and dendritic cells;[58] however, this marker has only been tested in two case series of equine AML and there is conflicting data on its specificity.[4,17] Many antibodies successfully used in flow cytometry can be applied to snap-frozen tissues (which is not routinely done) or to hematologic or cytologic slides. However, immunostaining of smears is labor-intensive and time-consuming process, limiting its routine application. Similar to flow cytometry, there are no standardized cutoffs for positive staining on cytologic or histologic smears.

Cytochemical Staining

Cytochemical staining was the traditional mainstay for determining lineage of leukemias and was the basis of the French–American–British (FAB) classification scheme,[5] that is still used in veterinary medicine[17,45,54,57,66] and, in part, in human medicine (see in the following text). Cytochemical stains are useful for confirming myeloid lineage, with the exception of erythroid cells, because granulocytes and monocytes express enzymes

TABLE 68.3 Antigens used for immunophenotyping of hematopoietic neoplasms by flow cytometry in humans and dogs, cats, and horses.*

Cell lineage	Human[20,56]	Dogs[c], cats[f], and horses[e1,2,4,45,54,57,65,66]
Stem cell	CD34, CD117, CD133	CD34[c,e], CD90[c]
Early myeloid cell	CD13, CD33, CD38, CD123	None
Differentiating or mature neutrophil	CD15, CD16, CD36, CD65, myeloperoxidase	CD4[c], CD11b[c,f], CD11c[c], CD90[e], CD172a[e], MPx[c], unspecified (e.g., neutrophil-specific antigen)[c,e,f]
Differentiating or mature monocyte	CD11c, CD14, CD36, CD64	CD1c[c], CD11b[c,f], CD11c[c], CD11d[c], CD14[c,e,f], CD90[c], CD163[e], CD172a[e], MHCII[c], MAC387[c]
B cell	CD5, CD19, CD22, CD10	CD5[c,f,e] (subset), CD19-like[e], CD20[c], CD21[c,e,f], CD22[c], CD79a[c,e,f], MHCII[c]
T cell	CD2, CD3 (cytoplasmic against epsilon not zeta chain), CD4, CD5, CD7, CD8	CD2[e], CD3[c,e,f], CD5[c,e,f], CD4[c,e,f], CD8[c,e,f], TCRαβ[c], TCRγδ[c], CD1c[c] (subset), CD11d[c] (subset), CD90[c] (subset), MHCII[c]
Common leukocyte		CD45,[c] CD18,[c] MHCII[e]
Megakaryocyte	CD41, CD42, CD61	CD41,[c] CD61[c]
Erythroid	CD36, CD235a	None

*This list is not exhaustive, including known cross-reactive antibodies or species-specific clones that have been used to phenotype leukemia in the selected species, specifically by flow cytometry. Underlined antibodies can be used on formalin-fixed paraffin-embedded section with immunohistochemical staining and some can be used across species (e.g., CD20, CD61). There are no standardized cutoffs for interpretation of positive cells with different authors stating various cutoffs (≥20% with ≥5% for CD34[54] and ≥20–30% with ≥10% for MPx[1,66]).

or proteins that react with the stains. By contrast, lymphocytes are generally negative for the stains, with some exceptions (Table 68.4). Since the advent of flow-cytometric-based immunophenotyping, cytochemical staining is rarely applied in veterinary medicine for diagnosis of AML. However, when flow cytometric results are inconclusive or nondiagnostic (e.g., concurrent expression of lymphocyte and myeloid markers, leukemias that are only CD34-positive and MHCII-negative), cytochemical staining can help confirm a diagnosis of AML in such cases. Indeed, cytochemical staining is still recommended for phenotyping leukemias, particularly AML-NOS, in human patients.[20,56,64] It is important to note that, similar to immunophenotyping, aberrant cytochemical staining can be seen in some cases of AML.[25]

Clonality Testing

Clonality testing in dogs and cats is usually done via polymerase chain reaction for antigen receptor rearrangements in T and B cell receptor genes (PARR).[35] However, clonal rearrangements in B and T cells have been reported in AML in human patients[13,39,50] and dogs,[54] and clonality testing should not be used to differentiate AML from lymphoid neoplasms.

CLASSIFICATION

Based on the 2008 updated and 2016 revised WHO criteria,[3,56,64] AML is classified into six different categories in human patients: (1) AML with recurrent genetic abnormalities, (2) AML with myelodysplasia-related changes, (3) therapy-associated AML, (4) AML-NOS, (5) myeloid sarcoma, and (6) myeloid proliferations related to Down's syndrome. Given the lack of comparable veterinary genetic testing and acknowledgment that there are no veterinary correlates to some human conditions, AML in animals is usually categorized as AML-NOS and assigned a morphologic subtype based on human criteria (Table 68.5). The AML-NOS category is primarily based on the FAB criteria established in 1976[5] and was used by the Animal Leukemia Study Group in 1991 to originally classify AML and MDS in dogs and cats.[34] It is still the most commonly used classification scheme

TABLE 68.4 Expected cytochemical reactions of commonly used stains for different leukocytes in dogs[c], cats[f], and horses[e].[4,25,26,34,54]

Leukocyte	Staining reaction
Neutrophil (mature, immature)	MPx[c,e,f], CAE[c,e,f], ALP[e], SBB[c,e,f]
Eosinophils	MPX[c,e], ALP[c,f], SBB[e]
Basophils	CAE[c,e,f], ALP[c]
Monoblasts, promonocytes	ALP[c], ANBE[e,f] (diffuse, chunky, ±fluoride inhibited**), ±SBB[c,e,f]
Monocytes	ANBE[c,e,f] (±fluoride inhibited), ±SBB[c,e,f]
T cells (subsets)	ANBE[c,e,f] (focal to multifocal, granular, ±fluoride resistant)
Megakaryocyte	ANBE[c,f]

ALP: alkaline phosphatase, ANBE: alpha-naphthyl butyrate esterase, CAE: chloroacetate esterase, MPx: myeloperoxidase, SBB: Sudan Black B.
*Not all stains are shown. A positive reaction is when ≥3% of blasts are positive.[54,56]
** Fluoride sensitivity or resistance is not routinely done, rather the overall pattern of staining in blasts is ascertained.

TABLE 68.5 Morphologic subtypees of AML-NOS in human patients, with classification features.[3,56,64]

Acute myeloid leukemia with minimal differentiation (AML-M0)
No evidence of myeloid differentiation morphologically or with cytochemical stains. Blasts are agranular. Myeloid origin confirmed by immunophenotyping (expression of stem cell markers and early myeloid antigens, e.g., CD13, CD33) or ultrastructure. Rarely express lymphoid antigens. Differential diagnoses include precursor lymphoid neoplasms (lymphoma or leukemia), acute megakaryoblastic, monoblastic, or erythroid leukemia, and mixed phenotype acute leukemia.

Acute myeloid leukemia without maturation (AML-M1)
Blasts (≥3%) are positive on cytochemical staining (e.g., MPx, SBB) or contain Auer rods (not seen in animals); blasts can be granular. Express early myeloid-associated antigens, but no or minimal differentiating antigens on immunophenotyping (Table 68.3). Can express lymphoid antigens (e.g., CD7, CD2, CD4). Differential diagnoses include precursor lymphoid neoplasms, AML with maturation or acute monoblastic leukemia.

Acute myeloid leukemia with maturation (AML-M2)
Evidence of neutrophilic differentiation (progranulocytes, myelocytes, and mature cells comprise ≥10% of marrow cells) with differentiating monocytes being <20% of marrow cells and blasts being positive for myeloid markers on cytochemical staining. Express early myeloid and differentiating neutrophil antigens (e.g., CD11b, CD15), with some cells expressing stem cell markers. Can express lymphoid antigens. Differential diagnoses include MDS with excess blasts, AML without maturation, and acute myelomonocytic leukemia.

Acute basophilic leukemia (AML-M2B)
Blasts contain coarse basophilic granules (which can resemble mast cell or basophil granules ultrastructurally) with few mature basophils. Blasts are positive for toluidine blue and negative for other cytochemical stains (MPx, SBB, CAE, ALP, ANBE). Blasts express early myeloid and differentiating myeloid antigens (e.g., CD11b), and may express stem cell markers. Usually lack CD25 (mast cells) and lymphoid antigens. Differential diagnoses include other AML genetic subtypes with basophilia, mast cell leukemia, and granular versions of lymphoid leukemia (rare in humans).

Acute myelomonocytic leukemia (AML-M4)
Consists of differentiating neutrophils (≥20% of marrow cells) and monocytes (≥20% of marrow cells) with promonocytes included in the blast count. Blasts may express both granulocyte and monocyte cytochemical stains, with some cases having dual positive cells (Figure 68.3a). Cells express differentiating granulocyte and monocyte antigens and there may be a subpopulation of blasts expressing stem cell antigens. Lymphoid antigen expression is rare. Differential diagnoses are AML with maturation, acute monocytic leukemia, and chronic myelomonocytic leukemia.

Acute monoblastic or monocytic leukemia (AML-M5)
Consists of differentiating monocytes (≥80% of marrow cells) with most cells being monoblasts or promonocytes in acute monoblastic or monocytic leukemia, respectively. Can have a neutrophilic component (<20%). Blasts express both monocyte-related cytochemical reactions and early myeloid and monocyte markers on immunophenotyping (macrophage antigens like CD163 are more often seen in monocytic leukemia). There may be a subpopulation of blasts expressing stem cell antigens. Lymphoid antigen expression can occur. Differential diagnoses for the monoblastic form include AML with minimal differentiation or without maturation, acute megakaryoblastic leukemia, precursor lymphoid neoplasms, and for the monocytic form are acute and chronic myelomonocytic leukemia.

Acute erythroid leukemia, pure erythroid type (AML-M6)
Consists of ≥80% nucleated erythrocyte precursors, with ≥30% proerythroblasts (rubriblasts) and <20% nonerythroid myeloblasts (of total marrow cells; those with ≥20% myeloblasts are put in other AML categories). Have immunophenotyping features of AML without maturation or with minimal differentiation (may not express erythroid-associated antigens), so diagnosis appears to be based largely on morphologic features. Do not usually express lymphoid antigens. Differential diagnoses include AML without maturation or minimal differentiation, precursor lymphoid neoplasms, and acute megakaryoblastic leukemia.

Acute megakaryoblastic leukemia (AML-M7)
Consists of ≥50% cells of megakaryocyte lineage. Blasts may have pseudopodia or cytoplasmic blebs and may see dysplasia in megakaryocytes (and other lineages). The marrow may be fibrotic. Blasts may express ANBE, but are negative for other myeloid stains (SBB, MPx, CAE). Cells can express early myeloid antigens and megakaryocyte markers (particularly cytoplasmic, because platelet-derived microparticles may bind to blasts of other lineages, giving false positive reactions). Blasts often lack stem cell markers and do not usually express lymphoid antigens. Differential diagnoses include AML without maturation or with minimal differentiation, acute monoblastic leukemia, acute erythroid leukemia, acute panmyelosis with myelofibrosis, precursor lymphoid neoplasms, and metastatic tumors.

Acute panmyelosis with myelofibrosis
Marrow is fibrotic (reticulin), but with hypercellular areas containing increased precursors of all lineages. Most difficult variant to identify blast percentage (most are 20–25%). Differential diagnoses include acute megakaryoblastic leukemia, chronic myeloproliferative disorders, and desmoplasia with metastatic tumors.

for leukemia in animals.[17,45,54,57,66] As indicated previously, the Animal Leukemia Study Group and many authors use a blast cutoff of ≥30% for diagnosis of AML.[1,25,26,34,57,66] However, many authors have adopted a 20% blast cutoff. This study group also used a complicated scheme to distinguish myelodysplastic syndrome from AML in cases with erythroid predominance, which mostly occurs in cats.[34]

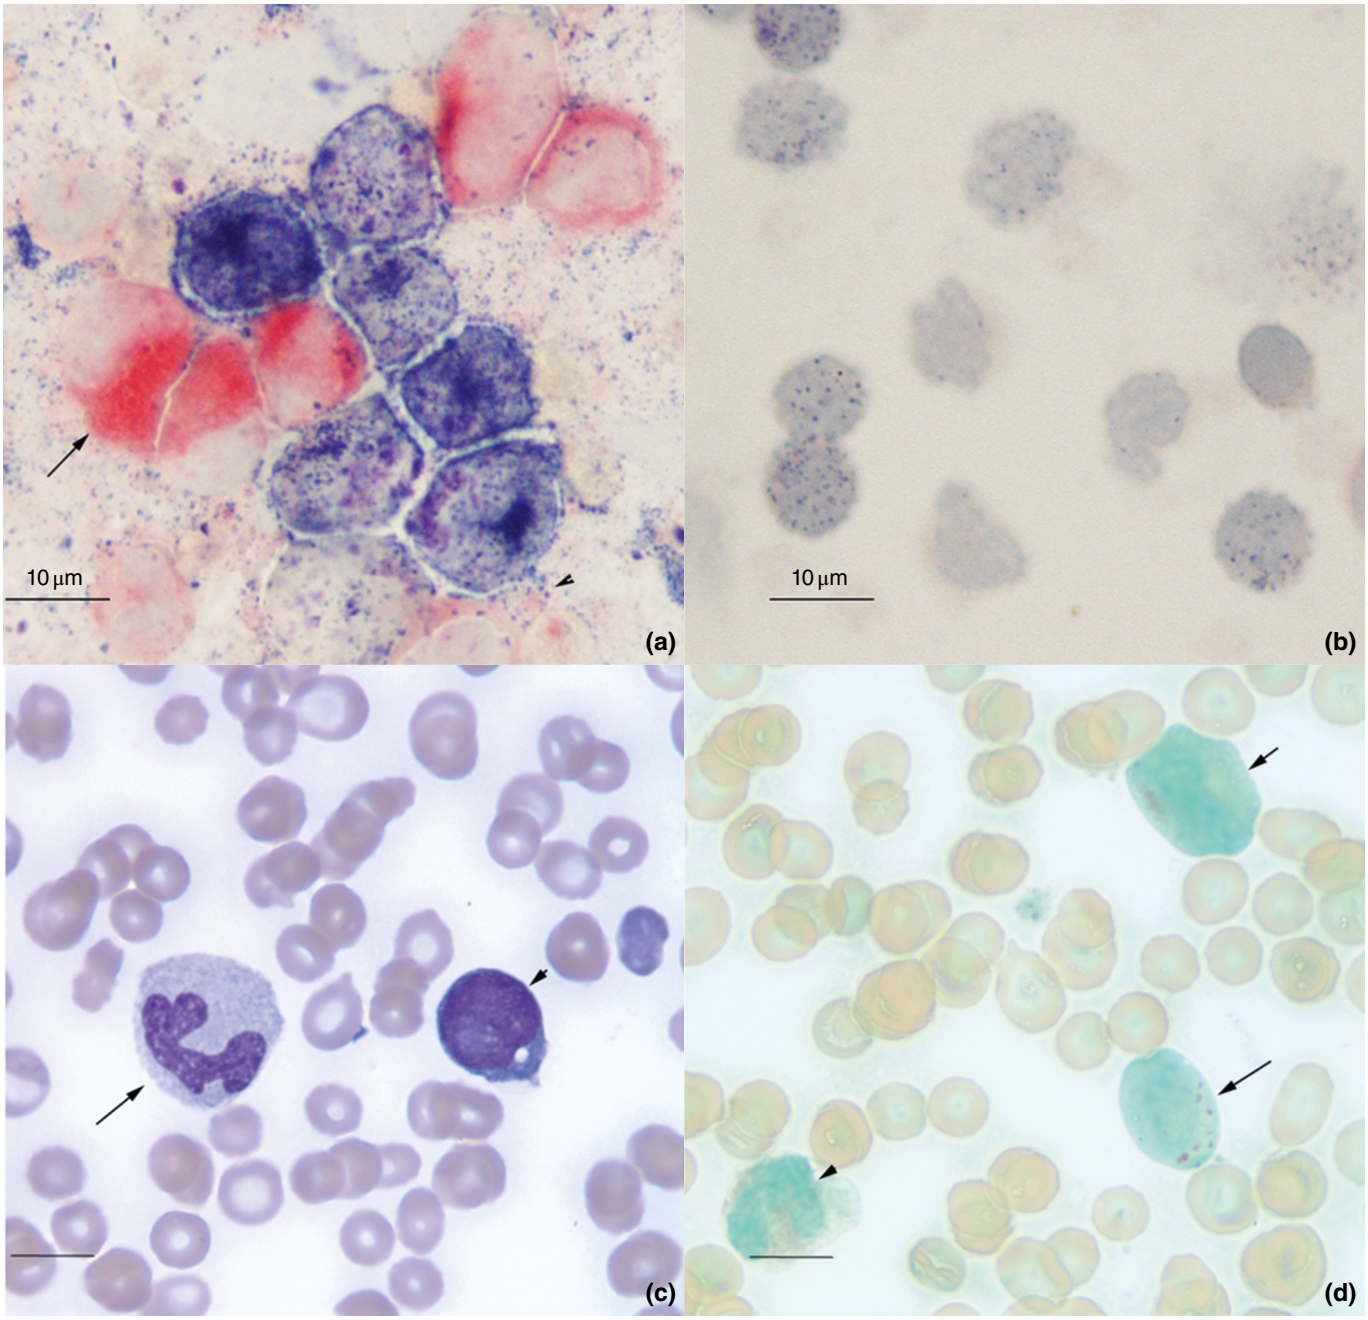

FIGURE 68.3 Cytochemical staining reactions in dogs with AML. (a) Blasts are positive for ALP (blue) and CAE (red) in the bone marrow of a dog with AML-NOS, acute myelomonocytic leukemia (same case as in Figure 68.2a). More-differentiated cells (myelocytes) are CAE-positive (arrow) and some blasts are double positive for ALP and CAE (arrowhead); (b) Blasts are only positive for ALP (blue) in the bone marrow of a dog with AML-NOS, acute monoblastic leukemia (same case as in Figure 68.2c,d); (c) A dysplastic neutrophil (arrow) and blast (arrowhead) in the blood from a dog with AML-NOS, acute myelomonocytic leukemia (modified Wright's stain) (bar = 10 µm); (d) Some blasts in the blood from the same dog have granular multifocal staining for ANBE (brown, long arrow; a pattern more typical of T cells), with more diffuse positivity in a promonocyte (short arrow) and monocyte (arrowhead) (bar = 10 µm). Other blasts had more diffuse ANBE reactivity (not shown). This case shows the overlap in staining patterns, which can complicate leukemia classification.

SPECIES SUMMARY

Acute Myeloid Leukemia in Dogs

Acute myeloid leukemia is most frequently recognized in dogs as compared to other species. Dogs usually present with nonspecific clinical signs of anorexia or inappetence, lethargy, and gastrointestinal signs such as diarrhea and vomiting.[1,18,26,54,65,66] Rare cases have presented for neurologic symptoms.[14,29] Some affected dogs can present with signs more commonly associated with lymphoma, including solitary or multiple peripheral lymphadenopathy, abdominal organomegaly (spleen, liver), and mediastinal masses.[1,18,21,26,54,66] Several dogs

have been referred to the author's institution with primary diagnoses of multicentric or mediastinal lymphoma, but have AML on phenotypic testing, illustrating the overlap in clinical presentation between these neoplasms. Dogs are mostly middle-aged, but AML can occur in dogs at or below 1 year of age.[1,18,26,45,54,66] There are no breed or gender predilections. Hematologic findings are usually the first clue as to an acute leukemia, because most affected dogs have bicytopenia or pancytopenia and circulating blasts.[1,18,26,45,54,66] Anemias are usually nonregenerative, but regenerative anemias can be seen.[18,54] Blast counts can be quite high and blasts can dominate in blood.[1,18,54,66] Some dogs lack circulating blasts[18,26,54] and can have normal hemograms.[1,54] Dysplasia can be evident in blood, marrow, and tissue aspirates, particularly in the myelomonocytic and megakaryoblastic variants.[16,54] Aspirates of enlarged organs or body cavity effusions may mimic lymphoma or reveal an infiltrative population among a residual lymphoid population (Figure 68.4). In published cases, the diagnosis of AML has been made on the percentage (using varying percentages) and morphology of blasts in the blood or bone marrow, on cytochemical staining reactions,[26,34] or on the basis of flow-cytometric-based immunophenotyping (varied expression of myeloid antigens and/or lack of lymphoid antigen expression).[1,45,57,65,66]

At the author's institution, blast morphology and flow cytometric immunophenotyping are first-line tests, and, as needed, are followed by cytochemical staining. The collective results of these tests are considered to distinguish AML from leukemic phase of lymphoma and ALL.[18,54] Using FAB criteria, the most common types of AML-NOS in dogs are acute monoblastic/monocytic or myelomonocytic leukemia,[1,18,54,66] with megakaryoblastic,[16,18,45,70] basophilic, and erythroid variants being quite rare.[45,61] Most dogs with AML are treated with chemotherapeutic protocols based on cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) or anthracycline–cytosine arabinoside combinations,[18,45,66] the first-line drug choice in human patients with AML.[19] At the author's institution, discrimination between AML and ALL is desired because anthracycline–cytosine arabinoside-based and CHOP-based protocols are the treatment of choice for AML and lymphoid neoplasms, respectively. Unfortunately, the prognosis remains dismal, with most dogs being euthanized shortly after diagnosis or within 1–4 months after chemotherapy,[18,45,66] with rare dogs surviving longer.[70]

Acute Myeloid Leukemia in Cats

Acute myeloid leukemia is less common in cats versus dogs[34] and is usually secondary to infection with FeLV,[31,62] although cats with AML and negative FeLV tests have been reported.[23,67] There have been three case series of AML in cats, all of which used a ≥30% blast cutoff.[9,25,33] One of these studies focused on FAB subtypes, clinicopathologic data, and neoplastic cell morphology.[33] Affected cats were generally young, with a median age of 4 years (range of 6 months to 16 years), and most were domestic short or longhair cats, with both males and females affected.[9,25] Similar to dogs, presenting signs consisted of inappetence, lethargy, weakness, and weight loss.[9] Unlike dogs, lymphadenopathy was not a common finding but hepatomegaly/splenomegaly was identified in one-third of the cats in one study.[9] As for dogs, cats were often cytopenic (one or more lineages) and 50–68% had circulating myeloblasts.[9,25] Anemia was typically severe[9,25,33] and frequently macrocytic,[9] despite the lack of a regenerative response. The macrocytosis is likely due to concurrent FeLV-induced myelodysplasia. Unlike dogs, a normoblastosis was seen in many cats. Dysplasia in single or multiple lineages was evident in blood.[9,25,33] Rare cats can have normal hemograms.[25] In one study, most cats with bone marrow evaluation had megakaryocytic and erythroid hypoplasia, except for cats with erythroleukemia (defined as >50% erythroid precursors, with ≥30% myeloblasts of nonerythroid cells).[9] All cats had evidence of erythroid dysplasia and the majority of cats had megakaryocytic dysplasia and stainable iron in marrow.[9] The presence of sideroblasts, siderocytes, and myelofibrosis is a supportive finding for hematopoietic neoplasia in cats, either MDS or AML.[8,9] On postmortem examination, neoplastic infiltrates can be found in spleen (red pulp), liver (primarily in the portal region), lymph nodes (medullary cords, medullary and subcapsular sinuses, and paracortical regions), and kidneys (corticomedullary). Intravascular tumor cells and tissue infiltrates may be seen in other tissues, including the central nervous system.[9] In the one study which categorized AML in 107 cats, the most frequent types were M1, M2, and M6,[33] with rare cases of acute basophilic and megakaryoblastic leukemia.[10,15] Testing for FeLV by ELISA was positive in most cats.[9,25] Most cats died or were euthanized within 1 week of diagnosis. Three cats treated supportively lived for 2 weeks to just over 2 months.[9,25]

Acute Myeloid Leukemia in Horses

Horses rarely suffer from AML, with only six and three cases being diagnosed over a period of 16 and 22 years in two separate studies,[4,17] versus 25–35 dogs over 4–8 years in three canine studies.[18,45,57] In the two equine case series, horses ranged from 2–26 years of age and clinical signs were nonspecific, including inappetence or anorexia, edema, lethargy, fever, and poor performance. Some horses had mild to moderate lymphadenopathy, affecting single or multiple peripheral lymph nodes. Unlike dogs and cats, where blasts can dominate the hematologic picture, horses with AML typically have bicytopenia or pancytopenia with low numbers of circulating blasts. The latter cells may not be included in a differential cell count in all horses, but can usually be identified on smear examination and are a clue as to the underlying cause of the cytopenias. Several horses had concurrent evidence of inflammation (left shift and toxic change in neutrophils, hyperglobulinemia, high serum amyloid A concentrations), likely from concurrent infections secondary to immunosuppression. Bone marrow aspirates are usually higher cellular with decreased megakaryocytes and erythroid precursors. Precise blast

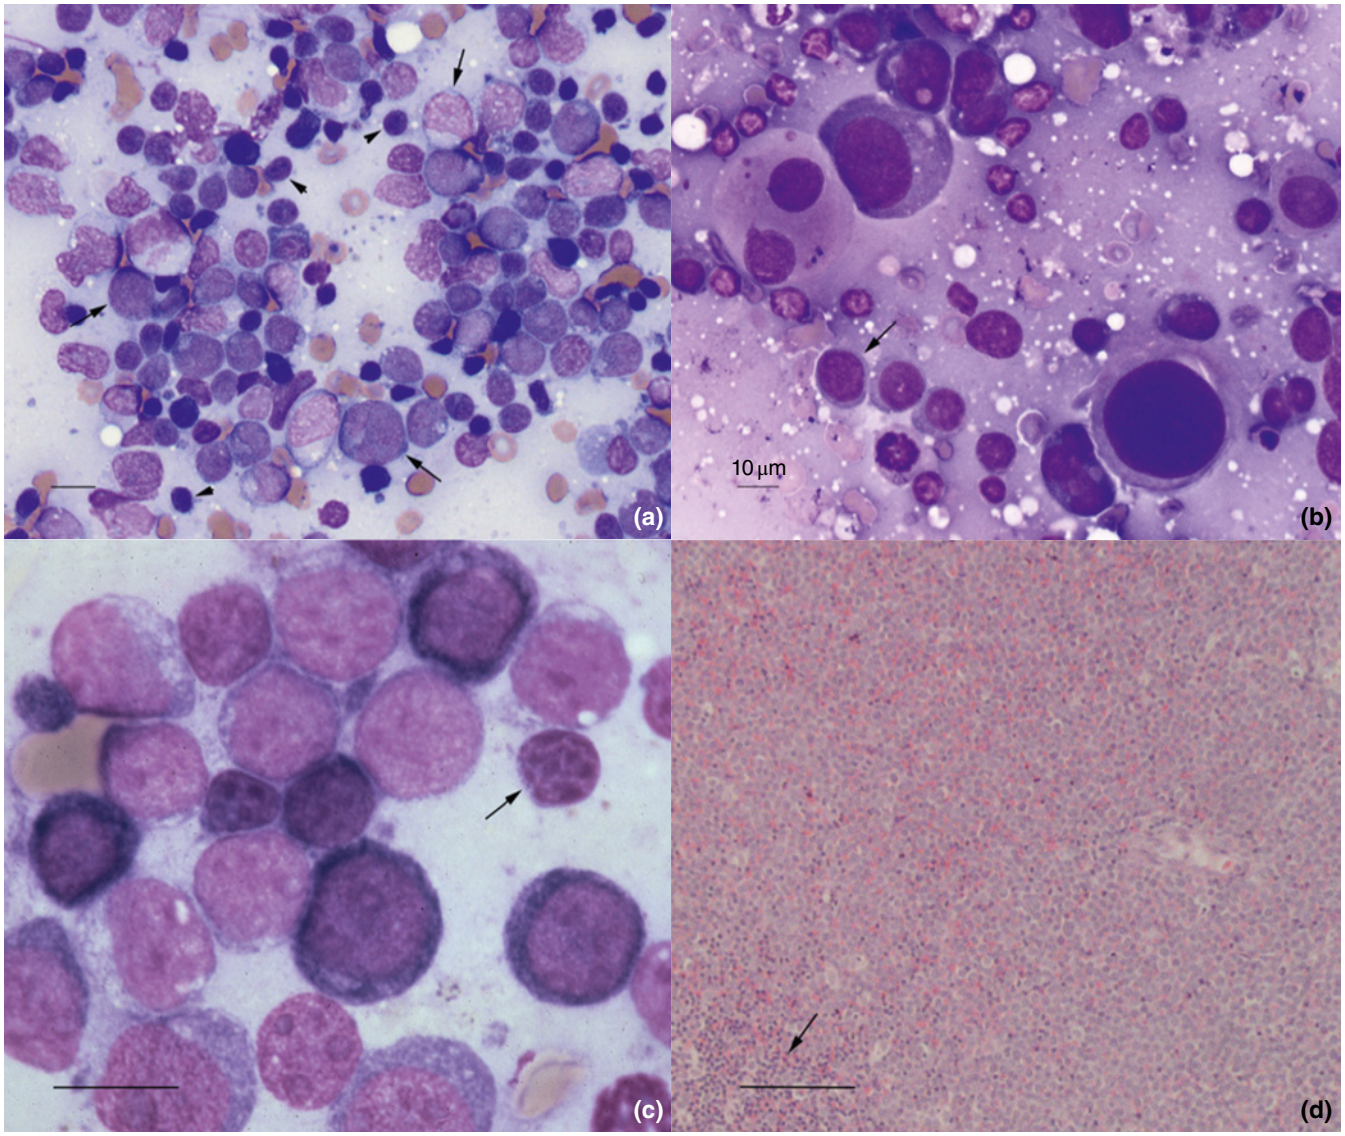

FIGURE 68.4 Lymph node infiltrates in dogs with AML. (a) Variably sized blasts (arrows), some of which have pleomorphic nuclei, are observed among a residual population of small lymphocytes (arrowheads) and plasma cells in a dog with AML-NOS, acute monoblastic leukemia (bar = 10 µm, modified Wright's stain). The main differential diagnosis would be an early lymphoma, an infiltrative lymphoma from another site, an infiltrative acute leukemia (AML or ALL), or a lymphoma emerging from remission. The nuclei of the blasts are monocytoid, raising suspicion for AML. The cytologic diagnosis in this case would have been nonspecific hematopoietic neoplasia, with a recommendation to review a blood smear, aspirate the bone marrow, or perform phenotyping for lineage determination; (b) Dysplastic megakaryocytes and presumptive megakaryoblasts (arrow) are present in this lymph node aspirate from a dog with AML-NOS, acute megakaryoblastic leukemia (modified Wright's stain); (c) Two populations of blasts, one with dark blue cytoplasm and the other with lighter blue cytoplasm, with low numbers of small lymphocytes (arrow) in a lymph node aspirate from a dog with AML-NOS, acute myelomonocytic leukemia (bar = 10 µm, modified Wright's stain). These two morphologic blast variants can be a useful finding to raise suspicion of AML in tissue aspirates; (d) The lymph node has been effaced by uniform blasts, with a residual population of small lymphocytes (arrow), in this histologic section of a lymph node from a dog with AML-NOS, acute monocytic leukemia (bar = 10 µm, H&E stain). On histologic examination, AML is frequently misdiagnosed as lymphoma (non-B or non-T, if phenotyping is done) on histologic examination of tissues, particularly if the tumor has effaced the tissue, is forming solid masses, and lacks vascular orientation or features of myeloid differentiation.

enumeration in horses can be more challenging, as they may contain fewer blasts than in dogs and cats and there may be a continuum between blasts and differentiated myeloid cells.[4,17] Some horses had concurrent dysplasia in one or more lineages.[4] On postmortem examination, tumor infiltrates can occur in multifocal perivascular to interstitial patterns in multiple tissues, particularly the lymph nodes, kidney, spleen, and liver, but also skin,

lungs, gastrointestinal tract, brain, heart, mediastinum, and mesentery.[4] Nodular lesions can be seen on visceral surfaces of thoracic and abdominal cavities and mesentery,[17] and lymph nodes can be effaced by the tumor.[4] In the study in which the leukemia was subclassified, myelomonocytic was the most common subtype, with one case each of eosinophilic and basophilic leukemia.[17] As with dogs and cats, the prognosis is poor, with most horses dying or being euthanized within 1 month of diagnosis.[4,17]

Acute Myeloid Leukemia in Other Species

Individual case reports of AML have been documented in ruminants,[40,71] reptiles,[32,59] and amphibians.[32] This author has identified cases of presumptive AML in bearded dragons and hedgehogs. In exotic species, it can be difficult to confirm a diagnosis of AML, because of aberrant cytochemical staining patterns and lack of immunologic markers to confirm AML or exclude lymphoid neoplasia.

Acronyms and Abbreviations

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; B-CLL, B-cell chronic lymphocytic leukemia; BL, Burkitt lymphoma; BLL, Burkitt-like lymphoma; BCR, breakpoint cluster region; BTK, Bruton tyrosine kinase; CFA, canine familiaris; CCND1, cyclin D1; CD, cluster of differentiation; CHOP, cyclophosphamide, doxorubicin hydrochloride, vincristine sulfate, and prednisone; CNV, copy number variation; DLBCL, diffuse large B-cell lymphoma; EMZL, extranodal marginal zone lymphoma; FL, follicular lymphoma; FAB, French–American–British; HPF, high powered field; KLF2, Kruppel-like factor; IGHV, immunoglobulin heavy chain variable; LDH, lactate dehydrogenase; LBL, lymphoblastic lymphoma; LPL, lymphoplasmacytic lymphoma; MHC, major histocompatibility complex; MCL, mantle cell lymphoma; MUM, mutated melanoma-associated antigen; MCL, myeloid cell leukemia; MZL, marginal zone lymphoma; MALT, mucosa-associated lymphoid tissue; NMZL, nodal marginal zone lymphoma; PLL, prolymphocytic leukemia. PARR, PCR for antigen receptor rearrangement; PAX, paired box; SLL, small lymphocytic lymphoma; SMZL, splenic marginal zone lymphoma; IRF, interferon regulatory factor; ALK, anaplastic lymphoma kinase; HHV, human herpesvirus; TP53, tumor protein 53 (TP53), CDKN2A, cyclin dependent kinase inhibitor 2A, ATM, ataxia-telangiectasia mutated,

INTRODUCTION

Leukemias and lymphomas of B-cell phenotype are relatively common in dogs, infrequent in cats, affect all breeds, ages, and sexes, and exhibit extraordinary biologic, morphologic, and clinical heterogeneity. In the last decade, investigations of the molecular and genetic drivers of lymphomagenesis and advances in monoclonal antibody technology have had significant clinical and biologic implications and help to explain the

complexity of these diseases. As a result, many subtypes of leukemia and lymphoma have been described, each apparently representing the neoplastic counterpart of a specific compartment of the hematopoietic–lymphoid system and having a distinct biologic behavior and treatment response (Table 69.1). In general, the diagnosis of leukemia or lymphoma requires a close integration between the oncologist and pathologist. All patients suspected of having a hematologic or lymphoid malignancy should undergo complete staging, which includes sampling of all possibly involved tissues and organs. The accurate diagnosis and complete classification of B-cell neoplasms requires a combination of morphologic examination and phenotypic or molecular studies. While the list of genetic aberrations in canine B-cell tumors has been growing, these molecular techniques are not yet incorporated into daily diagnostic practice. This chapter describes the clinical and pathological features of veterinary B-cell tumors and highlights the most significant differences and analogies with their human counterparts (Table 69.2).

TABLE 69.1 Revised WHO classification of the mature B-cell, T-cell, and NK-cell neoplasms.

B-cell neoplasms
- Precursor B-lymphoblastic leukemia/lymphoma
- Mature (peripheral) B-cell neoplasms
- B-cell chronic lymphocytic leukemia/prolymphocytic leukemia/small lymphocytic lymphoma
- Lymphoplasmacytic lymphoma
- Mantle cell lymphoma
- Follicular lymphoma
- Marginal zone B-cell lymphoma:
- Extranodal mucosa-associated lymphoid tissue type (± monocytoid B-cells)
- Splenic marginal zone lymphoma (± villous lymphocytes)
- Nodal marginal zone lymphoma
- Plasmacytoma/plasma cell myeloma
- Diffuse large B-cell lymphoma
- Burkitt lymphoma
- Burkitt and Burkitt-like lymphomas

T-cell and putative natural killer-cell neoplasms
- Precursor T-lymphoblastic lymphoma/leukemia
- Mature (peripheral) T-cell neoplasm
- T-cell chronic lymphocytic leukemia/prolymphocytic leukemia
- Large granular lymphocyte leukemia (LGL)
- Mycosis fungoides/Sezary syndrome
- Peripheral T-cell lymphomas, unspecified
- Hepatosplenic γδ T-cell lymphoma
- Subcutaneous panniculitis T-cell lymphoma
- Angiocentric lymphoma
- Intestinal T-cell lymphoma (± enteropathy-associated)
- Anaplastic large cell lymphoma, CD30+

Hodgkin lymphoma

TABLE 69.2 Subtypes of human large B-cell lymphoma. Bold denotes distinct entities here.

Diffuse large B-cell lymphoma, not otherwise specified (NOS)
- Morphological variants (centroblastic, immunoblastic, anaplastic, and other rare variants)
- Molecular subtypes (germinal center B-cell subtype; activated B-cell subtype)

Other large B-cell lymphomas
- T-cell/histiocyte-rich large B-cell lymphoma
- Primary diffuse large B-cell lymphoma of the CNS
- Primary cutaneous diffuse large B-cell lymphoma, leg type
- EBV-positive diffuse large B-cell lymphoma, NOS
- Diffuse large B-cell lymphoma associated with chronic inflammation
- Lymphomatoid granulomatosis
- Large B-cell lymphoma with interferon regulatory factor (IRF4) rearrangement
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- Anaplastic lymphoma kinase (ALK)-positive large B-cell lymphoma
- Plasmablastic lymphoma
- Human herpesvirus (HHV)8-positive diffuse large B-cell lymphoma
- Primary effusion lymphoma

High-grade B-cell lymphoma
- High-grade B-cell lymphoma with MYC and BCL2 and/or BCL6 rearrangements
- High-grade B-cell lymphoma, NOS

B-cell lymphoma, unclassifiable
- B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classic Hodgkin lymphoma

PRECURSOR B-CELL NEOPLASMS

Acute Lymphoblastic Leukemia and Lymphoblastic Lymphoma

Clinical Features

Acute leukemias, either myeloid or lymphoid in origin, are rare in domestic animals, although reported in dogs, cats, cattle, and horses.[100] Acute leukemias in dogs occur with a bimodal distribution showing frequency peaks at 3–4 and 8–10 years, respectively.[66] Clinical features of acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) overlap, and definitive lineage identification requires ancillary techniques. Clinical signs in patients with ALL are usually acute in onset and nonspecific in nature. Anorexia, lethargy, and weakness are the most reported, but vomiting, fever, weight loss, diarrhea, polyuria/polydipsia, and epistaxis may occur. Splenomegaly is a frequent finding, while severe lymphadenomegaly is rarer.[114,100] The prevalent hematological presentation in ALL (i.e., severe infiltration of bone marrow (BM) and/or bone marrow and modest lymph node enlargement) may help to differentiate ALL from its nodal counterpart (lymphoblastic lymphoma (LBL)).

In ALL, according to several studies, anemia occurs in 60–90% of canine cases and thrombocytopenia is even more frequent (about 90% of cases). Leukocytosis is evident in more than 70% of cases, but circulating blasts are found in more than 90% of dogs.[8,66,95] Leukopenia and neutropenia may also rarely occur. In two different studies, leukocytosis was described as variable with median values of 60 and 73 × 10^3/μL, respectively.[8,66] Bone marrow cellularity is normal to hypercellular with presence of more than 20% of blasts among all nucleated cells in bone marrow or peripheral blood.[100] Myelophthisis may be a common finding and mitotic figures may be found in peripheral blood and bone marrow samples. Finally, tumor cell morphology cannot be used to definitively differentiate ALL and AML, and this distinction requires additional diagnostics. Blast cell appearance may be variable among cases. In human medicine, the French–American–British (FAB) classification attempted to classify blasts according to morphology in three different classes (namely, ALL-1, ALL-2, and ALL-3). With the advent of immunophenotyping using specific monoclonal antibodies, this classification has been replaced on that based on immunotype. In veterinary medicine, no extensive studies using FAB classification for ALL are reported and this has been supplanted by immunophenotypic, cytogenetic, and molecular subclassification. Neoplastic blasts may show variable size, with nuclei ranging from less than two RBC to more than two RBC in diameter, scant to moderately abundant basophilic cytoplasm, often with perinuclear clear halo, and round to indented nucleus with decondensed chromatin (Figure 69.1). Nucleoli may be inconspicuous to visible and cytoplasmic clear vacuoles may be found.[83]

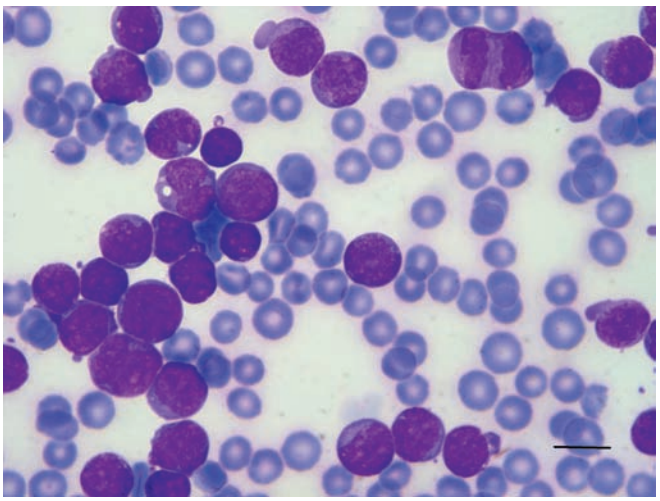

FIGURE 69.1 Peripheral blood from a dog with acute lymphoblastic leukemia (ALL). Neoplastic blasts are medium-sized (nuclei about two erythrocytes in diameter) with scant, basophilic cytoplasm, occasional vacuolization and cytoplasmic blebs, and oval to indented nuclei with smooth chromatin and visible nucleoli. Peripheral anemia and thrombocytopenia are frequent features. May–Grünwald–Giemsa.

ALL is considered a rapidly fatal disease in animals with overall survival times ranging from few days to (rarely) weeks.[26,43,66] Although extensive studies with standardized diagnostic and therapeutic approaches are lacking, some retrospective case collections reported that a normal neutrophil count, lack of anemia, and severe leukocytosis are positive prognostic factors.[66] Treatment is largely unsatisfactory, with most cases showing a poor response to chemotherapy or experiencing rapid recurrence. Although most veterinary oncologists recommend a cyclophosphamide, doxorubicin hydrochloride, vincristine sulfate, and prednisone (CHOP)-based chemotherapy with or without the addition of cytosine arabinoside, efficacious protocols have not been developed so far.[29,66]

Pathologic Features

The tissue distribution, phenotype, cell lineage, and maturation stages of neoplastic cells in blood and/or bone marrow are crucial to differentiate ALL from AML and stage V lymphoma with severe blood involvement, and to further define cell lineage in ALL. As noted previously, the definitive phenotype of lymphoid blasts is not possible based on cytology and CBC alone, and immunophenotyping and/or cytochemistry is necessary. Flow cytometry is a powerful immunophenotyping technique, but its application for the diagnosis of veterinary ALL is often unrewarding. This is partly due to a paucity of antibodies recognizing precursor cells in dogs and cats and the realization that neoplastic cells may lack expression of lineage-specific antigens. Neoplastic cells in ALL are uncommonly positive to common leukocyte markers cluster of differentiation (CD45) and CD44 and weakly positive to CD18 integrin.[22,39] As a marker of precursor cells, CD34 positivity has been reported in 37% and 76% of canine ALL.[2,8] CD34 is a membrane glycoprotein expressed by precursor cells of both lymphoid and myeloid lineage, and cross-reactive antibodies to CD34 are available for the dog. Expression of CD34 on leukemic cells in human ALL ranges from 44% to 70% of cases and correlates with a poorer prognosis. Also, in dogs, CD34 positivity is strongly suggestive of acute leukemia, although aberrant CD34 positivity has been described in some lymphoma subtypes.[40,108] A B-cell origin of ALL is assigned by positivity to antibodies against CD79a, CD20, and/or CD21. However, most cases of ALL fail to express such mature antigens and the final diagnosis is often acute undifferentiated leukemia. Neoplastic cells demonstrate variable expression of major histocompatibility complex (MHC) II.[93]

By definition, bone marrow or peripheral blood shows more than 20% blasts, but blasts in many ALL may strongly exceed this percentage, accounting for more than 90% of bone marrow nucleated cells. Cellularity is increased and few fat cells may persist around the large vessels of the central cavity. Focal foci of residual hematopoiesis may also be found.

Splenomegaly is a common feature in ALL and microscopic evaluation often reveals uniform infiltration by

neoplastic cells with focal areas of hemorrhagic infarction and atrophy of lymphoid follicles. The liver and other organs may be also involved. Interestingly, cell morphology in cytology may vary in different organs or tissues. Based on the experience of the authors, a slight variation in immunoreactivity may be found occasionally among neoplastic cells found in different tissues. The reason of this finding is unknown, but immunophenotypical aspects should be interpreted with care in samples obtained from different organs. Although severe lymphadenomegaly is rare in ALL, moderate lymph node enlargement may occur. Infiltrated lymph nodes contain a population of neoplastic blast cells resembling those in peripheral blood with residual small lymphocytes and plasma cells. It is important to note that it is not possible to differentiate ALL from LBL, particularly if few residual lymphocytes are present there. Like ALL, lymphoblastic lymphoma is a neoplasm of precursor cells. The predominant solid tissue presentation and the lack of severe blood and bone marrow infiltration are parameters used to differentiate LBL from ALL. However, some authors and the most recent revised WHO scheme[3] suggest that ALL and lymphoblastic lymphoma might represent two different presentations of the same disease. Cytologically, LBL is characterized by a population of lymphoblasts, small cells with mild variably basophilic cytoplasm, and a unipolar round or often indented nucleus with a perinuclear halo. Chromatin is finely dispersed, and nucleoli are generally inapparent. Many mitotic figures are found. Like ALL, canine LBL may be of B or T lineage, but mature antigens are generally poorly expressed.

MATURE B-CELL NEOPLASMS

B-Cell Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Clinical Features

Chronic lymphocytic leukemia is the most frequent leukemia in dogs and cats and may be of either T- (more frequently) or B-cell origin. In dogs, B-cell chronic lymphocytic leukemia (B-CLL) is characterized by bone marrow involvement and peripheral lymphocytosis with no or mild peripheral cytopenia.[105] Neoplastic cells show prolonged life span, with decreased apoptosis and proliferation rate, thus accumulating in the bone marrow.[99] The slow accumulation of clonal cells in bone marrow might be the cause of mild clinical symptoms and the frequent indolent clinical behavior. A recent retrospective showed a predisposition of B-CLL in 10 small canine breeds and in two large canine breeds (English Bulldog and Pit Bull).[11] Affected dogs showed a median age at onset of 11 years explaining the high frequencies of small breeds affected. Splenomegaly is common, whereas lymphadenomegaly is usually reported as mild.[99] However, the frequency of lymphadenomegaly is probably underestimated and was recently identified in 46% of cases with B-CLL.[11]

A consensus criteria classification for canine B-CLL is lacking, but in the study of Bromberek et al.,[11] B-CLLs were diagnosed if more than 5000 lymphocytes/μL and more than 60% of lymphocytes were small B cells. Median lymphocyte count was about 25,000/μL, but extreme lymphocytosis (>50,000/μL) was also frequent and leukocyte counts often exceeded those of ALL. Anemia was reported in 26% of cases and it was generally mild. Thrombocytopenia and neutropenia were rare.[11] Some larger cells may be found suggesting a possible evolution of the disease in a more accelerated phase, but a real blast crisis is a very rare event. Based on the authors' experience, canine B-CLL is a slowly progressive disease that can culminate in multiorgan failure. However, Richter syndrome may also occur. Richter syndrome is a quite rare, peculiar evolution reported in about 10% of human B-CLL, characterized by the transformation of B-CLL into a solid lymphoma, mainly diffuse large B-cell lymphoma (DLBCL).[48] A similar evolution and incidence were reported in dog.[23] Clinically, the disease is accelerated with a fatal course. The demonstration of the same clonal rearrangement is mandatory to differentiate Richter syndrome from a second malignancy.[23]

In human medicine, two B-CLL classification schemes are used: The Rai system and the Binet system. Both schemes are based on the number of affected lymphoid tissue groups and the presence of anemia or thrombocytopenia and classify cases as low, intermediate, or high risk. To date, a similar staging system is not available for domestic animals, but it is reasonable to consider the presence of anemia, thrombocytopenia, or organ involvement as features for an advanced stage. Treatment of B-CLL is generally conservative unless clinical signs are present. Treatment appears to have a limited effect on prolonging survival and B-CLL has a median survival of more than 1 year from the diagnosis.[21] In cats, B-CLL appears to be uncommon and, as such, extensive studies on feline B-CLL are lacking. In a recent study on cats with lymphocytosis (total lymphocyte higher than 6000 lymphocytes/μL), B cell expansion was found in 16–19% of cases, but in 94% of cases PCR for antigen receptor rearrangement (PARR) analysis showed polyclonal results.[82] This result is in accordance with those obtained in another study on feline CLL in which just one out of 18 cases was B-phenotype,[12] supporting the extreme rarity of B-CLL in cats.

Pathologic Features

Lymphocytosis composed of small B cells is the most relevant clinicopathologic feature of B-CLL (Figure 69.2). The three published case series in which immunophenotype was available reported median concentrations of lymphocytes of 137,489 ± 103,833 (n = 7; range not reported),[95] 35,980 lymphocytes/μL (n = 17; range, 8000–201,000)[21] and 24,600 lymphocytes/μL (n = 191; range, 5000–812,544).[11] A nuclear diameter less than two times the volume of RBC or smaller than a neutrophil is suggestive of small cells. Alternatively, forward scatter

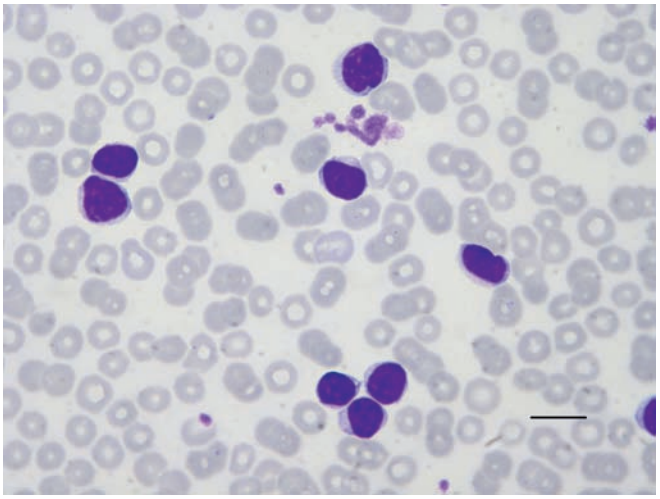

FIGURE 69.2 Peripheral blood from a dog with B-chronic lymphocytic leukemia (B-CLL). Neoplastic lymphocytes are small (nuclei less than two erythrocytes in diameter) with scant, clear, or slightly basophilic cytoplasm, round to oval nuclei with condensed chromatin, and inconspicuous nucleoli. May–Grünwald–Giemsa.

(FSC)-determined flow cytometrically may be used to estimate cell size. A lymphocyte/neutrophil FSC ratio <0.55 confirms the small size of cells. If lymphocyte counts do not exceed 10,000/μL, bone marrow fine-needle aspiration may be used to identify infiltration (more than 30% of total nucleated cells) of small lymphocytes. PARR and/or flow cytometry may be also useful to exclude reactive lymphocytosis. Neoplastic cells are positive to B-cell markers CD21, CD22, CD20, and CD79a and to cytoplasmic immunoglobulin. MHC II and CD25 are generally positive, thus suggesting a mature phenotype, but some variable expression is reported in the quantitative expression from case to case and in different breeds.

B-Cell Prolymphocytic Leukemias

Prolymphocytic leukemia (PLL) is a rare entity. To date, neither extensive studies on B-cell PLL nor flow cytometry data are available in dogs or cats. Thus, there is no consensus on the diagnosis of PLL. As proposed, PLL is characterized by a proliferation of small- to medium-sized cells with a moderately abundant light cytoplasm extended in a so-called hand-mirror shape. Neoplastic cell nuclei are round or slightly indented, multiple chromocenters are often visible, while nucleoli are rare. Typical presentation resembles CLL with leukocytosis often exceeding 50,000 cell/μL and severe infiltration of bone marrow. Prolymphocytic leukemia is rarely described in cattle, while in cats and dogs it is generally interpreted as an accelerated phase of CLL. Severe infiltration of spleen and less marked infiltration of liver and lymph node can be found. Both T- and B-cell PLL are described. Differentiation of PLL from CLL is mainly based on cellular size and morphological appearance of more immature cells.[99]

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma (LPL) is a neoplasm of small and intermediate B-lymphocytes usually involving lymph nodes and spleen, which generally does not fulfill the criteria for any of the other small B-cell lymphoid neoplasms.[103] A peculiar morphological feature of LPL is represented by the presence of neoplastic cells with plasmacytic morphology. LPL occurs in all domestic animals, but is seen most frequently in older cats, involving the intestine and mediastinum in almost 50% of cases. Also, it is described preferentially occurring in the intestine of the horses. The disease is classified as indolent and rare, even if the morphology is very similar to CLL/small lymphocytic lymphoma (SLL) leading to potential misdiagnosis. Moreover, no relevant clinical features have been described both in dogs and cats.[56,71,76,99]

Pathologic Features

In LPL, affected lymph nodes retain the normal architectural features with dilated sinuses and residual germinal centers (Figure 69.3a). There is a monotonous proliferation of small lymphocytes with a plasmacytic morphology. Few cases show severe architectural alteration and have follicular growth pattern with more prominent residual germinal centers. The presence of prominent large B cells should raise the possibility of either disease progression or an alternate diagnosis. LPL cells express CD20 and CD79a.[103] No data are reported for (paired box) PAX-5 immunoassaying. Conversely, CD5 and CD3 are most typically negative. Interestingly, one study identified a weak expression of transferrin receptor 1 (TfR1) in LPL compared to aggressive lymphoma histotypes.[75] TfR1 is a type II transmembrane glycoprotein that binds and internalizes transferrin–iron complexes. Cytologically, LPL is characterized by a dominant population of small lymphocytes, often with moderately abundant cytoplasm, eccentric nuclei, and a visible Golgi zone, suggestive of plasma cells (Figure 69.3b,c). Mitotic figures are generally few. Cytology is of limited use to differentiate LPL from other small cell lymphomas, even when associated with flow cytometry. No pathognomonic flow cytometric patterns have been reported in veterinary medicine and neoplastic cells express common B-cell markers such as CD21, CD20, and CD79.

Marginal Zone Lymphoma

Marginal zone lymphoma (MZL) refers to a group of indolent B-cell lymphomas that originate from the marginal zone of the follicles. MZL occurs in all animals, but is most frequently recognized in dogs and occasionally in cats. MZLs account for approximately 15% of lymphomas in dogs.[47] Historically, canine MZL has been described as having an indolent clinical course, a low mitotic index, and slow progression. However, a recent work has described a more aggressive disease course for dogs developing the nodal form.[27]

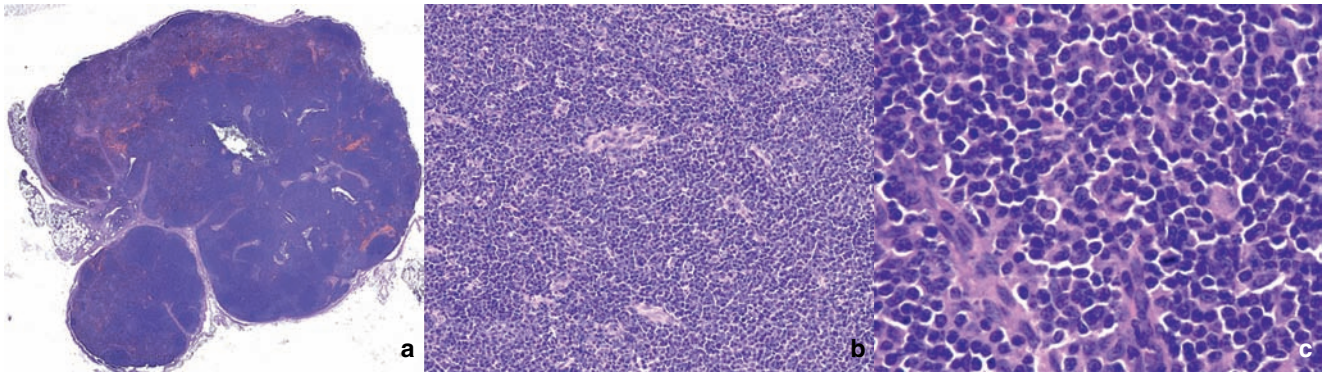

FIGURE 69.3 Lymph node from dog with lymphoplasmacytic lymphoma. (a) Histologically, the lesion is diffuse and involves the entire node. Node is enlarged in volume and shows multifocal hemorrhages and edema. The capsule is taut and diffusely reduced in thickness; (b) The growth pattern is diffuse and composed of tumor cells without evidence of residual germinal centers. Mitoses are infrequent and cell boundaries are irregularly distinct; (c) Diffuse population of small lymphocytes associated with larger plasmacytic forms can be observed. H&E.

In both humans and dogs, three anatomic types of MZL are described: (1) extranodal marginal zone lymphoma (EMZL) of mucosa-associated lymphoid tissue (MALT) lymphoma, (2) nodal marginal zone lymphoma (NMZL), and (3) splenic marginal zone lymphoma (SMZL).[99] MZLs are characterized by a characteristic growth pattern of medium-sized cells (1.5–2 times the red blood cell), with scant eosinophilic cytoplasm, a round nucleus, and a single prominent central nucleolus (medium macronucleolated cells).

Clinical Features

The clinical data related to canine NMZL are sparse and have been largely drawn from pathologic rather than clinical series. NMZL occurs predominantly in adult medium-sized breed dogs and causes localized or generalized lymphadenopathy. In more advanced cases, dogs tend to remain asymptomatic, but stage V disease and splenic involvement are common.[27] The liver is less frequently infiltrated, but cytologic interpretation is always needed. Unlike SMZL, bone marrow and blood are frequently involved in NMZL. In a recent case series, peripheral blood infiltration was detected via flow cytometry in 97% of dogs with advanced disease and the median percentage of neoplastic cells was 6.4%, while BM was infiltrated in 57% of dogs.[27] In another study, dogs with peripheral blood infiltration ≥30% demonstrated a shorter time to progression compared with dogs showing blood infiltration <30%. In the same study, it was also shown that dogs with bone marrow infiltration <1% lived significantly longer than those having infiltration of 1–20% or ≥20%.[58]

Regarding SMZL, it has been described mainly in dogs and is the most frequent lymphoma affecting the spleen.[67,90,91] SMZL represents clinically a distinct form and is likely unrelated to NMZL and MALT. SMZLs generally have a favorable prognosis and most of the cases are incidentally identified on routine abdominal ultrasound examination. However, nonspecific clinical signs can be observed, such as hemoabdomen, lethargy, anorexia, vomiting, and weight loss. Bone marrow and peripheral blood are typically not infiltrated, even in advanced clinical stages. Splenectomy is curative in most cases, although symptomatic disease may prompt the need for chemotherapy. A large case series of SMZLs in dogs reported an overall median survival time after splenectomy of 383 days; if only cases that survived >1 week after splenectomy were analyzed, the median survival time increased to 571 days.[67] Negative prognostic factors include postoperative sepsis and dehiscence. Interestingly, in this study, three dogs lived more than 1000 days confirming the good outcome in dogs affected by SMZL.

Pathologic Features

There are two patterns of infiltration in NMZL: nodular and diffuse. The nodular growth pattern is evident in the early phase and is characterized by well-formed nodules surrounding and colonizing reactive germinal centers. The node focally retains its normal architecture, in which the follicles are surrounded by cells with clear cytoplasm. In the diffuse pattern, which is evident in advanced disease, sheets of neoplastic cells efface the nodal architecture (Figure 69.4). Regardless of their distribution, neoplastic cells are small- to medium-sized with a variable number of scattered blasts. Neoplastic lymphocytes have a prominent single, central nucleolus and abundant lightly stained cytoplasm. The number of mitoses is low (three to five per high powered field [HPF]) except in advanced cases.[103] MZL cells strongly express CD79 and CD20 and lack CD3. No data are reported for PAX-5 immunostaining.[7] A large cell component, usually <30% of the infiltrate, is generally identified. NMZLs with a higher density of large cells (30%–50%) are described, but no evidence of more aggressive behavior is reported. The presence of sheets of large cells is generally an indication of transformation to a diffuse large B-cell lymphoma.[20]

Cytologic smears show a dominant population of medium-sized lymphoid cells with round nucleus and a

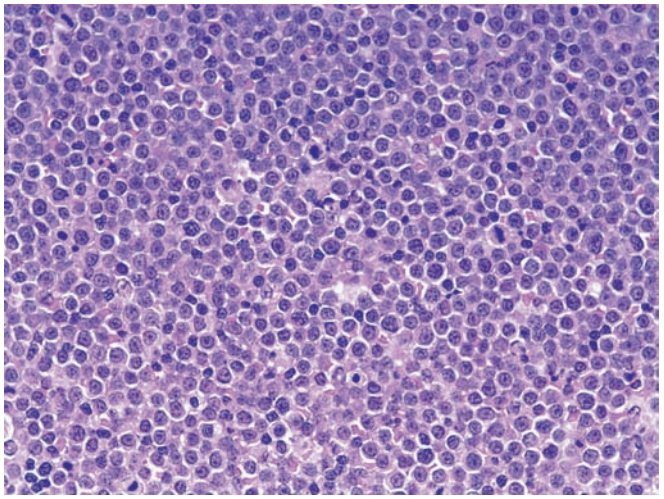

FIGURE 69.4 Lymph node from dog with marginal zone lymphoma (MZL). Histologically, the neoplastic lymphocytes are diffusely homogeneous and originate from the marginal zone area, with most cells having a prominent single central nucleolus. There are few tingible body macrophages and mitoses. H&E.

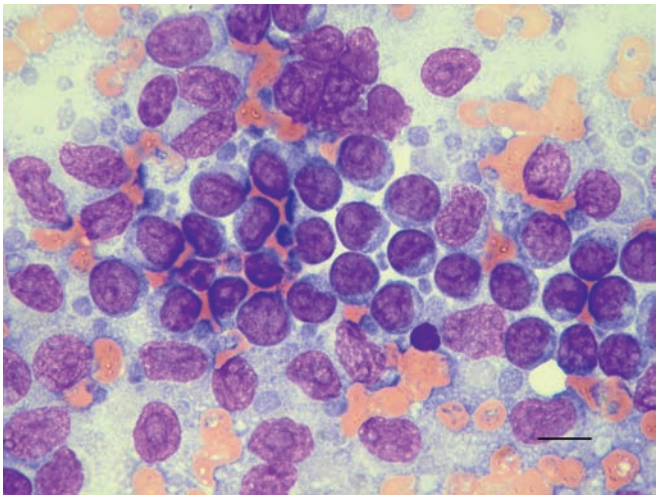

FIGURE 69.5 Cytologic smear from a dog with nodal marginal zone lymphoma (NMZL). A homogeneous population of medium-sized blasts (nuclei about two erythrocytes in diameter) with scarce blue cytoplasm, round/oval nuclei with decondensed chromatin, and single central prominent nucleolus is present. May–Grünwald–Giemsa.

prominent central macronucleolus (Figure 69.5). Centroblasts and immunoblasts are rare, but tend to increase during progression. Mitotic figures are rare to intermediate. Flow cytometric immunophenotype confirm the B phenotype (CD21, CD20, and CD79), and Ki67 value is intermediate or low. Differently from human medicine, immunophenotypic markers are currently not available to discriminate NMZL, SMZL, and MALT in dogs.

An important morphologic and biological consideration in the diagnosis of canine NMZL is its relationship with DLBCL.[41] This distinction can be particularly problematic in nodal lymphomas with a consistent histological or cytological infiltration of large B cells. In 2013, Frantz et al., evidenced by DNA microarray transcriptomic similarities, suggested that DLBCL and MZL might represent a continuum of the same disease. One year later, investigators compared transcriptome of nine NMZL with 32 DLBCL using a similar approach and the results showed a complete overlapping of the two tumors at the transcriptomic level.[35] Similarly, genomic copy number aberrations investigated by array comparative genomic hybridization reported no significant differences in the genomic profiles between NMZL and DLBCL, confirming the high similarity of these two histotypes also at the genetic level.[41] These findings align with the recent work in humans indicating that there is a continuum between NMZL and DLBCL.[22]

Grossly, splenic MZL is characterized by a marked nodular or multinodular expansion of white pulp with frequent merging and coalescence of the follicles. Microscopically, germinal centers are atrophic and unrecognizable (Figure 69.6a). There is a prominent expansion of the marginal zone due to a population of intermediate-sized lymphoid cells. These cells contain a moderate amount of cytoplasm and a round to oval to irregular nucleus with clumped chromatin and a single, small central nucleolus. Occasional interspersed larger cells (centroblast-like) are also identified.

The neoplastic cells in SMZL usually show immunoreactivity for CD20, CD45, CD79a, PAX-5, and Bcl-2 and are negative for CD3, CD10, Bcl-6, and cyclin D (Figure 69.6b). Also, SMZL may demonstrate scattered neoplastic cell positivity for CD5, mutated melanoma-associated antigen 1 (MUM-1), myeloid cell leukemia-1 (MCL-1), and cyclin D3.[92] Conversely, cytological and flow cytometric aspects do not differ from those of NMZL.[27]

Comparative Features

In humans, MALT lymphoma, SMZL, and NMZ represent three distinct types of mature B-cell neoplasms.[94] While MALT lymphomas account for 7–8% of all lymphomas, SMZL and NMZL are much less common with each one representing less than 2% of lymphomas. The MZLs could be considered a continuum of disease which makes a precise diagnosis often impossible in the case of disseminated disease.[10,15] All MZL types present trisomies of chromosomes 3 and 18 and deletions at 6q23 (TNFAIP3 gene), somatic mutations of genes coding for proteins involved in chromatin remodeling, and nuclear factor kappa B (NF-κB).[10,80] Mutations affecting the NOTCH pathway and the transcription factor KLF2 (Kruppel-like factor) are more common in SMZL and NMZL than MALT lymphomas.[14,81,89] While SMZL is specifically characterized by deletions of chromosome 7q, NMZL shows inactivation of protein tyrosine phosphatase receptor type D (PTPRD) and a much higher prevalence of mutations affecting lysine-specific methyltransferase 2D (KMT2D).[14,49,69,81,88] SMZL and NMZL do not present specific recurrent chromosomal translocations, instead observed in MALT lymphomas, in which, at least three of them activate the NF-κB pathway.[10,112]

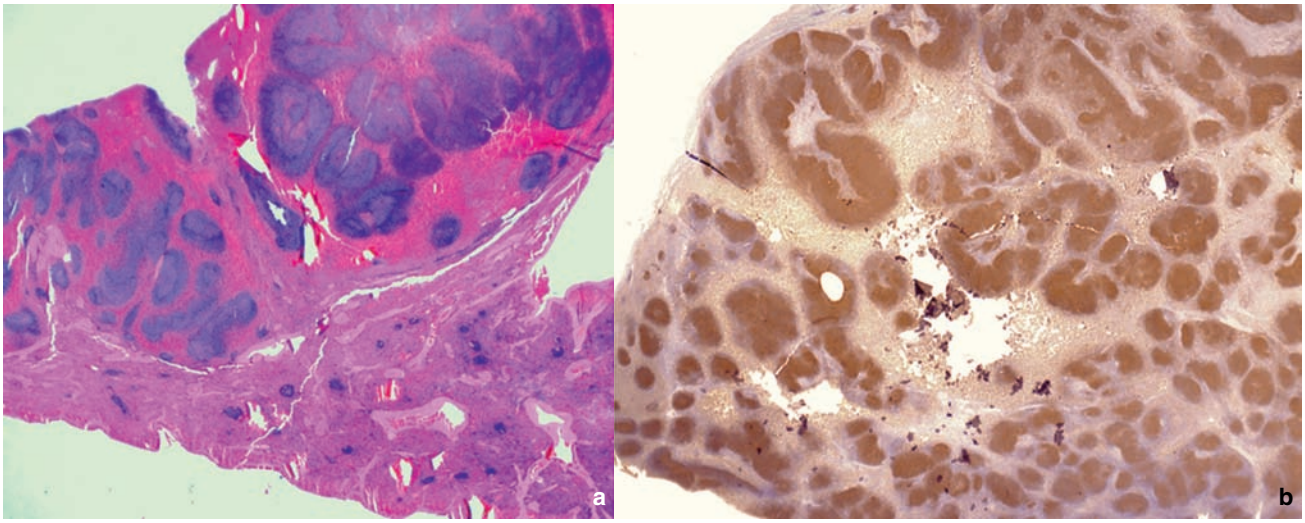

FIGURE 69.6 Spleen from dog with marginal zone lymphoma. (a) The spleen is characterized by diffuse and irregular coalescence of follicular areas. The germinal centers are faded and obliterated, multifocally they tend to coalesce. Sinus blood flow is altered by compression and results into hemorrhagic infarction. A small portion of normal spleen is visible. H&E; (b) CD20 immunostaining shows multiple follicular areas positive and a clear distinction between follicular centers and peripheral marginal zone is lost.

In humans, MALT lymphoma clearly arises from B cells in the context of chronic autoimmune or infectious inflammations.[112,113] It is well established that gastric MALT lymphoma, the most common in humans, is associated with *Helicobacter pylori* chronic gastritis.[112,113] Similarly, MALT lymphomas in other anatomical sites have been associated with other infectious agents: orbital adnexal MALT lymphoma with *Chlamydia psittaci*, cutaneous MALT lymphoma with *Borrelia burgdorferi*, immunoproliferative small intestine disease (IPSID) with *Campylobacter jejuni*, and pulmonary MALT lymphoma with *Achromobacter xylosoxidans*.[112,113] Finally, hepatitis C virus is associated with all the MZLs.[25,33,73,74,104] The importance of the chronic inflammation is further supported by the pattern of immunoglobulin heavy chain variable (IGHV) rearrangements in MZL, which strongly indicates the lymphoma cells have undergone an antigen-driven process. MZLs usually present somatically mutated IGHV genes with intraclonal variation due to ongoing mutations and a biased usage of some IGHV segments.[10,24,98,110–112] Similar to humans, one study of five canine NMZL cases showed variable ongoing somatic IGHV mutations.[78]

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is a distinct subtype of lymphoma characterized by follicular proliferation of mature B-lymphocytes. MCL is derived from antigen-naïve pre germinal center B cells (GCB) located in the mantle zone and surrounding normal germinal centers.[103] Neoplastic lymphocytes are small- to medium-sized with irregular and indented nuclei. Most nuclei lack visible nucleoli, and the tumor shows a low mitotic rate. MCL in humans is characterized by cyclin D1 expression. Human MCLs have a distinct immunophenotypic profile characterized by expression of CD5, CD20, and other phenotypical markers.[68] This is completely unknown in veterinary medicine.

Clinical Features

In animals, MCL is rare. Unlike MZL, which tends to evolve after a long period of marginal zone hyperplasia, MCL appears not to be detected at a stage of hyperplasia. This is contrast with human MCL, in which the presence of cyclin-D1-positive lymphoid cells restricted to the mantle zones and bearing the cyclin D1 (CCND1) rearrangements is recognized as "in situ mantle cell neoplasia" according to the WHO classification.[94] MCL tends to present as a multinodular and multifollicular proliferation that then undergoes coalescence. Associated changes in the spleen include atypical plasmacytosis with fibrohistiocytic nodules and occasionally focal hemorrhagic infarction.[99] In a study of 388 cases of B-cell lymphoma, only four were suggestive of MCL.[72] However, these cases were characterized by a high mitotic rate and a high Ki-67 index, which contrasts with human MCL. Eleven cases of canine MCL were identified in a collection of 461 cases with an incidence in the dog of about 2%. The age of affected dogs ranged from 1.5 to 15 years with a mean of 8 years. MCL appears to be similarly rare in cats in which one case was identified in a study of 150 cases of lymphoma.[99] Another peculiar feature of the canine MCL is the relative higher frequency as primary lymphoma in the spleen and rectum than in the nodes.[99]

Pathologic Features

In the lymph node, MCL usually effaces the normal architecture showing one of two growth patterns:

mantle zone growth (follicular) or diffuse. MCLs with a mantle zone growth pattern can be difficult to diagnose, especially when only a moderate lymphadenopathy is reported. These cases require complete lymph node extirpation and tru-cut samples should be always avoided. This form of MCL is characterized by an expansion of the follicle mantle area by tumor cells surrounding a reactive, "naked" germinal center. However, differentiating follicular MCL from follicular or mantle cell hyperplasia can be difficult. With disease progression, neoplastic cells proliferate to cause paracortical atrophy and fading of hyalinized germinal centers.[107] Given the difficulties in diagnosing follicular MCL, lymphoid clonality testing should be considered in suspect cases. Diffuse MCL, which is the most common variant, is characterized by the involvement of the entire node (Figure 69.7). Based upon neoplastic cell morphology, two main variants of MCL are reported in the human WHO classification, classical and blastoid. In dogs, MCL resembles the classical variant, as it is characterized by a monotonous proliferation of small- to medium-sized lymphoid cells with scant cytoplasm, variably irregular nuclei, evenly distributed condensed chromatin, and inconspicuous nucleoli. Nuclear morphology is best visualized in cytologic smears. Histologically, differentiating diffuse MCL from SLL or CLL may be difficult.[99] By immunohistochemistry (IHC), the neoplastic cells in MCL express CD20 and CD79. Specific description on cytological and flow cytometric aspects in domestic animals is currently lacking. Considering the indolent clinical course, bone marrow and blood are usually not involved.[27]

Macroscopically, splenic MCL is characterized by a generalized nodular-pattern-like SMZL. Hemorrhages and organized hematomas are also reported as secondary lesions. Histologically, white pulp nodules are enlarged with a variable involvement of the red pulp. Some tumor foci surround hyalinized and hypocellular germinal centers, which indicates their relationship to fading follicles. Mantle cells in the spleen generally have strong immune reaction to antibodies for CD45, CD79a, and Bcl-2 and are negative to CD3, CD10, Bcl-6, and cyclin D1.[92]

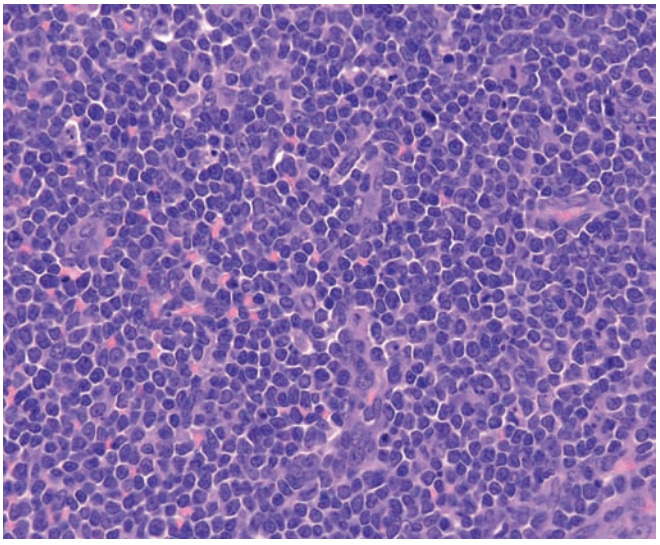

FIGURE 69.7 Lymph node from dog with mantle zone lymphoma. Histologically, a diffuse growth of neoplastic lymphocytes is observed causing an architectural effacement. The population is homogeneous and cells resemble centrocytes of the germinal center associated with few large and pleomorphic cells. H&E.

Comparative Features

Human MCL accounts for 5–10% of all lymphomas.[13,31,55,94] As mentioned, the genetic hallmark of the human disease is the chromosomal translocation juxtaposing the CCND1 gene to the immunoglobulin heavy-chain genes. Other frequent genetic lesions include inactivation of the tumor suppressor genes tumor protein 53 (TP53), cyclin dependent kinase inhibitor 2A (CDKN2A), and ataxia-telangiectasia mutated (ATM), and somatic mutations affecting genes coding chromatin-remodeling genes and the NF-κB pathway.

Follicular Lymphoma

In both humans and veterinary species, follicular lymphoma (FL) is a B-cell neoplasm composed of small centrocytes and large centroblasts. In a retrospective study of 502 canine lymphoma cases, 20 cases of FL were identified. In one review of 176 cases from the New York City area, there were 19 cases of FL for a total incidence of 5.7%. In a review of 602 feline cases of lymphoma, only six (1%) were diagnosed as FL. A review of 1198 cases of bovine lymphoma, identified by inspection at Canadian slaughter plants, documented four cases (0.3%) of FL. Follicular lymphoma appears to be rare in the horse, where the incidence appears to be less than 1%. Given the challenges of diagnosing FL, its true incidence in veterinary species is unknown, but it is likely somewhere between 2% and 4% of all canine lymphoma cases.[41]

Clinical Features

Dogs with FL tend to have a multicentric disease, involving both peripheral and intracavitary lymph nodes, with no sex, age, and breed predisposition. In most cases, FL is discovered at an advanced disease stage, highlighting its capacity to progress unnoticed. There is no consensus treatment for canine FL.[27] Given the low prevalence of FL in animals, no studies identifying prognostic factors, or the impact of blood and bone marrow infiltration, are available. Peripheral blood and bone marrow involvement would likely be difficult to identify via cytology or flow cytometry alone, given the small size of the neoplastic cells. PARR might play a possible role, but no specific studies are available to date.

Pathologic Features

FL is a neoplasm composed of B cells originating from the follicle center (germinal center). The size of node is moderately increased, and the capsule is characteristically

thin and taut, with the peripheral sinus compressed and compromised in areas where extranodal tissues infiltrated by neoplastic cells are present. The neoplastic population is composed of both centrocytes and centroblasts or large transformed cells. FL produces a nodular infiltrate in lymph nodes that eventually effaces normal germinal centers. Characteristically, the lymphoid follicles in FL lack a well-defined mantle zone and polarization. Early cases of FL may have a starry-sky pattern resembling a reactive process complicating the morphological evaluation (Figure 69.8). FL also exhibits atrophy of the paracortical and medullary areas. The pre-existing reticulin network is usually compressed to the periphery of the neoplastic follicle, resulting in the formation of variably prominent interfollicular reticular trabeculae. This modification is observed by Manuel's silver impregnation stain.

The major differential diagnosis for FL is benign follicular hyperplasia. Differentiating FL from follicular hyperplasia can be difficult, as FL recapitulates the architecture, growth pattern, cytology, and immunophenotype of normal/hyperplastic germinal centers.[99] However, there are several clues that can help differentiate the two. In FL, the lymphoid nodules are usually closely packed with a back-to-back arrangement and have comparable size and shape, which differ from florid follicular hyperplasia. In follicular hyperplasia, many of the follicles within the tissue

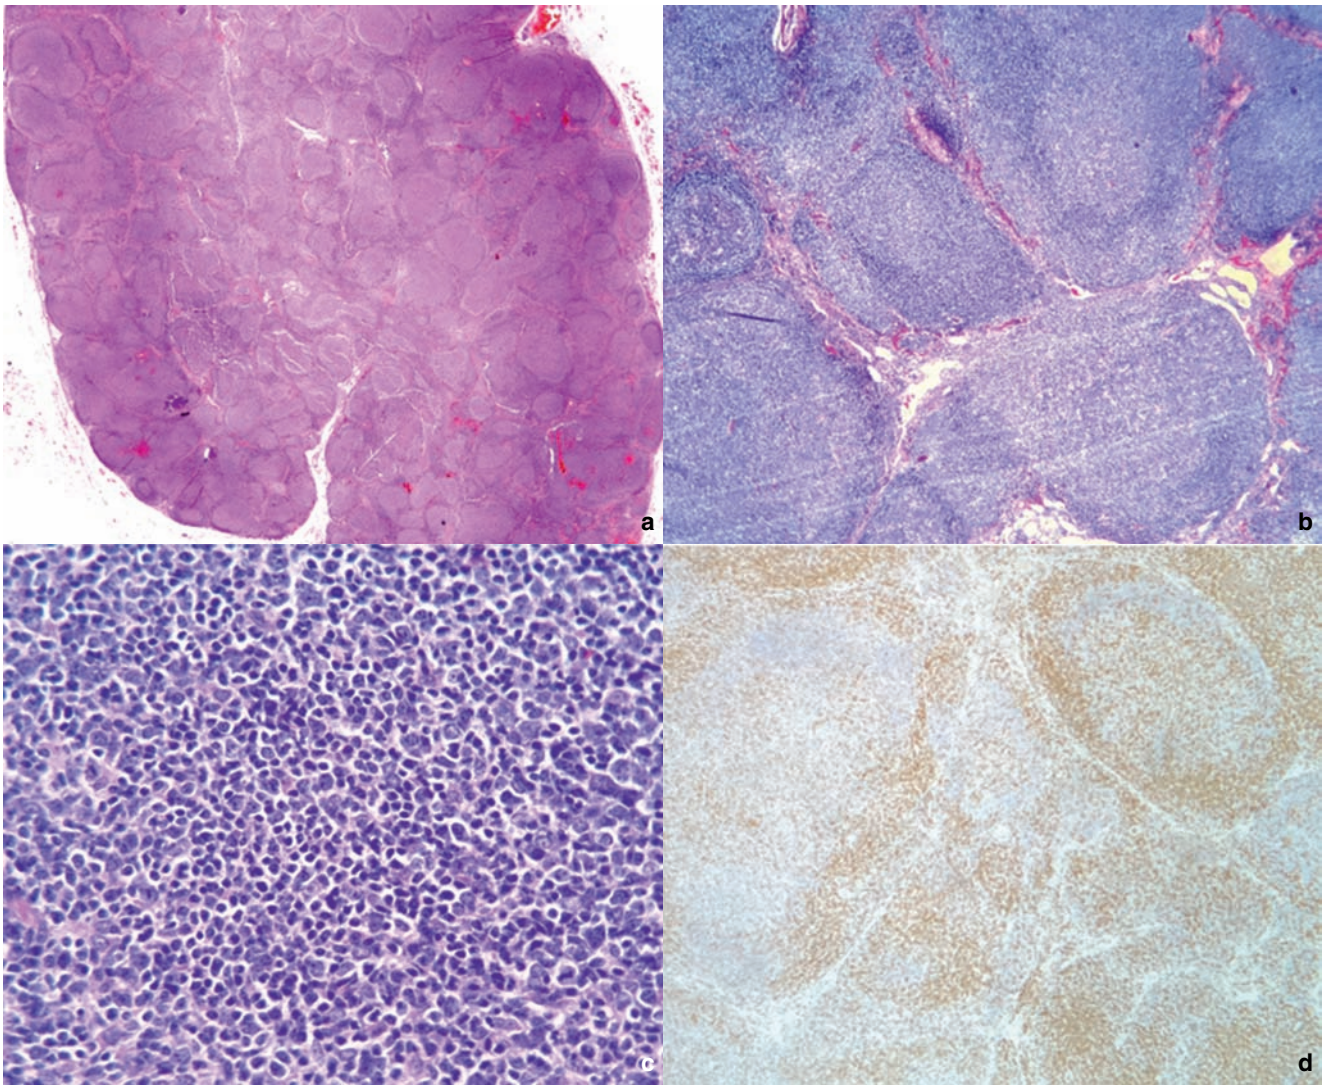

FIGURE 69.8 Lymph node from dog with follicular lymphoma. (a) Lymph node architecture is effaced by enlarged follicles with a starry-sky pattern and a lack of mantle zones. Conversely, marginal zone differentiation is still present multifocally at the periphery of the neoplastic follicles; (b) The entire lymph node is replaced by a nodular proliferation characterized by neoplastic follicles composed of mostly small lymphoid cells with a rim of germinal center cells at the periphery; (c) The cellular composition is typically heterogenous and atypical cells are intermediate in size, showing a blastoid appearance and lacking of nucleoli. A moderate number of centroblasts are present; (d) CD3 immunostaining identifies few T cells in the neoplastic follicles.

have antigen-related polarity and there is usually some level of residual mantle cell cuff. These features are lost in the neoplastic follicles of FL. In follicular hyperplasia, the involvement of perinodal tissue is frequently present, but is almost never nodular or follicular, as usually occurs in FL. Given this morphologic overlap, clonality testing is essential in accurately differentiating FL from hyperplastic lesions. Considering the importance of tissue architecture, small biopsies (tru-cut) of affected lymph nodes are not recommended.

Considering the importance of tissue architecture and the multifocal distribution of the neoplastic follicles, cytology is of limited use in the diagnosis of FL. When adequate, cytology may show a mixed population of centrocytes and small lymphocytes with percentage of centroblasts variable according to the grade. Mitotic figures are few (less than one to two per five HPF), as well as positivity to Ki67. The presence of a population composed by follicular cells and centroblasts without an increased number of plasma cells and the absence of a progressive differentiation may suggest FL, but a definitive diagnosis is impossible using cytology alone. Similarly, although flow cytometry can confirm the B-cell origin of the neoplasm, it cannot definitively diagnose FL. In human medicine, CD10 is a valuable marker of FL, but no antibodies have been reported in veterinary medicine. In dog, a histological grading scheme for FL has been proposed; however, this histotype is so rare that the utility of such a scheme is uncertain.

In the authors' experience, transformation of FL to DLBCL occurs in the dog. The comparison of biopsy material from the same dog revealed an evolution of follicular morphology to a diffuse architecture with a mixture of medium-to large lymphoid cells and a higher number of mitotic figures. However, an unequivocal demonstration of transformation would require the demonstration of a clonal relationship between the original FL and subsequent neoplasm. Given that a true follicular architecture may be very subtle in most of FL cases, immunohistochemistry should be always performed to achieve a final diagnosis. FLs are strongly positive with CD79a and CD20 and are negative with CD3. A meshwork of dendritic cells and T cells is identified in follicular areas, but is usually sparser and more irregularly distributed than in follicles.

Splenic FL has not been reported in animals, whereas three cases of primary colorectal FL have been described in dog.[79] Histologically, all cases were described as well-circumscribed, nodular masses confined to the submucosa. The masses were diagnosed as FL based on the presence of prominent, often confluent, lymphoid follicles with expanded germinal centers that had lost the morphologically distinct light and dark zones consistent with normal polarity. A mixed population of intermediate-sized centrocytes with characteristic indented, heterochromatic nuclei and indistinct nucleoli and centroblasts with large euchromatic nuclei and multiple large amphophilic nucleoli that often marginalized along the nucleolemma were found.

Comparative Features

In humans, FL is the second most common type of lymphoma, accounting for approximately 20% of all lymphomas with a higher incidence in Western Europe and USA than in the other places.[32,37,94] The FL genetic hallmark is the presence of the t(14;18)(q32;q21) chromosomal translocation, which relocates the BCL2 gene (18q) adjacent to the immunoglobulin heavy-chain genes locus (14q) resulting in the overexpression and accumulation of the anti-apoptotic protein Bcl-2. Many other genetic lesions are also frequent, and, importantly, the lymphoma cells have a very strict relationship with nontumoral cells present in the microenvironment.[28,37,50]

Diffuse Large B-Cell Lymphoma

DLBCL is the most frequent type of lymphoma in dogs, accounting for about 60% of lymphomas diagnosed in this species, but it is described in all domestic animals.[47] DLBCL may occur in nodal and extranodal sites and encompasses marked morphologic, genetic, epigenetic, transcriptomic, and clinical heterogeneity.[6] Involved lymph nodes are typically enlarged due to the diffuse proliferation of medium or large B cells. Two cytomorphological variants are described in dogs (i.e., centroblastic or immunoblastic forms), but no clinical benefit of this subtyping has been identified. Centroblasts are large noncleaved lymphoid cells resembling the proliferating cells of the germinal center with oval to round vesicular nuclei, with fine chromatin and multiple membrane-bound nucleoli, and scanty amphophilic to basophilic cytoplasm. Immunoblasts have an oval or round nucleus with opened chromatin and a large central solitary nucleolus, and abundant deeply basophilic cytoplasm. DLBCL has been associated in cats and cattle to retroviral infections, but lymphomas also occur in the absence of viral involvement.[101,106]

In dogs, emerging data both from omics platforms and clinical trials indicate the importance of breakpoint cluster region (BCR) signaling in the pathogenesis of DLBCL.[6,86] The interruption of BCR signaling by target drugs has substantial antitumor activity in an in vitro model and dogs with DLBCL.[38] A similar mechanism is described in human activated B-cell (ABC)-DLBCL, characterized by a constitutive activation of NF-κB. These data are unknown in the canine species and the integration of viral genomes into neoplastic cells should be also investigated to completely exclude the viral pathogenesis.[6]

Clinical Features

Dogs with DLBCL typically demonstrate painless peripheral lymphadenopathy with variable clinical signs secondary to the effects of lymphoma on infiltrated organs, such as spleen, liver, gastrointestinal tract, or bone marrow. Due to the nonspecific nature of these findings, weeks to months may elapse before the diagnosis of lymphoma is established.

Peripheral lymphadenopathy is moderate to severe, whereas extranodal involvement occurs in less than 20% of cases at initial presentation.[57] Anemia and thrombocytopenia may be present and represent negative prognostic factors, as does an increased serum lactate dehydrogenase (LDH) level.[1,17,59,62]

Neoplastic cells are found in the peripheral blood and bone marrow in about half of dogs with DLBCL.[57] However, this percentage is highly variable depending upon analytic approach (cytology, flow cytometry, or PARR) or cutoff values.[51,59] The prognostic value of low-level peripheral blood infiltration is unknown, but a recent study has shown that the percentage of infiltration in bone marrow is inversely correlated with lymphoma-specific survival and time to progression.[59] Furthermore, an infiltration cutoff value of 3% to discriminate prognosis has been proposed. Dogs with lymphoma surviving more than 2 years had an absence of bone marrow infiltration in another study.[60] Importantly, bone marrow infiltration can be documented in dogs lacking either cytopenias or circulating neoplastic cells.[61] In cats with high-grade lymphoma or large granular lymphoma, up to 15% are leukemic, but studies aimed at correlating this feature with outcome are lacking.[34,53]

Circulating neoplastic cells may be medium- to large-sized with prominent nucleoli resembling those of lymph node aspirates, but frequently they do not reflect the morphology of neoplastic cells in lymph nodes. Flow cytometry can easily quantify the percentage of large B cells (CD21+/CD22+) in peripheral and marrow blood with a higher sensitivity and specificity than cytology. PARR may be more sensitive and specific to confirm infiltration, but its prognostic role has not been elucidated.[5] DLBCL must be distinguished from large T-cell lymphoma, late-stage MZL, and intermediate-sized Burkitt-like lymphoma (BLL). In certain forms of Burkitt-like lymphoma, the histology (intermediate-sized cells, numerous mitotic figures, and numerous tingible body macrophages) overlaps with DLBCL.

First-line treatment consists of traditional dose-intense chemotherapy; however, it is rarely curative. The goal of treatment is palliative, aiming at improving quality of life by ameliorating symptoms of disease, and possibly prolonging survival. The backbone of current therapy is represented by systemic multiagent chemotherapy, incorporating drugs such as vincristine, cyclophosphamide, and doxorubicin, with or without L-asparaginase.[18,36,87] Shorter treatment cycles are the goal of ongoing research to minimize treatment-related toxicity. In recent years, immunotherapy in combination with chemotherapy has been established as a powerful way to treat DLBCL.[57] In human cases, the treatment of choice for newly diagnosed patients with advanced DLBCL is R-CHOP (rituximab—a monoclonal antibody targeting CD20−, cyclophosphamide, doxorubicin, vincristine, and prednisolone) chemo-immunotherapy, which results in 5-year survival in the range of 60%.[19]

Pathologic Features

In dogs, three morphologic variants of DLBCL have been reported, namely, centroblastic, immunoblastic, and anaplastic variant. The first two types have been described in the earlier text. The anaplastic variant is characterized by marked pleomorphism of tumor cells that may resemble Reed–Sternberg cells or carcinoma cells. Notably, given the lack of clinical outcome or treatment data differentiating these morphologic variants, sub-classification is of limited value in veterinary medicine.[4] Affected lymph nodes are enlarged with a thin capsule and neoplastic colonization of perinodal tissues. The neoplastic growth is diffuse with fading or

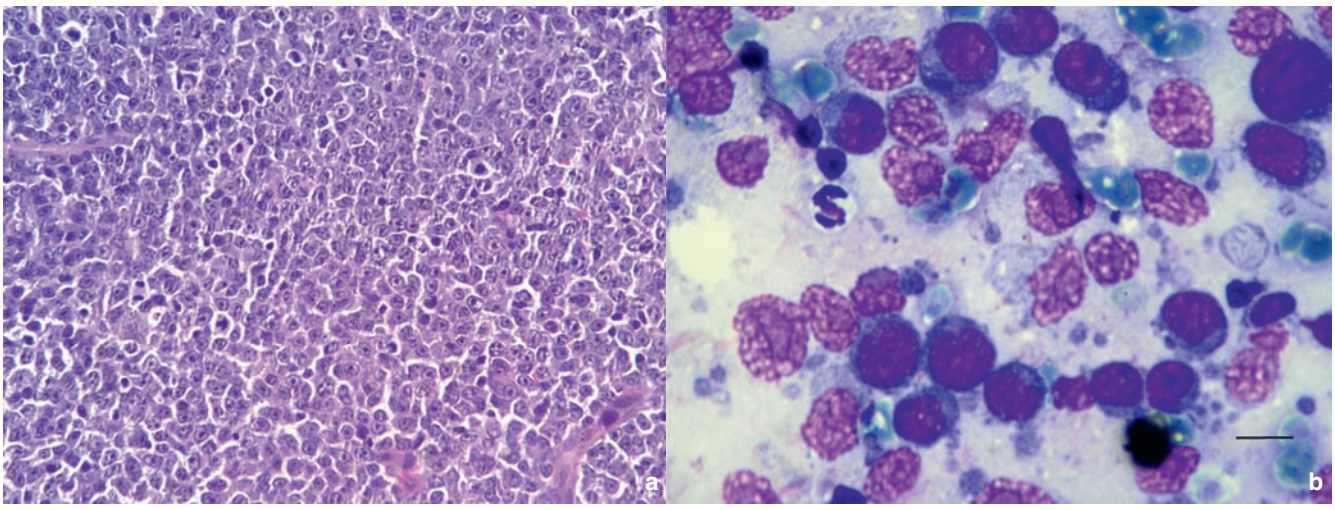

FIGURE 69.9 Lymph node from dog with diffuse large B-cell lymphoma immunoblastic type. (a) Diffuse effacement of node architecture is observed. The neoplastic population is characterized by large nuclei with a fine chromatin and a single, centrally located prominent macronucleolus with variable amounts of eosinophilic cytoplasm; (b) Cytologically, neoplastic cells comprise a homogeneous population of large (nuclei larger than two erythrocytes in diameter) blasts with deeply basophilic cytoplasm, round nucleus with decondensed chromatin, and single, central prominent nucleolus. May–Grünwald–Giemsa.

compression of residual germinal centers. Compression of the peripheral sinuses and complete effacement of medullary structures are common. Necrosis may be seen in dogs undergoing chemotherapy treatment. DLBCL tends to be monomorphic and the immunoblastic variant is defined when the population is almost entirely composed of immunoblasts (>90%) (Figure 69.9a). Centroblastic DLBCL is more pleomorphic having both centroblasts and immunoblasts (Figure 69.10a). Many cases, however, are difficult to subclassify into one of the previous categories, having features intermediate between variants. The anaplastic variant of DLBCL, which is uncommon in dogs, is characterized by large neoplastic B cells with bizarre nuclei, and abundant amounts of cytoplasm. The differential diagnoses are aggressive Burkitt-like lymphomas, peripheral T-cell lymphomas, and histiocytic sarcomas. The final diagnosis is always performed with immunohistochemistry.

Mitotic rate is variable in DLBCL. In a recent study, survival of dogs with DLBCL was correlated to the mitotic index. Median survival in dogs with fewer than 20 mitoses per 400× field was 188 days, whereas the median survival of dogs with 21 or more mitoses per 400× field was much shorter (31 days).[102] However, this study has lacked clinical staging data and standardized therapeutic protocols. Affected tissues in canine DLBCL often contain variable number of tingible body macrophages, which appears to be associated with the apoptotic rate of the lymphoma. In affected tissues, small foci of small-sized cells with densely staining nuclei that demonstrate sharp shallow nuclear indentations and inapparent nucleoli may be seen. These cells are CD3+ and CD5+ tumor infiltrating T cells that were recently found to express PD-1 marker and may be associated with prognosis.[5]

The cytology of DLBCL is variable and may reveal a dominant population of large immunoblasts, centroblasts, or, more frequently, a heterogeneous population of centroblasts, immunoblasts, and medium-sized macronucleolated cells (Figures 69.9b and 69.10b). In cats, the immunoblastic variant tends to be prevalent over centroblastic. Several macrophages, often containing tingible bodies, are found and cytoplasmic fragments are often seen in the background. Mitotic figures may vary from three to more than five per HPF. The neoplastic cells typically express pan-B-cell markers such as CD20, CD79a, and PAX-5.

Flow cytometry reveals a population of cells with high FSC that express CD45, CD44, CD18, CD21, CD20, CD22, CD79a, MHC II, and surface immunoglobulin (Figure 69.10c). Low expression of MHC II may be associated with a poorer outcome in B-cell lymphoma.[77] Occasionally, CD34 may be aberrantly expressed, but no association with outcome has been demonstrated. To date, no flow cytometric markers have been shown capable of differentiating DLBCL from other B-cell lymphoma and a definitive diagnosis must combine immunophenotyping and histopathology.

DLBCL can also be classified based on the anatomic location, including intravascular, mediastinal, splenic, and primary effusion types of lymphoma. One variant of large B-cell lymphoma, which has an affinity for vessels, localizes in any tissue, but it has a major affinity for the central nervous system (CNS).[30] Macroscopic findings at postmortem examination are characterized by multifocal hemorrhagic areas, particularly in the forebrain with a bilateral distribution of tumor cells. Histologically, both neuroparenchymal and meningeal vessels are infiltrated by neoplastic aggregates that occupy the vascular lumen with no apparent cohesion with the endothelium. Neoplastic cells have marked anisokaryosis with multinucleated and binucleated cells, round to oval voluminous nuclei, markedly pleomorphic, round to polyhedral, with distinct cell borders and variable nucleus/cytoplasm ratios. Multiple prominent nucleoli are visible, and several atypical mitotic figures are evident. Immunohistochemistry is always needed to confirm the diagnosis and the phenotype. CD20 and PAX-5 are usually positive.

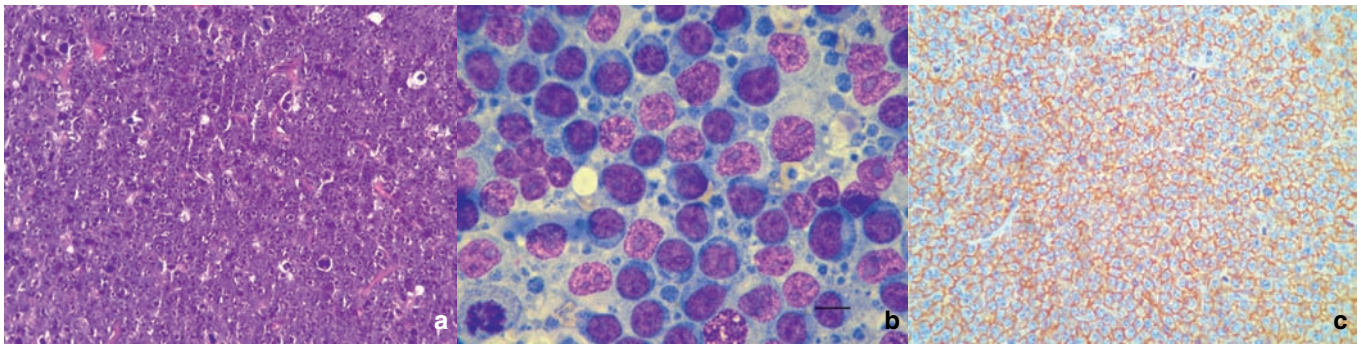

FIGURE 69.10 Lymph node from dog with diffuse large B-cell lymphoma centroblastic type. (a) A diffuse effacement of node architecture is observed. The neoplastic population is characterized by medium- to large-sized cells with vesicular nuclei, irregular (clumped) chromatin, and several nucleoli located at the periphery close to the nuclear membrane. H&E; (b) Cytologically, neoplastic cells are composed by a variable population of medium to large (nuclei equal or larger than two erythrocytes in diameter) blasts with deeply basophilic cytoplasm, often with evident perinuclear clear halo, round to oval nucleus with smooth chromatin, and multiple prominent nucleoli. Several lymphoglandular bodies are visible in the background and mitotic figures are often visible. May–Grünwald–Giemsa stain; (c) CD20 immunostaining shows diffuse membrane-positive staining of centroblasts.

Hemorrhagic infarction due to multifocal partial to complete venous thrombosis is common. In a case series of cerebral intravascular lymphoma, pulmonary involvement was also observed.[30] The pulmonary involvement was limited to small-caliber pulmonary veins and interstitial capillaries, whereas arteries and larger-caliber vessels were spared. Animals with this form of lymphoma usually show a rapid onset of depression, disorientation, tetraparesis, recurrent seizures, and ataxia. Because of poor prognosis and progressive worsening of the neurological condition, euthanasia is performed in most cases.

Mediastinal large B-cell lymphoma is rare in dogs, but common in cats.[64] This disease is usually diagnosed by ultrasound-guided fine-needle aspiration or tru-cut biopsy.[9] In a series of 602 cases of feline lymphoproliferative diseases, mediastinal lymphomas showed an aggressive biological behavior and were graded as high-grade.[101] These lymphomas show a high rate of necrosis and a high degree of mitotic activity. The most common presenting signs include lethargy, anorexia, polyuria/polydipsia, coughing, dyspnea, and vomiting. Splenic DLBCL is reported, but the frequency is low, and it is less common than marginal zone and mantle cell lymphoma. The growth is initially multifocal and becomes rapidly coalescing.[99] The tumor expands within the white pulp, compressing the red pulp, which leads to grossly visible, coalescing nodules adjacent to associated hemorrhage and infarction.

Comparative Features

Gene expression studies of canine DLBCL have identified patterns associated with prognosis and tumor biology. In two different studies, dogs with DLBCL showed a molecular profile resembling the ABC-DLBCL in humans. The signature is characterized by the expression of genes involved in the activation of B cells, as well as genes normally expressed by plasma cells, thus suggesting a post-GCB origin. Constitutive nuclear factor (NF)-κB, MYC, and PI3K signaling pathways were demonstrated to promote malignant cell survival in these lymphomas.[65,78,86] Two Bruton tyrosine kinase (BTK) inhibitors (ibrutinib and acalabrutinib) underwent early preclinical evaluation in dogs with B-cell lymphoma further confirming the role of NF-κB activation in the pathogenesis of this tumor and highlighting a possible crucial upstream effect of BTK in driving NF-κB pathway.[44,46] Additionally, RNA-seq of 50 dogs with DLBCL revealed two groups showing different survivals; dogs with enrichment of immune system signatures had an unfavorable prognosis.[6]

A small number of copy number variations (CNVs) have been identified in canine DLBCL. The most extensive and highly recurrent CNVs were gains of canine familiaris (CFA) 13 and 31, but recurrent gain of the MYC oncogene and absence of deletion of the CDKN2A/B tumor suppressor gene locus were also identified. The clinical impact of this data is not wholly certain, but the gain of CFA 13 was found more frequently in dogs demonstrating a complete response after treatment compared with dogs that relapsed during treatment and in dogs initially diagnosed with stages III and IV disease. Moreover, the gain of CFA 31 was more frequent in dogs with a worse prognosis. Additional epigenetic modifications, such as methylation aberrations, were found to be associated with a more aggressive disease, worse clinical outcome, and unique patterns of gene expression.[5]

In humans, DLBCL is the most common type of lymphoma, encompassing 25–35% of all cases in Western countries and even higher in other countries.[94,97] DLBCL has always been considered a heterogenous disease and genomic technologies have identified multiple subtypes, including 16 distinct entities in the latest WHO classification.[94] The main variant is diffuse large B-cell lymphoma, not otherwise specified (DLBCL-NOS), which encompasses multiple subgroups with specific genetic, biologic, and clinical features. The two main subtypes are the GCB and ABC.[70,94] Clinical outcome is worse for ABC-DLBCL than for GCB-DLBCL patients and the distinction between them is considered mandatory.[52,94,96] Between 2018 and 2020, additional subgroups based on genetic lesions have been identified.[16,85,109]

Burkitt Lymphoma

In humans, Burkitt lymphoma (BL) and BLL are well-characterized diseases. However, in veterinary medicine, both entities are highly controversial, reported in dogs, and rarely in cats and pigs.

Clinical Features

Burkitt lymphoma is an aggressive B-cell malignancy reported to account for 4% of canine lymphomas.[44] Given its rarity, there is limited knowledge about its clinical behavior and response to therapy. It is described as having a rapid clinical course and affected dogs demonstrate generalized lymphadenopathy with variable extranodal disease at the time of diagnosis. One retrospective study reported a good response to chemotherapy with 26% of dogs surviving more than 2 years; however, dogs were not uniformly staged.[45] A recent work by the authors describes a series of dogs with BLL that demonstrate generalized lymphadenopathy present for a median of 20 days (range 7–90) with rare extranodal involvement. Despite treatment with CHOP-based chemotherapy or chemo-immunotherapy, overall prognosis was poor, with a median overall survival of 228 days and a median time to progression of 130 days (Front Vet Sci, 2021 Mar 17;8:647009. doi: 10.3389/fvets.2021.647009. eCollection 2021).

Pathologic Features

Histologically, both BL and BLL are challenging diagnoses. In 2014, a blinded group of veterinary pathologists with an expertise in hematopathology failed to consistently differentiate BL and BLL from DLBCL.[103] The architecture of affected lymph nodes is characterized by a diffuse proliferation of neoplastic cells that compresses

normal cells (Figure 69.11). Neoplastic cells are intermediate-sized (1.5–2 RBCs in diameter) with round to oval nuclei and a vesicular appearance. Cytoplasm is moderately abundant and with formalin fixation there may be slight cytoplasmic retraction, leading to squared-off edges between neighboring cells. Although three to five nucleoli have been reported in human BL, there are usually fewer in canine BLL with mild anisokaryosis. BL and BLL are highly proliferative and the mitotic rate is 10/HPF or greater. There are numerous tingible body macrophages (usually two to three times the number of mitoses) creating a starry-sky pattern. Liver, mesenteric lymph nodes, intestinal wall, and spleen involvement have been reported in the dog, but the histopathology of these lesions has never been described. Histologic differential diagnoses for Burkitt tumors include anaplastic forms of DLBCL, ALL, and LBL. The latter two can be differentiated based on nuclear features, namely, aggregated chromatin, parachromatin clearing, and small nucleoli in Burkitt tumors versus uniformly dispersed chromatin and obscured nucleoli in ALL and LBL. Cytologically, canine BLL is described as a monomorphic population of small (less than two RBCs in diameter) cells with a round, noncleaved nucleus, and deeply blue cytoplasm often with clear vacuoles. Nucleoli are often visible and multiple. Macrophages with tingible bodies are frequent causing the peculiar "starry-sky" appearance to the cytological smear. Mitotic figures are frequent. Using IHC, both BL and BLL stain strongly with CD20, CD79a, and PAX-5. Flow cytometry supports the B-cell origin with positivity to CD20, CD21, and CD79a, but, given the rarity of this lymphoma subtype, specific studies on cytological and flow cytometric are lacking.

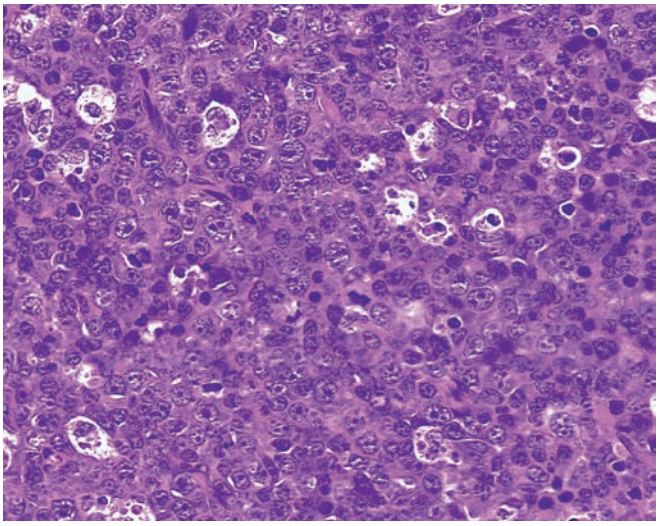

FIGURE 69.11 Lymph node from dog with Burkitt lymphoma. The node is characterized by intermediate to large neoplastic lymphoid cells with distinct cell borders, moderate anisokaryosis with cleaved or oval-shaped nuclei, and vesicular appearance. Numerous tingible body macrophages phagocytizing apoptotic debris and starry-sky appearance are present.

Comparative Features

Specific information on molecular or chromosomal changes in BLL in animals is lacking. In humans, BL comprises three epidemiological variants: endemic BL, sporadic BL, and immunodeficiency-associated BL.[94] The endemic BL is the most common form in equatorial Africa and in Papua New Guinea, where it is the common pediatric cancer. The geographical distribution of endemic BL overlaps with regions endemic for malaria, and, in almost all the cases, the lymphoma cells contain Epstein–Barr virus (EBV) genome. Although seropositivity for EBV has been reported in dogs and cats, the demonstration of viral DNA in lymphoma cells is missing. Sporadic BL is the most common variant in Western countries, but it accounts for only 1–2% of all lymphomas. Only 20–30% of sporadic cases are EBV-positive. Immunodeficiency-associated BL mainly occurs in patients with a severely compromised immune system, such as patients infected with human immunodeficiency virus (HIV), patients after organ transplantation, or patients with congenital immunodeficiency. Human BL is characterized by the presence of the t(8;14)(q24;q32) chromosomal translocation, juxtaposing the MYC oncogene into the immunoglobulin heavy-chain locus. Rare variants involve MYC and the immunoglobulin kappa or lambda loci.[42,84]

Acronyms and Abbreviations

BM, bone marrow; BMSC, bone marrow stromal cell; CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine); CD, cluster of differentiation; CEMP, cutaneous extramedullary plasmacytoma; CT, computed tomography; CP, cutaneous plasmacytosis; EMP, extramedullary plasmacytoma; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; HVS, hyperviscosity syndrome; IFE, immunofixation electrophoresis; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IRF, interferon regulatory factor; IRF4, interferon regulatory factor 4; MGUS, monoclonal gammopathy of unknown significance; MM, multiple myeloma; MRD, myeloma-related disorders; MRI, magnetic resonance imaging; NCEMP, noncutaneous extramedullary plasmacytoma; NFκB, nuclear factor kappa B; OAF, osteoclast-activating factor; PBSC, peripheral-blood-derived stem cell; PET, positron emission tomography; PFI, progression-free interval; PT, prothrombin time; PTT, partial thromboplastin time; RANK, receptor activator of the nuclear factor kappa B; RANKL, receptor activator of the nuclear factor kappa B ligand; REAL, revised European American Lymphoma classification; SOP, solitary osseous plasmacytoma; SPB, solitary plasmacytoma of bone; SSA, sulfosalicylic acid; TNF-α, tumor necrosis factor-α VAD, vincristine adriamycin (doxorubicin) prednisone; VBAP, vincristine BCNU adriamycin (doxorubicin) prednisone; VBMCP, vincristine BCNU melphalan cyclophosphamide prednisone; VEGF, vascular endothelial growth factor; VEGF-R1, vascular endothelial growth factor receptor 1; WM, Waldenström's macroglobulinemia; MHC, major histocompatibility complex.

Plasma cell tumors represent a spectrum of diseases characterized by clonal (predominantly monoclonal) proliferation of homogeneous immunoglobulin (Ig)-producing plasma cells or B cells.[41] They encompass clinically indolent conditions such as monoclonal gammopathy of unknown significance (MGUS) and Waldenström's macroglobulinemia (WM), as well as malignant processes including multiple myeloma (MM) and solitary plasmacytoma (solitary osseous plasmacytoma (SOP) and extramedullary plasmacytoma (EMP)). All these disorders share common cytomorphologic features, Ig production patterns, and immune dysfunction.

Five major classes of Ig—IgG, IgA, IgM, IgD, and IgE—are synthesized by normal B cells and plasma cells, whereas neoplastic plasma cells secrete one of these molecules or, occasionally, only light-chain molecules. When the production of heavy- and light-chain molecules is unbalanced, the excess of light-chain proteins is excreted in the urine (i.e., Bence Jones proteinuria). In non-secretory-type myeloma, plasma cells do not secrete these proteins.

MULTIPLE MYELOMA

Epidemiology

MM is estimated to account for <1% of all malignant tumors occurring in domestic animals and approximately 8% of all hematopoietic malignancies in dogs.[40,53] The true incidence of MM in cats is unknown, but it appears to be less common in this species, and it is extremely rare in other domestic animals.[20,62] In humans, more than 50% of MM patients are older than 70 years. Likewise, older dogs (average 8–9 years)[53,62] and cats (average 12–14 years)[31,62] are most affected.

Etiology

Factors associated with the development of MM in companion animals have not been clearly identified. In humans, exposure to ionizing radiation is consistently linked to MM development. Genetic and hereditary factors may also play a role. Recurrent infections or antigenic stimulation have been proposed as predisposing factors, although epidemiologic studies have not confirmed this association.

A link between MM and feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infection has not been identified, but the diagnosis of disease among siblings suggests a familial association.[31] The role of oncogenes, tumor-suppressor genes, and cytokines and their interaction with the bone marrow (BM) microenvironment in the etiopathogenesis of the disease are being investigated in animal models. Overexpression of cell cycle regulators such as cyclin D1 and dysregulation of receptor tyrosine kinase have been implicated in the pathogenesis of plasma cell tumors and MM.[10] Progression of B-cell lymphoma to MM in one dog and of solitary plasma cell tumors to MM in both dogs and cats has been reported.[66] Furthermore, rapid, aggressive progression of a cutaneous plasma cell tumor to plasma cell leukemia has been reported in a Bernese Mountain Dog.[70] MGUS, described as a premalignant condition, rarely progresses to MM.

Pathogenesis and Disease Evolution

Multiple myeloma is characterized by the proliferation of malignant plasma cells or their precursors, arising as a clone from a single cell. It is a germinal center-derived tumor with a B-cell phenotype and Ig gene hypermutation and rearrangement. MM is associated with a dysregulation of genes responsible for controlling cell growth and survival, resulting in a multistep process that involves alterations in oncogenes and tumor suppressor genes.[9] Alterations in molecular mechanisms of cell control have been implicated in the disease etiology.[10,42]

Like other lymphocytes, B cells do not have multilineage potential, but they can self-renew at multiple steps of development. These properties may be coopted by malignant plasma cells to maintain a "stem cell" phenotype. It has been demonstrated that memory B and T cells share common gene signatures with hematopoietic stem cells involved in the self-renewal process.[44] Multiple myeloma stem cells also may possess or acquire drug resistance: (1) by maintaining quiescence; (2) by increasing intracellular detoxifying enzymes; or (3) by expression of drug transporters on the surface membrane, as has been demonstrated for brain tumors and leukemic stem cells.[4,29] Stem cell signaling pathways also may support cancer stem cells; e.g., aberrant activation of the Hedgehog signaling pathway has been associated with the development of MM, and its inhibition induces plasma cell proliferation.

It has been hypothesized that a subset of MM may derive from MGUS. Furthermore, monosomy 13 seems to be implicated in the transition of MGUS to MM.[3] Interactions between cancer cells and microenvironment (bone marrow stromal cells (BMSCs) and extracellular matrix) are mediated by myeloma-cell-derived adhesion molecules, which are essential for tumor cell localization, growth, and survival. Moreover, increased microvessel density has been demonstrated in human patients with MM compared to patients with MGUS.[67,78] Immunohistochemical studies also have shown vascular endothelial growth factor (VEGF) expression by myeloma cells, thus implying the potential role and clinical relevance of angiogenesis in MM. While VEGF does not appear to have considerable proliferative effects on myeloma cells, it plays an important role in cancer cell migration and angiogenesis.[64,65] Indeed, myeloma cells have been shown to express the vascular endothelial growth factor receptor 1 (VEGF-R1), which may provide an interesting therapeutic target for emerging anti-angiogenic strategies.

The secretion of tumor necrosis factor-α (TNF-α) by myeloma cells not only stimulates the production by BMSCs of interleukin-6 (IL-6), an essential growth and survival factor for these cancer cells, but also induces nuclear factor kappa B (NFκB) activation leading to the upregulation of adhesion molecules.

Clinical Manifestations of Disease

The infiltration of various organ systems by neoplastic cells, the production of cytokines by the tumor or the bone marrow microenvironment, and the high circulating level of a single type of immunoglobulin (M-component) lead to a wide array of clinical manifestations. Multiple myeloma patients are usually immunocompromised and thus highly susceptible to infections. This occurs due to suppression of normal Ig concentrations secondary to a variety of factors, including a direct effect of the monoclonal Ig, bone marrow crowding, decreased T helper cell function, and macrophage-related factors influencing the progression of B cells to plasma cells.[59]

A variety of pathologic conditions are associated with MM, including bleeding diathesis, hyperviscosity syndrome (HVS), renal disease, cardiac disease, skeletal lesions, hypercalcemia, bone marrow hypoplasia, and hypercholesterolemia. The pathogenesis of bleeding diathesis is likely multifactorial. The M-component may interfere with normal coagulation

and lead to hemostatic defects by various mechanisms that include: (1) inhibition of platelet aggregation and release of platelet factor 3; (2) adsorption of minor clotting factors; (3) induction of abnormal fibrin polymerization; and (4) functional decrease in calcium.[45,73] Clinically, hemorrhages occur in approximately one-third of dogs and one-fourth of cats affected by MM.[31,53,62] In instances where myelophthisis is present due to profound bone marrow infiltration, thrombocytopenia may develop and contribute to hemorrhagic events. Approximately 50% of dogs affected by MM have abnormal prothrombin time (PT) and partial thromboplastin time (PTT). In a retrospective study of MM in 16 cats, thrombocytopenia was identified in just over 50% of the cats and one had evidence of a prolonged PT.[62] In another study of feline myeloma-related disorders (MRD), thrombocytopenia was identified in one of 15 cats. In the remaining cats, platelet counts were either within the normal reference range or deemed adequate on blood smears. PT and PTT were evaluated in two cats and were normal in both cases. None of the cats in this study had clinical evidence of bleeding tendencies, although subclinical coagulopathies may have been undetected.[11]

Hyperviscosity syndrome is characterized by clinicopathologic abnormalities that occur secondarily to increased serum viscosity, which is associated with the M-component. Hyperviscosity syndrome is most commonly associated with IgM macroglobulinemia due to the high molecular weight of IgM.[26] However, it also can occur in presence of IgA and rarely with IgG.[53] Hyperviscosity syndrome leads to bleeding diathesis, neurologic signs (such as seizures, depression, coma), congestive heart failure, renal failure, and ophthalmic abnormalities, including tortuous and dilated retinal vessels, retinal hemorrhages, and retinal detachment, sludging of blood within small vessels, and impaired delivery of nutrients and oxygen to tissues. Approximately 20% of dogs with MM develop HVS and it has been reported in a few cats.[11,62]

Renal disease occurs in approximately 30–50% of dogs and about 30% of cats with MM.[53,62] The pathogenesis of renal disease is likely multifactorial and implicated mechanisms include: (1) tumor infiltration within the renal parenchyma; (2) hypercalcemia; (3) amyloidosis; (4) decreased renal perfusion due to HVS; (5) dehydration; (6) ascending urinary tract infections; (7) Bence Jones proteinuria; and (8) development of light-chain casts causing interstitial nephritis.[53] Light-chain proteins have a low relative molecular mass and are normally filtered through the renal glomerulus. In MM, however, an imbalance between heavy- and light-chain proteins occurs, which leads to an excess of light chains that can precipitate and cause renal tubular obstruction and injury. In the absence of a concurrent monoclonal spike, light-chain proteinuria is most likely indicative of light-chain disease. Bence Jones proteinuria has been estimated to occur in approximately 25–40% of dogs and approximately 65% of cats with MM.[53,62] Urine protein electrophoresis remains the preferred diagnostic modality to detect monoclonal light-chain proteinuria.

Heart failure may occur because of hyperviscosity-related myocardial hypoxia and increased cardiac workload. In addition, amyloid deposition in the myocardium and anemia may exacerbate the severity of this condition. Approximately 50% of cats with MM in one study had an idiopathic heart murmur.[62] In another study, two cats exhibited signs consistent with heart failure prior to their MRD diagnosis.[11]

Skeletal lesions can be either solitary (well-circumscribed, "punched-out" area of osteolysis) or multiple (diffuse osteopenias) and occur in approximately 50–56% of dogs with MM.[53] Rarely, pathologic fractures are seen. Skeletal lesions are typically identified in bones involved in active hematopoiesis (e.g., ribs, vertebrae, pelvis, and proximal and distal aspects of long bones). In cats, the reported incidence of lameness or bone lesions ranges from approximately 7% to 67%.[31,57,62] In a study of MRD in cats, a pathologic humeral fracture was noted in one cat, although complete survey radiographs were not performed in all cases.[11]

Hypercalcemia has been reported in approximately 15–20% of dogs and 20–25% of cats affected by MM.[31,62,72] It is thought to result from the release of an osteoclast-activating factor (OAF) by either the bone marrow microenvironment or by cancer cells locally in bone.[53] Parathyroid-hormone-related peptide also may contribute to the pathogenesis of MM-related hypercalcemia.[69] In humans, IL-1, IL-6, TNF-α, and the receptor activator of the nuclear factor kappa B ligand (RANKL) all modulate osteoclast activity and may contribute to hypercalcemia. As the M-component may bind calcium, the functional consequences of an increased total calcium concentration should be evaluated using an ionized calcium determination.

Approximately 30% of dogs and 75% of cats have normocytic normochromic nonregenerative anemia associated with anemia of inflammatory disease, myelophthisis, hemostatic abnormalities resulting in blood loss, or increased RBC destruction induced by HVS.[53] In humans with MM, decreased erythropoietin responsiveness has been documented. Multiple myeloma-related thrombocytopenia and neutropenia can also be observed in cats and dogs.[31,62]

Hypocholesterolemia was noted in approximately 69% of affected cats in one study.[62] This finding was inversely correlated with globulin concentration and was suspected to be related to downregulation of hepatic cholesterol production in the attempt to maintain adequate oncotic pressure despite the presence of hyperglobulinemia.

Diagnosis

Diagnosis of multiple myeloma in dogs typically follows documentation of bone marrow plasmacytosis, presence of osteolytic bone lesions, and identification of M-component in serum or urine. In addition, demonstration of plasma cell clonality or progressive increase in the M-component can inform a diagnosis when lytic bone lesions are absent.[79] In cats, plasma cell morphology and visceral organ involvement are

considered for diagnostic purposes, as bone marrow plasmacytosis is not as common or marked as it is in dogs.[57,62] Symptoms suggestive of MM include the onset of bone pain or back pain, renal failure, anemia, and a history of recurrent infections. Patients exhibiting these signs should be evaluated with a complete blood count, serum biochemical profile, and urinalysis. Serum and urine protein electrophoresis should be performed in the presence of hyperglobulinemia and proteinuria, respectively, to confirm the presence of a monoclonal gammopathy and identify the class of Ig involved in the disease process. In patients lacking a hyperglobulinemia, serum protein electrophoresis may be insensitive for the detection of M-proteins.[70] In patients experiencing bleeding, a hemostatic profile should also be performed, and serum viscosity measurements considered. In dogs affected by MM, the incidence of IgA and IgG is comparable, whereas in cats, IgG is most commonly involved.[53,69,72] Rarely, occurrences of biclonal gammopathies have been reported and, on occasions, cryoglobulinemia has been described in dogs.[20]

Screening for Bence Jones proteinuria should not be based solely upon urine dipstick because this modality primarily detects albuminuria. The sulfosalicylic acid (SSA) test provides greater sensitivity for globulin detection, but specificity is low due to the concomitant detection of albumin, globulin, Bence Jones proteins, proteases, and polypeptides. In people, false positive results for Bence Jones proteins detected by means of heat precipitation can occur due to excessive amount of polyclonal light-chain proteins in patients affected by a variety of conditions, including non-plasmacytic tumors and chronic renal failure. Therefore, urine protein electrophoresis remains the preferred diagnostic modality for the detection of monoclonal light-chain proteinuria.

Bone marrow infiltration by MM can be quite variable, with many patients having an amount of plasma cells greater than 5%.[79] The appearance of malignant plasma cells can range from normal to mildly pleomorphic to bizarre and atypical forms. Plasma cell morphology can be an important predictor of severity of disease (Figure 70.1).[23] In humans, histopathologic grade is correlated with disease progression, with grade I disease being slow-growing in contrast to grade III disease (plasmablastic-type) having an aggressive behavior.[6]

Survey radiographs are typically recommended to screen for skeletal lesions. These vary from areas of osteopenia observed in early stages of diseases to lytic, "punched-out" lesions typical of later stages. Biopsy and histopathology of a lytic lesion may sometimes be necessary for a definitive diagnosis. Skeletal lesions are rare in patients with Waldenström macroglobulinemia where cancer cells more commonly infiltrate other organs, including liver, spleen, and lymph nodes.[26,34]

In cats, the frequent identification of abdominal organ neoplasia (85% of organs with an imaging abnormality) underscores the need to incorporate abdominal imaging as part of the routine staging (Figure 70.2).[57] In one study where liver cytology was performed in 10 of 15 feline MRD cases, plasma cell neoplasia was confirmed or suspected in 8 cases in the absence of liver enzyme elevation. In the same study, splenic cytology was positive or suspicious for plasma cell neoplasia in 10 out of 12 cases. One cat with confirmed splenic and hepatic involvement had no obvious abnormalities on abdominal ultrasonography.[11]

(**Source:** Photomicrographs courtesy of Dr. Laura Snyder, Marshfield Labs.)

A funduscopic examination should be performed to rule out ocular lesions, such as retinal hemorrhages, retinal detachment, venous tortuosity, dilation, sacculation, and blindness. Other conditions associated with monoclonal gammopathies that should be considered as differential diagnoses include lymphoproliferative disorders, such as lymphoma and acute or chronic lymphocytic leukemia, chronic infections (e.g., ehrlichiosis and leishmaniasis in dogs, and feline infectious peritonitis in cats), immune-mediated disorders, and other neoplastic conditions.[62]

Treatment

Treatment of MM with oral melphalan and prednisone is considered standard-of-care therapy in dogs. In cats, this combination appears to be more myelosuppressive than in dogs, potentially leading to treatment discontinuation. A recent study comparing the efficacy and toxicity of different chemotherapy protocols for feline MRD indicated that a combination of cyclophosphamide and corticosteroids was well-tolerated and could be considered as first-line treatment for cats with systemic disease.[11] In general, the goal of the treatment in any species is to reduce the bulk of the tumor and the symptoms of disease. Although complete eradication of disease is only rarely achieved, chemotherapy is often effective in decreasing tumor burden, reducing serum Ig levels, promoting bone remodeling, and providing symptomatic relief. Overall, this leads to improved quality and possibly duration of life.[53,54]

Melphalan is an alkylating agent whose oral absorption is unpredictable, requiring administration to be made preferably on an empty stomach. In dogs, melphalan is initially administered at 0.1 mg/kg orally once a day for 10 days, and then at 0.05 mg/kg orally every other day. Prednisone is generally administered at 1 mg/kg for the first 10 days of therapy, and then decreased to 0.5 mg/kg every other day. Treatment is continued indefinitely, until relapse or myelosuppression occurs. Possible myelosuppression is generally monitored via serial complete blood counts performed biweekly for 2 months and monthly thereafter. A pulse-dosing regimen, where melphalan is administered at 7 mg/m^2 orally for 5 consecutive days every 3 weeks, has been used successfully in patients experiencing dose-limiting thrombocytopenia with the more conventional low-dose treatment described in the earlier text. In cats, a dosing schedule similar to the one used in the dog has been reported.[17,31] An alternative protocol uses melphalan at 2 mg/m^2 every 4 days continuously.[57] In a study of feline MRD, melphalan was used at 2 mg/cat every 2–7 days, resulting in discontinuation of therapy in five cases due to grade 3–4 myelosuppression. In the same study, cyclophosphamide was used in some cases as first-line treatment at a starting dose of 25 mg/cat orally twice weekly. There were no cases where treatment was discontinued due to hematologic toxicity.[11]

Cyclophosphamide is an alkylating agent prodrug, which is activated in the liver into 4-hydroxycyclophosphamide and aldophosphamide. It is supplied as a sterile powder for injection and in tablet form for oral use. Due to its platelet-sparing effect, cyclophosphamide may be used in place of melphalan in thrombocytopenic patients, under careful monitoring.

Other alkylating agents including chlorambucil (leukeran) and 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU or lomustine) also have been used to treat MM in dogs and cats.[21] Chlorambucil, administered at 0.2 mg/kg orally once daily, has been used successfully for the treatment of IgM macroglobulinemia in dogs. CCNU has been used in cats at 50 mg/m^2 orally every 21 days, resulting in one partial response.[81] Combination chemotherapy protocols incorporating vincristine, carmustine (bis-chloroethylnitrosourea, BCNU), melphalan, cyclophosphamide, and prednisone (VBMCP) or vincristine, melphalan, cyclophosphamide, and prednisone/vincristine, BCNU, doxorubicin, and prednisone (VMCP/VBAP) have been extensively utilized in people, but outcomes are essentially comparable to those of patients treated with prednisone and melphalan alone.

Glucocorticoids have been shown to induce apoptosis in vitro via inhibition of IκB activation and decreased NFκB activity. The administration of high-dose dexamethasone in conjunction with vincristine and doxorubicin (VAD) was investigated in humans with refractory myeloma and resulted in a response rate greater than 50%. Rapid tumor response, alleviation of bone pain, resolution of hypercalcemia, and absence of cumulative damage to bone marrow stem cells were remarkable advantages of this treatment combination.[1,5]

Anecdotally, in dogs, responses of a few months duration have been achieved with a combination of doxorubicin (30 mg/m^2 intravenously every 21 days), vincristine (0.7 mg/m^2 intravenously on days 8 and 15), and prednisone (1 mg/kg orally daily).[79] Rescue approaches have been taken in dogs with refractory myeloma with high-dose cyclophosphamide (limited success) and liposome-encapsulated doxorubicin, which resulted in a durable remission in one dog.[37] A partial response to the tyrosine kinase inhibitor toceranib has been reported in a dog with refractory MM.[42]

The efficacy of interferon (IFN) for the treatment of MM is controversial. While a response rate of approximately 20% was reported in humans with relapsed myeloma, the addition of IFN to standard chemotherapy approaches failed to provide a significant benefit to the overall survival time in a meta-analysis of 2286 patients.[50] A monoclonal antibody-mediated delivery of IFNα has been developed to enhance tumor cell killing in MM and B-cell malignancies and has shown some promise in preliminary studies.[83]

High-dose chemotherapy in association with autologous transplantation using BM or peripheral-blood-derived stem cells (PBSCs) is now widely used for the treatment of hematological malignancies including MM.[22,32] This approach yielded complete remissions in refractory human patients, but mortality rate due to bone marrow suppression was high. Contamination of most bone marrow and blood stem cell samples with neoplastic cells has been shown in MM even after high-dose chemotherapy.[15,16,18,51] The presence of tumor cells within the autograft has resulted in recurrence of disease, emphasizing the need to optimize purging techniques.

In humans with indolent myeloma, treatment is generally withheld until disease progression, symptomatic manifestations, or new lytic bone lesions develop. However, bisphosphonates such as zoledronic acid have been used to prevent or delay the onset of bone lesions and associated bone pain. Denosumab is a human, monoclonal antibody of IgG2 class that binds to RANKL with high specificity and has been recently proposed as an alternative to bisphosphonates for myeloma bone disease.[76]

Treatment of human patients affected by indolent myeloma with the anti-angiogenic agent thalidomide resulted in a 66% response rate and the drug appeared to have potential to delay the onset of clinical signs associated with the disease. The efficacy of thalidomide for the treatment of refractory/relapsed MM has also been confirmed. The combination of thalidomide and dexamethasone has yielded response rates greater than 50% in patients with relapsed myeloma and 70% in newly diagnosed patients.[61,67,80] Studies evaluating the role and possible efficacy of thalidomide for the treatment of MM in pet animals are lacking.

Bortezomib, a proteasome inhibitor, induces apoptosis of MM cells and inhibits their binding to BMSCs, which otherwise would trigger the transcription of IL-6 via an NFκB-dependent pathway.[33] In a multicenter phase II trial of bortezomib, a 35% response rate was achieved with a median duration of remission of 12 months and an overall survival time of 16 months. Addition of dexamethasone to the treatment regimen improved responses in 19% of treated patients.

Response to therapy is assessed based on amelioration of clinical signs as well as improvement in the radiographic appearance of skeletal lesions and clinicopathologic abnormalities.[53] Because complete resolution of MM is extremely rare, a ≥50% reduction in the pretreatment of M-component (Bence Jones proteins or Ig) is considered a good response to therapy.[45]

Patients experiencing severe clinical signs secondary to hypercalcemia and renal impairment, HVS, or pathologic fractures may require additional therapy specifically directed to the clinical complications of disease. For example, fluid therapy and diuretics may need to be instituted for patients with severe hypercalcemia. Similarly, plasmapheresis may be beneficial in minimizing clinical signs of hyperviscosity, while aggressive fluid therapy may be necessary for patients with renal failure.

Prognosis

In humans with MM, the course of disease is extremely variable, with survival times ranging from less than 1 year with aggressive forms to more than a decade in indolent forms. Prognostic variables in people include: (1) tumor burden (serum calcium, immunoglobulin, albumin, α_2-microglobulin, number of lytic bone lesions, percentage of bone marrow plasmacytosis); (2) tumor biology (mitotic rate, IgA myeloma, plasma cell labeling index); (3) tumor microenvironment (bone marrow microvessel density and matrix metalloproteinase 9 level, among others); (4) treatment (12 months or less of prior treatment, achievement of complete remission, tandem transplantation, second transplantation within 6 months); and (5) patient (performance status, albumin level, other unrelated conditions). Beta-2 microglobulin has been consistently identified as a predictor of survival in MM. It is a light-chain protein belonging to the class I of histocompatibility antigens expressed on the surface of nucleated cells and released into the blood. Because beta-2 microglobulin is excreted by the kidneys, its level reflects tumor burden as well as renal function.[13,25]

In humans, a nodular pattern of bone marrow infiltration appears to be associated with a worse prognosis compared to a diffuse pattern.[5] In addition, severity of disease has been correlated with cell morphology. For example, plasmablastic disease has been associated with a more aggressive behavior of the cancer.

In dogs with MM, the short-term prognosis is good in respect to initial tumor control and improvement of quality of life. However, the long-term prognosis is generally poor due to high likelihood of tumor relapse and recurrence of clinical signs as well as development of resistance to chemotherapeutic agents. In a study of 60 dogs with MM treated with melphalan/prednisone combination chemotherapy, 8% did not respond to

therapy; 43% achieved complete remission (defined as normalization of serum Ig); and 49% achieved a partial remission (defined as less than 50% decrease in the pretreatment Ig level). The median survival time was 540 days. Negative prognostic factors identified in this study include presence of hypercalcemia, extensive bone lysis, and evidence of Bence Jones proteinuria.[53]

The reported median survival of cats with MM and other MRDs ranges from 4 months to greater than 1 year. [11,17,31,53,72] In a recent study of feline MRD, median survival was 252 days and 394 days for cats initially treated with melphalan and cyclophosphamide, respectively.[11]

IgM macroglobulinemia has been identified and treated only in a small number of dogs. In nine dogs treated with chlorambucil, 77% achieved remission and the reported median survival time was 11 months.[45]

SOLITARY AND EXTRAMEDULLARY PLASMACYTIC TUMORS

EMP is a neoplastic plasma cell tumor originating from soft tissues in the absence of primary bone marrow disease and both cutaneous (CEMP) and noncutaneous (NCEMP) forms have been described.[40,50] SOP or solitary plasmacytoma of bone (SPB) is an isolated lesion of bone origin with potential to progress to systemic MM.[46,56] Plasma cell tumors account for approximately 2.4% of all canine tumors and most commonly occur at cutaneous sites (86% of cases), followed by mucous membranes of lips and oral cavity (9%), colon, and rectum (8%). Approximately 22–28% of EMPs in dogs are located within the oral cavity.[14] Feline EMPs have been reported to occur in skin, upper lip, gingiva, orbit, gastrointestinal tract, brain, and retroperitoneal space, and their incidence appears to be low.[12,28,43,48,49,58]

The median age of dogs affected by plasmacytomas is 9–10 years and breed predispositions include American Cocker Spaniel, English Cocker Spaniel, and West Highland White Terrier. The median age of affected cats is 10.6 years, and the European Shorthaired Cat is overrepresented.[43,63] Individual cases have been reported in Abyssinian, Persian, and Burmese breeds.

Historically, EMP carries a better prognosis than MM. However, the biological behavior of EMP highly depends upon its anatomic location. For example, EMPs in cutaneous and oral cavity locations are generally associated with a low metastatic rate, and thus may be curable by means of surgery alone. Multicentric oral EMPs have been reported in a small number of dogs, both within the same location and a different location in the mouth.[74] Surgery remains the treatment of choice in these cases, if feasible. Intravascular neoplastic cells have been described in examined sections of canine cutaneous plasmacytomas in one study, more commonly in association with tumors of the distal limbs (36%) compared to other locations (11%), but this finding did not affect prognosis.[19] Progression of cutaneous EMPs to systemic disease has been documented in two cats, one of which developed MM, the other nodal and distant metastatic disease.[12,66] Noncutaneous and nonoral forms of EMPs typically have a more aggressive behavior. Gastrointestinal EMPs, affecting esophagus,[30] stomach,[47] small intestine,[36] and large intestine,[36,39,47] are frequently associated with lymph node metastases, although monoclonal gammopathies and bone marrow involvement are rare. Penile EMP has been reported in two dogs. One dog was treated with surgery and radiation therapy and remained free of disease for >1600 days.[82]

Solitary osseous plasmacytoma has been reported to occur in ribs and zygomatic arch of dogs. Solitary osseous plasmacytoma frequently progresses to MM, although this may take months to years to occur.[47,56]

Clinical Manifestations of Disease

Clinical manifestations are dependent on the anatomic location of the tumor. Cutaneous forms generally manifest as a solitary, raised, alopecic, smooth nodule 1–10 cm in diameter, and clinical signs of illness are typically absent. Bleeding from the mouth was the chief complaint in canine oral EMP. Gastrointestinal EMP is associated with nonspecific signs, whereas colorectal EMP often results in tenesmus, rectal prolapse, rectal bleeding, and hematochezia.[39] Pain, lameness, and neurologic signs may be observed in dogs with SOP affecting the appendicular or the axial skeleton.

Diagnosis

Fine-needle aspiration or biopsy is needed to confirm a diagnosis of SOP or EMP. Reclassification of reticulum-cell sarcomas as plasmacytomas has resulted in an increased incidence of this type of tumor in veterinary medicine.[14]

Plasmacytomas are generally characterized by a monomorphic population of plasma cells with occasional binucleate or multinucleate cells present. A polymorphic blastic plasma cell that appears to be associated with a more aggressive behavior in the dog has also been described.[10,39] Immunohistochemical detection of cytoplasmic Igs with predominant clonality for κ- or λ-chains is a common finding and 97–100% of EMPs are positive for λ-chain reactivity.[2,47] Moreover, monoclonal light-chain reactivity is helpful in differentiating plasmacytomas from other round cell tumors. However, Ig heavy chains (IgG and IgA chains) have been confirmed in other feline tumor cells, which often contain amyloid deposits. [12,43,49,63] Canine plasmacytomas stain positively for IgG, A, or M as well as cluster of differentiation (CD)45, CD18, CD45RA, and CD79a (Mb-1) leukocyte antigens. Immunohistochemical labels utilized in veterinary medicine also include multiple myeloma oncogene 1/interferon regulatory factor 4 (MUM1/IRF4) and CD20. However, the limited availability of antibodies for use in veterinary medicine makes characterization of normal and neoplastic plasma cells difficult. Using a standard flow cytometry panel, normal canine plasma cells typically have low to absent CD21 antigen

expression, and high CD45 and major histocompatibility complex (MHC) class II expressions.[70]

Cutaneous plasmacytoma cells frequently express monoclonal immunoglobulins and vimentin.[19] A divergent pseudoglandular configuration of cutaneous plasmacytoma has been described in dogs where pseudoglandular structures resemble neoplastic acini seen in epithelial tumors. In one study, these neoplastic cells were strongly immunopositive to MUM1 and immunonegative to pancytokeratin AE1/AE3.[55] While the cyclin D1 marker has been identified in MM, no association has been found that relates cyclin D1 to plasmacytomas. Interestingly, the identification of this marker in EMPs has been postulated to be a possible indicator of a highly aggressive malignancy or a metastatic lesion from MM.[10] Lymphocyte clonality testing is often used as an adjunctive tool to characterize lymphoid neoplasms.[77] It has also been utilized to provide evidence in support of a diagnosis of EMP.[70,75] Specifically, clonality testing based on the immunoglobulin heavy chain (IGH) gene has been described in canine and feline plasmacytomas. The sensitivity of detecting IGH clonality was examined in canine cutaneous plasmacytomas and frequency of detection was low, ranging from 0 to 34.5% in one study, possibly due to somatic hypermutation of the IGH locus.[75]

A complete staging should be performed before initiation of therapy to rule out systemic involvement, which, if present, would alter treatment recommendations and prognosis. Diagnostic modalities should include serum protein electrophoresis, skeletal survey radiographs, bone marrow aspiration, and cytology, particularly for SOPs and gastrointestinal EMPs due to their higher metastatic potential.

Treatment

Surgery is considered the treatment of choice for cutaneous plasmacytomas, and, on rare occasions, melphalan and prednisone therapy has been successfully utilized in canine and feline cases where surgery resulted in incomplete tumor margins or local tumor recurrence. Surgery is also recommended in patients with SOPs associated with a pathologic fracture or with neurologic compromise. Spinal cord decompression combined with removal of the primary tumor and spinal cord stabilization may need to be performed in selected patients. The efficacy of radiation therapy in palliating bone pain associated with the tumor itself and/or the presence of pathologic fractures has been reported; however, most patients eventually developed MM.[46,56]

In patients with SOPs and no evidence of systemic involvement, it is debatable as to whether chemotherapy should be instituted at the same time as local therapy. Likewise, gastrointestinal EMPs are managed solely with surgery, unless systemic disease is documented, in which case the incorporation of chemotherapy would be warranted. Mandibulectomy or maxillectomy is recommended for treatment of oral plasmacytomas accompanied by boney infiltration.[14] All dogs with oral plasmacytomas excised with incomplete surgical margins experienced local tumor regrowth in one study.[81] Periodic monitoring and restaging are pivotal in allowing early detection of tumor regrowth and metastatic disease.

Prognosis

Oral, cutaneous, and mucocutaneous plasmacytomas are associated with a good prognosis and can be cured by means of surgery alone, provided complete surgical margins are achieved.[10,81] Anecdotally, multiple plasmacytomas that eventually resulted in death of affected dogs have been reported. Tumor cell proliferation rate (based on Ki-67 staining) and histopathologic grade have not been found to hold prognostic significance in dogs or cats, although a more aggressive behavior has been attributed to a polymorphic blastic type of canine plasmacytoma.[10,48] Cyclin D1 expression and presence of amyloid also do not seem to have clinical significance.[10]

Radiation therapy is an effective treatment option for solitary plasmacytomas. This is most likely due to the high-grade nature of round cell tumors that makes them susceptible to therapy. Long-term survival times have been reported for dogs with gastrointestinal EMPs or EMPs affecting liver, uterus, or other abdominal organs, undergoing surgery and/or chemotherapy.[39,46,47] The median survival time of nine dogs with colorectal plasmacytomas was 15 months;[39] two dogs treated with surgery alone experienced tumor regrowth 5 and 8 months postoperatively. DNA aneuploidy and c-myc oncoprotein content of canine plasmacytomas were analyzed by means of flow cytometry and found to be predictive for survival; however, findings strongly correlated with noncutaneous forms of disease, suggesting that location of the tumor is a prognostic indicator of equivalent importance.[24]

In cats, prognostic information is limited mostly due to the rarity of these tumors and the related paucity of cases reported in the literature. In general, principles of therapy that apply to dogs should be also applied to feline patients.

CUTANEOUS PLASMACYTOSIS

Cutaneous plasmacytosis (CP) is a rare syndrome occurring in humans and recently described in dogs.[8] In people, CP is characterized by multiple cutaneous plasma cell tumors appearing as raised lesions or red-brown plaques without bone marrow, liver, spleen, and lymph node infiltration. Polyclonal hypergammaglobulinemia is a typical finding.[38] CP is generally considered a benign process with indolent behavior; therefore, therapy is usually reserved for patients with clinical signs (such as fever or lymphadenopathy) or compromised quality of life. Both topical and systemic treatments have been utilized for more aggressive cases with limited efficacy.[35]

In a recent study of canine CP, more than 50% of patients had 10 or more lesions, described as pink to red, raised, alopecic or ulcerated. Most patients were asymptomatic.[8] While the degree of staging varied among patients, confirmed or suspected regional lymph node or abdominal visceral involvement were reported in some cases. A polyclonal gammopathy was identified in two of three dogs in which total protein concentrations were elevated.[8] Histologically, tumors were characterized by dense sheets of anaplastic round cells with eccentric nuclei and marked anisocytosis and/or anisokaryosis. This is in contrast with CP in people, which typically consists of an expansion of mature plasma cells. Neoplastic cells were positive to plasma cell immunoreactivity (MUM1, lambda light chain, and CD79).[8] The most common first-line treatment consisted of melphalan chemotherapy with an overall response rate of 74% and a median progression-free interval (PFI) of 143 days. Median PFI after the first treatment for all treatments combined was 153 days. Median survival was 542 days, suggesting a fair to good prognosis with treatment despite a relatively short PFI. Treatment with a combination of an alkylating agent and corticosteroids seems appropriate first-line systemic treatment for cases in which locoregional treatment is inadequate or not feasible.[8]

WALDENSTRÖM'S MACROGLOBULINEMIA

WM is a rare lymphoproliferative, immunosecretory disorder occurring in dogs, cats, and humans. According to the WHO classification scheme, it is considered a form of lymphoplasmacytic lymphoma that involves spleen, bone marrow, and lymph nodes and can manifest with IgM-related signs of cryoglobulinemia or hyperviscosity.[7] This description corresponds to the lymphoplasmacytic type of immunocytoma incorporated into the Kiel classification and to the revised European American Lymphoma classification (REAL) lymphoplasmacytic lymphoma/immunocytoma. A consensus has not yet been reached among pathologists regarding the new classification, most likely due to the subjectivity involved in the distinction between small or plasmacytoid lymphocytes and plasma cells.

Waldenström's macroglobulinemia is characterized by bleeding tendencies, anemia, lymphadenopathy, and high-serum viscosity with a high-molecular-mass M-component, and is associated with a monoclonal expansion of B cells infiltrating the bone marrow or other lymphoid organs producing an IgM serum paraprotein. IgM consists of high relative molecular mass and positively charged proteins that can bind to RBCs leading to rouleaux formation. Waldenström's macroglobulinemia differs from MM in that bone lysis is generally absent and hepatosplenomegaly, lymphadenopathy, or both are frequently encountered clinical findings. Peripheral neuropathy, HVS, and HVS-associated complications, including retinal hemorrhage, epistaxis, cardiac and renal damage, and central nervous system abnormalities, can occur. In addition, IgM can cause immune-mediated disorders such as cryoglobulinemia, cold agglutinin hemolytic anemia, and peripheral neuropathies secondarily to autoantibody activity.[27,60] Bleeding diathesis has been reported to occur in approximately 33% of affected dogs and it is suspected to derive from the interference of IgM with clotting factors and/or platelet aggregation.[45] Possible laboratory findings in both humans and dogs include anemia, pancytopenia, leukocytosis or leukopenia, hypercalcemia, IgM hypergammaglobulinemia, and Bence Jones proteinuria.[27] In addition to WM, the production of IgM paraproteins has been reported in association with MM, chronic lymphocytic leukemia, splenic marginal zone lymphoma, extranodal marginal zone lymphoma, plasmacytoid lymphoma, and non-neoplastic conditions such as leishmaniosis.[7,27,45]

In human patients, findings that may aid in differentiating WM from other non-neoplastic monoclonal gammopathies or MGUS include the degree of bone marrow infiltration and the amount of M-component, and it has been suggested that the minimum threshold of IgM level is 30 g/L and the percentage of plasma cells in bone marrow is 20%.[40] Diagnostic features of this disease in dogs are still a matter of debate. Immunophenotyping and serum immunofixation electrophoresis (IFE) are often necessary to diagnose lymphoproliferative disorders more definitively in pet animals.

Treatment of WM is unlikely to provide a cure; rather, it is directed at diminishing tumor burden and alleviating clinical signs associated with the disease. Approximately 77% of dogs with IgM macroglobulinemia respond favorably to prednisone therapy combined with alkylating-agent-based chemotherapy, and median survival times range from 11 months to 14 months.[52] Chlorambucil is most frequently used in conjunction with prednisone, but melphalan and cyclophosphamide have also been shown to have activity against IgM macroglobulinemia.[27,40]

Acronyms and Abbreviations

HRS, Hodgkin/Reed–Sternberg; LP, lymphocyte predominant; WHO, World Health Organization; HL, Hodgkin lymphoma; CHL, classic Hodgkin lymphoma; NLPHL, nodular lymphocyte predominant Hodgkin lymphoma; HLL, Hodgkin-like lymphoma; HIV, human immunodeficiency virus; RS cell, Reed/Sternberg cell.

INTRODUCTION

Hodgkin lymphoma (HL) is a human lymphoid neoplasm most commonly affecting cervical, axillary, and inguinal lymph nodes. HL encompasses a number of subtypes, which are all characterized by variable numbers of a morphologically unique population of large and often multinucleated neoplastic cells. The nomenclature of these cells can be cumbersome and requires clarification. These cells, based upon their morphology, are termed lymphocyte predominant (LP) cells, Hodgkin cells, or Reed–Sternberg (RS) cells. Based upon morphologic similarities, the latter two are often combined and denoted as Hodgkin/Reed–Sternberg (HRS) cells. Similarly, LP cells may be referred to as lymphocytic and histiocytic (L&H) cells. Importantly, these cells are often surrounded by robust inflammation and represent a small component of the overall cell population.[6,7,21,22] In humans, viral disease such as Epstein–Barr virus and human immunodeficiency virus (HIV) have been implicated as causative agents for classical Hodgkin lymphoma (CHL).[7,21]

HISTOLOGY OF HUMAN HODGKIN LYMPHOMA

There are multiple classification schemes and thus subtypes of Hodgkin lymphoma. Like non-Hodgkin lymphoma, these subtypes differ in histomorphology, clinical characteristics, and immunophenotype. However, in all cases, the neoplastic HRS or LP cells are germinal center B-cells.[21,22] HRS cells and their lacunar variants (see in the following text) are found in CHL, whereas LP cells are found in nodular lymphocyte predominant Hodgkin lymphoma (NLPHL). On histologic preparations, RS cells are large cells with a moderate to often high nuclear to cytoplasmic ratio, blue-pink cytoplasm, and one or more lobulated nuclei with a single large nucleolus (Figure 71.1). Some binucleated cells appear to have mirror-image nuclei. Hodgkin cells are a variant of RS cells, but have a single, nonlobulated nucleus. Lacunar variants of HRS cells are also described and are an artifactual subtype related to tissue processing leaving thin, filamentous cytoplasmic projections to

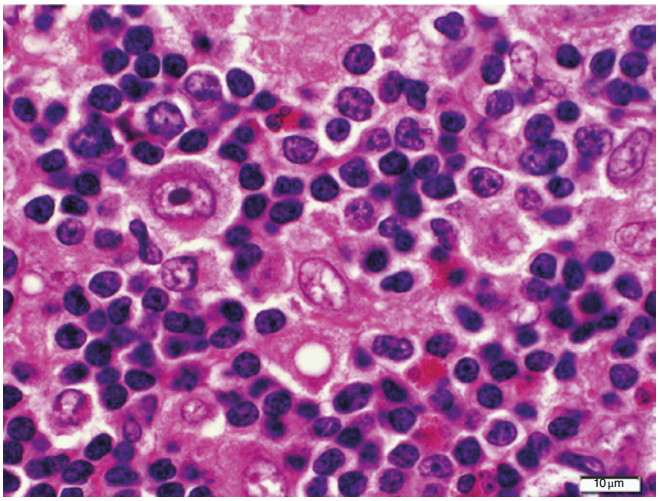

FIGURE 71.1 Human lymph node with CHL. HRS cells are noted among an inflammatory background of small lymphocytes and eosinophils. HRS cells are large and uninucleate to binucleate with large nuclei with open chromatin and often a prominent nucleolus. (**Source:** Slides from Cornell tutorial.)

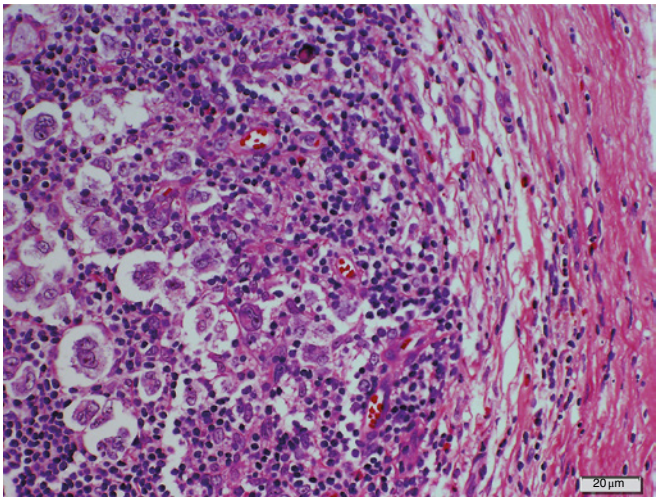

FIGURE 71.2 Human lymph node with nodular sclerosis CHL. Foci of lymphoid proliferation are accompanied by large numbers of lacunar-type Reed–Sternberg cells (left center; note areas of peripheral clearing). Note the prominent nucleoli in several of the Reed–Sternberg cells. The right side of the image is made up of broad bands of dense mature collagen separating the lymphoid nodules. H&E stain. (**Source:** Slides from Cornell tutorial.)

the cell margin and a clear space reminiscent of osteocytes in lacunae (Figure 71.2).[7,21] LP cells are smaller than HRS cells, have a moderate to high nuclear to cytoplasmic ratio, and have single lobulated nucleus. The lobulated nucleus of the LP cell explains why these cells are often termed "popcorn cells" (Figure 71.3).[6,22] HRS and LP cells can be misidentified as macrophages or histiocytic cells and, thus, immunophenotyping may be required for characterization.

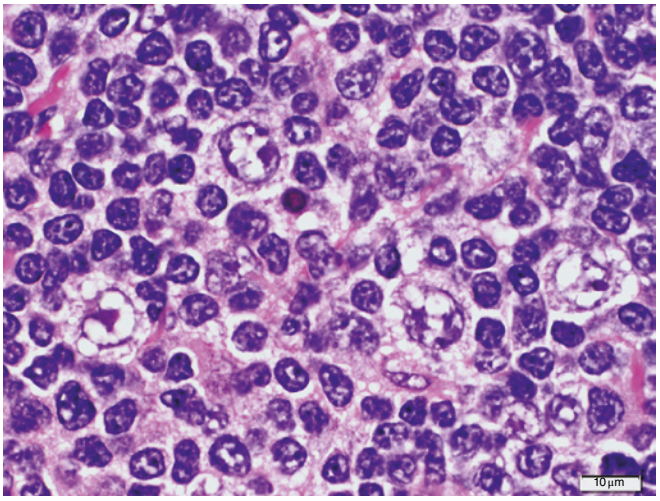

FIGURE 71.3 Human lymph node with NLPHL. Note many LP cells with a "popcorn cell" appearance among small to intermediate lymphocytes. IHC is necessary to differentiate lobulated RS cells and LP cells in some instances. H&E stain. (**Source:** Slides from Cornell tutorial.)

CLASSIFICATION OF HUMAN HODGKIN LYMPHOMA

The World Health Organization (WHO) classification of Hodgkin lymphoma includes two unique types: (1) CHL and (2) NLPHL. CHL contains four subtypes: (1) nodular sclerosis CHL; (2) mixed-cellularity CHL; (3) lymphocyte-rich CHL; and (4) lymphocyte-depleted CHL.[21] Each of these types and subtypes requires coordination of clinical and histological findings for diagnosis. Sometimes immunohistochemical (IHC) and other molecular techniques may be needed for an accurate diagnosis. A brief description of each type and subtype is provided in the following text; however, in-depth detail of the human disease is beyond the scope of this chapter and the reader is referred elsewhere for more information.[7,21]

Classic Hodgkin Lymphoma

CHL is characterized by low numbers of HRS cells within a background of mixed inflammatory cells.[1,21] Affected patients frequently demonstrate enlargement of cervical lymph nodes, although other peripheral lymph nodes can be involved. The disease is often slow growing and biologically indolent, but multiorgan metastasis (with infrequent bone marrow involvement) is described. Patients uncommonly present with primarily extranodal disease.[7]

Nodular Sclerosis CHL

This is the most common subtype of CHL, comprising more than 60% of cases. Affected patients present with enlargement of lymph nodes located above the diaphragm.[7] Histologically, this subtype is characterized by broad bands of collagenous connective tissue

separating nodular areas of lymphoid proliferation. The neoplastic RS cells are relatively numerous and are of the lacunar-type. These cells frequently have eosinophilic cytoplasm as the cells undergo necrosis. The nonneoplastic population consists of variable percentages of small and medium lymphocytes, numerous eosinophils, and neutrophils dispersed in a fine supporting fibrovascular network. In the most recent WHO classification, nodular sclerosis CHL was subdivided into two grades based upon the magnitude of lymphocyte depletion and percentage of anaplastic lacunar cells.[7,22]

Mixed-Cellularity CHL

This is the second most common subtype of CHL. Affected patients often present with systemic signs and disease.[7] Histologically, the minority population of RS cells tend to be of the classic type with binucleation and prominent nucleoli and the inflammatory infiltrate comprises a mixture of small lymphocytes with variable numbers of neutrophils, eosinophils, plasma cells, and macrophages. There is only fine fibrosis, but foci of necrosis are frequently present.[7]

Lymphocyte-Rich CHL

This is a recently described subtype of CHL, but shares some similarities with NLPHL.[7] It is characterized by a diffuse or nodular lymphoid proliferation with infrequent classical RS cells. In some instances, cells similar in morphology to LP cells can be present, necessitating IHC to differentiate lymphocyte-rich CHL from NLPHL in these cases.[7]

Lymphocyte-Depleted CHL

This is the least common subtype of CHL, representing approximately 1% of cases. This subtype affects older individuals that present with systemic signs and extensive, below-the-diaphragm, organ involvement, involving the liver, spleen, retroperitoneal lymph nodes, and bone marrow. Architecturally, the tissues are characterized by diffuse fibrosis of nonmature collagenous connective tissue with cell depletion mainly involving small lymphocytes. The RS may occur in clusters and in some cases display anaplastic features.[7,21]

Nodular Lymphocyte Predominant Hodgkin Lymphoma

NLPHL is a recently characterized subtype of Hodgkin lymphoma that demonstrates unique epidemiological, histological, immunological, and clinical characteristics. According to previous classification schemes, NLPHL may have been classified as lymphocyte-rich CHL. Patients generally present with persistent, slowly progressive peripheral lymph node enlargement, commonly affecting the axillary and cervical lymph nodes. Histologically, there is widespread disruption of the lymph node architecture by a diffuse, nodular, or a mixed infiltrate of small lymphocytes, histiocytes (some with epithelioid characteristics), and LP cells.[6,7,21,22] Six immunoarchitectural patterns of NLPHL are recognized and the reader is referred elsewhere for their description.[5,6,22] The LP cells are often present in easily identifiable numbers, but can be rare in some instances. Although typical LP cells are morphologically distinct from HRS cells, immunohistochemistry may be necessary for definitive differentiation.[6,7,21]

IMMUNOPHENOTYPE AND IMMUNODIAGNOSTICS

CD15 and CD30 are often useful and the most recognizable antigens used in the diagnosis of Hodgkin lymphoma.[7] The IHC detection of both antigens on HRS cells is expected in most cases of CHL. It is important to note that CD30 expression can be found in other lymphoid neoplasms and coexpression of CD15 can help improve specificity. Despite their B-cell origin, CD20 and CD79 positivity is infrequent in HRS cells, although PAX-5 is expressed in most cases of CHL. CD45 expression is generally absent in HRS cells. In NLPHL, the LP cells may demonstrate low to absent expression of CD30 and CD15 with consistent expression of CD20, CD79, and CD45.[6,7] Numerous additional IHC markers have been evaluated and the reader is referred elsewhere for this information.[6,7,10] The neoplastic B cells from both CHL and NLPHL demonstrate clonal somatic immunoglobulin gene rearrangement.[7,14,21]

TREATMENT AND PROGNOSIS

Prognosis is excellent for patients with CHL, with cure rates over 80%. Radiation therapy and surgical debulking are highly effective, although adjuvant chemotherapy may be needed. For NLPHL, there is disagreement regarding its optimal treatment and survival rates are quite variable, depending on stage and age at diagnosis. However, overall prognosis is considered good.[6] For more detailed treatment and prognostic information, the reader is referred elsewhere.[21]

DIFFERENTIAL DIAGNOSES

Histological mimics of CHL include subtypes of non-Hodgkin lymphoma, inflammatory/reactive diseases (such as infectious mononucleosis), and certain nonlymphoid neoplasms (e.g., metastatic carcinoma or melanoma). Specific neoplastic histologic differentials for CHL include B-cell lymphoma unclassifiable with features consistent with gray-zone lymphoma, primary mediastinal large B-cell lymphoma, diffuse large B-cell lymphoma, NLPHL, and anaplastic large-cell lymphoma. Extensive information is available on differentiating these from CHL.[6,7,21]

For NLPHL, histologic differentials include follicular lymphoma, peripheral T-cell lymphoma—not otherwise specified, lymphocyte-rich CHL, and follicular hyperplasia with progressively transformed germinal centers.

T-cell-rich/histiocyte-rich large B-cell lymphoma (TCRBCL) is an additional histologic differential for both CHL and NLPHL. Genotyping can be useful to differentiate it from CHL, but a distinction from NLPHL can be more difficult. Some have proposed that T-cell-rich/histiocyte-rich large B-cell lymphoma may exist on a continuum with, or represents an aggressive transformation of, diffuse NLPHL.[6,7] Notably, a similar dilemma exists in animals, in which it is unclear if T-cell-rich large B-cell lymphoma and Hodgkin-like lymphoma (HLL) are identical or distinct entities. Unfortunately, many antibodies used to distinguish these neoplasms in humans are not readily available in animals.

HODGKIN-LIKE LYMPHOMA IN ANIMALS

In animals, there is no definitive evidence for the existence of Hodgkin lymphoma as a distinct lymphoma subtype. Importantly, this absence of evidence, which in part results from a lack of a specific repertoire of diagnostic antibodies and the recognition that animal cases do not align with the human Hodgkin lymphoma scheme, should not be considered evidence of absence.[24] There are a number of case series and case reports in which affected animals demonstrate disease characteristics similar to Hodgkin lymphoma. Given this diagnostic uncertainty, affected animals are appropriately diagnosed with HLL. With only limited studies on species-specific reagents, the diagnosis of HLL in animals requires the constellation of clinical presentation, cytology, histology, and immunohistochemistry.[3,17]

Further muddying the diagnostic waters, the distinction between HLL and TCRBCL in animals is unclear. In humans, immunophenotyping and other molecular diagnostics are important tools used to make this distinction, particularly as TCRBCL can have large multinucleated cells resembling HRS and LP/L&H cells.[17,23] CD15 and CD30 expression patterns, among other IHC markers and genotypic evaluation, are helpful for this differentiation, but these are not all available in veterinary medicine.[23] In cats, one study has evaluated the preliminary use of CD30 in feline lymphoma, including its potential for the differentiation of HLL and NLPHL or TCRBCL; however, this is a preliminary study with only seven of 60 total lymphoma cases being diagnosed as either HLL, NLPHL, or TCRBCL and lacking clinical follow-up.[3] A single study identified CD15 and CD30 positive Reed–Sternberg-like cells in a dog with pulmonary lymphoid granulomatosis, concluding these atypical lymphoid cells were immunohistochemically similar to those in human primary pulmonary HL.[17] At the time of this chapter's preparation, a clear distinction between these two entities has not been realized and, as such, this review will focus on HLL. Among veterinary species, HLL is best described in cats, although partial and single animal reports have described HLL in dogs, horses, and ferrets.[2,4,9,11,12,15,16,20,23,25,27,28,30] There are rare case reports of HLL in nondomestic species.[13,19,29]

Cats

In published reports, the distinction between feline HLL and TCRBCL is not always clear and it is uncertain whether these truly represent two distinct lymphoma subtypes.[23,24,27] Notably, the authors of the largest (20 cases) review of feline HLL highlight that previous publications of feline TCRBCL report cases that are similar to human CHL and NLPHL.[4,20,27] Cats with HLL, similar to humans with HL, typically present with solitary, slowly evolving lymph node enlargement (often cervical) that may extend to contiguous lymph nodes (commonly prescapular or mediastinal lymph nodes).[27]

Single case reports of cats with an atypical clinical presentation of HLL based on the identification of RS-like cells outside the cervical or contiguous nodes on cytological or histological evaluation are reported. Specific examples include conjunctival, subcutaneous with spontaneous regression of disease, and primary cerebellar HLL.[9,16,30] It is challenging to determine from these single case reports if these are separate subtypes or later-stage presentations of HLL.

Cytological and Histological Findings

The lymph node cytology of feline HLL is characterized by a heterogeneous lymphocyte population that consists primarily of small- and intermediate-sized lymphocytes with scattered plasma cells, vacuolated macrophages, and small numbers of large RS-like cells. The RS-like cells are discrete, large (20–40 μm diameter), and contain a moderate amount of pale amphophilic to basophilic cytoplasm. These cells are binucleated or multinucleated with fine to coarsely granular chromatin and multiple prominent nucleoli (Figure 71.4).[23] Importantly, the lack of RS-like cells on cytologic preparations should not exclude a diagnosis of HLL, as they are a minor component of the lymphoid population and may be missed on sampling.[27] Accordingly, HLL can be challenging to diagnose by cytology alone. In these cases, the aspirates are often interpreted as reactive lymphoid hyperplasia with occasional histiocytes or "histiocytic" cells.[23,27]

Histology is necessary to definitively diagnose HLL (in cats and other species). Across all morphologic subtypes, the histology of feline HLL is analogous to human HL. Specifically, four histologic subtypes of feline HLL have been described that are similar to their human HL subtypes, namely: NLPHL, mixed-cellularity CHL, lymphocyte-rich CHL, and nodular sclerosis CHL.[23,27] However, these subtypes did not perfectly align with current or previous human histomorphologic classification systems.[23,27]

The neoplastic RS-like and LP/L&H-like cells of feline HLL comprise a minor component of the overall background inflammatory population. In feline HLL, the RS-like cells are morphologically similar to human HRS cells

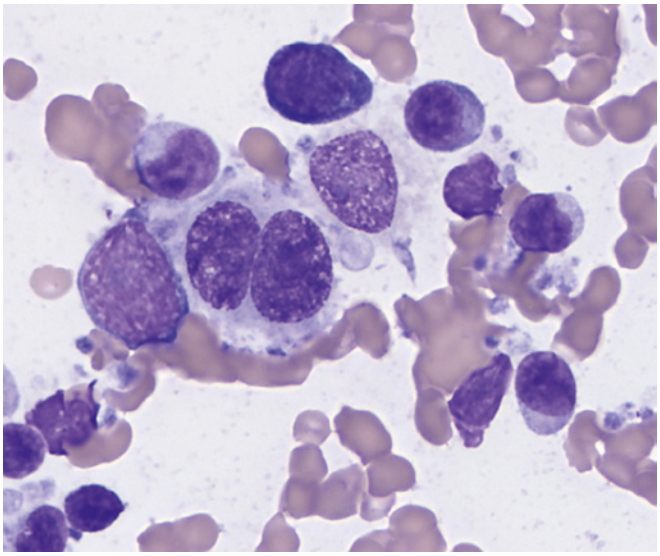

FIGURE 71.4 Fine-needle aspirate cytology sample from a cervical mass in a cat. Binucleate and large RS-like cell among small, intermediate, and large lymphocytes. Diff-Quik stain, 100× objective. (**Source:** Provided by Dr. Jennifer Steinberg.)

and the LP/L&H-like cells are similar to human LP cells. RS-like cells are large discrete cells (25 µm diameter) with a single large, pale, vesicular nucleus or larger (30–40 µm diameter) binucleated and multinucleated cells (up to five to six nuclei occasionally in rings) with sparse cytoplasm and rare mitosis (Figure 71.5).[23] LP/L&H like-cells display a delicate, multilobed nucleus resembling popped or exploded popcorn kernels (i.e., "popcorn cells").[23,27]

Immunohistochemistry is vital to the diagnosis of HLL.[23] In veterinary medicine, given the lack of general availability of CD15 and CD30, the detection of the RS-like cells, and thus the diagnosis of HLL, is based upon the identification of cells with HRS-like morphology that lack expression of CD18, CD3, CD20, and CD79a. One study evaluated the potential use of CD30 in the identification of RS-like cells and in the differentiation of classical HLL, NLPHL and TCRCBL in cats with initial positive results for the identification of RS-like cells and HLL, although further evaluation is needed.[3] LP/L&H-like cells are documented based on their morphologic characteristics and expression of CD20, CD45, and CD79a. The latter immunophenotype distinguishes them from HRS-like cells.[23,27]

Transformation and Prognosis

HLL in cats is largely considered an indolent disease. In one study, evaluating 20 cats with HLL, survival times in untreated cats ranged from months to 4 years.[27] However, additional studies and large case sets are needed to better define disease progression.

Dogs

In dogs, owing to the sparse published literature, there is limited understanding of the natural biology of canine HLL.[12,28] In one case report, a 3-year-old dog presented with cervical lymphadenopathy, vomiting, and diarrhea. Two months after presentation, the dog was euthanized, and necropsy identified numerous masses. Histologically, the masses were composed of a minority population of HRS-like cells among a majority background of small lymphocytes, globular leukocytes, eosinophils, and neutrophils. The HRS cells had inclusion-like and prominent nucleoli and mirror cells were identified. The HRS cells were negative for CD30 and CD15, but despite this the dog was diagnosed with HLL based on the appearance of the HRS cells.[12] In comparison to cats, dogs tend to have systemic involvement, including liver, spleen, lungs, and skin. Although additional cases are needed to better understand this disease process in dogs.[26]

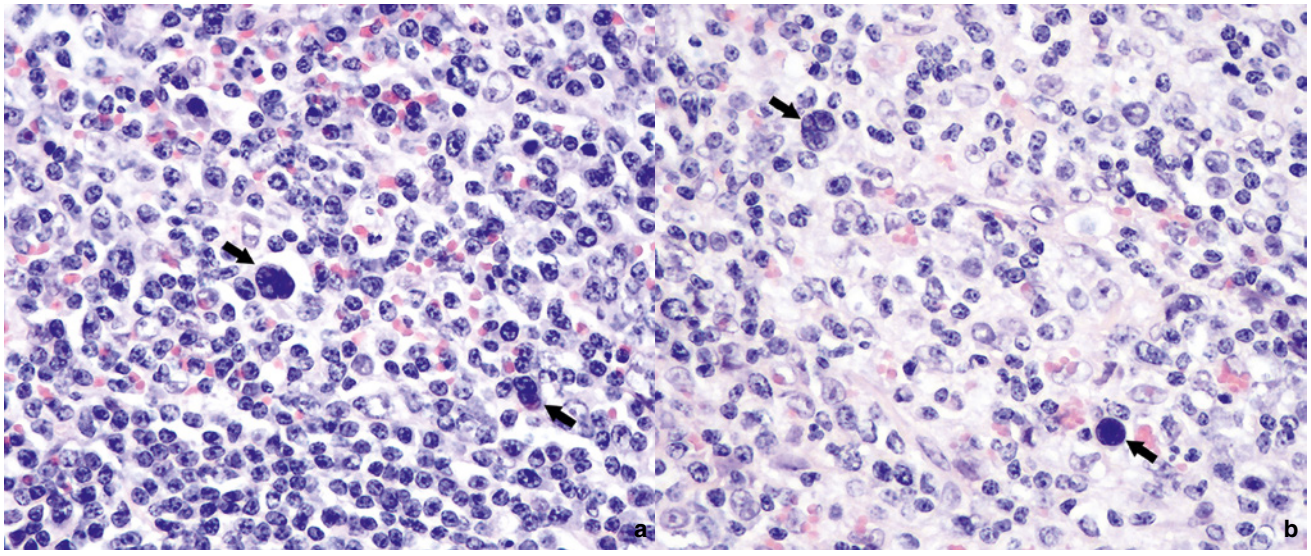

FIGURE 71.5 (a) and (b) Cervical mass histopathology from the same cat as Figure 71.4. Note large, binucleated, or multinucleated Reed–Sternberg-like cells (arrows) scattered among intermediate lymphocytes. H&E stain, 40× objective. (**Source:** Provided by Dr. Jennifer Steinberg.)

Horses

No explicitly diagnosed cases of HLL have been published in the horse. However, there are two publications of equine TCRBCL which have been erroneously cited as HLL.[8,11,16] Across both reports, affected horses commonly demonstrated subcutaneous disease with rare peripheral lymph node involvement. Histologically, the neoplastic infiltrate was composed of a minor population of large, pleomorphic B cells with large and often multiple nuclei with a vesicular chromatin pattern and multiple and prominent nucleoli. The more numerous background lymphocyte population was predominated by small T cells.[8,11]

Other Species

Other species with in which HLL has been reported comprise ferrets, skunks, a killer whale, transgenic mice, and rats.[2,13,18,19,29] Most of the affected animals had multifocal lymphadenopathy with HRS-like cells. The transgenic mice, interestingly, had HRS-like cells that were CD30 positive, had B-cell-derived IgH gene rearrangements, and somatic hypermutations that occur in germinal center B cells, similar to human HRS cells.[18]

INTRODUCTION

Compared to B cells, T cells are more diverse and have a multitude of functions including killing of infected/neoplastic cells, cytokine production, and immunoregulation. T cells are highly heterogeneous, and more than 100 antigens characterize different types with unique functions and anatomic locations. Each individual lymphocyte is antigen-specific and undergoes clonal expansion after responding to cognate antigen. Considering enormous clonal expansion and concomitant changes in gene expression during differentiation, lymphocytes may be particularly prone to acquire chromosomal translocations and oncogenic mutations that result in inappropriately regulated proliferation manifesting in neoplasms such as lymphoma or lymphocytic leukemia.[76]

Proliferations of B and T cells can be differentiated using flow cytometry and/or immunohistochemistry (IHC) to detect lineage-specific surface and/or cytoplasmic antigens. With IHC, T-cell neoplasms are defined by detection of CD3 (the T-cell signal transducer) and absence of B-cell antigens such as CD20, CD21, CD79a, and PAX5, and B-cell neoplasms by the converse constellation of antigens.[158,172] Formalin exposure alters epitope accessibility and conformation; and most antibodies directed to canine or feline lymphocyte epitopes recognize only native antigens on nonfixed cells such as detected in flow cytometry or frozen sections. Therefore, molecules characteristic of T-cell subtypes, such as CD4, CD8, and the T-cell receptor (TCR), are currently only identifiable on unfixed specimens. Major histocompatibility class II (MHCII) is expressed on lymphocytes but not neutrophils, while CD45, the common leukocyte antigen, is expressed on all leukocytes, and CD34 on leukocyte precursors (and non-leukocytes).[36,71,111,169]

Neoplastic T cells are characterized by clonal rearrangement of genes coding for the TCR, which can be detected by high-resolution analysis of DNA amplified from specific segments of the V, D, and J genes comprising the TCR. By itself, detection of clonally rearranged TCR (or B-cell receptor) genes may be insufficient to diagnose T-cell neoplasia, since cross-lineage rearrangement of TCR genes may occur in lymphocytes phenotypically of B-cell type, non-neoplastic T-cells in older dogs, and acute myeloid leukemia cells in dogs.[67,68,72,144,153] The fidelity of lineage-specific antigen detection on neoplastic T cells may be variable. For example, loss of cell surface CD3 may be observed in T-cell neoplasms positive for CD4, CD5, or CD8.[36,71] These findings emphasize the importance of diagnosing lymphoid neoplasms by appropriate combinations of microscopic assessment, immunophenotyping via a panel of antibodies, and assessment of clonality.

CANINE T-CELL NEOPLASMS

Compared to B-cell lymphoma, T-cell lymphoma is less common in dogs, accounting for 20–40% of all lymphomas.[105,116,126,153,158,163] Acute lymphocytic leukemia (ALL) is a rare diagnosis in dogs, and current information is based on individual case reports or retrospective small case series that lack assessment with a uniform set of diagnostic tests. Therefore, although T-acute lymphoblastic leukemia (T-ALL) was more commonly reported than B-acute lymphoblastic leukemia (B-ALL), evidence for higher frequency of either type is limited.[119,145,151,161,165] Among chronic lymphocytic leukemia (CLL) types, T-cell lineage is more common than B-cell lineage.[28,151,177]

There is genetic variation in the predisposition to B- versus T-cell lymphoma among breeds. For example, Basset Hounds and Cocker Spaniels are more likely to have B-cell lymphoma, while Boxers and Irish Wolfhounds are more likely to have T-cell lymphoma.[88,105,123]

Classification of T-Cell Neoplasms in Dogs

In 1994, the International Lymphoma Study Group proposed a revised World Health Organization (WHO) classification for human lymphoid neoplasms that combined morphologic, immunologic, and genetic assessment.[64] Revisions in 2001, 2008, and most recently 2016 have incorporated clinical features and new genetic and molecular knowledge.[149,150]

This WHO classification of human lymphoid neoplasms was adapted for dogs, and a similar classification that considers tissue architecture, location, and a limited array of IHC findings arose from a consensus study.[49,157,158,163] Accordingly, canine lymphoid neoplasms are also categorized broadly into precursor lymphoid, mature B-cell, mature T-cell, and natural killer (NK) cell neoplasms, and further classified into subtypes (Table 72.1).[150] Multicentric lymphoma is the most common form of T-cell lymphoma in dogs, and includes peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS), T-zone lymphoma (TZL), and T-cell lymphoblastic lymphoma (TLBL). Other relatively common T-cell neoplasms in dogs are T-chronic lymphocytic leukemia (T-CLL), epitheliotropic cutaneous T-cell lymphoma (CTCL), and enteropathy-associated T-cell lymphoma (EATL).

Precursor T-Cell Neoplasms

T-ALL and TLBL are precursor T-cell neoplasms with tumor burden predominantly in bone marrow, or lymph nodes and thymus, respectively. According to the WHO description, in humans a T lymphoblast is a small to medium cell with one or several nucleoli, scant cytoplasm that sometimes contains vacuoles, commitment to T-cell lineage as indicated by expression of CD3 and rearrangement of the TCR, and absence of differentiating antigens such as CD4 and CD8.[150,158] In veterinary medicine, the term lymphoblast is sometimes used to describe large lymphocytes with nucleoli.[12] This is inconsistent with the WHO nomenclature, and also inconsistent with the morphologic appearance of cells in cases of T-ALL (Figure 72.1a) in dogs. Therefore, it is recommended that lymphocytes be described according to morphologic appearance, and that the term "lymphoblast" be reserved

TABLE 72.1 The main T-cell lymphoma types in dogs according to the WHO classification.

Entity	Clinical features	Cytopathology	Histopathology	Immunophenotype[b]	Prognosis
Precursor cell neoplasms[a]					
T-ALL	• Usually bicytopenia or pancytopenia • Usually marked lymphocytosis	• Small to medium cells with one or several small nucleoli • Scant amount of cytoplasm	• Extensive bone marrow involvement • Myelophthisis	$CD34^+$, $CD3^+$, $CD4^\pm$, $CD5^\pm$, $CD8^\pm$, $MHCII^-$	• Limited data • Likely guarded
LBTCL	• Most often nodal followed by mediastinum or intestine • Frequent hypercalcemia	• Irregular-shaped nuclei, inconspicuous nucleoli • Frequent mitoses	• Diffuse effacement of lymph nodes • Irregular nuclei, frequent mitoses	$CD3^+$, $CD4^+$, $CD5^\pm$, $CD8^\pm$, $MHCII^{-/low}$ TCR αβ	• 1–4 weeks without therapy • 3–5 months with combination chemotherapy
Mature cell neoplasms					
CLL	• Mild to marked lymphocytosis • Cytopenias are rare • Often incidental diagnosis	• Small to medium cells • Nucleoli inapparent • May have cytoplasmic granules	• Splenomegaly due to hypercellular and expanding red pulp	$CD3^+$, $CD4^\pm$, $CD5^\pm$, $CD8^\pm$, $MHCII^+$, TCR αβ > γδ	• Survival typically years after diagnosis without therapy • Anemia and/or marked lymphocytosis at diagnosis are negative prognostic factors
PTCL-NOS	• Most often peripheral node enlargement • Variable duration of enlargement • May have hypercalcemia	• Pleomorphic cell appearance • Mostly medium cell size • Often pale cytoplasm • May have variable nuclei	• Diffuse lymph node effacement with variable extracapsular extension	$CD3^+$, $CD4^\pm$, $CD5^\pm$, $CD8^\pm$, $MHCII^{low/+}$	• Survival highly variable • CD4–/CD8+/MHCII+ and CD4–/CD8–/MHCII+ had better prognosis than other types
TZL	• Most often single enlarged node • Slowly progressive enlargement • Mild lymphocytosis	• Small to medium cells with dense nuclei • Characteristic unilateral cytoplasmic extension	• Paracortical expansion • Remnant small follicles at periphery of node • Cleaved or indented nuclei	$CD3^+$, $CD4^\pm$, $CD5^\pm$, $CD8^\pm$, $MHCII^+$, $CD45^-$, $CD21^{low/mod}$	• Survival typically >1 year without therapy • Survival may be >3 years
CTCL	• Skin or mucocutaneous junction nodules • Ulceration, erythema, hypopigmentation	• Pleomorphic cells • Frequent nuclear lobation, indentation	• Epitheliotropism in MF and PR • MF involves dermis • Epidermal changes • Non-epitheliotropic form is less common	$CD3^+$, $CD4^-$, $CD5^\pm$, $CD8^+$, $MHCII^+$, TCR αβ or γδ	• Limited data • 5–7 months with chemotherapy • 3–5 months without chemotherapy
HS-TCL	• Clinically ill patient • Peripheral lymph nodes not enlarged • Fever, anorexia • Anemia ± thrombocytopenia	• Medium to large cells • Cytoplasmic granules common • May see inflammation and hemic cell phagocytosis	• Neoplastic cells centered on hepatic sinusoids • Splenic red pulp effacement	$CD3^+$, $CD4^-$, $CD8^+$, $MHCII^+$, $CD11b^+$, TCR γδ, granzyme B^+	• Limited data • Most cases survival days to weeks
HC-TCL	• Jaundice, hepatic enzymopathy • Peripheral lymph nodes not enlarged	• Medium-size cells proximal to hepatocytes	• Invasion of hepatic cords • Cells may be intrahepatocytic	$CD3^+$, $CD4^-$, $CD8^+$, $MHCII^+$, $CD11b^-$, TCR γδ	• Limited data • Suggested survival weeks to months

[a] ALL = acute lymphoblastic leukemia; LBTCL = lymphoblastic T-cell lymphoma; CLL = chronic lymphocytic leukemia; PCTL-NOS = peripheral T-cell lymphoma, not otherwise specified; TZL = T-zone lymphoma; CTCL = cutaneous T-cell lymphoma; HS-TCL = hepatosplenic T-cell lymphoma; HC-TCL = hepatocytotropic T-cell lymphoma.
[b] The most common immunophenotype is indicated. CD3 may be present only intracellular and not on the cell surface.

for small to medium cells that have nucleoli and are positive for CD34, and either positive or negative for CD4, CD5, or CD8. Neoplastic cells in T-ALL and LBTCL are morphologically similar, and differentiation between T-ALL and LBTCL is based on predominance of neoplastic cells in blood and bone marrow versus in nodal and extranodal sites, respectively.[150]

T-Acute Lymphoblastic Leukemia

The diagnosis of ALL is based on presence of abnormal circulating lymphocytes, bone marrow effacement, cytopenia, and absence of nodal enlargement. While there is no agreed lower limit for the proportion of blasts in the bone marrow to confirm a diagnosis of ALL in humans or dogs, the threshold of >20% as recommended for acute myeloid leukemia in both species is likely appropriate.[96,150] Common clinicopathological abnormalities in ALL include thrombocytopenia, anemia, neutropenia, increased serum alkaline phosphatase activity, and hypercalcemia.[12] Once a diagnosis of ALL has been made, categorization as T-ALL depends on immunotyping and/or detection of a clonal TCR. Similar as in human T-ALL, membranous or cytoplasmic expression of CD3 is the hallmark of T-ALL, and if CD4, CD5, or CD8 is present (Figure 72.1b), PTCL with secondary leukemia should be considered. Presence of CD34 characterizes most canine T-ALL, while all are negative for the B-cell markers CD20, CD21, CD22, and CD79a.[12,146,150]

There is limited information on prognostic factors, response to therapy, and outcome for dogs with T-ALL. Lymphoblast phenotype plus CD34 detection was associated with worse prognosis than lack of CD34 detection in human ALL,[30,34,154] which may also apply to T-ALL in dogs.[171] Similarly, marked lymphocytosis is a negative prognostic indicator in humans, and was also reported to be an adverse predictor in dogs.[12,38,66,] However, T-ALL in dogs requires more precise definition, and analysis of outcome in relation to consistent assessment and treatment.

Lymphoblastic T-Cell Lymphoma

Lymphoblastic T-cell lymphoma (LBTCL) originates in either the lymph nodes or extranodal tissue, and accounts for approximately 4% of all canine lymphomas.[158] There is a higher prevalence of this lymphoma type in the Boxer breed.[88,89] Lymphocytosis may occur with LBTCL necessitating distinction from ALL. Primary tumors are most often in peripheral lymph nodes, but the mediastinum and gastrointestinal (GI) tract are also often affected.[89,106] Among dogs with nodal or extranodal lymphoma with concurrent lymphocytosis, lymphoblastic B-cell lymphoma (LBBCL) was slightly more common than LBTCL.[126,151,158] Hypercalcemia has been reported in 59–68% of patients with LBTCL compared to 12% with T-ALL.[12,89,106]

Cytologically, LBTCL consists of intermediate-sized cells with blue cytoplasm, irregular-shaped nuclei, inconspicuous nucleoli, and frequent mitoses (Figure 72.2). Histopathological findings in lymph nodes consist of a paracortical expansion of intermediate-sized lymphocytes that have indented nuclei with dense nuclear chromatin and indistinct nucleoli, and a high mitotic rate. Mitotic nuclei may be subtle due to limited staining of separated chromosomes, and there is complete effacement of the node with capsular thinning and focal perinodal extension.[20,158] Early in the disease process, LBTCL may be difficult to distinguish from the PTCL-NOS subtype, but the higher frequency of mitotic activity identified with an IHC stain such as Ki-67 is helpful. Immunohistochemistry is necessary to distinguish LBTCL from LBBCL due to their similar histological appearance.[158]

Lymphoblastic T-cell lymphoma cells are precursor cells, and most often are positive for CD3, TCR αβ, and CD4.[49] Phenotypes characterized by CD3, TCR αβ, and $CD4^+/CD8^+$ or $CD4^-/CD8^-$ or $CD4^-/CD8^+$ have also been described.[49] Distinction of LBBCL from PTCL-NOS may be challenging based on cytologic appearance, and histomorphology may be required.[89] Mediastinal LBTCL is most likely $CD3^+$, TCR $\alpha\beta^+$, and $CD4^+/CD8^+$.[81] In one study, low expression of MHCII in $CD4^+$ LBTCL was reported.[6] Immunophenotyping by flow cytometry is useful to differentiate mediastinal LBTCL from thymoma or thymic hyperplasia.[81]

A recurrent mutation deleting the CDKN2 locus that encodes the cyclin kinase inhibitors p16, p15, and the p53 regulator p14/ARF has been identified in LBTCL and other high-grade T-cell lymphomas; by contrast, this abnormality was not present in any B-cell or low-grade T-cell lymphomas.[47]

Lymphoblastic T-cell lymphoma is an aggressive form of lymphoma associated with a shorter survival than other forms of multicentric lymphoma. Boxer dogs diagnosed with LBTCL had a median survival time of 109 days (range 8–214 days; 34 patients). Most patients in that study were treated with combination chemotherapy, but a few received only prednisone monotherapy.[89] In another study, Boxers with T-cell lymphoma treated with combination chemotherapy had a median survival of 141 days (95% confidence interval [CI]) 115–167 days; nine patients).[58] Although histological classification was not reported, since Boxers primarily develop LBTCL, the results nevertheless support a relatively poor response to therapy.[88,89] In another study of lymphoblastic lymphomas (including LBTCL, LBBCL, and Burkitt lymphoma), a median survival time of 160 days (40 patients; range not provided) was reported; interestingly, in that study, survival time with only prednisone therapy was similar to no therapy, but combination chemotherapy prolonged survival time.[157]

Mature T-Cell Neoplasms

Chronic Lymphocytic Leukemia

CLL is a mature lymphocyte neoplasm primarily of adult dogs (typically 7–13 years old).[135,151,161] Across several studies, T-cell type accounted for 60–90% of all CLL, which usually had an indolent disease course.[135,151,161] In recent WHO classifications, the entity T-CLL in humans was reclassified as T-cell prolymphocytic leukemia,

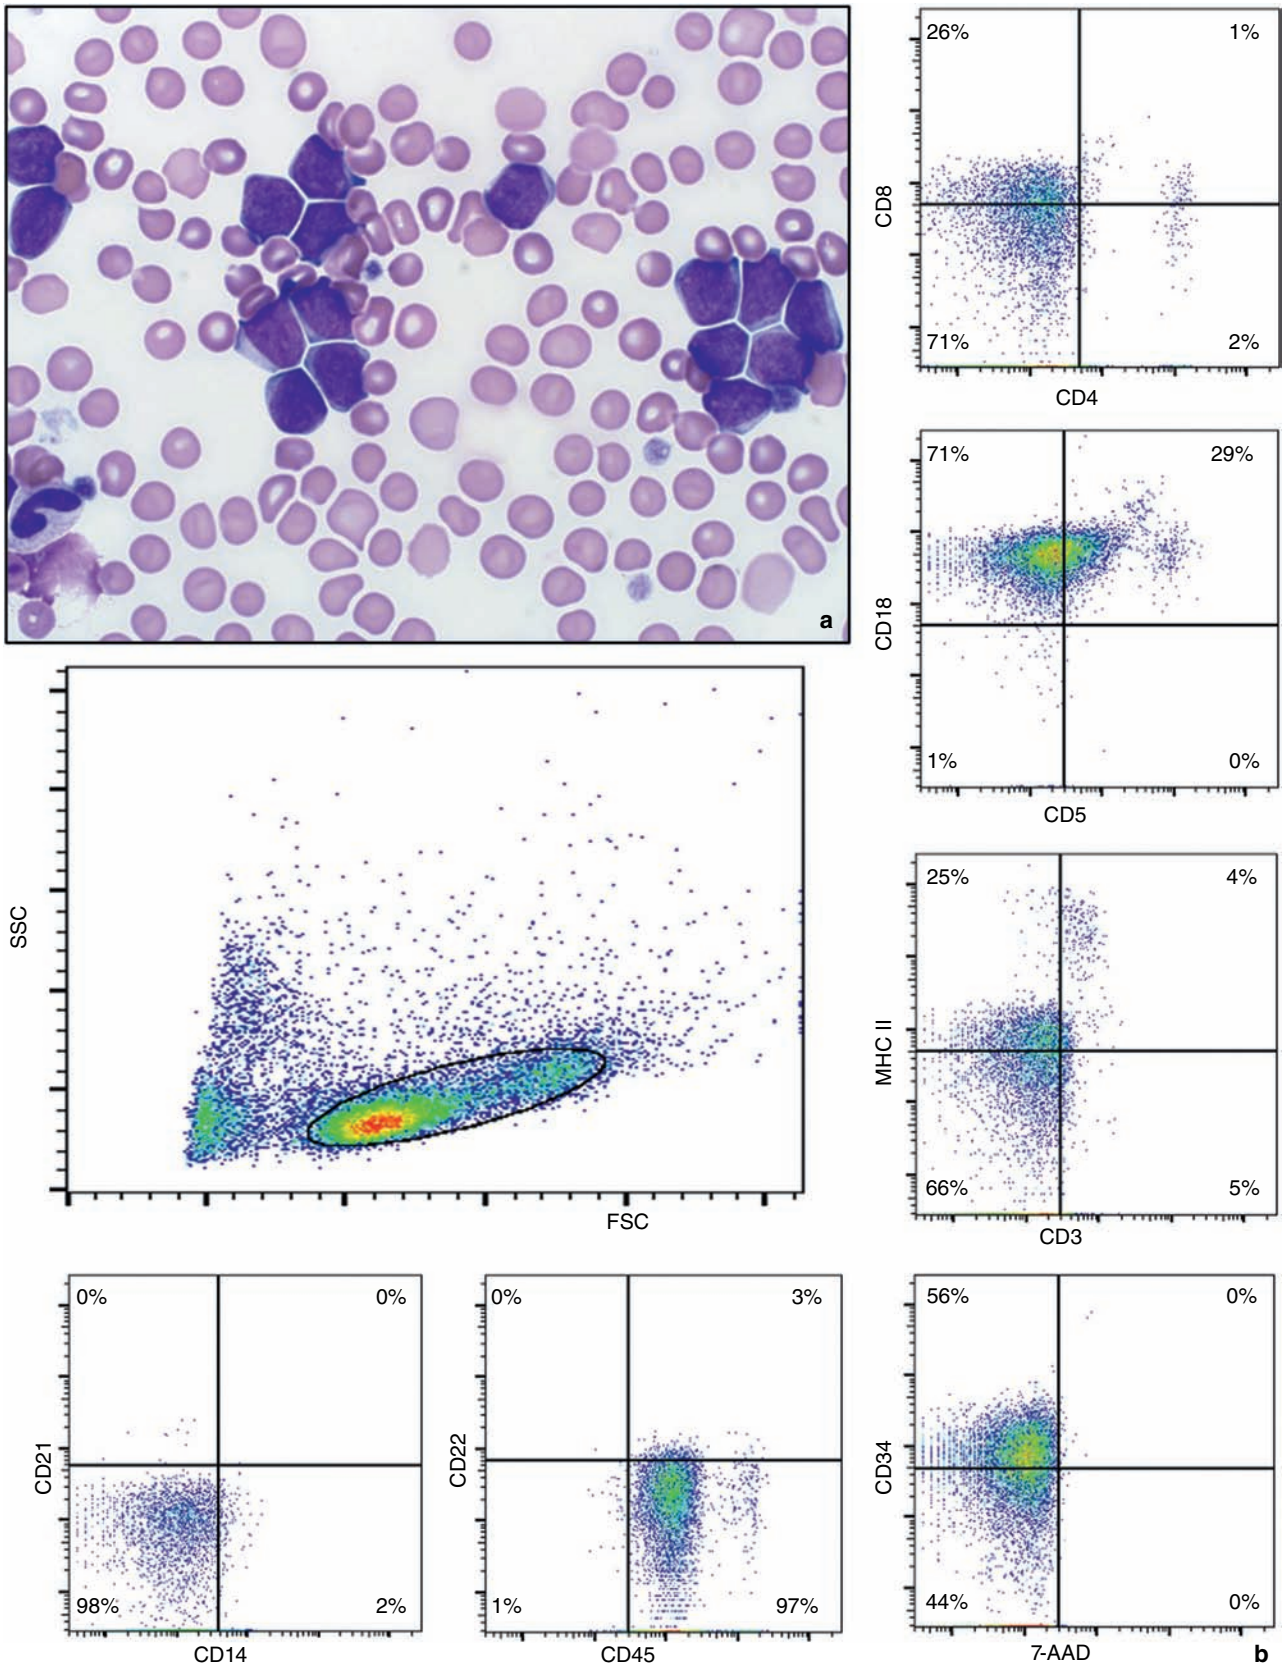

FIGURE 72.1 (a) Blood film from a 10-year-old Portuguese Water Dog with anemia and thrombocytopenia, and WBC count of 140.4 × 10^9/L. Lymphocytes predominate and are of medium size with a small amount of blue cytoplasm, irregular to angular-shaped nuclei with dense chromatin, and a single nucleolus; (b) On flow cytometric analysis, forward and side light scatter identify a population of cells with low side scatter. Cells are $CD3^{low}$/$CD5^{low}$/$CD8^{mod}$/$CD18^{hi}$/$CD34^{hi}$/$CD45^{hi}$/$MHCII^{mod}$. Interpretation: T-acute lymphoblastic leukemia (T-ALL). The dog was treated with combination chemotherapy and euthanized after 65 days due to disease progression.

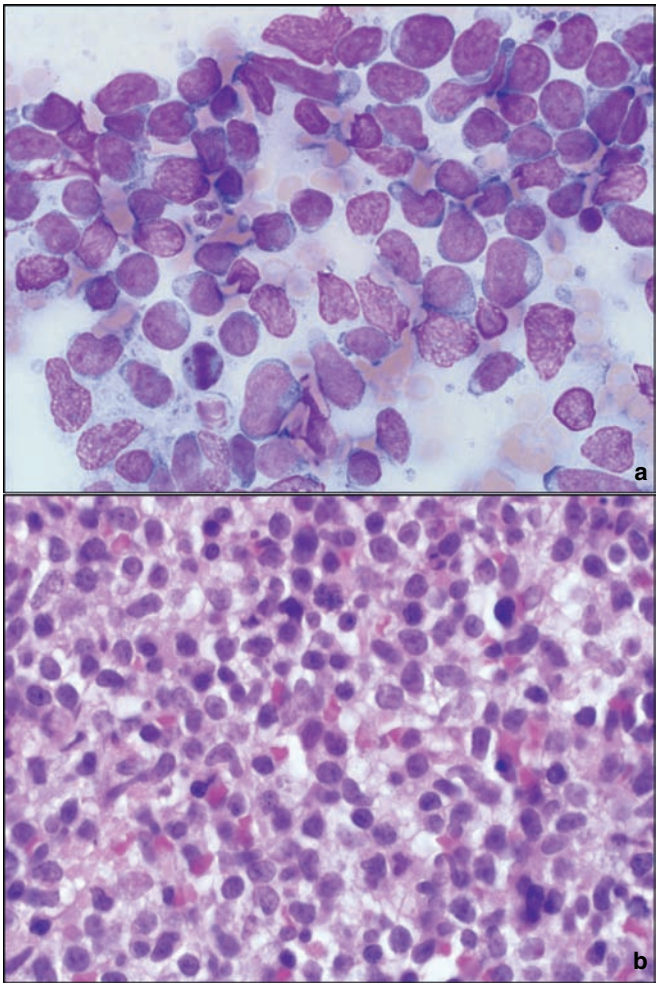

FIGURE 72.2 Lymph node aspirate and biopsy sections from a 7-year-old Boxer with hypercalcemia. The dog had multiple markedly enlarged lymph nodes. (a) Cytologically, the sample consists of medium-size lymphocytes with a small amount of dark blue cytoplasm, pleomorphic, including indented, nuclei and prominent small nucleoli; (b) Histologically, cells are also pleomorphic with round to angular to reniform nuclei, and small discrete nucleoli. On flow cytometric analysis, the cells were $CD3^{mod}/CD4^{hi}/CD5^{hi}/CD18^{hi}/MHCII^{low}$. Interpretation: Lymphoblastic T-cell lymphoma. The dog was treated with combination chemotherapy, did not achieve remission, and was euthanized 3 months after diagnosis.

which is a neoplasm with an aggressive disease course. Hence, despite similar presentation of an increased number of circulating small cells, canine T-CLL is biologically different than human T-cell prolymphocytic leukemia.[27,150,170]

Canine T-CLL is often an incidental diagnosis on a CBC obtained for preventative geriatric medical care. Absolute lymphocytosis typically consists of 10×10^9 cells/L to 50×10^9 cells/L, but numbers $>500 \times 10^9$ cells/L have also been reported.[27,146] The cells can vary in size from small to medium, and often contain subtle to prominent azurophilic cytoplasmic granules. Nucleoli are typically inapparent.[151] Most dogs present without cytopenia, or may have mild to moderate anemia or rarely thrombocytopenia.[151] Neither hypercalcemia nor hyperphosphatemia is a feature of T-CLL.[74,79] Splenic involvement is extensive in most cases and may result in splenomegaly, while bone marrow infiltration is sparse and likely occurs late in disease.[94]

Despite being distinguishable by cell and granule size, granular CLL is sometimes referred to as T-cell large granular lymphocytic (LGL) leukemia. This nomenclature is confusing. The originally described T-LGL is an aggressive type of lymphoma in dogs (and cats), usually of intestinal or peri-intestinal, and sometimes of mediastinal origin, which is often accompanied by low-grade leukemia.[94,120,142] The granules in these neoplastic lymphocytes are usually fewer in number and large, and the cells themselves are also large. Reasons for this mistaken nomenclature being applied to canine CLL may have resulted from its similarities with human LGL leukemia.[94,150]

Most T-CLLs consist of $CD3^+$ lymphocytes, although absence of cell surface of CD3 has also been reported.[27,151,161,170] Loss of cell surface CD3 expression occurs in several T-cell neoplasms and indicates the need to assess for other T-cell markers (i.e., CD4, CD5, CD8) or for intracellular CD3.[27] Markers that characterize most T-CLL are CD8 (consistent with the granular cytomorphology) and MHCII.[28,135,146,151,161] T-CLL variants without cytoplasmic granules appear to be inconsistently positive for CD4 or CD8.[161] Presence of the TCR αβ is more common than that of the TCR γδ.[161] Consistent CD11d (integrin $\alpha_d\beta_2$) expression by granular T-CLL cells aligns with origin of the neoplasm from splenic red pulp T-cells.[94]

T-CLL is an indolent neoplasm with a favorable prognosis characterized by median survival times of 930–1098 days.[27,170] Negative prognostic indicators include anemia and lymphocytosis $>30 \times 10^9$ cells/L at the time of presentation.[27,170] Malignant transformation of CLL to a more aggressive lymphoma is referred to as Richter's syndrome, which has been reported in humans and dogs.[29,150] In both species, this appears to occur more often with B-CLL but it has also been reported for canine T-CLL.[29,150]

Peripheral T-Cell Lymphoma, Not Otherwise Specified

PTCL-NOS is an umbrella category that consists of lymphomas that do not fit into other T-cell categories. "Peripheral" refers to any extrathymic location; however, multiple lymph nodes are most commonly affected in this form of lymphoma.[158] This subtype accounts for approximately 15% of all canine lymphomas.[157,158]

The cytopathology of lymphomas in this subtype varies. Medium-size cells with round to angular, pleomorphic nuclei and pale cytoplasm describe the most common manifestation (Figure 72.3), but types with cytoplasmic basophilia and granules, single or multiple nucleoli of variable prominence, and other features, have also been noted (Figure 72.4).[36] Accordingly, the histopathologic features of this subtype are also varia-

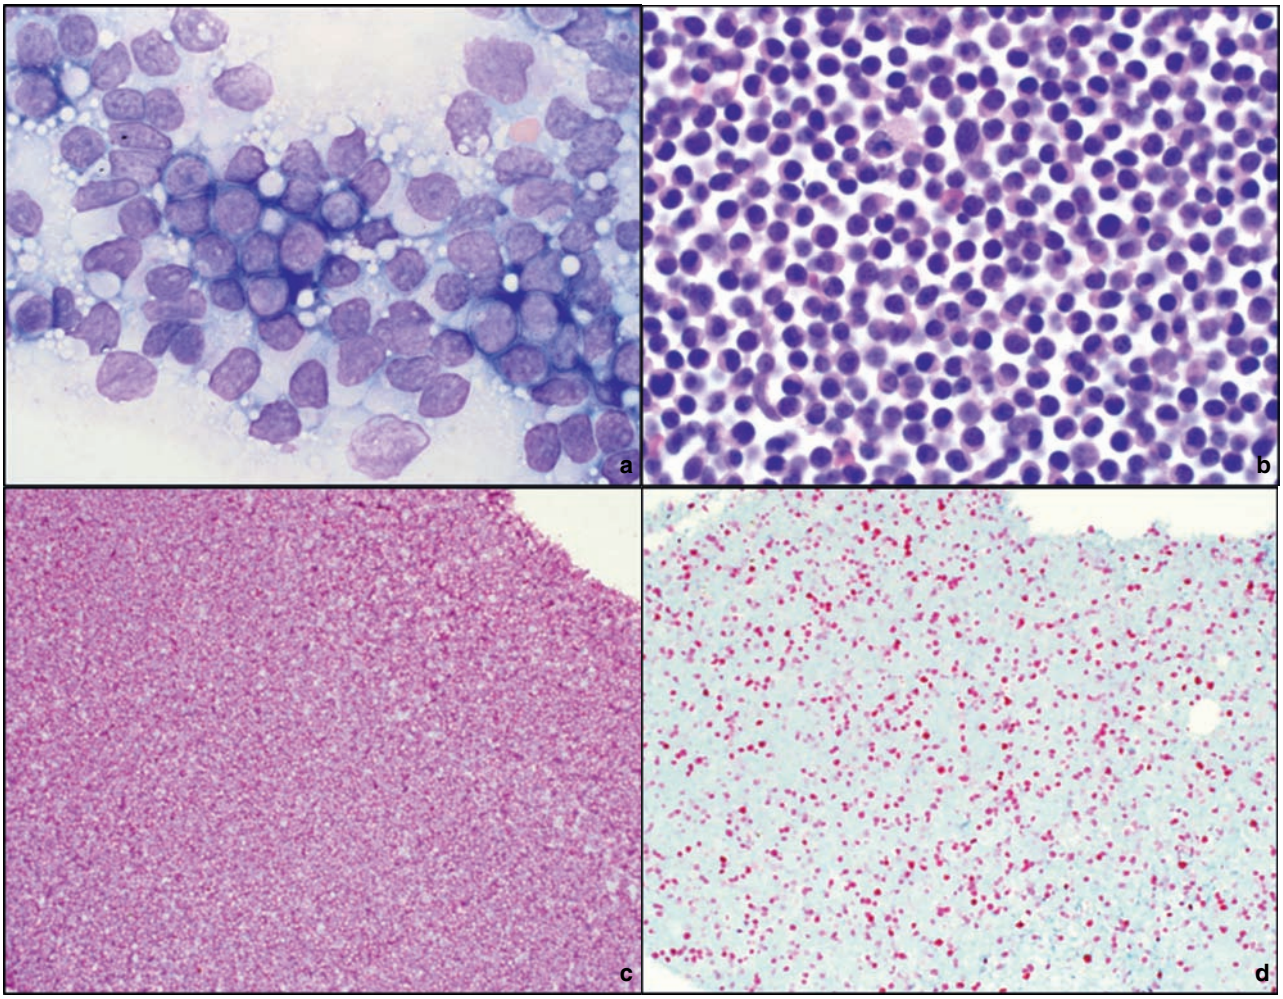

FIGURE 72.3 Lymph node aspirate and biopsy sections from a 13-year-old Poodle cross dog. The dog had a single enlarged prescapular lymph node for approximately 6 months. The lymph node continued to gradually enlarge to approximately 5 × 6 × 4 cm^3. (a) Cytologically, the sample consists of small- to medium-size lymphocytes with abundant watery blue cytoplasm, round to oval nuclei, and inapparent nucleoli; (b) Histologically, cells are uniformly round with round to slightly oval, often eccentrically located nuclei; (c) Cells are uniformly and strongly positive for CD3, and (d) 20–30% of cells are positive for Ki-67. On flow cytometric analysis, the cells were $CD3^{hi}/CD5^{hi}/CD8^{hi}/MHCII^{mod}$, consistent with PTCL-NOS. The dog was treated with lomustine and prednisone for 3 months, but the size of the lymph node continued to increase. Development of a hepatopathy 7 months after diagnosis prompted euthanasia.

ble. Most PTCL-NOS lymphomas consist of intermediate to large lymphocytes that diffusely efface lymph nodes, sometimes extending past the capsule and into the perinodal tissue.[63] The mitotic index is low to intermediate, but characteristic of this subtype is the relative absence of tingible body macrophages. Flow cytometrically, PTCL-NOS is characterized by positivity for CD3 and CD4, low to moderate MHCII, and frequent loss of CD5.[63] Some but not all dogs with this type of PTCL-NOS have hypercalcemia.[63] Variants with cytomorphologic features similar to late-stage/aggressive TZL or early/indolent LBTCL may be within this subtype.[158] Human PTCL-NOS has been further divided into distinct categories by immunophenotype and molecular features, and similar effort has characterized a few canine PTCL-NOS subtypes.[71,117,141,126,134] Histopathologically, $CD4^+/8^-$, $CD4^-/8^+$, and $CD4^-/CD8^-$ PTCL-NOS subtypes were not reliably distinguishable.[63] Potential cytopathological differences remain to be explored. The same recurrent mutation causing deletion of the CDKN2 locus in LBTCL has also been identified in high-grade PTCL-NOS.[47] Analysis of gene expression patterns in a limited number of $CD4^+/8^-$ cases of PTCL-NOS identified enrichment in a broad range of pathways.[63]

Although prognostic data including survival and response to therapy are of limited utility given the heterogeneous nature of PTCL-NOS, in one study a median survival of 162 days for high-grade PTCL-NOS was reported.[157] Subtypes with longer progression-free

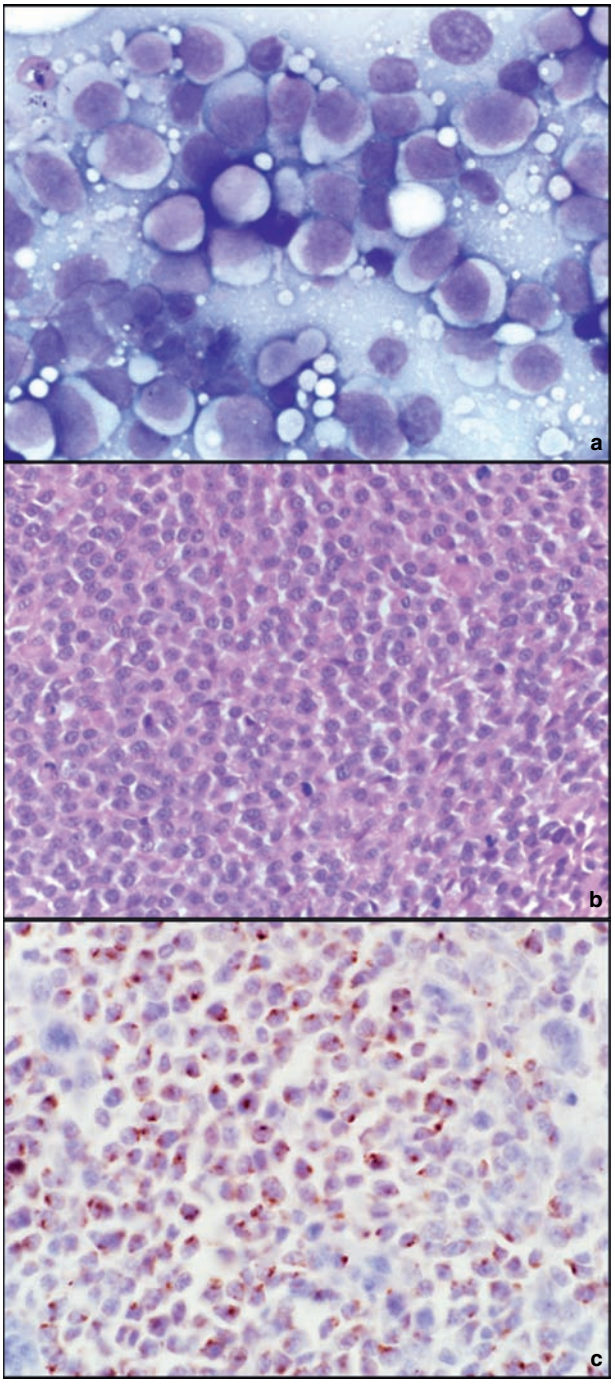

FIGURE 72.4 Lymph node aspirate and sections from a 9.3-year-old Mastiff with multiple moderately enlarged peripheral lymph nodes, lymphocytosis (12×10^9/L), and no clinical illness. (a) Cytologically, the lymphocytes are large with abundant pale blue cytoplasm, irregularly shaped nuclei, and a single small nucleolus; (b) On histopathology, lymphocytes are tightly packed, have a moderate amount of eosinophilic cytoplasm, uniform size, and three to five mitoses per 40× field; (c) On IHC, most cells have punctate positivity for granzyme B. By flow cytometry, cells were $CD3^{low}$/$CD5^{low}$/$CD8^{hi}$/$MHCII^{hi}$. Interpretation: PTCL-NOS. Two doses of doxorubicin induced no change in lymph node size or the magnitude of lymphocytosis. Treatment with lomustine resulted in remission. The dog died 20 months after diagnosis due to heart failure. Postmortem, there was no evidence of lymphoma.

interval and survival among PTCL-NOS were $CD4^-$/$CD8^+$/$MHCII^+$ and $CD4^-$/$CD8^-$/$MHCII^+$.[36]

Unclassifiable, High-Grade Plasmacytoid-Type Lymphoma Unclassifiable, high-grade plasmacytoid-type lymphoma is a rare form of PTCL-NOS in dogs and does not have an analog in the WHO classification of human neoplasms. Although these tumors cytologically resemble plasma cells, they express T-cell markers. Clinical presentation includes regional or generalized lymphadenopathy with hepatic, splenic, mediastinal, cardiac, bone marrow, and peripheral blood involvement. Hypercalcemia may be present. Survival appears to be short, even with chemotherapy.[10,49,125] Histologically, there are a large number of tingible body macrophages creating a characteristic starry-sky appearance.[125] Detection of CD3 and CD8 is characteristic, though coexpression of CD4 is also possible, but these tumors are multiple myeloma oncogene-1 (MUM-1)-negative.[10,49,125]

Renal T-Cell Lymphoma Renal PTCL-NOS is a rare but anatomically unique subtype of T-cell lymphoma that usually involves both kidneys. Neoplastic cells may be shed in sufficient quantity into urine to form the basis for diagnosis.[53,173] Several dogs with renal PTCL-NOS were polycythemic, which was attributed to tumor or increased renal interstitial cell erythropoietin production.[40] The disease course of renal PTCL-NOS appears rapid with typically extensive extrarenal involvement at the time of diagnosis.

T-Zone Lymphoma

TZL, formerly termed small clear cell lymphoma, is an indolent form of lymphoma that is common in dogs but not humans.[150,158] In dogs, it accounts for 3–12% of all lymphomas.[126,157,158] A predisposition has been suspected in Golden Retrievers and Shih Tzu dogs;[62,104,141] however, this may be linked to geographic location.[93] The prevalence of TZL in Golden Retrievers varies regionally within the United States, with dogs being diagnosed with TZL more often in the Northeast and East North Central regions than in other regions.[134] A postulated non-neoplastic counterpart of TZL cells (T-zone-like cells of undetermined significance; TZUS) was detected more often and in larger number in nontumor-bearing older Golden Retrievers (30.6% of individuals) than in dogs of other breeds (14% of individuals).[68] Furthermore, genetic analysis of TZL in Golden Retrievers identified single-nucleotide polymorphisms (SNP) on chromosomes 8 and 14.[80] The SNPs on chromosome 8 were in a region proximal to thyroid-regulating genes, and were suggested to contribute to a reduced risk for development of TZL in Golden Retrievers with hypothyroidism.[80]

Typically, a single peripheral lymph node is enlarged, although extranodal (lingual) TZL has been reported.[62] Cytologically, neoplastic cells typically have small round nuclei with dense chromatin and absent nucleoli. They have abundant pale blue cytoplasm that frequently extends asymmetrically into one direction producing a so-called "hand-mirror" appearance (Figure 72.5a).[178] It is

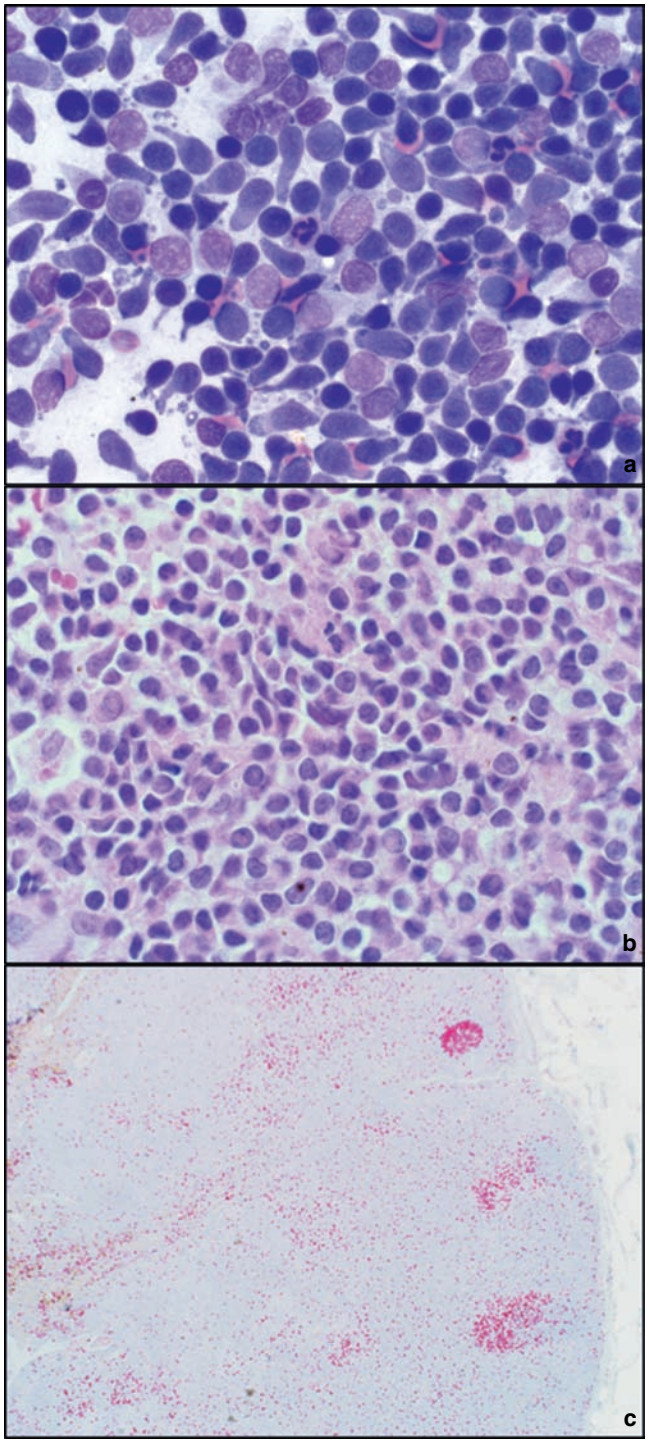

FIGURE 72.5 Samples from a 13-year-old Shih Tzu with incidentally identified bilateral mild mandibular lymph node enlargement and lymphocytosis (6×10^9/L). (a) The lymph node aspirate consists predominantly of round or elongate cells with dense, darkly stained chromatin. The cytoplasm is light blue, and many cells have a single cytoplasmic extension. Small centrally placed nucleoli are apparent in some cells. There are also larger cells with less darkly stained nuclei; (b) Moderately dense population of small to medium lymphocytes with oval to round nuclei, a central nucleolus, and angular cell shape; (c) Ki67 IHC highlights the follicles toward the periphery of the lymph node with higher mitotic activity than neoplastic lymphocytes in the paracortical region. Flow cytometrically, the lymphocytes were $CD3^-/CD5^{mod}/CD8^{hi}/CD18^{hi}/CD21^{low}/CD45^-/MHCII^{hi}$. Interpretation: T zone lymphoma.

important to note that such projections can also be seen in reactive lymphocytes or as an artifact of slide preparation. Histopathologically, there is an apparent paracortical expansion of small- to intermediate-sized T cells with moderately abundant cytoplasm, indented or cleaved nuclei, and indistinct nucleoli (Figure 72.5b). Instead of effacing the lymph-node architecture, these cells expand and displace nodal follicles until these are compressed against the capsule (Figure 72.5c). The capsule is minimally thinned, and neoplastic cells do not extend beyond the capsule. Mitotic activity is nearly absent among neoplastic cells and is lower than in remnant follicles.[158]

The TZL cells are consistently positive for cytoplasmic CD3, though cell surface CD3 may be low or absent.[36,44,158,159] Most TZL cells by flow cytometry are $CD8^+$, or $CD4^-/CD8^-$. Concurrent detection of CD4 and CD8 on neoplastic cells, or TZL that consists of subpopulations that are either $CD4^+$ or $CD8^+$ (likely two clones), has also been reported.[36,92,141] Cells of TZL are typically strongly positive for MHCII, which is a distinguishing feature from high-grade $CD4^+$ PTCL-NOS or LBTCL.[141]

Unique immunotypic features of TZL are absence of CD45 and faint to intermediate presence of CD21.[93,141] Absence of the CD45 antigen is due to reduced gene expression in neoplastic cells, and was also noted in presumed non-neoplastic TZL precursor cells.[68,91] Positivity for CD25 is an additional feature of TZL.[102,103] Whether absence of CD45 is a distinctive feature of TZL, or also occurs in other types of lymphoma, has been debated.[26,122] The vast majority of reports have attributed absence of CD45 on neoplastic lymphocytes to TZL.

Clinical disease is typically absent in dogs with this type of lymphoma. Forty-eight to 64% of dogs with TZL had lymphocytosis, and almost all had neoplastic cells in circulation.[44,92,104,141] Therefore, it is important to differentiate TZL from T-CLL, which may have similar cytomorphology. The presence of lymphocytosis does not appear to adversely affect survival.[44] TZL is associated with very long survival with and without chemotherapy. Median survival times ranged from 22.5 to 33.5 months.[44,92,102,159] In two studies, shorter median survival times of 55 and 180 days were observed in a few patients that were clinically ill at the time of diagnosis.[5,92] In a separate study, one of 16 dogs with TZL died due to progression of a concurrent diffuse large B-cell lymphoma (DLBCL).[102] In other studies, combination chemotherapy relative to no therapy provided no significant survival benefit for TZL and other indolent T-cell lymphomas.[36,157]

Cutaneous T-Cell Lymphoma

Cutaneous lymphomas are relatively uncommon extranodal neoplasms that, in both humans and dogs, have heterogeneous clinical presentations. Cutaneous lymphomas represent 1–2% of all canine skin tumors,[57,168] and are predominantly diseases of older animal with a mean age of 9–12 years.[35,108,111] Retroviral particles were noted in a cell line obtained from a dog with Sézary syndrome, but infectious agents have not convincingly been identified in canine lymphoma.[56] An association between

atopic dermatitis and cutaneous lymphoma has been noted in humans and dogs.[128,139]

Cutaneous lymphomas are subdivided into epitheliotropic and non-epitheliotropic forms based on the presence or absence of neoplastic lymphocytes in the epithelium of the epidermis and/or adnexa, respectively. Epitheliotropic lymphoma is more common than non-epitheliotropic lymphoma.[99] In both humans and dogs, T-cell origin is most common with denotation as CTCL.[35,111] Here, we have applied the WHO classification as a framework to organize the descriptive properties of CTCL in dogs, recognizing that not all of the current veterinary literature fits into this scheme. Entities in veterinary medicine with WHO classification counterparts are the epitheliotropic forms mycosis fungoides (MF), pagetoid reticulosis (PR) and Sézary syndrome, and the non-epitheliotropic form.

Cutaneous Epitheliotropic T-Cell Lymphoma Clinical features of MF and PR are variable and may consist of cutaneous nodules, generalized exudative dermatitis, and oral or mucocutaneous ulcers. The lesions were often associated with erythema, scaling, crusting, pruritus, ulceration, alopecia, hypopigmentation, plaque formation, and/or discrete masses.[45,108,168] Aspirates of discrete masses typically yield a uniform population of medium to large lymphocytes with roundish to irregular or lobulated nuclei (Figure 72.6), but do not allow distinction of subtypes of CTCL. Histopathologically, both MF and PR are neoplasms involving the epidermis, and MF also involves the underlying dermis.[16,35,45,108,133] Lymphocytes may form intradermal aggregates inaptly referred to as "Pautrier's microabscesses." Additional epidermal changes can include acanthosis, hyperkeratosis, spongiosis, ulceration, and secondary inflammation.[61] Prominent dermal involvement or invasion into the subcutis may be referred to as MF d'emblé or tumor-stage MF.[45,108]

Immunophenotypically, CTCL are $CD3^+$, and either $CD4^-/CD8^+$ (approximately 80%) or $CD4^-/CD8^-$ (approximately 20%). The TCR in MF cells is either αβ or γδ, but PR cells consistently express the γδ TCR.[108] Tumor cells are usually $MHCII^+$ and variably $CD5^+$.[36,111,108] Similar as in human CTCL, coexpression of CD3 and CD20 (a B-cell marker) has been reported in canine tumors.[14,41]

Most survival studies had low sample size and different therapies. Median survival was from 3 to 5 months without therapy or only prednisolone therapy, 6 months with lomustine therapy, 9 months with L-asparaginase therapy, and 11 months with synthetic retinoid therapy.[11,45,113,167] Surgical cure of solitary lesions has been reported.[45,168] Although lomustine therapy resulted in a 30% complete remission rate, differences in survival between dogs treated with lomustine, prednisolone, or no therapy were not significant.[45,85] A larger retrospective study (80 patients) showed median survival of 207 days with chemotherapy and 64 days without chemotherapy.[22] Patients with solitary lesions survived longer (median 231 days) than those with multiple lesions (median 104 days).[22] Of interest, patients with mucocutaneous/mucosal epitheliotropic lymphoma had a median survival of 490 days.[22]

Sézary Syndrome Sézary syndrome is a progressive form of MF defined by skin lesions similar to CTCL, generalized lymphadenopathy, and neoplastic T cells in lymph nodes and peripheral blood.[150] Sézary syndrome is rare in both humans and dogs.[48,56,136] Circulating neoplastic cells are usually recognized as abnormal on blood film review. Histologically, skin lesions are similar to those of MF.[48,56,136,150] The immunophenotype of canine

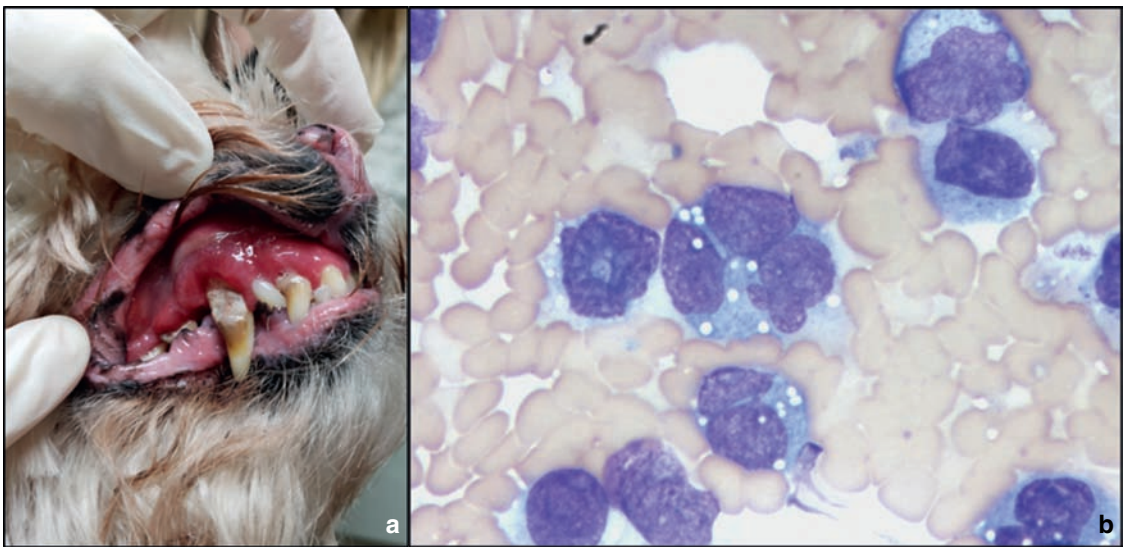

FIGURE 72.6 (a) Dog (13 years) with masses at the mucocutaneous junction, gingival disease, and planum depigmentation; (b) Aspirate of a mass consists of large lymphocytes with irregular, indented, or multilobed nuclei, pale blue cytoplasm, and cytoplasmic vacuoles. Histopathologic diagnosis: Epitheliotropic CTCL.

Sézary syndrome cells is not well described, but appears to be $CD3^+$ and $CD4^-/CD8^+$, similar to MF.[48,56,136]

Cutaneous Non-Epitheliotropic T-Cell Lymphoma Non-epitheliotropic lymphoma is the least common type of cutaneous lymphoma in dogs, and both B-cell and T-cell types have been reported.[2,77,109,129,155] Clinically, these can present similar to epitheliotropic canine CTCL, with frequently affected sites including the face, lower extremities, neck, and trunk.[109] Cytologically, non-epitheliotropic CTCL does not have distinctive features, but some forms have an extensive and pleomorphic inflammatory component. Histopathological findings are highly variable but characterized by dermal infiltration of large, atypical lymphocytes with minimal or absent epidermal involvement. Detection of CD3 can be variable or absent, while CD18 and CD45 are uniformly detected, rendering distinction between atypical lymphocytes and histiocytes challenging.[8,109] Limited information is available regarding additional immunophenotypic characteristics, though a few $CD4^-/CD8^+$ and $CD4^-/CD8^-$ tumors have been reported along with variable detection of CD5.[8,110]

Too few cases have been reported for meaningful survival analysis, but in one study six patients died from the disease after a median survival of 9 months, while one dog survived 3 years.[109] These findings suggest marked variation in the biology of non-epitheliotropic CTCL.

Enteropathy-Associated T-Cell Lymphoma

EATL refers to a primary lymphoma of the gastrointestinal tract. It is a relatively uncommon form of lymphoma in both humans and dogs, comprising 5–10% of human non-Hodgkin lymphomas and 5–7% of canine lymphoma.[31,37,150,163] The most commonly affected site in both dogs and humans is the small intestine, though EATL also occurs in stomach and colon.[31,33,51,52,150] In humans, EATL has been linked to celiac disease, though a similar correlation has not been identified in dogs.[150,164]

Grossly, GI lymphoma can be focal or multifocal, with thickening and ulceration of the intestines.[33] EATL is divided into types 1 and 2. EATL type 1 is more common in dogs and involves transmural infiltration by lymphocytes that are generally large and anaplastic. EATL type 2 involves discrete, patchy to complete effacement of the lamina propria by small, cytologically unremarkable lymphocytes that can be difficult to differentiate from reactive lymphocytes.[160] Epitheliotropism, including the presence of intraepithelial nests of five or more lymphocytes, occurs in 60–75% of EATL, and is helpful in differentiating EATL type 2 from inflammation.[33,82,160] In three cases, EATL type 1 cells were positive for CD3 and CD20 and had clonally rearranged the γ chain of the... TCR, implying that these were indeed EATL, and that CD20 should not be used to differentiate between T- and B-cell origin at this anatomic location.[118]

Very few studies have examined the immunophenotype of canine EATL. In one study, tumors were $CD4^+/CD8^-$ with γ TCR rearrangement.[36] This is different from human EATL, which is typically $CD4^-/CD8^+$ or $CD4^-/CD8^-$ with αβ TCR expression.[150] It has been suggested that EATL type 1 and 2 may differ in the frequency of cells positive for the transcription factor FOXP3.[90]

Most dogs with EATL type 1 have a grave prognosis, with reported median survival times ranging from 13–62 days, which may be skewed by a diagnosis late in the disease course.[36,51,143] On the other hand, dogs with EATL type 2 without treatment had a median survival of 279 days, and dogs treated with chemotherapy had median survival of 628 days.[32] In another study, a median survival of 424 days with therapy was noted.[82]

Subcutaneous Panniculitis-Like Lymphoma

In humans, subcutaneous panniculitis-like lymphoma is a rare tumor of cytotoxic lymphocytes that accounts for less than 1% of all non-Hodgkin lymphomas.[150] In dogs, it is similarly rare, with one report of five dogs.[117] In single or multiple subcutaneous masses, neoplastic lymphocytes invade the subcutaneous adipose tissue and mimic panniculitis. The neoplastic cells extend into the dermis and approach, but do not involve, the epidermis. The lymphocytes are small- to intermediate-sized with distinct nucleoli, a high mitotic index, and CD3 positivity.[117]

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphoma is a relatively common form of T-cell lymphoma in humans which is categorized by the presence or absence of a recurrent genetic translocation involving the anaplastic lymphoma kinase (ALK) gene.[150] The tumors consist of unique large anaplastic cells, often a mixed inflammatory infiltrate, and large Reed–Sternberg-like cells.[150] This is an uncommon lymphoma in dogs that, without IHC, is difficult to differentiate from anaplastic diffuse large B-cell lymphoma or histiocytic sarcoma.[1] In humans, these tumors are positive for CD30, and, remarkably, also for CD4 and cytotoxic proteins such as granzyme B and perforin.[150] The immunophenotype in dogs is not well studied.[150] Five cases reported as part of a large multicenter study had a favorable response to chemotherapy.[150,157]

Intravascular Large T-Cell Lymphoma

Although typically a B-cell neoplasm in humans, intravascular large cell lymphoma can also be of T- or NK-cell type.[21] This is a rare tumor in dogs, with both T- and B-cell types described.[83,95] Inimitably, neoplastic lymphocytes are noted within blood vessels rather than in hemolymphoid tissues. The cells then disseminate into organs, typically causing kidney disease and central nervous system signs due to infiltration of the brain or spinal cord.[95] Neoplastic cells can be found in circulation (Figure 72.7), though lymphocytosis has not been reported. The cells are large, pleomorphic, and can have granular morphology.[83,95]

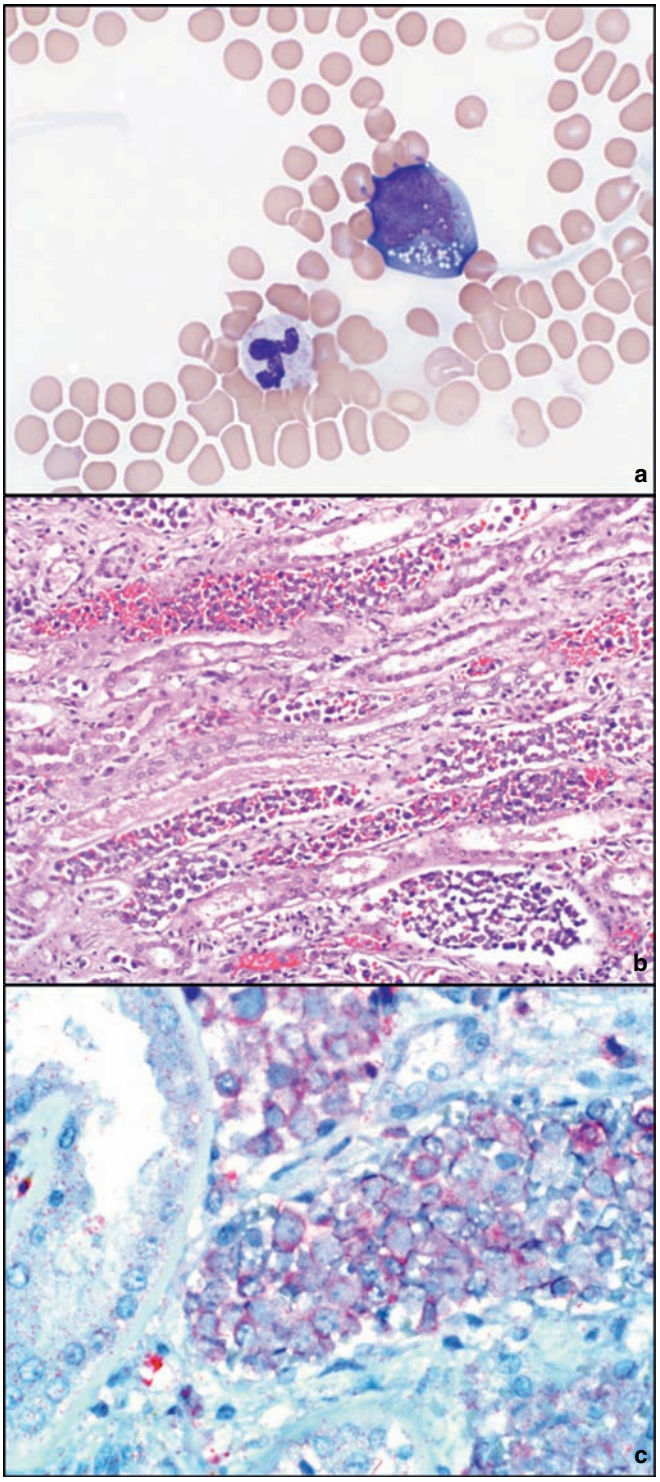

FIGURE 72.7 Samples from a 6-year-old dog with a 10-day history of hyporexia, vomiting, diarrhea, and weight loss. On presentation, the dog was tachypneic and had acute kidney injury. (a) There were rare, large, atypical lymphocytes with cytoplasmic granules and vacuoles on the blood film; (b) Renal biopsy showed venules filled with aggregates of large lymphocytes; (c) The cells were CD3-positive on IHC. Interpretation: Intravascular T-cell lymphoma. Postmortem, extensive intravascular neoplastic lymphocytes were identified throughout most tissues.

Extranodal T-Cell Lymphoma, Nasal Type

Extranodal nasal T-cell lymphoma is a rare tumor in humans with a higher incidence in East Asia and Latin America where the majority of cases are associated with Epstein–Barr virus (EBV) infection.[150] In dogs, nasal T-cell lymphoma is also very rare with only two reported cases.[69,155]

Hepatosplenic T-Cell Lymphoma

Analogous to the human disease, hepatosplenic T-cell lymphoma (HS-TCL) in animals is a rare T-cell neoplasm characterized by primary involvement of liver and spleen, absence of peripheral lymphadenomegaly, cytopenia, and an aggressive biological behavior. In animals, this entity has been primarily recognized in dogs.[24,54,71,147] The number of published cases is too low to identify a breed, sex, or age predisposition. Clinically, dogs present with fever, splenomegaly, progressive lethargy, anorexia, weight loss, and diarrhea or vomiting ranging from 1 week to 3 months prior to presentation. A variably regenerative anemia is a consistent finding, and thrombocytopenia and hypoproteinemia are seen in most cases. A lymphocytosis is generally not observed. Cytologically, neoplastic cells are intermediate to large and often contain cytoplasmic granules suggestive of a cytotoxic phenotype (Figure 72.8a).

Erythrophagocytosis or thrombophagocytosis by neoplastic cells and macrophages is frequently observed and is reflective of a secondary hemophagocytic syndrome (Figure 72.8b). Erythrophagocytosis secondary to HS-TCL must be differentiated from immune-mediated hemolytic anemia and hemophagocytic histiocytic sarcoma.[55,71] Histologically, neoplastic lymphocytes are centered on hepatic sinusoids and the splenic red pulp with occasional involvement of regional lymph nodes. The bone marrow is inconsistently involved, but peripheral lymph nodes are generally spared. The dominant immunophenotype of the neoplastic lymphocytes has been characterized as $CD3^+$, $CD4^-$, $CD8\alpha^+$, $CD8\beta^-$, TCR $\alpha\beta^-$, TCR $\gamma\delta^+$, $CD11d^+$, and granzyme B^+.[55,71] Based on the frequent expression of CD11d and TCR γδ, it has been proposed that HS-TCL in dogs arises from γδ T cells of the splenic red pulp.[55,71] The frequent expression of granzyme B additionally points toward a cytotoxic T-cell origin of the neoplastic cells.[55,71] All cases for which clonality testing has been performed had a clonally rearranged T-cell receptor gamma locus.[25,70,147] With one exception, the survival time in all published cases has been, regardless of therapy, short, ranging from a few days to less than a month.[25,55,71,147]

Together, these data support HS-TCL as a distinct WHO entity in dogs that closely resembles the human disease. Hepatosplenic T-cell lymphoma may exist in other species, but only isolated case reports exist in cats and horses.[19,131] The findings in a horse and a cat were consistent with the findings described for dogs with the exception that the cat responded to treatment and lived for 2.5 years.

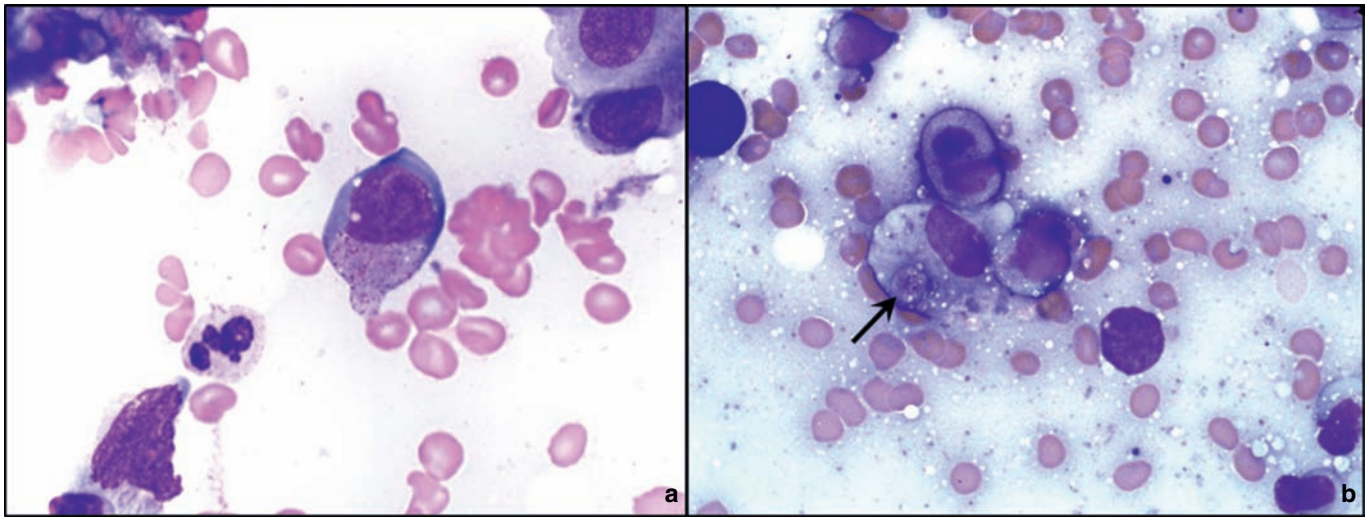

FIGURE 72.8 Splenic aspirates from an 11-year-old dog with marked anemia and thrombocytopenia. (a) Large lymphocytes with fine eosinophilic granules predominate; (b) Macrophages and lymphocytes containing platelets (arrow) or RBC were noted. Flow cytometrically, lymphocytes were $CD3^+$, $CD8^+$, $MHCII^{low}$. Interpretation: Hepatosplenic $CD8^+$ T-cell lymphoma.

Hepatocytotropic T-Cell Lymphoma

Hepatocytotropic T-cell lymphoma (HC-TCL) has been proposed as an entity in dogs that shares features with HS-TCL but is characterized by a more intimate association of neoplastic lymphocytes and hepatocytes (Figure 72.9), as well as differences in clinical presentation and immunophenotype.[71] Akin to HS-TCL, HC-TCL arises from γδ T cells and affects liver and spleen without causing peripheral lymph node enlargement. However, patients with HC-TCL present with severe jaundice and cholestasis. Anemia is not a primary feature and erythrophagocytosis and secondary hemophagocytic syndrome are not observed. Histologically, neoplastic lymphocytes invade hepatic cords and neoplastic cells are negative for the splenic red pulp marker CD11d. Hepatic lymphoma with emperipolesis has been described in cats, but additional data are needed to substantiate this group of elusive neoplasms as a distinct entity.[121,148]

FELINE T-CELL NEOPLASMS

Feline lymphoma is relatively common in cats, accounting for 10–50% of all feline tumors.[59] In prevalence studies prior to approximately 1990, many feline lymphomas were associated with feline leukemia virus (FeLV) infection, while data from the last few decades, since the advent of FeLV testing and vaccination, reflect a higher frequency of FeLV-negative lymphomas.[87] Recent data indicate that approximately 25% of feline lymphomas are of T-cell origin.[156] Both ALL and CLL in cats are predominantly of T-cell type.[13] As in dogs, there are several studies whereby the WHO classification has been adapted to characterize feline lymphoproliferative neoplasms.[162,174,175]

Precursor T-Cell Neoplasms

T-Acute Lymphoblastic Leukemia

Feline T-ALL is reported, but much less commonly than in humans and dogs. Limited information is available on this subtype, but few cases described were $CD3^+$ and/or $CD5^+$.[13]

Lymphoblastic T-Cell Lymphoma

Feline LBTCL is similar to the canine counterpart with a predilection for nodal and thymic/mediastinal sites. Prior to control of FeLV infection, LBLT accounted for up to 70% of feline lymphomas.[87] Lymphomagenesis due to FeLV infection results from insertion of a retrovirus promoter gene near the *c-myc* gene.[114] Spontaneous mediastinal LBTCL is also reported in cats, and is now more common than FeLV-induced LBTCL.[42] FeLV-associated LBTCL has a worse prognosis than non-FeLV-associated LBTCL with median survival times 25 and 373 days, respectively.[97,42]

Mature T-Cell Neoplasms

T-Cell Chronic Lymphocytic Leukemia

Over 90% of feline CLL are of T-cell origin, and virtually all are $CD4^+$.[18,166] Median age at the time of diagnosis is 12.5 years, and the most common clinical sign is weight loss; other signs include lethargy, vomiting, and diarrhea. Anemia or thrombocytopenia may be present, but are typically mild. Lymphocyte counts range from 10–325 × 10^9 cells/L, or rarely higher.[18] CLL cells are primarily of small size with mature condensed nuclear chromatin, slightly indented or cleaved nuclei, and indistinct nucleoli.[18,166] Infiltration of the

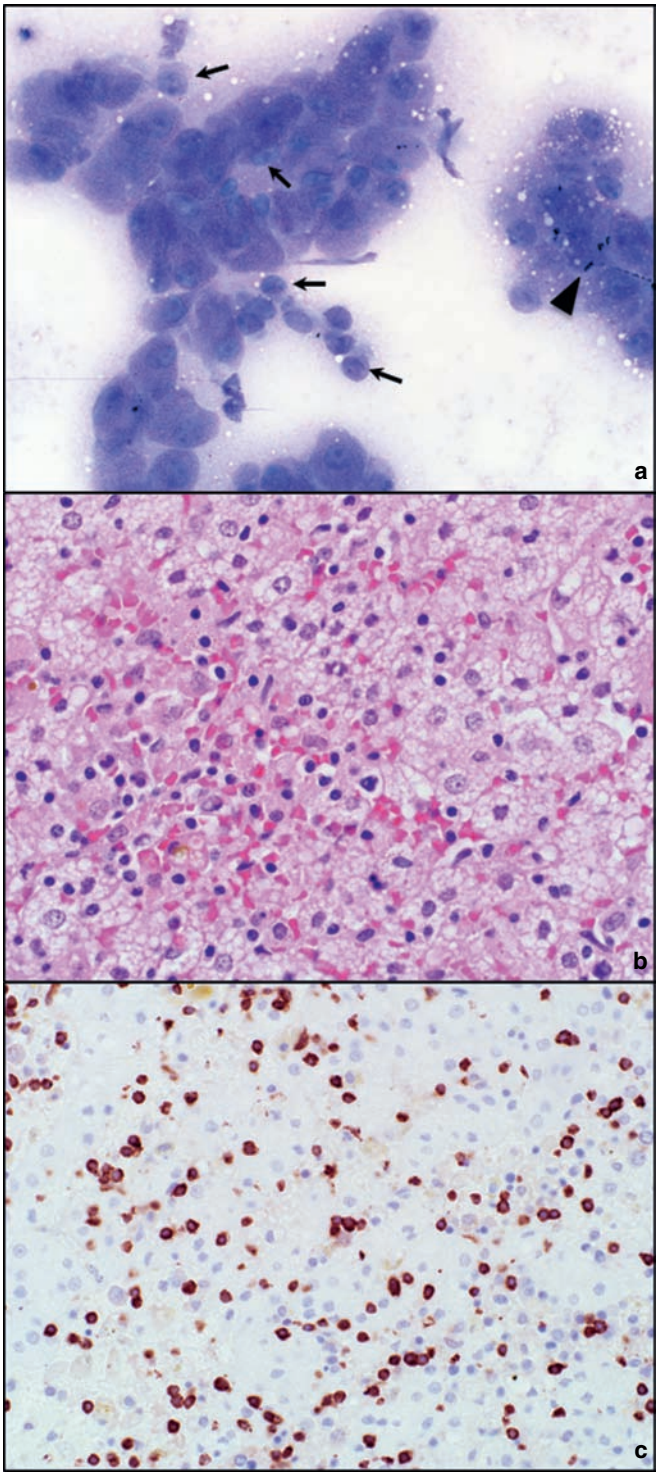

FIGURE 72.9 Samples from a 10-year-old dog with increased liver enzymes and jaundice. The liver and spleen were hyperechoic and irregular, respectively, on ultrasonic examination. (a) A liver aspirate consists of hepatocytes with occasional bile casts (arrowhead), and medium-size lymphocytes (arrows) in close relation to hepatocytes; (b) A liver biopsy shows numerous medium-size lymphocytes among and within hepatic cords. Similar cells were present throughout the splenic red pulp; (c) The cells were CD3-positive on IHC. Interpretation: Hepatocytotropic T-cell lymphoma.

bone marrow is variable suggesting that the neoplasm does not originate in the bone marrow.[18,166] Splenic involvement and concurrent EATL have been reported in cats with T-CLL.[18] Feline CLL generally has a favorable prognosis with median survival after diagnosis of 14.4 months.[18]

Peripheral T-Cell Lymphoma, Not Otherwise Specified

After EATL, PTCL-NOS is the second most common, accounting for 23% of feline lymphomas.[162] Clinical findings vary depending on the location of the tumor, and cytological and histopathological findings are similarly variable as in dogs.[1] Unlike in dogs, most cases of feline PTCL-NOS are extranodal, although rare nodal tumors are also observed. The primary extranodal location is the gastrointestinal tract, where PTCL-NOS needs to be distinguished histologically from EATL.[162] Non-epitheliotropic cutaneous, subcutaneous, laryngeal, upper respiratory, renal, and central nervous system PTCL-NOS have also been reported.[23,162,175] A minority of cutaneous vaccine-associated and tarsal lymphomas are of T-cell type, though B-cell lymphoma is more common in both locations.[17,130]

Since location does not reliably distinguish T-cell type from B-cell type, and immunophenotyping is not always performed in survival analysis, reliable median survival times are not available to separate these locations into distinct entities. One study showed overall median survival time of 6.1 months for cats with PTCL-NOS.[175]

Feline Large Granular Lymphocyte Lymphoma Feline LGL lymphoma is a unique type of PTCL-NOS that does not have a counterpart in the human WHO classification scheme. Age at the time of diagnosis is 10–11 years. Clinical signs are generally nonspecific but pronounced, and include inappetence, lethargy, weight loss, and vomiting. Frequently, a palpable abdominal mass is present. Complete blood cell counts often reveal a variable degree of anemia as well as neutrophilia, thrombocytopenia, and rarely eosinophilia.[43,78] An LGL lymphocytosis is common, and may be subtle or $>400 \times 10^9$/L.[132] Test results for feline immunodeficiency virus and FeLV are typically negative.[43,78] The feline gammaherpesvirus 1 has been detected in a single intestinal LGL lymphoma.[3]

Feline LGL lymphoma frequently affects more than one anatomic location, with a predilection for the small intestine, mesenteric lymph nodes, liver, and spleen. Cytologically, the neoplastic cells are typically intermediate size with characteristic prominent magenta/azurophilic cytoplasmic granules, round to indented/cleaved nuclei with fine granular to lacey chromatin and variably distinct nucleoli.[78] Immunophenotypically, LGL lymphoma is $CD3^+$, frequently $CD8\alpha\alpha^+$, and sometimes $CD4^+/CD8\alpha\alpha^+$ or $CD4^-/CD8^-$. Detection of the leukointegrin αE CD103 on the majority of LGL lymphocytes suggested small intestinal intraepithelial lymphocyte origin.[132]

Median survival for treated cats was <3 months from the time of diagnosis, and only 2 days for untreated cats, which may reflect diagnosis at an advanced disease stage.[127,132] In another study, it was suggested that lack of clinical abnormalities and lymphocytosis at the time of diagnosis were associated with longer survival.[43]

Extranodal Subcutaneous Lymphoma This subtype of PTCL-NOS in cats is relatively uncommon and does not have a WHO counterpart.[150] Approximately one third of subcutaneous lymphomas in cats are T-cell origin. Median age at time of diagnosis was 11 years, and lesions were present for several days to several months.[98] A small proportion of cats have lethargy, weight loss, and anorexia, and are retrovirus positive.[98]

The lesions consist of large, atypical lymphocytes infiltrating the deep dermis and subcutaneous fat. Frequent macrophages are present, creating a starry-sky appearance on histopathology. Extensive central coagulative necrosis is a consistent finding.[98]

Feline Enteropathy-Associated T-Cell Lymphoma

Unlike in humans and dogs, EATL is the most common form of lymphoma in cats, accounting for up to a third of all lymphomas and 50–84% of all gastrointestinal lymphomas.[87,107,124,162] The most commonly affected site is the small intestine, particularly the jejunum, while gastric and colonic involvement is much less common.[107] Although 60% of cats diagnosed with EATL have a prior history of inflammatory bowel disease, and some have lesions of both conditions in the intestines, whether and how frequently inflammation precedes neoplasia remains to be determined.[112]

Cats with EATL are typically older than 10 years of age and had a median age at diagnosis of 12.5 years.[107] Clinical signs mimic those of inflammatory bowel disease and include weight and muscle loss, inappetence, vomiting, and possibly diarrhea.[137] Lymphocytosis is present in 85% of cats with EATL of granular cell morphology.[132] Paraneoplastic eosinophilia and, less commonly, basophilia have also been reported in feline EATL.[9] Most cats have negative retrovirus test results.[107,124]

Feline EATL can be mucosal or transmural, with the former accounting for >80% of tumors. Mucosal tumors may present in a variety of distribution patterns, while the transmural lesions are most often focal or multifocal. Mucosal tumors consist primarily of small- to intermediate-sized lymphocytes suggestive of the EATL type 2 form.[107,174] These indolent lymphomas primarily affect the lamina propria without submucosal involvement and 60% have an increased number of intraepithelial lymphocytes that are more commonly in the villus than crypt epithelium. Most transmural lesions consist primarily of large lymphocytes that are granzyme B^+. In contrast to EATL type 2 lesions, EATL type 1 tumors have a heavy submucosal infiltration and, in advanced lesions, involve the muscularis propria and surrounding tissues. Thus, transmural lesions tend to be more consistent with EATL type 1, though they do not fully meet all histopathological criteria of this entity in other species.[107,174] Histopathologically, small cell lymphomas can be difficult to distinguish from inflammatory bowel disease, and features such as epitheliotropism, degree of infiltration, proportion of dilated crypts, severity of villus changes, proportion of plasma cells, and detection of clonally rearranged TCRs may be useful.[15] Aspirates of intestinal mass lesions or enlarged mesenteric lymph nodes may yield diagnostic specimens consisting predominantly of large lymphocytes that reflect EATL type 1, but they rarely allow distinction between inflammation and small cell lymphoma.

Feline EATL is defined by CD3 positivity, and IHC can assist with visualizing intraepithelial lymphocytes.[107] Detection of MHCII is variable, and further characterization is hampered by limited antibody availability.[15] Detection of a clonally rearranged T-cell receptor has a reported sensitivity and specificity of up to 90% and up to 100%, respectively, compared to histopathology and immunohistochemistry, but is dependent on factors such as primer coverage and amplicon resolution.[107,112] In one study, cross-lineage monoclonal rearrangement of the immunoglobulin heavy chain locus was noted in 9% of feline EATL; these cases also had polyclonal rearrangement of the TCR γδ locus.[4]

Treatment generally consists of prednisolone and chlorambucil, and, unsurprisingly, EATL type 2 is associated with longer survival than EATL type 1.[127,175,107] Survival was shorter with lomustine rather than glucocorticoid and chlorambucil rescue therapy (median survival 492 days).[127] Median survival for cats with EATL type 1 was 1.5 months, and for those cats with concurrent granular lymphocytosis it was only 19 days.[107,132]

Cutaneous T-Cell Lymphoma

Epitheliotropic Cutaneous T-Cell Lymphoma Feline CTCL is rare and compromises <1% of feline lymphomas and feline skin tumors.[50,162] The disease occurs in middle-aged to older cats, with the median age at diagnosis ranging from 10–13.5 years. Like dogs, disease progression is gradual. Clinical signs refer to isolated or generalized lesions, often affecting the face. The lesions include erythematous plaques or patches, scaly alopecic patches, and nonhealing ulcers or nodules.[46]

Mass lesions are amenable to cytological diagnosis (Figure 72.10), and characterized by large, atypical lymphocytes. Histopathological features include epitheliotropism, but intraepidermal lymphocyte aggregates appear to be less common than in dogs. The follicle epithelium is consistently but mildly affected. Spongiosis, parakeratosis, keratinocyte apoptosis, and inflammation may be present. Pagetoid reticulosis has not been identified in cats, but disease progression to Sézary syndrome has been reported.[46,176]

Neoplastic cells are consistently positive for CD3, and one case of CTCL was perforin-positive.[23,46,115]

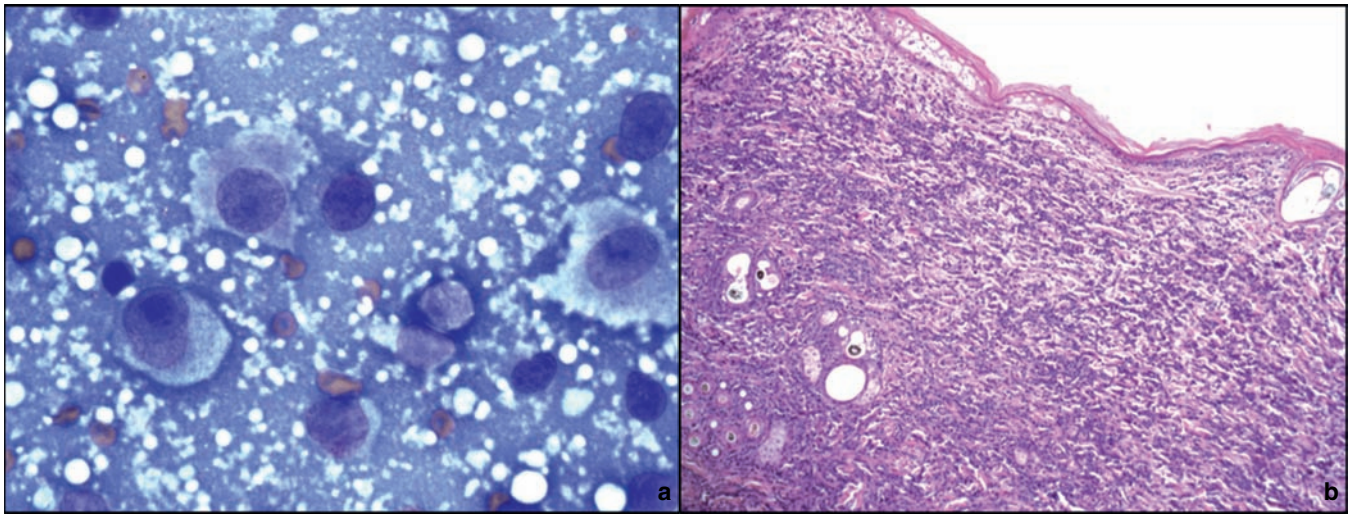

FIGURE 72.10 Samples from a cutaneous mass of a 9-year-old cat. (a) The aspirate consists of pleomorphic lymphocytes, including several very large lymphocytes with prominent nucleoli; (b) The mass consists of aggregates of large lymphocytes that infiltrate the dermis and superficial subcutis. Lymphocytes were $CD3^+$. Interpretation: Cutaneous T-cell lymphoma.

Tarsal Non-Epitheliotropic Cutaneous Lymphoma Cats are susceptible to a unique non-epitheliotropic cutaneous lymphoma of the tarsus. A majority of these are B-cell type, but some are of the PTCL-NOS subtype. Median age at time of diagnosis was 12 years, and lesions consisted either of individual or multiple masses proximal to each other. Systemic signs of illness were rare, and no association with retroviral infection was identified.[17] The tumors are characterized by sheets of intermediate to large lymphocytes effacing the affected tissue without epitheliotropism. Necrosis is common, tumors have a high mitotic rate, and are locally progressive.[17]

Cutaneous Anaplastic Large T-Cell Lymphoma Although non-epitheliotropic cutaneous lymphoma is more common than epitheliotropic lymphoma in cats, only a minority are of T-cell type.[17,130] A few of these tumors that fit into the WHO classification were consistent with the anaplastic large T-cell lymphoma subtype. Some were associated with vaccine injection sites.[130]

Angioimmunoblastic T-Cell Lymphoma

Feline angioimmunoblastic T-cell lymphoma is also very rare with only four cases reported. Of these, one was located in the eye and one was gastrointestinal; the remaining locations were not specified.[162,175] This type of lymphoma is characterized by proliferating high-endothelial venules with perivascular cuffing by immunoblastic lymphocytes.[1]

Extranodal T-Cell Lymphoma, Nasal Type

Nasal lymphoma in cats accounts for approximately 10–13% of all lymphomas, 20–40% of extranodal lymphomas, and 70% of all feline nasal tumors.[23,65,152,156] Unlike in humans, most nasal lymphomas in cats are B-cell type with T-cell lymphomas comprising <10%.[23,138,150,156] Nasal lymphoma is a disease of older cats, and lesions can be restricted to the nasal cavity or also affect the nasopharynx.[86,138] The most common clinical signs are nasal discharge and sneezing; additional signs may include unilateral or bilateral epistaxis, stridor or stertor, dyspnea, epiphora, ocular discharge, anorexia, and facial deformities.[138,152]

Aspirates of nasal masses can be readily diagnosed as lymphoma by cytology if an appropriate sample has been collected. Histopathologically, epitheliotropism may be noted in T-cell and B-cell nasal lymphoma, therefore immunohistochemistry is needed to differentiate these.[86] Cell size is variable.[86,138] In humans, these tumors are comprised of cytotoxic lymphocytes, and in some cat nasal lymphomas, cytoplasmic granules were also reported.[86,138] Mean survival with upper respiratory tract T-cell lymphoma was 53 days.[138]

Feline Intravascular Large T-Cell Lymphoma

A single case of intravascular large T-cell lymphoma was reported in a 7-year-old Siamese cat. The brain and kidneys were the most affected sites.[84]

EQUINE T-CELL NEOPLASMS

In horses, large surveys identified lymphoma as the third most common neoplasm and as the eighth most common cutaneous neoplasm.[75,140] Histomorphologic and immunohistochemical assessment of 203 tumor samples indicated that T-cell-rich B-cell lymphoma (TCRBCL) was the most common subtype (43%),

followed by PTCL (22%), DLBCL, and other less common subtypes.[39] Among 88 specimens of cutaneous lymphoma (which included 33 cases previously classified[39]), 84% were classified as TCRBCL and 13% as cutaneous T-cell lymphoma, with other infrequent subtypes.[101] In an earlier study of 37 cases of equine lymphoma, 26 (70%) were categorized as PTCL and five (14%) as TCRBCL.[100] Thus, there may be a discrepancy in the relative frequency of different subtypes of equine lymphoma, which may reflect sample bias, geographic prevalence of different subtypes, or differences in application of classifying criteria.

In veterinary pathology, TCRBCL is typically a histopathological diagnosis based on identification of fewer, large, often atypical, cells identified as B cells by CD20 or CD79a IHC, and numerous small lymphocytes that are $CD3^+$. In humans, entities with similar histomorphology may be nodular lymphocyte predominant Hodgkin lymphoma (NLPHL), which has indolent behavior and is restricted to a limited group of peripheral nodes, or T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL), which is a rapidly progressive tumor.[60] Based on microdissected single-cell antigen receptor gene rearrangements and mutations, and application of a range of antibodies specific for different lymphocyte maturational stages, it is now recognized that NLPHL and THRLBCL in humans represent opposite ends of the spectrum of a particular type of B-cell lymphomas.[60] It is likely that equine TCRBCL, which has similarly variable histomorphology, often also including histiocytes, encompasses multiple overlapping entities. Immunohistochemical assessment of such complex neoplasms with just two antibodies is insufficient to confidently identify the neoplastic component, and until a greater range of antibodies and more comprehensive correlation with patient outcome are available, caution is indicated for assignment of the cellular origin of the neoplasm.

Frequently reported clinical features of equine lymphoma, regardless of T- or B-cell type, are weight loss, edema, and pyrexia.[39,73,100] Edema was unrelated to albumin concentration, and likely reflects hemodynamic effects of tumor burden. Systemic inflammation, as implied by hyperfibrinogenemia, hyperglobulinemia, and/or hypoalbuminemia, was present in the majority of horses with lymphoma; and cytopenia, most commonly anemia, was identified in 62%.[100] Therefore, many types of equine lymphoma are associated with systemic abnormalities.

Subtypes of T-cell lymphoma in horses are like those in dogs and cats. Diagnostic samples of intestinal T-cell lymphoma are challenging to obtain antemortem, but EATL types 1 and 2 have been identified in horses as in other species.[7] Mediastinal lymphoma is most often of T-cell type, and may be diagnosed by cytologic evaluation of pleural fluid samples (Figure 72.11). While TCRBCL was the most common subtype among cutaneous lymphomas, epitheliotropic T-cell lymphoma akin to MF in dogs and cats was second most common.[101]

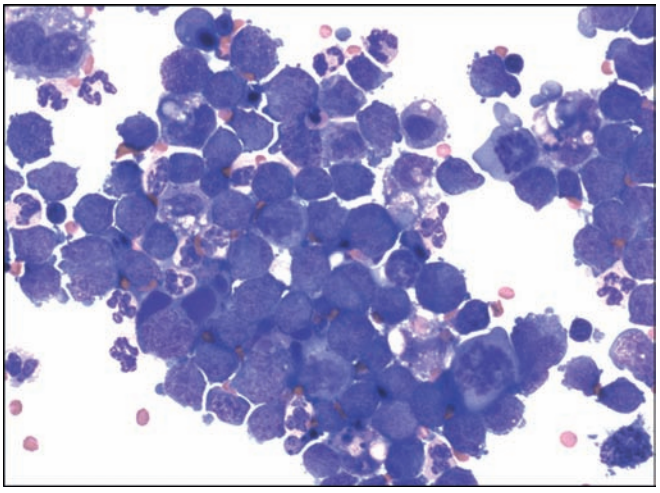

FIGURE 72.11 Cytocentrifuge preparation of pleural effusion fluid from a 6-year-old horse. The lymphocytes are very large in relation to RBC, and there are frequent mitoses and macrophages. At postmortem, the horse had a large mediastinal mass, and lymphocytes were $CD3^+$ by IHC. Interpretation: T-cell lymphoma.

Acronyms and Abbreviations

AgNOR, argyrophilic nucleolar organizer region; CTMC, connective tissue mast cells; COX-2, cyclooxygenase-2; FGF, fibroblast growth factor; GI, gastrointestinal; H&E, hematoxylin & eosin; MCM7, minichromosome maintenance protein-7; MCT, mast cell tumor; MI, mitotic index; MNA, mean nuclear area; MMC, mucosal mast cells; MVD, microvascular density; PCNA, proliferating cell nuclear antigen; WHO, World Health Organization.

CANINE MAST CELL TUMOR

Signalment, Incidence, and Etiology

The mast cell tumor (MCT) accounts for approximately 20% of all canine skin tumors.[28,53] No age or sex predilection has been recognized, although increased breed-related incidence has been reported. Shar Peis reportedly have more biologically aggressive MCTs than Boxers and Pugs, who are predisposed to MCTs less prone to distant metastasis.[58,68] No definitive cause for MCT has been elucidated, although the possibility for a genetic cause is suspected, due to increased prevalence in certain breeds.[28]

History and Clinical Signs

MCTs demonstrate a wide variability of biologic behavior. They are most common in cutaneous tissues, with fewer subcutaneous and extracutaneous MCTs. Tumors in multiple locations typically represent distant metastasis rather than multiple primary tumors.[23] Owners often report that these masses wax and wane, as mast cell granules contain histamine, heparin, and vasoactive amines that can induce erythema, urticaria, and pruritus when released.[22] As release is triggered by physical manipulation, MCTs in locations that can be licked or scratched are most prone to intermittent redness and swelling.

Occasionally, patients present with vomiting, abdominal pain, and evidence for gastrointestinal (GI) bleeding, as histamine release triggers upregulation of gastric acid production, via stimulation of H_2 receptors on gastric parietal cells. Chronic external blood loss due to ulceration can result in iron deficiency anemia.[23] Histamine levels can be quantified in plasma and are often elevated in patients with MCTs.[21]

Diagnosis

MCTs are readily diagnosed on cytologic examination. These neoplasms are composed of individualized mast cells with centralized round nuclei and abundant pale cytoplasm that contains numerous magenta granules, which often obscure the nucleus. When stained with aqueous solutions (e.g., Diff-Quik®), the granules may fail to uptake stain, potentially due to dissolution of granule contents. This artifactual change can be minimized by allowing slides to remain in the fixative component of the stain for at least 5 minutes, or by using a methanol-based Romanowsky stain. It is important to recognize that an absence of cytoplasmic granules may be due to cell degranulation, tumor microenvironment, or poor differentiation. Aspirates from MCTs which are degranulated often have abundant magenta granules in the background.

As canine mast cell granules contain interleukin (IL)-5, a cytokine which induces eosinophil migration, aspirates of most canine MCTs contain a mixture of both mast cells and eosinophils.[39] Additionally, tryptase-containing mast cells have been demonstrated to secrete fibroblast growth factors (FGF) that induce fibroblast proliferation and promote wound healing.[3,46] The presence of these plump mesenchymal cells can occasionally complicate the microscopic diagnosis, as the possibility for a neoplastic mesenchymal population (e.g., sarcoma) with a mast cell infiltrate must be excluded. Mast cells containing both tryptase and chymase demonstrate both collage proliferation and collagenolysis, which appear as brightly eosinophilic fibrous bands.[14,47]

Staging

The World Health Organization (WHO) staging system for MCTs consists of five tiers (0–IV) (see Table 73.1), with substages I and II which correlate with the absence or presence of clinical signs, respectively.[28] In the five-tiered system, dogs with stages 0 and I disease have prolonged survival when compared with dogs with higher-stage disease.[33] A consensus panel, which included members of the Veterinary Cancer Society and the European Society of Veterinary Oncology, disputes the organization of the WHO tiers, as dogs with stage II disease (single tumors) often exhibit worse outcomes than dogs with stage III disease (multiple tumors).[2,20,23] The recommended staging procedures vary among oncologists. However, it is generally accepted that easily resectable, well-differentiated MCTs confined to the skin warrant only aspiration of the draining lymph node (even if normal sized). However it is critical to ensure that the correct lymph node is aspirated through review of known lymphatic drainage or with the use of lymphoscintigraphy, as the node closest to the MCT may not be the draining node. In one study, only 60% of draining nodes would have been sampled if only the anatomically closest node had been sampled.[72]

Cytologic evaluation of lymph nodes for MCT metastasis can be challenging, as non-neoplastic mast cells are common lymph node residents and there is no definitive way to microscopically discriminate neoplastic from non-neoplastic mast cells. Relatively increased numbers of mast cells, while subjective, may suggest mast cell metastasis; however, manipulation of MCTs can cause recruitment of non-neoplastic mast cells to the draining node via the lymphatics.[23] For this reason, it is advised that lymph node aspiration occur prior to any physical MCT manipulation.[28] Although a system for evaluating the significance of mast cells in draining lymph nodes has been proposed, it remains largely unused due to its limited known prognostic utility.[25,34] Thus, cytopathologists often rely on overall number, mast cell pleomorphism, and arrangements in aggregates, to document microscopic metastasis. As architectural arrangement is more accurately assessed with histology, excisional biopsy of the draining lymph node is often performed. A four-tier histologic classification for nodal mast cell metastasis has shown promise in predicting disease progression[70] (see Table 73.2).

TABLE 73.1 WHO staging system for canine MCTs.[23]

Stage	Diagnostic criteria
0	One dermal tumor, incompletely removed, with no lymph node involvement
I	One dermal tumor, with no lymph node involvement
II	One dermal tumor, with lymph node involvement
III	Multiple dermal tumors or large, deep tumors with or without lymph node involvement
IV	Any tumor with distant (beyond local node) metastasis

TABLE 73.2 Histologic grading system for nodal metastasis in dogs with MCT.[70]

Stage	Diagnostic criteria
HN0	Zero to three isolated mast cells in sinuses and/or parenchyma per 400× field
HN1	More than three isolated mast cells in sinuses and/or parenchyma in a minimum for four 400× fields
HN2	Clusters of mast cells in sinuses and/or parenchymal or sinusoidal mast cell sheets
HN3	Disruption or effacement of nodal architecture by mast cells

Proposed interpretation: HN0 = non-metastatic; HN1 = pre-metastatic; HN2 = early metastasis; HN3 = overt metastasis.

With highly pleomorphic, known metastatic, or nonresectable MCTs, abdominal imaging is often utilized for detection of organomegaly. Although most ultrasonographically unremarkable abdomens lack mast cell metastasis, aspiration of normal-appearing liver and spleen may be warranted based on the presence of known or suspected nodal metastasis.[10,56,65] Although formerly recommended, buffy coat analysis is no longer advised in dogs, as mastocytemia is more likely the result of a non-neoplastic process than a neoplastic one.[29]

Grading

Cytologic

Grading of neoplasms involves evaluation of microscopic criteria to predict disease progression. While traditionally performed on histologic sections, cytologic grading schemes for canine cutaneous MCT (cMCT) have been developed. These grading systems vary from direct application of histologic criteria to the de novo development of a predictive cytologic grading algorithm. Although both types of cytologic grading systems correlate well with histology, they tend to overestimate the number of high-grade tumors.[12,19,56] This overestimation may result in unnecessarily aggressive staging, surgery, or, potentially, euthanasia. As such, cytologic grading is recommended as a screening test with a high likelihood that low cytologic grade correlates with relatively benign biologic behavior.[12]

The cytologic feature most predictive of biology is tumor cell granularity, as poorly granular tumors metastasize at a higher rate than highly granular tumors. The ability to recognize cells that are poorly granulated, rather than poorly stained or degranulated, is essential to cytologic grading. Other features associated with aggressive biologic behavior include anisokaryosis, binucleation, multinucleation, and bizarre nuclear morphology.[12,44] In highly granulated MCTs, where nuclear morphology is obscured, staining cytologic specimens with H&E, which minimizes granule staining, may be of value in assessing nuclear features.[44]

Histologic

Three histologic grading systems exist, two of which are commonly utilized: the three-tier (Patnaik) system and the two-tier (Kiupel) system.[24,37] The Patnaik system utilizes tumor cellularity, tumor cell morphology, mitotic index (MI), degree of tissue involvement, and stromal reaction, to assign a histologic grade of I–III.[37] Grade I tumors are associated with an excellent prognosis, requiring only complete surgical excision, whereas grade III tumors are more aggressive and require adjunctive chemotherapy. Using this scheme, most MCTs are assigned a histologic grade of II, which is a subtype associated with a 5–22% metastatic frequency.[9,54] This predominance of grade II tumors and a wide interpathologist variability limit the clinical utility of the Patnaik system.[35] The Kiupel grading system was developed, in part, to eliminate this "gray zone" of grade II tumors. The Kiupel system utilizes karyomegaly, mitotic index, multinucleation, and bizarre nuclear morphology as criteria for classifying MCTs as either high- or low-grade.[24] This system has been demonstrated to have high prognostic value with minimal interobserver variability.[54] Currently, as recommended by the Veterinary Cancer Society's Oncology–Pathology Working Group, most pathologists report both grades.[7] However, even using the strict criteria defined by both systems, grading inconsistencies remain, particularly with regard to margin evaluation and subcutaneous MCTs.[41]

Proliferation Markers

Indicators of cell proliferation rate have been utilized to prognosticate clinical outcome in MCT patients. These indicators include MI, the percentage of cells expressing proliferating cell nuclear antigen (PCNA), minichromosome maintenance protein-7 (MCM7), and/or Ki-67, and the presence of argyrophilic nucleolar organizer regions (AgNORs).[8,27] Each marker provides information about a different component of the cell cycle or proliferation rate. While consensus is lacking on their utility and practical application, all proliferation markers have been reported as useful prognostic indicators in dogs with MCTs.[22]

Mitotic Index

MI is assessed on H&E sections and represents the number of mitoses in 10 high-power (100× objective) fields. Although inter-region variability and differences in lens aperture make standardization difficult, the utility of MI as a predictor of outcome is well documented, with relatively low MI (e.g., <7) tumors associated with less-aggressive biologic behavior than tumors with a high MI.[15,49,66]

PCNAs

PCNAs are nonhistone nuclear proteins required for DNA synthesis and are most commonly detected during the S-phase of mitosis. They are detected using immunostaining, and semi-quantitative scoring methods are used to determine the fraction of proliferating cells.[59] Although higher PCNA estimates are reported in metastatic versus non-metastatic MCTs, PCNA is considered less useful than MI and AgNORs, perhaps because of lack of uniformity in quantification procedures and due to the presence of nonspecific staining.[28,59]

MCM7

Minichromosome maintenance proteins are a group of proteins essential for DNA replication. Proteins 2–7 are bound together and to chromatin in phase G_1 of the cell cycle and they are removed from the nucleus and remain in the cytoplasm during the S-phase and in subsequent phases. They are responsible for ensuring the appropriate order of mitosis and for restricting the cell to a single

mitosis per cycle. With the help of morphometric software, MCM7 can be quantified using immunostaining and an index generated from the number of positive versus negative cells. A higher MCM7 index has been associated with a shorter mean survival in canine cMCT.[8]

Ki-67

Ki-67 is a nuclear protein expressed in all cycling cells, but is absent in all resting cells (in G_0). As with PCNAs, assessment of the Ki-67 expression is done with immunohistochemistry.[69] The fraction of cells expressing Ki-67, termed the Ki-67 labeling index, has been positively correlated with disease progression in numerous neoplasms (including canine cMCT), but its stand-alone utility is limited.[23,57]

AgNORs

AgNORs are structures within nucleoli that are responsible for transcription of ribosomal RNA. Due to their affinity for silver, these areas stain black with a specialized silver stain. The number of AgNORs per nucleus has been associated with both cell proliferation rate and rate of tumor growth in canine cMCT.[69] However, no consensus cutoff score for AgNORs has been reached, thus diminishing its utility.[23] Use of a combined Ki-67 and AgNOR score has shown promise as a prognostic indicator, as it combines both the number of cycling cells (Ki-67) and the proliferation rate (AgNOR) into a single metric, which may prove useful in predicting biologic behavior.[62]

Other Prognostic Indicators

c-kit

KIT is a tyrosine kinase receptor normally located on the surface or within the membrane of numerous cells, including mast cells, hematopoietic stem cells, and melanocytes. When phosphorylated, KIT initiates an intracellular signaling cascade that induces cell proliferation, differentiation, and maturation.[50,51] KIT is detected in histologic sections using immunostaining and its pattern of localization (i.e., cytoplasmic versus membranous) is associated with receptor dysregulation.[23] Mutations in both the extracellular and the transmembrane domains of the c-kit gene have been identified in 25–30% of intermediate and high-grade MCTs. The cause of the high mutation of the c-kit gene in canine MCTs is unknown, but it is not demonstrated to be germline in nature, and is thus not heritable.[28] The detection of specific mutations is associated with differences in prognosis depending on mutation type. Thus, PCR for c-kit mutations, rather than immunologic detection of the KIT receptor, may become valuable as a prognostic tool in canine MCTs.[23]

Cell Morphometry

Cell morphometry is computer-assisted image analysis, which requires specialized software and advanced training. It can be applied to both cytologic and histologic specimens to determine mean nuclear area (MNA) and microvascular density (MVD), the latter with the concurrent immunostaining for factor-VIII-related antigen and cyclooxygenase-2 (COX-2). Using MNA analysis, larger nuclei have been correlated with shorter mean survival times, and higher MVD have been linked to higher histologic grade in canine MCT.[5,17,30,38,40,66]

FELINE MAST CELL TUMOR

Mast cell neoplasia in cats is best divided into three clinical entities: cutaneous, visceral, and intestinal. As these represent different clinical entities, each will be discussed separately.

Cutaneous

Signalment, Incidence, and Etiology

The MCT accounts for approximately 21% of all feline skin tumors.[71] There has been a dramatic increase in the number of feline cMCTs since 1950 and the global incidence may vary by geographic distribution.[28] Most cMCTs occur in cats over age four, although young Siamese cats may have an increased incidence of atypical MCTs.[23] No definitive age predilection has been identified. No definitive cause for feline MCT has been elucidated, although gain-of-function mutations in the c-kit gene are reported in up to 68% of cats with cutaneous MCT.[23] However, in one study of cats with multiple cMCTs, the majority of neoplasms contained different c-kit mutations within individual tumors, suggesting that additional factors play a role in the development of feline MCTs.[53]

History and Clinical Signs

Most feline cMCTs are solitary, although multiple clustered or diffuse lesions can exist.[28] Tumors most commonly occur on the head and neck, with fewer on the truck and extremities. Typical feline cMCTs are raised and alopecic, with variable degrees of erythema, although occasional plaque-like lesions resembling feline eosinophilic granulomas are described.[28]

Diagnosis

The majority of feline cMCTs are well-differentiated and easy to diagnose on cytology, although they are often less granular than their canine counterpart.[23] However, there is an atypical-appearing subtype of feline cMCT that contains few well-granulated mast cells admixed with scattered histiocytes, lymphocytes, and eosinophils.[28,71]

Staging

Although there is no standardized staging system for feline MCTs, a search for multiple cutaneous nodules is recommended. If more than one mass is noted,

aspiration of the spleen is advised, even if ultrasonographic evaluation is unremarkable, as splenic involvement is described in cats with multiple MCTs and splenectomy has been associated with prolonged survival time.[26]

Unlike in dogs, buffy coat evaluation may be valuable, as cats rarely have circulating mast cells in the absence of MCT.[16] Most cats with peripheral mastocytosis have splenic involvement, rather than only cutaneous MCTs.[61]

Grading

There is no standardized diagnostic approach, including cytologic or histologic grading scheme, for feline cMCT. Previous attempts to apply the canine Patnaik grading scheme were unhelpful.[11,32] While some recommend dividing these neoplasms into two types, mastocytic and histiocytic, others advocate for a system containing three types, namely, well-differentiated, pleomorphic, and atypical (histiocytic).[23,28] A European consensus group composed of both pathologists and oncologists suggests dividing these tumors into mastocytic and histiocytic types, with further division of the mastocytic type into well-differentiated and pleomorphic subtypes.[9]

Although the proposed terminology is confusing, the vast majority of feline cutaneous MCT are easily diagnosed. Occasionally, tumors of the atypical or histiocytic types lack characteristic granules and may require special stains (e.g., Giemsa or toluidine blue). These tumors occur rarely and may initially be confused with histiocytic inflammation or non-mast cell neoplasia.[23] Unlike their canine correlates, feline cMCTs typically contain low numbers of eosinophils and minimal collagenolysis.[23] This is likely due to the fact that the granules of feline mast cells lack eosinophil chemotactic factor and other collagenolytic substances.

While pleomorphism does not typically correlate with aggressive biologic behavior in feline cMCTs, a high mitotic index and high tumor burden (>5) have been associated with poor outcome, regardless of histologic type.[22,53] Immunohistochemical staining and most proliferation markers have proven minimally helpful in prognostication of feline cMCTs. While high Ki-67 expression has been associated with more biologically aggressive MCTs, no definitive cutoff score has been determined, limiting the utility of this index.[53]

Visceral

Signalment, Incidence, and Etiology

MCTs are one of the most common splenic lesions in cats, accounting up to 15% of all splenic pathology.[63] Older cats are typically affected and there is no known breed or sex predilection.[26,63] While the spleen is the primary site, concurrent involvement of the liver, intraabdominal lymph nodes, bone marrow, lung, and intestine has been reported.[28]

History and Clinical Signs

Cats with visceral MCT most commonly present with systemic signs, including vomiting, anorexia, and weight loss. Palpable splenomegaly and the presence of an eosinophil and/or mast-cell-rich effusion may be noted. GI ulceration with hemorrhage or hypotensive shock may be evident, due to the release of mast cell mediators.[28]

Diagnosis/Staging

Visceral MCTs are typically diagnosed with cytologic examination of effusions and splenic aspirates. In some cats with multicentric disease, there are no ultrasonographic lesions, while in other cases, discrete nodules are noted.[18] Buffy coat examination may be helpful both initially and to monitor response to therapy, as the number of circulating mast cells may positively correlate with response to therapy and disease progression.[28] Following splenectomy, median survival time for feline visceral MCTs is 12–19 months.[28]

Intestinal

Signalment, Incidence, and Etiology

Similar to cats with splenic MCTs, cats with intestinal MCT most commonly present with systemic signs, including vomiting, diarrhea, anorexia, and weight loss. One or more palpable intestinal masses may be present and the presence of an eosinophil and/or mast-cell-rich effusion may be noted.[28] eighty-five percent of feline intestinal MCTs are located within the small intestine, with roughly equal distribution between the duodenum, jejunum, and ileum. Colonic involvement is much less frequent.[28]

Diagnosis/Staging

Intestinal MCTs can be challenging to diagnose, as neoplastic cells often lack characteristic metachromatic granules on both cytologic and histologic preparations. This may be due to the fact that there are two different types of mast cells, connective tissue mast cells (CTMC) and mucosal mast cells (MMC), both of which reside in the intestinal tract and exhibit different MMCs (see Chapter 47), which comprise a large number of feline intestinal MCTs, and exhibit low granularity due to either poor differentiation or poor granule preservation. Use of non-formalin fixatives (e.g., Carnoy's) may better preserve mast cell granules in specimens stained with both H&E and special stains.[23,45]

As feline intestinal MCTs often spread to distant locations, both abdominal and thoracic imaging can be used to determine disease spread.[28] Buffy coat smears are less useful for monitoring disease progression and response to therapy, as peripheral mastocytosis is rarely seen in cats with intestinal MCT. Prognosis is typically poor in these cats, as most exhibit distant metastasis at the time of presentation.[28]

MAST CELL TUMORS IN OTHER SPECIES

MCTs have been reported in numerous veterinary species, including horses, cattle, pigs, ferrets, goats, snakes, and iguanas.[1,4,6,13,23,31,42,43,48,60,64]

In horses, MCTs are uncommon. They are overrepresented in males and Arabians and typically present as a single, variably appearing mass over the head, neck, or legs.[13,23] The vast majority are cured with surgical excision, although low numbers of equine MCTs reportedly spread to local lymph nodes.[43,48] Diagnosis is typically easily accomplished in both cytologic and histologic specimens, where both eosinophils and collagenolysis can be observed. Equine MCTs occasionally demonstrate dystrophic mineralization, which can complicate the diagnosis.[23] No definitive predictors of biologic behavior have been discovered for equine MCTs.[13,23]

MCTs in cattle are typically malignant and disseminate widely to both lymph nodes and viscera, although occasional solitary cMCTs have been reported.[1,23] Microscopic appearance of bovine MCTs is variable, ranging from well-granulated with abundant eosinophils to poorly granular with rare eosinophils. As such, a diagnosis of round cell neoplasia in cattle warrants special or immunohistochemical stains to distinguish MCT from histiocytic lesions.

Both solitary cutaneous and disseminated MCTs, including cases of mast cell leukemia, have been reported in pigs, although the overall incidence of MCTs is very low in this species.[6,31,60] Porcine MCTs may exhibit poor granularity, which may result from a predominance of mucosal mast cell-origin tumors and may require nontraditional fixatives for histologic specimens.[31,45] Due to the low prevalence of porcine MCTs, there is little information regarding prognosis or response to therapy.

MCTs are the most common cutaneous neoplasm of ferrets. MCTs in ferrets appear similar microscopically to those in cats and are relatively easy to diagnose.[4,35] Visceral and intestinal forms also exist. Despite their prevalence, the paucity of pet ferrets makes the overall number of these neoplasms low, limiting available prognostic and treatment information.

AN OVERVIEW OF CANINE AND FELINE HISTIOCYTIC DISEASES

There are several well-defined histiocytic proliferative diseases that have been recognized in dogs (Table 74.1).[55] These disorders represent a frustrating group of diseases because it may be difficult to differentiate them from granulomatous, reactive inflammatory disorders or from lymphoproliferative diseases in regular paraffin sections. The clinical presentation and behavior and responsiveness to therapy vary tremendously between the syndromes observed.

The reactive histiocytoses have only been identified in dogs; there is no known feline counterpart. The reactive histiocytoses, cutaneous histiocytosis (CH) and systemic histiocytosis (SH), are related disorders arising from activated interstitial dendritic cells (DCs). Reactive histiocytoses are histiocyte- and lymphocyte-rich inflammatory disorders associated with a degree of immune dysregulation, which promotes lesion persistence. Cutaneous histiocytosis presents with single or multiple lesions, which tend to wax and wane, and may even spontaneously regress. Some cases respond to prednisone, some respond to tetracycline and niacinamide, and the remainder persist and may require more

TABLE 74.1 Histiocytic diseases of dogs and cats.

Disease	Species	Cell of origin	Key morphological features	Immunophenotype
Cutaneous histiocytosis	Dog	iDC-activated	Vasocentric lesions are focused on mid-dermis to subcutis ("bottom-heavy"). Lesions are pleocellular but are dominated by histiocytes and lymphocytes. Lympho-histiocytic vasculitis is commonly observed. Histiocytes lack cytologic atypia, and multinucleated giant cells are rare. Skin-draining lymph nodes may be infiltrated.	CD1a, CD4, CD11c/CD18, CD90, Iba-1, CD204 (variable)
Systemic histiocytosis	Dog	iDC-activated	Lesions are identical to cutaneous histiocytosis in skin. Lesions extend to lymph nodes, ocular and nasal mucosae, and internal organs.	CD1a, CD4, CD11c/CD18, CD90, Iba-1, CD204 (variable)
Histiocytoma	Dog	LC	Lesions have an epidermal focus ("top-heavy"), and intra-epidermal foci are common. Histiocytes have diverse nuclear morphology (round, ovoid, indented, or complex nuclear contours). Multinucleated cells and cytologic atypia are rare.	CD1a, CD11c/CD18, E-cadherin, Iba-1, CD204 (negative)
Cutaneous Langerhans cell histiocytosis	Dog	LC	Multiple cutaneous lesions are observed. Metastasis to lymph nodes and internal sites is possible. Lesions are otherwise identical to histiocytoma, but may have a higher frequency of multinucleated cells and cytologic atypia.	Identical to histiocytoma
Histiocytic sarcoma	Dog, cat	iDC	Mass lesions are observed in spleen, lung, lymph node, periarticular, and other primary tissue sites. Histiocytes are pleomorphic, mononuclear, and multinucleated giant cells with marked cytological atypia.	CD1a, CD11c/CD18, Iba-1, CD204 (variable)
Histiocytic sarcoma—hemophagocytic	Dog, cat	Macrophage	Mass lesions are lacking. Diffuse splenomegaly and insidious infiltration of liver lung and bone marrow are consistently observed. Splenic red pulp is expanded by erythrophagocytic histiocytes. Mononuclear and multinucleated giant cells with cytologic atypia are common. Alternatively, histiocytes may have little cytological atypia.	CD1a (low), CD11d/CD18 (dog), Iba-1, CD204
Dendritic cell leukemia	Dog	iDC	Predominant blood and bone marrow involvement is observed. There is diffuse infiltration of spleen, lung, and liver. Histiocytes manifest moderate cytologic atypia in blood and tissues.	CD1a, CD11c/CD18, Iba-1*, CD204*
Feline progressive histiocytosis	Cat	iDC	Skin nodules and plaques are observed. Lesions occupy the dermis with an epidermal focus. Intra-epidermal foci (40%) occur. In early lesions, histiocytes have minimal cytologic atypia. In later lesions, histiocytes manifest cytological atypia as described for histiocytic sarcoma.	CD1a, CD11c*/CD18, CD5 (50%), Iba-1, CD204 (variable)
Pulmonary Langerhans cell histiocytosis	Cat	LC	There is multinodular to diffuse involvement of all lung lobes. Lesions consist of cohesive histiocytic infiltrates, which obliterate terminal airways and extend to pleural surfaces. Birbeck granules observed by TEM.	CD1a*, CD11c*/CD18, E-cadherin, Iba-1*, CD204*

TEM = transmission electron microscopy; LC = Langerhans cell; iDC = interstitial dendritic cell; CD1a* = expected, not assessed to date; CD11c* = expected but not yet assessable in cats; Iba-1* = not reported; CD204* = not reported.

aggressive immunosuppressive therapy. Systemic histiocytosis is a familial disease of Bernese Mountain Dogs that occurs sporadically in other breeds. SH presents with prominent skin manifestations identical to CH, but systemic involvement, including mucous membranes (ocular and nasal), lymphoid organs, lung, and bone marrow, may occur. Although the lesions may wax and wane, SH is a progressive disease that often requires continuous immunosuppressive therapy with cyclosporine or leflunomide.

Canine cutaneous histiocytoma (CCH), which exhibits evidence of Langerhans cell (LC) differentiation, usually occurs as a solitary lesion in young dogs and spontaneously regresses. Cutaneous Langerhans cell histiocytosis (cLCH) covers a spectrum of disease in which multiple cutaneous lesions are consistently observed. In some cases, lymph node and systemic metastasis are also observed. Individual skin lesions otherwise resemble those in CCH. Hence, these two diseases could be considered part of a larger spectrum of disease with diverse biological behavior. Feline counterparts of CCH and cLCH have not been reported.

The histiocytic sarcoma (HS) complex occurs in dogs and cats. Histiocytic sarcomas occur with a high incidence in Bernese Mountain Dogs, Rottweilers, Flat-coated Retrievers, Golden Retrievers, and sporadically in many other breeds. The incidence of HS in cats is much lower than in dogs. Histiocytic sarcomas occur as localized lesions in spleen, lymph nodes, lung, bone marrow, skin and subcutis, brain, and articular tissue of appendicular joints. HS may occur as multiple lesions in single organs (especially spleen and skin), and rapidly disseminate to involve multiple organs. This form of the disease was formerly called malignant histiocytosis (MH), but is now more appropriately termed disseminated HS. HSs mostly arise from interstitial DCs. However, the hemophagocytic form of HS is a distinctive clinicopathologic entity, which arises from splenic red pulp (± bone marrow) macrophages. Durable responses to chemotherapy are difficult to achieve.

There are two feline histiocytic diseases that do not have a canine equivalent: feline progressive histiocytosis (FPH) and pulmonary Langerhans cell histiocytosis (pLCH). FPH is the most common histiocytic disease in cats, begins as cutaneous nodules and plaques, and is essentially a low-grade HS with an initially indolent behavior. Later in the clinical course, the lesions are more aggressive. Pulmonary LCH is a disease of aged cats (10–15 years), which causes progressive respiratory failure due to extensive obliteration of the pulmonary parenchyma by an infiltrate dominated by LCs.

HISTIOCYTIC LINEAGES

The cellular spectrum covered by the term histiocyte has evolved over time. Histiocyte is now considered an overarching term to describe cells of DC or macrophage lineage.[16,26] Histiocytes differentiate from CD34+ stem cell precursors into macrophages and several DC lineages, which encompass LCs and interstitial DCs. Langerhans cells occur within epithelia of the skin and alimentary, respiratory, and reproductive tracts.[52] Interstitial DCs occur in perivascular locations in many organs except the brain, although they do occur in the meninges and choroid plexus.[22] Among the most studied DCs are those that occur in skin; these include epidermal LCs and dermal DCs, which are interstitial DCs. Dendritic cells that occur in T cell domains in peripheral lymphoid organs (lymph node and spleen) are known as interdigitating DCs. Interdigitating DCs in lymph nodes are comprised of resident DCs and migratory DCs. The migratory DCs arrive in lymphatics from tissues and consist of LCs and interstitial DCs.[85] The majority of canine and feline histiocytic diseases involve proliferations of cells of LC or interstitial DC lineage. Hemophagocytic histiocytic sarcoma (HHS) is currently the only histiocytic disease of dogs and cats that has been shown to originate from macrophages.[55]

Cytokines and growth factors that influence DC development include fms-like tyrosine kinase (FLT3) ligand, granulocyte–macrophage colony-stimulating factor (GM-CSF), stem cell factor, tumor necrosis factor alpha (TNF-α), interleukin 4 (IL-4), and transforming growth factor beta 1 (TGF-β1).[44,85] Macrophage development from CD34+ precursors is influenced by GM-CSF and macrophage colony-stimulating factor (M-CSF). Blood monocytes can differentiate into either macrophages under influence of M-CSF or into DCs under the influence of GM-CSF and IL-4.[83,84] Langerhans cell differentiation is critically dependent on TGF-β1 stimulation.[44,52,73] Epidermal keratinocytes constitutively secrete TGF-β1, which promotes the differentiation of LCs from dermal CD14+ precursor cells. These precursor cells upregulate C–C chemokine receptor 6 (CCR6) and migrate into the epidermis to become immature epidermal-resident LCs in response to locally produced macrophage inflammatory protein 3 alpha (MIP-3α or CCL20). Langerhans cells localize within epithelia via E-cadherin homotypic adhesion.[44,52] Langerhans cells, in the quiescent conditions that prevail in normal skin, are subject to slow turnover and are maintained by self-renewal or renewal from a dedicated dermal precursor cell.[44,52] Dermal interstitial DCs are subject to more rapid turnover and are repopulated by a blood-borne precursor (perhaps the monocyte) and by local self-renewal.[52,100] Culture of LCs in the presence of GM-CSF and IL-4 results in further differentiation of LCs into functionally mature DCs with enhanced potential to present antigen to T cells with appropriate costimulation. These latter conditions are present in states of cutaneous inflammation.[44]

IMMUNOPHENOTYPIC MARKERS OF HISTIOCYTES

Dendritic cells are the most potent antigen-presenting cells (APC) for induction of immune responses in naïve T cells. The development of canine- and feline-specific

monoclonal antibodies has enabled the identification of DCs and macrophages in canine and feline tissues, especially skin.[53,72,77] Dendritic cells occur in two major locations: (1) within the epidermis (LCs), and (2) within the dermis, especially adjacent to postcapillary venules (dermal interstitial DCs).[100] Canine and feline DCs express CD1a molecules which together with major histocompatibility complex (MHC) class I and class II molecules are responsible for presentation of peptides, lipids, and glycolipids to T cells.[47,53,61,77,79,97] Hence, DCs are best defined by their abundant expression of molecules essential to their function as APC. In skin, the family of CD1 proteins is largely restricted in expression to DCs; while MHC class I and II are more broadly expressed. Antigen presentation is only effective in activating naïve T cells in the presence of costimulation, which is mediated by B7 family members (CD80, CD86) expressed on DCs. Termination of immune responses is accomplished via signaling through the checkpoint inhibitors CTLA-4 and PD-1, which are expressed on T cells (Figure 74.1).[9,12,46,78]

The β-2 integrins (CD11/CD18) are critically important adhesion molecules, which are differentially expressed by all leukocytes. β-2 integrins are heterodimeric molecules consisting of one of four α subunits (CD11a–d) and a single β subunit (CD18 or β-2).[23,24,94] Canine-specific monoclonal antibodies for the known human β-2 integrin α subunits CD11a (αL), CD11b (αM), and CD11c (αX) were produced (Leukocyte Antigen Biology Laboratory, UC Davis—LABL). Also, a monoclonal antibody specific for a novel canine β-2 integrin α subunit was discovered.[24] This antibody was then used to characterize the canine protein, which led directly to the discovery of the human analog designated αD and by inference CD11d.[95] Subsequently, CD11d expression was used to define macrophage origin in HHS, which differed markedly from HS of interstitial DC origin, which expressed CD11c.[5,58]

CD11/CD18 expression is highly regulated in normal canine macrophages and DCs. CD11c is expressed by LCs and interstitial DCs; while macrophages predominately express CD11b (or CD11d in hematopoietic environments such as the splenic red pulp and bone marrow). A subset of dermal interstitial DCs also expresses CD11b.[23,24,72] In diseased tissues, these β-2 integrin expression patterns may be broadened. β-2 integrins are detectable in feline tissues; however, monoclonal antibodies specific for feline CD11a and CD11c are not available. Feline CD11b and CD11d are detectable with cross-reactive anticanine monoclonal antibodies (LABL). Canine and feline CD18 and canine CD11d are detectable by species-specific monoclonal antibodies that were developed for use in formalin-fixed paraffin-embedded (FFPE) tissue (LABL). These monoclonal antibodies have greatly facilitated the investigation of histiocytic diseases in dogs and cats.[2–5,13,21,28,53,58,61]

Histiocytes (macrophages and DC) express ionized calcium-binding adaptor molecule-1 (Iba-1), which is detectable in many species in FFPE tissue.[35,69] Macrophages express an array of scavenger receptors including the class A scavenger receptors, CD163 and CD204. The latter is more broadly, but not uniformly, expressed by macrophages.[37] For example, microglia in the brain do not express CD204, although it is expressed by perivascular macrophages. Epidermal LCs and interdigitating DCs in normal tissues do not express CD163 and CD204.[37,92] CD163 and CD204 are markers of M2 macrophages, which, in contrast to M1 macrophages, inhibit inflammation.[41] Dendritic cells in other locations can express CD163 and CD204.[10,50,98] Detailed characterization of the expression pattern of class A scavenge receptors on the diverse DC populations in dogs and

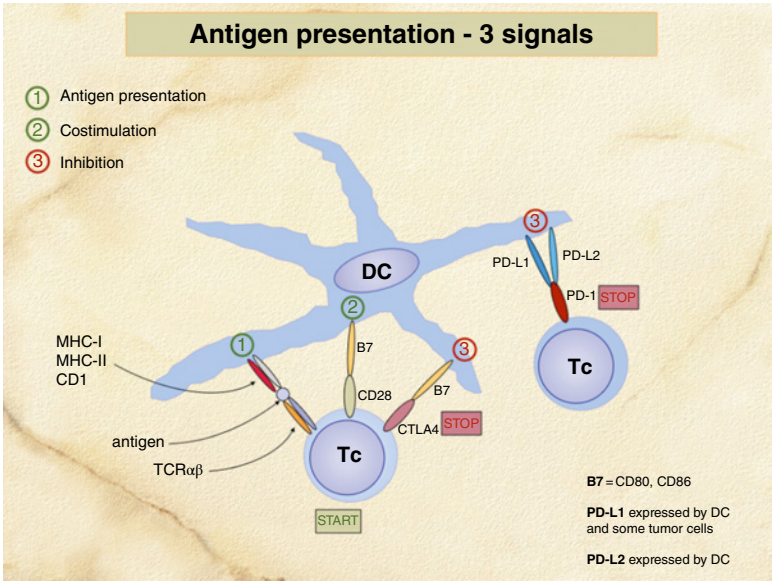

FIGURE 74.1 DCs express molecules involved in antigen presentation (CD1, MHC1, MHCII) and costimulation (B7 family: CD80 and CD86). DCs also signal through the checkpoint inhibitors expressed on T cells (CTLA-4 and PD-1), which leads to inhibition of immune responses.

cats is currently lacking. Langerhans cells and dermal interstitial DCs are also distinguishable by their differential expression of E-cadherin (LCs+) and Thy-1 (CD90) (dermal interstitial DCs+).

DENDRITIC CELL MIGRATION

The migration of DCs (as veiled cells) beyond the skin to the paracortex of lymph nodes, where they join forces with interdigitating DCs, occurs in the normal steady state and is enhanced in inflammatory states.[52,100] Successful interaction of DCs and T cells in response to antigenic challenge involves the orderly appearance of costimulatory molecules (B7 family—CD80 and CD86) on DCs, and their ligands—CD28 and cytotoxic T-lymphocyte antigen 4 (CTLA-4) on T cells (Figure 74.1).[9,78] In situ DCs have low expression of MHCII and costimulatory molecules and are more receptive to antigen uptake. Migratory DCs upregulate MHC class II and B7 family members and become more adept at antigen presentation to T cells.[9]

Aspects of the developmental and migratory program of DCs are recapitulated in canine and feline histiocytic diseases. Defective interaction of DCs and T cells may contribute to the development of canine CH and SH, which are related interstitial DC disorders that likely occur in the context of disordered immune regulation. The distant migratory potential of DCs is of immense clinical significance in the adverse prognosis of histiocytic sarcomas, which largely originate in interstitial DCs and rapidly disseminate via metastasis.

CANINE REACTIVE HISTIOCYTOSES

Reactive Histiocytoses—General Considerations

Reactive histiocytoses have been described in dogs only and are either confined to skin and draining lymph nodes (CH) or involve skin and extracutaneous sites (SH). Systemic histiocytosis was first described in Bernese Mountain Dogs and a familial association was apparent.[56] Histiocytic sarcomas occurred in the same families of Bernese Mountain Dogs as SH, but progression of SH to HS was not observed.[60] Systemic histiocytosis occurs in other large breeds of dogs. Overall, SH is a rare disease and CH is far more common. Cutaneous histiocytosis was first described in dogs as a waxing and waning dermatitis and panniculitis of unknown etiology, in which the lesions were dominated by histiocytes.[51]

The concept that CH and SH are related diseases emerged from a study in which an identical lesion topography and histiocyte immunophenotype were described.[3] Both are believed to be antigen-driven, but no etiologic agent/antigen has been discovered.[3] The lesions are dominated by activated dermal interstitial DCs and T cells, which frequently creates a lympho-histiocytic dermal vasculitis. The lymphoid component, which can vary throughout and between lesions, is enriched for CD8+ T cells.[3] The role played by these T cells is unknown, as spontaneous regression of SH or CH does not occur as it does in CCH. Instead, T cells, as an antigen-responsive element, may be involved in the proliferation, activation, and differentiation of DC via T cell-derived cytokines such as GM-CSF and TNF-α.[44,85] The hypothesis that an immunoregulatory deficit underlies the development and progression of CH and SH is bolstered by their clinical behavior and response to therapy. Both diseases are marked by spontaneous remissions and relapses (particularly early in the disease) and the only effective therapies are either immunosuppressive or immunomodulatory, including prednisolone, cyclosporine A, leflunomide, and tetracycline/niacinamide.[54,67] In light of their capacity to wax and wane and spontaneously resolve, assessing the effects of therapy in SH and CH is challenging.

CUTANEOUS HISTIOCYTOSIS VERSUS SYSTEMIC HISTIOCYTOSIS

Cutaneous histiocytosis is an inflammatory lympho-histiocytic proliferative disorder that primarily involves the skin and subcutis.[51] CH occurs in a number of breeds with no clear breed predisposition.[3,51,67] Lesions may involve the local lymph nodes, although the incidence of lymph node involvement is unknown (as lymph nodes are not commonly sampled when skin biopsies are taken unless there is marked lymphadenomegaly). The lesions most often occur as multiple cutaneous and subcutaneous nodules up to 4 cm diameter, and solitary lesions are uncommon. Overlying skin ulceration is common. Lesions may disappear spontaneously, or regress and appear at new sites simultaneously. Topographically, lesions may be found on the face, nose, neck, trunk, extremities (including foot pads), perineum, and scrotum.[3,51,67]

SH is a generalized histiocytic proliferative disease involving the skin, ocular and nasal mucosae, and peripheral lymph nodes. The disease predominately affects young to middle-aged dogs (2–8 years). Although SH was originally described in related Bernese Mountain Dogs, it has been observed, albeit less commonly, in the Rottweiler, Labrador Retriever, Basset Hound, Irish Wolfhound, and others.[3,56] Familial occurrence of SH is evident in Irish Wolfhounds in the Pacific Northwest (USA) (Moore—unpublished data). The clinical signs of SH vary with disease severity and extent, but may include anorexia, marked weight loss, stertorous respiration, and conjunctivitis with marked chemosis. Multiple cutaneous nodules may be distributed over the entire body, but, similar to CH, are especially prevalent in the scrotum, nasal bridge, nasal planum, and eyelids. Ulceration of the skin overlying the nodules is common and peripheral lymph nodes may be palpably enlarged by the histiocytic infiltrates.

Morphologic Features—Reactive Histiocytoses

In skin, the microscopies of SH and CH are essentially identical. In both, there is typically a "bottom-heavy" topography (Figure 74.2) characterized by extensive involvement of the deep dermis and subcutis with inconsistent involvement of the superficial dermis (with rare epidermotropism by histiocytes). Discrete perivascular lesions in the mid-dermis often coalesce in the deep dermis and subcutis. A lympho-histiocytic vasculitis (Figure 74.3) is common and may lead to vascular compromise, infarction of surrounding tissues, and ulceration of the overlying epidermis. The infiltrate is pleocellular, but histiocytes and lymphocytes outnumber neutrophils, plasma cells, and eosinophils. Histiocytes have large round to oval, indented, folded, or twisted nuclei and contain abundant pale eosinophilic cytoplasm with occasional vacuoles. Multinucleated histiocytes and histiocytes with bizarre, misshapen nuclei and mitotic figures, which are characteristic of HS, are lacking in CH and SH. In affected lymph nodes, histiocytes selectively invade the paracortex and sinuses. In severe lesions, the histiocytic infiltrate obliterates the cortex, trabeculi, and capsule with possible perinodal infiltration.

Inflamed non-epitheliotropic cutaneous T-cell lymphoma (CTCL) may be confused with CH.[57] The key discriminatory features are: (1) the identification of clusters of atypical T cells and (2) variable expression of CD3 by neoplastic T cells—so-called "CD3 antigen loss." Definitive diagnosis is reliant upon clonality testing, which will detect clonal T cell expansion within the reactive/inflammatory T cell and histiocyte infiltration.[38,57]

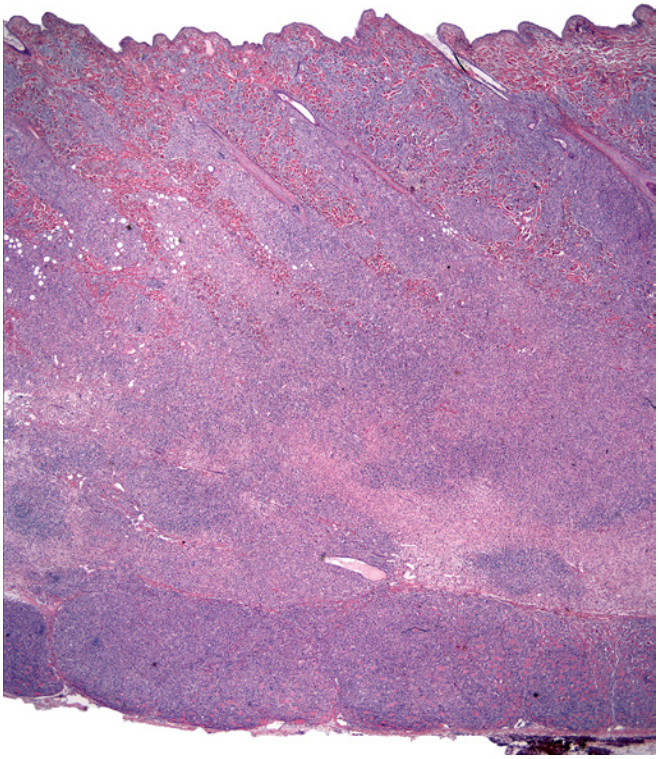

FIGURE 74.2 Cutaneous histiocytosis. Histiocytic infiltrates spare the superficial dermis and coalesce in the deep dermis and subcutis. H&E.

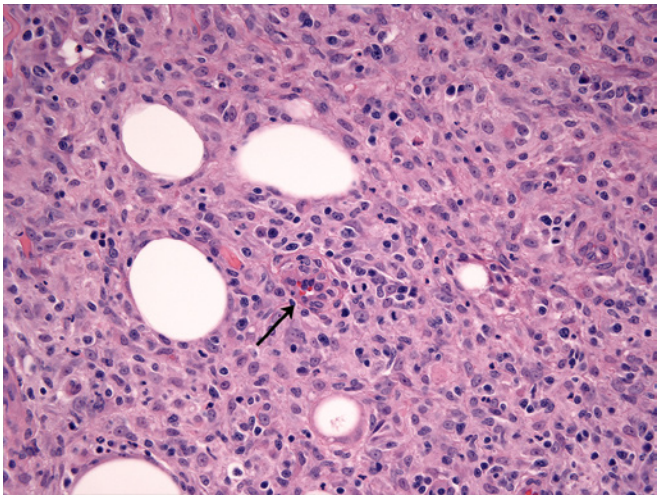

FIGURE 74.3 Cutaneous histiocytosis. Cohesive infiltrates of well-differentiated histiocytes and fewer lymphocytes in the subcutis. Lymphocytes and histiocytes infiltrate a vessel wall (arrow). H&E.

The complete distribution of SH lesions is often only fully appreciated at necropsy. Histiocytic lesions have been observed in lung, liver, bone marrow, spleen, peripheral and visceral lymph nodes, kidneys, testes, orbital tissues, nasal mucosa, and other sites. Like the skin, lesions in these sites are vasocentric and the infiltrates radiate to obliterate surrounding tissue. The lesions may only be microscopic, but mass formation has also been observed.

Immunophenotypic Features

The immunophenotypes of SH and CH, which is one of an activated interstitial DC, are virtually identical.[3] Histiocytes in both express markers expected of DCs, such as CD1a, C11c/CD18, and MHC class II. Histiocytes are $CD4^+$ (a marker of DC activation) and $CD90^+$ (Thy-1), which is expressed by normal dermal interstitial DCs, but lack expression of E-cadherin. Hence, the immunophenotype of histiocytes in CH and SH is the inverse of cutaneous histiocytoma and cLCH, which lack expression of CD4 and CD90, and distinct from HS, which lacks expression of CD4.[5,61] Of these antigens, only CD90, CD18, MHC class II, and E-cadherin are assessable in formalin-fixed tissue sections, whereas CD1a, CD4, and CD11c are not. More recently, the author has assessed expression of Iba-1 and CD204 in CH and SH lesions. Although Iba-1 was diffusely expressed by lesional histiocytes, CD204 expression was variable and most prominent in the dispersed histiocytes at the periphery of the lesions (Moore—unpublished data).

TREATMENT OPTIONS IN SH AND CH

A full evidence-based summary of the treatment of SH and CH is beyond the scope and intent of this chapter; however, the following are general concepts. Systemic histiocytosis is a difficult and frustrating condition to treat. The response to steroids is variable, although results are better for CH than for SH. Hence, steroids are worth trying given the expense of alternative treatments. Intractable cases, which may require maintenance therapy, are best treated with more aggressive immunosuppressive drugs, including cyclosporine A and leflunomide. However, published data are lacking. In some cases of CH and SH, spontaneous regression of lesions or episodic disease activation can occur. As such, aggressive immunosuppressive therapy may not be necessary until disease progression is evident or troublesome sites are involved. A retrospective evaluation of 32 cases of CH identified tetracycline and niacinamide as an effective treatment. Recurrence of lesions occurred in nine dogs; multiple recurrences occurred in seven of these dogs. At the conclusion of the study, 26 dogs were alive and lesion-free. Ten dogs were on maintenance therapy, most commonly with tetracycline/niacinamide (eight dogs). Recurrence of CH was more likely in dogs with lesions involving the nasal planum.[67]

CANINE CUTANEOUS HISTIOCYTOMA COMPLEX

Cutaneous Histiocytoma

Histiocytomas usually occur as solitary lesions, which often undergo spontaneous regression.[62,89] Multiple histiocytomas (i.e., cLCH) occur in <1% of cases and are more common in Shar Pei dogs.[2,89] Postexcisional recurrence is extremely rare and development of a histiocytoma at a new site occurs at extremely low incidence. Metastasis of solitary histiocytomas to local lymph nodes has been observed.[25,61] Regression of these lesions is the most common outcome, although systemic spread has also occurred.

Cutaneous histiocytomas originate from cells that manifest LC differentiation.[48,49,61] Demonstration of LC differentiation, in part, rests upon the identification of a cytoplasmic variant of the surface C-type lectin, langerin (CD207). Internalization of langerin mediates the formation of Birbeck granules (BGs), which are cytoplasmic structures that define LCs and distinguish them from interstitial DCs. Birbeck granules have been found in the LCs of species that express a functional langerin molecule, including mice, humans, pigs, cats, and many others.[52,65,77] However, BGs have not been observed in canine epidermal DCs, which are presumed to be LCs.[59] The lack of BGs in these presumed LCs may reflect unique features of canine langerin, including known structural abnormalities in its carbohydrate recognition domain, which is predicted to diminish mannose binding or its lack of exon 3, which encodes the neck region required for oligomerization and mannose binding.[65] In support of this, mice bearing langerin-lacking exon 3 do not form Birbeck granules.[74]

In accordance with their presumed LC origin, BGs have not been conclusively illustrated in CCH. Despite their lack of BGs, an LC origin to CCH is based on the aggregate of immunophenotypic and ultrastructural features.[7,31,39,49,61] Histiocytomas do exhibit ultrastructural features characteristic of DCs and also express CD1a and often E-cadherin, which are important functional markers expressed by LCs. Histiocytomas arise in the dermis and may invade the epidermis in a subset of lesions. Hence, histiocytomas do not arise directly from intra-epidermal LCs. It is quite possible that they arise from dermal precursors of LCs similar to the cells described by Larregina and others.[44] These CD14+ dermal cells downregulate CD14, and express CD1a, E-cadherin, and langerin following culture with TGF-β1. They also express CCR6 and are responsive to MIP-3α (CCL20), which is a chemokine produced by keratinocytes that facilitates migration of CCR6+ LCs into epidermis. CD14+ dermal cells did not possess BGs when first isolated, but did develop BGs after culture with TGF-β1. CD14+ LC precursors are found in perivascular locations in superficial and deep dermis. It is not known if an analogous CD14+ LC precursor exists in the dog, but the prospect that CCH might originate from a perivascular dermal LC precursor is an attractive hypothesis, which could also explain the stratified expression pattern of E-cadherin within some histiocytomas—stronger expression closer to the epidermis, which is a rich source of TGF-β1.[71]

Morphologic Features

Histiocytomas are often dome-shaped exophytic growths with complete or partial alopecia that are less than 2 cm in diameter. Topographically, the tumor infiltrate demonstrates a tropism for the superficial dermis and epidermis to create a "top-heavy" lesion. Tumor histiocytes may invade the epidermis as individual cells or nests of cells (Figure 74.4). In one study, invasion of the epidermis by individual histiocytes or nests of histiocytes occurred in >60% of lesions.[61] Although epidermal invasion is likely not as prevalent as that report suggests, it is a diagnostically useful feature and should be carefully evaluated. Importantly, such invasion may raise concern for epitheliotopic CTCL, and immunophenotyping using antibodies specific for CD3 and CD18 is necessary to resolve this dilemma. Tumor histiocytes may display a range of cytological features. Nuclei may be round to oval, indented, or convoluted with rare multinucleated forms, but anisokaryosis and hyperchromatic nuclei are unusual. The mitotic index in histiocytomas is variable, but is often high. The cytoplasm is usually abundant and eosinophilic.

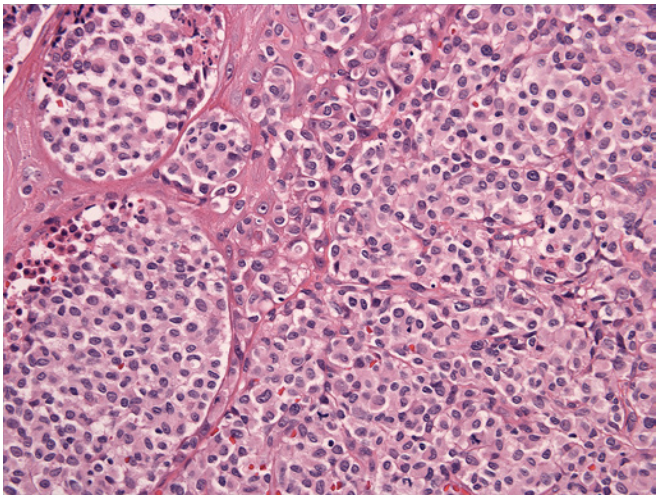

FIGURE 74.4 Canine cutaneous histiocytoma. Nest of histiocytes in the epidermis. H&E.

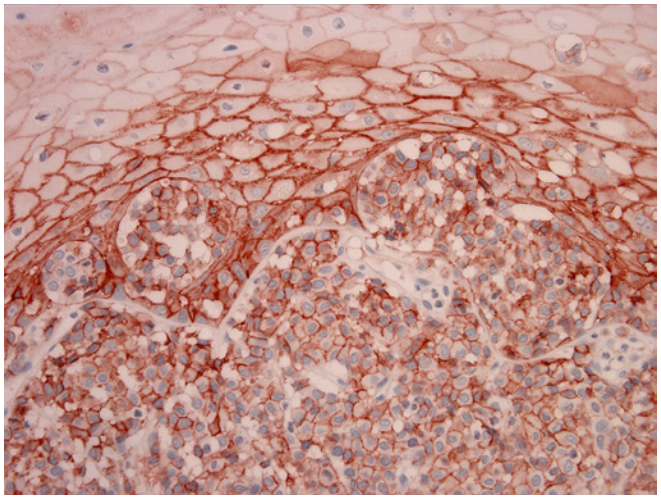

FIGURE 74.5 Canine cutaneous histiocytoma. E-cadherin expression by epitheliotropic histiocytes and by epidermal keratinocytes.

Immunophenotypic Features

The most comprehensive immunophenotype of canine histiocytomas was established using acetone-fixed sections from snap-frozen tumor tissue.[61] Based on this, and subsequent work, tumor histiocytes in canine histiocytoma have been found to diffusely express CD1a, CD11a/CD18, CD11c/CD18, CD44, CD45, and MHC class II, variably express CD11b/CD18 and CD54, and to lack expression of CD90 (Thy-1) and CD45RA.[79] Additionally, tumor histiocytes express E-cadherin, which is also expressed by normal LCs to localize in the epidermis via homotypic interaction with keratinocytes (Figure 74.5). The true incidence of E-cadherin expression in canine histiocytomas is not known, but it is very likely less than 100% observed in the published reports.[8,71] Histiocytomas lacking E-cadherin expression occur in our case series (Moore and Affolter—unpublished data). The staining pattern of E-cadherin may be limited to the histiocytic infiltrate immediately adjacent to the epidermis. Also, E-cadherin may be expressed by non-CCH, canine round cell tumors especially intracellularly, but also in the cell membrane.[71] Immunophenotyping with multiple markers can clearly resolve this issue, and E-cadherin expression remains a valuable indicator of LC differentiation in CCH. Furthermore, differential expression of CD90 and E-cadherin is useful in distinguishing proliferative diseases of interstitial DCs (CD90+) and LCs (E-cadherin+). Utilization of Iba-1 and CD204 adds further clarity in the diagnosis of CCH, as histiocytomas express Iba-1 but do not express CD204.[37]

CUTANEOUS LANGERHANS CELL HISTIOCYTOSIS

Histiocytomas are almost always solitary lesions, and the existence of multiple histiocytomas is uncommon. However, there are several reports of extensive skin involvement with multiple histiocytomas.[11,29,30,34,61,64] These cases may best fit under the umbrella of cLCH, as skin is the initial site of origin even when systemic disease eventuates. Cutaneous LCH is well documented in humans as a single-system disease and as a component of systemic disease.[63,80] Affected dogs may have literally hundreds of cutaneous lesions ranging from nodules to masses, which elevate the epidermis and may be accompanied by redness, alopecia, and ulceration. Lesions at mucocutaneous junctions and in tissues of the oral cavity may also occur. Although lesions are initially limited to skin, involvement of draining lymph nodes and, rarely, internal organs may occur.

Shar Pei dogs were overrepresented in a cohort of dogs afflicted by cLCH (about 20% of cases), but the disease occurred in many other breeds. Delayed regression of cLCH was common and lesions persisted for up to 10 months prior to regression. About 50% of the dogs with cLCH were euthanized due to complications in management of the extensive ulcerated lesions and failure of timely regression (Moore and Affolter—unpublished data). If cLCH involved lymph nodes, the prognosis was markedly worse. In all instances, these dogs were euthanized. The clinical course of dogs that experienced systemic spread of cLCH was even more rapid and all dogs were euthanized or died. Necropsies were performed on some dogs. Peripheral lymph nodes and lungs were consistently affected, but metastatic disease can be widespread and involve many other organs (Moore and Affolter—unpublished data). This spectrum of disease manifestation and diverse clinical behavior most resembles rapidly progressive multisystem LCH of humans.

Morphologic Features

Individual lesions of cLCH often do not differ markedly from CCH. The lesions are often large masses, which span the dermis and extend into the subcutis and muscle.

In aggressive cases, the lesions manifest a higher degree of cytologic atypia, but maintain tropism for the epidermis. Histiocytes may have more anisokaryosis and multinucleated cells than is typical for CCH, but these are not consistent features. Lymphatic invasion by neoplastic histiocytes portends lymph node involvement, which is an adverse prognostic indicator. Systemic lesions are consistently observed in lung where the infiltrates have a peribronchial distribution.

Immunophenotypic Features

The histiocytes in cLCH share the immunophenotype of histiocytes in CCH.

TREATMENT OF HISTIOCYTOMA COMPLEX

Solitary CCHs are either surgically removed or undergo spontaneous regression. Cutaneous LCH and cLCH with systemic involvement are refractory to therapeutic intervention, as immunosuppressives (e.g., corticosteroids and cyclosporine A) have not shown efficacy. Spontaneous remission is possible in cLCH and this occurs in about half of the cases, unless lymph node involvement occurs. In one published report, response of cLCH to immunomodulatory therapy with griseofulvin was reported.[64] Others have tried immunomodulation with levamisole without success in cLCH. Treatment with 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU or lomustine) was effective in causing lesion regression, but the responses were not durable.[55] A 6-year-old German Shorthaired Pointer with cLCH and internal disease was treated with toceranib and then masitinib after initial lomustine/vinblastine/l-asparaginase therapy failed (2 months). This dog enjoyed an extended survival (11 months after initiation of toceranib therapy) before succumbing to progressive disease. Although c-kit expression was not documented in this dog, unpublished data from the author suggest that another tyrosine kinase was likely active in his lesions. Further evaluation of toceranib and masitinib as a therapy for cLCH has not been conducted but is warranted.

HISTIOCYTIC SARCOMA COMPLEX

Histiocytic Sarcoma—General Considerations

HS are most often derived from cells with the immunophenotype of interstitial DCs, although the exact sublineages of DCs are not determined in most cases.[5] Specific candidates include interdigitating DCs in lymphoid tissues and perivascular interstitial DCs in other tissues. Given the ubiquitous distribution of these cells, HS can arise in almost any tissue. HS may be localized (i.e., originating at a single-tissue site) or disseminated (i.e., spread beyond the local draining lymph node to involve distant sites). Disseminated HS is the currently accepted terminology for what was originally reported as malignant histiocytosis. HS is principally a disease of dogs, although clinically identical, localized and disseminated HS has been infrequently reported in cats.[19,27,28,43,70]

The HS complex of diseases was first recognized in Bernese Mountain Dogs, in which a familial association was apparent.[60] Subsequent pedigree analyses support a polygenic mode of inheritance in this breed.[1,60,66] Although other breeds are predisposed to HS complex diseases, including Rottweilers, Labrador Retrievers, Golden Retrievers, and Flat-coated Retrievers, HS can occur sporadically in any breed.[5,18] Notably, the Pembroke Welsh Corgi has been associated with localized HS in the brain and in the lung.[35,36,91] Recently, studies of the genomic loci involved in HS in Bernese Mountain Dogs and Flat-coated Retrievers have identified abnormalities in tumor suppressor gene loci cyclin dependent kinase inhibitor 2A/B, (CDKN2A/B), retinoblastoma protein 1 (RB1), and phosphatase and tensin homolog (PTEN) that are broadly similar to those described in human HS.[33,82] Recently, a gain of function mutation in protein tyrosine phosphatase non-receptor type 11 (PTPN11) was identified in HS in Bernese Mountain Dogs; the same mutation had been identified in human HS. This mutation activates the MAPK pathway. Preliminary investigation of mitogen-activated protein kinase (MEK) inhibitor, trametinib, which targets the mitogen-activated protein kinase (MAPK) pathway, in canine HS cell lines and a mouse xenograft model shows promise.[88,90]

Clinical signs of HS are vague and include anorexia, weight loss, and lethargy. Other signs depend on the site of involvement, including cough and dyspnea with pulmonary involvement, seizures, incoordination and paralysis with central nervous system (CNS) involvement, and lameness with periarticular/articular HS (PAHS). Dogs with HS of interstitial DC origin often have mild, nonregenerative anemia.[1,58] More severe regenerative anemia, thrombocytopenia, hypoalbuminemia, and hypocholesterolemia have been consistently documented in HHS.[58] Hypercalcemia may also be encountered with HS, although the incidence is low (3%).[86]

Morphologic Features

Primary lesions of HS occur in spleen, lymph node, lung, bone marrow, CNS, skin and subcutis, and in periarticular and intra-articular tissues of the limbs. Secondary sites are widespread, but consistently include liver and lungs (with splenic primary), and hilar and mediastinal lymph nodes (with lung primary). In the original report of HS in Bernese Mountain Dogs, a high incidence of primary lung lesions was apparent.[60] Notably, pulmonary HS may have been mistaken for anaplastic large-cell carcinoma before the advent of lineage-specific cell markers. Similarly, approximately 50% of canine synovial tumors in one study were reclassified as HS by utilizing an anticanine CD18 monoclonal antibody (LABL).[5,21]

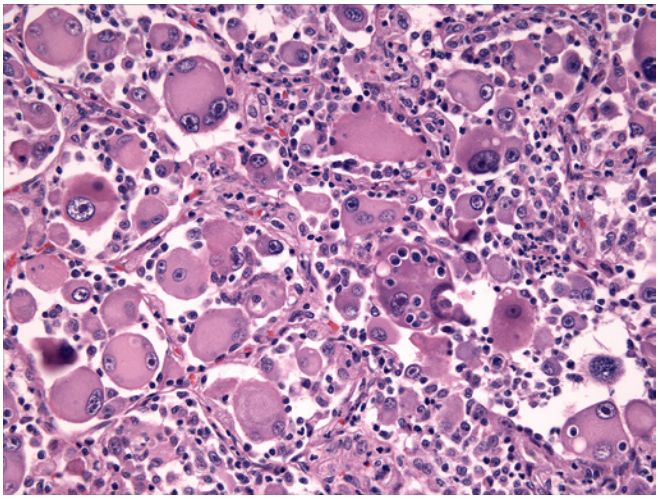

FIGURE 74.6 Histiocytic sarcoma. Cytologically atypical mononuclear and multinucleated giant cells in HS. Many cells are phagocytic. H&E.

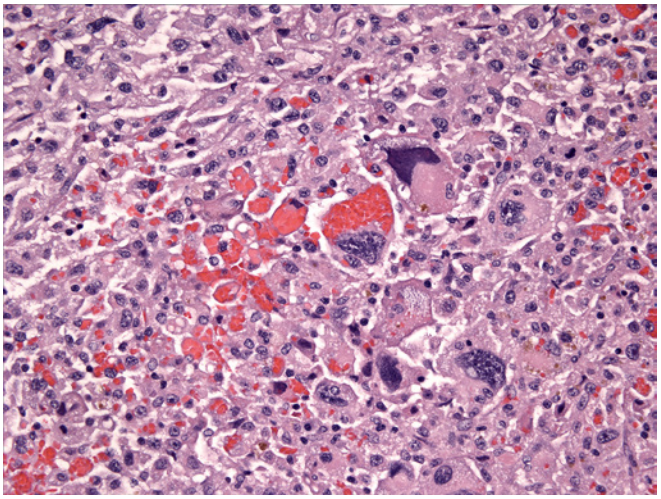

FIGURE 74.7 Hemophagocytic HS. Prominent erythrophagocytosis by cytologically atypical histiocytes in the splenic red pulp. H&E.

Lesions of HS that originate from interstitial DCs are typically destructive masses with a uniform, smooth-cut surface and are white/cream to tan in color. Lesions may be solitary or multiple within an organ (especially spleen). Periarticular/articular HS has a distinctive appearance: it occurs as multiple tan nodules located beneath the synovial lining (see in the following text). HHS, which originates from macrophages (see in the following text), does not initially form mass lesions in the primary sites (spleen and bone marrow). Typically, diffuse splenomegaly is observed, although ill-defined mass lesions may be seen. HHS may coincide with HS of interstitial DC origin and, in these instances, both diffuse splenomegaly and discrete mass formation are observed.[58]

HS lesions are composed of sheets of large, pleomorphic, mononuclear, and multinucleated giant cells, which have marked cytological atypia and numerous bizarre mitotic figures (Figure 74.6). Some lesions may consist of spindle cells, either alone or mixed with the mononuclear and multinucleated giant cells. Such lesions can resemble spindle cell sarcomas of diverse cell lineage (fibroblast, myofibroblast, and smooth muscle origin) and confirmation of histiocytic lineage requires immunohistochemistry (IHC).[5,35,37,69] Phagocytosis of red cells, leukocytes, and tumor cells occurs in HS, but less frequently than HHS (Figure 74.7).

Immunophenotypic Features

Immunostaining of most HS lesions reveals that tumor histiocytes express leukocyte surface molecules characteristic of interstitial DCs, including CD1a, MHC class II, and CD11c/CD18. In contrast to CH/SH, expression of CD4 by neoplastic histiocytes has not been observed in HS.[5] The β-2 subunit of the leuko-integrins (CD18) is readily demonstrable in formalin-fixed tissue sections of HS lesions (Figure 74.8). Importantly, as lymphomas may express abundant CD18, it is important to exclude a lymphoid origin (e.g., large-cell lymphoma) by staining

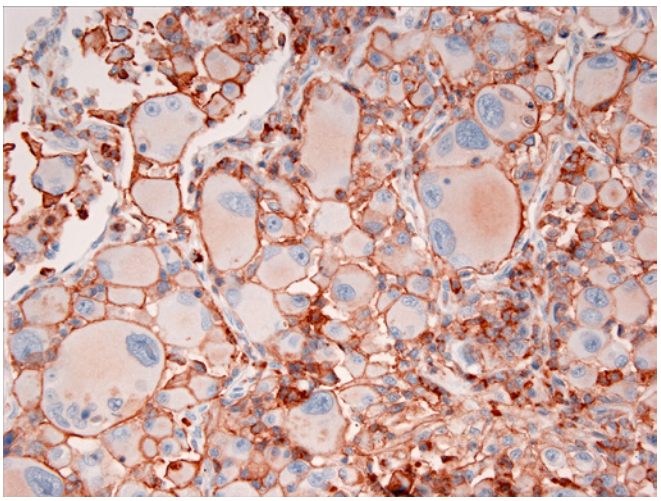

FIGURE 74.8 Histiocytic sarcoma. CD18 expression by atypical histiocytes. This most likely represents expression of CD11c/CD18.

for lymphocyte-antigen-receptor-associated molecules (CD3 and CD79a) and CD20.[5] Iba-1 is also expressed in HS lesions regardless of subtype and is not expressed by lymphocytes.[35,69] CD204 expression is inconsistent in HS, unless there is differentiation toward the macrophage lineage. In HHS, histiocytes express markers most consistent with macrophage differentiation including (CD11d/CD18) (Figure 74.9), Iba-1, and CD204 (Moore—unpublished data).[58]

HISTIOCYTIC SARCOMA—DISTINCTIVE SYNDROMES

There are several unique variants of HS that deserve separate description because of particular clinical or clinicopathological associations that are often crucial to successful diagnosis.

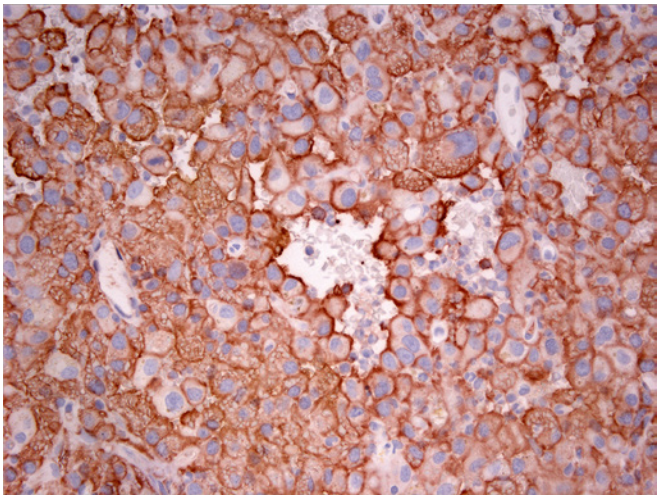

FIGURE 74.9 Hemophagocytic HS. CD11d expression by atypical histiocytes in the splenic red pulp—reflects expression of CD11d/CD18.

Hemophagocytic Histiocytic Sarcoma

Dogs with HHS present with a distinctive clinicopathologic syndrome characterized by a moderate to marked, regenerative, Coombs'-negative, hemolytic anemia and thrombocytopenia. They have mild hyperbilirubinemia without jaundice at initial presentation. Most dogs have hypoalbuminemia and often hypocholesterolemia. This clinical picture is often confused with immune-mediated hemolytic anemia and thrombocytopenia (Evans syndrome). Hemophagocytic HS carries the worst prognosis of all forms of HS with a median survival of only 4 weeks after diagnosis. Factors contributing to poor outcome include development of severe anemia and coagulopathy with disease progression.[58] In another study, in which the efficacy of CCNU was assessed as a treatment for HS, a cohort of dogs that presented with anemia, hypoalbuminemia, and thrombocytopenia had a median survival of 28 days or less (versus 106 days for all dogs). The form of HS was not further classified in this subset of dogs; laboratory data were consistent with HHS.[86]

Dogs with HHS have diffuse splenomegaly and lack grossly visible masses in sites of metastasis (e.g., liver and lung). This gross appearance is enforced by the growth pattern of the neoplastic histiocytes, which expand the splenic red pulp more or less diffusely. Neoplastic cells exhibit marked erythrophagocytosis and are accompanied by interspersed foci of extramedullary hematopoiesis. They invade red pulp sinuses and travel to the liver where they insidiously invade the sinusoids. Examination of sections of lung will reveal erythrophagocytic histiocytes within the pulmonary vasculature. The bone marrow is simultaneously infiltrated and erythrophagia is observed there as well. There are two reports of HS in cats, in which the lesions in three cats closely resembled the pattern and distribution of canine HHS.[28,43] Cytologically, the splenic neoplastic histiocytes often demonstrate more atypia than their bone marrow counterparts.[58] However, even the well-differentiated cells are aggressive, as evidenced by hepatic and pulmonary invasion.

Neoplastic histiocytes in HHS express a surface antigen profile similar to splenic red pulp and bone marrow macrophages. They express CD11d/CD18, Iba-1, CD204 and have low expression of CD11c and variable (negative to weak) CD1a expression. CD11d, CD18, Iba-1, and CD204 are assessable in FFPE sections in dogs, and this greatly facilitates the diagnosis of HHS (Figure 74.9) and the detection of often inconspicuous metastatic, intravascular lesions in liver and lung.[37,58,69] Feline HHS, based on lack of CD1 expression, is also thought to arise from macrophages.[28] Expression of CD11d and CD204 has not been thoroughly investigated due to the paucity of cases and the need for unfixed tissue.

PERIARTICULAR/ARTICULAR HISTIOCYTIC SARCOMA

PAHS is a localized form of HS, which occurs on the limbs. The lesions originate either within the joints (intra-articular) and/or adjacent to the joints (periarticular) of the appendicular skeleton. PAHS is the most common joint tumor of dogs and occurs in cats at much lower incidence. The stifle and elbow joints are most commonly affected, but lesions may occur in the coxofemoral joint, scapulohumeral joint, tarsus, and carpus. Rottweilers, Labrador Retrievers, Golden Retrievers, Flat-coated Retrievers, and Bernese Mountain Dogs have a high incidence of PAHS.[18,21,70,96] Invasion of bone can occur with advanced disease. Since skeletal lesions can be observed in disseminated HS, it is important to determine if the skeletal involvement is subsequent to a soft-tissue mass originating near the synovial tissues.[81] Early detection and treatment of PAHS are potentially curative, while disseminated HS has a worse prognosis.[5,40] However, PAHS is capable of widespread dissemination as reflected by the median survival of affected dogs with evidence of metastatic disease (about 5–8 months) versus those without (17 months).[21,40]

PAHS has a distinctive appearance: it occurs as multiple tan nodules located beneath the synovial lining that may encircle the affected joint. Hence, these lesions begin outside of the synovial space either within the joint and/or in a periarticular location. Microscopically, the lesions display a micronodular growth pattern that may coalesce into masses in advanced lesions. The lesions most often originate beneath the synovium, and the synovial lining is usually intact above the tumor. In advanced lesions, these topographical relationships may be obscured by effacing mass formation. Cytologically, the neoplastic cells in PAHS, through their atypia and pleomorphism, resemble HS in other sites. However, a marked inflammatory infiltrate is usually recognizable within the lesions. Lymphocytes (mostly T cells), neutrophils, and well-differentiated histiocytes are prevalent. Inflammation of the adjacent synovium with lymphocyte, plasma cells, and histiocytes is also observed.[21]

A history of cranial cruciate rupture or other traumatic joint injury is associated with the development of PAHS.[21,96] Synovitis, dominated by T cells and dendritic cells, has been reported in association with rupture of the cranial cruciate ligament.[45] While no causal relationship has been defined between synovial inflammation and the development of HS, there is ample evidence of confirming the progression of inflammation to neoplasia in other disease states.[20]

The immunophenotype of histiocytes in PAHS is most similar to that of perivascular interstitial DCs (CD1a+ CD11c/CD18+ Ib-1+ CD204–) rather than synovial type A cells (CD1a– CD11b/CD18+ Iba-1+ CD204+), which are intercalated between synovial type B cells (synovial fibroblasts) in the synovial lining. In FFPE tissue, PAHS lesions express CD18 and Iba-1 (Figure 74.8) with variable expression of CD204. It is important to note that this expression profile is not tumor-specific and is shared by inflammatory histiocytes. This distinction is key in the differentiating PAHS from synovial cell sarcoma. Synovial cell sarcoma is neoplasm that is likely derived from synovial type B cells (specialized synovial fibroblasts). Synovial fibroblasts are highly synthetic cells that can produce a diverse array of inflammatory mediators, including macrophage-recruiting chemokines.[75] Hence, it is not surprising that synovial cell sarcomas are often infiltrated by large numbers of CD18+ histiocytes. Importantly, in synovial cell sarcoma, a dominant CD18– neoplastic population is present among the many CD18+ histiocytes. This contrasts with the uninterrupted sheets of CD18+, cytologically atypical histiocytes in PAHS.

CENTRAL NERVOUS SYSTEM HISTIOCYTIC SARCOMA

The central nervous system may be infiltrated by HS as a primary location or as a consequence of metastatic spread in disseminated HS. Extracranial metastasis of primary CNS has not been reported. CNS HS most often originates in the leptomeninges, and the lesions are composed of large numbers of mixed inflammatory cells (lymphocytes, histiocytes, plasma cells, and neutrophils) and a variable number of cytologically atypical histiocytes. In two case series of CNS HS, Pembroke Welsh Corgis were overrepresented.[35,91]

CNS HS commonly presents as a solitary subdural mass and less commonly as diffuse meningeal infiltrates. The immunophenotype of CNS HS has yet to be fully clarified. In one report, the neoplastic histiocytes in the focal variant expressed MHC class II, Iba-1, and two macrophage scavenger receptors (CD163 and CD204). In this same report, the diffuse variants did not express either scavenger receptor.[35] These findings are slightly different than our published and unpublished data, which describe the expression of interstitial DC markers (CD1a, CD11c, and MHC class II) on neoplastic histiocytes.[5] Given that macrophage scavenger receptors are present on subsets of interstitial DCs, this could be one potential point of reconciliation of the divergent data.[50] Also, dendritic cells are located in the meninges and choroid plexi, but not in the brain, which would represent a resident population from which HS could develop.[22]

DENDRITIC CELL LEUKEMIA

Peripheral blood involvement in HS is rare and there have been only two reports of DC leukemia in dogs. In both dogs, large numbers (30,000–60,000 per microliter) of atypical histiocytes were observed in peripheral blood.[6,76] In both dogs, the DC lineage (CD1+ CD11c+ CD11d– MHCII+) was confirmed by immunophenotyping of cell smears or by flow cytometry. Diffuse infiltration of affected organs (bone marrow, spleen, lung, and liver) without mass formation was characteristic of a leukemic infiltrate. Although this pattern of infiltration mimics HHS, this condition does not involve peripheral blood and is associated with regenerative, extravascular hemolytic anemia and marked erythrophagocytosis by CD11d+ neoplastic histiocytes.

TREATMENT OF HS COMPLEX

Localized HS affecting skin and subcutis have been cured by early surgical excision, which in some instances has been successfully supplemented by local radiation therapy.[87] In the case of PAHS, amputation of the affected limb (preceded by appropriate staging) is enforced by the inoperable nature of the primary lesions. Disseminated HS is generally not a surgical disease as early metastasis is common. Chemotherapy with CCNU (lomustine) has been reported with outcome impacted by disease burden. In one report, although the median survival for all treated dogs was only 106 days, a small number of dogs with minimal residual disease had prolonged survival (>431 days). In this same study, the authors identified hypoalbuminemia and thrombocytopenia as negative prognostic variables, as affected dogs survived less than 1 month.[86] Notably, these dogs may have had HHS, which share these clinicopathologic features and poor survival.[58] Combination therapy using lomustine and doxorubicin has been used in an alternating treatment regime.[14]

The discovery of activating mutations in PTPN11 (SHP2) in Bernese Mountain Dogs has fueled interest in targeted therapies focused on MAPK pathway. MEK inhibitors including trametinib and cobimetanib are potential treatments for dogs with MAPK pathway activation. A clinical trial for dogs with HS and other cancer types is being conducted with trametinib at the University of Wisconsin. Several research groups are developing immunotherapies that could be used in the

future to treat HS and other cancers. These include chimeric antigen receptor (CAR) T cell therapy and antibody-directed immune checkpoint blockade. Targets for the former include B7-H3 (CD276), CD20, and CD19, and for the latter, PD-1, PD-L1, and CTLA-4 (Figure 74.1).[15,32,68]

FELINE PROGRESSIVE HISTIOCYTOSIS

FPH is a disease of middle-aged to older cats (7–17 years).[4] The initial presentation of FPH may be a solitary skin nodule, although usually multiple papules, nodules, or plaques develop, measuring up to 1.5 cm in diameter. The nodules are firm, nonpruritic, and nonpainful. The surface is often alopecic and may be ulcerated. The lesions are mostly located on the head, lower extremities, or trunk. Occasionally, the lesions are limited to one extremity. The lesions may wax and wane, but spontaneous regression does not occur. In FPH, a proportion of cats develop invasive, expansile masses in lymph nodes and internal organs including the lungs, kidneys, spleen, and liver.

FPH behaves as a low-grade HS and appears to originate from interstitial DCs.[4] The initial clinical course is indolent, but affected cats have a poor long-term prognosis. Surgical removal is not a good option, as lesions can reoccur at sites distant from the surgical excision. In a multicenter study of feline histiocytic disorders (HS and FPH), expression of platelet derived growth factor (PDGF)-beta was observed in the majority of cats including four of five cats with FPH. Extended survival following treatment with tyrosine kinase inhibitors masitinib and toceranib was reported in one cat; one cat responded to lomustine/cyclophosphamide, one cat responded briefly to lomustine/toceranib, and another responded to prednisolone. One cat achieved a spontaneous remission, which is highly unusual.[93]

Morphologic Features

Microscopic lesions consist of diffuse dermal histiocytic infiltrates, which may extend into the subcutis. Early in disease, the histiocytes are well-differentiated, and, as such, it is important to rule out infectious agents with special stains. However, later in the course, histiocytes are more atypical and consistent with HS (based on serial biopsies from the same cat). The overlying epidermis may be ulcerated and approximately 40% of lesions manifest epitheliotropism (Figure 74.10). Early in disease, histiocytes have irregular, vesicular nuclei and finely dispersed chromatin, but late-stage lesions are essentially morphologically identical to HS. Electron microscopic investigation of FPH in two cats did not demonstrate BGs (indicative of LC differentiation) in the neoplastic histiocytes. The mitotic activity varies and atypical mitoses are seen. A varied reactive infiltrate, composed of dispersed lymphocytes and fewer neutrophils, may be seen.

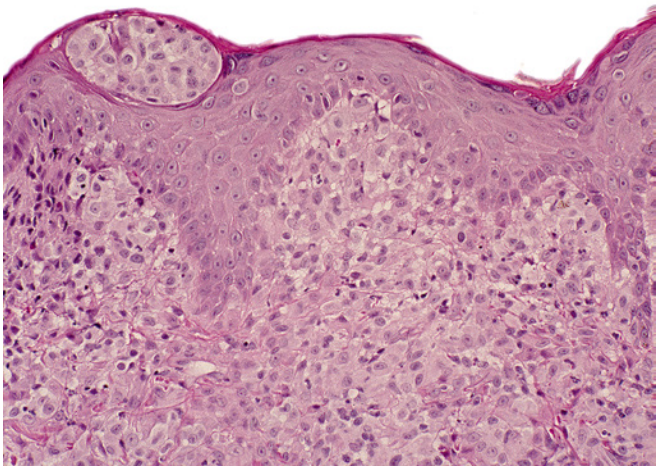

FIGURE 74.10 Feline progressive histiocytosis. Cohesive sheets of immature histiocytes infiltrate the superficial dermis and extend into the epidermis as a solitary focus. H&E.

Immunophenotypic Features

Neoplastic histiocytes in FPH express CD1a, CD18, MHC class II, and Iba-1 with rare E-cadherin expression (10% of cases), sporadic CD5 expression (approximately 50% of cases), and variable CD204 expression (Moore—unpublished data).[4] This immunophenotype is most consistent with an interstitial DC origin. Notably, CD5+ DCs have recently been identified in humans, they are potent inducers of cytotoxic T cells and Th22 cells. They have a role in the maintenance of barrier immunity in skin and mucosal sites.[42] The reactive lymphocytes that infiltrate the lesions mostly express CD3 and CD8.[4]

FELINE PULMONARY LANGERHANS CELL HISTIOCYTOSIS

Pulmonary LCH is an uncommon disease. The original report described three cats and, since then, four additional cases have been encountered by the chapter's author (Moore—unpublished data). All cases have been diagnosed at necropsy. It appears to be a disease of aged cats (10–15 years) characterized by progressive, terminal respiratory failure.[13] Affected cats present with severe respiratory distress characterized by tachypnea, increased respiratory effort, or open-mouthed breathing. Thoracic radiographs reveal a diffuse bronchointerstitial pattern with military-to-nodular opacities throughout all lung lobes. Given its rarity, the biology of feline pulmonary LCH is not fully clarified. A neoplastic origin is favored based on the cytological characteristics of the LC infiltrate and the consistent extrapulmonary lesions. However, molecular clonality studies were not conducted in support of that conclusion. Notably, pulmonary LCH occurs in humans, especially among smokers. In humans, it is believed to be a reactive disorder and often resolves after smoking cessation.

Although some lesions harbor clonal expansions of LCs, the majority of lesions demonstrate polyclonal LC proliferation.[99]

Morphologic Features

The lungs of affected cats are diffusely firm and entirely effaced by ill-defined, coalescing nodular masses (2–5 mm). When coalescing, the nodules efface larger areas of parenchyma and extended from peribronchiolar locations to the pleural surface. Extrapulmonary spread to pancreas and kidney is variably observed. The tracheobronchial lymph nodes and lymph nodes draining affected abdominal organs are also enlarged and diffusely effaced.

Pulmonary lesions are unique, and consist of cohesive histiocytic infiltrates within terminal and respiratory bronchioles (Figure 74.11). The infiltrates partially obliterate the airway walls, fill the lumens, and extend into adjacent alveolar ducts and alveoli. The cells are moderately pleomorphic in size and nuclear morphology, which is often complex (convoluted, twisted, or folded) (Figure 74.12). Transmission electron microscopy (TEM) revealed characteristic BGs in the cytoplasm of lesional histiocytes, which is consistent with an LC origin to these cells.

Immunophenotypic Features

The lesional histiocytes express CD18 and E-cadherin. CD1 expression has not been evaluated in pulmonary LCH, as only FFPE tissues have been available. Interestingly, E-cadherin expression is often markedly reduced in extrapulmonary lesions, which may indicate downregulation of E-cadherin expression associated with LC migration (as occurs in normal LCs when they migrate from epithelia to lymph nodes).

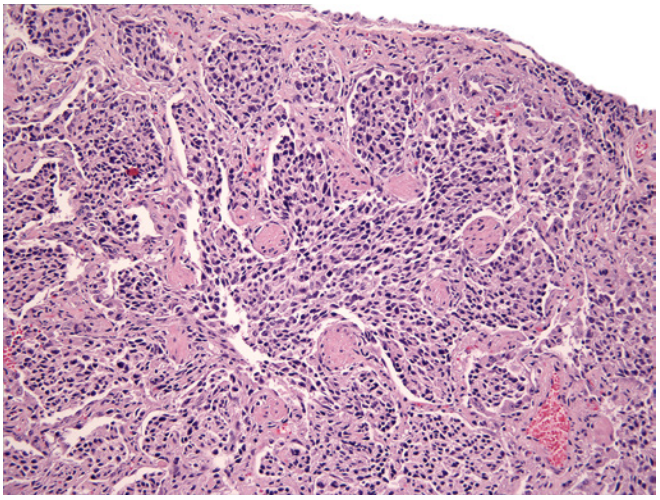

FIGURE 74.11 Feline pulmonary LCH. Cohesive sheets of histiocytes fill the alveolar duct and extend to the alveoli and pleura. H&E.

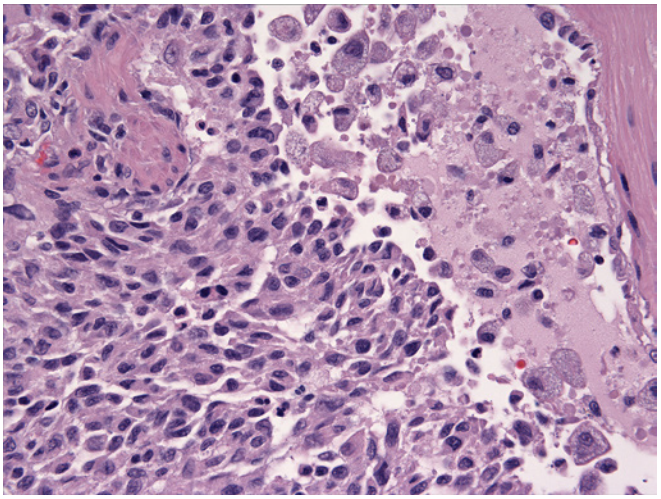

FIGURE 74.12 Feline pulmonary LCH. Moderately pleomorphic histiocytes with complex nuclear membranes invade the bronchial lumen, which is filled with foamy macrophages. H&E.

CONCLUSION

Histiocytic proliferative diseases occur as neoplastic processes and inflammatory processes with immune dysregulation in dogs. The latter do not occur in cats. Most histiocytic proliferative diseases originate from LCs or interstitial DCs in both dogs and cats. Macrophage differentiation has thus far only been demonstrated in HHS. The finer future characterization of histiocytic diseases will rely on the development of a greater array of markers of histiocytic lineage and the application of gene expression profiling on lesional histiocytes. Studies of this nature will hopefully lead to more effective targeted therapies for individual histiocytic diseases.

Acronyms and Abbreviations

AMR, Ashwell–Morell receptor; Arp, actin-related protein; BFU-MK, burst-forming unit-megakaryocyte; BMEC, bone marrow endothelial cell; CalDAG-GEFI, calcium diacylglycerol guanine nucleotide exchange factor I; CBF, core binding factor; CD, cluster of differentiation; CFU-MK, colony-forming unit-megakaryocyte; CK2β, casein kinase 2 (beta subunit); CMP, common myeloid progenitor; CXCR, chemokine receptor; DMS, demarcation membrane system; E#, day of embryonic development, # indicates age of the embryo in days after conception; ETS, erythroblast transformation specific; FGF-4, fibroblast growth factor-4; FCR, receptor for the FC portion of immunoglobulin; FLI1, Friend leukemia integration 1; FOG1, Friend of GATA1; GA, guanine adenine nucleotides; GABP, GA-binding protein; GATA1 and 2, GATA-binding proteins 1 and 2; G-CSF, granulocyte colony-stimulating factor; GP, glycoprotein; GTP, guanosine triphosphate; IL, interleukin; LIF, leukemia inhibitory factor; Lin^-, lineage negative; JAK, Janus kinases; MAPK, mitogen-activated protein kinases; Meg-CFC, megakaryocyte-colony-forming cells; MEP, megakaryocyte–erythroid progenitor; Mpl, myeloproliferative leukemia; NF-E2, nuclear factor-erythroid 2; PECAM-1, platelet–endothelial cell adhesion molecule-1; PF4, platelet factor-4; PINCH1, particularly interesting new cysteine-histidine-rich protein 1; PIP4Kα, phosphatidylinositol-5-P-4-kinase α RUNX, runt-related transcription factor; SDF, stromal-cell-derived factor; STAT, signal transducers and activators of transcription; TPO, thrombopoietin; VCAM-1, vascular cell adhesion molecule-1; WASp, Wiskott–Aldrich syndrome protein; WAVE, WASp-family verprolin-homologous protein.

THROMBOPOIESIS OVERVIEW

Megakaryocyte–Erythroid Progenitor

Megakaryocytes are derived from a bipotent megakaryocyte–erythroid progenitor (MEP).[7] Although the MEP was once thought to arise from a committed common myeloid progenitor, the MEP is now believed to arise directly from an uncommitted short-term hematopoietic stem cell.[1] Primitive MEPs and megakaryocyte-colony-forming cells (Meg-CFCs) have been detected in mouse embryo yolk sacs and give rise to primitive glycoprotein (GP)Ibβ-positive platelets that are of large diameter, highly reticulated, and relatively hypogranular.[33] These early platelets can be detected in circulation in mouse embryos as early as embryo day (E) 10.5. By E11.5, definitive MEPs and Meg-CFCs within fetal liver become the predominant source of megakaryocyte

progenitor expansion and produce platelets that are more similar in size and granularity to adult platelets. It is not known whether primitive platelets produced within the yolk sac represent a population of platelets distinct from those produced by the fetal liver and bone marrow.

Bipotent MEPs cannot be distinguished morphologically from small lymphocytes in bone marrow but have a unique cell surface protein expression pattern that includes interleukin (IL)-7Rα$^-$/lineage negative (Lin$^-$)/c-Kit+/Sca-1$^-$ clusters of differentiation (CD)34$^-$/FCRγ^{lo}.[18] Once commitment to megakaryocyte lineage occurs, cells begin to express CD41 and CD61 (integrin $\alpha_{IIb}\beta_3$ or GPIIb and GPIIIa), CD42 (glycoprotein Ib), and glycoprotein V. Two morphologically distinct colonies leading exclusively to megakaryocyte production have been identified in vitro: burst-forming unit-megakaryocyte (BFU-MK) and colony-forming unit-megakaryocyte (CFU-MK).[18]

Bone Marrow Endothelial Cells

The bone marrow can be divided into two anatomical and functional entities with respect to development of hematopoietic cells: the endosteal zone, where nondividing stem cells reside, and the more centrally located vascular niche that promotes stem cell differentiation and eventually mobilization of mature hematopoietic cells to the blood (see Section I). Originally, precursor cells were thought to migrate from the endosteal zone toward the vascular niche for further maturation and entrance into circulation.[11] Recent studies suggest there may be two separate pools of hematopoietic cells, including megakaryocytes.[30] Within the bone marrow, bone marrow endothelial cells (BMECs) support proliferation and differentiation of hematopoietic cells as a consequence of direct contact and release of cytokines. In turn, megakaryocytes nurture BMECs by secreting survival and growth factors. Platelet–endothelial cell adhesion molecule-1 (PECAM-1) may play a role in movement of megakaryocytes toward the vascular sinuses. Transendothelial migration and proplatelet formation and release are dependent on the interaction of megakaryocytes with BMECs via adhesion molecules, including vascular cell adhesion molecule-1 (VCAM-1) and integrin $\alpha_4\beta_1$.

TRANSCRIPTION FACTORS

Several transcription factors determined to be critical for thrombopoiesis in humans and mice likely play a similar regulatory role in other species.

GATA1 and GATA2

GATA-binding protein 1 (GATA1) is an X-chromosome-encoded transcription factor that plays a key role in megakaryopoiesis and erythropoiesis. GATA2 is a closely related transcription factor that has early effects on maintenance of hematopoietic stem cells and multipotential progenitors.[35] GATA1 possesses distinct structural elements necessary for binding promoters and cofactors involved in progenitor cell development and differentiation. Several erythroid and megakaryocyte-specific genes contain GATA motifs in critical *cis*-regulatory elements. For megakaryocytes, these genes include those encoding for GPIIb, GPIbα, GPIbβ, GPIX, platelet factor-4 (PF4), and the thrombopoietin receptor, myeloproliferative leukemia protein (cMpl, CD110). GATA1 activity is necessary for the divergence of megakaryocytic and erythroid progenitors from the MEP. Megakaryopoiesis is more sensitive to levels of GATA1 than erythropoiesis.[29] Several GATA1 mutations in humans are accompanied by a role reversal in which megakaryocytes are small and possess nuclei with reduced lobulation and erythroblasts are large and multinucleated.[5,9]

Friend of GATA1, Friend Leukemia Integration 1, and GA-Binding Protein

Friend of GATA1 (FOG1) is an essential cofactor of GATA1. Mutations in GATA1 that result in impairment of GATA1 binding with FOG1 result in X-linked macrothrombocytopenia in people. Friend leukemia integration 1 (FLI1) is a member of the erythroblast transformation specific (ETS)-family of transcription factors and interacts synergistically with GATA1 in the activation of megakaryocyte-specific genes. The heterodimeric guanine adenine nucleotide binding protein complex (GABP) is another ETS-binding factor that regulates gene expression in megakaryocytes. GABP, a complex composed of alpha and beta subunits, binds to promoters of early megakaryocyte-specific genes such as GPIIb and c-Mpl, whereas FLI1 primarily affects expression of late megakaryocyte-specific genes, including GPIbα, GPIX, and PF4. The alpha component of GABP mediates DNA binding of the complex, whereas the beta component mediates transcriptional activation and nuclear localization of GABPα.[26] GABP and FLI1 both can bind to promoters of early and late megakaryocyte-specific genes and regulate activity of the GATA1/FOG complex. This overlap in function allows partial compensation if either activity is lost.

Core Binding Factors

A family of transcription factors referred to as core binding factors (CBFs) is critical in megakaryopoiesis and megakaryocytic differentiation. The CBF family contains three DNA-binding proteins (runt-related transcription factors (RUNX1), RUNX2, and RUNX3) and a non-DNA-binding protein (CBFβ). RUNX1 is a heterodimer composed of core binding factor α-2 (CBF α-2) and CBFβ. RUNX1 interacts with GATA1 and has an essential role in early hematopoiesis and vasculogenesis.[32] RUNX1 may also play a role in lineage determination. RUNX1 mutations in humans are associated with thrombocytopenia and platelet function abnormalities associated with decreased dense granule formation.[21] In humans, CBF α-2 mutations have been

associated with decreased levels of protein kinase C-θ,[31] resulting in impaired activation of platelet integrin $\alpha_{IIb}\beta_3$.

Nuclear Factor-Erythroid 2

Nuclear factor-erythroid 2 (NF-E2) is a key transcription factor involved in enhancing early megakaryopoiesis and in promoting megakaryocyte maturation. NF-E2 is a heterodimer consisting of a hematopoietic-specific p45 subunit and two p18 subunits, MafG and MafK. Mice with deleted genes for NF-E2 are severely thrombocytopenic, and megakaryocytes have reduced granules, a disorganized demarcation membrane system, fail to form proplatelets, and are unable to generate signals necessary for fibrinogen binding.[28] Megakaryocyte targets for NF-E2 include genes encoding for thromboxane synthase, β1-tubulin, Rab27b, caspase-12, calcium diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI), and particularly interesting new cysteine-histidine-rich protein 1 (PINCH1). PINCH1 is an adaptor protein that interacts with integrin-linked kinase, which in turn binds with cytoplasmic tails of integrins and thus may be important in mediating migration and interaction of megakaryocytes in the bone marrow microenvironment.[39]

MEGAKARYOCYTE MATURATION AND PLATELET FORMATION

In humans and domestic animals, megakaryocytes are located primarily in bone marrow. However, in adult mice, the spleen is considered a primary hematopoietic organ and generates all hematopoietic cell lineages, including megakaryocytes. Megakaryocytes undergo some degree of fragmentation in the pulmonary circulation in most mammalian species.

Endomitosis

During the early stages of megakaryocyte development, progenitor cells undergo typical cell division as they acquire lineage-specific markers. In later stages of development, megakaryocytes begin several rounds of endomitosis in which anaphase, telophase, and cytokinesis are skipped, resulting in DNA division without cell division.[37] Mature megakaryocytes are polyploid cells and DNA content or ploidy correlates with the number of platelets a megakaryocyte will ultimately produce. The progression from megakaryocytic cell division to endomitotic replication is due to the lack of formation of a normal functioning mitotic spindle.[14]

Stathmin expression may be necessary for induction of endomitosis in megakaryocytes. Stathmin is a phosphoprotein that promotes microtubule depolymerization and is phosphorylated and dephosphorylated in a cell-cycle-dependent fashion. Stathmin is phosphorylated/inactivated as cells enter mitosis to allow for assembly of the mitotic spindle and then dephosphorylated/activated at the end of mitosis to allow dissolution of the mitotic spindle. Studies with K562 erythroleukemia cells suggest that during early megakaryocyte development, stathmin expression levels are high, corresponding with normal cell division. During later stages, stathmin expression levels are reduced, resulting in abortive megakaryocytic mitosis and polyploidization.[14] Recently, ligand stimulation of CD226, an Ig superfamily protein found in the cell membrane of platelets and mononuclear leukocytes, has been demonstrated to mediate megakaryocyte activation, differentiation, and ploidy development.[40] Interestingly, silencing of CD226 downregulates expression of transcription factors GATA1 and FLI1, but not nuclear NF-E2.

Demarcation Membrane System and Proplatelet Formation

Terminal megakaryocyte differentiation occurs after endomitosis and is associated with tubular invagination of the plasma membrane resulting in formation of the demarcation membrane system (DMS).[27] The current model of platelet formation suggests that the DMS functions to provide a membrane reservoir for the formation and extension of proplatelets.[27] Prior to proplatelet formation, there is an accumulation of the phospholipid PI-4,5-P2 as a result of megakaryocyte lipid kinase activity. Specifically, phosphatidylinositol-5-P-4-kinase α (PIP4Kα) is thought to generate PI-4,5-P2 by acting on the substrate PI-5-P. PI-4,5-P2 is thought to trigger actin polymerization by enhancing binding of Wiskott–Aldrich syndrome protein (WASp) to actin-related protein (Arp2/3). WASp–Arp2/3 complex formation probably triggers Rho-family guanosine triphosphate (GTP)ses with activation of WASp-family verprolin-homologous protein (WAVE) resulting in actin fiber assembly.[25] Actin polymerization is associated with dilation and movement of the DMS to the cell periphery in preparation for microtubule assembly.[25]

Synthesis of platelet granules occurs simultaneously with formation of the DMS and granules are packaged and mobilized, as microtubule assembly occurs in the extension of proplatelets. The microtubule motor kinesin is believed to transport organelles and granules along microtubules.[24] Movement is bidirectional, as microtubules slide past each other. Once organelles and granules enter the proplatelet tip, they are captured there for packaging within the developing platelet.[24] In addition to organelles, spliceosomes and pre-mRNAs are packaged into newly forming platelets, thus providing platelets with the capacity for protein synthesis.

Microtubule assembly is a dynamic process: time-lapse photography shows alternating extension and retraction as well as bending and branching of proplatelet shafts. Platelets form from the tips of proplatelet shafts; thus, branching provides a mechanism for formation of more platelets per proplatelet extension. Branching and bifurcations of proplatelet extensions are mediated by actin forces. Elongation of proplatelets,

however, is mediated by dynein, a molecular motor protein that mediates microtubule sliding necessary for proplatelet extension.

Microtubules are hollow polymers formed by α/β-tubulin dimers. β1-Tubulin is the most abundant platelet β-tubulin isoform. β1-Tubulin-null mice demonstrate increased expression of other β-tubulin isoforms, nevertheless they are thrombocytopenic with reduced numbers of platelet marginal microtubule bands. Two missense mutations in β1-tubulin causing macrothrombocytopenia in dogs have been described: one in Cavalier King Charles Spaniels (and >25 other breeds), and a second seen mainly in Cairn, Norfolk, and Jack Russell Terriers[6,10] (P. W. Christopherson, personal observations).

Proplatelets are formed in a spiraling manner starting at the periphery and moving centripetally toward the nucleus. Proplatelets consist of long beaded strands that fragment in circulation when subjected to shear. Shear stress within bone marrow sinusoids probably assists in fragmentation of proplatelets from megakaryocyte bodies after proplatelets are extended through the subendothelium. Activation of proplatelets is thought to be avoided by extension of large, cytoplasmic fragments into the lumen of sinusoidal vessels.[15] Proplatelet formation consumes the entire megakaryocyte cytoplasm leaving behind only the nucleus which enters an apoptotic pathway.

THROMBOPOIETIN AND OTHER KEY HORMONES

Thrombopoietin

Thrombopoietin (TPO) is a key humoral regulator of platelet production.[3,19] TPO initially was identified as the ligand for c-Mpl, the normal mammalian proto-oncogene version of a murine myeloproliferative leukemia virus.[38] The open reading frame for human TPO protein, including the signal peptide, encodes 353 amino acids. In cats, dogs, horses, cattle, pigs, and mice, the open reading frame encodes 349, 352, 350, 349, 353, and 356 amino acids, respectively.[3,20] The amino acid sequence of TPO is conserved across species, demonstrating 79%, 85%, 89%, 83%, 82%, and 81% homology between human versus cat, dog, horse, cow, pig, and mouse, respectively.[12] The amino-terminal end of TPO is highly homologous with erythropoietin in all species and is the portion of the protein that engages the TPO receptor. The carboxy-terminal domain is highly glycosylated, which is necessary for TPO survival in circulation and for secretion of TPO from cells. Truncated forms of TPO are found in circulation, particularly in thrombocytopenic animals.[17] TPO is cleaved by thrombin at two sites, generating polypeptides that vary in activity. Cleavage of TPO at Arg^{191} in the carboxy-terminal domain results in a polypeptide with enhanced activity; however, activity is destroyed by thrombin cleavage at Arg^{117} within the amino-terminal domain.

Studies have documented that although TPO is critical for normal megakaryopoiesis, TPO also is important for overall hematopoiesis and plays a role in enhancing expansion of hematopoietic stem cells.[2] TPO binding to cMpl results in activation of Janus kinases (JAKs) and signal transducers and activators of transcription (STAT) factors STAT3 and STAT5. JAK2 is bound constitutively to cMpl and upon activation phosphorylates tyrosine residues within cMpl and within STATs, phosphatidylinositol3-kinase (PI3K), and mitogen-activated protein kinases (MAPKs). STAT3 and STAT5 are required for regulation of normal megakaryopoiesis and have been found to be dysregulated in some myeloproliferative disorders and in megakaryoblastic leukemias in humans.

TPO is synthesized primarily by the liver and to a lesser extent in kidney and by bone marrow stromal cells. TPO receptors are located on platelets, megakaryocytes, and vascular endothelial cells. Although the numbers of TPO receptors on endothelial cells far exceed the numbers found on megakaryocytes and platelets, endothelial TPO receptors are not involved in regulation of TPO levels. Under steady-state conditions, TPO is produced constitutively and binds to its ligand c-Mpl on platelets and megakaryocytes. Bound TPO is internalized and degraded and not available for stimulating thrombopoiesis above steady-state levels. TPO production is also regulated by the uptake of senescent platelets depleted of sialic acid by the Ashwell–Morell receptor (AMR).[13] The AMR is found exclusively on hepatocytes in mice and when activated, triggers downstream cell signaling leading to TPO production.

During episodes of thrombocytopenia, TPO levels increase, resulting in enhanced thrombopoiesis. The responsiveness of megakaryocytes to TPO is regulated somewhat by the maturity of the megakaryocyte. Megakaryocytes that are GPIIb+ GPIb+ undergo fewer endomitotic cycles in response to TPO compared to younger megakaryocytes that are GPIIb+ GPIb−. The enhanced endomitotic capability of GPIIb+ GPIb− megakaryocytes is due to lack of binding of 14-3-3ζ adaptor protein to the cytoplasmic tail of GPIbα. Lack of sequestration of 14-3-3ζ results in enhanced phosphorylation and activation of Akt by PI3K. Activated Akt increases the post-translational stability of cyclins, which play a role in promoting endomitosis and increasing ploidy. Although TPO production is constitutive under steady-state conditions, severe thrombocytopenia can result in enhanced production of TPO by bone marrow stromal cells. Inflammatory conditions can result in enhanced hepatic TPO production, mediated by IL-6, which induces reactive thrombocytosis.[16] During certain pathologic conditions, the steady-state mechanism of TPO production is altered, such that TPO levels are discordant with levels expected based on platelet numbers. In some cases of severe idiopathic thrombocytopenia, particularly where megakaryocytes are markedly increased in number and size, TPO levels may not be as high as expected due to binding of TPO to cMpl receptors on megakaryocytes (Figure 75.1).

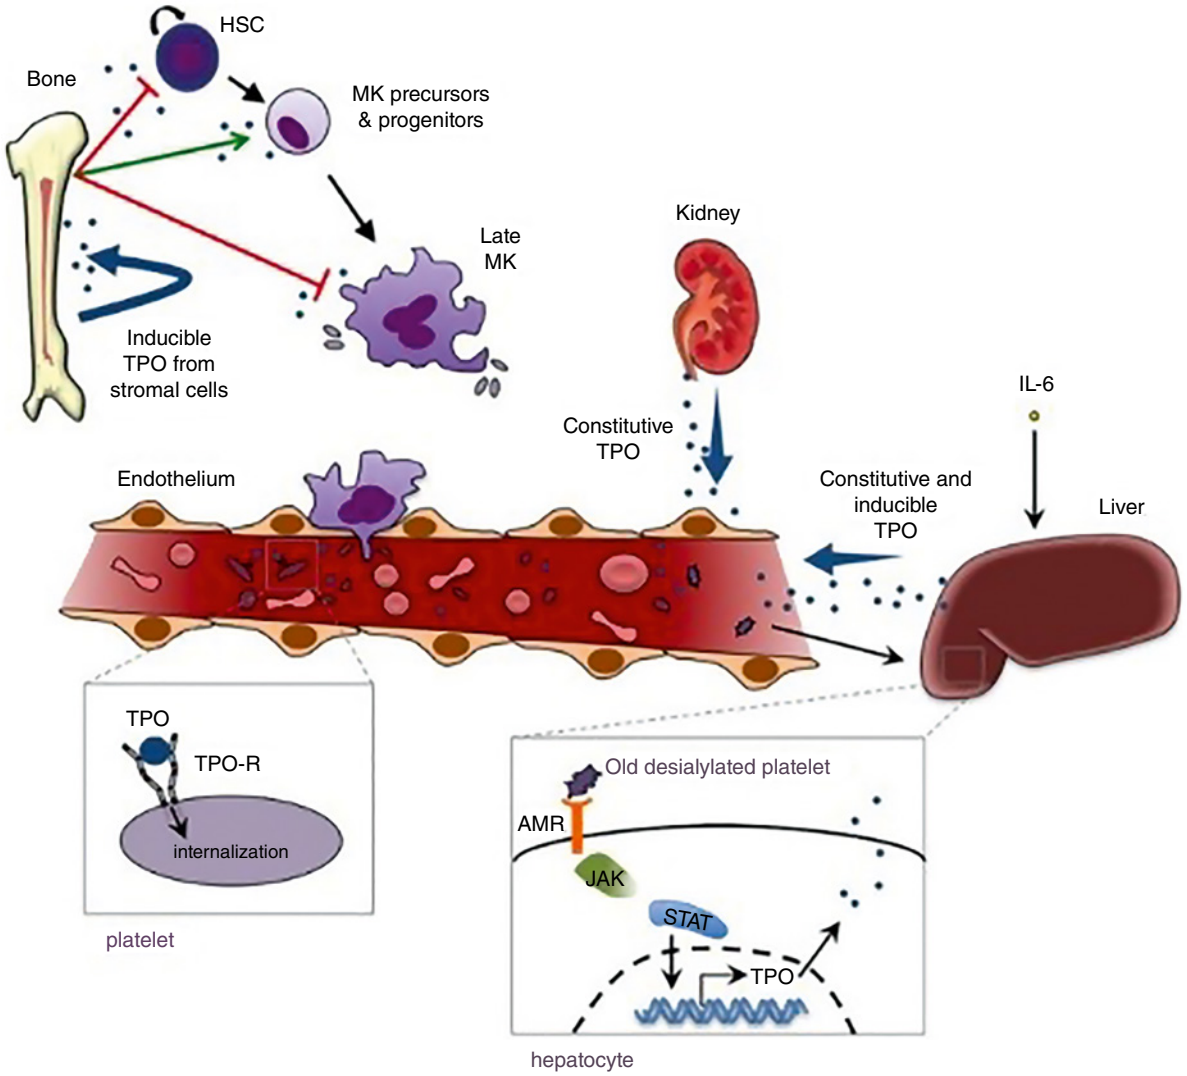

FIGURE 75.1 Thrombopoietin (TPO) production, function, and homeostasis. TPO is mainly produced by hepatic parenchymal cells and by endothelial cells of hepatic sinusoids. TPO production can also occur in proximal tubule cells of the kidney and in bone marrow stromal cells. The production is mainly constitutive (with no change in TPO mRNA levels), and regulation is mediated by negative feedback of the TPO receptor (TPO-R, c-mpl) expressing platelet pool that internalizes and destroys free circulating TPO. IL-6 is able to induce hepatic TPO mRNA production in reactive/inflammatory thrombocythemia. Additionally, binding of old desialylated platelets to the hepatic Ashwell–Morell receptor (AMR) promotes liver TPO mRNA production. TPO plays a dual role in hematopoiesis, including an inhibitory role (red lines with bars) acting to maintain stem cell quiescence and cell cycle arrest of late megakaryocytes (MKs), and a stimulatory role acting on immature precursors (common myeloid progenitor (CMP) and MEP) and promoting growth of very early progenitors of megakaryopoiesis (BFU-MK and CFU-MK). (Source: Varghese et al.[36] © 2017 Varghese, Defour, Pecquet and Constantinescu)

Stromal-Cell-Derived Factor-1

cMpl-null mice are markedly thrombocytopenic, but still capable of platelet production. Stromal-cell-derived factor-1 (SDF-1) can function alone or synergistically with TPO to enhance thrombopoiesis and may be responsible for maintaining low-level thrombopoiesis. SDF-1 interaction with chemokine receptor 4 (CXCR4) may be responsible for movement of megakaryocyte progenitors to the vascular niche necessary for initiation of thrombopoiesis. Movement of megakaryocytes to the vascular sinusoid compartment of bone marrow, mediated by SDF-1 and fibroblast growth factor-4 (FGF-4), induces megakaryocyte maturation and platelet formation.[5]

Other Cytokines, Growth Factors, and Proteins Involved with Thrombopoiesis

Although TPO is an important regulator of thrombopoiesis throughout all stages of megakaryocyte development, other cytokines act in synergy with TPO primarily in early stages of megakaryopoiesis. IL-3 synergizes with TPO to produce several hematopoietic lineages, but IL-3 effects are limited to the CFU-MK stage. Stem cell factor and granulocyte–macrophage

colony-stimulating factor act in synergy to enhance proliferation and expansion of bone marrow progenitors and megakaryocyte lines. Granulocyte colony-stimulating factor (G-CSF) combined with TPO can trigger hematopoietic stem cells to enter the cell cycle and support colony formation. In later stages of megakaryocyte development, G-CSF has been shown to suppress megakaryopoiesis. IL-11, IL-12, and erythropoietin also stimulate proliferation of megakaryocyte progenitors. PF4 has been shown to inhibit megakaryocytopoiesis in vitro. PF4 is stored in platelet alpha granules; aberrant platelet activation within bone marrow with subsequent PF4 release (e.g., radiation, chemotherapy) may contribute to thrombocytopenia. Earlier studies indicated that IL-1α and leukemia inhibitory factor (LIF) affect later stages of megakaryocyte maturation and platelet release. More recently, it has been shown that IL-1α can cause a more sudden platelet release reaction from megakaryocytes through the action of caspase-3, possibly during instances of sudden need.[23] Recent studies have shown that CK2β, a regulatory subunit of casein kinase 2, is vitally involved in thrombopoiesis regulation (and platelet activation) with roles in tubulin polymerization, megakaryocyte fragmentation, and proplatelet formation.[22] CK2β regulates calcium influx into platelet cytoplasm via inositol-triphosphate activity.

MEGAKARYOCYTE PLOIDY AND PLATELET MASS AMONG SPECIES

There are four to five times more megakaryocytes in mouse bone marrow than in human bone marrow, and mouse megakaryocytes are smaller. The difference in size is not related to ploidy distribution, since the modal ploidy value for both species is 16N. Megakaryocyte modal ploidy is 32N for dogs and rabbits. In cats, the modal value is evenly split between 32N and 64N.[8] In 1-week-old calves, the modal ploidy of cultured megakaryocytes was 64N, whereas in cattle aged 12–17 months the modal ploidy value was 32N.[34] Megakaryocyte ploidy is not consistently related to platelet mass and platelet mass is not constant across species. In dogs and cats, platelet size is inversely proportional to platelet number, whereas there is no correlation between platelet number and size in cows, goats, or ponies. Platelet number and size are directly proportional in horses. Mean platelet mass ranges from 1.8×10^6 to 2.5×10^6 fL/μL in cows, dogs, goats, and cats. In mice, platelet mass is 5.2×10^6 fL/μL, while in horses platelet mass is 0.72×10^6 fL/μL.[4]

Acronyms and Abbvreviations

ADP, adenosine diphophosphate; Arp, actin-related protein; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; DTS, dense tubular system; GMP140, granule membrane protein 140; GP, glycoprotein; GTP, guanosine triphosphate; ICAM, intercellular adhesion molecule; LAMP, lysosomal-associated membrane protein; LIMP, lysosomal integral membrane protein; OCS, open canalicular system; PADGEM, platelet-activation-derived granule external membrane protein; PDGF, platelet derived growth factor; PECAM, platelet endothelial cell adhesion molecule; PGH2, prostaglandin H2; PMCA, plasma membrane calcium ATPase; PtdIns, phosphatidylinositol; SERCA, sarco/endoplasmic reticulum calcium ATPase; RGD, arginine glycine aspartic acid; STIM1, stromal interaction molecule 1; TSSC6, Tumor-suppressing subchromosomal transferable fragment cDNA 6; TXA, thromboxoane; VLA-2, very late activation antigen-2; VWF, von Willebrand factor; WASp, Wiskott–Aldrich syndrome protein.

MEMBRANE STRUCTURE

Lipid Raft Microdomains

Platelet membranes are similar to those of other cells and are characterized by phospholipids arranged in a bilayer forming a hydrophobic core. Interspersed within the fluid lipid matrix are densely compacted lipid raft microdomains primarily composed of sphingolipid and cholesterol molecules, and fewer numbers of protein molecules. These lipid rafts are capable of lateral mobility and enhance signaling in initial phases of platelet activation, and mediate cytoskeletal reorganization events critical for clot retraction.[9]

Receptors

Proteins and glycoproteins (GP), serving as specialized receptors important in platelet responses are present both within and outside membrane lipid rafts. GPIb-IX–V and GPVI, receptors involved in von Willebrand factor (VWF) and collagen binding, respectively, are examples of proteins primarily located within lipid rafts. Glycoprotein complex IIb–IIIa (GPIIb–IIIa), also known as integrin $\alpha_{IIb}\beta_3$,[3] is the most prevalent glycoprotein complex on the surface of platelets and is located outside of lipid rafts.[26] Although GPIIb–IIIa is not located within lipid raft microdomains, the complex does upregulate phosphatidylinositols, in particular

phosphatidylinositol(4,5)bisphosphate (PtdIns(4,5)P2), as part of the outside-in signaling cascade. This process may be facilitated by interaction with tetraspanins located within microdomains distinct from lipid rafts.[34] PtdIns(4,5)P2 induces the recruitment of several actin-modulating proteins resulting in the interaction of the cytoskeleton with microdomains. The interaction of the cytoskeleton with lipid raft microdomains is necessary for sustaining the forces necessary for clot retraction.[9] GPIIb–IIIa receptors are the primary mediators of platelet aggregation by binding fibrinogen, although these complexes also bind VWF and assist with early stages of platelet adhesion to the subendothelium. The major receptors present on the surface of platelets are summarized in Table 76.1.

TABLE 76.1 Classification and function of major platelet membrane receptors.

Classification	Function	References
Integrins		
$\alpha_{IIb}\beta_3$ (GPIIb–IIIa; CD41/CD61)	Known as the fibrinogen receptor. 50,000–80,000 receptors per platelet. Mediator of platelet aggregation; platelet activation is required to induce a conformational change for ligand binding. Ligands include several arginine glycine aspartic acid (RGD)-containing proteins including fibrinogen, VWF, thrombospondin, fibronectin, and vitronectin	60
$\alpha_v\beta_3$ (CD51/CD61)	Known as the vitronectin receptor. 200–300 receptors per platelet. Platelet activation is required to induce a conformational change for ligand binding. Ligands include RGD-containing proteins such as vitronectin, fibrinogen, and osteopontin	4, 62
$\alpha_2\beta_1$ (GPIa–IIa; CD49b/CD29)	Known as very late activation antigen-2 (VLA2) on lymphocytes. 2000–3000 receptors per platelet. Major collagen adhesion receptor; platelet activation required for collagen binding via this receptor	48
$\alpha_5\beta_1$ (CD49e/CD29)	Known as the fibronectin receptor. Augments platelet adhesion; platelet activation is not required for fibronectin binding	56
$\alpha_6\beta_1$ (CD49f/CD29)	Known as the laminin receptor. Augments platelet adhesion; platelet activation is not required for laminin binding	30, 74
Leucine-rich repeat		
GPIbIX–V (CD42b/42c–CD42a–CD42d)	Known as the VWF receptor; also binds Mac-1 and P-selectin. Functions in platelet adhesion under high shear. 60,000 receptors per platelet	2
G-protein-coupled receptors		
Protease-activated receptors (PAR)	Function as thrombin receptors. Platelets have 3 PAR receptor types that vary with species. PAR1 and PAR4 are major human PARs; PAR3 and PAR4 major rodent PARs, other species less defined	10, 17
ADP receptors	P2Y1 and P2Y12 are expressed on platelets. P2Y1 is coupled to Gq and initiates calcium mobilization resulting in shape change and reversible platelet aggregation. P2Y12 is coupled to Gi resulting in inhibition of adenylate cyclase and lowering of cyclic adenosine monophosphate (cAMP). P2Y12 activation is associated with irreversible platelet aggregation	61
Thromboxane receptor (TXA_2)/prostaglandin H2 (PGH_2)	Two receptors are expressed, TPα and TPβ, which are coupled to G proteins; TPα is coupled to Gs, while TPβ is coupled to Gi. TXA_2 and PGH_2 interact with both receptor types. Both types of receptors are predicted to be present on platelets from cattle, horses, and cats, no evidence exists for TPβ receptors on dog platelets	80, M. K. Boudreaux, unpublished observations
Prostacyclin receptor (PGI_2)	PGI_2 receptors are coupled to Gs. Prostacyclin binding results in activation of adenylate cyclase, enhanced cAMP production, and inhibition of platelet activation	75
Platelet-activating factor (PAF) receptor	PAF mediates platelet shape change and aggregation. PAF receptors are coupled to Gi and Gq. PAF can also initiate signal-dependent translation pathways in human platelets	86
Adenosine receptor	Three receptor subtypes are expressed. Adenosine receptor activation results in cAMP elevation and inhibition of platelet aggregation	1, 32
Adrenergic receptor	Alpha-2A adrenergic receptors are present on platelets, which are coupled to Gi. Epinephrine binding results in reduction of cAMP and potentiation of platelet activation. May play a role in enhancing thrombus stability	66
Serotonin receptor	Coupled to G-proteins leading to calcium mobilization and enhancement of platelet activation. Two subtypes have been detected on human platelets	1

(*Continued*)

TABLE 76.1 (Continued)

Classification	Function	References
Immunoglobulin/ITAM/ITIM		
GPVI-FcRγ	Major collagen receptor. Composed of two immunoglobulin C2 loops, which bind collagen. Is complexed with FcRγ, which contains an ITAM that is tyrosine phosphorylated during platelet activation. Receptor contributes to platelet activation and aggregation and may contribute to maintaining blood vessel integrity during inflammation in an aggregation-independent fashion	11, 35
FcγRIIA	Immune receptor expressed on human but not mouse platelets. Binds IgG. Plays a role in heparin-induced thrombocytopenia	14
FcεRI	IgE immune receptor. Activation induces release of serotonin and RANTES and thus may play a role in allergic inflammatory responses	37
Intercellular adhesion molecule (ICAM)-2	Present on the surface of activated and nonactivated platelets. The only β2 integrin ligand on platelets; may play a role in leukocyte–platelet interactions	25
Platelet endothelial cell adhesion molecule (PECAM)-1 (CD31)	Composed of six C2 immunoglobulin domains, a transmembrane domain, and a short cytoplasmic tail containing two ITIM domains. Plays dual roles as an inhibitor and enhancer of platelet activation. Has an inhibitory effect on ITAM-based collagen responses and also promotes $\alpha_{IIb}\beta_3$-mediated outside-in signaling	47, 81
CD47	Thrombospondin receptor; also known as integrin-associated protein (IAP). TSP binding results in enhanced platelet activation via inhibition of nitric oxide/cyclic guanosine monophosphate (cGMP) signaling	41
Tetraspanins		
CD9	Present on resting platelet plasma membrane in association with $\alpha_{IIb}\beta_3$. May be involved in recruiting phosphatidylinositol kinase activity, specifically PI4K, to integrin-based signaling complexes	40
CD82	Studies in lymphocytes suggest a role in linking signaling through raft microdomains with the actin cytoskeleton.	22
CD151 (PETA-3)	Present on resting platelet plasma membrane in association with $\alpha_{IIb}\beta_3$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$. May play a role in integrin-mediated signaling	30
Tumor-suppressing subchromosomal transferable fragment cDNA 6 (TSSC6)	Associated with $\alpha_{IIb}\beta_3$ in resting platelets in cholesterol-rich microdomains that upon activation facilitate signal transduction events, including outside-in integrin signaling	34
Others		
P2X1	ATP receptor that enhances calcium entry. Plays a role in reinforcing and amplifying platelet activation	61
CD36 (GPIV, GPIIIb)	Ligands include thrombospondin, modified phospholipids, and long-chain fatty acids. Contributes to thrombus formation by binding to phosphatidylserine exposed on endothelial-cell-derived microparticles resulting in enhanced platelet activation	33
C1q	May play a role in classical complement pathway activation on platelet surfaces, particularly under high-shear conditions	63
Serotonin reuptake	Receptor is distinct from serotonin activation receptor. Responsible for serotonin transport across the platelet plasma membrane. Selective serotonin reuptake inhibitors inhibit platelet reactivity	72
Glycosyl phosphatidylinositol (GPI)-anchored proteins	At least five GPI-anchored glycoproteins are expressed. These include CD55, CD59, CD109, and prion protein. Platelets contain >96% of prion protein in human blood. Prion proteins are primarily present within alpha granule membranes and become expressed with platelet activation. Prion proteins are associated with platelet-derived microparticles and exosomes following thrombin-induced platelet activation	68
Thrombopoietin receptor (MPL)	A member of the tyrosine kinase receptor family. Important for regulating platelet production. Receptors are internalized when bound by TPO. TPO binding does not activate platelets, but does enhance platelet activation	53

ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; MPL, myeloproliferative leukemia protein; PETA-3, platelet and endothelial cell tetraspan antigen-3; RANTES, regulated on activation, normal T cell expressed, and presumably secreted; PI4K, phosphatidylinositol 4 kinase; TPO, thrombopoietin.

CYTOPLASMIC STRUCTURAL AND MEMBRANOUS ELEMENTS

Microtubules

A circumferential band of microtubules is located just beneath the platelet membrane.[36] Microtubules are hollow, cylindrical structures composed of protofilaments formed by alpha–beta tubulin dimers arranged in a helical head-to-tail fashion. Microtubules are responsible for the maintenance of the disc-shaped form of the circulating platelet.[44] Under physiologic conditions, β1-tubulin is solely expressed as a component of microtubules within megakaryocytes and is essential for the orderly fragmentation of platelets from the megakaryocyte cytoplasm.[70]

Open Canalicular System (OCS)

The surface-connected canalicular system or OCS connects to the surface of the platelet and extends deep within its cytoplasm in an extremely tortuous maze of open and interconnecting channels.[82] This system was thought to be a remnant of the demarcation membrane system of megakaryocytes, but the absence of the OCS in some mammals[87] and the presence of the OCS in thrombocytes of birds[77] and fish[19,52] have cast doubts to its origin. The OCS can act as a conduit for the uptake of particles and for the release of granule contents by activated platelets. Particles such as viruses or bacteria can be taken up by the OCS; this activity usually results in platelet activation. Alpha and lysosomal granules are documented to fuse and evacuate their contents into the OCS around engulfed bacteria or viruses, but communication with the outside is always maintained, unlike phagocytic vacuoles of leukocytes. Thus, platelets are not considered to be true phagocytes.[83] The OCS is everted to some extent during platelet activation, which increases the number of surface receptors available for ligand binding, since many of the same receptors found on the platelet surface also line the OCS.[28] Ruminant and equine platelets do not possess an OCS,[31] although their megakaryocytes do possess a demarcation membrane system.[78] Platelets from these species do not expand their surface area during activation, do not have a mechanism for uptake of particles, and release their granule contents by fusion of granules directly to the outer membrane. Figures 76.1 and 76.2 are platelet electron micrographs comparing overall appearance for several species.

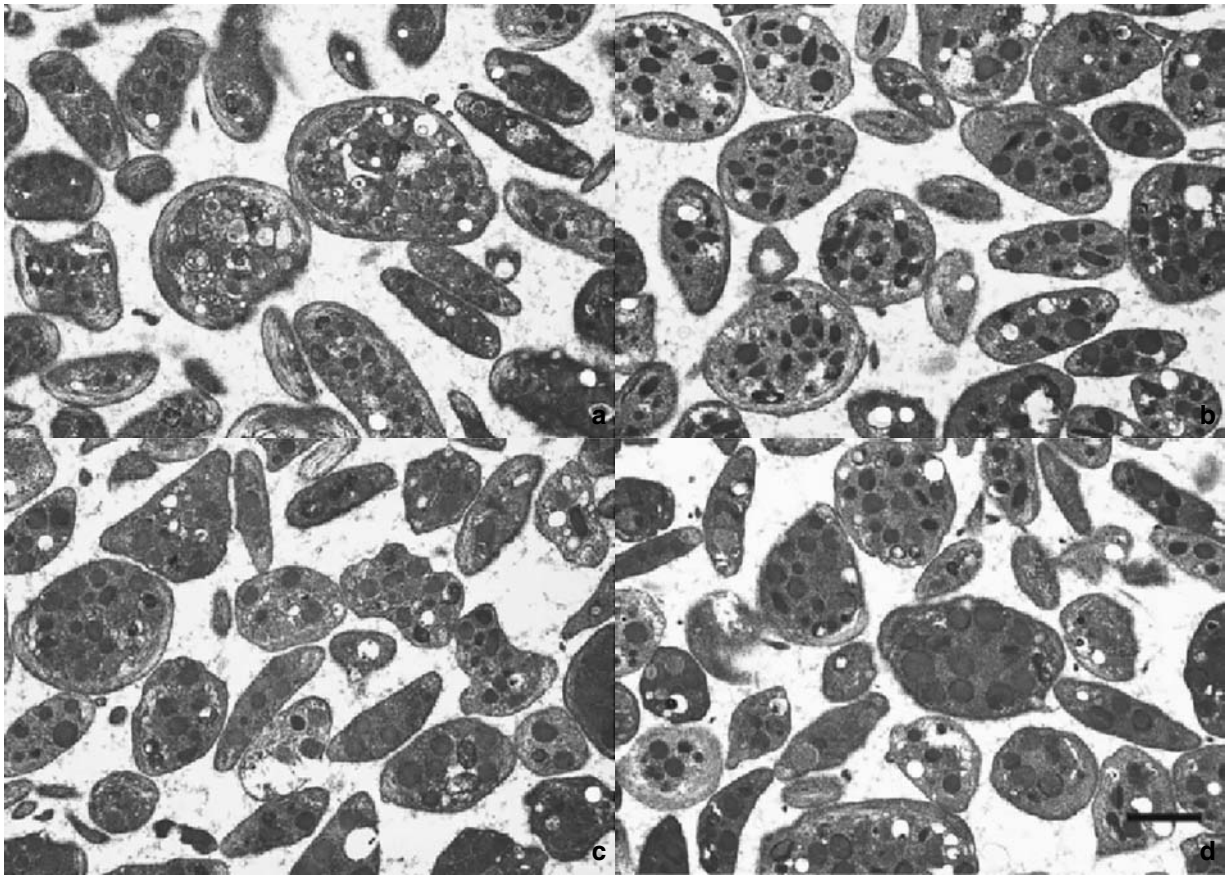

FIGURE 76.1 Electron micrographs of platelets obtained from (a) alpaca, (b) cow, (c) goat, and (d) sheep for overall comparison of platelet morphology. Alpha granules appear light to dark gray and are prevalent and variably sized and shaped in these species. The electron-dense content of most of the dense granules has been lost leaving vacuolar-like spaces. Microtubules can be observed in the periphery of some platelets. An open canalicular system is not present in these species. Bar = 2 μm. (**Source:** Courtesy of Dr. Maria Toivio-Kinnucan, Auburn University)

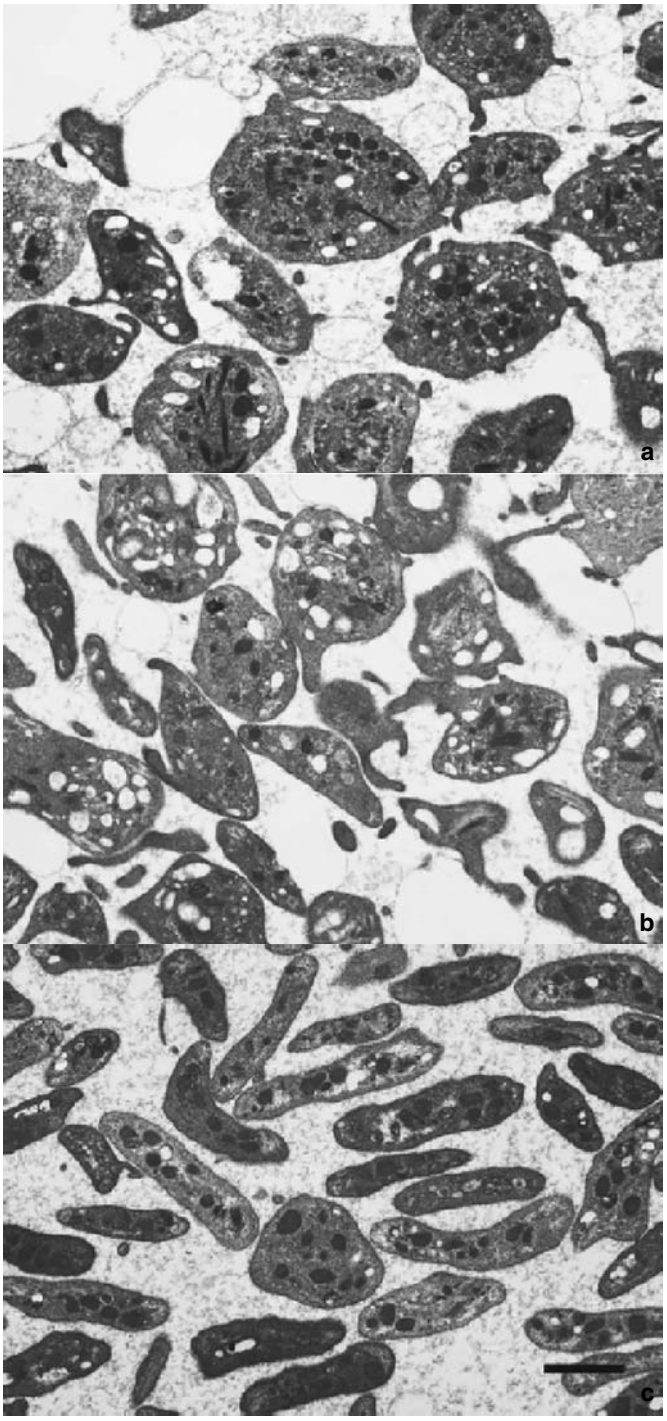

FIGURE 76.2 Electron micrographs of platelets obtained from (a) cat, (b) dog, and (c) horse. Alpha granules are numerous and variable in size and shape as seen with ruminant platelets. An open canalicular system is present in cat and dog platelets, but absent in horse platelets. Bar = 2 µm. (**Source:** Courtesy of Dr. Maria Toivio-Kinnucan, Auburn University)

Dense Tubular System (DTS)

The DTS exists as thin elongated membranes in the cytoplasm of resting platelets. The DTS is a remnant of the smooth endoplasmic reticulum of the megakaryocyte and is located near microtubules. Unlike the OCS, it does not communicate with plasma or granule membranes. DTS membranes contain cyclooxygenase and thromboxane synthase and thus participate in prostaglandin metabolism. The DTS is also a site for calcium sequestration by the platelet; calcium movement is facilitated by ATPase pumps termed sarco/endoplasmic reticulum calcium ATPases (SERCAs), which are tightly coupled to plasma membrane calcium ATPases (PMCAs). Plasma membrane calcium ATPases function to move calcium ions to the extracellular space, while SERCAs pump calcium ions into the DTS. Rapid calcium influx in response to release of intracellular stores, referred to as store-operated calcium entry, is mediated by a plasma membrane channel protein, Orai1, and a calcium sensor in the endoplasmic reticulum, stromal interaction molecule 1(STIM1).[79]

Mitochondria

Platelet mitochondria support the metabolic activities of resting platelets and play regulatory roles in platelet activation and apoptosis. Sustained high intraplatelet calcium leads to mitochondrial membrane potential collapse in a process linked to outer membrane phosphatidylserine exposure. Externalization of this negatively charged phospholipid supports assembly of active coagulation complexes and is a marker of platelet aging in circulation.[64]

CYTOSKELETON

Platelets possess a cytoskeleton on the cytoplasmic side of the plasma membrane composed of actin, spectrin (fodrin), adducin, filamin, and glycoprotein-Ib-IX–V (the VWF receptor). The membrane cytoskeleton interacts with an extensive cytoplasmic actin network. Adducin links the ends of cytoplasmic actin filaments to membrane-associated spectrin strands. Filamin subunits bind to actin and to the cytoplasmic tails of the GPIbα subunits resulting in strengthening of the interaction of the spectrin/actin network with the plasma membrane.[36] During platelet activation, adducin molecules dissociate from the ends of actin filaments allowing disassembly and reorganization of actin. Actin disassembly is promoted by gelsolin and cofilin. Gelsolin undergoes a conformational change in response to increased cytoplasmic calcium allowing the protein to interdigitate and disrupt actin filaments. Cofilin becomes activated as a result of dephosphorylation during platelet activation and functions to sever and promote actin disassembly along with gelsolin. Actin reassembly during the formation of filopodia and lamellipodia by activated platelets is mediated

by the actin-related protein (Arp) 2/3 complex. Proteins involved in activation of the Arp 2/3 complex include cortactin and Wiskott–Aldrich syndrome (WASp) family proteins. Actin reassembly and myosin II binding and activation are critical for platelet spreading, granule movement, granule release, and clot retraction.

GRANULES

Platelets have three main types of storage granules: dense, alpha, and lysosomal, and they are heterogeneous in content and morphology.[50] Alpha and dense granules are thought to be derived from a common multivesicular body intermediate, and thus their membranes share several common components[85] (Table 76.2).

Dense Granules

The dense granules or dense bodies, as their name implies, are electron-dense when viewed using an electron microscope, and serve as storage sites for adenine nucleotides, serotonin, calcium, and inorganic phosphates.[57,67] The adenine nucleotide (ADP/ATP) ratio is roughly 1.5 within dense granules. The pool is metabolically inert and not available as an energy source. Serotonin is actively transported from plasma into dense granule cores and the serotonin concentration within dense granules is 1000 times higher than plasma concentrations. Dense granules contain 70% of the total calcium within platelets. This calcium pool is not mobilized during platelet activation, unlike the calcium pool within the DTS. Inorganic phosphates, calcium, serotonin, and adenine nucleotides are held together tightly within dense granules as a result of intermolecular forces, thus contributing to their stability and density.[73] Human and pig platelet dense granules contain high levels of lysolecithin;[24] however, lysolecithin was not detectable in the dense granules of rabbit platelets.[20] Dense granules also contain ganglioside GM3 and phospholipids including phosphatidylethanolamine, phosphatidylinositol, phosphatidylcholine, and sphingosine.[15] Organelle proteomics has led to the discovery of 40 proteins within dense granules, many of which had not been known to be present within this organelle. Dense granule protein categories include cell signaling proteins, molecular chaperones, cytoskeletal proteins, proteins involved in glycolysis, and proteins involved in platelet function.[39] Dense granule membranes contain several receptors that become expressed on the plasma membrane as a result of dense granule fusion with the surface during the platelet release reaction. Some of these receptors are shared with other granule membranes and with the plasma membrane (Table 76.2).

Alpha Granules

Alpha granules, the largest and most numerous of the platelet granules, correspond to the azurophilic granules viewed by light microscopy. They are unique in terms of structure and packaging function. Structurally, alpha granules are composed of two major compartments, a dark centrally located nucleoid region and a peripherally located electron-lucent gray matrix region apparent at the electron microscopic level. The nucleoid region contains proteoglycans, which confer stability to the granules. The nucleoid region is where beta-thromboglobulin and platelet factor 4 as well as other proteins are localized. Von Willebrand factor, multimerin, and factor V colocalize within tubular structures located in the outer part of the gray matrix region. Fibrinogen, thrombospondin, and fibronectin are primarily located in the gray matrix region in an area between the nucleoid and outer gray matrix region. Compartmentalization of VWF and fibrinogen within alpha granules has been documented in mouse, human, and porcine platelets.[69] Compartmentalization of proteins may serve to allow platelets to differentially release proteins in response to activation.[71] Mouse alpha granules are more heterogeneous in terms of shape, size, and distribution compared to human alpha granules.[69] Alpha granules contain proteins that are synthesized by megakaryocytes in addition to plasma proteins that are endocytosed as platelets circulate in blood. Alpha granule proteins that are synthesized by megakaryocytes fall into two categories: megakaryocyte-specific (such as beta-thromboglobulin and platelet factor 4) and those

synthesized by other cells and concentrated within platelet alpha granules (such as factor V and platelet derived growth factor (PDGF).[76] The latter proteins are sometimes referred to as platelet-selective proteins. The most well-recognized protein endocytosed by platelets is fibrinogen whose uptake is mediated by the glycoprotein-IIb–IIIa (integrin $\alpha_{IIb}\beta_3$) receptor. Proteins present in low levels within alpha granules such as albumin and immunoglobulin are passively taken up by platelets and do not require specific receptors. A proteomic analysis of human platelet alpha granule proteins provided a list of 284 proteins, 44 of which have not been previously identified within platelet alpha granules.[55] Alpha granule membrane proteins, much like dense granule membrane proteins, become expressed on the platelet surface after platelet secretion as a result of fusion of granules with the OCS or outer platelet membrane. The most well-known alpha granule membrane protein expressed on the surface of activated platelets is P-selectin or CD62P (formerly known as granule membrane protein 140 (GMP140)[46] and as platelet-activation-derived granule external membrane protein (PADGEM)).[51] Since its discovery, P-selectin has also been detected on the membranes of dense granules.[42] Monoclonal antibodies have been developed to detect the presence of P-selectin on the surface of activated platelets in dogs.[27] Other proteins present within alpha granule membranes include GPIb-IX–V, GPIIb–IIIa, PECAM-1, vitronectin receptor, and GPIV (Table 76.2). Some of these membrane proteins have also been detected within the membranes of dense granules.[84]

Lysosomal Granules

Lysosomal granules contain acid-dependent hydrolases including glycosidases, proteases, and lipases.[23] Lysosomal granules can be identified in platelets and megakaryocytes using specific cytochemical stains.[5] Secondary lysosomes have been detected in bovine megakaryocytes and platelets.[58] Lysosomal membranes also contain proteins that become exteriorized during the platelet release reaction (Table 76.2). Membrane proteins, which include lysosomal integral membrane protein (LIMP or CD63) and lysosomal-associated membrane proteins 1 and 2 (LAMP-1 and LAMP-2),[29] are heavily glycosylated to protect them from hydrolytic enzymes stored within these granules.[59] While initially LAMPs were thought to be solely present within lysosomal granule membranes, LAMP-2 and LAMP-3 have been detected within dense granule membranes as well.[43] Additional lysosomal membrane proteins are present that mediate transport of ions and amino acids across the membrane to maintain an acidic luminal pH.

CHAPTER 77

Platelet Signal Transduction and Activation Response

PETE W. CHRISTOPHERSON and MARY K. BOUDREAUX

Overview of Platelet Function
Platelet Receptors and Activation Pathways
  ADP/ATP Receptors
  Collagen Receptors
Thromboxane Receptors
  Thrombin Receptors
Platelet–Leukocyte Interactions and Thromboinflammation
Procoagulant Activity

Acronyms and Abbreviations

AA, arachidonic acid; CalDAG-GEFI, calcium diacylglycerol guanine nucleotide exchange factor I; CCL2, chemokine ligand-2; cPLA2, cytoplasmic phospholipase A2; CXCL8, chemokine IL-8; cyclic adenosine monophosphate (cAMP); DAG, 1,2-diacylglycerol; DTS, dense tubular system; GDP, guanosine diphosphate; GIRK, G-protein-gated inwardly rectifying potassium channel; GP, glycoprotein; GTP, guanosine triphosphate; ICAM-1, intercellular adhesion molecule-1; IP3, inositol triphosphate; ITAM, immunoreceptor tyrosine-based activation motif; LAT, linker for activation of T cells; LFA-1, lymphocyte function-associated antigen-1; Lin-11,Isl-1,Mec-3 (LIM); MLC, myosin light chain; NHE1, Na/H exchanger; PAK, p21-activated kinase; PAR, protease-activated receptor; PE, phosphatidylethanolamine; PI3K, phosphoinositide-3-kinase; PIP, phosphatidylinositol phosphate; PIP3, phosphatidylinositol (3,4,5)-trisphosphate; PIP2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C; PS, phosphatidylserine; PSGL-1, P-selectin glycoprotein ligand-1; ROCK, Rho-associated coiled-coil-containing kinase; SLP-76, Src homology domain-containing leukocyte phosphoprotein of 76 kDa; TF, tissue factor; TP, thromboxane receptor; TRAP, thrombin receptor-activating peptide; TXA, thromboxane A2; VCAM-1, vascular cell adhesion molecule-1.

OVERVIEW OF PLATELET FUNCTION

Platelets are the first line of defense against bleeding at sites of vascular injury and are major reactants in thrombotic, inflammatory, and neoplastic processes. Platelets have cell surface receptors that recognize signals from their environment and communicate those signals to a complex network of biomolecules that include ions, proteins, nucleotides, and phospholipids. While the details of many key networking pathways that elicit platelet responses are known, others remain to be elucidated. Platelet reactions orchestrated via these complex signaling networks include adhesion, aggregation, granule release, retraction, microvesiculation, and procoagulant expression.

When agonist molecules bind to platelet receptors, they induce inside-out signaling resulting in structural changes in glycoproteins on the platelet membrane surface that then allow binding of proteins that mediate platelet adhesion and aggregation (Figure 77.1; see also Chapter 76). In turn, binding of adhesive proteins to receptors results in outside-in signaling events that promote and enhance platelet granule release, platelet aggregate and fibrin formation, and clot retraction.

Cross-talk between platelet receptors and signaling molecules is a key component of platelet activation.

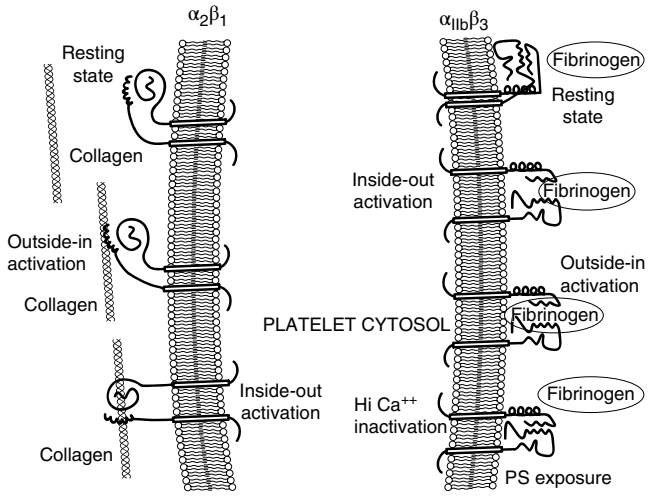

FIGURE 77.1 Platelet activation transforms the resting state of platelet membrane adhesion receptors for collagen ($\alpha_2\beta_1$) and fibrinogen ($\alpha_{IIb}\beta_3$) by altering their conformation states. Effector molecules generated by various signaling pathways in response to outside-in or inside-out signaling control the strength, reversibility, or irreversibility of collagen or fibrinogen binding. Formation of tight and irreversible complexes consolidates platelet adhesion and aggregation. When intraplatelet ionized Ca^{2+} is increased for prolonged periods, $\alpha_{IIb}\beta_3$ becomes secondarily inactivated and can no longer bind fibrinogen.

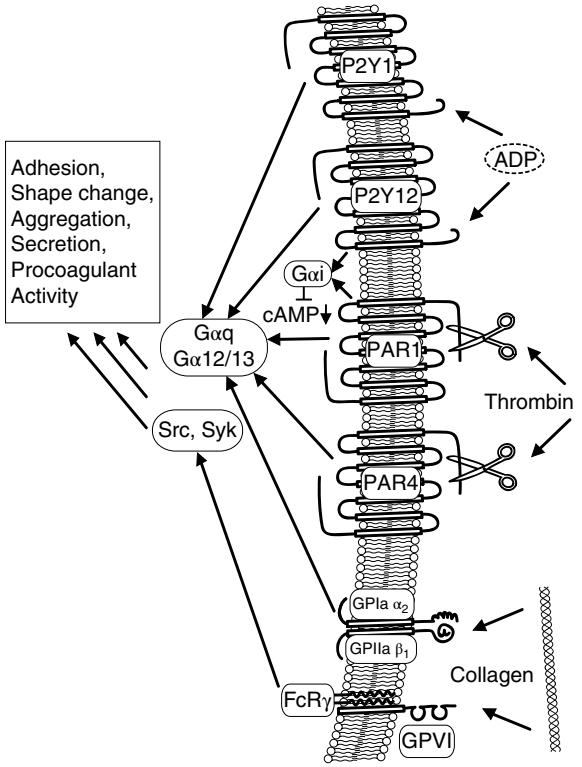

FIGURE 77.2 G-protein-coupled receptors (GPCRs) link platelet-signaling pathways. The extracellular domains of paired receptors for ADP ($P2Y_1$ and $P2Y_{12}$), thrombin (PAR1 and PAR4), and collagen ($\alpha_2\beta_1$ and GPVI) interact with their specific ligands to mediate outside-in signaling pathways. The thrombin receptor is activated when thrombin binds to and cleaves the extracellular *N*-terminal domain unmasking a new tethered *N* terminus that binds to the second extracellular loop of the receptor. In contrast to $\alpha_2\beta_1$, which is a GPCR, GPVI signals collagen-initiated platelet activation through sequential activation of Src and Syk family tyrosine kinases.

Adding to the complexity of platelet signaling events is the ability of platelets to synthesize proteins, referred to as signal-dependent translation.[72] This chapter reviews platelet-signaling events communicated through the major activation receptors present on platelets, as well as pathways and receptors involved in platelet–leukocyte interactions and expression of procoagulant activity.

PLATELET RECEPTORS AND ACTIVATION PATHWAYS

ADP/ATP Receptors

Platelets have three distinct P2 purinergic receptors, $P2Y_1$, $P2Y_{12}$, and $P2X_1$.[16] $P2Y_1$ and $P2Y_{12}$ are G-protein-coupled ADP receptors, mediating platelet shape change and aggregation responses. The $P2X_1$ receptor is a ligand-gated cation channel ATP receptor responsible for fast calcium entry, and may play a role in collagen and shear-induced platelet activation (Figure 77.2).[34,45,46]

$P2Y_1$ is coupled to a Gαq protein subunit; signaling via Gαq results in activation of phospholipase C β2 (PLCβ2), Rho A, Rac, and Src family kinases.[26] PLCβ2 mediates intracellular calcium mobilization and protein kinase C (PKC) activation via hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2) within platelet membranes, to inositol triphosphate (IP3) and 1,2-diacylglycerol (DAG).[31,46] IP3 mediates calcium mobilization from intraplatelet stores sequestered within the dense tubular system (DTS). DAG and ionized calcium activate diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI), which in turn facilitates the displacement of guanosine diphosphate (GDP) and loading of guanosine triphosphate (GTP) within Rap1b. GTP-bound Rap1b plays an important role in mediating the change in conformation of $\alpha_{IIb}\beta_3$ necessary for fibrinogen binding and platelet aggregation. The importance of CalDAG-GEFI downstream of PLCβ2 in mediating inside-out signaling events leading to activation of $\alpha_{IIb}\beta_3$ is illustrated in mice, dogs, and cattle with mutations in CalDAG-GEFI.[5,6,14] All of these animals have a bleeding diathesis and impaired platelet responses to ADP and collagen (see Chapter 84).

$P2Y_1$ activation results in platelet shape change as well as a reversible wave of platelet aggregation. Platelet shape change occurs as a result of both calcium-sensitive and calcium-insensitive pathways contributing to phosphorylation of myosin light chain (MLC).[48] The calcium-sensitive pathway is mediated by calcium-calmodulin. The calcium-insensitive pathway is mediated by Rho A/p160ROCK downstream of Gαq. Rho-associated coiled-coil-containing kinase (p160ROCK) is a serine/threonine protein kinase that is directly targeted by Rho

A. Activation of p160ROCK alters the balance between MLC phosphatases and MLC kinases in favor of MLC kinases, resulting in MLC-kinase-mediated phosphorylation of MLC necessary for platelet shape change.[15] The RhoA/p160ROCK pathway is important in mediating the disruption of the microtubule ring that transforms platelets from discs to spheres, and is also critical for maintaining the change in shape.[49] Rac, a Rho-family GTPase that is activated by $P2Y_1$, is thought to be important in mediating platelet spreading and anchoring via activation of a p21-activated kinase (PAK).[4] Activated PAK is thought to activate the serine/threonine kinase Lin-11, Isl-1, Mec-3 (LIM)which targets and phosphorylates cofilin, inhibiting cofilin's ability to depolymerize actin.[3]

Rac activation by $P2Y_1$ is potentiated by $P2Y_{12}$ signaling.[62] By contrast, $P2Y_1$ signals Src kinase activation and the inhibition of the phosphoinositide-3-kinase (PI3K)-dependent phase of $P2Y_{12}$ signaling. This inhibition is thought to be an important negative feedback mechanism regulating platelet activation mediated by ADP.[26]

$P2Y_{12}$ activation does not contribute to platelet shape change, but is associated with platelet aggregation and granule release, thromboxane generation, expression of procoagulant activity, and inhibition of adenylyl cyclase.[63] Engagement of $P2Y_{12}$ is also required for amplification of platelet activation induced by ADP and low concentrations of other platelet agonists including thromboxane A2 (TXA2), collagen, and thrombin. $P2Y_{12}$ is coupled to the heterotrimeric G protein complex $G\alpha i2\beta\gamma$.[70] ADP binding to $P2Y_{12}$ results in uncoupling of $G\alpha i2$ and $G\beta\gamma$, which act as separate signaling molecules. $G\alpha i2$ inhibits adenylate cyclase resulting in lowering of cyclic adenosine monophosphate (cAMP) levels. $G\beta\gamma$ dimers activate PI3K, Akt/protein kinase B, Rap1b, and G-protein-gated inwardly rectifying potassium channels (GIRKs).[34]

The PI3K isoforms that function downstream of $G\beta\gamma$ in platelets are PI3Kγ and PI3Kβ. The two isoforms seem to function in distinct but complementary roles leading to platelet aggregation and release. PI3Kγ plays a role in enhancing granule secretion, while PI3Kβ is necessary for sustaining platelet aggregation and formation of stable thrombi.[30] Akt/protein kinase B activation is thought to be mediated via PI3Kγ. Deficiency of Akt/protein kinase B in mice results in impaired platelet aggregation and release, and like PI3Kβ, it is required for formation of stable thrombi.[69] PI3Kγ and PI3Kβ, via generation of phosphatidylinositol (3,4,5)-trisphosphate (PIP3), activate Rap1b, a critically important step in mediating the $\alpha_{IIb}\beta_3$ conformational change required for fibrinogen binding and platelet aggregation.[39]

GIRK channels containing GIRK1 and GIRK4 subunits are involved in the activation of Src kinases. Channel activation is coupled to $G\beta\gamma$ and ADP occupancy of the $P2Y_{12}$ receptor. Src kinases in turn phosphorylate and activate cytoplasmic phospholipase A2 (cPLA2).[60] $P2Y_1$ activation and signaling via Gq as well as signaling through $\alpha_{IIb}\beta_3$ are also necessary for cPLA2 activation.[32] When phosphorylated, cPLA2 is translocated from the cytoplasm to membranes where it functions to release membrane-bound arachidonic acid (AA) leading to the generation of thromboxane. Human patients with congenital $P2Y_{12}$ deficiency and $P2Y_{12}$ knockout mice have prolonged bleeding times and exhibit bleeding, illustrating the importance of this receptor in hemostasis. The absent aggregation response of $P2Y_{12}$-deficient platelets can be restored if platelets are activated concomitantly with ADP and epinephrine, presumably due to epinephrine being negatively coupled to adenylate cyclase in a manner similar to $P2Y_{12}$.[10] A mutation in the $P2Y_{12}$ gene found in Greater Swiss Mountain dogs has also been associated with an aggregation defect and signs of hemorrhage (see Chapter 84).

The $P2X_1$ receptor is an ATP receptor that is antagonized by ADP; early studies demonstrating $P2X_1$ receptor responses to ADP were later shown to be a result of ATP contamination of ADP preparations.[40] $P2X_1$ activation is associated with the change in conformation of platelets from discs to spheres with the rapidly reversible formation of multiple short pseudopodia.[54,55] ATP binding to $P2X_1$ is associated with a rapid, reversible calcium influx followed by rapid desensitization of the receptor.[44] Calcium influx is thought to activate MLC kinase which is responsible for mediating the shape change response. $P2X_1$ activation also results in centralization of granules without granule release and formation of platelet microaggregates.[21,65] Microaggregate formation is likely a result of calcium influx coupled with protein kinase C activation leading to Erk2 activation.[34] Like the $P2Y_{12}$ receptor, $P2X_1$ also participates in amplification of platelet responses to low concentrations of other agonists, including ADP, collagen, thrombin, and thromboxane.[21,23,44] Dense granule release of ATP induced by low concentrations of agonists triggers $P2X_1$-mediated calcium influx resulting in reinforcement and amplification of platelet activation. $P2X_1$ also seems to be essential in thrombus formation and growth at sites of vascular injury under high shear forces.[27]

Collagen Receptors

Platelets have two receptors primarily responsible for direct response to collagen; glycoprotein VI (GPVI) and integrin $\alpha_2\beta_1$[53] (Figure 77.2). The platelet glycoprotein-Ib-IX–V complex, which interacts with collagen indirectly, is critically important in initiating platelet contact with collagen under high shear conditions. The glycoprotein-Ib-IX–V complex mediates transient arrest of platelets from flowing blood and weak tethering of platelets on exposed subendothelial surfaces through the binding of von Willebrand factor (VWF) A1 domain to the GPIbα region of the receptor complex. As tethered platelets roll along exposed subendothelium, they encounter collagen fibrils, which bind to glycoprotein VI. This leads to inside-out signaling and activation of integrins $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$, the release of ADP, and thromboxane formation, which in turn reinforce GPVI interactions.[43] Activated $\alpha_2\beta_1$, transformed to a high-affinity state, binds tightly to specific

sequences in collagen, allowing firm platelet adhesion and spreading.[35] Activated $\alpha_{IIb}\beta_3$, also transformed to a high-affinity state, reinforces firm platelet adhesion and supports platelet aggregation.[57]

Integrin $\alpha_2\beta_1$ and GPVI are thought to signal through a shared network of signal transduction proteins. The shared signaling pathway may explain why the absence of either GPVI or integrin $\alpha_2\beta_1$ does not result in a significant bleeding diathesis.

Glycoprotein VI is a member of the immunoglobulin superfamily type I transmembrane proteins; it is noncovalently associated with the Fc receptor gamma-chain (FcR γ-chain). The FcR γ-chain has an immunoreceptor tyrosine-based activation motif (ITAM). When stimulated with collagen, the FcRγ-chain is tyrosine phosphorylated by the Src kinases, Lyn and Fyn.[24] This leads to the recruitment and activation of Syk tyrosine kinases, which lead to the phosphorylation and activation of other signaling molecules.

Adaptor molecules such as linker for activation of T cells (LAT) and Src homology domain-containing leukocyte phosphoprotein of 76 kDa (SLP-76) coordinate assembly of a multiprotein signaling complex necessary for activation of phospholipase Cγ2 (PLCγ2) and PI3K. LAT is a membrane-associated adapter molecule that is anchored to lipid rafts in platelet membranes.[50] Activation of PLCγ2 leads to cleavage of phosphatidylinositol 4,5-bisphosphate into IP3 and DAG. IP3 mediates the release of calcium from stores within the dense tubular system. DAG and calcium bind to CalDAG-GEFI, resulting in activation of PKC and activation of Rap1b. Rap1b activation plays a role in inducing the change in conformation of $\alpha_{IIb}\beta_3$ to a high-affinity state necessary for binding of fibrinogen and platelet aggregation. Although GPIb-IX–V also stimulates PLCγ2 activation, the tyrosine phosphorylation pattern is distinct from that occurring via GPVI, resulting in weaker PLCγ2 activation and diminished phospholipase activity.[64]

Collagen-induced platelet aggregation is largely dependent on ADP signaling through $P2Y_{12}$. TXA generation and resulting platelet aggregation and release result in signaling through the $P2Y_{12}$ receptor by secreted ADP and a positive feedback on platelet secretion through the PI3K pathway.[46]

Thromboxane Receptors

TXA and prostaglandin H2 interact with the same receptors. Human platelets have two distinct thromboxane A2–prostaglandin H2 receptors, TPα and TPβ, that are products of alternative splicing. These receptors differ only in their C-terminal or tail domains.[29] TPα is a high-affinity binding site for thromboxane and mediates platelet shape change and intracellular calcium movement. TPα couples positively to adenylate cyclase via Gq and activates PLCβ which hydrolyzes PIP2, resulting in generation of IP3 and DAG. TPβ is a low-affinity binding site and mediates platelet aggregation and secretion. TPβ couples negatively to adenylate cyclase via Gi and inhibits cAMP formation. Most dogs demonstrate a weak AA response characterized by shape change and reversible platelet aggregation without granule release.[33] Addition of epinephrine prior to AA corrects the impaired aggregation and release response.[20] Canine platelets are predicted to lack TPβ receptors based on the absence within the dog genome of the coding region necessary for synthesizing the alternative C-terminal domain for TPβ. This may partially explain the generally weak response of canine platelets to AA stimulation in vitro. Epinephrine, by linking to Gi, may mimic the effects of TPβ, thus allowing for full platelet aggregation and release. A bovine TPα receptor has been cloned and characterized.[41]

Platelets generate TXA from AA. AA is liberated from dense tubular membrane phospholipids by the action of phospholipase A2 in response to agonist stimulation. Cytosolic cPLA2 is phosphorylated during thrombin, ADP, and collagen-induced platelet activation. Phosphorylation of cPLA2, in combination with a rise in intracellular calcium, results in cPLA2 translocation to the membrane where it releases arachidonic acid from the sn-2 position of membrane-bound phospholipids. Arachidonic acid is converted sequentially to prostaglandin G2 (PGG2), prostaglandin H2 (PGH2), and TXA via cyclooxygenase-1, prostaglandin hydroperoxidase, and thromboxane synthase. The resulting thromboxane generation results in platelet aggregation and dense granule release.

TXA synthase inhibitors do not inhibit platelet reactivity due to the enhanced production of prostaglandin H2 under these conditions and the ability of prostaglandin H2 to activate the receptor.[67]

Thrombin Receptors

Platelet thrombin receptors include the glycoprotein complex-Ib-IX–V and protease-activated receptors (PARs). The Ibα subunit of the Ib-IX–V complex has a thrombin-binding site that overlaps with the binding site for VWF.[52] The GPV subunit is cleaved and removed from the complex by thrombin during platelet activation. GPV is thought to negatively modulate platelet activation; cleavage of GPV is a necessary first step prior to binding of thrombin to Ibα. Thrombin binding to Ibα mediates platelet activation via induction of ADP release and signaling through $P2Y_{12}$. Ibα is also thought to act as a cofactor in the activation of PAR1 by thrombin.[17] Thrombin bound to Ibα is protected from inactivation by antithrombin.[18]

Protease-activated receptors are G-protein-coupled receptors that are characterized by the presence of a tethered ligand (Figure 77.2). Protease-activated receptors are activated when enzymes cleave at a specific site near the N-terminal exodomain resulting in formation of a tethered peptide sequence that can in turn bind to a G-protein-coupled receptor on the same molecule. Peptide sequences that match the tethered ligands generated by thrombin cleavage, referred to as thrombin receptor-activating peptides (TRAPs), have been used with varying success in vitro to activate animal platelets.[9,11] In most species, TRAPs are not as effective as the comparable tethered ligand in inducing platelet

aggregation or release. Three PAR types that vary with species have been identified in mammalian platelets. Human platelets have PAR1 and PAR4, and mouse platelets signal through PAR3 and PAR4, however PAR subtypes in other species are not well-defined. PAR1 couplings to Gq, G13, and Giz are thought to be of most importance in mediating thrombin effects on platelets.[12]

The PI3 kinase pathway is considered to be of importance in stabilizing thrombin-induced platelet aggregates, although thrombin can activate platelets independently of Gi activation. On human platelets, PAR1 binding results in a rapid spike in calcium influx, while PAR4 binding is associated with a slower and sustained calcium influx that is considered vital to eliciting secondary signals necessary for complete platelet activation.[13] Canine platelet PARs have not been fully evaluated; functional studies indicate that canine platelets possess PAR4 receptors and may possess PAR1.[5] Comparative genomics reveals sequence homology for all the PAR subtypes (PAR1 through PAR4) between dogs and people. Nevertheless, canine platelets do not respond to TRAPs designed from either human or canine sequence[19] (M. K. Boudreaux, personal observation). Mouse platelets lack PAR1 expression; however, PAR3 on mouse platelets acts as a cofactor in supporting cleavage and activation of PAR4. PAR3 alone is unable to mediate signaling leading to platelet activation, but rather acts as a cofactor for promoting PAR4 cleavage in the presence of low thrombin concentrations.[42] Recent studies have indicated that thrombin binding of both GPIb-IX and PAR receptors may be required for peak platelet activation.[22]

PLATELET–LEUKOCYTE INTERACTIONS AND THROMBOINFLAMMATION

The GPIbα subunit of platelet glycoprotein complex-Ib-IX–V is a ligand for endothelial P-selectin, as well as VWF, both of which translocate from Weibel–Palade bodies to endothelial surfaces in response to stimuli such as thrombin and histamine.[2,56,71] The binding site on GPIbα for P-selectin is very similar to the binding site of P-selectin glycoprotein ligand-1 (PSGL-1), which allows leukocytes to roll along the vascular endothelium. Both GPIbα and PSGL-1 are membrane mucins and possess a heavily *O*-glycosylated region that separates the ligand-binding region from the plasma membrane.[38] Both receptors also contain an acidic region immediately amino-terminal to the mucin-like region that is important for ligand binding.[36] Unlike PSGL-1, which requires extensive post-translational modification, including fucosylation of side chains in order to interact with P-selectin, GPIbα is capable of binding to endothelial P-selectin without modifications.

GPIbα can also bind to integrin αMβ2 (Mac-1) on neutrophils,[61] likely via the I domain within the αM subunit, which closely resembles the A1 domain of VWF. This interaction, which requires conversion of Mac-1 to the ligand-binding competent form, may contribute to neutrophil attachment to the endothelium or subendothelium at sites of endothelial activation or injury. Platelet P-selectin can bind to PSGL-1 on neutrophils, monocytes, and T-cells providing a mechanism for initial adhesion of leukocytes to platelets. Firm platelet–leukocyte adhesion is mediated by binding of Mac-1 to fibrinogen bound to the surface of activated platelets.

Firm leukocyte–platelet interactions can also be mediated by intracellular adhesion molecule-2 (ICAM-2) on platelets which can bind to αLβ2 (lymphocyte function-associated antigen-1 (LFA-1); CD11a/CD18) on leukocytes. Platelets can also release CD40L, which binds to CD40 on vascular endothelial cells resulting in chemokine secretion and upregulation of adhesion molecules.[28] Platelets also secrete IL-1β, which can induce endothelial cell secretion of IL-6, CXCL8, and CCL2 and upregulation of adhesion molecules such as E-selectin, vascular cell adhesion molecule-1 (VCAM-1), ICAM-1, and αvβ3.[25] In people and mice, pattern recognition receptors, particularly toll-like receptors, have been identified on platelets and provide a mechanism for platelet activation to participate in the innate immune response.[47] Together, all of these leukocyte interactions link platelets to the inflammatory process. The platelet transmembrane receptor C-type lectin receptor-2 (CLEC-2) and its primary ligand podoplanin have a prominent role in the prevention of blood–lymphatic mixing, but their interaction is also involved in thromboinflammation due to increased expression of podoplanin on macrophages and stromal cells.[51]

PROCOAGULANT ACTIVITY

Platelet activation triggers significant remodeling of the platelet cell surface. This is associated with the activation and clustering of receptors for adhesion molecules, receptor-mediated outside-in signaling, relocation and binding of proteins and other biomolecules from the cytosol to membrane surfaces, secretory organelle movement and fusion, and a dramatic redistribution of membrane phospholipids and formation and release of platelet-membrane-derived microparticles.

Mammalian cells and platelets exhibit an asymmetric distribution of aminophospholipids. In nonactivated platelets, negatively charged aminophospholipids phosphatidylserine (PS) and phosphatidylethanolamine (PE) are located primarily on the inner leaflet of the plasma membrane. An aminophospholipid translocase is responsible for transporting PS and PE to the inner membrane leaflet and maintaining asymmetry. When platelets are activated by stimuli that induce high intraplatelet calcium, such as collagen or thrombin alone or particularly when combined, PS is rapidly externalized to the outer membrane leaflet. Inhibition of translocase

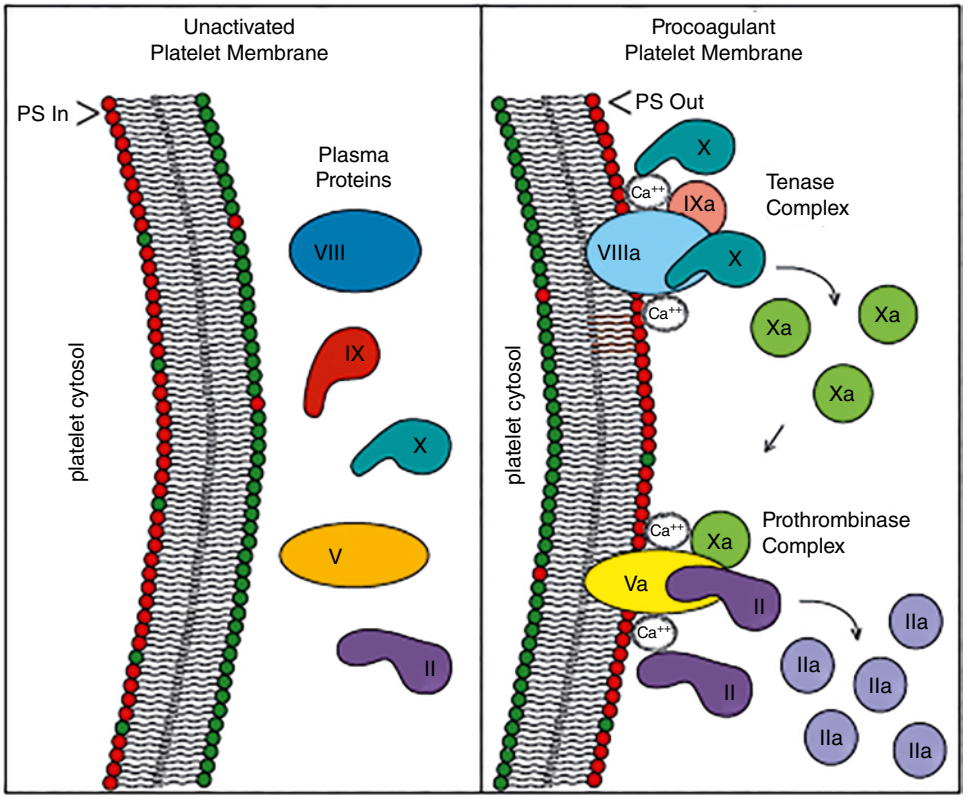

FIGURE 77.3 Signaling pathways activated by collagen and thrombin trigger externalization of phosphatidylserine (PS). When PS is externalized, specific coagulation proteins can bind to the platelet surface. The platelet then acts as a scaffold for assembly of the tenase and prothrombinase complexes, which accelerate thrombin (II_a) generation and clot formation at the site of vessel injury.

activity is believed to maintain PS externalization (Figure 77.3). Exposure of PS is also accompanied by the release of PS-enriched procoagulant microparticles.[68]

Platelets' ability to rapidly externalize PS by shuffling phospholipids between the two leaflets of the membrane bilayer is referred to as "scramblase" activity. The process is energy-independent and is now attributed to a calcium-dependent anoctamin family transmembrane protein, TMEM16F.[37] TMEM16F also plays a role in platelet PS externalization associated with cell death signals and apoptosis.[7]

The presence of PS on the surface of platelets is essential for platelet procoagulant activity. Rare bleeding disorders associated with a deficiency of platelet procoagulant activity have been reported in people and dogs.[7,66] Phosphatidylserine expression on platelets and platelet-derived microparticles facilitates the binding of coagulation proteins, which when anchored to PS and the activated platelet surface form procoagulant reaction complexes (see Chapter 87). These include the extrinsic tenase complex (factor VIIa + tissue factor (TF) + factor X), intrinsic tenase complex (factor X + factor IXa + factor VIIIa), and the prothrombinase complex (factor Va + factor Xa + factor II). Once assembled, the complexes allow for protein associations, which improve catalytic efficiency of the reactions. For example, the prothrombinase complex is about 300,000 times more efficient than Xa alone in generation of thrombin from prothrombin, and the intrinsic tenase complex is 100,000 times more active than factor IXa alone as an activator of factor X.

The assembly of enzyme and substrate complexes on the PS-enriched surface of activated platelets serves to localize and concentrate procoagulant factors at sites of injury. Since antithrombin preferentially targets uncomplexed reaction products for neutralization, the anchored reaction products are protected from neutralization and inhibition.

Studies have also shown that in human and porcine platelets, expression of procoagulant activity is dependent on a change in intracellular pH and Na influx, which occurs with activation of the Na/H exchanger (NHE1), and potentially other mechanisms.[58] NHE1 can be phosphorylated and activated by PKC. NHE1 also has two PIP2-binding domains, which are required for optimal activation, suggesting that PIP2 may play a role in mediating PS exposure in activated platelets.[1,8]

Activated platelets are also capable of synthesizing and expressing tissue factor on their surface, which contributes to the procoagulant activity of platelets. Platelets possess pre-mRNA transcripts, which are spliced and translated into protein upon platelet activation. Cdc2-like kinase-dependent splicing is thought to play a role in this mechanism.[59]

Acronyms and Abbreviations

APTT, activated partial thromboplastin time; BFU-Meg, burst-forming unit-megakaryocyte; CFU-Meg, colony-forming unit-megakaryocyte; CKCS, Cavalier King Charles Spaniel; CMP, common myeloid progenitor cell; DIC, disseminated intravascular coagulation; DMS, demarcation membrane system; ER, endoplasmic reticulum; GM-CSF, granulocyte–monocyte colony-stimulating factor; HUS, hemolytic uremic syndrome; IL, interleukin; MPC, mean platelet component concentration; MPV, mean platelet volume; OCS, open canalicular system; OSPT, one-stage prothrombin time; PCDW, platelet component concentration distribution width; PCT, plateletcrit; PDW, platelet distribution width; PT, prothrombin time; SDF-1, stromal cell-derived factor-1; TTP, thrombotic thrombocytopenic purpura; VWF, von Willebrand factor.

PLATELET KINETICS

The last decade has seen significant progress in the understanding of megakaryocyte and platelet development, maturation, and functional life span. These mechanistic insights have deepened our knowledge of platelets' role in various pathological states and hold promise for discovery of novel therapeutic compounds.[92]

Megakaryocytopoiesis: Stem Cell Progenitors

The development of the megakaryocyte–erythroid progenitor cell is complex, and now believed to incorporate different hierarchical pathways (see Chapter 75). Unilineage progenitor cells (megakaryocyte–erythroid progenitor cells and others), and possibly megakaryocyte-committed progenitor cells, may develop directly from hematopoietic stem cells (HSC), without passing through myeloid progenitor cell lines. Phenotypic

markers such as von Willebrand factor (VWF), CD41 (GpIIb), and CD61 (GPIIIa), previously thought to be expressed only after megakaryocyte differentiation, are now recognized at earlier developmental stages of HSC. These HSC may be programed to ultimately become megakaryocytes.[80,120]

The primitive megakaryocytic burst-forming unit (BFU-Meg) is the first defined megakaryocyte stage that has a high proliferative capacity, producing from 100 to 500 megakaryocytes per colony in a 1-week time period.[6,48] Following the BFU-Meg, the more mature megakaryocytic colony-forming unit (CFU-Meg) gives rise to approximately 3–50 megakaryocytes per colony. The BFU-Meg and CFU-Meg stages characteristically express CD34, CD33, and CD41, followed by later expression of CD61, CD42, and CD36. The first morphologically recognizable cell of the megakaryocyte lineage in marrow is the promegakaryoblast. Before this stage, the morphology of the earlier progenitors resembles a small lymphocyte. The promegakaryoblast has a high nuclear to cytoplasmic ratio, dark blue cytoplasm, and is approximately 10 μm in diameter.[48,117] The megakaryoblast has a kidney-bean-shaped nucleus, dark blue cytoplasm, and is approximately 15–50 μm in diameter. As the later stages of megakaryocyte precursors undergo endomitosis, the cells lose CD34 expression, and increase ploidy, cell size, and volume. The hematopoietic pluripotential stem cells and early megakaryocyte progenitor cells are positive for CD34 and have low expression of CD41.[48,53] Cells that become committed to the megakaryocyte lineage acquire the expression of CD61 and CD42, and expression of CD41 increases.[48,53] The promegakaryocyte loses its mitotic properties and goes through endomitosis to create a polyploid megakaryocyte. Genomic DNA duplication occurs in the endomitotic process, with nuclear envelope breakdown but lacking the final steps of mitotic condensation and separation of the chromosomes and cytoplasm.[89] Studies have shown that defective cytokinesis and karyokinesis prevent the megakaryocyte from completing mitosis.[6,68,92] The megakaryocyte can attain ploidy as high as 128 N, with a modal ploidy in most mammals of 16 N.[16] This process causes megakaryocytes to become the largest hematopoietic cells in the marrow, reaching diameters up to 150 μm. The higher ploidy likely corresponds to an increased cell volume, and ultimately larger numbers of platelets produced.[16]

Megakaryocytopoiesis: Platelet Release from the Bone Marrow

Each megakaryocyte is capable of generating several thousand platelets. In humans, daily platelet production is estimated to be approximately 35,000 ± 4300 platelets/μL or 1×10^{11} total platelets.[16,50,53] The sequence from megakaryocyte development to release of new platelets takes approximately 4–5 days.[50] In the marrow, mature megakaryocytes migrate to the sinusoids to be closely positioned near endothelial cells.[65] Long pseudopods extend from the megakaryocyte into marrow sinusoids and thereby facilitate megakaryocyte intravasation to the peripheral circulation.

The first cytoplasmic extension from the megakaryocyte into the blood stream was believed to be the proplatelet. However, recent studies by Brown et al. indicate that much larger extensions are seen in the blood. These protrusions contain internal membrane structure that fuses at multiple points with the plasma membrane, enabling mobility and forward movement into the bloodstream.[9] In this model, proplatelets represent a later stage of thrombopoiesis characterized by elongate processes formed via microtubule and membrane reorganization. Proplatelets subsequently become thinner and smaller as they form preplatelets, which later undergo fission events to generate discoid platelets that continue to mature and divide in the blood stream.

Several unique systems in megakaryocytes are needed for the development of multiple cytoplasmic fragments from one large cell. These systems rely on a well-developed cytoskeleton and the demarcation membrane system (DMS).[99] The cytoskeleton in megakaryocytes and platelets consists of key proteins including actin, myosin, and tubulin. Actin influences both the shape and the flexibility of platelets, as the actin filaments create an internal cytoskeleton connected to the plasma membrane and to each other.[81] The β1 tubulin is the major constituent protein in the microtubulin system and is a unique protein found only in megakaryocytes. Microtubules are mainly responsible for the extension of proplatelets from megakaryocytes, providing a site to which motor proteins bind. Actin proteins play a main role in generating a bifurcation from the proplatelet that will later separate to create a platelet.[41] The DMS develops in the course of megakaryocyte maturation, and represents a continuation of the plasma membrane that invaginates into the cell. The origin and formation of the DMS membrane has yet to be confirmed. A recent study provided evidence that the DMS is formed by a combination of invagination of the megakaryocyte plasma membrane and synthesis of additional membrane structures from intracellular stores, mainly the Golgi and endoplasmic reticulum (ER).[25] The excess membrane later surrounds the multiple small cytoplasmic platelets produced at later stages of megakaryocytopoiesis.[25,99]

The final process of platelet shedding occurs in the circulatory space,[16,108] with recent studies indicating that platelet release occurs within the bone marrow and also in the pulmonary vasculature.[60]

Thrombopoietin (TPO) is the major cytokine that regulates all stages of megakaryocyte and platelet production. In addition to thrombopoietin, megakaryocytes and platelet production are regulated by several growth factors and cytokines (see Chapters 75 and 82). Megakaryocyte progenitors are stimulated by interleukin (IL)-3, IL-6, IL-11, IL-12, granulocyte–monocyte colony-stimulating factor (GM-CSF), and erythropoietin.[37] Additional factors include IL-1, stem cell factor, and leukemia inhibitory factor.[16,37] Stromal cell-derived factor-1 (SDF-1) is thought to play a role in megakaryocyte migration.[39]

Platelet production is regulated by total platelet mass rather than platelet numbers. In situations of increased demand, platelet production can increase as much as 20-fold or higher.[53] Interactions between TPO and the TPO receptor, myeloproliferative leukemia protein (cMpl), play a major role in maintaining platelet mass.[77] Thrombopoietin is secreted primarily from the liver and upon release binds to its high-affinity receptor, cMpl, present on platelets and megakaryocytes. After binding, TPO is internalized and degraded and thus not available to stimulate further megakaryocytopoiesis above steady-state levels.[53,57] Hepatic uptake of senescent platelets, mediated by the Ashwell–Morell receptor (AMR), also stimulates TPO production (see Chapter 75).[62]

Platelet Life Span and Senescence

In health, a steady state exists between the number of platelets produced and platelets destroyed. Platelets circulate for 4–10 days in most mammalian species, with approximately 30% of the total platelet mass transiently compartmentalized in the spleen. As platelets age, they are removed from circulation by splenic and hepatic macrophages. Recent studies demonstrate that platelet life span is regulated by the Bcl-2 family of proteins in pro- and anti-apoptotic pathways similar to the regulation of nucleated cell aging.[61,85] As platelet proteasome peptidase activities decrease, the resultant increase in misfolded proteins causes increase in pro-apoptotic proteins, such as Bax.[76] The senescence signals of platelets include exposure of phosphatidylserine on the outer platelet membrane, which stimulates platelet phagocytosis by macrophages, and membrane glycoprotein desialylation facilitating clearance by hepatic AMR.[46,62,69] Similar to erythrocyte senescence, denatured or damaged membrane glycoproteins may display neoepitopes that are recognized by naturally occurring antibodies.[46] A smaller percentage of platelets are continually removed from circulation in their role of maintaining endothelial integrity.[35,46]

Platelet Granule Formation and Release

Platelets contain three major types of granules: α-granules, dense granules, and lysosomes. The formation of these granules starts in the megakaryocyte and continues through platelet maturation. Proteins are trafficked into granules via both synthesis in the ER and endocytosis, whereby plasma proteins are bound, absorbed, and loaded into the granules.[100]

The open canalicular system (OCS) is a continuous membrane structure similar to the DMS described in the megakaryocyte.[99] It is through these channels that plasma proteins and other substances are transported in and out of the platelet. Interestingly, some veterinary species including cow, horse, and camels lack the OCS. The significance of this finding is unclear, as platelet activation responses are generally similar for these species when compared to mouse, rat, rabbit, dog, and human that have the OCS. In species that lack the OCS, granule secretion occurs via fusion directly with the plasma membrane.[30] In species that have the OCS, secretion involves fusion of granules with the OCS, causing the release of granule contents through the OCS channels. The SNARE family proteins are key proteins that regulate fusion of the OCS and the granules.[99] Additionally, the OCS allows the platelets to expand and change shape once activated, though this property is retained also in species that lack the OCS.

Platelet Participation in Inflammation and Neoplasia

Beyond their hemostatic properties, platelets play important roles in inflammation, cellular growth and development, wound healing, angiogenesis, and cancer metastasis. Platelets participate in the inflammatory response through direct interactions with leukocytes and endothelial cells, release of cytokines and chemokines, and activation of the complement system (see Chapters 91 and 92).[110] Activated platelets express surface proteins, including P-selectin, that enhance adherence to or activation of inflammatory cells in addition to activation of complement system. Tumor cells also bind to platelets via P-selectin, thereby promoting microthrombus formation. Additionally, platelets assist in the transmigration of inflammatory cells through the endothelial cells, to reach extravascular sites of inflammation.

A correlation between increased platelet counts and poor prognosis has been described for many tumor types, supporting a role for platelets in promoting tumor metastasis. Platelet and tumor cell relationships are mechanistically complex.[3,11] Platelets protect and transport tumor cells in microthrombi through the blood stream, secrete mediators that enable tumor cell invasion through endothelium, and stimulate angiogenesis that assists in tumor survival. Platelets not only physically protect the tumor cells during transportation but also appear to downregulate the immune system.[11,70] In addition, platelets present the major histocompatibility complex class I, allowing tumor cells to be identified as self and escape natural killer cell recognition and destruction. The platelet–tumor relationship appears to be bidirectional, as tumor cells are capable of inducing thrombopoiesis.[70] To add to this complexity, platelet-derived microparticles can induce apoptosis of tumor cells by insertion of miRNA into the tumor and causing stimulation of suppressor genes.[71]

Nonmammalian Species

The cellular equivalent of platelets in birds, reptiles, amphibians, and fish is the thrombocyte. Thrombocytes are small, round, oval, or spindled nucleated cells. As in mammals, the primary function of thrombocytes is hemostasis, and thrombocytes are the second most common blood cell after erythrocytes. Avian thrombocytes may also be important in innate immunity, since these cells have phagocytic capability and can remove foreign material from blood (see Chapter 95).[38] In addition to

hemostasis, reptilian thrombocytes have been demonstrated to play a role in wound healing.[106]

Thrombopoiesis is similar in avian and reptilian species in that thrombocytes originate in the bone marrow from a distinct mononuclear cell. The stages in thrombopoiesis include thromboblasts, immature thrombocytes (early, mid, and late stages), and mature thrombocytes. In general, as thrombocytes develop, they decrease in size, the cytoplasm changes from basophilic to pale blue or colorless, and the cell and nuclear shape change from round to oval.

Thrombocyte numbers in most avian species range between 20,000 and 30,000/μL or approximately 10–15 thrombocytes per 1000 erythrocytes; two or more thrombocytes per monolayer area under oil immersion (100×) is considered normal or adequate in most birds.[14,28] In normal reptiles, thrombocyte numbers in blood range between 25 and 350 thrombocytes per 100 leukocytes.[106] Numbers of thrombocytes in fish blood range from 60,000 to 70,000/μL.[78] Manual counts for thrombocytes in fish can be performed using a hemacytometer, but given the tendency to clump, accurate counts are difficult to obtain. Thrombocytes of certain fish species do not appear to have phagocytic ability.[90]

MECHANISMS OF THROMBOCYTOPENIA

Thrombocytopenia, defined as a decrease in circulating platelet number, is the most common acquired hemostatic disorder in veterinary and human medicine. Thrombocytopenia results most often from decreased or defective platelet production or from increased platelet consumption or destruction. Less frequently, heredity thrombocytopenia or abnormal distribution of the platelets can be the mechanism of thrombocytopenia. Figure 78.1 presents an algorithm for clinical diagnosis of thrombocytopenia and mechanistic categories are described in the following sections.[123] The pathogenesis of thrombocytopenia is covered in more detail in Chapters 80 and 81.

Hereditary Thrombocytopenia

Hereditary thrombocytopenias have been described in several breeds of dog (see Chapter 84), with Cavalier King Charles Spaniels (CKCS) having the highest breed prevalence.[8] Additional affected breeds include Akita dogs, Norfolk and Cairn Terriers, and a relatively mild thrombocytopenia in Greyhounds.[32,42] Distinct mutations

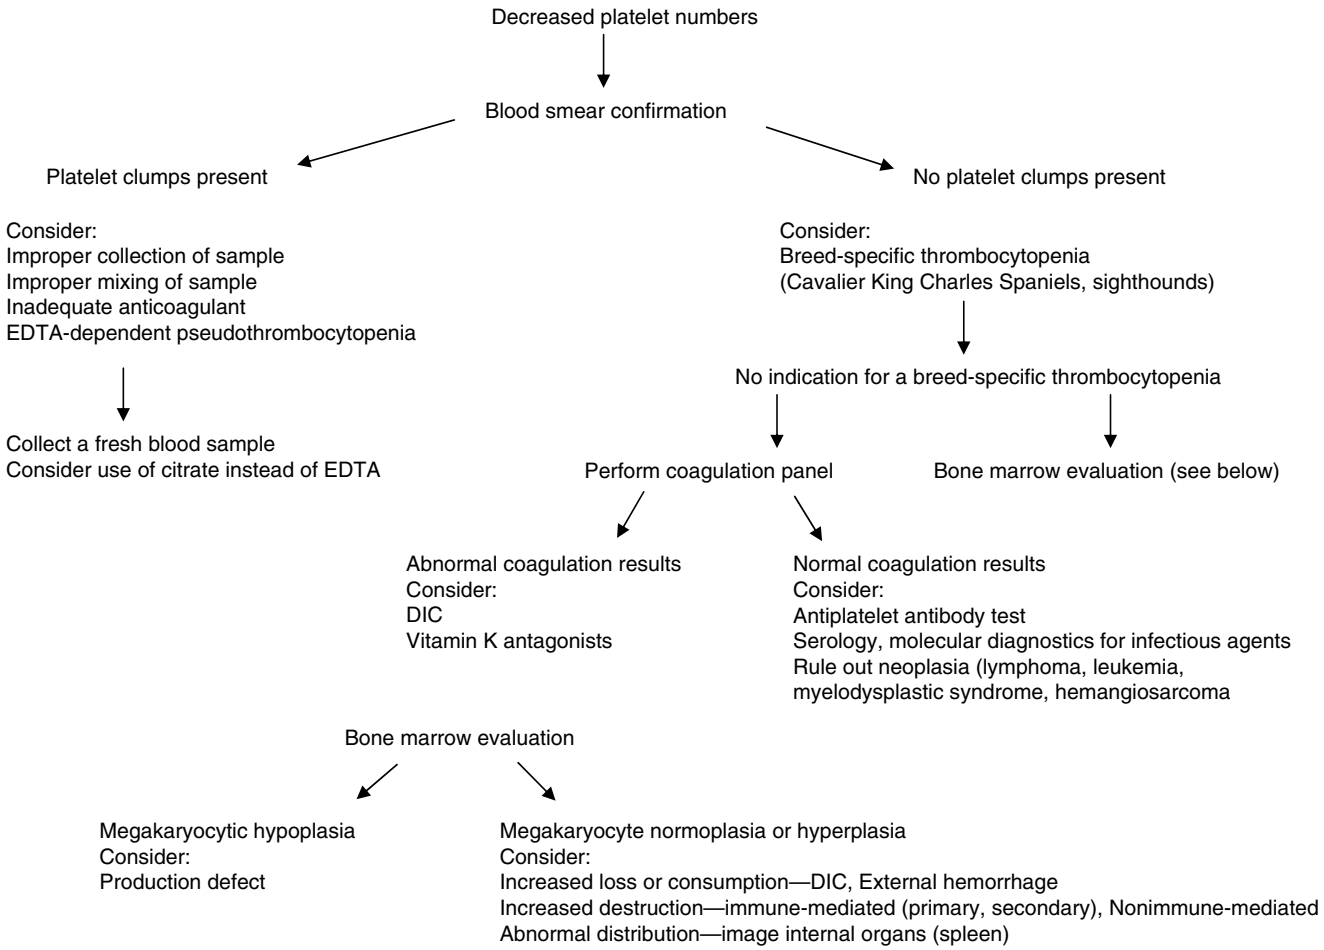

FIGURE 78.1 Diagnostic approach to thrombocytopenia.

in the gene encoding β1 tubulin have been identified as causing macrothrombocytopenia in CKCS and the related Norfolk and Cairn Terrier breeds.[21] Interestingly, members of the Felidae family display unique sequence variants in conserved regions of the β1 tubulin gene compared with other mammals.[7] This difference may be the underlying mechanism contributing to the high platelet volume variability seen in domestic and big cat species.

Decreased or Defective Platelet Production

Causes of decreased platelet production that result in thrombocytopenia can specifically target the megakaryocyte, but more frequently, other hematopoietic cells are also affected.

Acquired megakaryocyte hypoplasia or aplasia has been reported as a rare cause of isolated thrombocytopenia in dogs and cats, believed to have an immune-mediated component.[31,58,75] General etiologies of bone marrow hypoplastic disease of one or more hematopoietic cell lines include drugs, chemicals, or toxins that have cytotoxic effects or produce idiosyncratic reactions; irradiation resulting in cell death and marrow suppression; infection with certain viruses (e.g., canine parvovirus, feline leukemia virus, feline immunodeficiency virus, equine infectious anemia virus, bovine viral diarrhea virus, African swine fever virus), rickettsial agents, myelophthisis from primary or metastatic neoplasia or myelofibrosis, or myelonecrosis.

Increased Platelet Loss or Consumption

Thrombocytopenia secondary to rapid loss of platelets may occur with massive trauma, acute external hemorrhage, or exchange blood transfusion. In situations of trauma or external hemorrhage, thrombocytopenia is generally mild to moderate, transient, and usually reversible as hemorrhage is controlled.[101]

Accelerated consumption of platelets can develop in concert with widespread activation of the coagulation system, and syndromes of endothelial injury or abnormal VWF processing. Disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS) are complex syndromes characterized by widespread consumption of platelets, resulting in moderate to severe thrombocytopenia. Disseminated intravascular coagulation is a common complication seen in both veterinary and human medicine (see Chapter 92). Thrombotic thrombocytopenic purpura and HUS occur in humans, but are rare in veterinary species (see Chapter 93). A syndrome resembling HUS has been reported in dogs, cats, horses, and a heifer.[1,17,23,47,66,73,91] Animal models of TTP and HUS have been described.[88,94,116]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation occurs secondary to a wide variety of diseases, and is characterized clinically by microthrombosis and variable hemorrhage. Common disorders associated with DIC include systemic infectious or inflammatory disease, neoplasia, and severe tissue trauma. The pathophysiology of DIC is discussed in detail in Chapter 92.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

In humans, TTP and HUS are the most common thrombotic microangiopathies. Thrombotic microangiopathies are characterized by endothelial damage, hemolytic anemia with schistocytosis, and thrombocytopenia associated with platelet-rich thrombus formation. Thrombotic thrombocytopenic purpura in people develops secondary to congenital or acquired (often immune-mediated) deficiencies of a disintegrin and metalloproteinase with thrombospondin type 1 motif, member 13 (ADAMTS13), the VWF-cleaving protease. In these patients, increased circulating ultrahigh-molecular-weight VWF multimers promote microvascular platelet thrombi formation.[107] Hemolytic uremic syndrome may occur either as a primary condition or as a secondary complication. Most cases of HUS occur in childhood after bloody diarrhea caused by *Shigella dysenteriae* serotype I or various *Escherichia coli* serotypes. Severe renal dysfunction is also a prominent feature of HUS. Plasminogen activator inhibitor type I and urine endothelin concentrations are increased in HUS patients.[4,101] Concentrations return to normal when patients enter remissions. Hemolytic uremic syndrome and TTP are discussed in more detail in Chapters 83 and 93.

Platelet Destruction: Immune-Mediated, Nonimmune-Mediated, and Complex Mechanisms

Immune-mediated destruction of platelets may be primary (idiopathic) or may occur in association with infectious agents, neoplasia, drugs, autoimmune, isoimmune, or neonatal-immune diseases. A diagnosis of idiopathic or primary immune-mediated thrombocytopenia is made after all other potential causes have been eliminated.

Immune destruction of platelet typically occurs when circulating platelets coated with antibody, antigen–antibody complexes, or complement are phagocytized by macrophages in the spleen, liver, and bone marrow, resulting in decreased platelet life span (see Chapter 80).

Platelet aggregation, phagocytosis, or lysis resulting in platelet destruction and thrombocytopenia can occur independently of immune-mediated events. Nonimmune-mediated platelet destruction occurs in some acute bacterial and viral infections and in cardiovascular disease (see Chapter 81).[34]

Platelet destruction in bacterial infections can occur as a result of platelet adherence or aggregation to activated monocytes or neutrophils. In Gram-negative infections, monocytes stimulated by endotoxin express tissue factor on their surface and generate thrombin.[95] Thrombin, a potent platelet agonist, causes platelet activation and aggregation. Platelets adhere to monocytes and are phagocytized. Exotoxins released from

Gram-positive bacteria may directly damage platelets and contribute to thrombocytopenia.[36,52,87,111]

The pathogenesis of thrombocytopenia associated with acute viral infections is often multifactorial, even though one mechanism may predominate. Direct platelet damage or lysis is one proposed mechanism of virus-associated thrombocytopenia. Myxovirus infections, including those due to Newcastle disease virus and influenza, decrease platelet survival by removal of platelet membrane sialic acid residues by viral neuraminidase.[109,112] Other viruses in which platelet damage is suspected include bovine viral diarrhea virus and hog cholera virus.[19,118]

In humans, platelet injury and clearance have been described secondary to arterial disease and vasculopathies, stenotic or prosthetic heart valves, or cardiac bypass surgery.[5,20,34] Turbulent circulation causes membrane damage and microparticle formation.[34] Interactions of platelets with damaged endothelial surfaces cause extensive platelet activation, clumping, and removal of platelets by the mononuclear phagocyte system.[5]

Many of the rickettsial diseases are associated with thrombocytopenia. Several mechanisms contribute to thrombocytopenia, including immune-mediated platelet destruction, direct damage, vasculitis, and platelet production deficits.

Abnormal Platelet Distribution

In health approximately 30–40% of the total circulating platelet pool may be stored in the spleen, referred to as physiologic platelet sequestration. The liver and bone marrow are additional sites of platelet sequestration.[2] Hypersplenism is a pathologic condition in which as much as 90% of circulating platelets become sequestered in the spleen. Hypersplenism is rare in animals, but a few suspected cases have been described.[49,56] In hypersplenism, thrombocytopenia is evident on a CBC, but the total numbers of platelets and platelet mass are actually normal. Platelet survival is usually normal, as is platelet production.[2,43] Hypersplenism is characterized by the presence of one or more cytopenias with corresponding bone marrow hyperplasia and significant splenomegaly.[35] Splenic size is an important factor determining the degree of thrombocytopenia. Although splenomegaly does not always result in thrombocytopenia, the spleen must be markedly enlarged to cause a severe decrease in circulating platelets.[82] All other causes of splenomegaly should be ruled out before a diagnosis of primary hypersplenism is made. Recommended treatment in these cases is splenectomy.

Severe hypothermia adversely affects platelet morphology and can cause a mild transient thrombocytopenia owing to pooling of platelets in the spleen.[49] Transient thrombocytopenia can also occur with endotoxemia and hypotension.

Pseudothrombocytopenia

Pseudothrombocytopenia (artifactual or spurious thrombocytopenia) is an in vitro phenomenon resulting from platelet clumping secondary to poor or difficult venipuncture and subsequent platelet activation or exposure of the blood to certain anticoagulants. Feline platelets are especially prone to activation during blood collection, with additional potentiating factors including a larger platelet size, a higher concentration of serotonin, irreversible aggregation and granule release when exposed to serotonin, and irreversible aggregation in response to low concentrations of ADP.[13,67,84] Because of their small size and the fact that many cats resist handling and restraint in unfamiliar settings, venipuncture is often challenging, which may increase the likelihood of platelet activation during collection.[78]

Pseudothrombocytopenia can also occur with overfilling of a blood collection vacutainer tube and subsequent improper or inadequate sample mixing.[83] EDTA is the anticoagulant most often implicated as causing pseudothrombocytopenia in people, as also described in horses, miniature pigs, and dogs.[33,44,86,119] Although there may be several factors, the leading mechanism for EDTA-dependent pseudothrombocytopenia involves autoantibody-mediated platelet agglutination.[26] Hidden epitopes become exposed within the platelet IIb–IIIa complexes as a result of complex destabilization occurring secondary to calcium removal from calcium-binding domains.[12,15,26] Platelet activation and clumping in samples collected in citrate anticoagulant has also been reported as a cause of spuriously low platelet counts in dogs.[108]

LABORATORY EVALUATION OF THROMBOCYTOPENIA

Complete Blood Count

A CBC should be the first test performed in any animal that is suspected of having a bleeding disorder. Generally, EDTA-anticoagulated blood yields stable platelet counts for 5 hours after collection when held at 20 °C and 24 hours when held at 4 °C; however, certain platelet parameters are affected by anticoagulant, time, or refrigeration.[74] Specific platelet parameters available on most automated CBCs include platelet count, mean platelet volume (MPV), and platelet distribution width (PDW). In addition to these automated parameters, microscopic examination of the blood smear for platelet morphology and size, and evidence of platelet clumping or adherence to leukocytes should be performed to confirm thrombocytopenia. Although manual methods are less accurate and precise compared to automated methods for platelet enumeration, they become necessary when platelet counts fall below the limit of sensitivity or linearity (usually 5000–20,000 platelets/μL) of a hematology analyzer. Manual platelet counts are best performed by experienced operators. If the platelet count is normal in an animal that has abnormal bleeding, petechiation, or ecchymosis, an abnormality in platelet function or a coagulopathy should be considered (see Chapters 84, 89, and 90).

Platelet Indices

Plateletcrit (PCT) may be a more reliable predictor of the clinical outcome of patients with thrombocytopenia than the number of platelets alone. In addition, examination of platelet indices may further enhance the diagnostic and the prognostic process in patients with thrombocytopenia.[115,122] The following section discusses the indices commonly used in human and veterinary medicine.

MPV estimates platelet size and is believed to be inversely proportional to platelet number in some species. Increases in MPV may be associated with regenerative response to thrombocytopenia, with some myeloproliferative diseases, and with hyperthyroidism.[27,102] Decreases in MPV have been reported in dogs with early manifestations of immune-mediated thrombocytopenia,[79] but are more often associated with bone marrow failure. Artifactual increases in MPV may arise when platelets are exposed to EDTA for prolonged periods of time, cooled to room temperature (25 °C), or refrigerated (4 °C), or if there is delayed exposure to an anticoagulant. While citrate anticoagulant yielded relatively stable MPV in blood stored at 37 °C in some studies,[40] canine citrate blood demonstrated increased MPV in a more recent study.[105] Evaluation of MPV in human medicine has proven useful in differentiating immune-mediated thrombocytopenia from other thrombocytopenic disorders and assisting in predicting the likelihood of clinical bleeding, with estimates of sensitivity of 93% and a specificity of 94.6%.[59] Clinical utility of MPV in veterinary medicine is not well-defined; however, a canine study reported that dogs with immune-mediated thrombocytopenia had higher MPV compared to a healthy population and that plateletcrit was an earlier marker for response to treatment than the platelet count alone.[96]

The use of platelet indices in nonthrombocytopenic disease has also been described.[10] Llewellyn et al. demonstrated that in dogs with surgical septic peritonitis, increased MPV is considered a negative prognostic factor.[64]

PDW represents an index of variation in platelet size. In humans, PDW was increased in patients with immune-mediated thrombocytopenia compared to patients with thrombocytopenia due to aplastic anemia; therefore, PDW may be useful in differentiating between hyperdestructive thrombocytopenia and hypoproductive thrombocytopenia due to aplastic anemia.[51] Additionally, the PDW can assist in differentiating reactive thrombocytosis from a myelodysplastic disease in humans, as the latter had a higher PDW in patients with thrombocytosis.[59]

The PCT (or thrombocrit) assesses total circulating platelet mass and is the percentage of the blood volume that is composed of platelets. It is determined by certain analyzers or calculated from platelet count and MPV. Expected values are usually less than 1%.

In dogs with experimentally induced endotoxemia and thrombocytopenia, the platelet count and the PCT were significantly decreased, and the MPV and PDW were increased.[121] PCT was found to be a better parameter than platelet count for assessing hemostatic status in CKCS, due to high breed prevalence of hereditary macrothrombocytopenia.[54,113]

Mean platelet component concentration (MPC) estimates the average platelet complexity by two-angle light scatter and is used to assess the presence of platelet granules, as indicators of platelet activation status and/or platelet maturation.[18] In veterinary studies, MPC was related to the activation state of feline platelets[122] and MPC was found to be decreased in septic foals, foals with DIC, and adult horses with inflammation, gastrointestinal obstruction, enteritis, ischemia, or thrombocytopenia.[97] Preanalytic variables that influence MPC include anticoagulant, sample age, storage temperature, and time.[29,105,114] Smith et al. reported that dogs with immune-mediated thrombocytopenia had decreased MPC; however, their data failed to replicate a previous report that found dogs with different inflammatory conditions had decreased MPC.[103]

Platelet component concentration distribution width (PCDW) is a measure of the variability of platelet density. Values of PCDW decrease due to platelet shape change from discoid to spherical as platelets undergo activation. PCDW also decreases with increasing storage time and may be useful for documenting the platelet storage lesion.[63] Although studies in thrombocytopenic animals are lacking, PCDW may help elucidate potential causes of thrombocytopenia secondary to platelet activation.

Immature platelet fraction (IPF) and reticulated platelets indicate the immature platelet fraction present in the blood, analogous to enumeration of reticulocytes in the red cell line. These parameters identify platelets that contain RNA remnants as a percentage of total platelet number and represent markers of megakaryocyte maturation and thrombopoiesis.[24,45] While immature platelets generally have increased MPV, reticulated platelets and IPF can more reliably identify immature platelets.[24,45] In cases of peripheral platelet destruction, the percentage of reticulated platelets or IPF is increased, whereas hypoproliferative thrombocytopenic patients have decreased percentages of reticulated platelets.[55] In veterinary studies, reticulated platelets were found to be increased in two horses that had DIC and several ponies experimentally infected with equine infectious anemia virus.[93] In dogs, preliminary studies have described methodologies for measuring reticulated platelets in clinical patients; however, diagnostic utility is not yet well-defined.[72,98,104]

Microscopic Evaluation of the Blood Smear

Microscopic examination of a blood film is necessary to evaluate platelet morphology and to ensure accuracy of automated platelet counts. Furthermore, decreased platelet counts should always be confirmed by microscopic examination of a blood smear, and, if necessary, the platelet count should be repeated on a freshly drawn blood sample. Delayed time of exposure to anticoagulation, improper mixing, or improper collection can all

contribute to falsely low platelet counts. EDTA-dependent pseudothrombocytopenia can be ruled out by restoration of normal platelet numbers and elimination of platelet clumps observed on blood smears when samples are drawn into citrate anticoagulant.

Evaluation of the blood smear should begin on low magnification to look for the presence of large platelet clumps. Often clumps are found on the feathered edge of the smear. If large clumps are found, this likely means that the number of platelets indicated by the hematology analyzer is falsely low. A general guideline for estimating platelet numbers on a blood smear is to determine the average number of platelets in 10 oil immersion fields using a 100× objective and multiply the average by 15–20 × 10^3 to obtain the estimated number of platelets per microliter.

Additional Diagnostic Tests

Once an animal is found to be thrombocytopenic, additional diagnostic testing is often necessary to elucidate the cause (see Chapters 80 and 81). Additional tests that are often performed include a coagulation panel, bone marrow analysis, serology or DNA analysis for infectious agents, and bacterial cultures.

Coagulation Panel

Determination of activated partial thromboplastin time (APTT), one-stage prothrombin time (OSPT; also referred to as prothrombin time or PT), and fibrinogen is ideal for characterizing patients with suspect hemostatic defects (see Chapter 88). Animals may be thrombocytopenic without additional abnormalities on a coagulation panel or they may have combined abnormalities suggestive of the underlying disease process. Among the common causes of thrombocytopenia, patients with primary immune thrombocytopenia typically have normal coagulation panel results, whereas patients with consumptive coagulopathy and DIC often demonstrate combined thrombocytopenia with abnormal coagulation results (see Chapter 92).

Bone Marrow Evaluation

Bone marrow evaluation of megakaryocytes may be necessary to determine if thrombocytopenia is secondary to a platelet production defect or is caused by peripheral platelet destruction or consumption. The typical finding in cases of defective platelet production is the absence, or decrease, in the number of megakaryocytes. Abnormal megakaryocyte morphology and size may also be observed. In most cases of peripheral platelet destruction, megakaryocyte numbers are normal to increased, often with concomitant increase in megakaryocyte size and ploidy. Aspiration and core biopsies of bone marrow offer distinct advantages. Cellular morphology is superior with aspiration biopsies, whereas core biopsies are more useful for evaluation of overall megakaryocyte numbers, myelofibrosis, or necrosis. For proper and complete bone marrow interpretation, a blood sample should be taken for a CBC at the time of bone marrow sampling. Sites for marrow collection include the iliac crest, greater tubercle of the humerus, and sternum, with species and size of the patient and operator preference determining the optimal choice.[22]

Acronyms and Abbreviations

ADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; ADP, adenosine diphosphate; ATP, adenosine triphosphate; BMBT, buccal mucosal bleeding time; CADP, cartridges coated with collagen and ADP; CEPI, cartridges coated with collagen and epinephrine; CT, closure time; DDAVP, desmopressin acetate (1-(3-mercaptopropionic acid)-8-d-arginine vasopressin monoacetate (salt) trihydrate); FITC, fluorescein isothiocyanate; GP, glycoprotein; GPRP, synthetic peptide Gly-Pro-Arg-Pro; IMHA, immune mediated hemolytic anemia; LTA, light-transmission aggregation; MP, Multiplate Analyzer, MPC, mean platelet component concentration; NSAID, nonsteroidal anti-inflammatory drug; PAF, platelet-activating factor; PFA, platelet function analyzer; POC, point of care; PPP, platelet-poor plasma; PRP, platelet-rich plasma; SPD, storage pool disease; ST, S wave to T wave; VWF, von Willebrand factor; VWD, von Willebrand disease.

Platelet function tests are primarily used in clinical settings to identify platelet hypofunction and thereby diagnose intrinsic platelet defects, predict bleeding risk, and monitor antiplatelet drug therapy. As platelet activation and hyper-reactivity are increasingly recognized as contributing to many disease processes, assays to detect platelet hyperfunction have gained interest.

This chapter discusses platelet function tests with clinical veterinary applications, rather than tests primarily used in research settings. Table 79.1 summarizes the platelet function tests described in this chapter.

BUCCAL MUCOSAL BLEEDING TIME

The buccal mucosal bleeding time (BMBT) test or oral mucosal bleeding time has been the classic in vivo test to evaluate primary hemostasis in small animals (Table 79.2), although other types of bleeding time tests have been described.[58] The BMBT is performed by measuring the time for cessation of blood flow from a standardized incision in the oral mucosa made with a disposable, single-use, spring-loaded lancet.[30] The equine template bleeding time, performed by triggering the lancet on a forelimb, has been reported to have poor

reproducibility, with coefficients of variation ranging from 26.8% to 45.5%.[65]

The BMBT has been used to screen patients preoperatively,[40] assess platelet function in an actively bleeding patient, characterize hereditary primary hemostatic disorders, and to evaluate drug effects.[5,8,30,50] In dogs affected with von Willebrand disease (VWD), the BMBT is reported to be prolonged by 85–100%, however, most reports consist of small case numbers.[8,12,30] Administration of desmopressin and cryoprecipitate has been reported to significantly shorten the BMBT, and the BMBT has been used to assess treatment response for dogs with VWD, and to monitor desmopressin acetate (1-(3-mercaptopropionic acid)-8-d-arginine vasopressin monoacetate (salt) trihydrate) (DDAVP) treatment for aspirin-induced impairment of platelet function.[12,13,18] The BMBT is reportedly prolonged in dogs with thrombocytopenia and severe azotemia.[30] However, in the author's experience, BMBT is not prolonged in dogs with congenital macrothrombocytopenia, presumably due to adequate total platelet mass. In a series of dogs with hereditary bleeding disorders, the BMBT was prolonged in dogs with primary hemostatic defects, i.e., thrombopathia and VWD, but normal in dogs with coagulation factor deficiencies.[8] Considerable variability in Greyhound BMBT has been described; with values that differed by ±2 minutes.[64] The BMBT correlated weakly with surgical blood loss in dogs;[40] and its value as a routine preoperative screening test in both human and veterinary medicine is debatable.[30,41] It has also been demonstrated that the type and size of lancet device used to perform a BMBT influence the results.[1] While the diagnostic utility of BMBT to predict bleeding risk is not established, the lack of availability of more sensitive or specific tests ensures its continued use in clinical veterinary medicine for point-of-care screening of primary hemostasis.

PLATELET AGGREGATION

Optical or turbidimetric platelet aggregation is the traditional "gold standard" method for testing platelet function in isolated platelet-rich plasma (PRP). The original assay was described in 1962 by Born and consisted of an absorptiometer with experiments performed at room temperature.[4] Whole blood aggregometry, based on changes in electrical impedance, was later developed as an alternate method with less-complex preanalytic processing. Regardless of method, aggregation is evaluated in response to addition of exogenous platelet agonists.

Platelet Agonists

ADP

ADP was the first known low-molecular-weight platelet aggregating agent. In human platelets, it induces shape change and reversible aggregation.

Secondary aggregation, sometimes observed after stimulation of PRP with ADP, is caused by secretion of dense granule constituents triggered by synthesis of thromboxane A_2. ADP plays a key role in platelet function by amplifying activation responses induced by other platelet agonists.

While considerable interspecies' differences in aggregation responses to various agonists exist, platelets from most species respond to stimulation by ADP at concentrations between 5 and 25 μmol/L.[54,62,68] Canine whole blood is an exception to this generality, since ADP does not induce consistent aggregation responses, possibly due to degradation of ADP by red blood cells and white blood cells.[32,57]

Collagen

Collagen, either of bovine or equine tendon origin, is typically the strongest of the agonists used in clinical laboratories. Collagen-induced platelet aggregation usually has a lag phase, during which the platelets adhere to the collagen fibrils and undergo shape change and release granule contents. Canine platelets respond in a dose-dependent manner to 1–20 μg/mL collagen.[32,54] Platelets from horses, cows, pigs, buffalo, and sheep all responded to collagen in one study, with equine platelets being the most sensitive.[62]

Arachidonic Acid

Arachidonic acid is converted to thromboxane A_2, a potent platelet agonist, through the actions of cyclooxygenase. The aggregation response induced by arachidonic acid is completely inhibited by aspirin in humans (see Chapter 94). Species differences exist in response to arachidonic acid stimulation, thereby limiting its value to evaluate the antiplatelet effects of aspirin and other nonsteroidal anti-inflammatory drugs (NSAID) on animal platelets.[14,32,62] Pelagalli[62] showed that arachidonic acid was less effective than ADP, collagen, or platelet-activating factor (PAF) in inducing aggregation of PRP from horses, buffaloes, pigs, and sheep, although a maximal aggregation response was achieved at 7.5 mmol/L. The use of arachidonic acid as an agonist in canine platelet aggregation experiments has been controversial. Jüttner[32] found no response to arachidonic acid at 0.5 and 1 mmol/L in any dogs tested, whereas others have found that canine platelets aggregate in response to arachidonic acid.[20,68] One study found that the variable platelet responses to arachidonic acid were breed-dependent,[14] and it has been suggested that the differences in sensitivity to arachidonic acid in dogs may reflect genetic differences in intracellular signaling pathways.[31]

Epinephrine

Epinephrine is the most unreliable of the agonists for platelet aggregation in animals. Epinephrine is usually regarded as ineffective by itself as an aggregation initiator, but has been used to enhance aggregation responses of other platelet agonists.

Thrombin

Thrombin is a potent platelet agonist; however, its ability to cleave fibrinogen to form a fibrin clot makes it a difficult agonist to use for platelet aggregation testing in plasma or whole blood milieux. The synthetic peptide, Gly-Pro-Arg-Pro (GPRP), which inhibits thrombin-induced fibrin polymerization but not platelet aggregation, can be added to reaction mixtures to facilitate evaluation of thrombin-induced activation response.[54]

Light-Transmission/Optical Platelet Aggregation

Light-transmission aggregation (LTA) is a specialized assay using warmed (37 °C) and stirred PRP or washed platelets, performed in photometers attached to a chart recorder or computer software that monitors sample turbidity over time. The instrument is standardized for each subject using PRP set as 0% aggregation and autologous platelet-poor plasma (PPP) set as 100% aggregation. As platelets aggregate in response to the addition of an exogenous platelet agonist, the sample becomes more clear and an increase in light transmission through the test sample is recorded (Figure 79.1).

Platelet aggregation response parameters include the percent maximal aggregation compared to PPP, the rate of aggregation (measured as the slope of the aggregation curve), and lag phase representing time from agonist addition to first aggregate formation.

Light-transmission aggregation is a very useful technique for characterization of platelet function defects. By using panels of agonists at various concentrations, it is possible to obtain a large amount of information on platelet receptor function, signaling pathways, and downstream response.[80] One limitation of LTA is its use of isolated platelets separated from other blood components and aggregated under low shear; conditions that do not mimic platelet adhesion, activation, and aggregation in damaged vessel walls.

Light-transmission aggregation can be affected by a variety of analytical and preanalytical variables. Meticulous venipuncture technique is required and evacuated collection tubes can be problematic due to ex vivo artifactual activation of platelets by the shear force of the vacuum. However, some laboratories use these tubes without causing significant ex vivo platelet activation.[47] Sodium citrate (0.102 mol/L, 0.129 mol/L, buffered or nonbuffered) at a ratio of nine parts blood to one part anticoagulant is the typical anticoagulant for platelet aggregation testing. Very low hematocrit can affect aggregation, as the final concentration of the citrate in plasma will be low compared to samples with normal hematocrit, thus yielding a higher concentration of free calcium in the plasma.[22]

The use of standardized platelet counts of PRP for platelet aggregation assays is somewhat controversial.[43,77] Aggregation response may vary in relation to platelet count;[29] however, diluting PRP with PPP can also influence results due to addition of activating substances in PPP that are released from platelets or other blood cells during processing.[42]

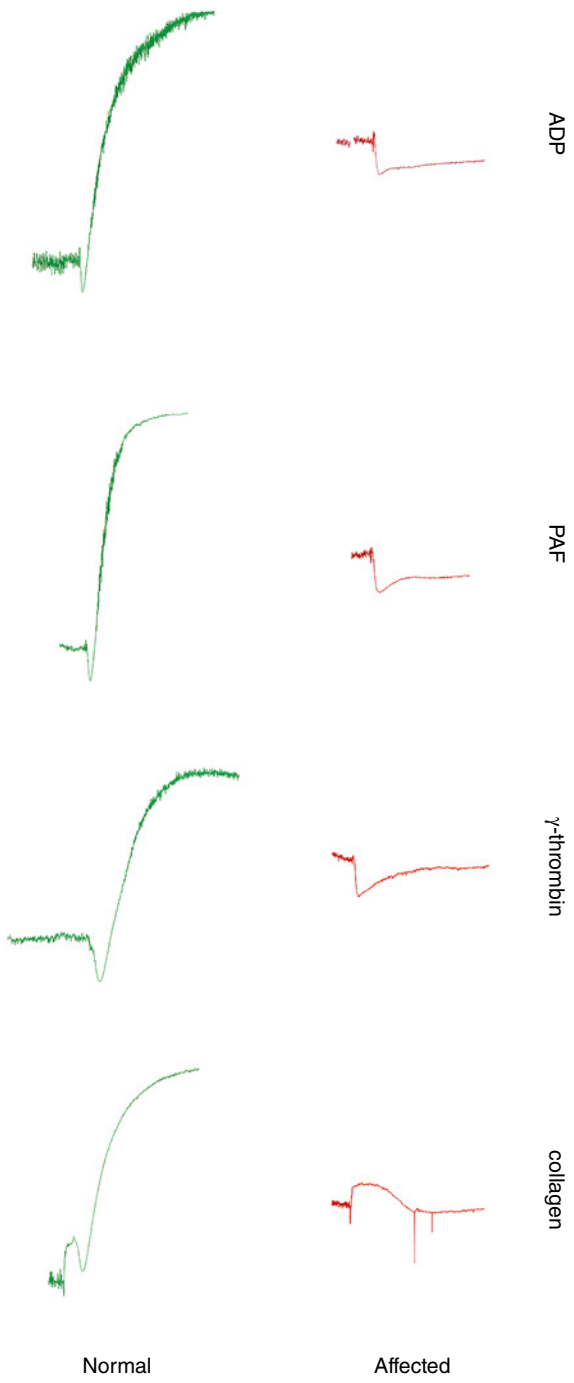

FIGURE 79.1 Normal platelet aggregation response to different agonists of a control dog (green; left-side tracings) versus a mixed breed dog with Glanzmann thrombasthenia (red; right-side tracings). Notice the universal lack of aggregation response to all agonists for the thrombasthenic dog. (Source: Haysom et al.[24])

Platelet Secretion Assays

Platelet dense granule release can be evaluated simultaneously with the aggregation response in a specialized aggregometer, called a lumiaggregometer. Lumiaggregation is based on the conversion of ADP, released from platelet dense granules, to ATP. This ATP then reacts with the firefly lantern extracts (luciferin and luciferase), generating adenyl-luciferin. Light is emitted when oxidation of adenyl-luciferin occurs. An ATP standard is used to calibrate the signal. Studies of platelet secretion allow assessment of signaling pathways culminating in both aggregation and degranulation. Secretion assays define the phenotype of storage pool disease and release defects, and allow diagnosis of platelet dysfunction in a subset of patients having clinical bleeding but normal aggregation tracings.[77]

Impedance/Whole Blood Platelet Aggregation

The impedance method can be used with either PRP or whole blood, although whole blood samples are used most widely. This method is based on the application of an alternating current across two electrodes and monitoring the change of resistance that is proportional to the size of the platelet thrombus that accumulates as platelets aggregate.[28] Compared with LTA, impedance methods use smaller blood volumes and require minimal preanalytic manipulation, thus preventing any loss of platelet subpopulations, or ex vivo platelet activation during centrifugation. Disadvantages include a relative insensitivity and inability to detect qualitative features of platelet activation, particularly shape change and the potential for inconsistent agonist response (P. W. Christopherson, personal observation).[32]

MULTIPLATE ANALYZER

The Multiplate system (Diapharma Group, Inc., West Chester, Ohio) is a newer generation impedance aggregometer that uses small volume (<500 µL) whole blood samples in single-use test cuvettes. The Multiplate measures platelet aggregation in hirudin- or heparin-anticoagulated blood exposed to various agonists.[33,48] The use of heparin is the preferred anticoagulant due to platelet autoaggregation induced by hirudin or citrate, and in one study, citrated samples had weak aggregation responses.[16,48]

Platelet Aggregation in Clinical Disorders

Clinical studies describe the use of aggregation in the evaluation of both inherited and acquired diseases. Glanzmann thrombasthenia, a quantitative defect in the glycoprotein complex IIb–IIIa (integrin $\alpha_{IIb}\beta_3$, fibrinogen receptor), has been identified in dogs and horses (see Chapter 84). The integrin $\alpha_{IIb}\beta_3$ is required for platelet aggregation, and the diagnostic features of Glanzmann thrombasthenia include absent aggregation to all physiologic agonists (Figure 79.1), and abnormal clot retraction.[6] Storage pool disease (SPD) is characterized by defective secretion of adenine nucleotides. Animals with dense-granule SPD may have impaired platelet aggregation response to ADP and collagen or normal platelet aggregation.[10] The SPD associated with Chediak–Higashi disease causes impaired platelet aggregation response to collagen and a virtually absent release of adenine nucleotides, measured by lumiaggregation.[27]

Platelet aggregation studies have been performed in animals with acquired platelet function defects secondary to uremia, immune-mediated thrombocytopenia, laminitis, infectious diseases, malignancies, heart disease, and drug-related disorders (see Chapter 85).[35,54,57,60,71] Multiplate has shown promise in the monitoring of aspirin and clopidogrel therapy in dogs[63] and has been used in the evaluation of platelet function in dogs with acute renal injury.[50]

PLATELET FUNCTION ANALYZER—PFA-100®, PFA-200®

Point-of-care instruments have been developed to replace bleeding time determinations as screening tests of primary hemostasis. The most widely used in veterinary medicine is the platelet function analyzer (PFA)-100® (Figure 79.2) and newer PFA-200® (Siemens, Munich, Germany). The test is designed to assess platelet adhesion and aggregation under conditions of high shear.

Test Principle

The PFA test is performed by pipetting citrated whole blood into a disposable cartridge. The blood sample is then drawn, under a constant vacuum, through a capillary tube and an aperture 150 µm in diameter. The membrane is coated with either collagen and epinephrine (CEPI) or collagen and ADP (CADP). The PFA-200 also offers a P2Y cartridge for assessment of P2Y12 receptor antagonism with certain drug therapies such as clopidogrel (Sysmex, Wymbush, Milton Keynes, UK). Activation of platelets and adhesion to the membrane are caused by the high shear rates (4000–5000 s^{-1}) generated in the PFA system and are mediated via a platelet surface glycoprotein-Ib-IX–V binding via von Willebrand factor (VWF) to collagen. Subsequent release of platelet granule contents and the presence of collagen and epinephrine or ADP on the membrane result in platelet aggregation. When the aperture is occluded by aggregated platelets, blood flow through the membrane stops. This is referred to as the closure time (CT).[36] Normal reference intervals for CT have been reported to be 53–98 seconds for CADP-CT and 92 to >300 seconds for CEPI-CT in dogs,[52] and 61–116 seconds for CADP-CT and 159 to >300 seconds for CEPI-CT in horses.[66] It is generally recommended that each laboratory establish its own normal range for CT, using samples drawn in a consistent concentration of sodium citrate for species controls and patients.

FIGURE 79.2 The PFA-100® instrument. (**Source:** Dade Behring)

Factors Affecting Closure Time

PFA CTs are sensitive to both platelet number and function. In dogs, there is an approximate linear relationship between CT and platelet count below 150 × 10^9/L.[53] However, no association has been found between platelet count and CT in Cavalier King Charles Spaniels with idiopathic inherited macrothrombocytopenia, likely due to normal total circulating platelet mass in these dogs.[72]

Closure time also increases with decreasing hematocrit in humans and dogs.[37,53] The exact threshold at which the CT is affected may vary between species. In dogs, a prolongation of the CT is seen at hematocrit values below 30–40%.[11,53] Plasma levels of VWF are an important determinant of CT because platelet aggregation at high shear rates depends on VWF concentration and function. In humans, it has been shown that plasma VWF levels modulate PFA CT to a greater extent than intrinsic platelet function.[23] An association between PFA-100 CT and VWF has been shown in healthy dogs,[70] and in dogs with inherited,[11,53] and acquired[71] von Willebrand disease.

The concentration of anticoagulant is an important determinant of CT in humans and dogs. Test times are longer in 0.129 mol/L (3.8%) citrate than in 0.109 mol/L (3.2%), probably due to greater calcium chelation. In dogs, the PFA-100 CT appears to be stable up to 8 hours after the blood sample is collected,[52] although testing within 2 hours is generally recommended. The manufacturer of the PFA-100 currently recommends testing within 4 hours for humans.

Detection of Platelet Function Defects

The PFA system is designed to assess human platelet function, thus species' differences in platelet response may complicate its use in animals. Very long CEPI-CTs and nonclosure (>300 seconds) are common for healthy, unmedicated dogs and horses.[11,53,66,72] It has been suggested that subjects with CEPI-CT > 300 seconds may

have an aspirin-like defect; however, normal plasma thromboxane B_2 levels were demonstrated in dogs with CEPI-CT > 300 seconds.[57] Unlike human platelet response, epinephrine does not consistently cause platelet aggregation in other species,[14] thus limiting clinical utility of CEPI determinations.

Hypofunction

The PFA is a sensitive test of von Willebrand disease in humans.[19] In two small case studies of dogs with von Willebrand's disease, all affected dogs had prolonged CADP-CT, suggesting a similar high sensitivity.[11,53] Callan and Giger[11] have reported a sensitivity of 95.7% and specificity of 100% for detecting primary hemostatic disorders (thrombocytopenia, thrombopathia, and type 1 von Willebrand disease) using the CADP cartridge; sensitivity was 95.7% and specificity 82.8% using the CEPI cartridge. The PFA has utility in monitoring responses to DDAVP in dogs with type 1 von Willebrand disease, where partial correction of CT typically is obtained. DDAVP administration has been found to significantly shorten the CADP-CT but not the CEPI-CT.[12]

Very few studies have documented the utility of the PFA system in detecting intrinsic platelet function disorders in animals. Callan and Giger[11] found that five out of six dogs with unspecified thrombopathia had prolonged CADP-CT, and a case report has described prolonged CADP-CT in a horse with Glanzmann thrombasthenia.[45] In people, the PFA CT is prolonged in cases of Glanzmann thrombasthenia (GPIIb–IIIa deficiency), Bernard–Soulier syndrome (GPIb-IX–V deficiency), and patients with δ-storage pool deficiency and primary secretion defects.[21,25]

Both the CADP-CT and CEPI-CT appear to be prolonged by acetylsalicylic acid in dogs and horses.[53,66] This finding contrasts with people. Aspirin's antiplatelet action in people is characterized by prolonged CEPI-CT, but normal (or near-normal) CADP-CT.[46] Dogs experimentally loaded with endotoxin had shortened CADP and CEPI-CT at 0.5 hours and prolonged CT 48 hours after inoculation. The initial shortened CT may reflect hemoconcentration more than actual platelet hyperfunction.[79] Dogs with heart diseases causing high-velocity blood flow (mitral valve regurgitation and subaortic stenosis) and an acquired type 2A von Willebrand disease have prolonged CADP and CEPI-CT (Figure 79.3). The mechanism has been suggested to be enhanced cleavage of VWF high-molecular-weight multimers by a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13), a plasma metalloprotease acting on VWF preferentially under conditions of high fluid shear stress.[70,71] A similar acquired defect with prolonged CT is described in humans with aortic stenosis.[73]

Hyperfunction

It is unclear whether shortening of the PFA CT truly reflects platelet hyperfunction/increased reactivity because there is lack of data that links shortened CT to clinical evidence of thrombosis or thrombosis-related outcome. Shorter CTs have been associated with S wave to T wave (ST) segment elevation myocardial infarcts in human patients, but data are lacking in veterinary medicine. Greyhounds have been found to have shorter CT compared to other dogs; however, this could be due to higher hematocrit found in this breed.[15] The PFA, in comparison to the Multiplate Analyzer and Plateletworks system, has shown to be useful in monitoring aspirin and clopidogrel therapy in dogs.[63]

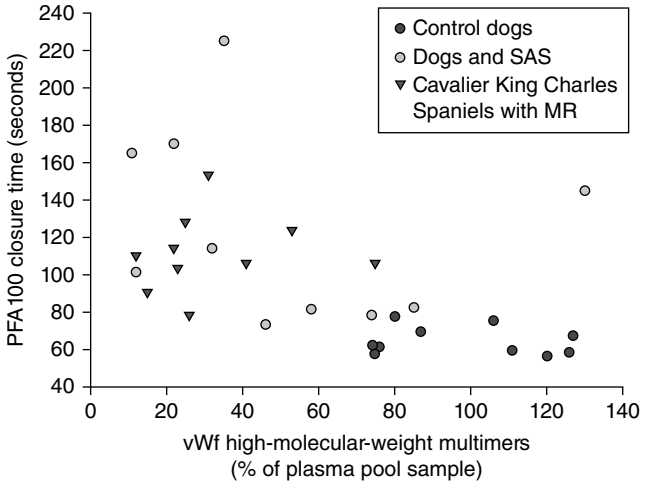

FIGURE 79.3 Platelet function analyzer closure times (Y axis) shown as a function of percentage high-molecular-weight von Willebrand factor multimers (X axis; sample relative to pool ratio). SAS, subaortic stenosis, MR, mitral regurgitation. (Source: Tarnow et al.[71])

FLOW CYTOMETRY

Flow cytometry is a versatile tool for study of platelet function. Flow cytometry may be used to: (1) measure the activation state of circulating platelets and their reactivity (by activation-dependent changes in the platelet surface, leukocyte–platelet aggregation, and procoagulant changes on the platelet surface), (2) diagnose platelet function defects (see Chapters 84 and 85), (3) monitor thrombopoiesis by quantifying reticulated platelets, (4) measure platelet count, (5) assess antiplatelet drug effects, and (6) detect platelet-bound antibodies. This section discusses the use of flow cytometry to characterize platelet activation status.

Flow cytometry measures specific characteristics of cells and cell fragments as they flow through a flow chamber and past the focused beam of a laser. The cells are usually labeled with a fluorescent compound or fluorescent-conjugated antibody, or can be analyzed unlabeled. When labeled cells pass through the laser, the laser light activates the fluorophore at the excitation wavelength, and the emitted fluorescence and the light scattering properties of each cell are detected. The intensity of the emitted light is directly proportional to the amount of bound fluorescent probe (see Chapter 143).

Flow cytometric assays evaluating platelet function can utilize washed platelets, PRP, or whole blood. Whole blood samples are typically labeled with a minimum of two fluorescent probes: a platelet-specific marker, to differentiate platelets from other cells in the blood, together with a "test" marker recognizing the activation parameter to be measured. Physiologic or nonphysiologic agonists can be used to assess in vitro platelet reactivity. Samples can be stabilized by fixation before or after addition of antibodies. Relevant isotype-matched antibodies or unstimulated cells may be used as labeling or experimental negative controls.[51]

The application of flow cytometry for evaluating platelet function in veterinary medicine is limited compared with human or murine studies by the relative lack of commercially available species-specific or cross-reactive monoclonal antibodies. Some platelet membrane proteins (e.g., integrin $\alpha_{IIb}\beta_3$) appear to be widely conserved across species, and many antihuman antibodies directed against this receptor are cross-reactive.[45,67,69]

Cytometric Markers of Platelet Activation

Flow cytometric assays gauge activation status of circulating platelets and platelet reactivity after in vitro agonist stimulation by detecting changes in surface expression of a receptor or other membrane component, or presence of a bound ligand. Detection of leukocyte–platelet aggregates and procoagulant platelet-derived microparticles has also been investigated as markers of platelet activation in veterinary medicine (Table 79.3).[51]

Markers of platelet activation include activation-dependent conformational changes in integrin $\alpha_{IIb}\beta_3$, exposure of granule membrane proteins, such as P-selectin, platelet surface binding of secreted platelet or plasma proteins (e.g., fibrinogen), and development of a procoagulant surface (assessed by Annexin V or lactadherin binding to phosphatidylserine).

Platelet P-selectin (CD62P) expression, denoting degranulation, is among the most common markers of platelet activation used in human medicine, and methods to detect this marker have been described for dogs, horses, and pigs.[38,50,55,67,69,78] Increased platelet surface P-selectin expression has been demonstrated in dogs with inflammatory disease,[56] and with immune-mediated hemolytic anemia.[75]

Assessment of fibrinogen binding has been described in dogs using a monoclonal antibody that recognizes a receptor-induced binding site (RIBS) on canine fibrinogen.[7,69] Moreover, exogenous fluorescein isothiocyanate (FITC)-labeled fibrinogen binding as a marker of platelet activation has been described in dogs and horses.[69,74]

Binding of an antifibrinogen antibody to platelet membrane surface fibrinogen as a marker of platelet activation has been described in horses and pigs.[34,39,59]

Detection of fluorescent-tagged Annexin V bound to outer platelet membrane phosphatidylserine has been described as a marker of procoagulant platelets in dogs and horses.[34,78] Annexin V detection is independent of species because it is a placental protein and not an antibody directed against a specific epitope. "Coated" platelet refers to a subpopulation of highly procoagulant cells generated by dual agonist stimulation with collagen and thrombin. These platelets are defined by the cytometric characteristics of phosphatidylserine exposure, bound α-granule proteins, membrane permeability to calcein, and shedding of membrane-derived microparticles. Coated platelet formation has been described in healthy dogs, and lack of this subpopulation is a feature of a hereditary canine platelet defect (Scott syndrome).[9]

Leukocyte–Platelet Aggregates

Leukocyte–platelet aggregates are formed via interaction between P-selectin exposed on the surface of activated platelets and the P-selectin glycoprotein ligand 1 counter receptor on the leukocyte surface.[51] Detection of leukocyte–platelet aggregates has been described in dogs (Figure 79.4) and horses,[67,69,78] and increased neutrophil–platelet aggregates has been associated with laminitis in ponies.[76]

Automated Measurements

Mean platelet component concentration (MPC) has been investigated as an automated measurement of platelet activity. The MPC estimates the refractive index of platelets. When activated platelets degranulate, the density

TABLE 79.3 Flow cytometric parameters of platelet activation.

Activation-dependent platelet changes	Method	Reference
Surface P-selectin exposure	Binding of monoclonal antibody AC1.2, 1E3, MD6 (dogs)	55, 69, 78
	Psel.KO.2.5, SwPsel.1.9 (pigs) CLBThromb/6, Psel.KO.2.7 (horse)	49, 67, 74

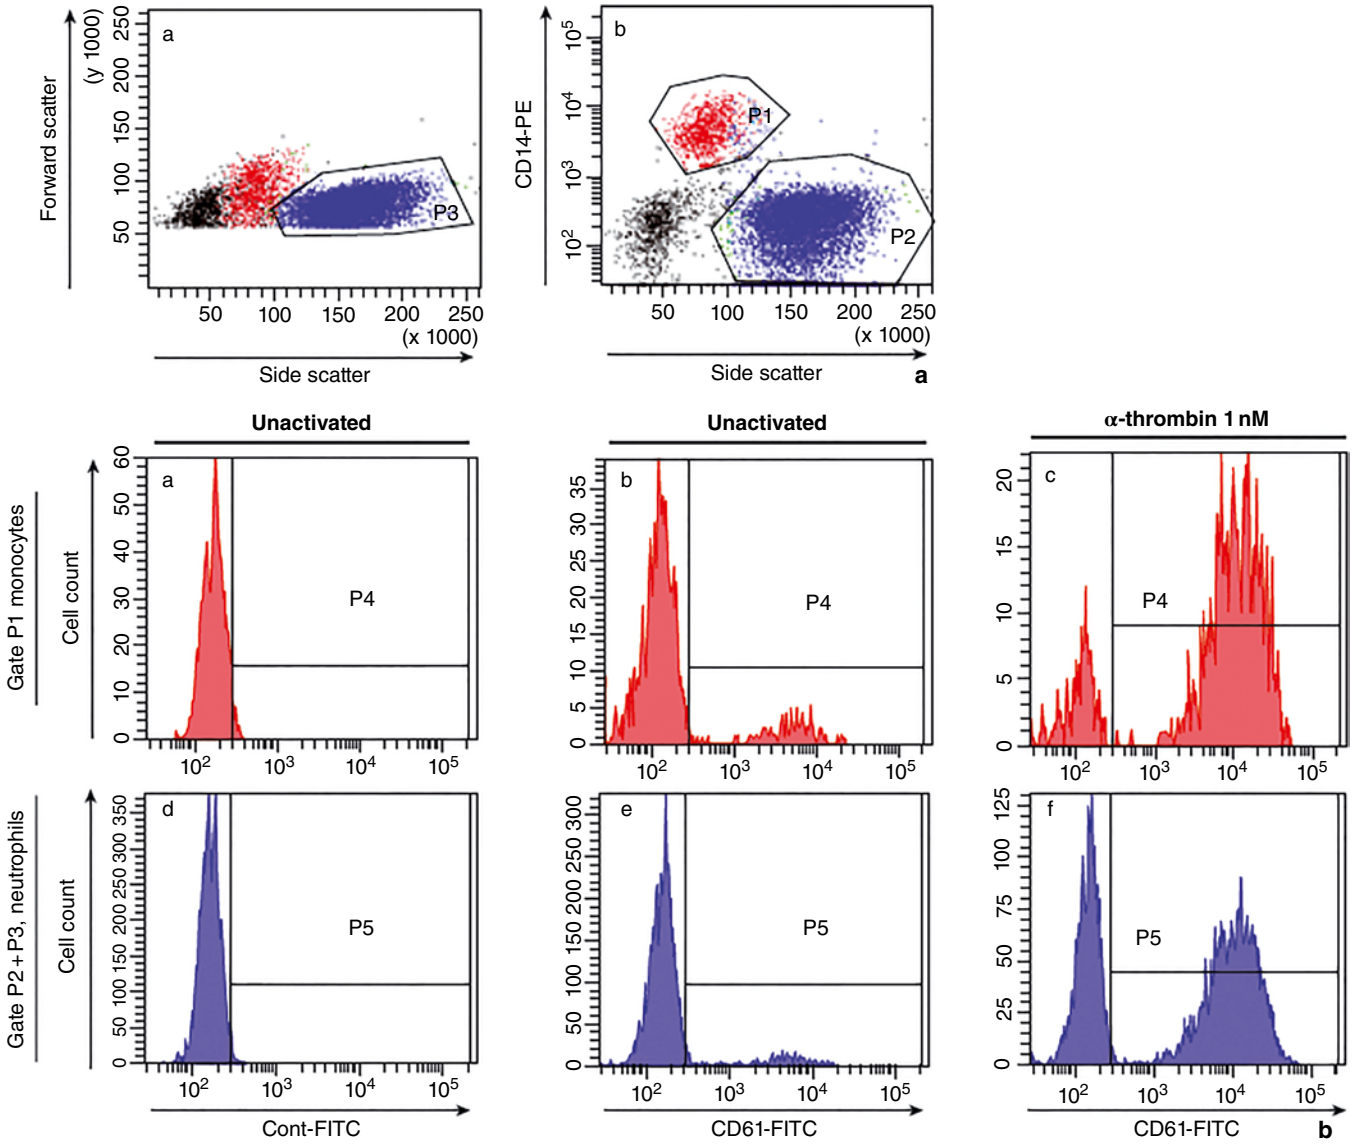

FIGURE 79.4 Flow cytometry gating logic for the detection of leukocyte–platelet aggregates in canine whole blood. (a) Monocytes and neutrophils were gated by a combination of light scattering and CD14-PE fluorescence. Bright CD14 and 90° (side) light scatter define monocytes (P1); dim CD14, forward, and 90° light scatter define neutrophils (P2 and P3); (b) Histograms are used to quantify leukocyte–platelet aggregates by percent CD61-FITC positive cells and CD61-FITC mean fluorescent intensity from P1 cells, monocytes (b-a, b-b, b-c) and P2 and P3 cells, neutrophils (b-d, b-e, b-f). Gates P4 and P5 are adjusted such that they include 1% of the isotype-control-stained (Cont-FITC) population (b-a, b-d). Unactivated samples had 9.6% monocyte–platelet aggregates (b-b), and 7.5% neutrophil–platelet aggregates (b-e). Activation with 1 nM α-thrombin gave 84.2% (b-c) and 59.7% neutrophil–platelet aggregates (b-f). (**Source:** Tarnow et al. [69])

decreases and the MPC decreases.[44] Decreased MPC has been associated with inflammatory disease in dogs, with a significant inverse correlation between platelet surface P-selectin expression and MPC.[56] Recent studies have suggested that MPC may be useful in prognosis prediction in dogs with immune mediated hemolytic anemia (IMHA).[81]

ADDITIONAL ASSAYS

Thrombelastography (TEG) is a viscoelastic point-of-care method that monitors the kinetics of thrombus formation and lysis in whole blood samples. Platelet mapping (TEG-PM, Haemonetics Corporation) is a modified assay designed to more specifically assess platelet function, particularly in patients receiving platelet inhibitory drugs. The assay is configured with different coagulation or platelet-activating agents designed to individually evaluate the contribution of coagulation factors, fibrinogen, and platelets to overall thrombus strength. Preliminary evaluations of the platelet mapping assay in dogs, cats, and horses have revealed some species' differences in agonist response versus human response, which, combined with the assay's high cost, may influence its clinical utility in animals.[2,3,74]

PlateletWorks (Helena Laboratories, Beaumont, TX) is a simple assay designed to evaluate platelet

activation response based on differential platelet counts in blood collection tubes containing platelet agonists versus an EDTA, baseline control tube. In pilot studies evaluating PlateletWorks in cats treated with clopidogrel, the assay successfully detected the drug's antiplatelet effects based on impaired collagen and ADP response post-treatment.[17,26]

Acronyms and Abbreviations

APC, antigen-presenting cell; ASH, American Society of Hematology; BUN, blood urea nitrogen; CV, coefficient of variation; FNAIT, fetal/neonatal alloimmune thrombocytopenia; GP, glycoprotein; HPA-1a, human platelet antigen-1a; IPF, immature platelet fraction; ITP, immune thrombocytopenia; IVIg, intravenous immunoglobulin; IWG, International Working Group; Mpl, myeloproliferative leukemia protein; MPS, mononuclear phagocytic system; MPV, mean platelet volume; PAIg, platelet-associated immunoglobulins; Tc, cytotoxic T cell; Th, T helper cell; Treg, regulatory T cell; TPO, thrombopoietin.

INTRODUCTION

Immune thrombocytopenia (ITP) is a common bleeding disorder in which autoimmune destruction of platelets and megakaryocytes results in severe thrombocytopenia. Although most commonly described in humans and dogs, ITP also affects cats and horses. Understanding of ITP pathogenesis is rapidly evolving. Traditionally considered to be an antibody-mediated disease, we now recognize ITP as a complex and heterogeneous syndrome that results from a combination of humoral and cell-mediated attack of platelets peripherally and of megakaryocytes in the bone marrow. This chapter focuses on ITP in dogs, the veterinary species in which it is most prevalent, and notes relevant differences in other species. Information from human ITP is referenced for knowledge gaps in veterinary medicine.

ITP NOMENCLATURE

In the medical literature, ITP historically stood for **i**diopathic **t**hrombocytopenic **p**urpura. However, this terminology was deemed inappropriate by the International Working Group (IWG) of human ITP experts, since bleeding signs are absent or minimal in most people with ITP.[93] The disease was retermed "immune thrombocytopenia" to emphasize its immune-mediated mechanism, but the same acronym was maintained (**i**mmune **t**hrombocyto**p**enia).[93] The veterinary literature includes

the terminology "**i**mmune-**m**ediated **t**hrombocytopenia" and the abbreviation IMT. However, the IWG recommendations are applicable for the animal disease counterpart, thus use of the acronym ITP in veterinary medicine provides consistency for comparative studies.

PRIMARY ITP PATHOGENESIS

ITP is an autoimmune disease characterized by both platelet destruction and impaired megakaryocyte and platelet production.[20] The pathogenesis of the immune dysregulation resulting in ITP is incompletely understood, and likely complex. Very little is known about ITP pathogenesis in companion animals, thus the following summarizes human disease pathogenesis. Since Harrington's seminal 1951 experiment in which transfusion of ITP plasma to healthy people induced thrombocytopenia, ITP has been known as a humoral disease.[41,63] Autoantibodies targeting platelet surface glycoproteins (GPs) lead to platelet clearance by the mononuclear phagocytic system (MPS), primarily of the spleen and, to a lesser extent, the liver.[20] However, it is now recognized that T cells also play a central role in platelet destruction in ITP.[20,81,100,117] A proinflammatory T helper cell (Th)1, Th17, and Th22 cytokine milieu predominates in many ITP patients that together promote macrophage activation, autoreactive B cell development, and T cell cytotoxicity.[20,63] Furthermore, T and B regulatory cells that normally serve to maintain self-tolerance are dysfunctional in ITP, allowing the autoimmune response to persist.[20,49,65] Several studies have found a reduction in regulatory T cell (Treg) number and function in people with ITP, and one pilot study found a decrease in Treg number in ITP dogs compared to healthy controls.[7,103,110] Interestingly, Treg numbers recover when human and canine ITP patients are in remission even if patients were treated only with thrombopoietin (TPO) mimetics. This finding suggests an immunomodulatory role for platelets, perhaps by providing a transforming growth factor-β reservoir.[2,7,63,99]

Although antibody-mediated platelet destruction is often central in ITP pathogenesis, some human patients lack detectable platelet autoantibodies. These patients have cytotoxic T lymphocytes that induce platelet destruction via apoptosis and perforin/granzyme-mediated cytotoxicity.[20,79,117,118] In some patients, antibodies and T cells attack megakaryocytes, resulting in decreased platelet production further compounding platelet destruction (Figure 80.1).[48,118] Megakaryocytes of dogs with ITP display signs of injury including foaminess, vacuolation, and reduction of cytoplasmic granularity.[51] Complement may also contribute to the immune-mediated destruction of both platelets and megakaryocytes.[84]

In addition to immune targeting of megakaryocytes and platelets, TPO levels are often inappropriately normal in human patients with ITP. TPO is the major regulator of platelet production that is necessary for survival, proliferation, and differentiation of megakaryocytes to platelets.[1,17,40] Until recently, TPO was thought to be produced constitutively by the liver and cleared through binding to its receptor, the myeloproliferative leukemia protein (Mpl) receptor, on platelets and megakaryocytes.[40] Thus, TPO concentration should be inversely proportional to the platelet or "Mpl" mass.[40] Although the Mpl mass plays a role in TPO regulation, a more elegant system may explain the normal levels of circulating TPO documented in human ITP patients. As platelets age, they are desialylated and subsequently recognized and cleared by the hepatic Ashwell–Morell receptor.[40] This removal, in turn, drives hepatic TPO expression providing a feedback mechanism: as more platelets are cleared, more TPO is produced (see Chapter 75, Figure 75.1). However, in a murine model of ITP, platelets opsonized with antiplatelet antibody are cleared by the splenic and hepatic MPS, thus shunting platelets away from the Ashwell–Morell receptor and failing to trigger hepatic TPO production.[40] Circulating TPO levels in people with ITP are inadequate or unable to effectively stimulate platelet production.[1] TPO levels in dogs with ITP have not been established, as there are no available assays for circulating canine TPO.

A genetic susceptibility to autoimmunity is recognized in human medicine; however, familial ITP is very rare, complicating discovery of susceptibility loci in human ITP.[8] A breed predisposition to develop ITP is consistently reported in the veterinary literature, with an overrepresentation of Cocker Spaniels and Old English Sheepdogs.[60,77,90,113] Given this breed predisposition, it is very likely that genetic factors contribute to ITP pathogenesis. Presumably, ITP results from the combination of a genetic predisposition with an environmental or infectious trigger, which often remains unidentified.[20] Indeed, the trigger for initial loss of self-tolerance in ITP is not understood.

SECONDARY ITP

Antiplatelet antibody formation in patients with secondary ITP is associated with an identifiable antigenic stimulus, often in the form of a drug, infectious agent, or neoplastic disorder (Table 80.1). Although the presence of increased platelet-associated antibodies or immunoglobulins (PAIg) in patients with thrombocytopenia and an underlying disease or drug exposure is compatible with secondary ITP, it does not prove that the secondary disease definitively triggered ITP.

Any medication can cause secondary ITP, but penicillins, sulfonamides, and cephalosporin antibiotics are the most frequent culprits. Drug-induced thrombocytopenia usually involves the association of a drug-dependent antibody with a platelet membrane protein and the drug.[4] Drug-induced thrombocytopenia tends to occur 5–10 days following first-time drug exposure, but can occur more rapidly, especially with repeat drug exposure.[4]

Many infectious diseases cause thrombocytopenia. Infection-associated thrombocytopenia is often multifactorial in origin including vasculitis, bone marrow

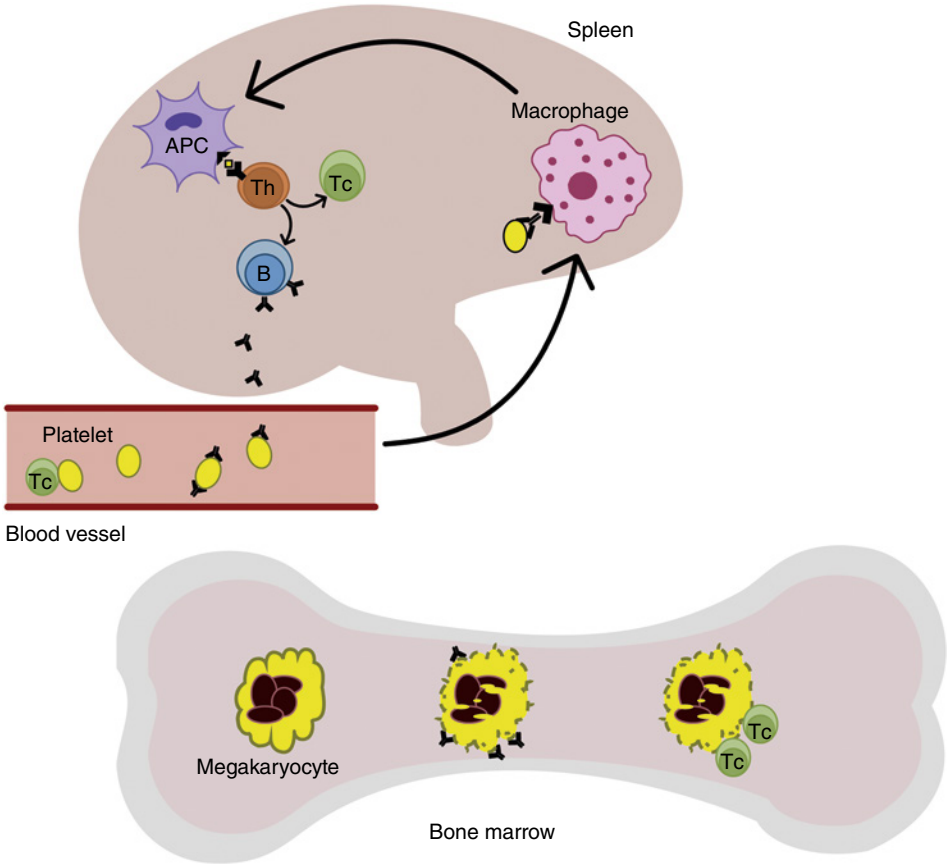

FIGURE 80.1 Mechanisms of platelet and megakaryocyte destruction in immune thrombocytopenia (ITP). ITP is a heterogeneous disease with a complex pathogenesis sustained by a positive-feedback loop. After loss of self-tolerance, T helper cells (Th) promote generation of autoantibody-producing B cells and/or autoreactive cytotoxic T cells (Tc). Autoantibodies can opsonize platelets, leading to their splenic and hepatic clearance by macrophages of the mononuclear phagocyte system. Macrophages can then serve as one type of antigen-presenting cell (APC), propagating the cycle. Dendritic cells can also serve as APCs. Tc can destroy platelets in the blood or spleen. Autoantibodies and autoreactive Tc may target megakaryocytes in the bone marrow, inhibiting platelet production. Thus, ITP is a disorder of both platelet destruction and decreased platelet production. (**Source:** Courtesy of Andrew Kingsbury, Center for Food Security and Public Health, Iowa State University)

suppression, and splenic sequestration. However, antiplatelet antibodies and subsequent platelet destruction likely play an important role, and PAIg are often reported in thrombocytopenic dogs and cats with many infectious agents, but especially vector-borne diseases.

Neoplasia-associated thrombocytopenia occurs through several mechanisms, including consumption from bleeding tumors, decreased production due to myelophthisis, and secondary ITP.[14] Though most studies report small numbers of patients, PAIg have been documented in patients with neoplasia. PAIg have also been documented in a few thrombocytopenic patients with non-neoplastic inflammatory diseases; however, the pathogenic role of the antibodies in these diseases is unknown.

In children, the measles, mumps, and rubella vaccine is linked to development of ITP and there is anecdotal evidence that vaccination may trigger ITP in dogs.[75] However, a retrospective, case-control study was unable to document an association between recent vaccination in dogs and development of ITP.[45]

ALLOIMMUNE THROMBOCYTOPENIAS

Alloimmune thrombocytopenia, a unique subtype of secondary ITP, results from exposure to foreign platelet antigens (alloantigens) and production of cognate antibodies (alloantibodies). Alloantibodies then mediate platelet opsonization and subsequent platelet destruction. Pregnancy and blood transfusion are the most common triggers of alloantibody production in people, resulting in fetal/neonatal alloimmune thrombocytopenia (FNAIT) or post-transfusion purpura.

FNAIT is a rare but potentially severe bleeding disorder that is caused by maternal IgG antibodies directed against a fetal/neonatal platelet antigen inherited from the father.[5] Passage of maternal antibodies occurs transplacentally or via colostrum. FNAIT is associated with a high risk of intracranial hemorrhage that can occur both antenatally or postnatally.[5] In veterinary medicine, NAIT has been described in pigs and horses, and experimentally in mules.[13,28,91]

Alloimmune	Neonatal alloimmune thrombocytopenia (horses, pigs),[13,28] post-transfusion purpura[62]

The antigens capable of triggering NAIT reside on platelet membrane glycoproteins and are well-characterized in humans. Fetal-maternal incompatibility of human platelet antigen-1a (HPA-1a) is the most common cause of NAIT in Caucasians.[85] The antigens responsible for FNAIT have not been characterized in veterinary medicine. Ideally, diagnosis of FNAIT is confirmed by identifying neonatal, but not maternal PAIg, and confirming maternal antibody reactivity with paternal and neonatal, but not maternal platelets. Therapy of FNAIT is recommended for severe thrombocytopenia, defined as <30,000 platelets/μL due to high risk of intracranial hemorrhage. Treatment options in human medicine include transient glucocorticoid therapy, intravenous immunoglobulin (IVIg) infusion (benefit unclear in a human systematic review), and platelet transfusions, ideally with maternal washed or type-compatible platelets.[5,85] As FNAIT is more severe with subsequent offspring, treatment algorithms based on risk stratification are used to guide human therapy, and avoidance of repeat breeding of incompatible dams and sires is recommended for veterinary patients.[85]

Post-transfusion purpura is a rare reaction defined by severe thrombocytopenia that develops 5–12 days following a platelet or red blood cell transfusion.[27] The patient must have been previously sensitized to the platelet alloantigen by pregnancy or transfusion, and re-exposure to the platelet antigen causes an anamnestic immune response.[27] In humans, post-transfusion purpura usually affects HPA-1-negative individuals.[27] The patient's own alloantigen-negative platelets, via an unknown mechanism, are also targeted leading to severe thrombocytopenia.[27] Recommended treatments in human medicine include steroids, IVIg, and plasma exchange. Prevention of recurrence includes use of washed red blood cell units or transfusion of platelet and red blood cell units from platelet antigen compatible donors.[27]

CLINICAL FEATURES OF PRIMARY ITP

Signalment

Primary ITP is most commonly described in dogs. Although two large retrospective studies of thrombocytopenic dogs found ITP in only 5% of the cases,[12,38] ITP is the most common cause of *severe*

thrombocytopenia in dogs. Dogs of any age, gender, or breed can develop primary ITP; however, affected dogs are more commonly young to middle age with reported median age of presentation ranging from 4 to 8 years.[12,60,77,90] In many studies, females outnumber male dogs.[12,60,90] Predisposed breeds include Cocker Spaniels, Toy Poodles, Miniature Poodles, Standard Poodles, Old English Sheepdogs, and in some reports, German Shepherds.[38,60,62,90,113] Primary ITP is rarely reported in cats.[9,32,50,55,106,114] Indeed, in a large retrospective study, thrombocytopenia was only reported in 1.2% of cats, and only one cat was diagnosed with ITP.[50] ITP in cats is often secondary to an underlying disease (Table 80.1). Similarly, primary ITP is rare in horses, and equine ITP is usually secondary to infections, drugs, or neoplasia, or is mediated by alloantibodies.

Clinical Presentation

Signs of ITP vary widely, including presentation for surface bleeding (i.e., hemorrhage involving skin and mucosal surfaces), or clinically inapparent with thrombocytopenia identified incidentally on blood count results. Overt hemorrhage is usually spontaneous, most often from cutaneous sites or oral mucosal petechiation, followed by gastrointestinal bleeding (Figure 80.2).[68,113] Abnormal bleeding can also occur at estrus, surgery, or venipuncture sites. Although spontaneous bleeding typically occurs at platelet counts below 30,000 platelets/μL, many ITP patients have no clinical signs of thrombocytopenia and platelet count is not a reliable predictor of bleeding risk for individual patients.[68] The cause of variable bleeding severity among patients with similar platelet counts is poorly understood and may represent combined and interacting influence of platelet activation by autoantibodies,[83] interference of antibodies with platelet function,[25,78] alterations in endothelial integrity secondary to thrombocytopenia,[36,58] and presence of circulating procoagulant microparticles.[52,105]

Cats may tolerate thrombocytopenia and demonstrate less-spontaneous bleeding than dogs.[50] This may be because feline platelets can be more readily activated and contain more serotonin, a platelet agonist, in their dense granules than dogs or humans.[55,73] Similarly, horses often lack overt hemorrhage despite severe thrombocytopenia.

Human primary ITP patients frequently complain of fatigue that is not correlated with bleeding or anemia,[42] whereas histories of veterinary patients are usually restricted to abnormal hemorrhage or weakness caused by blood loss anemia.

Physical examinations of ITP patients may be normal, but typical findings include petechiae and ecchymoses, oral bleeding, epistaxis, gastrointestinal hemorrhage (melena, hematochezia, and hematemesis), and/or hematuria.[68,77] Petechiae and ecchymoses are particularly common on the oral mucosa, abdomen, and pinnae. A thorough dilated fundus exam should be performed in all ITP patients, since ocular bleeding often occurs; ranging from mild scleral hemorrhage and pinpoint retinal bleeds to hyphema and severe retinal hemorrhage.[102] Findings related to anemia such as pallor, tachycardia, and systolic murmur may be present. Severe hemorrhage leading to anemia is most commonly associated with gastrointestinal bleeding, though it can result from epistaxis and hematuria.[77,113] There are some reports of fever in dogs with primary ITP, but fever may be due to undiagnosed secondary etiologies.[77,90] Splenomegaly may be present due to extramedullary hematopoiesis.[90] Although rare, intracranial and spinal cord hemorrhage can occur with resultant signs of altered mentation, or localized neurologic deficits referable to the site of hemorrhage.

DIAGNOSIS OF PRIMARY ITP

In human medicine, primary ITP is defined as a platelet count of under 100,000/μL in the absence of other causes or disorders that may be associated with thrombocytopenia.[75] Similarly, in veterinary medicine, primary ITP is a diagnosis of exclusion. Other causes of thrombocytopenia including nonimmune platelet consumption, decreased production of platelets, and diseases associated with secondary ITP must be investigated (Chapter 81, Table 80.1).

The first step in an ITP workup is to confirm thrombocytopenia by performing a manual platelet count based on examination of a stained blood smear and ruling out platelet clumping. This is especially important in cats that often have pseudothrombocytopenia due to feline platelet reactivity and difficulty for some hematology analyzers to differentiate their similarly sized red blood cells and platelets.[116] EDTA and heparin can both result in platelet clumping and subsequent pseudothrombocytopenia in horses.[43,53] If

suspected, pseudothrombocytopenia should be ruled out by repeating a platelet count on a new citrate sample or, in cats, collecting blood directly into heparinized capillary tubes for fresh blood smear preparation accompanied by a manual platelet count.

Congenital macrothrombocytopenia should be suspected in dogs with chronic thrombocytopenia in the absence of bleeding signs (see Chapter 84). Hereditary macrothrombocytopenia due to β1 tubulin gene mutations has been identified in the Cavalier King Charles Spaniel, Norfolk and Cairn Terriers, and many other breeds.[33] Similarly, many healthy Greyhounds have platelet counts below typical canine reference intervals.[15]

In a recent study of 61 thrombocytopenic dogs, 57% were determined to have primary ITP, 28% secondary ITP due to lymphoid/myeloid neoplasia (9.8%), infectious disease (9.8%), liver disease (5%), or drug exposure (3%), and 15% had nonimmune thrombocytopenia attributed to bone marrow aplasia or consumptive coagulopathy.[59,68] Consumptive thrombocytopenia is typically ruled out with hemostasis tests to identify disseminated intravascular coagulation, or other thrombotic disorders. Investigations for secondary causes of ITP include review of medication and travel history, blood chemistry panel and urinalysis, imaging, and screening for relevant pathogens. Serologic testing and direct pathogen detection, including PCR tests, may be required for diagnosis of vector-borne disease, as one study documented that combining these methodologies increased sensitivity by up to 58%.[66]

While there is no gold-standard diagnostic test for ITP, platelet parameters derived from automatic blood cell counts and ancillary tests of platelet production or destruction have been used to support a diagnosis of ITP in veterinary and human medicine.

Platelet Count and Size

In several studies, platelet count was significantly lower in dogs with primary ITP than dogs with other causes of thrombocytopenia.[29,38,68] Even when comparing primary versus secondary ITP, thrombocytopenia was more severe in dogs with primary disease.[29,68] Although platelet counts overlap, severe (<20,000 platelets/μL) thrombocytopenia is suggestive of primary ITP.

High mean platelet volume (MPV) is generally a feature of young and more active platelets; however, appropriate validation studies have not yet demonstrated diagnostic utility of platelet size indices to differentiate causes of thrombocytopenia in people.[57] Dogs with ITP were found to have significantly higher MPV compared with healthy controls in one clinical study;[96] however, no differences were found in a second study using a different hematology analyzer.[82] Yet another study found MPV to be lower in dogs with primary ITP compared with dogs with nonimmune thrombocytopenia.[29] Low MPV may reflect relative increases in microparticles included in automated platelet counts, or impaired thrombopoiesis due to megakaryocyte-targeted destruction. Together, these studies indicate that increased MPV may be a feature of ITP in some cases, but the finding of normal to low MPV does not exclude the diagnosis of ITP.

Determination of MPV, however, may help differentiate ITP from hereditary macrothrombocytopenias. One human study found that an MPV of >12.4 fL differentiated hereditary macrothrombocytopenia from ITP with reasonable sensitivity (83%) and specificity (89%).[76] While discriminatory value of MPV has not been explored in dogs, determination of plateletcrit as a measure of total platelet mass has been described as a useful test to differentiate clinically relevant thrombocytopenia from hereditary macrothrombocytopenia in Cavalier King Charles Spaniels.[109]

Reticulated Platelets

Platelets newly released from megakaryocytes contain small amounts of RNA, and are referred to as reticulated platelets (see Chapters 75 and 78). Analogous to reticulocytes denoting erythropoiesis, circulating reticulated platelets are markers of megakaryopoiesis. Reticulated platelets were first characterized using flow cytometric techniques to detect thiazole orange staining of intraplatelet RNA. Although methodologically difficult to standardize, in humans, reticulated platelet assays have shown diagnostic utility for differentiating hypoproliferative thrombocytopenia from platelet consumptive and destructive disorders.[44] More recently, advanced, fully automated hematology analyzers (Sysmex XE and XN series, Sysmex Corporation; Abbott CELL-DYN Sapphire, Abbott Diagnostics) measure reticulated platelets in parameters referred to as immature platelet fraction (IPF) or percent reticulated platelets, respectively. These automated assays can be standardized and are better suited for routine and high-throughput testing. Some human studies of thrombocytopenic patients have shown increased IPF fractions in ITP patients; however, these studies have also revealed differences between analyzers that can limit usefulness of the assay.[24] A recent, well-designed prospective study assessing immature platelet indices on both the Sysmex XE and Abbott CD Sapphire found that while the Sysmex (not the Sapphire) demonstrated a significant increase in immature platelets in human ITP patients compared to those with bone marrow failure, both machines demonstrated broad overlap between the patient groups.[24] The authors speculated that this overlap is due to a shift toward immature platelets that occurs in any thrombocytopenic state regardless of etiology, analogous to the anemia "reticulocyte shift," and to decreased platelet production that occurs in many ITP patients.[24,71]

A canine study compared a flow cytometric, reticulated platelet assay with the Sysmex automated IPF assay in healthy and thrombocytopenic dogs.[82] The two methodologies demonstrated fair correlation and expected increases in immature platelet fractions in dogs with hyperproliferative thrombocytopenia; however, short (<18 hour) sample stability was noted for both methods along with high coefficients of

variation (CV). Another prospective study of dogs with thrombocytopenia determined that reticulated platelet percentages >8% (as determined by flow cytometry) combined with positive direct or indirect PAIg distinguished primary ITP from other causes of thrombocytopenia with high sensitivity but low specificity.[3] Overall, the utility of immature platelet fractions/reticulated platelets as ITP diagnostic tools appear low in both people and dogs.

Bone Marrow Evaluation

Bone marrow examination is not recommended in the initial evaluation of uncomplicated adult or childhood ITP; however, bone marrow examination is considered potentially useful for patients with refractory disease, atypical presentation, or age greater than 60 years.[89] Combined morphologic and flow cytometric assessments are performed in these patients and may reveal causes of secondary thrombocytopenia, lymphoproliferative/myeloproliferative disease, and other bone marrow disorders.[21] Bone marrow examinations are not typically included in the diagnostic workup of canine ITP in clinical reports.[77,90,98] A retrospective study of dogs with thrombocytopenia concluded that bone marrow cytology did not provide diagnostic or prognostic information in dogs with severe thrombocytopenia.[74] Similarly, a large retrospective study of dogs with ITP found that megakaryocyte hypoplasia did not impact survival or time to platelet count recovery.[77] One recent retrospective study of thrombocytopenic dogs contradicted these studies, showing that the finding of megakaryocytic hypoplasia on bone marrow exam was associated with bleeding and nonsurvival.[22] However, this study was small and statistical comparisons were not performed between groups. Possible indications for bone marrow examination in evaluation of ITP patients include suspect underlying marrow disease due to multiple cytopenias, poor response to therapy, or search for possible lymphoproliferative disease. When marrow evaluation is warranted, a sternal marrow aspirate can be considered as a less invasive alternative to the humerus or ilium.[26] Feline bone marrow examinations may be of higher yield in thrombocytopenic cats due to underlying viral infections (e.g., feline leukemia virus) and neoplasia.[50]

Platelet Autoantibodies

Autoantibodies directed against platelet antigens play a key role in platelet destruction; however, the presence of antiplatelet antibodies is not included in current consensus criteria for routine diagnosis of human ITP given that assays lack sensitivity and specificity.[89] Different assay configurations detect circulating antiplatelet antibodies (indirect methods) and membrane-bound PAIg (direct methods). Direct assay methods are generally more sensitive than indirect assays; however, platelets constitutively express immunoglobulin receptors that cause nonspecific antibody binding and complicate interpretation of a "positive" test.[87,108] Assay sensitivity is impeded by the fact that ITP is not always an antibody-mediated process. Up to 40% of human ITP patients lack detectable antiplatelet antibodies, presumably due to cytotoxic T-cell-mediated platelet destruction.[21] In human medicine, assay specificity is greatly enhanced by measuring platelet glycoprotein-specific autoantibodies. The platelet antigens primarily targeted by autoantibodies include GPIIb/IIIa (CD41/CD61, fibrinogen receptor), GPIb/IX (CD42c/CD42a, von Willebrand factor receptor), and GPV (CD42d).[87] The monoclonal antibody-specific immobilized platelet antigen assay (MAIPA) and bead-immobilized monoclonal antibody assays are configured to define each ITP patient's autoantibody specificity. The assays are based on detection of trimolecular complexes formed by a monoclonal antibody to a defined platelet glycoprotein, the patient's autoantibody, and the platelet membrane that carries the respective epitopes of each of these antibodies.[87,108] MAIPA specificity for ITP diagnosis is reported to be as high as 98%, but still lacks sensitivity (81% sensitive), potentially due to T cell as opposed to antibody-mediated autoimmunity.[87] Surveys of ITP patients reveal that autoantibodies targeting GPIIb/IIIa are the most common; found in approximately 70–80% of patients, with anti-GpIb complex antibodies found in 20–40% of patients.[63] The only case series describing the target antigen in dogs with ITP identified anti-GPIIb and GPIIIa antibodies in the serum of 4/17 (24%) of affected dogs.[61] Another study documented that plasma from a canine ITP patient immunoprecipitated glycoprotein Ib/IX.[97]

While PAIg assays are not used for diagnosis, recent studies demonstrate their potential value in optimizing treatment and monitoring response. Whereas antibodies to GPIIb/IIIa lead to macrophage clearance of platelets by the Fc receptor, anti-GPIb antibodies trigger platelet desialylation via platelet neuraminidase-1, which results in clearance via the hepatic Ashwell–Morell receptor (Figure 80.3).[40,63] Patients with anti-GPIb antibodies appear to be refractory to IVIg therapy due to non-Fc-receptor-mediated platelet clearance.[64] As demonstrated in recent case reports, these patients may instead respond to sialidase inhibitors like oseltamivir.[63,101] Although glycoprotein-specific PAIg and platelet desialylation testing is performed in research laboratories, these assays are not routinely performed in human medicine and have not been described in veterinary studies.

Flow cytometric assays to detect PAIg without defining target platelet antigen have been described in case series of canine thrombocytopenia.[3,29,112] As in human medicine, the diagnostic utility of canine PAIg assays for ITP has not been clearly demonstrated, mostly due to lack of sensitivity and specificity. A recent prospective study of dogs with thrombocytopenia determined that the sensitivity and specificity of direct and indirect platelet-associated IgG and IgM assays combined were 76.5% and 65.5%, respectively, for distinguishing primary ITP from other causes of

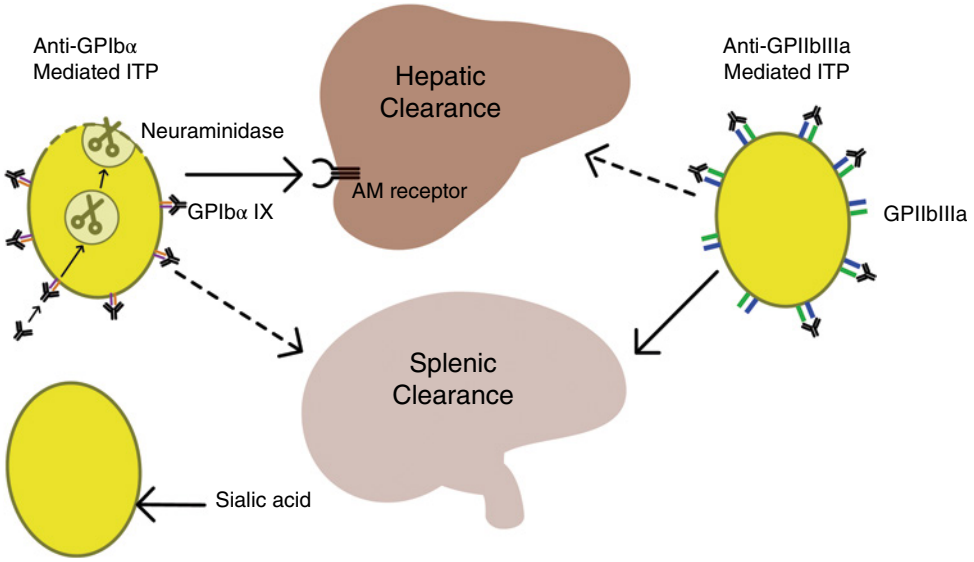

FIGURE 80.3 Autoantibody specificity determines pathway of platelet clearance in immune thrombocytopenia (ITP). Anti-GPIIb–IIIa antibodies lead to Fc-receptor-mediated mononuclear phagocyte clearance in the spleen and, less so, in the liver. Anti-GPIbα antibodies result in platelet activation and neuraminidase-1 surface translocation. Neuraminidase-1 in turn cleaves sialic acid residues from GPIbα and leads to Fc-independent hepatic clearance of the desialylated platelets via the Ashwell–Morell receptor (AM). (**Source:** Courtesy of Andrew Kingsbury, Center for Food Security and Public Health, Iowa State University)

thrombocytopenia.[3] Limitations of PAIg assays include a lack of standardization and defined controls, and non-specific antibody binding during sample storage. Furthermore, PAIg are well documented in many cases of canine secondary ITP, thus limiting the ability of PAIg testing to differentiate primary from secondary ITP (Chapter 81, Table 81.1).[29,112] Assays to define the targeted platelet glycoprotein could prove useful in dogs as in people to increase diagnostic specificity and potentially to guide treatment choice. To date, development of these assays is hampered by limited availability of commercial antibodies that recognize the main canine platelet membrane glycoproteins.[95]

Although PAIg testing is not specific for primary ITP, the finding of bound antibody is supportive of antibody-mediated platelet destruction, and persistent high PAIg may help guide treatment in cases where the patient has not responded to first-line drug therapy as expected.[21] The decision to begin tapering immunosuppressive therapy could also be guided by measurement of PAIg.[87] As in dogs, PAIg assays for cats and horses are not widely available, lack standardization, and play a limited role in ITP diagnosis at this time.

Circulating Thrombopoietin Levels

The recognition that many human ITP patients have inappropriately normal TPO levels and will respond to TPO mimetic drugs has revolutionized human ITP treatment. The diagnostic utility of TPO testing, however, has not been established[89] and TPO assays are primarily performed in research laboratories. Surveys of TPO levels in thrombocytopenic patients reveal overlap between values for consumptive thrombocytopenias and controls, but increases up to several thousand folds in patients with hypoproliferative thrombocytopenias.[1] While the utility of TPO levels for ITP diagnosis is uncertain, a potential prognostic relevance has been identified. Patients with relatively high TPO, defined as >95 pg/mL, were found to have only transient or partial response to TPO mimetic therapy.[67] Assays to measure canine TPO are not currently available.

TREATMENT OF PRIMARY ITP

Immunosuppression

Immunosuppression with glucocorticoids, often in combination with adjunctive immunosuppressive agents, is the mainstay of ITP treatment in dogs. Prednisone is generally started at 2 mg/kg/day, or 50–60 mg/m^2 for dogs over 25 kg. Once daily prednisone therapy compared to fractionated therapy may be associated with fewer side-effects.[104] Cats have inefficient prednisone absorption and/or conversion to prednisolone, the active drug form, thus prednisolone should be selected over prednisone for feline ITP treatment.[16] Interestingly, one feline ITP patient described in the literature responded to dexamethasone and not prednisolone for unknown reasons.[106]

There are no prospective, controlled studies to guide the selection of an adjunctive immunosuppressive agent in dogs with ITP. Empiric considerations for the use of adjunctive immunosuppressive agents in dogs include weight >25 kg with increased risk of severe steroid side-effects, severe hemorrhage requiring transfusion support, or failure of steroid therapy alone after 7 days. Commonly used immunosuppressive drugs for veterinary patients include cyclosporine, azathioprine, and mycophenolate

mofetil. Cyclosporine's immunosuppressive action can be monitored with a pharmacodynamic assay (Pharmacodynamic Laboratory, Mississippi State University College of Veterinary Medicine).[92] Azathioprine should not be used in cats, as they can develop severe, even fatal, drug-induced myelosuppression due to their low concentrations of thiopurine methyltransferase, limiting their ability to metabolize the drug.[30] Most horses with ITP respond to glucocorticoids, but azathioprine has been of benefit in refractory patients.[46,70] Use of single-agent mycophenolate was reported in five dogs with non-transfusion-dependent ITP in which corticosteroids were considered contraindicated.[115] There is currently no evidence of benefit to combined, triple immunosuppressive therapy, and triple therapy was associated with poor outcome in a retrospective study, thus combined therapy should be avoided.[77]

Therapy with Vincristine and Intravenous Immunoglobulin

Vincristine and IVIg have been shown to rapidly increase platelet counts in dogs with ITP, and are indicated for those with severe hemorrhage, especially gastrointestinal bleeding or life-threatening respiratory or central nervous system bleeding. Vincristine is speculated to increase platelet count by preventing microtubule polymerization and thereby accelerating megakaryocyte fragmentation and platelet release from bone marrow. In addition to accelerated thrombopoiesis, vincristine may impair phagocytosis of opsonized platelets.[6] In one prospective controlled study of severe ITP dogs, administration of vincristine (0.02 mg/kg) intravenously once in combination with prednisone was associated with more rapid increase in platelet count and shortened hospitalization compared to treatment with prednisone alone.[94]

Human IVIg is a sterile plasma derivative consisting primarily of IgG from healthy human donors. IVIg's mechanism of action in ITP is likely multifactorial and includes blocking antibody-mediated platelet clearance by saturating macrophage Fc receptors.[118] Other theoretical mechanisms include modulation of T-cell subsets to increase the proportion of regulatory T cells and inhibition of autoantibody production.[118] A prospective clinical trial of canine ITP demonstrated that treatment with IVIg combined with prednisone shortened time to achieve a target platelet count and hospitalization duration compared to prednisone treatment alone.[10] A subsequent study demonstrated that vincristine and IVIg are equally as effective in shortening platelet count recovery time and hospital duration in dogs with ITP.[6] Due to expense of IVIg, vincristine is usually the first emergent ITP therapy selected. In very severe cases, these therapies can be used in combination.

Novel Therapies

In people with ITP, frontline treatments include short courses of corticosteroids and IVIg, while second-line therapies include an anti-CD20 antibody (rituximab), splenectomy, and TPO receptor agonists.[75]

Treatment with TPO receptor agonists was adopted in human ITP based on recognition of inappropriately normal circulating TPO in this patient population. The TPO receptor agonists romiplostim (Nplate®) and eltrombopag (PROMACTA®) have revolutionized ITP treatment in people. Whether TPO is low in dogs or other species with ITP is unknown. Eltrombopag, a small molecule that binds to a transmembrane region of the TPO receptor, is not predicted to bind to the corresponding canine receptor.[54] By contrast, romiplostim, a peptide fusion protein, interacts at a conserved region of the canine TPO receptor with homology to the human protein. Romiplostim was used successfully in a pilot study of five dogs with ITP.[54] However, this study was not controlled, thus further research into canine TPO levels and romiplostim therapy in canine ITP patients is warranted.

Splenectomy is also a second-line ITP therapy in human medicine with reported response rates of 60% lifelong remission.[21] There is limited data on splenectomy efficacy in canine ITP; however, a recent retrospective study reported significant increases in platelet counts post-splenectomy, an 80% (12/15 dogs) 20-day survival rate, and 72% of surviving dogs requiring no long-term medical therapy.[34]

CD20 antibodies are believed to target autoantibody production via a B-cell-depleting effect. Rituximab, a chimeric anti-human CD20 antibody, has a response rate of 50–60% in people, but is associated with fewer sustained remissions than splenectomy. Despite its efficacy, rituximab can be associated with significant immunosuppression and other side-effects such as progressive multifocal leucoencephalopathy.[21] Rituximab does not bind canine B cells and there are currently no available anti-CD20 antibodies for veterinary patients.[47]

Transfusion Therapy

Blood transfusions may be required for ITP patients with signs referable to severe bleeding at critical anatomic sites or blood loss anemia. Although transfused platelets may have short circulatory half-life and not significantly alter platelet count, they may provide essential hemostasis at critical sites of bleeding. Hemorrhage from the gastrointestinal tract may be severe enough to warrant packed red cell or fresh whole blood transfusion. Human ITP guidelines recommend that platelet transfusions be reserved for those patients experiencing hemorrhagic bleeding or requiring invasive surgery.[75] A recent study determined that platelet transfusions, in the absence of these conditions, were not associated with improved clinical outcomes in human ITP patients.[35]

Platelet transfusion products include fresh whole blood, fresh platelet-rich plasma, fresh platelet concentrate (the standard product utilized in human blood banks), cryopreserved platelets, and a novel lyophilized canine platelet product, StablePlateRx™ (see Chapters 86 and 101). Fresh whole blood is the most readily available platelet source in many clinical settings; however, development of a commercial shelf-stable

product, StablePlateRx™, may provide wider access to platelet replacement therapy and enable more proactive transfusion of patients. Analyses of a prospective randomized controlled multicenter study comparing this product to cryopreserved platelets in bleeding thrombocytopenic dogs are currently underway.

ITP Treatment Goals

Treatment goals of ITP are not straightforward due to its clinical heterogeneity with highly variable signs of bleeding. Much of the overall disease burden of ITP is caused by uniform administration of high-intensity and long-term immunosuppressive therapy and potential for severe side-effects including secondary infections and bone marrow suppression. Indeed, in severe human ITP, mortality results equally from refractory hemorrhage as it does from secondary infections in immunosuppressed patients.[88]

While veterinarians routinely aim to normalize platelet counts, American Society of Hematology (ASH) guidelines do not recommend treating adult ITP patients unless platelet counts are less than 30,000 platelets/μL or there is active bleeding.[75] Additionally, ASH guidelines recommend, in the absence of bleeding signs, a treatment goal of over 30,000 platelets/μL.[75] Reconsidering ITP treatment goals in veterinary medicine to better align them with human recommendations may be warranted and may result in less treatment-associated morbidity.

Markers of ITP Disease Severity

Risk of spontaneous bleeding is generally associated with platelet counts less than 30,000/μL.[21] Although this threshold gives some indication of bleeding risk, not all patients with ITP bleed at low platelet counts, while others bleed excessively. Clinical bleeding assessment tools including the recently developed canine bleeding assessment tool, "DOGiBAT," may better reflect disease severity than do platelet counts.[68,80] Validated biomarkers of disease severity to guide treatment intensity are lacking; however, in human medicine, flow cytometric platelet function assays, thromboelastometry, and absolute IPF have shown promise in predicting bleeding in ITP patients.[21,31,37] A few disease severity markers have been recognized in dogs. In a retrospective study of 73 dogs, elevated blood urea nitrogen (BUN) on admission was associated with decreased survival (57% survival to discharge vs. 85% survival for dogs with BUN in the reference range).[77] Similarly, dogs with melena on admission were much less likely to survive to discharge (60%) compared to dogs without melena (90%) and were more likely to require a transfusion.[77]

PRIMARY ITP PROGNOSIS

The overall prognosis for dogs with ITP is good. Most dogs achieve hemostatic platelet counts within 5–7 days of therapy, though some patients have prolonged recovery times.[10,77,94] Reported mortality rates range from 10 to 30%.[60,90] While most dogs can eventually be weaned off immunosuppressive therapy over a range of months to years, others relapse following recovery (9–58% recurrence rate) requiring recurrent or chronic immunosuppressive therapy.[77,90,113] However, many studies define relapse as any decrease in platelet count, not necessarily a clinically significant decrease. Recalibrating to a goal of a safe platelet count would likely be associated with lower relapse rates.

Although uncommon in cats, reported rate of survival to hospital discharge for feline primary ITP is 85%.[9,32,50,55,106,114] While most cats experienced long-term survival ranging from 15 months to over 5 years, frequent relapses and development of diabetes mellitus secondary to chronic steroid therapy were described in one cases series.[9,106,114] Another cat with ITP developed a *Nocardia* infection presumably secondary to chronic immunosuppressive therapy.[32]

Reports of equine ITP describe a favorable prognosis and many cases with short disease duration. Recoveries often occur within 14–21 days, suggesting the presence of an unidentified secondary etiology.[111] More chronic ITP courses requiring prolonged glucocorticoid therapy are also described in horses.[111]

SUMMARY

Despite advances in our understanding, much about ITP pathogenesis and the inciting cause of loss of self-tolerance remain unknown. Consequently, diagnostic tests for ITP are lacking and few biomarkers exist to predict disease severity or help individualize treatment. Future research is needed to continue unraveling ITP pathogenesis and ultimately fill these gaps for safer, more targeted treatment and improved patient outcomes.

CHAPTER 81

Nonimmune-Mediated Thrombocytopenia

JULIE ALLEN

Introduction
Diagnosis of Thrombocytopenia
  Pseudothrombocytopenia
  True Thrombocytopenia
Basic Mechanisms for Thrombocytopenia
  Platelet Production Disorders
    Congenital or Breed-Associated Thrombocytopenia
  Platelet Loss
  Platelet Consumption
    Disseminated Intravascular Coagulation
    Thrombotic Microangiopathies
  Platelet Destruction
    Immune-Mediated Platelet Destruction
    Nonimmune-Mediated Platelet Destruction
    Hemophagocytic Syndrome
  Platelet Distribution Disorders
Disease Categories of Thrombocytopenia
  Infectious Thrombocytopenia
  Drug-Induced Thrombocytopenia
  Neoplasia-Associated Thrombocytopenia
  Liver-Disease-Associated Thrombocytopenia
  Dilutional Thrombocytopenia
  Gestational thrombocytopenia

Acronyms and Abbreviations

ADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; APTT, activated partial thromboplastin time; AT, antithrombin; BVD, bovine viral diarrhea; CBC, complete blood count; CDV, canine distemper virus; DIC, disseminated intravascular coagulation; EDTA, ethylenediaminetetraacetic acid; EIA, equine infectious anemia; ELISA, enzyme-linked immunosorbent assay; EVA, equine viral arteritis; FDP, fibrin/fibrinogen degradation product; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; FIP, feline infectious peritonitis virus; GI, gastrointestinal; GPIIb–IIIa, glycoprotein IIb–IIIa; HUS, hemolytic uremic syndrome; ITP, immune-mediated thrombocytopenia; LDL, low density lipoprotein; MPC, mean platelet component; MPS, mononuclear phagocytic system; MPV, mean platelet volume; PCR, polymerase chain reaction; PSAIg, platelet-surface-associated immunoglobulin; PT, prothrombin time; SFTSV, severe fever with thrombocytopenia syndrome virus; TPO, thrombopoietin; TTP, thrombotic thrombocytopenic purpura; VEE, Venezuelan equine encephalitis; VLDL, very low density lipoprotein; VWF, von Willebrand factor.

INTRODUCTION

Thrombocytopenia is defined as a platelet count below the lower limit of the reference interval. Thrombocytopenia is common in many species and is generally an acquired process accompanying an underlying disease or disorder.[12,30,51,104] Uncomplicated, mild to moderate thrombocytopenia is usually subclinical and clinical signs (e.g., fever, lethargy, anorexia) are related to the underlying condition. Thrombocytopenia is typically identified from review of a blood smear or a CBC. Spontaneous bleeding due to thrombocytopenia is rare when platelet concentrations are greater than 30,000–50,000/μL; however, some studies have suggested that platelet count alone is unreliable in ascertaining bleeding risk.[73]

Animals with severe thrombocytopenia or thrombocytopenia complicated by coagulopathy, vasculopathy, or platelet dysfunction often present with signs of primary hemostatic failure.[5] Findings may include petechiae or ecchymoses (often on the ventrum and inguinal region, or mucous membranes), and epistaxis, hematuria, gastrointestinal, gingival, vaginal, or ocular hemorrhage. Excess hemorrhage may develop following trauma, surgery, and venipuncture.

Platelet concentration in the blood reflects a balance between platelet production and platelet consumption, destruction, or redistribution to the vasculature of organs (see Chapter 78). In most healthy animals, platelet life spans are approximately 5–10 days. Platelets are continually consumed during repair of small vascular defects and senescent platelets are removed primarily by splenic macrophages. Platelet life spans are significantly longer in splenectomized dogs when compared to nonsplenectomized controls.[22]

Human studies have shown that 10^{11} platelets are produced every day and population turnover occurs every 8–9 days. In response to increased demand, platelet production can increase 20-fold or more.[54] Platelet production is affected by a number of growth factors (see Chapter 75); however, thrombopoietin (TPO) is the primary regulator of megakaryopoiesis and thrombopoiesis.[27,72] Thrombopoietin is primarily produced by hepatocytes, stromal cells in the bone marrow, and renal epithelial cells. In healthy animals, TPO is constitutively produced and the blood concentration is generally inversely related to platelet mass. Interleukin-6 has been shown to induce hepatic TPO production in inflammatory states.[27] Thrombopoietin binds to receptors on platelets and megakaryocytes. When circulating platelet mass is decreased, the concentration of unbound TPO available to stimulate megakaryopoiesis and thrombopoiesis is increased. Production of TPO is increased in some disease states (see Chapter 82).[15,108]

TABLE 81.1 Diagnostic tests for thrombocytopenia.

Assay	Comments[a]
Complete blood count	
Platelet concentration	Automated or manual Confirm and track thrombocytopenia
Mean platelet volume	Increase suggests enhanced thrombopoiesis
Mean platelet component	Decrease suggests platelet activation
Blood smear examination	Detect platelet clumps Estimate platelet concentration Detect organisms or neoplastic cells Detect large platelets—suggests increased production Evaluate for inflammatory leukogram
Hemostasis profile	Evaluate for consumptive coagulopathy (DIC)
Bone marrow examination	Assess megakaryocyte density and morphology Detect organisms, neoplastic cells, necrosis, inflammation, myelofibrosis
Serology	Detect exposure to infectious agents
PCR	Detect infectious agents
Flow cytometry	Detect PSAIg Measure reticulated platelets to assess platelet production Detect activation markers

[a]DIC, disseminated intravascular coagulation; PSAIg, platelet-surface-associated immunoglobulin.
Source: Based on Paltrinieri et al.[86]

DIAGNOSIS OF THROMBOCYTOPENIA

Common diagnostic tests are listed in Table 81.1 (and Chapter 78). When thrombocytopenia is detected by an automated hematology analyzer, it is important to examine a blood smear to check for platelet clumps, estimate platelet concentration to confirm the thrombocytopenia, and evaluate platelet morphology.[86]

Pseudothrombocytopenia

Pseudothrombocytopenia occurs when platelets are excluded from counting for any reason.[8] Small platelet clumps may not be detected by automated analyzers; thus, falsely lowering measured platelet concentrations. Most instruments will flag possible clumps and platelet histograms can be evaluated for abnormalities. A study in cats reported that platelet concentrations determined with an impedance hematology analyzer were often decreased; however, examination of a blood smear confirmed thrombocytopenia in only 3.1% of cats.[83] The disparity was attributed to platelet clumps and lack of size-separation of platelets from erythrocytes.[43,60] When clumps are detected in a sample, the measured platelet concentration is inaccurate, but may reflect the minimum number of platelets. Small clumps can be mistakenly counted as leukocytes by certain analyzers. Platelet concentration determined by analyzers that use a buffy-coat technique are less affected by platelet clumping than impedance hematology analyzers.[60]

Atraumatic venipuncture, with proper blood collection and handling techniques, is critical to minimize platelet activation and clumping. Various additives to inhibit platelet aggregation have also been investigated including prostaglandins, theophylline, adenosine, and dipyridamole, along with techniques such as vortex mixing samples.[43] Potent prostaglandin analogs, including iloprost, have demonstrated efficacy in normalizing platelet counts, but do not eliminate all clumping.[95,126]

Platelet clumps may form ex vivo in an EDTA-dependent manner.[68] In people, EDTA-related calcium chelation may result in a conformational change in glycoprotein IIb–IIIa (GPIIb–IIIa) that exposes cryptoantigens that bind to nonpathologic, but activating autoantibodies. EDTA-dependent pseudothrombocytopenia has rarely been reported in dogs, horses, and pigs.[31] Collection of blood in a citrate tube may clarify whether thrombocytopenia is due to EDTA;[68,84,117] however, aggregation can occur with citrate due to calcium chelation's role in the etiogenesis. Blood collection in fluoride oxalate tubes, or addition of amikacin or kanamycin, has been reported to resolve this pseudothrombocytopenia in humans.[68] Avoidance of delays in sample processing and low temperatures are practical measures to minimize clumping and hence pseudothrombocytopenia.[31]

Platelet satellitism can also contribute to falsely low platelet counts.[8,68] Platelets accumulate around neutrophils due to bridges formed by autoantibodies bound to platelet GPIIb–IIIa and neutrophilic FcγRIII receptors, usually in the presence of EDTA. This can rarely be seen with other leukocytes via unknown mechanisms.[8,68] Macrothrombocytosis may produce low platelet concentrations because large platelets are excluded by some automated hematology analyzers. Plateletcrit or manual platelet count may provide a more accurate platelet concentration.[54,125] Other causes of pseudothrombocytopenia include cold agglutinin disease and the therapeutic use of monoclonal antibodies in humans.[68] Pseudothrombocytopenia does not cause an increased bleeding tendency; however, the failure to recognize this artifact could lead to complications of unnecessary testing and treatment.

True Thrombocytopenia

Qualitative and quantitative data are available from a routine CBC to further characterize true thrombocytopenias. Increased numbers of macroplatelets on a blood smear suggest increased thrombopoiesis and may be associated with increased mean platelet volume (MPV). Increased MPV (exclusive of breed-related macrothrombocytopenia) suggests adequate to increased thrombopoiesis.[65] Decreased mean platelet component (MPC) suggests in vivo platelet activation. However, platelet volume indices have not been proven to help elucidate the pathophysiologic cause of thrombocytopenia.[11,102]

Test selection to define the cause of thrombocytopenia depends on clinical presentation and screening test results (see Chapter 78).[91] A complete hemostasis profile (prothrombin time [PT], activated partial thromboplastin time [APTT], fibrinogen concentration, fibrin degradation products [FDPs], D-dimer, and antithrombin activity) is used to characterize disseminated intravascular coagulation (DIC) (see Chapters 88 and 92). Examination of blood and cytology smears of bone marrow samples may reveal infectious organisms or neoplastic cells. Serology or PCR assays may identify infectious disease. Flow cytometry is used to detect immature reticulated platelets, platelet-surface-associated immunoglobulin (PSAIg), or activated platelets. Measurement of reticulated platelets may help differentiate thrombocytopenia due to shortened platelet survival from thrombocytopenia due to platelet production disorders.[29,129] Reticulated platelets were increased in dogs and horses with destructive or consumptive thrombocytopenia.[99,103] Identification of PSAIg may support a diagnosis of immune-mediated disease, but these assays do not differentiate primary from secondary immune-mediated thrombocytopenia (ITP).[129] Detection of activated platelets suggests prothrombotic states or DIC.[103]

Bone marrow examination aids in differentiating thrombocytopenia due to production disorders based on decreased or absent megakaryocytes.[94] Neoplastic cells or etiologic agents may be identified. Megakaryocytes are normal or increased if thrombocytopenia is due to platelet destruction or consumption. However, megakaryocytes can be unevenly distributed in bone marrow aspirates and core biopsies are often required for accurate assessment.[112] A study in thrombocytopenic dogs reported that bone marrow cytology rarely provided useful diagnostic or prognostic information, suggesting that bone marrow aspiration was most likely to be useful in refractory thrombocytopenia or patients with bicytopenia or pancytopenia.[77] Immunofluorescent antimegakaryocyte antibody assays can be performed on bone marrow cytology preparations; however, the sensitivity and specificity of these assays are low.[121]

BASIC MECHANISMS FOR THROMBOCYTOPENIA

Platelet Production Disorders

Decreased platelet production may result from disorders that specifically target megakaryocytes or from diseases that have direct effects on multiple hematopoietic cell lines, or by altering the microenvironment in the bone marrow (see Chapters 75 and 78). Bicytopenia or pancytopenia suggests bone marrow disease.[94]

Selective megakaryocytic hypoplasia is uncommon. Acquired immune-mediated amegakaryocytic thrombocytopenia has been reported in dogs and cats.[21] Megakaryocytic hypoplasia can be associated with drugs, infections, or neoplasia. Neoplasia may be metastatic to the bone marrow or hemic in origin, causing replacement of the normal hematopoietic cells. Other causes of hypoplasia include irradiation and myelonecrosis. Hereditary megakaryocytic hypoplasia is documented in people, but rarely reported in veterinary species.[82]

High-quality bone marrow samples are required to adequately assess bone marrow production. Due to variable megakaryocyte distribution within cytology samples, core biopsy samples are recommended for definitive diagnosis of megakaryocytic hypoplasia.[94]

Congenital or Breed-Associated Thrombocytopenia

Thrombocytopenia is an incidental finding in certain dog breeds (see Chapter 84). Greyhounds typically have a mild to moderate thrombocytopenia (platelet concentrations >100,000/μL) when compared to non-breed-specific reference intervals.[131] In one greyhound study, none of the samples tested had detectable PSAIg, indicating that the thrombocytopenia is not immune-mediated.[101] The stem cell competition theory is a possible mechanism, i.e., platelets and erythrocytes originate from a bipotential stem cell such that Greyhounds with high red cell concentrations have correspondingly lower platelet counts. Greyhounds also have relatively large spleens, suggesting that sequestration is a contributing factor.[54,131]

Canine hereditary macrothrombocytopenias due to mutations in the gene encoding beta-1-tubulin have been described in several breeds (see Chapter 84). These defects result in unstable microtubules and altered proplatelet formation. A common mutation has been identified in approximately 30–50% of the Cavalier King Charles spaniels screened.[23] The same mutation has been identified sporadically in Labrador retrievers, labradoodles, shih tzu, Chihuahua, Maltese, Jack Russell terriers, Havanese, poodles, English toy spaniels, boxers, cocker spaniels, and bichon frise, and a distinct beta-1-tubulin mutation has also been documented in Norfolk and Cairn terriers.[39] PennGen provides a searchable database of veterinary laboratories that offer genetic tests for these hereditary macrothrombocytopenias, and other hereditary disorders in dogs and cats.

Macroplatelets result in overlap in size between platelets and erythrocytes in automated analyzers. Consequently, plateletcrit may provide a more reliable estimator of platelet mass, since plateletcrits are typically within reference limits in macrothrombocytopenic patients versus those with true thrombocytopenia and normal platelet size.[125,127]

May–Hegglin anomaly is a rare congenital macrothrombocytopenia due to a mutation in the gene encoding nonmuscle myosin heavy chain IIA (*MYH9*). The trait is also characterized by neutrophil inclusions, and has been reported once in veterinary medicine in a pug mix (see Chapter 84).[36] Other inherited thrombocytopenias are likely present in veterinary species, since numerous mutations in various transcription factors involved in thrombopoiesis and the thrombopoietin receptor gene, *MPL*, have been identified in human hereditary thrombocytopenias.[82]

Platelet Loss

External hemorrhage may result in mild to moderate thrombocytopenia. Platelet concentration decreased by up to 50% in dogs with experimental acute, severe blood loss. Thrombocytopenia due to blood loss is usually self-limiting and resolves when hemorrhage ceases.[62] When severe thrombocytopenia occurs in conjunction with hemorrhage, it is likely that hemorrhage is due to thrombocytopenia rather than thrombocytopenia resulting from hemorrhage.

Dogs and cats presenting with severe hemorrhage due to anticoagulant rodenticide toxicity may have variable and potentially severe thrombocytopenia.[57,58,66,106] Likely mechanisms for thrombocytopenia include loss secondary to hemorrhage combined with platelet consumption.[106]

Platelet Consumption

Accelerated platelet consumption occurs with disorders that cause widespread damage to endothelial cells or trigger massive activation of coagulation via other mechanisms. In people, well-characterized platelet consumptive disorders include DIC, vasculitis, and thrombotic microangiopathies, such as thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) (see Chapter 93).[61]

Disseminated Intravascular Coagulation

DIC is common in veterinary species (see Chapter 92). Patients with DIC typically have laboratory abnormalities in coagulation and fibrinolytic pathways.[116] DIC is never a primary condition; it occurs secondary to a variety of disorders characterized by excessive and unregulated coagulation. DIC varies from overt or uncompensated to nonovert or compensated. In nonovert DIC, excess thrombin generation is balanced by inhibitory pathways. In overt DIC, widespread microthrombi formation may lead to consumption of coagulation factors and platelets, and result in bleeding. and bleeding. Clinical signs vary from subclinical in nonovert DIC to signs of severe, life-threatening hemorrhage, shock, or multiorgan failure in overt DIC. Clinical signs referable to the underlying condition are often present. The consequences of hemorrhage are easily recognized; however, clinical signs and death are often attributable to tissue hypoxia and organ dysfunction resulting from microthrombosis.[116]

Specific disorders associated with DIC include infections (e.g., septicemia, endotoxemia, leptospirosis), malignant neoplasia, severe tissue injury (e.g., trauma, surgery, burns), immune-mediated disorders (e.g., immune-mediated hemolytic anemia), conditions that cause blood stasis (e.g., shock, severe dehydration), heatstroke, systemic hypersensitivity reactions, pancreatitis, and hepatic failure.[6,16,41,116] Snake venoms may directly activate coagulation factors or induce DIC from tissue injury.[46]

Thrombocytopenia accompanying DIC varies from mild to severe. No single test is diagnostic for DIC (see Chapters 88 and 92).[42,116] Laboratory criteria include thrombocytopenia, coagulopathy (prolonged APTT or PT, hypofibrinogenemia), enhanced fibrinolysis (increased FDPs or D-dimer), loss of natural anticoagulants (e.g., decreased AT activity), and the presence of schistocytes or keratocytes on a blood smear.[42,71,116] Various veterinary scoring systems exist and a recent canine study suggested that applying

in-house coagulation assay reference intervals improved diagnosis and predictions of mortality from overt DIC.[42]

Thrombotic Microangiopathies

Thrombotic microangiopathies are uncommon, life-threatening conditions characterized by disseminated microvascular thromboses, secondary ischemic organ damage, microangiopathic hemolytic anemia with schistocytes, and thrombocytopenia (see Chapter 93). Unlike DIC, microangiopathies are rarely accompanied by abnormalities in coagulation and fibrinolysis assays. The underlying pathogenesis is heterogeneous, occurring secondary to hereditary and acquired disorders.[60]

HUS is often associated with renal insufficiency. The most common form in human beings occurs in children after infectious diarrhea, particularly involving Shiga-toxin-producing *Escherichia coli* (STEC).[60] Atypical forms of HUS in humans are associated with inherited or acquired defects in complement regulation, or following organ transplantation and cyclosporine therapy. Although rare, HUS has been described in dogs, cats, cattle, and horses.[3,25,28,49,96] Possible HUS was seen in three cats following renal transplantation and cyclosporine administration.[3] Ruminants are often the source of *E. coli* infections, but other domestic species, including dogs and cats, carry STEC and have been implicated in possible zoonotic transmission.[60] Cases of human HUS have also been documented secondary to infection with *Capnocytophaga canimorsus* from dog- or cat-bite wounds.[113,114]

TTP is characterized by frequent neurologic dysfunction, moderate severity renal insufficiency, and microthrombi rich in platelets and von Willebrand factor (VWF). Many human TTP cases are now believed to result from inherited or acquired deficiency of a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13), a metalloprotease that cleaves VWF and prevents circulation of the most thrombogenic, high-molecular-weight multimers of VWF (see Chapters 83 and 93).[113] TTP has not been well documented in veterinary species; however, there are murine and primate models of experimentally induced TTP. A human ELISA, recently validated for measuring canine ADAMTS13 activity, may facilitate recognition of TTP in dogs.[74]

Platelet Destruction

Immune-Mediated Platelet Destruction

ITP is common in dogs and sporadically recognized in other species (see Chapter 80).[29] ITP occurs secondary to antibody-mediated complement-induced platelet lysis or removal by the mononuclear phagocytic system (MPS). Direct T-cell-mediated cytotoxicity, impaired T regulatory cell activity, and impaired megakaryopoiesis and thrombopoiesis are also implicated in ITP pathogenesis.[109] In people with primary ITP, IgG or IgM autoantibodies targeting epitopes of glycoprotein complexes GPIIb/IIIa, GPV, and/or GPIb/IX are most common.[109] Autoantigens are rarely identified in animals with primary ITP; however, antibodies targeting GPIIb/IIIa and GPIb were detected in a canine study.[129] In secondary ITP, the immune response is associated with an underlying disorder such as systemic immune-mediated diseases (e.g., immune-mediated hemolytic anemia), neoplasia (e.g., lymphoma, hemic neoplasia, various solid tumors), drug administration, or infections.[29]

Nonimmune-Mediated Platelet Destruction

Nonimmune platelet destruction occurs in disorders that cause platelet aggregation, phagocytosis, or lysis independent of antibody or complement. Nonimmune platelet destruction is often a feature of thrombocytopenia due to infections, drugs, or neoplasia. Mechanisms include direct platelet damage causing lysis or premature removal, release platelet agonists, cytokine-mediated activation of the MPS leading to enhanced platelet phagocytosis, hemophagocytic syndrome, or phagocytosis by neoplastic cells.

Hemophagocytic Syndrome

Hemophagocytic syndrome, or lymphohistiocytosis, is characterized by a non-neoplastic proliferation of activated macrophages and lymphocytes and hypersecretion of cytokines.[2,47,50,85] It can be a primary disorder, e.g., due to a genetic defect in lymphocyte cytotoxicity, or an acquired disorder secondary to infectious, immune-mediated, neoplastic or metabolic disease.[92,105] Clinical signs include fever (interleukin-1-mediated), peripheral cytopenias (often anemia and thrombocytopenia, less commonly neutropenia), hepatosplenomegaly, hyperferritinemia, hypoalbuminemia, hypofibrinogenemia, and often increased liver enzymes.[85] The cytopenias result from combined cytokine-mediated bone marrow suppression and phagocytosis. Hypertriglyceridemia is seen in humans (particularly children), presumably mediated by increased acute phase proteins, such as serum amyloid A, that enhance low density lipoprotein (LDL) removal from the circulation. Hypocholesterolemia, attributed to increased uptake or use of cholesterol, is more common in veterinary patients. Additionally, inflammatory cytokines can reduce lipoprotein lipase activity, thereby decreasing conversion of very low density lipoprotein (VLDL) to LDL and lowering cholesterol through decreased lipoproteins and cholesterol content.[79] Signs of hemophagocytic syndrome overlap with diagnostic criteria for several other disease states including systemic inflammatory response syndrome, viral infections, and neoplasia. In humans, the diagnosis is based on the presence of at least five out of eight criteria established by the Histiocyte Society.[34,47] Hemophagocytosis may be apparent in bone marrow, spleen, and/or lymph node samples, and serial sampling may be required to identify this phenomenon. Documentation of hemophagocytosis is not required for diagnosis in humans if other criteria are fulfilled, and hemophagocytosis is not pathognomonic.

Hemophagocytic syndrome can be mild to fatal. Several distinct disease genes have been associated with primary hemophagocytic lymphohistiocytosis (HLH) in humans and in mouse models. All are involved in the production or release of cytotoxic granules from T lymphocytes, including a mutation in the gene encoding perforin.[92,105] Chronic inflammation is suspected to play a role in inciting the acquired syndrome, with associated immune disorders in humans including lupus and systemic juvenile idiopathic arthritis.[92,105] Lymphoma (primarily T cell, but also B cell) is a common neoplastic trigger, presumably mediated by persistent antigenic stimulation and cytokine release by the neoplastic cells. Infectious diseases associated with HLH include leishmaniasis, tuberculosis, and salmonellosis. An underlying condition is not always identified. In veterinary patients, the major diagnostic dilemma is differentiating this syndrome cytologically from histiocytic sarcoma or forms of T-cell lymphoma.[1,78] Immunohistochemistry on fresh frozen tissue can aid in definitive diagnosis of neoplasia, but its availability is limited. Flow cytometry may also help differentiate HLH from lymphoma; however, clinical differentiation is often based on response to therapy.

Platelet Distribution Disorders

Total platelet mass consists of platelets in circulation and platelets reversibly sequestered or marginated in the vasculature of tissues, particularly the spleen, liver, and bone marrow. In healthy animals, 30% or more of total platelet mass may be stored in the spleen.[128] Redistribution thrombocytopenia refers to reversible platelet sequestration in tissues. Total platelet mass is not affected; thus, thrombopoiesis is not influenced. Platelet pooling has been reported in the liver and spleen of dogs with hypothermia and in the lungs of endotoxemic dogs.[115,130] Mild to moderate thrombocytopenia may result from sequestration in any condition associated with hepatosplenomegaly and increased blood pooling. For example, resolution of thrombocytopenia has been reported in dogs with splenic torsion after surgical correction.[118]

Hypersplenism, resulting in cytopenias, may occur in patients with portosystemic shunting, even in the absence of splenomegaly.[14,70] The condition recurs following splenectomy, which can also increase the risk of portal vein thrombosis. In spite of cytopenias, hypersplenism is often clinically inapparent.[14] Hypersplenism was recently described in a miniature horse with pancytopenia, but the histopathologic description of the spleen was more consistent with a diagnosis of hemophagocytic syndrome. The differentiation of these syndromes is challenging, as increased macrophage activation has been described as a component of hypersplenism.[24,97]

Platelet sequestration is not expected to cause signs of hemorrhage, unless complicated by platelet dysfunction or coagulopathy. Diagnosis of redistribution thrombocytopenia relies on discovery of the cause of organomegaly and ruling out other causes of thrombocytopenia.

DISEASE CATEGORIES OF THROMBOCYTOPENIA

Thrombocytopenia in veterinary species is frequently associated with infection, neoplasia, drug therapy, and liver disease.[30,45,51,104] The pathogenesis of thrombocytopenia in many of these disorders is likely multifactorial.

Infectious Thrombocytopenia

Thrombocytopenia frequently accompanies infections (see Table 81.2).[26,30,45,51,104] Many organisms impair thrombopoiesis by direct infection of bone marrow megakaryocytes, stimulation of an immune response targeting megakaryocytes, or inciting bone marrow inflammation and production of myelosuppressive cytokines. Additional pathophysiologic mechanisms may include increased platelet consumption due to platelet activation and clearance, DIC, direct infection of platelets causing destruction or removal by the MPS, secondary ITP, or platelet sequestration in the spleen or other tissues.[26,37]

Endotoxemia and inflammatory cytokines elicited by bacterial infections may directly activate endothelial cells, neutrophils, monocytes, and platelets. These activated cells upregulate production and release of platelet agonists, including thrombin and platelet-activating factor. Activated platelets in turn promote tissue factor expression by monocytes, activation of the coagulation cascade, and, via expression of P selectin, induce platelet–leukocyte aggregates.[26,63] Damaged endothelial cells decrease production of inhibitory substances such as prostaglandin I_2. Inflammatory cytokines activate the MPS leading to platelet phagocytosis.[63]

Rickettsial bacteria are commonly associated with thrombocytopenia.[80] Acute infection with *Ehrlichia canis* is associated with ITP and nonimmune platelet destruction in dogs. Chronic infection is associated with bone marrow hypoplasia. Dogs experimentally infected with *E. canis* demonstrated thrombocytopenia, platelet activation, and antiplatelet antibodies, and were hypercoagulable and hypofibrinolytic. Platelet activation and hypercoagulability may explain lack of overt bleeding in some profoundly thrombocytopenic dogs.[110] Other rickettsial bacteria associated with thrombocytopenia include *Anaplasma platys* in dogs, *Rickettsia rickettsii* in dogs, *Neorickettsia risticii* in horses, and *Anaplasma phagocytophilum* in several species. *A. phagocytophilum*, the cause of granulocytic anaplasmosis (granulocytic ehrlichiosis), directly infects megakaryocytes without altering platelet production, but may evoke an antiplatelet immune response.[57 and 58] The pathogenesis of thrombocytopenia in *A. platys* infection is suspected to be direct injury to platelets by replicating organisms, and to formation of antiplatelet antibodies.[124] Vasculitis and platelet consumption may result in thrombocytopenia in *R. rickettsii* infection. The cause of thrombocytopenia in *N. risticii* infection in horses likely involves consumption due to DIC.[33] Other

TABLE 81.2 Causes of thrombocytopenia in dogs, cats, horses, and cattle.

Species	Category	Specific examples
Dog	Infectious	Viruses: distemper, herpes virus, infectious hepatitis, parvovirus, SFTSV Bacteria: septicemia, endotoxemia, *Anaplasma phagocytophilum*, *A. platys*, *Ehrlichia canis*, *Rickettsia rickettsii*, leptospirosis, salmonellosis, bartonellosis, borreliosis Fungi: histoplasmosis, candidiasis Protozoa: babesiosis, leishmaniasis Parasites: heartworm disease
	Neoplasia	Hemangiosarcoma, lymphoproliferative and myeloproliferative neoplasia, various solid tissue neoplasms
	Drugs/toxins	Antibiotics (e.g., sulfonamides, cephalosporin), chemotherapeutic drugs (e.g., cyclophosphamide, doxorubicin), anti-inflammatory drugs (e.g., phenylbutazone, carprofen), phenobarbital, thiacetarsamide, estrogen, snakebites
	Miscellaneous	ITP, DIC, distribution disorders
Cat	Infectious	Viruses: FeLV, FIV, FIP, parvovirus Bacteria: septicemia, endotoxemia, *A. phagocytophilum*, *Mycoplasma* sp., salmonellosis, bartonellosis Fungi: histoplasmosis Protozoa: cytauxzoonosis, toxoplasmosis Parasites: heartworm disease
	Neoplasia	Lymphoproliferative and myeloproliferative neoplasia, various solid tissue neoplasms
	Drugs/toxins	Chemotherapeutic drugs, griseofulvin, methimazole, propylthiouracil
	Miscellaneous	ITP, DIC, distribution disorders
Horse	Infectious	Viruses: EIA, EVA, VEE Bacteria: septicemia, endotoxemia, *A. phagocytophilum*, *Neorickettsia risticii*, salmonellosis
	Neoplasia	Lymphoproliferative and myeloproliferative neoplasia, various solid tissue neoplasms
	Drugs/toxins	Phenylbutazone, trimethoprim, penicillin, trichothecene mycotoxin, snakebites
	Miscellaneous	ITP, neonatal alloimmune thrombocytopenia, DIC, gastrointestinal disorders, distribution disorders
Cattle	Infectious	Viruses: BVD Bacteria: septic metritis/mastitis, septicemia, endotoxemia, salmonellosis Protozoa: babesiosis, theileriosis
	Drugs/toxins	Bracken fern toxicity, trichothecene mycotoxin
	Miscellaneous	ITP, DIC, distribution disorders, displaced abomasums

bacterial infections (e.g., leptospirosis, salmonellosis, borreliosis, bartonellosis) are sporadically associated with thrombocytopenia.[56,88]

Sepsis-associated thrombocytopenia is a marker of disease severity and a prognostic indicator; thus, platelet counts are included in human sepsis scoring systems.[26,63] The role of platelets in sepsis and the mechanisms that cause thrombocytopenia are not fully elucidated. Platelets participate in innate immunity and can internalize bacteria and viruses; however, whether this helps control infection or facilitates spread is unclear.[63] Thrombopoiesis appears to be upregulated during sepsis as evidenced by increased TPO and reticulated platelets.[63] Platelet activation mediated by endotoxin signaling through platelet and inflammatory cell toll-like receptors may lead to increased platelet consumption. Platelets also accumulate in the liver during sepsis and are subject to hemophagocytosis.

Viral infections are well-recognized causes of thrombocytopenia in animals. In dogs, thrombocytopenia occurs with canine distemper virus (CDV), herpes virus, infectious hepatitis, and parvovirus infection. Thrombocytopenia in CDV infection results from viral damage to platelets, secondary ITP, and decreased production due to infection of megakaryocytes.[4] Thrombocytopenia associated with herpes virus or infectious hepatitis virus infection results from endothelial damage and DIC.[119] In cats, thrombocytopenia is associated with feline infectious peritonitis (FIP), feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and parvovirus infection.[30] Thrombocytopenia in FIP is multifactorial and results from vasculitis, secondary ITP, direct viral damage to platelets, and DIC.[13] In horses, thrombocytopenia occurs with equine infectious anemia (EIA), equine viral arteritis (EVA), and Venezuelan equine encephalitis (VEE) virus infection.[104] Thrombocytopenia in EIA results from cytokine-mediated impairment of platelet production, secondary ITP, and nonimmune platelet destruction.[98] In cattle, thrombocytopenia is associated with bovine viral diarrhea (BVD) virus and primarily results from megakaryocyte damage and decreased thrombopoiesis, combined with peripheral

platelet consumption.[9,20] In pigs, thrombocytopenia follows infection with African swine fever or classical swine fever. In classical swine fever, thrombocytopenia likely results from increased vascular permeability, direct damage to platelets, platelet activation, impaired megakaryopoiesis, and platelet removal mediated by increased cytokine production due to MPS infection.[10,100] A new tick-borne virus, severe fever with thrombocytopenia syndrome virus (SFTSV), has been reported in Asia (particularly China). Clinical signs in humans include fever, gastrointestinal (GI) signs, dyspnea, hemorrhage, neurologic signs, lymphadenopathy, leukopenia, and thrombocytopenia.[120] The virus is carried by *Haemaphysalis longicornis* ticks and is a member of the *Bunyaviridae* family.[69] The SFTSV is zoonotic, infecting domestic and wild animals, and birds are suspected to spread the virus.[52]

Other agents associated with thrombocytopenia include protozoa (e.g., babesiosis, cytauxzoonosis, leishmaniasis, theileriosis, and toxoplasmosis), fungi (e.g., disseminated candidiasis, histoplasmosis), and metazoan parasites (e.g., heartworm infection in dogs and cats). Babesiosis often causes profound thrombocytopenia. Surprisingly, overt hemorrhage is uncommon, likely due to increased platelet activation, and thrombocytopenia is unrelated to survival.[40] Increased MPV has been observed in dogs infected with *Babesia spp*. Thrombocytopenia may involve immune-mediated platelet destruction, splenic sequestration, and DIC.[38]

Thrombocytopenia secondary to infection varies from mild to severe. Diagnostic tests include direct pathogen identification from microscopic examination of blood, bone marrow, or cytology smears, molecular techniques, via culture, or serology.

Drug-Induced Thrombocytopenia

Thrombocytopenia may follow exposure to drugs or toxins; however, confirmation of causation is difficult (see Chapters 15 and 80).[18] Drugs associated with thrombocytopenia in veterinary species are listed in Table 81.2. Decreased platelet production and increased platelet clearance, via immune-mediated and nonimmune-mediated processes, may cause drug-related thrombocytopenia. Chemotherapeutic drugs, including antimetabolites and alkylating agents, cause dose-dependent, predictable myelosuppression leading to pancytopenia. Chemotherapeutic-induced thrombocytopenia is usually transient and resolves after drug withdrawal or dosage adjustment; however, overdosage may result in irreversible bone marrow damage.[48] Other drugs (e.g., potentiated sulfonamides) are associated with idiosyncratic and unpredictable thrombocytopenia. Some drugs increase platelet clearance via nonimmune mechanisms such as macrophage or growth-factor-mediated endothelial activation.[18]

Drug-dependent antibodies may induce thrombocytopenia by targeting platelets and/or megakaryocytes, or by causing ADAMTS13 deficiency and resultant VWF-mediated platelet-rich thrombus formation.[18] Additionally, platelet apoptosis may play a role.[111] Pathologic antibodies may bind to a drug or metabolite adsorbed to the platelet membrane, a drug–platelet antigen complex, or a hidden antigen newly exposed on the platelet membrane. The MPS then clears platelets with bound antibody. Rarely, drug-independent ITP persists after drug withdrawal. PSAIg has been detected in dogs following administration of sulfonamides and in horses following administration of trimethoprim and penicillin.[64,76] Heparin-induced thrombocytopenia is characterized by large vessel thrombosis and thrombocytopenia. The pathogenesis involves antiplatelet factor 4/heparin antibodies; however, the syndrome has not been described in veterinary patients.[44]

Some drugs directly activate platelets causing increased consumption, or injure platelets causing removal by the MPS. Snake venoms may directly aggregate platelets, interact with platelet glycoproteins, induce thrombin-like substances that cause platelet aggregation, or result in platelet sequestration at sites of envenomation.[46]

Diagnosis of drug-associated thrombocytopenia generally relies on a history of drug exposure and normalization of platelet concentration (usually within 1–2 weeks) following cessation of drug therapy.

Neoplasia-Associated Thrombocytopenia

Thrombocytopenia is commonly associated with neoplasia.[17] A large study of thrombocytopenic dogs reported a 20.8% incidence of neoplasia,[12] with similar incidence in thrombocytopenic cats.[30] Common tumor types include lymphoma, carcinoma, hemangiosarcoma, and other hematopoietic neoplasia. Thrombocytopenia is frequently multifactorial; secondary to chemotherapy, decreased platelet production, or DIC.[67,122] Chemotherapeutic drugs cause thrombocytopenia via megakaryocyte toxicity, promoting immune-mediated destruction, splenic sequestration, and via thrombotic microangiopathy. Inadvertent bone marrow irradiation may also cause thrombocytopenia.[90]

In addition to chemotherapy, decreased platelet production may result from myelophthisis, secretion of estrogen by neoplastic cells, and bone marrow infiltration by hematologic neoplasia. Solid tumor infiltrates are less common, but may be seen with prostatic, mammary, pulmonary, and gastric tumors. The presence of splenic extramedullary hematopoiesis may give clues of underlying bone marrow disease due to rubricytosis and other morphologic changes in the peripheral blood, e.g., ovalocytes.[90] Neoplastic processes that cause significant hepatosplenomegaly, e.g., lymphoma, mast cell neoplasia, hemangiosarcoma, can result in platelet sequestration.[17] Thrombocytopenia secondary to DIC frequently complicates neoplasia. In one study, over 10% of dogs with malignant neoplasia had DIC, particularly hemangiosarcoma, mammary carcinoma, and pulmonary adenocarcinoma.[75] Neoplasia is the most commonly recognized cause of DIC in cats.[32]

Secondary ITP may cause thrombocytopenia in hemic and nonhemic neoplastic disorders. In humans, ITP is most commonly associated with lymphoproliferative diseases such as Hodgkin's lymphoma, large granular

leukemia, and chronic lymphocytic leukemia.[90] Other proposed mechanisms for neoplasia-induced thrombocytopenia include distribution disorders with platelet pooling (particularly with large vascular tumors such as hemangiosarcoma), platelet loss with tumor-associated hemorrhage, or platelet destruction by neoplastic cells. Thrombocytopenia was identified in 88% of dogs with hemophagocytic histiocytic sarcoma, presumably mediated by platelet phagocytosis by neoplastic cells.[79]

Clinical signs of neoplasia-induced thrombocytopenia are related to the underlying neoplasm, with variable hemorrhage. Diagnosis is based upon cytologic or histopathologic confirmation of neoplasia. Severe thrombocytopenia may influence treatment; however, a recent study demonstrated no increase in hemorrhagic complications in thrombocytopenic veterinary patients administered standard chemotherapy doses.[35]

Liver-Disease-Associated Thrombocytopenia

Thrombocytopenia of multifactorial causes is common in humans and animals with chronic and acute liver disease.[87] Severity of thrombocytopenia may have prognostic significance.[107] Proposed mechanisms include portal hypertension and splenomegaly with platelet sequestration, decreased TPO synthesis, and secondary ITP, particularly with viral hepatopathies. Thrombocytopenia can complicate diagnosis and treatment of liver disease. One study in dogs and cats showed that a platelet count less than 80,000/L was a significant risk factor for complications of percutaneous ultrasound guided biopsy,[7] and another study found that platelet count less than 150,000/L was associated with transfusion and open laparotomy in dogs undergoing laparoscopic liver biopsy.[89] In addition to platelet transfusion (see Chapter 86), treatment options in people include recombinant cytokines and TPO receptor agonists.[87]

Dilutional Thrombocytopenia

Dilutional thrombocytopenia has been reported in humans after major surgery or following massive transfusion, and in dogs following massive transfusion. In a study of 15 dogs that received either half of their estimated blood volume within 3 hours, or more than their total blood volume in 24 hours, all developed moderate thrombocytopenia (many had mild thrombocytopenia prior to transfusion) and electrolyte, acid base, and coagulation changes.[62] Thrombocytopenia in these cases likely results from transfusion of stored blood products devoid of platelets, large volume crystalloid administration, and platelet consumption due to the underlying disease process.[62]

Gestational Thrombocytopenia

Gestational thrombocytopenia occurs in 11.6% of human pregnancies and is usually mild, with minimal consequences for mother or child. However, platelet counts <100,000/L are associated with a higher incidence of neonatal thrombocytopenia and risk of recurrence in future pregnancies. The causes of thrombocytopenia may include hemodilution and increased platelet clearance.[19] Gestational thrombocytopenia is rare in animals, with reports limited to mice and cows,[123] and transient thrombocytopenia in a rabbit following amniotic fluid embolization in the absence of DIC.[93]

Consequences of Thrombocytosis

Acronyms and Abbreviations

CALR, calreticulin; CML, chronic myeloid leukemia; CMPD, chronic myeloproliferative disease; ET, essential thrombocythemia; GM-CSF, granulocyte–monocyte colony-stimulating factor; IDA, iron deficiency anemia; IL, interleukin; JAK2, janus kinase 2; MDS, myelodysplastic syndrome; MPL, myeloproliferative leukemia protein; MPN, myeloproliferative neoplasm; MPV, mean platelet volume; PCT, plateletcrit; PDW, platelet distribution width; PMF, primary myelofibrosis; PV, polycythemia vera; PVSG, Polycythemia Vera Study Group; SD, standard deviation; TPO, thrombopoietin; WHO, World Health Organization.

INTRODUCTION

Thrombocytosis, or thrombocythemia, is specifically defined as a high platelet count above the reference interval established for a given species. The methods available for measuring platelet count include estimates from stained peripheral blood smears, manual hemocytometer counts, quantitative buffy coat analysis, and automated methods based on impedance or laser-induced light scatter. Methods vary in precision and accuracy and the same sample may yield different values using different methods.[18,51,73] Therefore, most veterinary laboratories establish reference intervals specific for their own equipment for routinely analyzed species. Interpretation of platelet count is more difficult for species lacking laboratory-defined intervals. Knowledge of the normal physiology of the animal, combined with published reference intervals, can be used as a guide to result interpretation. Platelet counts in healthy animals vary markedly between species. Small rodents have relatively high counts, whereas horses have relatively low counts such that a normal platelet count in a mouse would be regarded as extreme thrombocytosis in a horse. The criteria for classifying thrombocytosis vary among clinical reports, making assessment of the frequency of the condition challenging. One review in dogs defined thrombocytosis as a platelet count >600 × $10^3/\mu L$,[47] whereas other studies categorized >500 × $10^3/\mu L$[4,91] as a thrombocytosis, with reported incidence ranging from 4.6–7.2%.[4,47,91] However, counts can be misleading as platelet mass (size × volume) may be a more clinically relevant indicator of hemostatic function, and platelet counts and platelet size often vary inversely. For example, Cavalier King Charles spaniels with breed-related macrothrombocytopenia have low platelet counts but normal platelet mass due to the large size of their platelets. As a result, assessment of plateletcrit (PCT) may be a more accurate method to assess platelet mass.[84]

Pseudohyperkalemia is an in vitro artifact of thrombocytosis that may develop in serum samples due to release of intracellular potassium during clotting.[19,40,57]

Potassium concentrations can be 0.6 ± 0.2 mEq/L (mean ± SD) higher in serum than plasma in dogs with platelet counts between 150 and 600 × 10^3/μL. This difference increases (1.6 ± 0.76 mEq/L) in dogs with higher counts (>600 × 10^3/μL) and can be quite marked (up to 5 mEq/L) in dogs with extreme thrombocytosis (>1000 × 10^3 platelets/μL).[19,40,58] To avoid this artifact, heparinized plasma is the preferred sample for potassium measurement.

Thrombocytosis may represent an artifact (pseudothrombocytosis), or physiologic thrombocytosis due to altered trafficking of platelets (i.e., release from storage pools) or increased platelet production (enhanced thrombopoiesis). Enhanced thrombopoiesis can be a secondary or reactive process, due to an increase in thrombopoietic factors from an underlying disease, or a primary disorder (Table 82.1).

TABLE 82.1 Causes and associated mechanisms of thrombocytosis.

Cause	Mechanism
Pseudothrombocytosis	
Red blood cell ghosts or fragments, fragile leukocytes, microorganisms, or lipemia	Nonplatelet cell fragments or particles counted as platelets
Physiologic	
Epinephrine (trauma, exercise, excitement)	Splenic contraction
Postsplenectomy	Lack of sequestration
Reactive	
Inflammation, infection, hematopoietic and nonhematopoietic neoplasia, trauma, rebound from thrombocytopenia, postsplenectomy	Cytokine-mediated—directly or indirectly through TPO production. Enhanced megakaryopoiesis
Iron-deficiency-related	Unknown
Drug-induced, e.g., vincristine, epinephrine	Drug-dependent: vincristine increases megakaryopoiesis and megakaryocyte fragmentation, whereas epinephrine causes splenic contraction
Primary	
Chronic myeloproliferative disease: Essential thrombocythemia, chronic myeloid leukemia, chronic basophilic leukemia, polycythemia vera, primary myelofibrosis	Acquired or inherited genetic mutations causing TPO-independent proliferation, e.g., JAK2 signaling mutations
Acute megakaryocytic leukemia	Acquired or inherited mutations
Hereditary/familial[a]	Common disease genes: *JAK2*, *CALR*, *MPL*, *THPO*, *TET2*

[a] Not reported in animals.

To understand the pathophysiology of thrombocytosis, the factors governing thrombopoiesis are briefly reviewed in the following text.

THROMBOPOIESIS: OVERVIEW

Platelets are produced from megakaryocytes in the bone marrow in adult animals by a unique process that involves fragmentation of long cytoplasmic extensions (proplatelets) that the megakaryocyte inserts between bone marrow sinusoidal endothelial cells[29,30] (see Chapters 75 and 78). In adult mice, the spleen is the primary platelet-producing organ and there is evidence that the lung may play a role in platelet synthesis, particularly in states of thrombocytopenia or relative marrow stem cell deficiency in murine models.[36] Megakaryocytes are formed from progenitor cells derived from hematopoietic stem cells. Megakaryocytes undergo endomitosis to become polyploid before maturing and packaging their contents into proplatelets.[27] Recent studies suggest that megakaryocytes at all stages of development are distributed throughout the bone marrow and most reside adjacent to vessels.[71] Platelets can also be released via rupture of mature megakaryocyte membranes if there is an acute demand or inflammation. The latter appears to be mediated by interleukin (IL)-1α.[48] It has been estimated that approximately 2000–3000 platelets are produced from each megakaryocyte, with the residual megakaryocyte nucleus degraded by phagocytes within the bone marrow.[27]

Thrombopoietin (TPO) is the main thrombopoietic hormone, produced primarily in the liver and kidney. Genetically engineered mice deficient in TPO or its receptor, MPL (product of myeloproliferative leukemia virus oncogene, *c-Mpl*), have platelet counts 10–15% of normal, supporting the presence of additional thrombopoietic factors.[29–31] Thrombopoietin binds to MPL to mediate downstream responses through the nonreceptor tyrosine kinase, janus kinase 2 (JAK2), which in turn activates the transcription factors, signal transducer and activator of transcription (STAT)3 and STAT5.[28] Signal transduction also occurs through Ras and Akt pathways.[29] The thrombopoietin receptor, MPL, is highly expressed on megakaryocytes and platelets, but is also expressed on other cell types, including hematopoietic stem cells. Other transcription factors, including GATA-1, RUNX1 and PU.1, are also involved in megakaryopoiesis.[20,41,81] Thrombopoietin mainly acts as a differentiation factor, stimulating stem cells to differentiate along the megakaryocytic lineage. It acts in concert (additively or synergistically) with other hematopoietic cytokines, including stem cell factor, IL-3, and erythropoietin, to promote megakaryocyte proliferation and polyploidy. Serum TPO levels are thought to be regulated by binding to MPL on platelets, with subsequent internalization and degradation. In a process referred to as the "sponge theory,"[39,70] circulating TPO levels are low in patients with thrombocytosis due to its binding

and internalization by high platelet mass. Conversely, thrombocytopenia results in relatively little TPO removal because of the few platelets in the blood.[33,70] Interleukin-6 can increase hepatic TPO production as does binding of senescent platelets to the Ashwell–Morell receptor on hepatocytes.[29] Insulin-like growth factor-1 can facilitate thrombopoiesis by promoting hematopoietic stem cell expansion, megakaryocyte differentiation, proplatelet formation, and platelet release mainly through activation of the Akt signaling pathway. The latter seems to be independent of TPO signaling, and requires the help of steroid receptor coactivator-3.[16] Growth hormone also seems to play a role in regulating late-stage thrombopoiesis. Additionally, microRNAs can affect megakaryocyte differentiation, particularly miR-28 and miR-180.[83]

The precise mechanisms controlling platelet release from proplatelets remain under investigation; however, this process involves adhesion of megakaryocytes to subendothelial matrix components (particularly fibronectin and thrombospondin), cytoskeletal elements (actin, microtubules), matrix metalloproteinases, and shear forces (which facilitate proplatelet fragmentation) (see Chapter 78).[39] By contrast, type I collagen seems to suppress proplatelet production.[39] The role of the bone marrow microenvironment is therefore extremely important. Stromal cell-derived factor-1, also known as chemokine 12, is considered vital for attracting megakaryocytes and other hematopoietic cells and stimulating their growth.[38] Other important thrombopoietic cytokines include the IL-6 superfamily members (IL-6, IL-11, leukemia inhibitory factor), granulocyte–monocyte colony-stimulating factor (GM-CSF), IL-1α, IL-3, and IL-12.[28] von Willebrand factor bound to GPIb/V/IX receptor seems to influence proplatelet formation.[81] Apoptosis has been speculated to play a role in platelet formation and activation;[13] however, recent studies have shown that the intrinsic apoptotic pathway and caspase-9 do not seem to be important.[90] Casein kinase 2 has been detected in platelets and megakaryocytes and is required for megakaryopoiesis and calcium-triggered platelet activation.[41,88] The final stages of platelet production appear to be TPO-independent and in vitro withdrawal of TPO is reported to stimulate proplatelet formation.

Alterations in any of the numerous factors that affect thrombopoiesis can therefore lead to thrombocytosis, including increased concentrations of thrombopoietic cytokines, ligand-independent MPL activation, and abnormal activation of the JAK2/STAT and PI3K–Akt signaling pathways.

CAUSES OF THROMBOCYTOSIS

Pseudothrombocytosis

Pseudothrombocytosis occurs if small, fragmented, or hemolyzed erythrocytes, leukocyte fragments (from normal or leukemic cells), or particulate cellular debris including bacteria, protozoa, fungi, cryoglobulin, or lipids are erroneously counted as platelets (Figure 82.1).[21,43,92] In humans, Howell–Jolly bodies and erythrocyte Pappenheimer bodies (iron inclusions) have been misidentified as platelets with older hematology analyzers.[43,92] Hemolysis can produce ghost cells, which are erroneously enumerated as platelets, as reported for equine blood stored at 4 °C.[17] Although this artifact can be analyzer-dependent, it can potentially occur with any automated method. Thus, it is important to always verify platelet counts by estimating numbers from stained blood smears. Although estimates are of questionable accuracy,[51] smear examination can quickly confirm an increased platelet count, identify morphologic defects in platelets, and potentially reveal abnormalities that may cause pseudothrombocytosis.

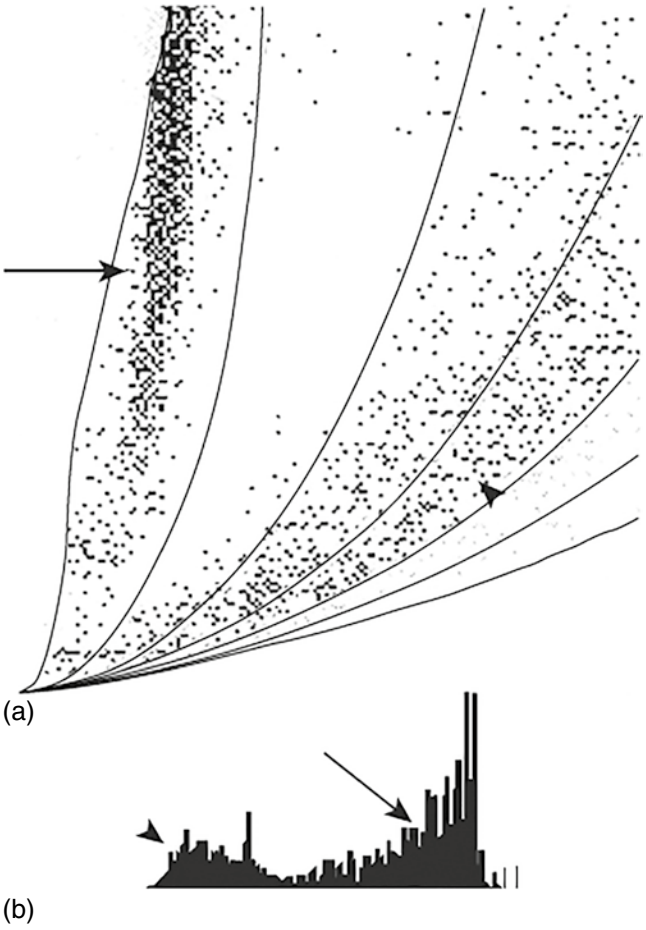

FIGURE 82.1 Pseudothrombocytosis in a hemolyzed sample from a dog with immune-mediated hemolytic anemia. (a) Hemolyzed red blood cells (arrow) are the events entering the upper left portion of the platelet cytogram (forward scatter versus side scatter dotplot) and are counted as platelets on ADVIA hematology analyzers (laser-light-scatter-based system); (b) The hemolyzed erythrocytes can also be visualized as a second population of macrocytic cells (arrow) in the platelet histogram (cell number versus cell volume) and will falsely increase the mean platelet volume (MPV) and platelet distribution width (PDW). The "true" platelet clusters are identified by the arrowhead in both cytograms. (Sources: Frotscher et al. [21]; Van Der Meer et al. [43]; Zandecki et al.[92])

Physiologic Thrombocytosis

Up to one-third of platelets are normally sequestered in the splenic red pulp.[87] These stores can be released upon splenic contraction mediated by epinephrine, although the effects in dogs are variable.[50] A transient or persistent thrombocytosis may occur postsplenectomy in humans,[35] and this has been described as an inconsistent finding in dogs for several months following splenectomy.[59] Some authors have also suggested the presence of an adrenaline-responsive, marginated platelet pool in the lungs, although this pool is likely small.[83]

Reactive Thrombocytosis

Reactive thrombocytosis (or secondary thrombocytosis) is due to cytokine stimulation of thrombopoiesis. It is the most common cause of thrombocytosis in humans and animals and occurs secondary to various disorders (Table 82.1).[4,47,61,68,69,91] Thrombocytosis in humans is typically asymptomatic. In a study of 890 adult subjects, 94% had reactive thrombocytosis of which over 50% were attributed to an infectious cause.[60] Several retrospective studies in dogs have shown that inflammation and neoplasia are the most common diseases associated with thrombocytosis, although different platelet count thresholds defined thrombocytosis in these studies.[4,47,91] Carcinoma is the most commonly associated tumor, closely followed by lymphoma. For patients with lymphoma, however, the waters are often muddied by the use of therapeutic agents such as corticosteroids and vincristine that may also contribute to thrombocytosis (see later section on drugs).[91] The platelet count can also rebound following treatment of any tumor with chemotherapeutic drugs. Drug effects may also be seen with immune-mediated disorders (the most common inflammatory disease associated with thrombocytosis in a number of studies) where corticosteroids are often used for therapy. A study of thrombocytosis in horses revealed infectious or inflammatory diseases, such as primary bacterial infection (peritonitis, pleuropneumonia, septic arthritis) and colitis, predominating as the underlying cause.[69] A retrospective study of thrombocytosis in 50 cats (defined as platelet counts greater than >700 × 10^9/L) again revealed that infection or inflammation were the most common diseases associated with reactive thrombocytosis, with the gastrointestinal tract and endocrine system being the most common organ systems affected.[61]

Paraneoplastic thrombocytosis has been seen with a variety of tumors, particularly solid tumors, such as human ovarian carcinoma.[37,56,89] Thrombocytosis can serve as a biomarker for cancer, sometimes appearing before the tumor is evident.[67] Tumors can increase TPO production, often via cytokines such as IL-6, leading to increased platelet production. Tumors may "hijack" platelet functions to promote progression and metastasis. Platelets can help neoplastic cells evade the immune system by coating circulating tumor cells; some tumor cells even mimic platelets by displaying similar markers.[82] Platelet-derived factors aid extravasation and transmigration of tumor cells and facilitate angiogenesis.[56] Studies in humans have shown that cancer patients with higher platelet counts had higher IL-6 and TPO levels and shorter progression-free survival times.[10,37,56] Therefore, current research is focusing on whether reducing platelet counts or inhibiting their function could block platelet-associated carcinogenesis. Patients taking aspirin for cardiovascular disease have a decreased risk of cancer metastasis;[64] however, more studies are needed into the role of platelets in neoplastic diseases.

Depending on the underlying cause, reactive thrombocytosis can be transient or persistent, so documenting a thrombocytosis more than once (particularly if done less than 1–2 months apart) does not exclude a reactive condition. In addition, the increase in platelet count can be quite marked in reactive conditions (>1000 × 10^3/μL) (Figure 82.2).

A plethora of cytokines are potentially responsible for reactive thrombocytosis, including TPO, IL-6, GM-CSF, IL-3, IL-11, and erythropoietin.[1] High cytokine levels may result from constitutive secretion by tumors or upregulation triggered by inflammation, infection, or neoplasia. The inflammatory cytokine IL-6 is considered one of the main mediators of reactive thrombocytosis. Concentrations of IL-6 levels are increased in patients with thrombocytosis due to inflammation and neoplasia and persistently high levels are supportive of reactive thrombocytosis.[77] IL-6 is thought to stimulate platelet

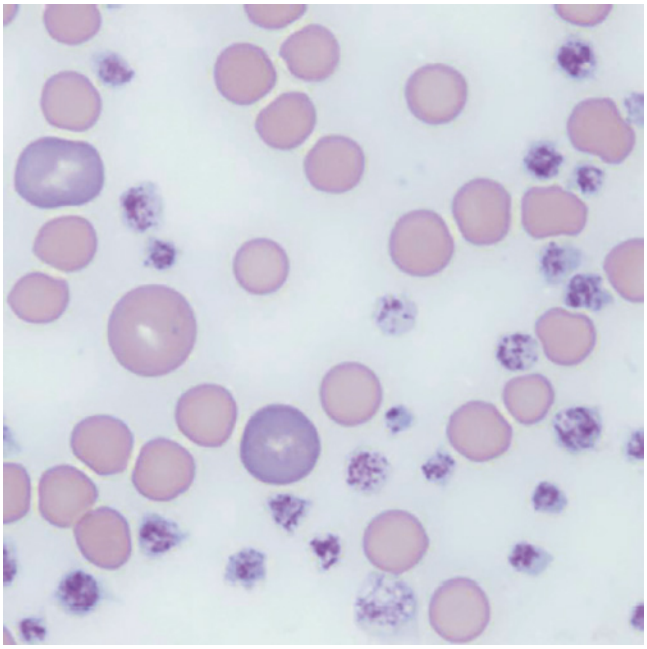

FIGURE 82.2 Peripheral blood smear from a 12-week-old kitten with iron deficiency anemia secondary to flea infestation. Many platelets, which vary markedly in size, are seen in the smear. The kitten had an extreme thrombocytosis (platelet count = 1900 × 10^3/μL), which was presumably reactive. Modified Wright's stain; 1000× magnification. (Source: Courtesy of Dr. Maria Toivio-Kinnucan, Auburn University)

production indirectly through induction of hepatocyte TPO production.[14] Measurement of cytokines, such as IL-6, could therefore be performed to confirm or refute the presence of reactive thrombocytosis.[1,10] However, cytokine measurement is often not practical and high values often normalize by the time thrombocytosis is identified. Surrogate markers of inflammation are often used, such as the measurement of acute phase proteins such as C-reactive protein.[15] Measurement of TPO is often not helpful in differentiating reactive from clonal thrombocytosis due to overlap of levels between the two groups;[11] however, clinical findings may aid in differentiation between these two disorders.

Iron Deficiency Anemia

Thrombocytosis, via an unknown mechanism, is common in patients with iron deficiency anemia (IDA), with platelet counts returning to within reference intervals after iron supplementation. Cytokine levels are often not increased in patients with iron deficiency compared to those with reactive thrombocytosis, leading to a preliminary hypothesis that iron deficiency somehow encourages megakaryocyte proliferation independent of thrombopoietin, IL-6, and IL-11.[26,32] A recent study in human blood donors found minimal correlation between serum ferritin and platelet counts,[26] a finding replicated in other studies.[32] Some authors have noted that platelet counts correlated instead with serum iron and transferrin saturation, and higher platelet counts, PCT, and MPV were observed in IDA patients having more severe and increasingly hypochromic anemias.[53] The expected increase in erythropoietin levels in IDA patients has been proposed to contribute to thrombocytosis through its homology with TPO and possible off-target action. In support of this theory, administration of erythropoietin results in thrombocytosis in healthy controls and renal failure patients. It is not clear, however, whether erythropoietin-induced red cell production results in iron deficiency or thrombocytopoiesis represents a more direct effect. A combined effect is possible because a mild increase in platelet count is still seen with concurrent iron supplementation.[72] On the other hand, a consistent relationship between erythropoietin levels and thrombocytosis has not been identified in IDA, and some severe IDA patients actually develop thrombocytopenia.[32] Although erythropoietin and TPO receptors display some homology, erythropoietin has not been shown to bind MPL in experimental studies.[12,45] The two hormones may act synergistically to increase platelet counts in IDA. Further mechanistic studies are needed to understand the effects of erythropoietin on thrombopoiesis and the likely multifactorial basis of thrombocytosis associated with IDA.

Drug-Induced Thrombocytosis

Numerous drugs have been associated with thrombocytosis in humans, including the vinca alkaloids (especially vincristine), gemcitabine, iron sulfate, ciprofloxacin, piperacillin/tazobactam, all-trans retinoic acid, clozapine, low-molecular-weight heparin, epinephrine, and erythropoietin.[86] It is possible that the thrombocytosis documented in patients on drug therapy is secondary to their underlying disease or a rebound from thrombocytopenia, rather than a drug response per se. Among the drugs utilized in veterinary medicine, vincristine is often administered for its effects on thrombopoiesis in the treatment of immune-mediated thrombocytopenia.[66] Erythropoietin is often used in the management of chronic renal failure and has also been associated with thrombocytosis as mentioned in the earlier text. Low-molecular-weight heparin (LMWH) has more recently come into use for the prevention and treatment of thromboembolism in cats with aortic (systemic) thromboembolism and dogs with immune-mediated hemolytic anemia. Thrombocytosis, of unknown etiology, has been described in humans treated with LMWH, but not in domestic species.[86] Epinephrine given to dogs in an experimental study induced a rapid (within a few minutes), transient (less than 60 minutes) thrombocytosis through splenic contraction, although there was large interanimal variability in the response.[50] The reported effects of glucocorticoids on platelet count are conflicting. Although hyperadrenocorticism has been associated with thrombocytosis in dogs,[52] several studies have not shown a consistent increase in platelet counts in healthy dogs given daily doses of up to 2 mg/kg prednisolone.[46,63]

The main differential diagnosis for reactive thrombocytosis in animals is essential thrombocythemia (ET). However, there are few reported cases of ET in dogs and cats,[7,23] indicating that thrombocytosis in most animals (like humans) is likely reactive.

ESSENTIAL THROMBOCYTHEMIA IN HUMANS

Essential thrombocythemia is a clonal disorder of hematopoiesis that primarily affects megakaryocytes. It is classified as a BCR-ABL-negative myeloproliferative neoplasm (MPN) or chronic myeloproliferative disease (CMPD), along with polycythemia vera (PV) and primary myelofibrosis (PMF) by the World Health Organization (WHO).[5,6,74,78] All of these disorders are characterized by mutations in *JAK2*, calreticulin (*CALR*), or *MPL*. Essential thrombocythemia is the most frequently diagnosed MPN and usually affects older patients (>60 years), with a higher prevalence in females (although males have an increased risk of venous thrombosis).[31,74] Up to two-thirds of ET patients are asymptomatic at diagnosis and their median survival time of 20 years is longer than PV and PMF.[74,78] Affected individuals most often suffer from microvascular thrombosis, but may develop macrovascular thrombosis (predominantly occurring in arteries supplying the brain, heart, and extremities) or, paradoxically, hemorrhage. Weight loss, pruritus, fatigue, and rarely splenomegaly are also noted.[79]

Essential thrombocythemia is characterized by a marked thrombocytosis in peripheral blood and bone

marrow megakaryocytic hyperplasia.[5] Leukocyte and erythrocyte counts are generally within normal limits. A left shift in neutrophils, marked dysplasia in any lineage, or dacryocytes suggests an alternate MPN diagnosis. Platelets can vary markedly in size with giant forms, but they are usually not dysplastic. A histologic hallmark of ET is the presence of large to giant megakaryocytes with deeply or hyperlobulated, occasionally staghorn-like nuclei, found singly or in small loose clusters diffusely throughout a normocellular to slightly hypercellular marrow. Other evidence of dysplasia is largely lacking and there is no or <5% reticulin fibrosis/grade 1 fibrosis (based on established criteria at the onset of disease).[5,74,80] The main differential diagnoses for ET are reactive thrombocytosis (which is far more common) and other MPN described in the following text.

The discovery of various mutations in *JAK2*, *CALR*, and *MPL* has advanced our understanding of the pathogenesis of ET and related MPN. Janus-associated kinase-2 has a critical role in megakaryocyte and other hematopoietic cell signaling, upregulates anti-apoptotic proteins, participates in *MPL* trafficking, and induces hematopoietic cytokine (e.g., IL-3, TPO) production.[2] The main *JAK2* mutation results in a phenylalanine for valine substitution at residue 617 (V617F) of the autoinhibitory domain and results in constitutive *JAK2* activation. The V617F mutation is not specific for ET and also occurs in PV (up to 90% incidence) and PMF, perhaps explaining the phenotypic and biologic similarities among these neoplasms.[2,74] Testing for the V617F mutation has been added to a proposed diagnostic scheme for ET (Table 82.2). However, ET is genetically heterogeneous with *JAK2* V167F found in at most 55% of ET patients. Mutations in the gene encoding *CALR* occur in 15–24% of ET patients (and 25–35% of PMF patients).[6,74] This multifunctional protein acts as a major calcium-binding (storage) protein in the lumen of the endoplasmic reticulum and it is found in the nucleus with a putative role in transcription regulation. Additionally, 4% of ET patients, 8% of PMF patients, and rarely PV patients have *MPL* mutations.[6,74] Mutations in *JAK2* also occur in other tumors, such as chronic myelomonocytic leukemia, acute myeloid leukemia, myelodysplastic syndrome (MDS), and chronic myeloid leukemia (CML), whereas *MPL* mutations can be seen in congenital amegakaryocytic thrombocytopenia. There is also emerging evidence of mutations in other genes in ET patients that affect cytokine signaling, thereby disrupting transcriptional and epigenetic regulation and RNA splicing. The absence of a mutation in a known disease gene in a suspect ET patient does not rule out ET because up to 20% of human patients are negative for all defined mutations.[5,6,74] Bone marrow sampling is required in these patients to evaluate for the typical morphologic features of ET and differentiate it from other MPNs (see Table 82.2).

Although patients with ET have reduced life spans compared to age- and sex-matched healthy individuals, survival times are approximately 33 years in patients under 60 years of age at diagnosis. Thus, ET is considered an indolent disease, compared to other MPN.[74,76]

TABLE 82.2 WHO criteria for essential thrombocythemia in humans.

Major criteria	Minor criterion
1. Platelet count >450 × 10^3/μL 2. Bone marrow biopsy showing proliferation of megakaryocytes with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant hyperplasia of other lineages, a left shift in neutrophil granulopoiesis or erythropoiesis, and usually no reticulin fibrosis (minor or grade-1 reticulin fibrosis is rare) 3. Not meeting WHO criteria for BCR-ABL+ CML, PV, PMF, MDS, or other myeloid neoplasms 4. Presence of *JAK2*, *CALR*, or *MPL* mutation	Presence of a clonal marker or absence of evidence for reactive thrombocytosis

Diagnosis of ET requires meeting all four major criteria or the first three major criteria and the minor criterion.

Unlike CML, ET evolves into acute leukemia in only 5% of cases, but can transform into PMF. Thrombohemorrhagic symptoms contribute to morbidity and mortality in ET patients; consequently, cytoreductive therapy is recommended for patients likely to develop these complications. Such therapy includes platelet apheresis, hydroxyurea, anagrelide (a quinazoline derivative that inhibits megakaryocyte proliferation and differentiation), busulfan, pipobroman, and interferon-α.[79] Aspirin is frequently administered to patients at risk for thrombosis. Newer drugs targeting generic or JAK2 kinases may have promise in treating ET.[22,85]

Differentiating Essential Thrombocythemia from Reactive Thrombocytosis

In humans, laboratory and clinical criteria are used to distinguish reactive thrombocytosis from ET (Table 82.3). Although platelet counts trend higher in ET, the degree of thrombocytosis cannot be relied upon for differentiation. There have been numerous studies evaluating MPV in MPN versus reactive thrombocytosis, but results have been conflicting.[34] However, a normal platelet distribution width (PDW) has a negative predictive value of 99.8% for MPN, i.e., more indicative of a reactive process.[34] Although a recent study found increased reticulated platelets in patients with ET versus healthy controls, the reticulated platelet percentage did not differentiate ET from other causes in patients with thrombocytosis.[54] A higher risk of thrombosis, associated with hyperaggregability, was seen in patients with increased reticulated platelets.[54,60] A diagnosis of ET is also favored by a history of thrombohemorrhagic events, mild to

TABLE 82.3 Criteria for differentiating reactive thrombocytosis from essential thrombocythemia in humans.

Criteria	Reactive thrombocytosis	Essential thrombocythemia
Clinical		
Underlying disease	Yes	No
Thrombosis or hemorrhage	No[a]	Yes
Splenomegaly	No	Mild to moderate (due to extramedullary hematopoiesis)
Laboratory		
Platelet morphology	Normal	Normal to giant platelets, may see hypogranular platelets
Bone marrow[b]	Normocellular to hypercellular (possible concurrent granulocytic hyperplasia) Megakaryocytic hyperplasia (normal size, morphology)	Normocellular megakaryocytic hyperplasia (large cells, hyperlobulated or "staghorn" nuclei seen in loose clusters)
Inflammatory markers (IL-6, fibrinogen, C-reactive protein)	High (may be normal)	Normal (may be high)
TPO levels	High or normal	High or normal[c]
Platelet aggregation	Normal	Abnormal (particularly to epinephrine) in 63–100%

[a] May occur if initiated by underlying disease.
[b] Although bone marrow changes are emphasized in the WHO classification scheme for ET, they may be quite subtle and are not present in all patients.
[c] High TPO levels in ET have been attributed to downregulation of MPL on platelets and megakaryocytes.

moderate nonprogressive splenomegaly (due to extramedullary hematopoiesis), no evidence of inflammation, abnormally large megakaryocytes in the bone marrow, and identification of *JAK2*, *CALR*, or *MPL* mutations.[2,11,31]

Differentiating Essential Thrombocythemia from other Chronic Myeloproliferative Disorders

Thrombocytosis is a common feature of all MPNs, although the incidence and degree of increase differ between them. There is also substantial overlap in clinical presentation, biology, and laboratory features between these diseases.[2,3,5,6] Differentiation first involves eliminating CML and MDS. The former is largely excluded by identifying typical changes in blood (moderate to severe nonregenerative anemia, marked leukocytosis with many blasts) and presence of the Philadelphia chromosome (BCR-ABL), although BCR-ABL-negative CMLs do occur.[3,78] Substantial dysplasia and genetic abnormalities, such as the del(5q), enable the diagnosis of most cases of MDS, including most of the MDS/MPN overlap syndromes.[3] Differentiating ET from MPNs such as PV and PMF can be challenging.[6] In 1986, the Polycythemia Vera Study Group (PVSG) developed diagnostic criteria for ET. The diagnosis was one of exclusion; i.e., ruling out reactive thrombocytosis (particularly due to iron deficiency), PV, and CML (mainly based on lack of the Philadelphia chromosome). In 2001, the WHO established a diagnostic scheme for ET. Like the PVSG criteria, ET was primarily a diagnosis of exclusion, with bone marrow histopathology added to exclude early or prefibrotic PMF. However, the WHO scheme excluded approximately 30% of ET patients with platelet counts below the designated cutoff (600,000/μL). The revised, 2008 WHO proposal used a platelet cutoff of 450×10^3/μL, incorporated testing for *JAK2*, *CALR*, and *MPL* mutations,[6,49] and emphasized the importance of differentiating ET from prefibrotic PMF as the latter has a much poorer prognosis.[3,6]

Although genetic testing is helpful, bone marrow evaluation is also key for differentiating ET from PV and PMF. In contrast to ET, PV is characterized by proliferation of all hematopoietic lineages with pleomorphic megakaryocytes.[74] "Masked" PV can appear similar to *JAK2*-mutated ET, as these patients are initially not polycythemic (due to concurrent iron deficiency), but the bone marrow changes can help differentiate between them.[74] In PMF, megakaryocytes are increased, abnormally distributed (adjacent to bony trabeculae and in sinuses), and display substantial atypia (dense clusters, nuclear:cytoplasmic asynchrony, irregularly folded, and hyperchromatic to hypochromatic nuclei), and there is usually obvious reticulin and/or collagen fibrosis.[6,74]

Prefibrotic PMF and MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T) are even more challenging, as they can appear very similar to ET.[6,78] In prefibrotic PMF, the bone marrow has a normal to small amount of reticulin (grade 0 or 1) like ET, but megakaryocytes are atypical as in full-blown PMF.[6,78] Additionally, patients with prefibrotic PMF often have granulocytic hyperplasia and erythroid hypoplasia, features lacking in ET patients. Prefibrotic PMF patients also have higher white blood cell counts, lower hemoglobin levels, higher lactate dehydrogenase activities, few peripheral erythroblasts or myeloblasts, and an increased incidence of palpable splenomegaly.[5,49] In MDS/MPN with ring sideroblasts and thrombocytosis, megakaryocytes have morphologic changes that resemble those seen in ET or PMF and patients can have *JAK2*, or less frequently *CALR* or *MPL*, mutations. However, affected patients have refractory anemia and dyserythropoiesis (15% or more of the erythroid precursors are ring sideroblasts), and can have additional mutations in the spliceosome gene, *SF3B1*.[3,6]

ESSENTIAL THROMBOCYTHEMIA IN ANIMALS

Many of the reported individual case reports of ET in animals do not fit current definitions of ET in humans and are likely reactive thrombocytosis, acute megakaryoblastic leukemia, or CML. In two cases that may be true ET (in a dog and a cat), PVSG criteria were used for diagnosis.[7,23] Both animals had a marked persistent thrombocytosis (>600 × 10^3 platelets/μL for >1 month), megakaryocytic hyperplasia, normal TPO levels, and no evidence of dysplasia, iron deficiency, or underlying inflammation. It is possible that ET is a different disorder in animals than in humans and diagnostic criteria for humans (including genetic mutations) may not be valid in animals, although the V617F *JAK2* mutation has been documented in dogs with PV.[9]

The main differential diagnosis for ET in animals is a reactive or cytokine-driven thrombocytosis, which is far more common regardless of platelet count.[4,47,61,69,91] Essential thrombocythemia is an extremely rare diagnosis in animals and, as in humans, remains one of exclusion. It is very difficult to differentiate ET from other chronic myeloproliferative diseases (e.g., CML), which are also quite rare. A diagnosis of ET should only be entertained in animals with a sustained (more than 1–2 months) and unexplained thrombocytosis and no evidence of CML or MDS (low numbers of myeloblasts, and no dysplasia, leukocytosis, or severe anemia). It is possible that the increased availability of sensitive markers of inflammation, such as acute-phase reactant proteins,[15] may help distinguish between reactive thrombocytosis and ET in animals. Testing for *JAK2* mutations is also available at some institutions for research purposes,[9] and may become more widely available with the advent of commercial genetic test services.

Thrombocytosis has also been reported with acute megakaryoblastic leukemia and other CMPD, including basophilic leukemia in animals.[42,62]

FAMILIAL/INHERITED THROMBOCYTOSIS

In humans, this rare disorder has been attributed to germline mutations in genes involved in thrombopoiesis (*MPL*, *TPO*, *JAK2*), resulting in non-neoplastic polyclonal thrombopoiesis.[2,8,55] High platelet counts are observed at birth or an early age. Affected individuals may be asymptomatic or suffer from thrombohemorrhagic complications.

CONSEQUENCES OF THROMBOCYTOSIS

Thrombohemorrhagic events represent the most serious consequence of thrombocytosis.[11,75] Reactive thrombocytosis is often self-limiting without specific treatment, although intervention might be considered for paraneoplastic cases.[25,37] Reactive thrombocytosis occasionally results in venous thrombosis in people, usually in concert with diseases or conditions such as hypercholesterolemia. Human patients with clonal thrombocytosis are often treated to minimize the possibility of thrombotic complications.[11,24,31] The latter comprise microvascular thromboses, with signs of headache, syncope, and erythromelalgia, to macrovascular thromboses causing stroke or transient ischemic attacks.[11] Age (>60 years), prior history of thrombosis, concurrent leukocytosis, and presence of *JAK2* mutations are all associated with an increased risk in patients with ET.[11,24] Antiplatelet therapy and measures to decrease concurrent risk factors are therefore often part of the therapeutic plan in ET patients. Paradoxically, some patients with clonal thrombocytosis can experience bleeding, typically from mucocutaneous junctions.[11] This is most often seen in patients with extremely high platelet counts (>1500 × 10^3/μL). The cause of hemorrhage is multifactorial and due partly to platelet function defects and acquired von Willebrand disease associated with increased platelet adsorption of large von Willebrand factor multimers and increased proteolysis of von Willebrand factor.[44,65,79] There is less information regarding the risk of bleeding or thrombosis in veterinary patients, with rare reports of thrombosis with paraneoplastic thrombocytosis.[25] Low-dose aspirin or clopidogrel could be considered in at-risk patients.

  Nontransfusion Therapy

Acronyms and Abbreviations

AVWS, acquired von Willebrand syndrome; ADAMTS13, a disintegrin and metalloprotease with thrombospondin repeats; DDAVP, deamino-8-D-arginine vasopressin; FVIII, coagulation factor VIII; GP, glycoprotein; MW, molecular weight; OMIM, online Mendelian inheritance in man; PFA, platelet function analyzer; ULVWF, ultralarge VWF; VWD, von Willebrand disease; VWF, von Willebrand factor; VWF:Ag, von Willebrand factor antigen; VWF:CB, von Willebrand factor collagen binding; VWF:RCo, von Willebrand factor ristocetin cofactor activity.

Von Willebrand disease (VWD) is the most common hereditary bleeding disorder in dogs[1,13] and people,[8,15,21] and the trait has been identified in many other species. The disease is heterogeneous, caused by a variety of defects in von Willebrand factor (VWF) protein that influence bleeding severity and complicate clinical diagnosis and management.[15,21,25]

DISEASE MECHANISM

The bleeding tendency of VWD is caused by quantitative and functional deficiencies of VWF, a large multimeric plasma glycoprotein (GP) required for platelet adhesion at sites of vessel injury (Figure 83.1).[8,15,17]

Endothelial cells are the major site of VWF synthesis and storage.[7,17] Platelets provide a secondary pool of VWF in some species; however, canine platelets contain only trace amounts of VWF.[5] Mature VWF circulates as long strands of subunits (multimers) assembled within the endoplasmic reticulum and Golgi apparatus. Initially, two VWF monomers join to form dimers, followed by the association of dimers into heterogeneous, variably sized multimers including ultralarge VWF (ULVWF). Multimers range in molecular weight (MW) size from 500 to 20,000 kDa. Endothelial cells secrete VWF via steady-state constitutive pathways and release the protein from storage organelles in response to stimuli such as thrombin and epinephrine.

Under normal blood flow conditions, VWF circulates as a globular protein that exhibits low affinity for platelets. Hydrodynamic forces generated at injury sites facilitate unfolding and elongation of VWF resulting in efficient binding of VWF's A2 domain to subendothelial collagen (see Figure 83.2). As the immobilized VWF is subject to

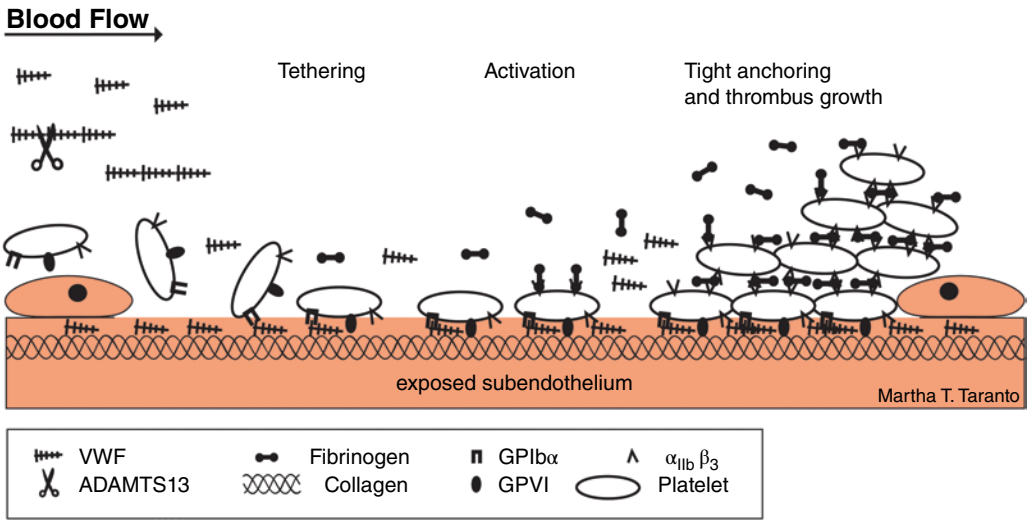

FIGURE 83.1 Schematic diagram illustrating the role of VWF in platelet adhesion, aggregation, and thrombus growth. At the site of blood vessel injury, platelets transiently adhere to subendothelial VWF via platelet GPIbα receptors. This slows platelet movement and triggers the engagement of platelet receptors, including the collagen receptor, GPVI. Receptor engagement results in platelet activation and stable attachment. Activated platelets secrete additional prostimulatory molecules and bind to plasma fibrinogen and VWF to form a tight anchoring matrix for platelet recruitment and ultimately thrombus formation. Upon release from endothelial cells, ultralarge VWF multimers are rapidly cleaved by ADAMTS13. (**Sources:** Favaloro[8]; Leebeek and Eikenboom[15]; Lenting et al.[17])

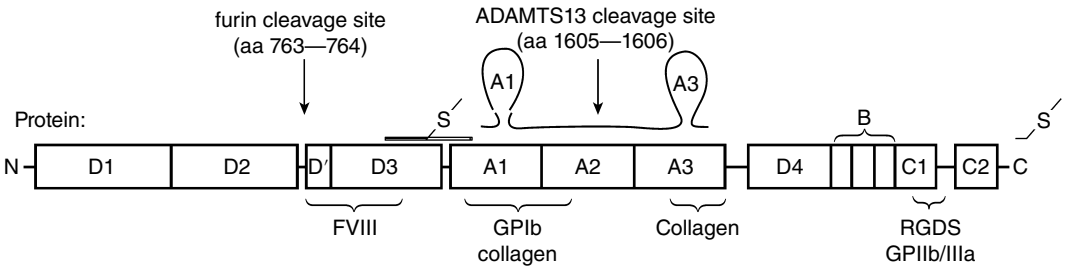

FIGURE 83.2 Domain structure of VWF protein. Functional regions representing binding sites to factor VIII (FVIII), platelet GPIb and GPIIb/IIIa (at R-G-D-S sites), and collagen are indicated below the protein sequence and cleavage sites for furin and ADAMTS13 are indicated above. The amino acid numbering represents human VWF protein.

increasing tensile forces, its A1 domain converts to a high-affinity binding site for platelet GPIbα. This platelet–VWF engagement leads to integrin-independent platelet adhesion and aggregation. VWF and fibrinogen mediate intraplatelet bridging upon activation of platelet integrin GPIIb–IIIa. High-MW VWF multimers are most effective in supporting platelet adhesion. Deficiency of VWF, or loss of high-MW forms, results in failure of platelet plug assembly, especially under high shear in the microvasculature. In addition to this role, VWF acts as a carrier for coagulation factor VIII (FVIII), circulating with FVIII in a noncovalent complex.

After secretion, ULVWF requires processing to prevent spontaneous interaction with platelets and potential formation of occlusive platelet thrombi. The protease, a disintegrin and metalloprotease with thrombospondin repeats (ADAMTS13), has a central role in this process (Figure 83.1).[7,17] The action of ADAMTS13 on globular VWF takes place slowly in plasma (12 hour VWF half-life); however, anchored VWF is rapidly cleaved after shear-induced unfolding and elongation.

DISEASE CLASSIFICATION

VWD Subtypes

Von Willebrand disease in people is classified into one of three categories based on plasma VWF concentration, function, and multimer structure (see Table 83.1).[8,15,24] This classification scheme can be applied to VWD in animals.[2,3,10,19,21,30] Type 1 VWD is a partial quantitative deficiency characterized by low VWF concentration (<50% of normal). In this form, the protein consists of a full complement of functional multimers and clinical severity generally correlates with reduction in VWF concentration.[8,15,21,25]

Type 2 VWD encompasses a group of VWF functional variants. Although four distinct subtypes are found in people, type 2A VWD is the only naturally occurring variant described in animals.[3,8,14,22,29,32] In this form, preferential loss of high-MW multimers accompanies low plasma VWF concentration. Consequently, residual VWF's ability to support platelet adhesion is greatly

TABLE 83.1 Classification of von Willebrand disease.

Type	VWF defect	Affected species (breeds)
1	Partial quantitative deficiency, residual VWF has normal structure and function	Dog (Airedale, Akita, Bernese Mountain Dog, Dachshund, Doberman Pinscher, German Shepherd, Golden Retriever, Greyhound, Irish Wolfhound, Kerry Blue Terrier, Manchester Terrier, Miniature Pinscher, Papillon, Poodles, Schnauzer, Welsh Corgi, other purebred and mixed breed dogs) Horse (Arabian) Mouse (RIIIS/J), genetically engineered (R1205H, Y1584C)
2A	Selective loss of large VWF multimers, decreased VWF–platelet and collagen interactions	Dog (German Shorthaired Pointer, German Wirehaired Pointer) Cow (Simmental) Horse (Quarter Horse, Thoroughbred) Mouse, genetically engineered (R1597W)
2B	Increased VWF affinity for platelet glycoprotein Ib	Mouse, genetically engineered (R1306W, V1316M, R1341Q)
2M	Impaired VWF binding to platelet glycoprotein Ib, normal multimer structure	Mouse, genetically engineered (VWFR1326H)
2N	Decreased VWF binding to FVIII resulting in rapid FVIII clearance	Mouse, genetically engineered (R763A, R854Q, R816W)
3	Complete VWF deficiency	Dog (Dutch Kooiker, Scottish Terrier, Shetland Sheepdog; sporadic cases in Australian Shepherd, Border Collie, Chesapeake Bay Retriever, Cocker Spaniel, Eskimo dog, Labrador Retriever, Maltese, Pitbull, and mixed breed) Cat (Himalayan, domestic cats) Pig (Poland, China) Primate (rhesus monkey) Mouse, genetically engineered (*VWF* –/–)

Sources: Favaloro[8]; Leebeek and Eikenboom[15]; Riehl et al.[24]

reduced. Genetically altered mouse strains have been developed that display all of the type 2 VWD phenotypes (2A, 2B, 2M, and 2N).[20] In addition to mutations in the VWF gene (*VWF*), defects in the platelet receptor GPIbα that enhance its VWF binding affinity produce a disease phenotype similar to type 2B VWD.[6]

Type 3 VWD refers to a complete absence of plasma VWF. In many species, lack of VWF is associated with concomitant reduction in FVIII.[10,19,20] However, dogs affected with type 3 VWD have relatively mild reduction in FVIII, presumably due to species differences in FVIII stability.[23,27]

Affected Species and Breeds

Clinical expression of VWD is best characterized in dogs;[1,3,4,5,13,18,23,24,28] however, family studies and case reports describe VWD in horses,[22] nonhuman primates,[19] cats[2,9] cows,[29] and laboratory strains of pigs[10] and mice,[16] as well as genetically engineered murine models[20] (Table 83.1). Type 1 VWD is the most common form in dogs and people, with cases identified in many purebred and mixed-breed dogs (Table 83.1). Type 2 VWD represents 10–20% of human cases[8,15]; however, this subtype has been found only in two related canine breeds (German Wirehaired and Shorthaired Pointers) in addition to horses and cattle. The most severe form, type 3 VWD, has been described as a familial trait in several breeds (Kooiker, Scottish Terrier, Shetland Sheepdog),[1,23,31] and sporadic cases occur in other breeds and species (Table 83.1). The true prevalence of VWD within affected breeds is difficult to determine. In the absence of random surveys, diagnosis bias favors screening affected individuals and their relatives. Selective breeding may eliminate the trait within a certain family, in spite of relatively high overall breed prevalence. The breed variants listed in Table 83.1 include published reports and recent case submissions to the authors' laboratory; however, new cases may develop in previously unaffected species and breeds.

INHERITANCE AND EXPRESSION PATTERNS

Molecular characterization of VWD in people reveals a variety of mutation types and numerous distinct mutations throughout the VWF gene (*VWF*).[6,12,15] In general, mutations causative for type 2 VWD are clustered in *VWF* regions required for multimer assembly and stability, or VWF–platelet interactions. Common mutations in type 3 patients include frameshift, nonsense, and large deletions that disrupt VWF synthesis. Mutations causative for type 1 VWD are found throughout *VWF*. Additionally, some type 1 variants, described in mice and people, are caused by mutations unlinked to the *VWF* locus that influence VWF protein stability or rate of synthesis.[12,16,20]

Hereditary VWD

Hereditary VWD is an autosomal trait; males and females transmit and express the trait with equal frequency. Most type 2 VWD kindreds and type 3 VWD

TABLE 83.2 Transmission and expression of recessive von Willebrand disease.

Parental status	Offspring status: predicted ratios[a]
Clear (VV) × clear (VV)	All clear (VV)
Clear (VV) × carrier (VV^m)	½ Clear (VV) & ½ carrier (VV^m)
Carrier (VV^m) × carrier (VV^m)	¼ Clear (VV) & ½ carrier (VV^m) & ¼ affected (V^mV^m)
Clear (VV) × affected (V^mV^m)	All carrier (VV^m)
Carrier (VV^m) × affected (V^mV^m)	½ Carrier (VV^m) & ½ affected (V^mV^m)
Affected (V^mV^m) × affected (V^mV^m)	All affected (V^mV^m)

[a] (VV) = VWD clear, male or female, no signs of bleeding; (VV^m) = VWD carrier, male or female, no signs of bleeding; (V^mV^m) = VWD-affected, male or female, clinical bleeding due to abnormal primary hemostasis.

families demonstrate simple recessive inheritance patterns.[15] Homozygotes inherit mutant *VWF* alleles from both parents and invariably express a bleeding tendency, whereas heterozygotes have one normal and one mutant *VWF* allele and are clinically normal (see Table 83.2).

Published reports describe two distinct mutations causative for canine breed variants of type 3 VWD.[23,31] A deletion mutation within exon 4 (c.255Cdel) and a splice-site mutation at the boundary of exon 16 (Int16G>A) have been identified in Scottish Terriers and Dutch Kooikers, respectively. A single base change (c.1657T>G) that generates a variant protein (p.Trp553Gly) has been associated with expression of type 2 VWD in German Shorthaired and Wirehaired Pointers.[32] Direct DNA tests that detect these mutations and other canine *VWF* mutations are commercially available for molecular diagnosis and carrier detection of VWD (links at PennGen). Due to the molecular heterogeneity of the VWD trait and many nonpathogenic *VWF* polymorphisms, selection of genetic tests requires knowledge of the relevant breed phenotype and confirmation that the sequence variant detected segregates with VWF deficiency and clinical expression of abnormal bleeding in that breed or line. Heterozygous carriers of types 2 and 3 VWD are expected to have low plasma VWF concentration, with values generally less than 50% of normal. Type-3-VWD-affected individuals, by definition, lack circulating VWF.[1,3,13,15]

The inheritance and expression of type 1 VWD is complex and typically dominant or dominant with incomplete penetrance.[4,6,12,15,24,25] The causative mutations underlying this phenotype in people are often classified as "dominant-negative," characterized by the presence of an abnormal gene product that affects VWF processing or clearance. Incomplete penetrance refers to a variability of disease expression among individuals carrying the same mutation. A range of clinical severity is also a common feature within canine breed variants of type 1 VWD.[1,4,13] A splice-site mutation at the end of exon 43 (c.7437G>A) has been associated with VWF deficiency in Doberman Pinschers,[11] and has been identified in many other breeds (see PennGen). While low plasma VWF concentration is a major risk factor for expression of canine type 1 VWD, the relationship of homozygosity or heterozygosity to expression of a bleeding tendency has not yet been fully characterized. Additional loci may influence disease penetrance, as in the human disease counterpart.[6,12,15]

Acquired VWD

Acquired von Willebrand syndrome (AVWS) refers to VWF quantitative and functional defects that develop as a consequence of other primary disease conditions.[8,15] The pathogenesis of AVWS in people includes antibody-mediated clearance secondary to immune disorders, shear-induced proteolysis due to cardiac disease, and increased VWF–platelet binding in thrombotic and neoplastic syndromes. In addition to these defined mechanisms, AVWS has been described in people (and animals) in association with hypothyroidism and treatment with plasma expanders (e.g., hydroxyethyl starch, dextran). An AVWS, characterized by loss of high-MW VWF multimers, has been reported in dogs with cardiac valvular lesions causing turbulent flow.[30] Screening to detect VWF defects is therefore warranted in animals with signs of mucosal hemorrhage and primary diseases associated with AVWS. Similarly, correction of acquired disorders that reduce VWF plasma half-life or impair its function may prevent exacerbation of hereditary VWD.

VON WILLEBRAND FACTOR ASSAYS

Definitive diagnosis of VWD is based on specific assay of plasma VWF.[8,15,21] Species differences in VWF antigenic structure and function require species-specific assays, or validation of human assays, for veterinary applications. Valid results also depend on collection techniques that prevent platelet activation and clot formation, conditions that deplete and degrade VWF in the sample specimen.[8]

Quantitative VWF Assays

VWF antigen (VWF:Ag) refers to the immunologic quantitation of VWF concentration. Determination of VWF:Ag is the initial step in characterizing VWD. The most sensitive and accurate assay methods in current use are ELISA and automated latex immunoassay (LIA).[8,21] Test results of VWF (and clotting factors) are conventionally reported as percentage of "normal." The VWF content of each test sample is compared with that of a reference standard having an assigned value of 100% or 100 units per deciliter (U/dL). Assay standards and reference intervals for animal VWF:Ag must be established by each testing laboratory. In

general, plasma VWF:Ag below 50% (<50 U/dL) indicates VWF deficiency.

Functional and Structural VWF Assays

Functional VWF assays measure various aspects of VWF interaction with platelets, collagen, or FVIII. The ristocetin cofactor assay (VWF:RCo) measures VWF-dependent platelet agglutination. This property of VWF depends on the presence of high-MW multimers and reflects VWF interaction with platelet GPIbα. VWF:RCo values are disproportionately decreased compared to VWF:Ag in people with types 2A, 2B, and 2M VWD.[8,15] VWF:RCo assays are difficult to standardize for clinical diagnosis in people and require modification for use in animals. Collagen-binding assays (VWF:CB) measure a functional property of VWF that also depends on the presence of high-MW VWF multimers. VWF:CB assays have begun to replace VWF:RCo for initial screening to detect type 2 VWD. These newer assays are more readily standardized among laboratories, and have been adapted for clinical assessment of VWD subtypes in dogs.[8,26]

VWF multimers are visualized using protein electrophoresis for size separation, followed by direct hybridization with anti-VWF antibodies, or transfer to a membrane (western blot) before antibody labeling. Multimer analyses are generally performed in research settings for detailed VWF characterization and VWD subtype classification of newly diagnosed breed or species variants.[3-5,8,10,15,22]

Point-of-Care Analyses

Bleeding time tests are in vivo measures of primary hemostasis performed by making a superficial incision in a capillary bed and monitoring the time to cessation of blood flow. Prolongation of bleeding time is compatible with severe forms of VWD (and platelet function defects); however, the bleeding time endpoint is also influenced by platelet count, hematocrit, and other conditions affecting blood viscosity.[8] In addition to nonspecificity, bleeding time tests have fallen out of use in human medicine because of high interoperator variability, patient discomfort, and poor predictive values.

The platelet function analyzer (PFA-100®, Dade Behring) is a table-top instrument that measures platelet plug formation in whole blood under high shear flow.[8,18] The test endpoint (closure time) refers to occlusion of an aperture coated with collagen and ADP or epinephrine. The instrument was developed as a noninvasive test of platelet and VWF function and has been evaluated in dogs and horses. The PFA-100® ADP/collagen closure time is sensitive to VWF deficiency and dysfunction in dogs, with reports of prolonged closure times in dogs with types 1, 2, and 3 VWD.[13,18] Many of the nonspecific conditions that influence bleeding time (e.g., thrombocytopenia, anemia) also affect the closure time endpoint, thereby limiting its use as a screening test in some clinical situations.

CLINICAL MANAGEMENT OF VWD

Clinical Signs

Clinical signs of VWD in all species include mucosal hemorrhage, cutaneous bruising, and prolonged bleeding after surgery or trauma. Specific sites of mucosal hemorrhage in VWD case series include epistaxis, hematuria, gastrointestinal hemorrhage, prolonged estral bleeding, and gingival bleeding at deciduous teeth.[1,3,4,15,25] These signs are typical of primary hemostatic defects, commonly seen in patients with thrombocytopenia, platelet dysfunction, and VWD. Small petechiae, however, are rarely seen in VWD patients. The bleeding tendency of type 1 VWD ranges from mild to severe. Mildly affected patients infrequently develop spontaneous hemorrhage, but may experience abnormal bleeding after surgery or trauma. Types 2 and 3 VWD are more severe, characterized by spontaneous and postinjury hemorrhage. Neonatal deaths caused by hemorrhage may occur, but many animals survive to adulthood, albeit with transfusion support. The anatomic site of tissue injury influences the consequences of hemorrhage. Minor hemorrhage into critical sites such as the central nervous system or respiratory tract may produce severe morbidity and mortality. Oronasal and urinary tract tissues are rich in fibrinolysins, and injuries to these tissues often cause more prolonged bleeding than superficial wounds.

Diagnostic Evaluation

Thrombocytopenia and coagulation factor deficiencies are common causes of hemorrhage; therefore, the initial evaluation of any patient suspected of having a bleeding diathesis should include platelet count and coagulation screening tests (Figure 83.3).

Bleeding scores derived from standardized questionnaires have been proposed to improve the diagnostic utility of VWD screening in people.[21] A brief hemostasis questionnaire is also useful as a screening tool to identify veterinary patients with hereditary or drug-induced bleeding disorders (see Table 83.3). If preliminary results reveal normal platelet count and coagulation panel results, then point-of-care tests of primary hemostasis

TABLE 83.3 Screening questionnaire to aid in the diagnosis of bleeding disorders.

1	Has this animal ever had spontaneous bleeding from nose, mouth, urinary tract, or noticeable bleeding at teething?
2	Has this animal ever had a surgical procedure, dentistry, or traumatic injury—did bleeding complications occur?
3	Has this animal ever required a transfusion because of anemia or hemorrhage?
4	Is this animal receiving medication or dietary supplements?
5	Are you aware of any bleeding problems in relatives or in this breed?

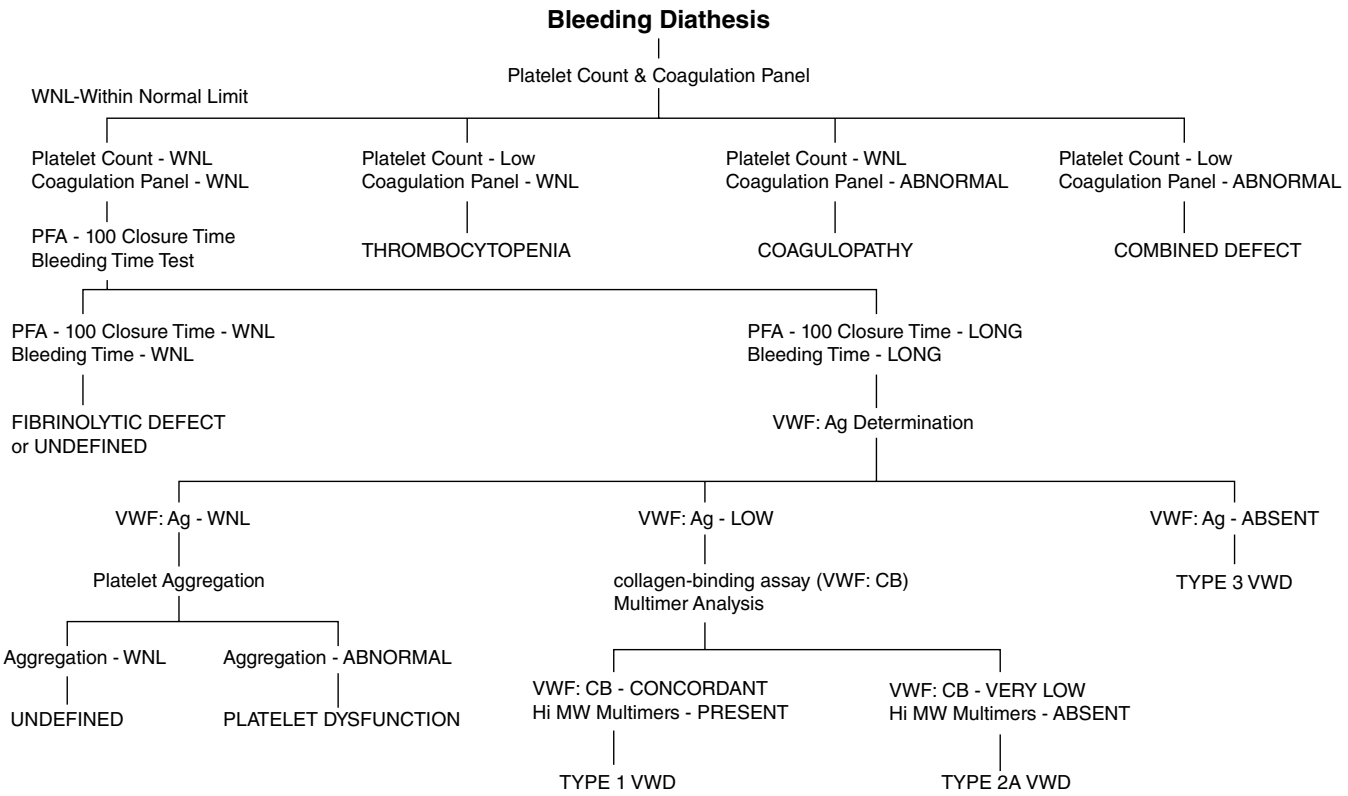

FIGURE 83.3 Diagnostic algorithm for assessment of VWD and other bleeding disorders.

and/or VWF:Ag should be performed to screen for VWD (see Figure 83.3). Prolongation of in vivo bleeding time (beyond 4–6 minutes) and PFA-100® collagen/ADP closure time (beyond 2 minutes) is compatible with VWD, and the finding of low plasma VWF (VWF:Ag < 50%) confirms VWF deficiency. A complete lack of plasma VWF (VWF:Ag < 0.1%) is definitive for severe, type 3 VWD. Diagnosis of type 2 VWD is based on quantitative deficiency, combined with additional structural and functional abnormalities (Table 83.1). In particular, a disproportionate defect of collagen binding (ratio of VWF:Ag/VWF:CB > 2) provides evidence of type 2A VWD. In patients with low, but functional VWF, the risk of abnormal hemorrhage ranges along the continuum of VWF:Ag values. In dogs and people, clinical expression of a bleeding tendency is typically associated with VWF:Ag < 25%, whereas VWF:Ag close to 50% is often clinically inapparent.[1,4,12,15] The current management strategy for type 1 VWD in people considers VWF deficiency a biomarker for hemostatic risk, with consideration of mutation type, and other parameters of intrinsic platelet function as potential modifying factors influencing clinical expression.[15,21]

Treatment of VWD

Management of VWD is directed at controlling active hemorrhage and preventing hemorrhagic complications in case of surgery. The clinical heterogeneity of VWD requires an individualized approach to account for disease classification and underlying conditions that might influence disease expression.

Transfusion Therapy Guidelines

Transfusion is the mainstay of emergency treatment and prophylaxis of VWD (see Chapters 86, 94, and 100). Plasma cryoprecipitate is the most specific component for rapid VWF replacement therapy, with fresh frozen plasma an acceptable alternative (see Chapter 100). The most successful strategy is early, high-dose transfusion to rapidly increase plasma VWF to levels capable of supporting platelet adhesion. Patients with types 2 and 3 VWD almost invariably require transfusion to undergo invasive procedures or stop an active bleed. Transfusion for type 1 VWD can be assessed based on clinical history, severity of VWF deficiency, any underlying disease, and the nature of the hemostatic stress. Patients with blood-loss anemia or requiring major surgical procedures should be transfused, whereas those with normal hematocrits or minor, cutaneous injuries may be successfully managed with limited or no transfusion. Severely affected patients may require repeated transfusion, with lower dosages at longer intervals to sustain hemostasis for 24–48 hours after initial control of bleeding. Stabilization of hematocrit and cessation of active hemorrhage are signs that hemostatic levels of VWF have been attained.

Nontransfusion Therapy

Hereditary VWD causes a lifelong bleeding tendency; therefore, invasive procedures are best avoided. Desmopressin acetate (deamino-8-d-arginine vasopressin [DDAVP]) is a synthetic vasopressin analog used as a procoagulant pharmacologic agent for type 1 VWD, mild forms of hemophilia A, and platelet defects in people (see Chapters 86 and 94). Desmopressin has been recommended as preoperative prophylaxis for type-1-VWD-affected dogs, although experimental studies reveal relatively small increases in plasma VWF concentration compared to the human response.[5] Close monitoring is therefore required, with transfusion available if desmopressin response is inadequate. In case of injury or nonelective surgery, local wound care may help support hemostasis and reduce transfusion requirements (see Chapter 94). Cautery, topical tissue adhesive, multilayer closure, and pressure wraps help to reduce blood loss at focal injury sites.

Signs of VWD can be exacerbated by concurrent thrombocytopenia and other disease conditions that affect hemostasis. Uremia, hyperproteinemia, anemia, hypothyroidism, and liver disease are among the more common disease conditions associated with primary hemostatic failure. Medical therapy to correct these disorders, and primary diseases associated with AVWS, is therefore important in the general management of VWD. Antiplatelet and anticoagulant drugs (e.g., sulfa drugs, nonsteroidal anti-inflammatory agents, heparin, dextran, and other plasma expanders) should be given cautiously, if at all, to patients with clinical signs of VWD.

OVERVIEW—INTRINSIC VERSUS EXTRINSIC PLATELET DISORDERS

Intrinsic platelet disorders are characterized by defects involving membrane receptor glycoproteins, secretory organelles, signal transduction proteins, or structural proteins that result in either platelet dysfunction (thrombopathia) or thrombocytopenia. A variety of inherited intrinsic platelet disorders have been documented in veterinary medicine at the functional, biochemical, and molecular levels (Table 84.1). Extrinsic platelet disorders are characterized by abnormalities in plasma or subendothelial proteins that are essential for platelet adhesion or aggregation. Extrinsic platelet disorders include von Willebrand disease (VWD, see Chapter 83) and hypofibrinogenemia or dysfibrinogenemia. Intrinsic and extrinsic platelet function disorders may be clinically indistinguishable. In vivo bleeding times are typically prolonged in both types of disorders, while coagulation screening tests are normal. Clinical signs suggestive of platelet disorders include petechial and ecchymotic hemorrhages and mucosal bleeding such as gingival bleeding, epistaxis, and urinary and gastrointestinal tract hemorrhage. Excessive bleeding during permanent tooth eruption is common, and may be an early indication of a bleeding diathesis. Clinical severity can vary widely, including unprovoked hemorrhage or excessive bleeding after surgery or trauma. In milder forms, clinical signs may be limited to periodic bruising or petechial hemorrhage. Internal hemorrhage within the brain or spinal cord may result in seizures, paralysis, or acute death. Unilateral or bilateral epistaxis may be spontaneous or associated with drug therapy that inhibits platelet function. Blood products and management strategies

for intrinsic and extrinsic platelet disorders differ; therefore, correct classification is necessary for appropriate treatment of each patient (see Chapters 86 and 100).

INHERITED MACROTHROMBOCYTOPENIA

Cavalier King Charles Spaniels (CKCS) have high prevalence of an autosomally inherited macrothrombocytopenia that does not cause a bleeding diathesis.[24,28,53,58,60] Platelet counts typically range from 30,000 to 100,000/μL in affected (homozygous) dogs with slightly higher counts in carrier (heterozygous) dogs, and variable numbers of large platelets with high mean platelet volume (MPV) present in dogs with either genotype. Affected CKCS have been reported as having hyporesponsive and hyperresponsive platelets; discrepancies likely due to different assays, methodologies, and the CKCS populations evaluated. Prolonged platelet function analyzer 100 (PFA-100) closure times reported in some CKCS are likely secondary to acquired VWD caused by concomitant mitral valve regurgitation, rather than inherited macrothrombocytopenia.[63] The high shear conditions generated with mitral valve regurgitation and other types of heart valve disorders can result in enhanced cleavage of von Willebrand factor (VWF) by a disintegrin and metalloprotease with thrombospondin repeats (ADAMTS13), an enzyme that cleaves VWF under high shear conditions (see Chapter 83).[64] The finding of low plasma VWF concentration and disproportionate loss of VWF collagen-binding activity are characteristic of this form of acquired VWD.

The large platelets in affected CKCS can be equal in size, or larger than erythrocytes, and tend to be spherical to oval in shape with prominent alpha granule staining. A missense mutation at coding nucleotide 745 (r.745g>a) in the β1-tubulin gene (*TUBB1*) is causative for inherited macrothrombocytopenia in CKCS.[25,28] The mutation codes for the substitution of an asparagine for aspartic acid at amino acid position 249 (Table 84.1). Aspartic acid 249 is part of a microtubule intra-protofilament binding site and the change in charge at this position is thought to impair microtubule assembly necessary for normal proplatelet formation and platelet production by megakaryocytes. Prevalence of the trait in CKS in the United States is high; a survey found 90% of the CKCS were carrying one or two copies of the *TUBB1* mutation.[28] In the same study, 65% of CKCS in Ireland were also heterozygous or homozygous for the mutation.

Since the discovery of the TUBB1 mutation in CKCS, the same mutation has been detected in 28 other dog breeds (M. K. Boudreaux and P. W. Christopherson, personal observation). A second *TUBB1* mutation has also been discovered in Cairn and Norfolk Terriers.[33] The mutation is within exon 1 (r.5g>a) and changes the encoded amino acid from an arginine to a histidine. This mutation is thought to have an effect on guanosine triphosphate (GTP) binding and has also been identified in Jack Russell Terriers (M. K. Boudreaux and P. W. Christopherson, personal observations). A pug with macrothrombocytopenia and neutrophilic cytoplasmic inclusions, analogous to May–Hegglin anomaly, has been described.[30] The dog's neutrophil function was normal, and platelets demonstrated reduced response to ADP. Partial sequencing of the human May–Hegglin disease gene, myosin-9 (*MYH9*), revealed that the dog was heterozygous for a nonsynonymous single nucleotide variant in exon 38 (r.5521g>a), a mutation previously described in a human May–Hegglin patient.

Disease genes other than *TUBB1* and *MYH9* have been identified as the cause of hereditary macrothrombocytopenias in people. A similar molecular heterogeneity is likely in dogs. Of note, a congenital macrothrombocytopenia has recently been described in Akita dogs who did not have the previously identified canine *TUBB1* mutations[29,36] (M. K. Boudreaux and P. W. Christopherson, personal observations).

MEMBRANE RECEPTOR DISORDERS

Glanzmann Thrombasthenia (GT)

Glanzmann thrombasthenia (formerly known as thrombasthenic thrombopathia) is characterized by absence or marked reduction in platelet glycoprotein complex IIb–IIIa (integrin $\alpha_{IIb}\beta_3$). This complex functions as the platelet fibrinogen receptor.[51] In people, GT is categorized into three main types: type I, type II, and variant. In type I, less than 5% of the receptor is detectable on platelet surfaces and clot retraction is absent. In type II, 10–20% of the receptor is present on platelet surfaces and clot retraction is detectable but reduced. In variant GT, the receptor is present but dysfunctional; clot retraction may or may not be detectable. In veterinary medicine, type I GT has been described in horses and dogs.[5,27, 45,48] The $\alpha_{IIb}\beta_3$ complex primarily binds fibrinogen; however, it can also bind other arginylglycylaspartic acid (RGD)-containing adhesive proteins, including VWF. Glanzmann thrombasthenia is inherited as an autosomal recessive trait and is characterized by the inability of platelets to aggregate in response to all agonists, including thrombin. The alpha and beta subunits of the fibrinogen receptor are encoded by separate genes; however, both are necessary for intracellular transport and formation of a stable complex on the platelet surface. All cases of GT described in domestic animals have been due to mutations in *ITGA2B*, the gene encoding the α_{IIb} subunit; mutations in the gene encoding β_3 have not yet been identified[7,8,19,20,37,44] (P. W. Christopherson, personal observations). Most mutations are in areas of the gene encoding for calcium-binding domains within α_{IIb} (Table 84.1). α_{IIb} subunits are not detected in flow cytometric assays using antibodies specific to the α_{IIb} subunit. Flow cytometric studies using antibodies to the β_3 subunit or to the $\alpha_{IIb}\beta_3$ complex may detect β_3 subunits associated with vitronectin receptors ($\alpha_v\beta_3$), which share

the β_3 subunit and may be increased in these patients.[50] Platelets isolated from dogs with GT do not bind canine activated platelet-1 (CAP-1), a monoclonal antibody specific for a receptor-induced binding site (RIBS) epitope on canine fibrinogen, when activated by strong agonists.[6]

Glanzmann thrombasthenia has been identified in Otterhounds, Great Pyrenees, Golden Retrievers, and mixed-breed dogs, and in horses in England, Australia, Canada, Japan, and the United States. The prevalence of carriers for the mutation in Otterhounds is between 25% and 30% based on records of genetic testing at Auburn University. Prevalence estimates in other breeds are unknown; however, Great Pyrenees carriers have been detected in several states, including Mississippi, Alabama, Florida, Missouri, Minnesota, Indiana, Illinois, Oklahoma, and Washington, suggesting that the causative mutation may be widespread in the breed. Equine Glanzmann thrombasthenic patients identified in Australia and Japan were not characterized at the molecular level;[49,62] however, an affected Quarter Horse diagnosed at Auburn University was compound heterozygous for two distinct mutations in *ITGA2B*. One mutation was identical to that described in horses in England and Canada. The second mutation was a 10-base deletion spanning the exon 11–intron 11 splice site. A 17-year-old Peruvian Paso mare with GT was documented to be homozygous for the same 10-base deletion.[56] The prevalence of mutations causing GT in horses is unknown. In 2018, a case of GT in a domestic short-haired cat was discovered at the University of California, Davis.[67]

P2Y12 ADP Receptor Disorder

Epistaxis and abnormal surgical hemorrhage has been described in Greater Swiss Mountain dogs homozygous and heterozygous for a deletion mutation in *P2RY12*, the gene encoding the major platelet ADP receptor.[12,31] In these reports, clinically affected dogs demonstrated impaired in vitro platelet activation and/or aggregation response to ADP stimulation. Familial screening of the index case revealed dogs homozygous and heterozygous for the mutation with no histories of abnormal hemorrhage. Similarly, highly variable penetrance of *P2RY12* mutations has been described for human cases.[17]

Bernard Soulier Syndrome

A mild to severe bleeding disorder resembling Bernard Soulier syndrome (BSS) has been identified in Cocker Spaniels.[34] Clinical signs included epistaxis, gingival hemorrhage, delayed post-operative hemostasis, and hematoma formation at venipuncture sites. Clinically affected dogs are homozygous for a large deletion mutation in *GP9* that codes for the VWF receptor, glycoprotein Ib (GP1b). Phenotypically, the trait comprises characteristic clinicopathologic features of BSS including macrothrombocytopenia, defective platelet adhesion, and abnormal GP1b expression.[34]

STORAGE POOL DISORDERS

Cyclic Hematopoiesis

Cyclic hematopoiesis is an autosomal recessive disorder of Gray Collies characterized by cyclic fluctuations in the number of circulating neutrophils, reticulocytes, and platelets.[18,26,46] Melanocytes are also affected in this disorder resulting in the gray color of affected animals. A bone marrow stem cell defect results in neutropenic episodes occurring approximately every 12 days. Mortality is high; most puppies die prior to 6 months of age due to fulminating infection. Thrombocytopenia does not occur, and platelet numbers fluctuate between 300,000 and 700,000/μL. Platelet dense granules are absent. Platelet reactivity to several agonists is defective; clot retraction and platelet adhesiveness are impaired. A mutation in *AB3B1*, the gene encoding adaptor protein complex 3 beta 1 subunit (AP3β1), has been linked to this disorder.[2] AP3β1 directs trans-Golgi export of transmembrane cargo proteins to granules. Recombinant granulocyte colony-stimulating factor has been used successfully in an experimental treatment trial of affected dogs.[66]

Chediak–Higashi Syndrome (CHS)

Chediak–Higashi syndrome is an autosomal recessive genetic disorder characterized by abnormal leukocyte, melanocyte, and platelet granulation. Affected animals have partial oculocutaneous albinism, increased susceptibility to infection, and a bleeding diathesis as a result of impaired platelet function. Platelets of affected animals lack dense granules and are deficient in granule storage pools of adenine nucleotides, serotonin, and divalent cations. Platelet aggregation in response to collagen, which is largely dependent on thromboxane generation and granule release of ADP, is markedly reduced in affected animals.[38] The disease was identified in a line of Persian cats: all of the affected animals exhibited a "blue smoke" hair color and pale irises with the development of bilateral nuclear cataracts in several animals as early as 3 months of age.[42] Affected cats experienced prolonged bleeding at incision sites and hematoma at venipuncture sites. Chediak–Higashi syndrome has also been diagnosed in Aleutian mink,[41] three breeds of cattle,[1,52,66] blue foxes,[59] killer whales,[55] and mice.[47] CHS in Japanese Black cattle, mice, and people has been linked to mutations in the lysosomal trafficking regulator gene (*LYST*), which encodes a 425-kDa cytoplasmic protein that may be involved with incorporation of proteins into lysosomal membranes.[43] Molecular studies have not been reported in Brangus or Hereford cattle or other species affected with CHS.

Dense Granule Defect

A dense granule defect has been described in a family of American Cocker Spaniels.[14] Affected dogs had a moderate to severe bleeding diathesis, particularly after trauma or surgery. Three of five affected dogs had

impaired platelet aggregation responses to ADP and collagen. Platelet[14] C-serotonin uptake and retention were normal; ATP content was also normal. ADP content was low resulting in an increased ATP/ADP ratio. Platelet morphology at the electron microscopic level was normal suggesting a functional dense granule defect. Molecular studies were not conducted and the disorder has not been recognized in Cocker Spaniels since the initial report.

SIGNAL TRANSDUCTION DISORDERS

Calcium Diacylglycerol Guanine Nucleotide Exchange Factor I (CalDAG-GEFI) Thrombopathias

Basset Hounds, Eskimo Spitz, Landseers of European Continental Type (ECT), and Simmental cattle have been identified with inherited signal-transduction platelet disorders, referred to as thrombopathias, that are virtually identical in presentation at the clinical and functional level.[4,16,32,35,41,57,61] Platelet aggregation responses to ADP and collagen are minimal to absent in affected animals. Platelet aggregation in response to thrombin is rate-impaired and is characterized by a lag phase, lengthening the time to complete aggregation. This thrombin activation response is sufficient to support normal clot retraction. Flow cytometric assays using antibodies to αIIb or β3 show normal receptor density. CAP-1 binding is absent on ADP or platelet activating factor (PAF-)activated thrombopathic canine platelets.[9]

The molecular basis for thrombopathia in Basset Hounds, Spitz, Landseers of ECT, and Simmental cattle is due to distinct mutations in *RASGRP2* that encodes CalDAG-GEFI.[9,10] All of the mutations are within areas encoding structurally conserved regions (SCRs) of the catalytic domain (Table 84.1). CalDAG-GEFI is a signal transduction protein that functions as a guanine nucleotide exchange factor (GEF) and facilitates guanosine diphosphate (GDP)/GTP switching by Rap1b. Rap1b is a Ras-related low-molecular-mass guanine-nucleotide-binding protein (GTPase) that is activated by the binding of GTP. Activated Rap1b is critically involved in activation and change of conformation of integrin $\alpha_{IIb}\beta_3$ necessary for fibrinogen binding and ensuing platelet aggregation.[3] The ability of thrombin to activate mutant platelets is thought to be attributable to the ability of protease-activated receptor 4 (PAR4) signaling to bypass CalDAG-GEFI and activate Rap1b directly or act via a pathway independent of Rap1b.[9,23]

The *RASGRP2* mutation in Basset Hounds appears to be widespread; results of DNA testing at Auburn University indicate that between 25% and 30% of Basset Hounds are carriers for the mutation. The mutation is more prevalent in Basset Hound lines used for show rather than for hunting and has also been identified in a Basset–Shar-Pei (Ba-Shar) dog.[21] Landseer-ECT is a European canine breed with prevalence of *RASGRP2* mutations based on testing at Auburn University, of around 25%. Distinct mutations of unknown or lower prevalence have also been identified in Eskimo Spitz, Simmental cattle, and in an Arabian horse (Table 84.1). Although CalDAG-GEFI is also expressed in brain tissue, neurological signs in people or animals with CalDAG-GEFI disorders have not been reported. CalDAG-GEFI may play a role in signal transduction events in other hematopoietic cells, including neutrophils. Redundant pathways, however, are likely responsible for preventing significant impairment of neutrophil function in animals with CalDAG-GEFI mutations (Table 84.2).

Signal transduction defects are believed to represent the most common group of hereditary intrinsic platelet defects in people. Due to the complexity in platelet signaling pathways, functional characterization of these defects requires comprehensive analyses of platelet activation response to a variety of agonists to identify defective pathways and likely candidate disease genes.[15,54]

Kindlin-3

A mutation in *FERMT3*, the gene encoding Kindlin-3, has been identified in a German Shepherd dog and a German Shepherd–Rottweiler cross with histories of prolonged bleeding, persistently high leukocyte counts, and susceptibility to infections.[11,39] Kindlin-3 is a signal transduction protein shared by all hematopoietic cells, which plays an essential role in integrin activation.

PLATELET PROCOAGULANT DEFICIENCY

Scott Syndrome

A defect of platelet procoagulant activity, comparable to the human platelet defect Scott syndrome, has been identified in German Shepherd dogs.[13,40] Clinical signs include abnormal post-traumatic and postoperative bleeding, and spontaneous epistaxis, hematoma formation, and hyphema. Affected dogs demonstrate normal

buccal mucosal bleeding times and normal platelet aggregation, adhesion, secretion, and clot retraction; however, calcium-induced platelet membrane externalization of phosphatidylserine (PS) and microvesiculation are markedly reduced. Consequently, Scott syndrome platelets do not fully support procoagulant complex assembly. The molecular basis for this disorder is a splice-site mutation in *TMEM16F*, the gene encoding a transmembrane calcium-dependent lipid scramblase, referred to as anoctamin-6 or *TMEM16F*.[13]

DIAGNOSIS AND MANAGEMENT

Hereditary platelet defects are generally uncommon disorders that require an index of suspicion for timely diagnosis. These traits are typically found in purebred animals due to propagation of breed-specific mutations from breed founders or popular sires. However, de novo mutations and inbreeding practices may result in new cases in mixed breed and previously unaffected breeds or lines. To date, all of the intrinsic platelet defects in animals demonstrate autosomal recessive inheritance patterns with males and females at equal risk for expression and transmission of the traits. Genetic counseling is warranted after diagnosis of an index patient. When mutation-type is known, molecular diagnostic testing allows accurate carrier detection to prevent production of affected individuals and ultimately reduce breed prevalence of clinically severe traits.

Persistent thrombocytopenia, characterized by the presence of large platelets, but without clinical signs, is characteristic of hereditary macrothrombocytopenia. These patients risk inappropriate and potentially harmful drug treatment. Documentation of a *TUBB1* mutation provides definitive diagnosis for the previously characterized breeds at risk. However, mutations in other genes have been documented to cause macrothrombocytopenia in people[29] and should be considered in the absence of previously discovered mutations.

Definitive diagnosis of hereditary bleeding diatheses due to intrinsic platelet disorders can be based on molecular diagnostic testing, if a breed or familial mutation has previously been defined. Academic and commercial laboratories offer a variety of tests, using either blood samples or cheek swabs to isolate DNA.[68,69] Alternatively, platelet function testing to identify distinct patterns of abnormalities will confirm the presence of a known trait or provide clues to a specific pathway or protein defect. Some point-of-care and remote platelet screening tests can be performed; however, many functional assays require that affected animals be on the premises of the testing facility for analyses within hours of sample collection (see Chapter 79).

Animals with macrothrombocytopenia do not require any special care, and patients with mild functional defects may be maintained comfortably as pets with avoidance of invasive procedures or the use of antiplatelet agents (see Chapters 86, 94, and 100). Transfusion of blood, components, or platelet concentrates may be required to supply functional platelets for surgical prophylaxis, and periodic platelet transfusion may be needed for patients with more severe functional defects to control recurrent hemorrhagic events (see Chapter 100). Administration of 1-desamino-8-D-arginine vasopressin (DDAVP) and antifibrinolytic agents are medical management strategies described for human platelet defects that are applicable for the animal disease counterparts (see Chapters 86 and 94).[19,22]

CHAPTER 85

Acquired Platelet Dysfunction

BENJAMIN M. BRAINARD

Introduction
Diseases Associated with Platelet Dysfunction
  Renal Disease
  Sepsis, Infectious Disease
  Systemic Inflammatory Response Syndrome Shock
  Hepatic Disease
  Cardiac Disease
  Neoplasia
  Endocrinopathies
Pharmaceuticals that Affect Platelet Function

Acronyms and Abbreviations

AA, arachidonic acid; aPTT, activated partial thromboplastin time; CKD, chronic kidney disease; CT, closure time; DIC, disseminated intravascular coagulation; GP, glycoprotein; HCM, hypertrophic cardiomyopathy; IMHA, immune-mediated hemolytic anemia; LPS, lipopolysaccharide; MPC, mean platelet component; MPV, mean platelet volume; OPA, optical (turbidimetric) aggregometry; PDW, platelet distribution width; PFA-100, platelet function analyzer-100; PRP, platelet-rich plasma; PT, prothrombin time; ROTEM, rotational thromboelastometry, SIRS, systemic inflammatory response syndrome; TEG, thromboelastography; WBPA, whole blood (impedance) aggregometry; VWF, von Willebrand factor.

INTRODUCTION

Acquired disease and drugs may cause platelet hypofunction or hyperfunction, resulting in hemorrhagic or prothrombotic phenotypes, respectively. While mechanistic studies are lacking, veterinary survey studies have described these clinicopathologic effects. Diagnostic tools to assess platelet function are reviewed elsewhere (see Chapter 79). Low shear assays include platelet aggregation in response to specific agonists (typically ADP, collagen, arachidonic acid [AA], or thrombin), performed as optical aggregometry (OPA) using platelet-rich plasma (PRP) or impedance aggregometry using whole blood (WBPA).[52] High shear assays mimic the stress that platelets encounter in flowing blood. The most widely available instrument, the platelet function analyzer-100 (PFA-100, Siemens), aspirates blood through an aperture coated with either ADP and collagen or epinephrine and collagen, and reports the time for aperture occlusion by a platelet plug as closure time (CT).[52] Viscoelastic assessments of coagulation (e.g., thromboelastography [TEG], rotational thromboelastometry [ROTEM]) record the change in viscosity of whole blood as it is transformed from a liquid to a gelid clot. Regardless of functional assay methodology and results, the clinical presentation and ancillary testing such as platelet count and coagulation profile must be considered prior to initiating therapy.

DISEASE CONDITIONS ASSOCIATED WITH PLATELET DYSFUNCTION

Renal Disease

Uremia is associated with platelet hypofunction, but the mechanism is not well defined. One study of 14 uremic dogs identified either decreased or increased OPA relative to healthy dogs, depending on agonist concentration.[78] By contrast, a second study of 22 uremic dogs failed to identify altered function using WBPA.[31] Overall, the decrement in aggregation in the first study was unlikely to be clinically relevant and hyperaggregability may have resulted from elevated fibrinogen,[24,78]

decreased serum albumin,[89] or low hematocrit.[62] A recent report in 11 dogs with naturally occurring chronic kidney disease (CKD) described prolonged average CT (although values for most animals were within the reference interval) while platelet expression of the von Willebrand factor (VWF) receptor, glycoprotein (GP)Ib, did not vary between CKD and control dogs. The same study described increased expression of platelet P-selectin and integrin αIIbβ3 (GPIIb/IIIa) compared to healthy dogs, suggesting enhanced platelet reactivity.[24] Plasma fibrinogen concentration was also higher in CKD dogs.[24] Other reports support the presence of clinically relevant bleeding or platelet hypofunction in canine patients with chronic and experimental uremia.[54,12,118] Human studies of various renal disorders have identified defects in membrane expression of GPIb and integrin αIIbβ3,[79] impaired thromboxane synthesis, lower platelet content of serotonin and ADP, impaired fibrinogen binding, or soluble inhibitors as causes of decreased platelet function.[102] In veterinary patients, the effects of uremia on platelet function and coagulation likely vary with the type and etiology of renal disease.

Sepsis, Infectious Disease

Many platelet function abnormalities have been described in humans and animals with sepsis. The release of proinflammatory cytokines during initial stages of sepsis increases circulating fibrinogen and results in enhanced platelet function and thrombocytosis. Progression to septic shock may be accompanied by thrombocytopenia secondary to disseminated intravascular coagulation (DIC) (see Chapter 92). Platelets may become hypofunctional with changes in the intravascular milieu (e.g., acidosis, hypothermia, hypocalcemia). In addition to sepsis-triggered DIC, platelet interactions with activated neutrophils and associated neutrophil extracellular trap formation (see Chapter 92) likely contribute to microthrombus formation.[68]

In experimental canine endotoxemia, a transient shortening of CT occurred 30 minutes after IV infusion of *E. coli* endotoxin, despite the development of thrombocytopenia.[125] The dogs receiving high-dose endotoxin displayed a prolonged CT 48 hours after infusion. In a small study of dogs with infection and systemic inflammatory response syndrome (SIRS), WBPA in response to collagen and platelet adherence to collagen in a flow chamber were significantly lower than values for healthy dogs.[29] This difference was more pronounced when platelets were primed with a thrombin receptor agonist. In another study, septic dogs sampled within 24 hours of diagnosis had decreased WBPA.[69] Decreased platelet aggregation occurs in humans with sepsis.[124] While platelet hypofunction alone may not result in a hemorrhagic phenotype, clinical signs of abnormal bleeding may develop when combined with therapies that further compromise hemostasis.

Infection with *Ehrlichia sp*. is associated with thrombocytopenia, but variable bleeding tendencies. In four dogs experimentally infected with *Ehrlichia canis*, circulating antiplatelet antibodies were observed, in addition to thrombocytopenia.[100] Although WBPA decreased concomitantly with thrombocytopenia, aggregation returned to baseline with recovery of platelet count. Notably, changes in some indices of platelet activation (e.g., mean platelet component [MPC] and platelet distribution width [PDW]) suggested that thrombocytopenia was accompanied by increased platelet activation, which might ameliorate thrombocytopenic bleeding. A report of dogs experimentally infected with *Ehrlichia platys* failed to document clinically significant changes in platelet aggregation despite the presence of thrombocytopenia.[34] Other studies of experimental canine ehrlichiosis revealed decreased OPA in the acute stage of disease. Thrombocytopenia in these cases may have influenced OPA.[11] Another report demonstrated decreased OPA in healthy dog PRP incubated with serum from Ehrlichia-infected dogs, suggesting the presence of a platelet-inhibitory antibody or other soluble factor.[44] In dogs with naturally occurring leishmaniasis, OPA may be decreased compared to healthy dogs with equivalent platelet counts.[87] Canine heartworm disease has been associated with platelet activation and increased platelet reactivity,[7] and *Angiostrongylus vasorum* infection in dogs is associated with consumptive thrombocytopenia and variable platelet reactivity.[1]

In horses, exposure of platelets to endotoxin results in activation and degranulation, likely mediated by lipopolysaccharide (LPS)-induced activation of leukocytes.[53,119] Infection with equine infectious anemia virus results in thrombocytopenia, presumably due to platelet activation and clearance, and the remaining platelets are hypofunctional in aggregation assays.[95] Equine herpesvirus also activates platelets, and may support pathologic thrombosis in infected horses.[104] Horses in the prodromal stages of carbohydrate-induced laminitis show platelet activation and increased number of platelet–neutrophil aggregates that, combined with endothelial dysfunction, may contribute to disease pathogenesis.

Systemic Inflammatory Response Syndrome and Shock

A phenomenon of platelet exhaustion resulting from chronic exposure to activated white blood cells and thrombin is believed to develop in some patients with noninfectious systemic inflammatory disease.[50,86] This manifests clinically as platelet hypofunction distinct from the platelet response to sepsis.[124] In addition, platelet hypofunction has been associated with trauma in humans.[17] In dogs with hemorrhagic shock, evidence of platelet dysfunction occurs despite relatively stable circulating platelet concentrations. In an experimental canine study that induced a 20% and then 40% decrease in blood volume and sustained hypotension, decreased WBPA developed and then resolved after autologous blood transfusion.[73]

More commonly, systemic inflammation results in platelet activation, which may support thrombus formation in susceptible patients. Platelet activation and degranulation are detected as decreases in MPC, measured using the ADVIA 120 hematology analyzer (Bayer

Corp.) or increases in the mean platelet volume (MPV) or PDW (see Chapter 78). One retrospective report[101] of dogs with inflammatory disease failed to show significant changes in these parameters; however, another report of 48 dogs with septic peritonitis described increased MPV, plateletcrit, and PDW.[72] Increases in platelet P-selectin expression (basal and poststimulation) and decreased MPC were associated with systemic inflammation and platelet activation in another canine cohort.[81] In dogs with naturally occurring *Babesia rossi* infection, platelet size and activation status were higher than healthy dogs, presumably counteracting hemostatic compromise from thrombocytopenia.[36]

Platelet–neutrophil aggregates in dogs with systemic inflammation may indicate enhanced platelet activation.[21] Neutrophils were more likely to have attached platelets from dogs with SIRS.[21] Dogs with naturally occurring *Babesia rossi* infection have increased circulating platelet–monocyte aggregates.[36] Immune-mediated hemolytic anemia (IMHA) is associated with systemic inflammation, and dogs with IMHA have increased circulating platelet–neutrophil aggregates and platelet P-selectin expression.[91,121] Low MPC (indicating platelet activation) occurs in dogs with IMHA, and lower MPC was associated with improved survival, perhaps indicating a response to inflammation.[127] Platelets of dogs with IMHA have increased tissue factor expression,[46] and platelets may play a role in the viscoelastic hypercoagulability in some dogs with IMHA.[42]

Hepatic Disease

Hepatic disease is associated with abnormalities of secondary hemostasis, as many coagulation factors and inhibitors are synthesized in the liver. Alterations in platelet function and mild to moderate thrombocytopenia have been described in veterinary patients with hepatic dysfunction.[22,58] Thrombocytopenia may be a result of nonovert DIC (see Chapter 92), occult hemorrhage, or an infective agent (e.g., leptospirosis), and may worsen as the disease progresses.[58] Thrombocytopenia in humans with acute hepatic failure appears to be independent of thrombopoietin concentration and due, in part, to platelet autoantibodies,[88] especially in patients with chronic disease. Almost half the dogs with massive hepatocellular carcinoma had platelet counts greater than 500,000/μL, attributed to malignancy-associated increases in thrombopoietin production.[70]

In dogs with congenital portosystemic shunts, impaired WBPA in response to AA and collagen has been described, although ADP-activated aggregation was normal.[123] Another study using WBPA identified similar results but noted increased OPA aggregation to collagen.[57] Impaired or increased platelet aggregation was not reflected in capillary bleeding time or CT.[57] TEG analyses in dogs with acute hepatic failure revealed decreased angle and maximum amplitude (MA), parameters affected by platelet function (although fibrinogen concentration was also decreased).[59] Dogs with acute liver disease and hepatic failure exhibited increased VWF activity, similar to humans with cirrhosis. Increased VWF availability may enhance adhesion of hypofunctional platelets, but platelet hypofunction occurs in people with acute and chronic hepatic disease measured using collagen-binding assays under flow conditions.[71] Proposed mechanisms of platelet hypofunction include disturbed transmembrane signaling, impaired thromboxane production,[65] and depletion of platelet storage pools of ATP and serotonin.[66]

Cardiac Disease

Platelet hypofunction has been demonstrated in dogs with chronic heart disease. Cavalier King Charles Spaniels (CKCS) with subclinical mitral valvular disease had significantly prolonged CT.[115] Evidence of platelet degranulation (e.g., low MPC, increased P-selectin expression) was lacking.[101] Prolonged CT and lower VWF activity were also seen in a cohort of Dachshunds with mild degenerative mitral valve disease.[80] A third report of dogs with cardiac murmurs caused by valvular insufficiency or stenosis also showed prolonged CT.[18] Decreased high-molecular-weight VWF multimers were described in a cohort of CKCS with myxomatous mitral valve disease,[109] and other studies support decreased platelet function in dogs with chronic valvular disease that correlates with severity of the regurgitant jet.[108,110] A single report suggested increased platelet function in CKCS with mitral valve disease.[83]

Platelet activation in cats with hypertrophic cardiomyopathy (HCM) was assessed using flow-cytometric expression of P-selectin in resting and ADP-activated platelets.[107] Cats with severe HCM had increased P-selectin expression in resting and stimulated platelets. Some cats with HCM had exaggerated OPA response to ADP.[45] Another study of cats with severe HCM did not find a difference in CT between healthy cats and those with HCM.[107]

Neoplasia

Many neoplastic diseases are associated with thrombocytopenia, generally attributed to consumptive coagulopathy (see Chapters 81 and 92). Few reports have specifically assessed platelet function. One study described an exaggerated WBPA response for a given dose of agonist in dogs with neoplasia, but did not stratify dogs by tumor type.[77] A report of dogs with lymphoma found that platelet aggregation was decreased at 1 hour following vincristine administration.[37] A longer-term study evaluating platelet function 10 days following vincristine administration did not show an alteration from baseline.[74] Vincristine may cause early release of reticulated platelets from bone marrow, a population with relatively increased reactivity.[43] Neoplasms resulting in hyperglobulinemia or a leukemoid response may result in decreased platelet function, presumably due to crowding or coating of the platelets with globulin molecules. Patients with polycythemia vera (see Chapter 26) or essential

thrombocytosis (see Chapter 82) may also have platelet adhesion abnormalities.[25]

Endocrinopathies

Some canine endocrinopathies have been associated with platelet dysfunction, and occasionally hyperfunction. Thrombocytosis is a common clinical finding in dogs and humans with hyperadrenocorticism. In some humans with hyperadrenocorticism or hypercortisolemia, increased platelet aggregation has been described, and there is evidence of increased thromboxane synthesis[39] and elevations in circulating ultra-large VWF multimers.[15] Although studies of coagulation function have been performed in dogs with naturally occurring hyperadrenocorticism and exogenous hypercortisolemia, definitive characterization of platelet function in these patients is lacking.[28,51,61,84,94] Closure time may be prolonged in dogs with hyperadrenocorticism.[63] TEG analyses of dogs with hyperadrenocorticism generally support increased coagulation function, with an undefined platelet contribution.[61]

Dogs with diabetes mellitus (DM) had increased ADP-stimulated aggregation and ristocetin-induced maximum aggregation, although VWF was not evaluated. Dogs with experimentally induced DM did not have changes in platelet aggregation.[41,60] In humans with type-2 DM, platelets are thought to be hyperreactive, with decreased inhibition compared to platelets of healthy patients receiving equivalent doses of clopidogrel and aspirin.[97] Glycation of platelet surface proteins may contribute to this hyperreactivity, in addition to increased P-selectin expression, impaired prostacyclin and nitric oxide response, and increased intracellular calcium.[30] Although chronic hyperglycemia may enhance platelet hyperreactivity, mechanisms defined in people have not been described in animals. Adverse vascular events in humans with type-2 DM are likely promoted by endothelial dysfunction, oxidative stress, and coronary artery disease.[96]

Dogs with hypothyroidism have smaller platelet size and cats with hyperthyroidism have larger platelet size;[106] however, platelet function in either disease has not been studied. One report of hypothyroid dogs demonstrated decreased circulating VWF concentration;[2] however, another report of dogs with hypothyroidism did not confirm these findings.[85] Human hyperthyroidism is associated with a thrombophilic state, primarily due to procoagulant excess, and no consistent platelet abnormalities.[103]

PHARMACEUTICALS THAT AFFECT PLATELET FUNCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) decrease inflammation through inhibition of cyclooxygenase (COX) enzymes which produce prostaglandins (PG). COX enzymes also catalyze the formation of thromboxane A_2 (TXA_2), a potent platelet agonist and vasoconstrictor. NSAIDs have variable inhibitory activity for COX isoforms,[105] and canine platelets may express both COX-1 and COX-2.[112] Animals treated with NSAIDs may experience platelet hypofunction due to impaired TXA_2 synthesis. Aspirin is an irreversible COX inhibitor, while other NSAIDs demonstrate reversible inhibition. Decreased platelet aggregation or prolonged CT was found in dogs treated with ketoprofen, carprofen, and meloxicam in some reports,[10,41,47,114,82] but not in others.[4,5,32,33,126] A single report described prolonged collagen/epinephrine CT after deracoxib therapy.[82] Horses treated with phenylbutazone, flunixin meglumine, or firocoxib had no changes in OPA or CT, despite decreased TXA_2 metabolite production in response to phenylbutazone or flunixin.[14]

Despite decreases in TXA_2 metabolites after aspirin therapy, some dogs demonstrate no change in platelet function.[55] A similar lack of platelet inhibition has been described in cats[16] and warmblood horses.[93] Although the lack of predicted response has been termed "aspirin resistance," the wide range of observed responses to varying dosages of aspirin brings into question routine use of aspirin as an antiplatelet agent in dogs or cats. Only eight of 24 healthy dogs receiving 1 mg/kg of aspirin PO, q 24h had prolonged CT, while all showed decreased urinary TXA_2 metabolites.[23] Sixteen dogs receiving the same aspirin dosage had variable response in multiple tests of platelet function,[40] while another report of 20 dogs failed to show decreased urinary TXA_2 metabolites.[49] A lower dosage of aspirin (0.5 mg/kg, PO, q 24 h, for 2 days) given to 10 dogs demonstrated variably decreased ADP or collagen-activated aggregation.[99] More recently, a study of six dogs given an escalating dosage of aspirin found that a threshold dose of 2 mg/kg, PO, q 24h reliably decreased OPA and prolonged CT.[76] Aspirin given to horses at 10 mg/kg PO for 5 days did not change ADP or collagen-induced OPA,[8] but another study noted slight prolongations in CT (ADP/collagen).[98] In cats treated with aspirin of varying dosages, platelet function as measured by CT and aggregometry was unaffected, despite demonstrable decreases in TXA_2 metabolites.[16,48]

The pharmacokinetics and pharmacodynamics of clopidogrel (see Chapter 94) have been described in dogs, cats, and horses. Clopidogrel requires hepatic conversion to an active metabolite, which irreversibly binds the platelet P2Y12 ADP receptor. Hepatic biotransformation can be affected by coadministered medications[111] and variability in hepatic P450 activity.[67] Clopidogrel decreases ADP-induced aggregation in dogs,[9] cats,[38,117] and horses,[8,13] and often decreases platelet reactivity. Collagen-induced aggregation in clopidogrel-treated patients is variably decreased. Because clopidogrel is an irreversible inhibitor, restoration of normal platelet function requires release of new platelets, generally 3–5 days after drug discontinuation in dogs,[9] cats,[38] and horses.[8]

Hydroxyethyl starches (HES) and gelatin-based synthetic colloid solutions can result in decreased platelet aggregation and decreased coagulation factor activities. Studies have evaluated high-molecular-weight (e.g., HES 670/0.8, HES 600/0.75) and lower-molecular-weight

(e.g., HES 130/0.4) starches. The second number in the product name is the substitution ratio of the starches and thus the molecular complexity. At in vitro dilutions of 1:5 or lower, HES solutions have no apparent clinically relevant effects on coagulation. In vivo, bolus IV administration (15 mL/kg) to anesthetized dogs caused transient hypocoagulability characterized by prolonged CT and coagulation dysfunction assessed by ROTEM.[90] Similar results have been described in horses following a 5 mL/kg IV bolus of either HES 670/0.75 or HES 130/0.4.[27]

HES solutions are used to treat low oncotic pressure and are generally administered as an IV constant rate infusion (CRI). In hypoalbuminemic dogs administered either 1 or 2 mL/kg/h of HES 130/0.4, IV, for 24 h, no changes in ROTEM parameters or prothrombin time (PT), activated partial thromboplastin time (aPTT), or fibrinogen concentration were seen.[6] Anesthetized dogs given an IV bolus of 15 mL/kg of HES 130/0.4 demonstrated transient (1 hour) prolongation of CT.[90] In dogs with experimental hemorrhagic shock administered 20 mL/kg HES 130/0.4 as an IV bolus, ROTEM and coagulation tests suggested hypocoagulability lasting 3 hour after the bolus.[19] Interestingly, HES did not prolong CT, whereas a treatment group that received 20 mL/kg of a 4% succinylated gelatin solution for resuscitation had significant prolongations of CT through the 3 hour time point. In this report, decreased factor VIII activity and VWF concentration developed with the onset of shock and worsened after fluid, but not whole blood, resuscitation. These decreases were attributed to dilutional effects and not to colloid.[75] Horses treated with a 10 mL/kg IV bolus of 0.9% saline, HES 130/0.4, or HES 600/0.75, developed decreased platelet counts, VWF concentration, and factor VIII by 1 hour after administration. These changes were accompanied by prolongation of CT that resolved by 8 hours in the HES 130/0.4 and saline groups, but remained prolonged in the HES 600/0.75 group for at least 24 hours.[27] These results suggest that small HES molecules have more rapid clearance than larger molecules.[26]

A transient decrease in platelet aggregation and platelet count has been reported for dogs after premedication with acepromazine and atropine,[3] a finding not confirmed in a subsequent study.[20] Few reports have evaluated the effects of anesthetic drugs on platelet reactivity; however, sevoflurane and propofol were associated with decreased aggregation.[64] Antibiotics may have transient effects on platelet aggregation. Tetracycline, cephalothin, and cefmetazole decreased canine platelet responses to ADP,[35,122] while amoxicillin, cephalexin, enrofloxacin, and doxycycline did not.[120] Other penicillin-related drugs may have antiplatelet effects at clinically relevant doses.[56] An in vitro study found no effect on platelet function of intravenous lipid therapy.[116] A recent study suggested that immunosuppressive medications including prednisone, cyclosporine, mycophenolate mofetil, azathioprine, and leflunomide do not have significant effects on platelet function of healthy dogs.[113] This report differs from another that documented increased ADP-induced aggregation in healthy dogs receiving immunosuppressive dosages of prednisone.[92]

CHAPTER 86

Treatment of Disorders of Platelet Number and Function

MARY BETH CALLAN

Treatment of Disorders of Platelet Number
- Primary Immune Thrombocytopenia
  - Immunosuppression and Immunomodulation
  - Thrombopoietin Receptor Agonists
  - Splenectomy
  - Blood Component Therapy
- Essential Thrombocythemia

Treatment of Disorders of Platelet Function
- Von Willebrand Disease
  - Desmopressin
  - Blood Component Therapy
  - Antifibrinolytic Agents
- Inherited Platelet Dysfunction
  - Blood Component Therapy
  - Desmopressin
  - Antifibrinolytics
- Acquired Platelet Dysfunction
  - Desmopressin
  - Antifibrinolytic Agents

Acronyms and Abbreviations

BMBT, buccal mucosal bleeding time; CRYO, cryoprecipitate; DDAVP, 1-deamino-8-D-arginine vasopressin; EACA, epsilon aminocaproic acid; ET, essential thrombocythemia; FFP, fresh frozen plasma; FWB, fresh whole blood; hIVIG, human intravenous immunoglobulin; ITP, immune thrombocytopenia; JAK, janus kinase; MA, maximum amplitude; PC, platelet concentrate; PFA-100, Platelet Function Analyzer-100; pRBC, packed red blood cells; PRP, platelet-rich plasma; TEG, thromboelastogram; TPO, thrombopoietin; TPO-RA, thrombopoietin receptor agonist; TXA, tranexamic acid; VWD, von Willebrand disease; VWF, von Willebrand factor.

TREATMENT OF DISORDERS OF PLATELET NUMBER

Disorders of platelet number include thrombocytopenia and thrombocytosis (see Chapters 80–82). Primary immune thrombocytopenia (ITP) is considered the most common cause of *severe* thrombocytopenia in dogs, but is diagnosed rarely in cats. Treatment of quantitative platelet defects is often directed at correction of underlying disorders. Guidelines and procedures for platelet transfusion are presented in this chapter (and see Chapters 94 and 101).

Primary Immune-Mediated Thrombocytopenia

Immunosuppression and Immunomodulation

Glucocorticoids are the mainstay of treatment for primary ITP and other immune cytopenias (see Chapters 35 and 36). Adjunctive therapy of ITP includes vincristine and human intravenous immunoglobulin (hIVIG). Vincristine's precise mechanism of action leading to increased platelet counts in patients with ITP is unknown. It has been proposed that vincristine, bound to platelet microtubules, is transported to the spleen, where it inhibits the phagocytic function of splenic macrophages.[1] Vincristine may also stimulate thrombopoiesis.[1] While

hIVIG has many actions, blockade of Fc receptors on macrophages is considered the mechanism for the observed response in dogs with ITP.[7,43] Both vincristine and hIVIG have been documented to shorten the duration of severe thrombocytopenia in dogs with primary ITP versus prednisone alone.[3,7,44] A comparison of platelet recovery times for dogs treated with single-dose hIVIG (0.5 g/kg IV) versus vincristine (0.02 mg/kg IV) in combination with glucocorticoids revealed no significant difference between treatments.[3] Therefore, vincristine is considered more cost-effective as first-line adjunctive treatment for initial management of canine primary ITP. Although single-dose vincristine is generally well tolerated, perivascular sloughing due to extravasation is a severe potential complication. Moreover, since the majority of dogs with primary ITP respond to glucocorticoids alone within 7 days,[7,44] adjunctive treatment may not be appropriate for all cases.

Beyond the comparison of vincristine and hIVIG, prospective, controlled studies comparing efficacy of adjunctive immunomodulatory agents in treatment of dogs with primary ITP are lacking. Retrospective studies and case series of canine primary ITP have described use of azathioprine,[22,39,41,48] cyclosporine,[13,39,41,48] and mycophenolate mofetil,[13,39,48] in combination with glucocorticoids (with or without vincristine); however, these studies are not designed to determine efficacy. A case series describing treatment with mycophenolate mofetil as a single agent in five dogs with presumptive primary ITP found that all dogs achieved a complete remission and had no evidence of relapse during a median follow-up of 16 months (range, 5–32 months).[54]

The optimal duration of treatment for dogs with primary ITP is unknown, but many dogs are empirically managed with tapering doses of immunosuppressive drugs over 4–6 months while monitoring for relapse.[39] Reported rates of relapse (typically defined as platelet count <150,000/μL after prior increase to within reference interval) for dogs with ITP vary widely, ranging from 9 to 47%.[25,39,41,48,52] Differences in treatment regimens and monitoring protocols likely contribute to such variability. A retrospective study comparing relapse rates among 45 dogs with ITP prescribed immunosuppressive therapy for a finite period of time (median, 137 days) or indefinitely (median, 640 days), found no difference, with relapse rates of 15% and 18.9% in the finite and indefinite treatment groups, respectively.[48] These results suggest no clinical benefit to continuing indefinite immunosuppression after initial diagnosis of primary ITP.[48]

While glucocorticoids are the mainstay treatment of primary ITP in dogs, oral prednisolone was deemed effective in only five of nine cats in two case series.[6,53] Other immunosuppressive agents administered included dexamethasone, cyclosporine, and chlorambucil, though there are insufficient cases to assess efficacy.[6,53] In a four-cat case series, each had a chronic course with frequent relapses and long-term immunosuppression was required for three cats that survived to discharge.[6]

Thrombopoietin Receptor Agonists

In addition to platelet destruction, ITP is characterized by suppressed platelet production (see Chapter 80).[38] Thrombopoietin receptor agonists (TPO-RAs), including romiplostim and eltrombopag, have been approved for treatment of chronic primary ITP in humans (see Chapter 80).[2] These agents bind to the TPO receptor c-Mpl, thereby increasing megakaryocyte growth and differentiation.[2] Thrombotic complications are potential adverse events of TPO-RA-induced thrombocytosis. A variable clinical response to TPO-RAs has been observed in humans with chronic ITP; nonresponders have higher endogenous TPO levels than responders.[2]

There is limited information on the use of TPO-RAs in veterinary medicine. Five dogs, including one with primary ITP, two with primary immune-mediated hemolytic anemia and ITP (Evans syndrome), and two with secondary ITP associated with ehrlichiosis, were treated with romiplostim at 3–5 μg/kg SC once weekly, after one or more relapses while receiving conventional immunosuppressive therapy.[28] An increased platelet count was observed within 3–6 days of administration of romiplostim in four of five dogs, all of which achieved complete remission within 2 weeks with no adverse effects.[28] The maintenance romiplostim dosage was decreased in all four dogs (2–3.4 μg/kg/week). The mean length of treatment was 13.8 weeks.[28] While these results are promising, high cost may limit romiplostim use in veterinary patients.

Splenectomy

Splenectomy has traditionally been a second-line therapy for relapsing or refractory primary ITP in humans, with reported 5-year response rate of 60–70%. More recently, the use of TPO-RAs and rituximab, an anti-CD20 antibody, has resulted in a tendency to avoid or delay splenectomy, despite the newer agents having lower response and higher relapse rates than splenectomy.[29] Major complications associated with splenectomy in humans include increased risk of bacterial infections, sepsis, and thrombosis.[29]

Anecdotal experience suggests that splenectomy may be an effective option for dogs with relapsing primary ITP; however, controlled studies are lacking. Among fourcase series, splenectomy was performed in 22 dogs with presumptive primary immune-mediated hematologic diseases, including 16 dogs with ITP only, three dogs with both ITP and immune-mediated hemolytic anemia, and three dogs with both ITP and immune-mediated neutropenia.[18,25,51,52] Fourteen of 22 dogs achieved remission or maintained a stable platelet count >60,000/μL postsplenectomy, and medications were discontinued in eight dogs. Thorough screening for occult vector-borne pathogens should be performed before splenectomy, since it is particularly difficult to clear Babesia spp., and other such infections after splenectomy.

Blood Component Therapy

Transfusion may be required in dogs with ITP experiencing severe mucosal bleeding, especially hemorrhage into the gastrointestinal tract. In such cases, packed red blood cell (pRBC) transfusions are indicated to provide additional oxygen-carrying support, and to enhance hemostasis. In a study evaluating a bleeding assessment tool (DOGiBAT—see Chapter 80) to standardize characterization of the severity of bleeding in dogs with primary ITP, 13 of 34 dogs (38.2%) received blood products during hospitalization, with pRBCs the most common blood product administered.[31] The admission platelet count was not correlated with transfusion, duration of hospitalization, or survival to discharge, indicating that platelet count alone does not consistently predict clinical bleeding.[31] Therefore, a "platelet transfusion trigger," i.e., a platelet count threshold to administer prophylactic platelet transfusions, is not appropriate for dogs with ITP. Furthermore, transfused platelets may be rapidly destroyed in dogs with ITP, rendering platelet transfusions of questionable benefit. However, in dogs with ITP experiencing uncontrolled or life-threatening bleeding (e.g., bleeding into the brain or lungs), platelet transfusions might provide short-term hemostasis despite negligible platelet count increments post-transfusion.

In clinical practice, fresh whole blood (FWB) is often the most readily available platelet product, but other options include platelet-rich plasma (PRP), platelet concentrate (PC), cryopreserved PRP/PC, and lyophilized platelets (see Chapter 101). In a prospective clinical trial of 37 thrombocytopenic dogs (27 primary ITP) randomized to receive canine lyophilized platelets or fresh PC, active bleeding was unchanged immediately post-transfusion in 18 of 22 dogs receiving lyophilized platelets and in all dogs receiving fresh PC.[14] In a retrospective evaluation of cryopreserved canine PC transfusions to thrombocytopenic dogs (28 of 43 with ITP), there was no difference in clinical bleeding or patient survival compared to a control group that did not receive any platelet products.[36] While not conducted as efficacy studies, cryopreserved and lyophilized platelets appeared to be well tolerated by thrombocytopenic dogs.[14,36]

Essential Thrombocythemia

Thrombocytosis (see Chapter 82) is frequently an incidental CBC abnormality, but marked thrombocytosis associated with hemorrhage or thrombosis may warrant treatment. Reactive thrombocytosis, even with platelet counts >1,000,000/μL, does not typically cause clinical signs. Resolution of reactive thrombocytosis involves treating the underlying disease (e.g., inflammation, infection, neoplasia, iron deficiency).

Essential thrombocythemia (ET), a chronic myeloproliferative disorder of clonal proliferation of megakaryocytes, is rare in animals (see Chapter 82). Case reports of probable ET in dogs and cats describe the use of radiophosphorus and hydroxyurea.[4,23,49] In human medicine, cytoreductive therapy is warranted only in patients with high-risk disease, defined as a history of thrombosis or advanced age (>60 years) with janus kinase (JAK)2 mutations. The first-line drug of choice is hydroxyurea and second-line drugs are interferon-α and busulfan.[50] In addition, low-dose aspirin has been recommended for humans with low- to high-risk disease to alleviate vasomotor (microvascular) disturbances associated with ET.[50] Use of ruxolitinib or other JAK2 inhibitors is not recommended as first-line therapy.[50] The molecular basis of ET in dogs and cats has not yet been elucidated and might differ from that in humans, thus preventing any benefit of JAK2 inhibition.

TREATMENT OF DISORDERS OF PLATELET FUNCTION

Disorders of platelet function include von Willebrand disease (VWD) (see Chapter 83), hereditary thrombopathia, or intrinsic platelet dysfunction (see Chapter 84), and acquired platelet function defects associated with various systemic disorders and medications (see Chapter 85).

Von Willebrand Disease

Medical management of VWD is aimed toward controlling spontaneous (e.g., epistaxis, hematuria) or post-traumatic or postoperative bleeding and supporting surgical hemostasis. While dogs with type 2 and type 3 VWD inevitably have a severe bleeding tendency, the phenotype among dogs with type 1 VWD is variable. Some type 1 VWD dogs have marked reduction in plasma von Willebrand factor (VWF) concentration, but no apparent bleeding tendency. Therefore, the need for prophylactic treatment, particularly with blood component therapy, should be assessed on a case-by-case basis.

Desmopressin

Desmopressin acetate (1-deamino-8-D-arginine vasopressin [DDAVP]), a synthetic analog of the neurohypophyseal hormone vasopressin, has been used to control bleeding in a variety of canine hemostatic disorders, but most often for VWD. DDAVP causes release of VWF from endothelial cell storage granules, referred to as Weibel–Palade bodies. A study evaluating the effects of DDAVP (1 μg/kg SC) to dogs with type 1 VWD found only modest increase in mean plasma VWF concentration (baseline, 10%; 1 hour post-treatment, 17%) but evidence of improved hemostatic function assessed by Platelet Function Analyzer (PFA)-100 and shortening of buccal mucosal bleeding time (BMBT).[11] DDAVP has been reported to be ineffective in controlling bleeding in patients with type 3 VWD, since it acts by releasing intracellular stores of VWF and these patients do not synthesize VWF protein.[5]

DDAVP is available as a sterile solution (4 μg/mL) for intravenous administration and a nasal spray (100 μg/mL)

that can be administered subcutaneously to dogs. The nasal spray is used more frequently due to lower cost. A recommended dose is 1 µg/kg SC, administered not more than once daily due to the risk of antidiuretic hormone effects of water retention and hyponatremia, as well as failure to elicit VWF release with repeated administration. DDAVP should be administered 30 minutes prior to surgery to assist surgical hemostasis.

Blood Component Therapy

Blood products containing VWF include FWB, fresh frozen plasma (FFP), and cryoprecipitate (CRYO), the latter representing the blood component of choice (see Chapters 83 and 100). Since CRYO contains a concentrated amount of VWF compared to FFP, CRYO is more easily administered and avoids volume overload. One of the main indications for CRYO or FFP is to control spontaneous or traumatic/surgical bleeding not amenable to topical therapies (e.g., compression, cautery, gel foam) or not responsive to DDAVP. Due to the short half-life of plasma VWF (approximately 12 hours), CRYO or FFP transfusions may need to be administered every 8–12 hours to control severe bleeding. In addition, CRYO or FFP can be administered prophylactically before surgery, particularly in dogs with a known bleeding tendency or for surgical procedures in which small volume hemorrhage could have devastating consequences (e.g., cervical ventral slot surgery). Sufficient CRYO or FFP (see Chapter 100 for dosage guidelines) should be given to ensure rapid increase in plasma VWF levels for effective platelet adhesion. However, prophylactic administration of CRYO or FFP is not always required, as DDAVP may be sufficient to prevent surgical bleeding in some dogs. In VWF-deficient dogs without a bleeding history that receive only DDAVP preoperatively, CRYO or FFP should be available in case excessive bleeding is observed during or after surgery. Similarly, blood-type-compatible and cross-match-compatible pRBCs should be available in the event of excessive blood loss.

Feline VWD is rare, with only two published case reports of type 3 VWD. Epistaxis was controlled in one cat with administration of FFP. Feline CRYO is not prepared routinely due to limited need and technical challenges associated with processing small volumes of FFP.[5]

Von Willebrand disease has been reported uncommonly in horses. Transfusion of fresh plasma (4 L) to an affected Thoroughbred mare effectively controlled epistaxis and periparturient hemorrhage.[42] However, a single preoperative transfusion of fresh plasma (2 L) did not prevent abnormal bleeding after surgical repair of an umbilical hernia and castration of an affected foal, suggesting that more aggressive transfusion support might be necessary to control surgical hemorrhage.[42] Use of DDAVP to manage VWD in horses has not been reported and the cost of the drug may be prohibitive in large animals.

Antifibrinolytic Agents

The antifibrinolytic agents epsilon aminocaproic acid (EACA) and tranexamic acid (TXA) are synthetic lysine analogs that reversibly bind to plasminogen, preventing plasmin from binding to fibrin, thereby slowing the rate of fibrinolysis. Antifibrinolytics are used to control bleeding due to VWD in humans, with suggested management including TXA with or without DDAVP for minor bleeding and TXA plus VWF concentrate for major bleeding.[37] Antifibrinolytics are typically administered until bleeding is controlled, or for 5–7 days postoperatively.[37]

While there are no published studies evaluating efficacy of antifibrinolytics for canine VWD, clinical experience suggests that TXA and EACA can be used as adjunctive therapy. In an in vitro model of hyperfibrinolysis, both TXA (10–20 mg/kg IV or 15–20mg/kg PO) and EACA (20–100 mg/kg IV or 100 mg/kg PO) improved clot strength and decreased fibrinolysis in a dose-dependent manner in blood samples from healthy dogs 1–4 or 1–6 hours after administration of EACA or TXA, respectively.[10,40] Although optimal dosing for dogs has not yet been determined,[33] pharmacokinetic and in vitro fibrinolytic studies[10,40] suggest dosing recommendations for TXA of 15–20 mg/kg PO or IV and for EACA dosing at 50–100 mg/kg PO or IV, both given q 6–8 hours.

In a retrospective study evaluating the safety of TXA in 68 dogs with bleeding due to a variety of causes, vomiting was the only observed adverse effect.[27] In experimental studies, vomiting was observed within 5 minutes of receiving intravenous doses >10 mg/kg.[26,27,40] Tranexamic-acid-induced vomiting is thought to result from activation of the tachykinin neurokinin 1 receptor.[26] Pretreatment with maropitant, a neurokinin 1 antagonist, could help prevent nausea. In a retrospective study of 122 bleeding dogs treated with EACA, no adverse events were reported; however, its efficacy is currently unlcear.[15]

Inherited Platelet Dysfunction

Variable bleeding tendencies are associated with inherited intrinsic platelet disorders (see Chapter 84). Guidelines from the United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) for management of bleeding associated with inherited thrombopathias in humans include use of antifibrinolytics to control minor spontaneous bleeding (e.g., epistaxis) and prevent excessive bleeding associated with dental extractions and surgical procedures. Antifibrinolytic therapy is begun the day before a scheduled procedure and continued for 5–7 days, or longer if needed.[8] Addition of DDAVP is considered if antifibrinolytics alone are ineffective. Platelet transfusions are recommended for severe platelet disorders and when other agents have failed.

Blood Component Therapy

Animals with hereditary thrombopathias experiencing severe, uncontrolled, or life-threatening bleeding require

platelet transfusions. In addition, prophylactic platelet transfusions should be considered in patients with a known bleeding tendency and documented (or suspected) thrombopathia undergoing surgery. Fresh PRP administered to a Great Pyrenees with Glanzmann thrombasthenia immediately before an elective ovariectomy provided effective surgical hemostasis.[9] Canine cryopreserved PC has been administered prophylactically to dogs with platelet procoagulant deficiency (Scott syndrome) prior to elective neutering and for management of nonsurgical hemorrhage, mainly epistaxis.[24] Since cryopreserved platelets externalize phosphatidylserine, they may offer a theoretical advantage to fresh platelets in promoting thrombin generation in these patients.[24]

Desmopressin

Administration of DDAVP has been associated with shortening of bleeding time or reduced bleeding tendencies in people with some forms of inherited intrinsic platelet dysfunction, such as platelet storage pool disease (platelet granule defect) and Bernard–Soulier syndrome (lack of platelet GPIb receptor), but not in Glanzmann thrombasthenia (lack of platelet GPIIb/IIIa receptor).[17,32] The mechanisms underlying improved hemostasis in such conditions remain unclear. It has been proposed that DDAVP improves platelet function via increased formation of procoagulant "COAT" platelets (referring to combined agonists, COllagen And Thrombin, that induce this response in vitro and the resultant coating of the platelet surface by a layer of adhesive and procoagulant proteins).[12]

Controlled studies evaluating efficacy of DDAVP in improving hemostasis in animals with inherited intrinsic platelet disorders are lacking. In light of the beneficial hemostatic effect of DDAVP observed in humans with a variety of hereditary platelet function disorders and its excellent safety profile in dogs, it is reasonable to consider a trial with DDAVP (1 μg/kg SC administered not more than once daily) in dogs with suspected or confirmed inherited thrombopathia.

Antifibrinolytics

Antifibrinolytics have been used in dogs with inherited thrombopathias in conjunction with blood component therapy, thus complicating assessment of their beneficial effect. Tranexamic acid (10 mg/kg IV q8h for a total of four doses) was administered postoperatively to seven German Shepherds with Scott syndrome that had received cryopreserved PC in preparation for elective ovariohysterectomy or castration.[24] Five of seven dogs developed mild to moderate incisional bruising and swelling that did not require additional therapy, whereas two dogs developed postoperative hemorrhage that required additional platelet transfusions.[24] Epsilon aminocaproic acid (30 mg/kg IV q8h) and fresh PRP were administered to a Greater Swiss Mountain dog heterozygous for a *P2RY12* ADP receptor mutation that developed a hemoabdomen post ovariohysterectomy, with successful control of the bleeding.[20] Similar to DDAVP, TXA and EACA are well tolerated by dogs and could be considered as adjunct therapy for management of bleeding in dogs with hereditary thrombopathias, recognizing that efficacy is uncertain in this situation.

Acquired Platelet Dysfunction

In patients with acquired platelet dysfunction (see Chapter 85), treatment and reversal of the underlying disease is the most effective approach to managing the resultant bleeding tendency. For example, in patients with severe kidney disease, hemodialysis to remove uremic toxins and administration of darbepoetin or pRBC transfusions for anemia should improve hemostasis. However, correction of the underlying disease is not always possible or does not yield timely results, thus platelet transfusions may be necessary to achieve hemostasis. Medical management with DDAVP and antifibrinolytic agents may be appropriate, based on human reports.

Desmopressin

Administration of DDAVP has been associated with a shortening of bleeding time or an improvement in bleeding tendencies noted in people with acquired platelet dysfunction due to aspirin ingestion, renal disease, and liver disease.[17,32] Studies evaluating efficacy of DDAVP in animals with acquired platelet dysfunction are lacking, though small case series in dogs have described shortening of prolonged BMBTs associated with aspirin administration,[16,46] chronic liver disease,[46] and chronic monocytic ehrlichiosis.[21] Furthermore, excessive intraoperative bleeding was not observed in three dogs with aspirin-induced platelet dysfunction treated with DDAVP before surgery for intervertebral disc disease,[16] and surface bleeding observed in dogs with ehrlichiosis subsided within 1 hour of DDAVP administration.[21]

Antifibrinolytic Agents

Antifibrinolytic agents may be used as adjunct therapy in people with acquired platelet dysfunction. Tranexamic acid reduced circulating plasminogen concentration, decreased fibrin/fibrinogen degradation products, shortened bleeding time, and improved platelet aggregation and secretion in people with severe chronic renal failure.[34] A study evaluating low-dose TXA (administered orally 5 days per week for 3 months) in chronic hemodialysis patients demonstrated improved platelet function as assessed by PFA-100 and increased blood hemoglobin levels compared to baseline.[45] However, use of TXA in patients with chronic kidney disease is controversial, as it is excreted primarily through the kidneys. Failure to adjust dosage has caused neurotoxicity (seizures, blurred vision, myoclonus), which resolved within a few days of discontinuing therapy.[30]

The use of antifibrinolytics to manage bleeding caused by acquired platelet dysfunction has not been evaluated in veterinary medicine. Both TXA and EACA have been administered to dogs with bleeding associated with neoplasia, surgery, trauma, liver failure, anticoagulant rodenticide intoxication, cyclophosphamide-induced hemorrhagic cystitis, and *Angiostrongylus vasorum* infection.[19,27,35,47] The efficacy of antifibrinolytics in ameliorating bleeding in most of these conditions is unclear, though TXA and EACA appeared to be well tolerated, with no thrombotic complications observed.

Hemostasis is a vital protective mechanism that prevents blood loss by sealing sites of injury in the vascular system. Hemostasis must be controlled, however, so that blood does not coagulate within the vasculature. Uncontrolled coagulation restricts normal blood flow, resulting in tissue hypoxia. Hemostasis consists of a tightly controlled and well-balanced interplay among a large number of cellular and protein participants. Endothelial cells lining the vasculature, cells outside the vasculature, and platelets all play important roles. Hemostatic proteins include inactive precursors (zymogens) that are converted to active enzymes, regulatory proteins (cofactors) that enhance the functionality of their corresponding coenzymes, and inhibitors that interfere with protein function through a variety of mechanisms (see Table 87.1).

Physiologic coagulation does not occur within the vasculature because of the nonreactive properties of the resting cellular participants, and because the majority of hemostatic proteins circulate in an inert or zymogen form. The initiation of coagulation in response to injury depends on the exposure of extravascular components that are not present within the bloodstream under physiologic conditions. Exposure of these extravascular participants initiates an explosive cascade of cellular activation, changes in cell-surface properties, and generation of active enzymes that produce a stable clot. Some of the cells and enzymes also trigger vascular wall responses, inflammatory pathways, and immune-defense mechanisms. Coagulation also initiates fibrinolysis, the process by which the clot is removed to restore blood flow. Ultimately, coagulation triggers the cell migration and proliferation that promote healing.

BIOCHEMISTRY OF COAGULATION

Coagulation Cascade Enzymatic Reactions

The clotting cascade consists of a series of enzymatic reactions. Protein participants circulate in the blood mostly as inert precursors, or zymogens. Zymogens are activated by limited proteolysis to form active enzymes. With the exception of thrombin, all of these enzymes have limited activity unless they bind to their protein cofactor and a procoagulant membrane surface. Upon complex assembly on a suitable membrane surface, the enzyme's bioactivity is markedly exaggerated to as much as several hundred–thousandfold.

Each cascade reaction is initiated when the active enzyme complex binds to its substrate, resulting in cleavage of the substrate to generate the next enzyme in the series. In many cases, positive feedback occurs because a downstream enzyme activates an upstream zymogen back, thereby markedly amplifying the generation of downstream enzymes from minimal activation of an upstream zymogen. Negative feedback is also a common feature in the coagulation cascade, with downstream enzymes generating inhibitors that downregulate activity of upstream enzymes. The generation of a blood clot is carefully controlled through the complex interplay of the initial trigger, amplification reactions, and inhibitors.

Coagulation Complexes (Cofactors and Enzymes)

The majority of coagulation enzymes are serine proteases with homology to trypsin, the prototype enzyme of this class. Serine proteases cleave after arginine residues. Other coagulation proteins have no enzymatic capabilities, rather they play regulatory roles in enhancing enzymatic activity. These proteins circulate in inactive forms, called procofactors. A procofactor must be cleaved by the appropriate enzyme to result in a fully active cofactor. Proteolytic activation of zymogens to enzymes and procofactors to cofactors can take several forms (Figure 87.1).

Many of these proteins contain disulfide bonds between two cysteine residues. Enzymatic cleavage of an activation site that lies between the cysteine residues will convert the single-chain protein to a two-chain protein of identical molecular weight, without removing any amino acids. When the activation site does not lie between disulfide bond cysteine residues, cleavage of a single site will result in two different protein fragments. The smaller, nonfunctional fragment is the activation peptide, while the remaining fragment is the fully activated enzyme or cofactor.

Some of the proteins contain multiple activation sites. If both lie between disulfide-bridged cysteine residues, then an activation peptide is released and a two-chain enzyme is produced. The order in which the target sites are cleaved may result in inactive intermediates, or partially or fully active intermediate enzymes. Complete cleavage of all of the sites will generally result in multiple fragments.

TABLE 87.1 Hemostatic proteins, factors, cofactors, and inhibitors.

Functional classification	Abbreviation	Current/previous names	Characterization
Extrinsic pathway	TF	Tissue factor/thromboplastin	Cofactor
	FVII	Factor VII/proconvertin	Zymogen
	FVIIa	Factor VIIa	Enzyme
Contact pathway	FXII	Factor XII/Hageman factor	Zymogen
	FXIIa	Factor XIIa	Enzyme
	PK	Prekallikrein/Fletcher factor	Zymogen
	K	Kallikrein	Enzyme
	HK	H-kininogen/Williams–Fitzgerald–Flaujeac factor, High molecular weight (MW) kininogen	Cofactor
Intrinsic pathway	FXI	Factor XI/plasma thromboplastin antecedent	Zymogen
	FXIa	Factor XIa	Enzyme
	FIX	Factor IX/Christmas factor	Zymogen
	FIXa	Factor IXa	Enzyme
	FVIII	Factor VIII/antihemophilic factor	Procofactor
	FVIIIa	Factor VIIIa	Cofactor
Common	FX	Factor X/Stuart–Prower factor	Zymogen
	FXa	Factor Xa	Enzyme
	FV	Factor V/labile factor	Procofactor
	FVa	Factor Va	Cofactor
	Pro	Prothrombin/factor II	Zymogen
	Fg	Fibrinogen/factor I	Substrate
	Fb	Fibrin	Final product
	FXIII	Factor XIII	Zymogen
	FXIIIa	Factor XIIIa	Enzyme
Coagulation inhibitors	α_1-PI	α_1-Protease inhibitor/α_1-antitrypsin	
	AT	Antithrombin/antithrombin III	Serpin
	HC	Heparin cofactor II	Serpin
	TFPI	Tissue factor pathway inhibitor/extrinsic pathway inhibitor	Kunitz inhibitor
	PC	Protein C	Zymogen
	APC	Activated protein C	Enzyme, inhibitor
	PS	Protein S	Cofactor
	TM	Thrombomodulin	Cofactor
	PZ	Protein Z	Cofactor
	ZPI	Protein-Z-dependent protease inhibitor	Enzyme
Fibrinolysis	PLG	Plasminogen	Zymogen
	PLM	Plasmin	Enzyme
	scuPA	Single-chain urokinase plasminogen activator/Prourokinase	Zymogen (slight enzyme)
	tcuPA (uPA)	Two-chain urokinase plasminogen activator/urokinase	Enzyme
	sctPA	Single-chain tissue-type plasminogen activator	Enzyme
	tctPA (tPA)	Two-chain tissue-type plasminogen activator	Enzyme
Fibrinolysis inhibitors	α_2-AP	α_2-Antiplasmin/plasmin inhibitor	Serpin
	PAI-1	Plasminogen activator inhibitor-1	Serpin
	TAFIa	Thrombin-activatable fibrinolysis inhibitor/carboxypeptidase U, B, or R	Enzyme
Nonspecific inhibitors	C1-INH	C1-inhibitor	Inhibitor
	α_2-MG	α_2-Macroglobulin	Inhibitor
	PN1	Protease nexin-1	Inhibitor
	PCI	Protein C inhibitor/plasminogen activator inhibitor-3	Serpin

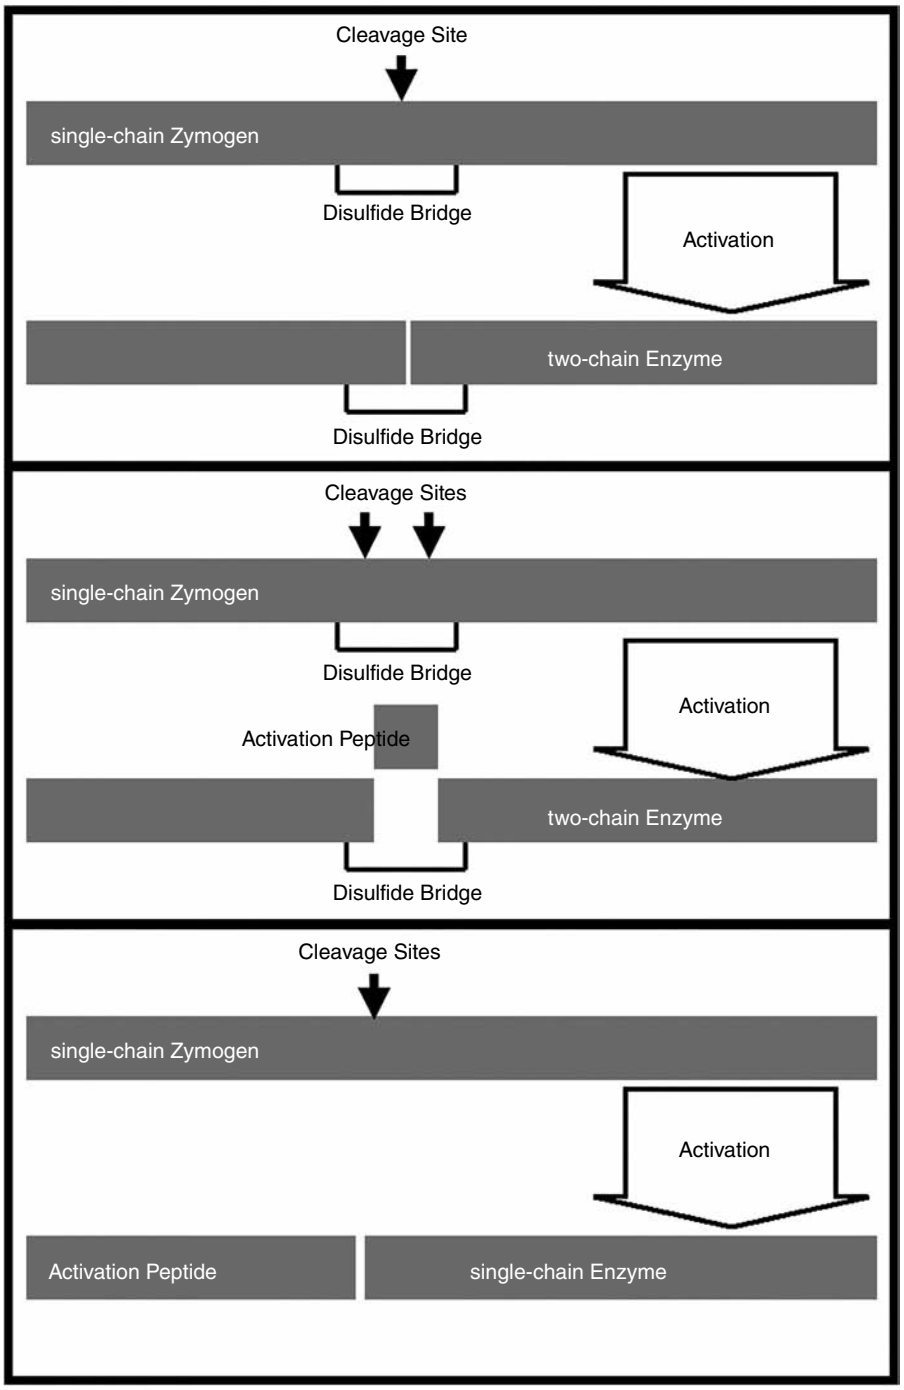

FIGURE 87.1 Enzymatic activation of coagulation proteins. Most coagulation proteins circulate as inactive, single-chain polypeptides containing disulfide bridges between nonadjacent cysteine residues. Depending on the location of the disulfide bridges and the cleavage site (or sites), enzymatic cleavage may result in a two-chain activated protein of identical size to the precursor, a two-chain activated protein (smaller than the precursor) and a released activation peptide, or a single-chain activated protein (smaller than the precursor) and a released activation peptide.

Fully functional enzymatic complexes often consist of both an enzymatic subunit (the serine protease) and a regulatory subunit (the cofactor).

Inhibition of Coagulation Enzymes

Coagulation and fibrinolysis enzymes are inhibited through several mechanisms: enzyme cleavage, active site blockade, stable complex formation, and substrate modification (Figure 87.2).[43]

Enzymatic inhibitors act by cleaving the target protein, cutting it into dysfunctional fragments. An example of this enzymatic inhibition is the cleavage of the cofactor activated factor V (FVa) by the serine protease, activated protein C (APC).

Active site blockade, a common mechanism of pharmacologic inhibitors, is also employed by naturally occurring inhibitors. Small molecule inhibitors may fit directly into an enzymatic site, thereby limiting substrate access.

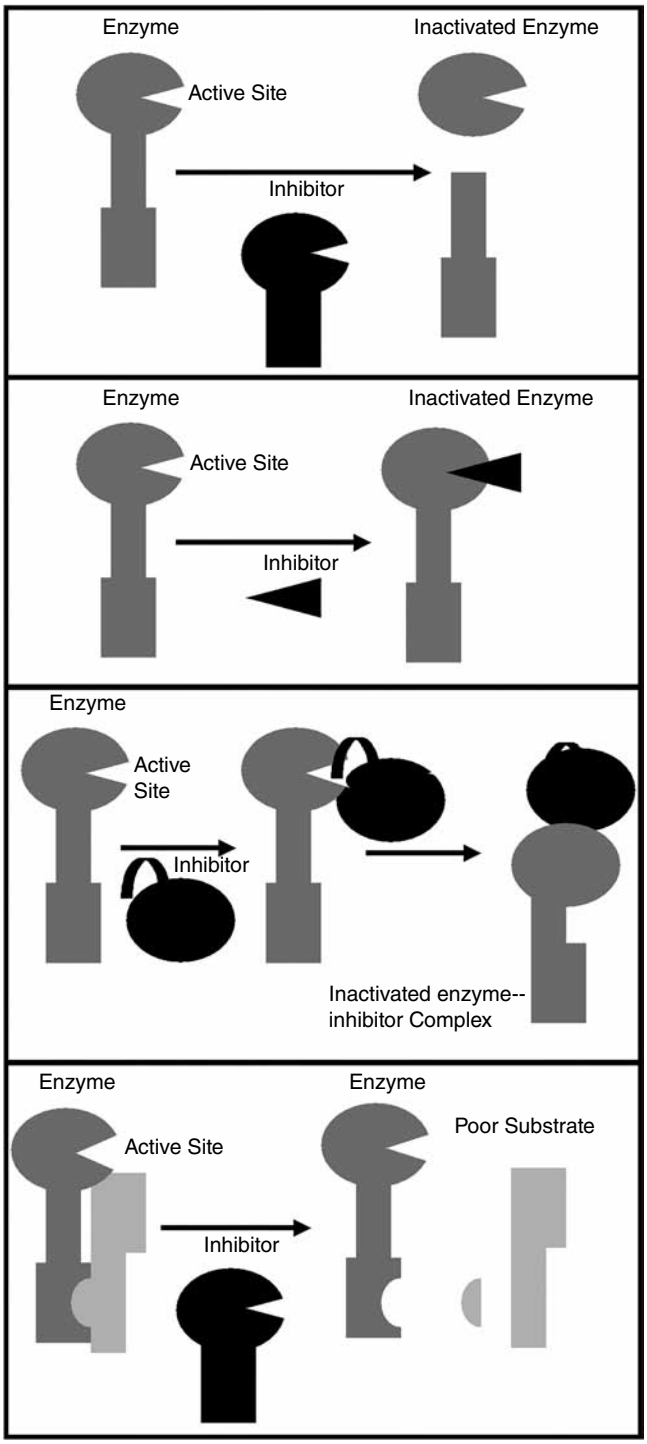

FIGURE 87.2 Coagulation enzyme and cofactor inhibition. Inhibitors work through a variety of different mechanisms: (1) Activated coagulation proteins can be inhibited by enzymes that cleave the target protein, damaging the structure and resulting in an inactivated protein. (2) Active site inhibitors bind the enzymatic site of the target enzyme, preventing the protease from cleaving its target protein. (3) Other inhibitors, such as serpins, display a "bait" peptide that looks like a substrate for the target enzyme. When the enzyme binds to and attempts to cleave the bait, the inhibitor changes in structure, resulting in a shift in position and structure of the target enzyme, which inactivates the enzyme into a stable complex with the inhibitor. (4) Some inhibitors modify the substrate rather than the target enzyme. These changes usually decrease binding interactions between the enzyme and the substrate, slowing or eliminating the ability of the enzyme to cleave its substrate.

Other inhibitors act through enzyme binding. The target enzyme and inhibitor form a stable complex that permanently inactivates the enzyme. An example of this mechanism is inhibition of thrombin by antithrombin-heparin. Antithrombin (AT) is a member of the serpin (serine protease inhibitor) class of inhibitors. These inhibitors employ a "suicide-substrate" mechanism. They contain a small peptide loop that acts as "bait" that mimics substrates of the target enzyme. Binding of the target enzyme to the bait results in serpin structural

modifications that shift the position and conformation of the enzyme to form a stable complex.

A few inhibitors work by changing the nature of the substrate, so that the enzyme cannot bind effectively to its target site. Thrombin-activatable fibrinolysis inhibitor (TAFI) cleaves fibrin residues such that plasmin binding is impaired and plasmin-mediated fibrinolysis is delayed.

Membrane Surface Interactions

The rate of coagulation is profoundly affected by the presence of appropriate membrane surfaces for enzymatic reactions. Membrane binding enhances enzyme activity because localization to a membrane surface helps properly align the participating proteins. Tissue factor (TF) is the only coagulation protein that is permanently attached to the membrane surface.[40] Some coagulation proteins (factors VII, IX, X [FVII, FIX, FX], prothrombin, proteins C, S, Z [PC, PS, PZ]) contain gammacarboxyglutamic acid (Gla) residues that enable protein binding to a membrane surface via interaction with calcium and negatively charged phospholipids. Calcium binding of the Gla domains of these proteins requires that the glutamic acid residues are carboxylated via intrahepatic post-translational modifications involving the vitamin K cycle (Figure 87.3). Incompletely carboxylated Gla proteins do not properly bind calcium and are unable to assemble on an activated membrane surface. The importance of carboxylation in membrane binding is dramatically illustrated by the profound adverse impact of vitamin K antagonists such as warfarin (see Chapter 89). The requirement of calcium for membrane binding explains the ability of calcium chelators (e.g., citrate and EDTA) to prevent activation of many coagulation enzymes.

Some cofactors (factors V and VIII [FV and FVIII]) also have regions that interact with phospholipids, allowing fully functional enzymatic complexes to assemble on a membrane surface. The mechanism of membrane binding is less well-described than Gla protein binding, but involves the stereochemical configuration of the phosphatidylserine (PSer) head group.[24,26]

COAGULATION PROTEINS THAT GENERATE THROMBIN

Previous coagulation models divided coagulation into the extrinsic, intrinsic, and common pathways (Table 87.1, Figure 87.4). The extrinsic pathway leads to generation of activated factor X (FXa) by the complex of TF and activated factor VII (TF–FVIIa). The terminology "extrinsic" pathway arose from the requirement for TF (an extravascular, cell-bound protein) as a clotting trigger. The intrinsic pathway proceeds with the contact activation of factor XII (FXII), followed by the cascading activation of the downstream protease factor XI (FXI), then FIXa–FVIIIa, and ultimately results in FXa generation. This pathway was termed the "intrinsic" pathway due to the fact that it did not require the addition of any extravascular trigger and appeared to be intrinsic to blood. The common pathway consists of the formation of the FXa–FVa complex, which activates prothrombin to generate thrombin. Thrombin then cleaves fibrinogen to fibrin, which spontaneously polymerizes into an insoluble fibrin gel.[9] These pathway classifications have been useful for in vitro laboratory evaluation, but such divisions do not occur in vivo.

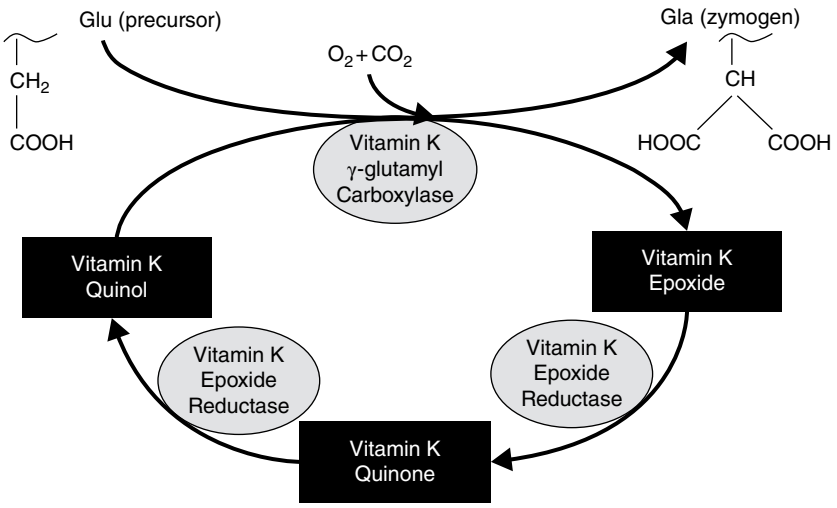

FIGURE 87.3 The vitamin K cycle. This cycle is necessary for hepatic production of fully functional vitamin-K-dependent coagulation proteins. These proteins (prothrombin, FVII, FIX, FX, PC, PS, PZ) are produced as precursors containing glutamic acid residues. The enzyme vitamin K γ-glutamyl carboxylase modifies these residues to γ-carboxyglutamic acid (Gla). The zymogens containing Gla residues are capable of binding Ca2+ to assemble on membrane surfaces and form active enzyme complexes. As a result of the carboxylase reaction, the vitamin K is converted to an epoxide, and must be regenerated via the activity of vitamin K epoxide reductase. Warfarin and its derivatives interfere with vitamin K epoxide reductase, preventing recycling of vitamin K epoxide to vitamin K quinol.

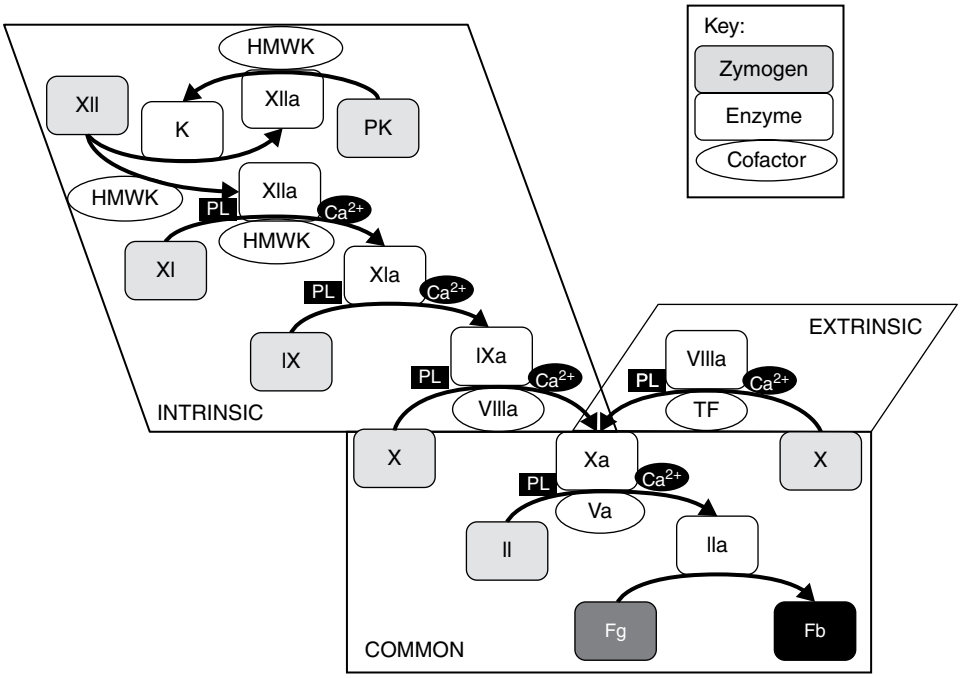

FIGURE 87.4 The cascade model of fibrin formation. This early model divided the coagulation system into separate, seemingly redundant pathways (extrinsic and intrinsic) either of which could result in the generation of FXa. The common pathway consisted of formation of the prothrombinase complex (FXa–FVa) and resulted in generation of thrombin, followed by cleavage of fibrinogen to form fibrin. Many of the enzymes and enzymatic complexes require calcium (Ca2+) and binding to active membrane surfaces (PL) for full activity. For simplicity, inhibitors of the various enzymes and feedback activation of procofactors to cofactors have been omitted. See Table 87.1 for abbreviations.

Contact Pathway (Kallikrein–Kinin Pathway)

The contact pathway consists of the zymogens FXII (Hageman factor) and prekallikrein (PK), and the cofactor high-molecular-weight kininogen (H-kininogen, HK). Activation of the two zymogens occurs spontaneously (autoactivation) upon assembly of the proteins on a suitable negatively charged surface.[8] Because FXIIa can cleave downstream coagulation proteases, contact activation ultimately results in generation of thrombin and therefore formation of a fibrin clot. Consequently, contact activation (i.e., creation of the enzymes FXIIa and kallikrein) occurs whenever blood comes in contact with an artificial surface. Contact activation always occurs, to some extent, when blood is removed from the vascular system. The contact pathway is the source of blood's apparent "intrinsic" clotting potential, and the reason blood coagulates when collected into a syringe or tube in the absence of anticoagulants. The amount of FXIIa and kallikrein generated depends on the negative charge of the artificial surface. Therefore, blood clots relatively slowly in plastic, more quickly in glass, and most rapidly when in contact with a strong negative charge. Note that contact activation is *not* calcium-dependent, and consequently is not abolished by collection of blood into calcium chelators such as citrate or EDTA. Activation of the contact pathway may influence viscoelastic tests that utilize a holding period, such as thromboelastography or thromboelastometry. An observed shift toward hypercoagulability during sample holding was most pronounced for equine blood samples, followed by canine, and then human blood samples, suggesting a hierarchy in contact pathway activation.[47,51] The results of this study illustrate species variability in the contact pathway (see Chapters 88 and 95).

Traditional coagulation cascade models depict the contact pathway and the extrinsic pathway as independent and redundant generators of FXa, and subsequent thrombin and fibrin production (see Figure 87.4). Current coagulation models indicate that the contact pathway, while an important feature of in vitro coagulation, is irrelevant for in vivo hemostasis. The evidence to support this concept includes comparative genomics data that reveal loss or inactivation of the FXII gene in cetaceans and non-mammalian vertebrates (see Chapter 95). In addition, many mammalian species (e.g., humans, mice, cats, and dogs) with inactivating FXII or PK mutations have no bleeding tendency.[41]

Research suggests that the contact pathway plays a role in pathologic thrombus formation.[17,19,41] The physiologically relevant negatively charged surface that allows contact activation to influence coagulation in vivo has not been identified, although RNA,[25] polyphosphate,[52] and misfolded proteins[30] have been proposed to serve this function.

Contact activation has a defined role, however, in several physiologic processes. Contact activation on negatively charged phospholipid cell membranes is primarily responsible for bradykinin generation. The contact pathway has additional anti-adhesive, profibrinolytic, proinflammatory, and antithrombotic properties, and is involved in angiogenesis (Figure 87.5).[8]

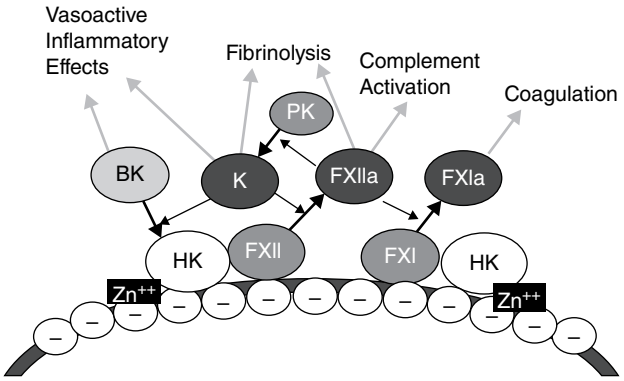

FIGURE 87.5 The contact pathway. This involves the assembly of FXII and K on a negatively charged surface, resulting in autoactivation of zymogen FXII to the enzyme FXIIa. FXIIa can then activate PK to K, and K can activate back more FXII to FXIIa. K also cleaves HK to generate BK, while FXIIa can activate FXI to FXIa. The major products of contact activation have important roles unrelated to coagulation, in inflammation, vasoactive regulation, and fibrinolysis. See Table 87.1 for abbreviations.

Factor XII

Factor XII is produced in the liver and circulates as a single-chain molecule with molecular weight of approximately 80 kDa. Cleavage by either kallikrein or plasmin generates a two-chain active enzyme (FXIIa) composed of a light and heavy chain. The heavy chain contains two sites that bind to negatively charged surfaces, and the light chain is a serine protease. Autoactivation to FXIIa may occur when FXII binds to a negatively charged surface, especially in the presence of Zn^{2+}. Prekallikrein, HK, and FXI are FXIIa's primary coagulation substrates; however, it also activates the complement pathway and cleaves single-chain urokinase plasminogen activator (scuPA) into its two-chain form. C1-inhibitor (C1-INH) is the major inhibitor of FXIIa.[8,48]

Prekallikrein

Prekallikrein is a single-chain molecule of about 86 kDa expressed in many tissues, with highest levels in the liver. Approximately 75% of PK circulates bound to HK. Conversion of PK to kallikrein by FXIIa occurs on a negatively charged surface when HK is also bound. This generates a light chain (containing the serine protease) and a heavy chain. Autoactivation of PK at a different cleavage site results in a less-active enzyme, β-kallikrein. Kallikrein's primary substrates are FXII and HK. Like FXIIa, kallikrein also cleaves scuPA. Kallikrein is primarily inhibited by C1-INH and α_2-macroglobulin (α_2-MG). Kallikrein is also inhibited by protein C inhibitor (PCI) and, when bound to HK, by heparin–AT.[8]

Kininogens

High-molecular-weight kininogen (H-kininogen) and low-molecular-weight kininogen are multidomain, distinct protein products of the same gene produced by alternative splicing. Both proteins contain an identical heavy chain (domains 1, 2, and 3) and domain 4. The light chain of HK contains domains 5 and 6, while the light chain of its low-molecular-weight form contains a different domain 5 and no domain 6.

Kininogens have a multitude of functions unrelated to coagulation. Domains 1, 2, and 3, respectively, inhibit atrial natriuretic peptide, prevent calpain-mediated platelet aggregation, and prevent thrombin binding to platelets. Upon cleavage by kallikrein, domain 4 releases the critical vasoactive peptide bradykinin. Domain 5 of HK contains the binding site for charged surfaces, has antiadhesive properties affecting protein and cell binding to neutrophils and endothelial cells, and also influences apoptosis. Domain 6 is the binding site for kallikrein and affects neutrophil activation. Endothelial cells, granulocytes, and platelets contain HK and express binding sites for HK on their resting membrane surface. Platelet activation results in dramatic increase in surface HK, due to release and increased expression of HK-binding sites. Zn^{2+} is absolutely required for binding of HK to membrane surfaces.[8]

Extrinsic (Tissue Factor) Pathway

Tissue Factor

Tissue factor, also known as thromboplastin, CD142, and factor III, is a glycosylated single-chain polypeptide of approximately 29.5 kDa. It is synthesized in a variety of cells, and expressed on the cell surface as an integral membrane protein. The extracellular portion of the molecule is responsible for interaction with coagulation proteins. The transmembrane domain anchors TF to the cell surface and is required for procoagulant activity. A small cytosolic domain is dispensable for coagulation functions, but is involved with intracellular signaling in TF's role as a cell-surface receptor.[38,40]

In physiologic circumstances, TF is expressed by adventitial cells surrounding blood vessels larger than capillaries, differentiating skin keratinocytes, and by other epithelial cells, particularly in mucous membranes and organ capsules. This distribution is consistent with TF's function as a protective "hemostatic envelope" whose role is instant initiation of coagulation. Under pathologic conditions, cytokines and other inflammatory mediators upregulate TF expression on other cell types. Endothelial cells, vascular smooth muscle cells, monocytes, and granulocytes may express TF in disease states. Tissue factor is also found in atherosclerotic plaques and is expressed by some neoplastic cells. Based on the lack of reports of TF deficiency in humans or animals, and the lack of viability of mice when the TF gene is deleted, TF expression appears to be essential for life.[40]

Tissue factor serves as the regulatory subunit of the TF–FVIIa enzymatic complex. Cell-surface TF, unlike most cofactors, fully functions as a cofactor without proteolysis. Although FVIIa is a weak enzyme alone, the TF–FVIIa enzyme complex is the most potent activator of coagulation. Consequently, TF–FVIIa is the first enzyme in the clotting cascade.

Tissue factor is primarily sequestered outside the vasculature to prevent intravascular coagulation; however, TF antigen has been detected at low levels in flowing blood. The source and role of this "blood-borne" TF are currently a matter of intense investigation. Blood-borne TF is thought to be associated primarily with monocytes. In addition, monocytes can release microvesicles (MVs) which are tiny blebs of the cell membrane whose expression profiles mimic their cell type of origin. Microvesicles from TF-bearing monocytes also express TF on the cell membrane. These shed microvesicles can be transferred to other cell types, thereby complicating differentiation of the cell type of origin of cell-surface TF. Tissue factor appears to accumulate in thrombi and may play a role in thrombus propagation. Circulating TF appears to be of limited procoagulant activity under normal circumstances. Some investigators believe that circulating TF is "encrypted" and must be cleaved by an enzyme for activity. Others believe that circulating TF is not fully active because the membrane surface on which it resides is not an appropriate procoagulant membrane.[38,40] Sphingomyelin, a phospholipid on the outer leaflet of the cell membrane, appears to play an important role in maintaining TF in the encrypted state. Researchers recently demonstrated de-encryption of TF after hydrolysis of sphingomyelin.[57]

Factor VII

Factor VII is a glycosylated single-chain polypeptide with a molecular weight of approximately 50 kDa. It is a vitamin-K-dependent protein produced in the liver and contains 10 Gla residues. It has the shortest half-life of the Gla proteins, so that FVII levels decrease rapidly if the vitamin K cycle or liver function is impaired. Factor VII binding to TF and to membrane surfaces via its Gla domain are calcium-dependent interactions. The FVII zymogen is converted to the enzymatically active FVIIa by proteolysis of a single peptide bond resulting in a two-chain molecule of identical size. Factor VIIa can be generated by a variety of downstream proteases, including FIXa, FXa, FXIIa, FVII activating protease, thrombin, and plasmin. Factor VII bound to TF can also be autoactivated by TF–FVIIa. The most important physiologic FVIIa activator has yet to be definitively determined.[40]

Factor VIIa is unique among coagulation enzymes in that it circulates with a long plasma half-life of approximately 2 hours (compared to other serine proteases whose enzyme half-lives are measured in seconds). Approximately 1% of total circulating FVII antigen is active FVIIa, although interindividual FVIIa levels vary considerably.[39] The intriguing question of how and where circulating FVIIa is generated remains unanswered. Factor IXa may be an important contributor of FVIIa generation, as patients deficient in FIX (hemophilia B) have very low levels of FVIIa.[58] Factor VIIa levels are higher in lymph than plasma, suggesting that some FVIIa may be generated outside the vasculature and returned to the bloodstream via lymphatic circulation.[36]

Because some FVII circulates as FVIIa, exposure of blood to TF as a result of injury leads to formation of both TF–FVII and TF–FVIIa complexes. The initial TF–FVIIa formation and its autoactivation are believed to generate sufficient enzymatic activity to trigger the clotting cascade via cleavage of the primary TF–FVIIa substrates, i.e., FIX and FX.[40] The TF–FVIIa complex is often referred to as the extrinsic tenase when its target substrate is FX. Deficiency of FVII is associated with a highly variable, but potentially severe bleeding tendency.[33]

Free plasma FVIIa is not inactivated by any plasma protease inhibitor, hence its long half-life. The TF–FVIIa complex is inhibited by the tissue factor pathway inhibitor (TFPI)–FXa complex, and by heparin–AT (albeit very slowly).[40] The inhibition of TF–FVIIa by heparin–AT is unique, in that heparin–AT binding to FVIIa releases a stable FVIIa–AT complex and regenerates fully functional TF. Consequently, high FVIIa–AT levels may be an indicator of systemic TF exposure.[33]

Intrinsic Pathway

The intrinsic cascade primarily occurs on the activated platelet surface. Platelet activation is a critical component of the intrinsic tenase complex (FIXa–FVIIIa). Upon activation, platelets expose many (approximately 6000 per platelet) binding sites for FIXa as well as 1000–2000 each for the cofactor, FVIIIa, and the substrate FX. Colocalization of FIXa, FVIIIa, and FX on the platelet surface increases the rate of FXa generation by many millionfold.

Factor XI

Factor XI is an approximately 160-kDa protein that is produced in the liver. Its structure is unique among coagulation proteins as a disulfide-linked dimer of two identical polypeptide chains. Factor XI circulates in plasma complexed with HK, which is required for FXI binding to negatively charged surfaces. Prothrombin can substitute for HK as a cofactor for binding to platelet surfaces.

Factor XI can be activated by FXIIa, FXIa, and thrombin in calcium-dependent reactions. Cleavage results in a 160-kDa enzyme with two disulfide-linked heavy chains and two active-site-containing light chains. Because FXII deficiency does not cause a bleeding tendency, it is likely that thrombin (rather than FXIIa) is the physiologically relevant enzyme generating FXIa. The GPIbα subunit of the platelet GPIb/IX/V complex binds FXI, localizing it and thrombin on the platelet for efficient cleavage. After activation, FXIa remains surface-bound where it cleaves its substrates, FXI and FIX. Factor IX is FXIa's preferred substrate.

Inhibition of FXIa depends on its localization. Plasma inhibitors include its major inhibitor, α_1-protease inhibitor (α_1-PI), and C1-INH, α_2-antiplasmin (α_2-AP), AT, protease nexin-1, plasminogen activator inhibitor-1 (PAI-1), and PCI. Platelet-bound FXIa is protected from

α_1-PI inactivation. When bound to the endothelial cell surface, protease nexin-2, in concert with surface heparan sulfate proteoglycans (HSPGs), strongly inhibits FXIa. This differential inhibition may serve to restrict FXIa-mediated cleavage of FIX to the platelet surface.

Factor IX

Factor IX's structure and size (approximately 55 kDa) are similar to FVII. Factor IX is a glycosylated single-chain polypeptide, produced in the liver. Post-translational carboxylation of 12 residues by the vitamin K cycle is required for normal Gla domain function and consequently for full-membrane-binding capability.[2]

Tissue factor–FVIIa or FXIa activate FIX bound (in the presence of calcium) to a procoagulant membrane surface. Cleavage of two FIX sites releases a 35-residue activation peptide, resulting in a two-chain enzyme of approximately 45 kDa. The catalytic domain is in the heavy chain portion of the molecule. The presence of detectable levels of the FIX activation peptide in blood suggests that coagulation is ongoing, but controlled by inhibitory pathways.[2] The primary substrate for FIXa is FX. The FIXa–FVIIIa complex on a suitable membrane surface (usually the platelet surface) in the presence of calcium is a powerful generator of FXa. Either FIX or FIXa may bind to endothelial cells, via specific receptors (collagen IV). Binding to the endothelial surface supports activation of FX by FIXa–FVIIIa in the absence of platelets. Factor IXa alone (without its cofactor FVIIIa) is able to activate FVII in the absence of TF. FIXa is primarily inhibited by AT–HSPG, although at a relatively slow rate compared to AT's inhibition of FXa or thrombin.

Factor VIII

Factor VIII synthesis and secretion are complex. Two distinct interactions involving metal ions (copper and calcium/manganese) are vital for normal FVIII structure and function. The primary site of FVIII production is unclear, although the liver and the reticuloendothelial system are strongly implicated. Factor VIII is synthesized as a single-chain protein containing three A domains, one B domain, and two C domains, with multiple free cysteine residues and disulfide bonds. After translation, FVIII is translocated to the endoplasmic reticulum (ER), for modification. Factor VIII is retained within the ER by two protein chaperone systems, immunoglobulin-binding protein and calnexin/calreticulin. Improperly folded FVIII is extracted from the ER and degraded. Factor VIII then transits to the Golgi apparatus for further processing, which includes cleavage at two sites. The resulting protein consists of a heavy chain (160 or 200 kDa) and a light chain (80 kDa), which are not connected to one another unless bound in a complex with von Willebrand factor (VWF) (see Chapter 83).[26]

Binding to VWF enables proper association of the two FVIII chains and markedly improves its intracellular and plasma stability. The ratio of the two proteins is maintained at one molecule of FVIII to 50–100 subunits of VWF. Although somewhat species-dependent, VWF deficiency is associated with lower levels of circulating FVIII, and infusion of desamino-8-D-arginine vasopressin (DDAVP) to increase circulating VWF levels elicits a concomitant increase in FVIII. Some FVIII is stored with VWF in storage granules, such as Weibel–Palade bodies of endothelial cells and α-granules of platelets.

Factor VIII can be dissociated from VWF by exposure to negatively charged phospholipids. Thrombin cleavage of FVIII at multiple sites activates FVIII to FVIIIa and releases it from VWF. Factor VIII can be activated by FXa, although the maximal activation by thrombin is greater than FXa.

Factor VIIIa interacts with PSer on membrane surfaces by stereoselective recognition of the PSer head group via a phospholipid-binding site in the light chain. Factor VIIIa also interacts with two platelet receptors, GPIb and $\alpha_{IIb}\beta_3$. Platelet binding of FVIII is inhibited by VWF. The FIXa–FVIIIa enzyme/cofactor complex assembles in a calcium-dependent manner on procoagulant phospholipid surfaces, and is referred to as intrinsic tenase, because its target substrate is FX. Factor VIIIa is inherently labile due to spontaneous dissociation of its subunits; however, FIXa binding stabilizes FVIIIa and delays decay. Factor VIIIa is cleared from the circulation by low-density lipoprotein receptor-related protein (LRP), a common cell-surface receptor found on a variety of cell types. Proteolytic cleavage by APC and FXa also inactivates FVIIIa.[26]

Common Pathway

Factor X

Factor X is a Gla protein of approximately 59 kDa. It is a glycosylated single-chain polypeptide requiring post-translational carboxylation of 11 glutamic acid residues. Factor X is activated to FXa by either extrinsic tenase (TF–FVIIa) or intrinsic tenase (FIXa–FVIIIa) on a suitable membrane surface in the presence of calcium. The activation is due to a single cleavage site and results in a 46-kDa enzyme.

Factor Xa forms the prothrombinase complex with its cofactor FVa. Factor Xa is strongly inhibited by AT–HSPG and by TFPI. It is also inhibited by the enzyme/cofactor protein-Z-dependent protease inhibitor (ZPI)/PZ. Inhibition by ZPI/PZ is calcium- and phospholipid-dependent.

Factor V

Factor V circulates in plasma as a glycoprotein of approximately 300 kDa. Portions of the molecule are very similar in structure to FVIII. Like FVIII, FV contains a copper ion, and requires post-translational modifications and molecular chaperones for successful cellular trafficking. Approximately 20% of FV in blood is contained within platelet α-granules. The plasma half-life of FV in human beings is fairly long (approximately 13 hours).[24]

Factor V is activated to FVa by cleavage at two sites that releases a large activation peptide, and a resultant

two-chain cofactor of about 160 kDa. Activation is primarily due to thrombin cleavage, but FXa can also activate FV when both are bound to a procoagulant membrane surface. Activation by FXa is less efficient than activation by thrombin. However, FV released from platelets is somewhat more susceptible to FXa activation than plasma FV.[24]

Factors Xa and FVa form an enzyme/cofactor complex, referred to as the prothrombinase complex, in the presence of calcium on PSer-containing membrane surfaces. While FVa binding to the membrane is not calcium-dependent, the binding of FX and prothrombin to the membrane is calcium-dependent, but of low affinity. Binding of FVa to a negatively charged membrane surface markedly increases the affinity of FXa for FVa, and enhances formation of the complex. Platelets and microparticles primarily provide this membrane surface in vivo.[24]

Proteolysis of FVa by APC results in its inability to bind prothrombin, and therefore functional loss of the prothrombinase complex. Inactivation of FVa by APC occurs more rapidly on endothelial cells than on activated platelet surfaces.[13,24]

Prothrombin

Prothrombin is a 72-kDa glycoprotein synthesized in the liver that (like other Gla proteins) undergoes vitamin-K-dependent post-translational carboxylation of 10 glutamic acid residues. Prothrombin is the second most abundant coagulation protein in plasma, after fibrinogen.[23]

In addition to the Gla domain, prothrombin contains two kringle domains and a serine protease precursor domain. Prothrombin cleavage at two distinct sites by prothrombinase generates its most abundant active form, α-thrombin. The first in vivo cleavage site is generally between the A and B chains of its serine protease domain to form the important intermediate, meizothrombin. Meizothrombin contains all the domains of the prothrombin molecule, with a fully active enzyme site, but it is less active toward fibrinogen and platelets than α-thrombin. After the second cleavage, prothrombin fragments 1 (containing the Gla domain and kringle 1) and 2 (containing kringle 2 domain) are removed. The A and B chains of the much smaller (36.7 kDa) α-thrombin molecule remain. Under some conditions, the order of cleavage is reversed, releasing the membrane-binding Gla domain prior to activation of the protease.[23]

Coagulation Inhibitors

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor is the key regulator of the extrinsic pathway. It is a Kunitz-type inhibitor, with three Kunitz domains, synthesized by endothelial cells and expressed on their surface. Alternative splicing creates two forms: TFPIα and TFPIβ. Approximately 15% of the blood-borne TFPI circulates in the active form, TFPIα, with the remainder carboxy-terminally truncated and bound to lipoproteins. Alternatively spliced TFPIβ is attached to the endothelial cell surface via interactions between the C terminal region and a glycosylphosphatidylinositol (GPI) anchor.[41] Cell-surface-associated heparan sulfates also play a role in the binding of TFPI to the endothelial cell.[1,34]

Platelet α-granules also contain TFPIα that is released upon platelet activation.[34] Polyphosphate released from platelet dense granules profoundly abrogates TFPI inhibition.[52] Intravenous heparin administration causes release of TFPI from the endothelial cell surface and a marked increase in plasma TFPI.[3] Free TFPI is cleared from the circulation primarily by the liver and kidneys.

TFPI is a slow tight-binding inhibitor that inactivates TF, FVIIa, and FXa. The inhibition of FXa can be overcome by high FXa generation. The TFPI–FXa complex is a strong inhibitor of TF–FVIIa, binding via the first Kunitz domain. The second Kunitz domain of TFPI binds to FXa; however, the FXa–FVa complex is protected from inhibition by TFPI, particularly if the substrate prothrombin also binds.[35] The third Kunitz domain regulates PS binding as PS serves as a TFPI cofactor, enhancing its inhibitory function.[46,54] In the absence of FXa, TFPI is only a weak inhibitor of TF–FVIIa.

Endocytosis and degradation of the quaternary complex (TFPI–FXa–TF–FVIIa) are mediated by cell-surface-associated LRP.[1]

Inherited deficiency of TFPI has not been described, suggesting that complete lack of this inhibitor is incompatible with life.

C1-Inhibitor

C1-Inhibitor, an acute phase protein, is the largest member of the serpin family and its main function is to inhibit the complement system. It has an unusual structure for this class of proteins, containing a typical serpin domain and an additional N-terminal domain of ill-defined structure and function. It is a relatively slow inhibitor of its target proteases, but C1-INH is potentiated by glycosaminoglycans such as heparin and heparan sulfates.[56]

The C1-INH is the major inhibitor of the contact pathway, acting on FXIIa and kallikrein, and the downstream protease FXIa. Hereditary deficiency of C1-INH has no impact on hemostasis. Rather, it causes excess episodic production of bradykinin, producing the disease phenotype hereditary angioedema.[56]

Antithrombin

Antithrombin is the prototype serpin; however, it is a relatively inefficient inhibitor of its target enzymes. The "bait" portion of the AT molecule is available only if AT binds to its cofactor. This cofactor is a specific pentasaccharide sequence that is found on approximately 30% of pharmaceutical unfractionated heparin molecules and on endothelial-bound HSPG molecules. Upon AT–pentasaccharide binding, the bait loop becomes available as a target for the enzyme and

inhibitory complex formation. Antithrombin's inhibitory activity is enhanced up to several thousandfold by interaction with heparins, but the impact varies with heparin structure and the target protease. Pentasaccharide alone is sufficient for AT inhibition of some enzymes, while longer heparin molecules are required for inhibition of others. In particular, AT inhibition of thrombin requires, in addition to the specific pentasaccharide sequence, heparin molecules of at least 18 sugar units to interact with thrombin.

Antithrombin molecules in circulation have limited inhibitory capabilities in the absence of the necessary pentasaccharide. Endogenous activation of AT occurs when it binds to heparans on the surface of the endothelial cell. Additionally, endothelial cell surface thrombomodulin (TM) can also bind AT, which enhances AT inhibition of thrombin approximately eightfold.[4,55]

In addition to thrombin, AT–heparin has broad inhibitory activity against a variety of serine proteases. These include FXIIa, FXIa, FXa, kallikrein, FIXa, and FVIIa. The primary targets are FXa and thrombin. Platelet-bound thrombin (via $GPIb_\alpha$) and thrombin bound to the fibrin clot or fibrin degradation products (FDPs) are refractory to AT–heparin inhibition. By contrast, inhibition of FVIIa requires that the enzyme be bound to its cofactor (TF) on a cell surface, and kallikrein is more readily inhibited when bound to HK on a cell surface.

Antithrombin bound to a target protease forms a stable complex with long half-life. The complexes are primarily cleared in the liver by LRP. Inherited or acquired AT deficiency is associated with development of pathologic thrombosis (see Chapter 91).[4]

Protein C Pathway

The PC pathway involves a complex interplay among endothelial cell-surface molecules, thrombin, PC, and PS. Activated PC is an essential regulator of thrombin generation due to its inactivation of the critical cofactors, FVa and FVIIIa. The thrombotic disorders in people attributed to inherited and acquired PC deficiency demonstrate its important anticoagulant action.

Protein C is an approximately 62-kDa vitamin-K-dependent protein, synthesized in the liver, containing a Gla domain with nine glutamic acid residues. It circulates as a two-chain zymogen that is activated by thrombin (or meizothrombin) to APC. Cleavage at two sites results in removal of a 12-residue activation peptide and formation of an approximately 56-kDa two-chain enzyme, APC. Plasmin activation also produces limited amounts of APC. As a Gla-containing protein, PC activation is calcium-dependent and markedly enhanced by negatively charged phospholipid surfaces, in particular phosphatidylethanolamine (PEth). Thrombin alone is a poor activator of PC unless it is bound to TM.[12]

Thrombomodulin is an endothelial transmembrane molecule that interacts with thrombin to influence its substrate specificity. Thrombomodulin inhibits thrombin's interaction with fibrinogen and protease-activated receptors (PARs), and markedly enhances the ability of thrombin to cleave PC. Cellular expression of TM is modulated by a large number of factors. It is upregulated in response to cyclic AMP, thrombin, vascular endothelial growth factor, and platelet factor 4. It is downregulated by inflammatory mediators (e.g., tumor necrosis factor, interleukin-1, endotoxin), hypoxia, transforming growth factor β, and neutrophil activation.[12]

Protein S is an approximately 69-kDa vitamin-K-dependent protein with a Gla domain that interacts with membranes. Protein S is the cofactor for APC-mediated cleavage of FVa and FVIIIa, and for TFPI's inhibition of FXa.[46] Approximately 60% of circulating PS is bound to a large (540 kDa) member of the complement system, C4-binding protein (C4BP). C4-binding protein is an acute phase reactant and therefore increases in inflammatory conditions. Protein S complexed with C4BP is unable to provide APC cofactor activity. Activated platelets and neutrophils contain proteases that cleave and inactivate PS.[11,12]

Endothelial protein C receptor (EPCR) is a transmembrane protein found primarily on arterial endothelium. The EPCR can substitute for negatively charged phospholipids in promoting activation of PC. It binds directly to PC via the Gla domain, anchoring it to the cell surface. The APC–EPCR complex is unable to bind PS and does not have anticoagulant activity, but may interact with other receptors, potentially contributing to the anti-inflammatory effects of APC.[12,13] Once APC is produced and dissociates from thrombin–TM or EPCR, it assembles with PS on a procoagulant membrane surface and rapidly inactivates FVa and FVIIIa. A mutation at one of the APC cleavage sites on FV ("FV Leiden") confers resistance to APC inactivation. This common hereditary prothrombotic disorder in people has not been identified in animals. Activated PC cleaves FVa more efficiently on endothelial surfaces than on platelets,[42] and FVIIIa is resistant to APC inactivation when bound to VWF. The anticoagulant activity of APC is highly species-specific.[12]

The PC pathway appears to have a major role in linking inflammation and coagulation, in part due to the ability of APC to downregulate thrombin generation. Additionally, APC alters gene expression in endothelial cells via activation of membrane surface PARs, resulting in anti-apoptotic and anti-inflammatory effects. Activated PC–PS also inactivates an important inhibitor of fibrinolysis (PAI-1).[12] Activated PC has a relatively long half-life of about 15 minutes. It is inhibited by α_1-PI, PCI, and α_2-MG.

Miscellaneous Inhibitors

Heparin cofactor II (HC) is a 66-kDa serpin with some similarities to AT. It requires binding to proteoglycans for full function, but the mechanism differs from that of AT. Heparin cofactor II is strongly activated by binding to dermatan sulfate and has a narrow spectrum of activity restricted to thrombin inhibition. Although HC–thrombin complexes are detectable in vivo, HC deficiency is not associated with increased risk of

thrombosis. Roles for HC in inflammation and wound healing, rather than in regulation of coagulation, have been suggested.[4]

ZPI is a 72-kDa serpin that strongly inhibits FXa when bound with its cofactor, PZ, on a phospholipid surface in the presence of calcium. Protein Z is a 62-kDa vitamin-K-dependent protein that binds to the membrane via its Gla domain. Thrombomodulin also acts as a cofactor for ZPI. Factor XIa is also susceptible to ZPI inactivation, in a heparin-dependent reaction that does not require calcium or phospholipids.

α_1-Protease inhibitor, PCI, and α_2-MG are inhibitors that act on a variety of serine proteases including the serine protease coagulation factors. α_1-Protease inhibitor is a 52-kDa molecule, synthesized primarily in the liver, whose major physiologic role is the protection of alveolar tissue from proteolytic damage by enzymes such as neutrophil elastase. It is an acute phase reactant, and is upregulated by inflammatory mediators.[15]

Protein C inhibitor is a 53-kDa serpin that inhibits APC, FXa, FXIa, kallikrein, thrombin, thrombin–TM, urokinase plasminogen activator (uPA), and tissue plasminogen activator (tPA). Its inhibitory activity is enhanced by heparin and it is involved in modulating vascular permeability, tissue regeneration, proteolysis in the kidney, and tumor cell invasion.[53]

α_2-Macroglobulin is a large, 725-kDa inhibitor of matrix metalloproteinases that works through a unique mechanism. The target enzyme cleaves an α_2-MG "bait" region to produce a conformational change that provides sites for covalent enzyme attachment. The enzyme binds and is entrapped by the inhibitor, with resultant α_2-MG–enzyme complexes internalized and degraded via LRP binding.

CELLS THAT PARTICIPATE IN HEMOSTASIS

Endothelial Cells

The endothelium, once considered an inactive barrier between the blood and the subendothelial tissues, is now recognized as a highly active organ. The endothelium has numerous functions, including regulation of coagulation and fibrinolysis, local control of vascular tone, systemic regulation of blood pressure, interaction with lipoprotein metabolism, production of angiotensin-converting enzyme, presentation of histocompatibility antigens, and interaction with leukocytes. The majority of endothelial cells reside in capillary beds due to the surface area distribution of the vascular system. Most interactions between the endothelium and flowing blood occur in capillaries, facilitated by the high ratio of endothelial cell surface to blood volume.

Antithrombotic Properties of Endothelium

Healthy endothelium plays a primary role in hemostasis by preventing coagulation in flowing blood (Figure 87.6). Consequently, disease conditions that affect endothelial function may lead to pathologic thrombus formation (see Chapter 91).

Nonactivated, resting endothelial cells have anticoagulant properties, in part due to proteins expressed on their surface, and via the glycocalyx that does not support coagulation reactions. Heparan sulfate proteoglycans are glycosaminoglycans expressed by endothelial cells on the luminal surface, in contact with flowing blood. Much larger abluminal stores of HSPG act as a reservoir. Antithrombin bound to HSPGs (at pentasaccharide sequences) is then able to inactivate its serine

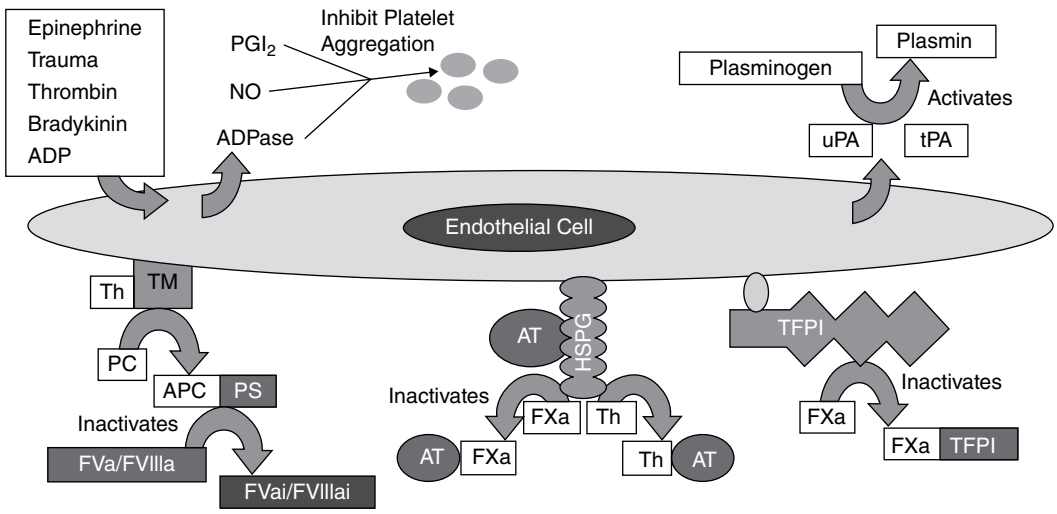

FIGURE 87.6 Anticoagulant properties of endothelial cells. Endothelial cells are thromboresistant under normal physiologic conditions. They express adenosine diphosphatase (ADPase) and synthesize and release prostacyclin (PGI_2) and nitric oxide (NO), leading to inhibition of platelet aggregation. They also produce urokinase (uPA) and tissue-type (tPA) plasminogen activators, which activate plasminogen to plasmin, the enzyme that lyses fibrin clots. Endothelial cells express thrombomodulin (TM), heparan sulfate proteoglycans (HSPG), and tissue factor pathway inhibitor (TFPI) on their membrane surface, which collectively inhibit generation of thrombin (Th). TM acts as a cofactor for activation of the protein C (PC) pathway; HSPG acts as a cofactor for antithrombin (AT) inhibition of FXa; TFPI inhibits FXa and TF–FVIIa.

protease targets (e.g., thrombin, FXa). Resting endothelial cells also express TM. Thrombin, once bound to TM, demonstrates anticoagulant rather than procoagulant properties. Thrombomodulin-bound thrombin is unable to cleave fibrinogen or activate PARs, and the TM–thrombin complex rapidly activates PC. Expression of TM is hundredfold higher in capillary endothelium compared to endothelium in the major vessels. Thrombin circulating in large vessels is therefore quickly removed by TM binding as blood passes through capillaries. Lastly, TFPI on the endothelial cell surface prevents thrombin generation by acting as an upstream inhibitor of FXa and TF–FVIIa.

Prothrombotic Properties of Endothelium

Endothelial cells store VWF in granules called Weibel–Palade bodies. This protein has important roles in FVIII biology, and in mediating platelet adhesion and aggregation (see Chapter 83). Endothelial cells express a specific G-protein-coupled receptor for thrombin. Thrombin binding to this receptor initiates a number of procoagulant and proinflammatory events. Intracellular signaling initiates endothelial secretion of VWF and P-selectin from Weibel–Palade bodies, nitric oxide (NO) release, and phospholipase A_2 activation that results in platelet-activating factor (PAF) production. Activated endothelial cells express intracellular adhesion molecule 1, generate interleukin-1, and secrete both plasminogen activators and PAI-1.

Other Properties of Endothelial Cells

Endothelial cells synthesize NO in response to a variety of stimuli including thrombin, histamine, ATP, bradykinin, and acetylcholine. Nitric oxide inhibits platelet activation and causes vasodilation. Thrombin and other stimuli also induce endothelial cell synthesis of prostacyclin (PGI_2), a platelet inhibitor that also maintains vascular relaxation.[8]

Platelets

Platelets are a fundamental reactant of normal hemostasis. Activated platelets adhere to the site of injury, secrete molecules necessary for coagulation and for wound healing, and form platelet aggregates that obstruct the site of injury to prevent further blood loss. Platelets provide the primary membrane surface for thrombin generation, allowing for formation of a platelet-rich fibrin clot (see Chapters 76 and 77).

Tissue-Factor-Bearing Cells

As previously discussed, exposure of TF on a TF-bearing cell is the physiologically relevant trigger for in vivo coagulation. Tissue-factor-bearing cells are primarily outside the vasculature, particularly in the adventitia, skin, mucous membranes, and organ capsules. Under pathologic conditions, leukocytes, endothelial cells, and neoplastic cells may also express TF.

Microvesicles

MVs are intact vesicles surrounded by membranes. They range in size from 2–20% of the size of a red blood cell (i.e., 0.1–1 μm diameter) and arise from activated or apoptotic cells. The term "microvesicle" may be used to describe ectosomes shed from the plasma membrane, apoptotic particles arising from the cytoplasm, and exosomes discharged upon release of intracellular multivesicular bodies. Cytokines (such as tumor necrosis factor and interleukin-6), thrombin, shear stress, and hypoxia can stimulate MV formation. Under normal conditions, MVs in circulation appear to be derived primarily from endothelial cells, platelets, and monocytes, but in certain disease states, MVs may arise from granulocytes and erythrocytes. Once released, MVs bind to specific receptors on the target cell type and, in some cases, fuse with the target cell membrane. Transfer of bioactive materials (e.g., lipids, proteins, mRNA, miRNA) occurs via release of MV components into the target cell. Fusion of MVs with target cell membranes makes it difficult to define and differentiate cells that form and release MVs versus cells that bind and express them. The quantity of circulating MVs is increased in certain illnesses such as diabetes mellitus, sepsis, and cardiovascular disease and may contribute to pathologic coagulation in a variety of disorders.[37] Shed MVs may also influence the composition and quality of stored blood products. In a study of stored canine packed RBCs, MVs were significantly higher in non-leuko-reduced products, increasing 5.5-fold during the 35-day storage period.[21]

Microvesicles may express cell-surface proteins similar to those found on their parent cell (e.g., ultralarge VWF multimers on endothelial cell-derived MVs, TF on monocyte-derived MVs). When co-expressed with procoagulant molecules (e.g., Pser), MVs provide a surface for coagulation reactions. The contribution of MVs to normal and pathologic hemostasis is currently under active investigation.[27,37,44]

The Role of Cell Surface Membranes

All cells are surrounded by a lipid membrane bilayer, which contains a large number of membrane surface proteins. In most mammalian cells, membrane bilayers consist primarily of cholesterol and phospholipids with neutral head groups such as phosphatidylcholine (PChol), sphingomyelin, sugar-linked sphingolipids, and PEth. The membranes also contain phospholipids with negatively charged head groups, primarily PSer. In the resting state, PEth and PSer are sequestered on the membrane's inner surface. This membrane asymmetry is essential and tightly controlled by lipid transporters. Enzymes referred to as "flippase" actively transport PSer from the external to the internal leaflet, while "floppase" refers to the transport of PChol in the opposite direction. These ATP-dependent enzymes maintain cell membrane asymmetry in the resting state.

Cell injury or activation stimuli that produce a sustained increase in intracellular calcium induce an

incompletely characterized "scramblase" activity that shuffles phospholipids between the membrane leaflets. This results in the appearance of PSer and PEth on the external membrane surface.[44,59] The scramblase responsible for rapid platelet PSer externalization has been identified as an anoctamin family transmembrane protein, TMEM16F (see Chapters 77 and 84).[29] Although the mechanisms of coagulation on activated membrane surfaces are not fully understood, it is known that membrane-surface PSer markedly (often by a factor of thousands to hundreds of thousands) increases the rate of coagulation reactions. The presence of PEth enhances the properties of PSer-expressing membranes, so that less PSer is required for maximum speed when PEth is present. It has been proposed that PEth aids in grouping PSer into clusters that support preferential binding of coagulation proteins.[40,61] Under normal physiologic conditions, cells do not express these procoagulant phospholipids on their outer membrane. As a consequence, thrombin production is limited to cell surfaces in an injured area that have been triggered to externalize PSer (and PEth). The ability of cells to control the composition of their membrane surface constitutes a powerful mechanism to localize coagulation reactions.[61]

CELL-BASED MODEL OF THROMBIN GENERATION

Our current understanding of hemostasis incorporates the role of cells. This model suggests that in vivo coagulation occurs in distinct overlapping phases that require the participation of two different cell types: TF-bearing cells and platelets.

Initiation

All evidence to date indicates that TF is the relevant initiator of coagulation in vivo. Cells expressing TF are generally localized outside the vasculature, which prevents initiation of coagulation under normal flow circumstances with an intact endothelium. Some circulating cells (e.g., monocytes) and MVs may express TF on their membrane surface, but this TF under normal conditions is thought to be inactive or "encrypted."[31,40]

Upon injury, flowing blood is exposed to a TF-bearing cell and FVIIa rapidly binds to TF.[39,40] The TF–FVIIa complex then activates additional TF–FVII to TF–FVIIa, which generates small amounts of FIXa and FXa. Although it occurs slowly, FV can be activated directly by FXa. The resultant enzyme and cofactor (FXa, FVa) form the prothrombinase complex, which subsequently cleaves prothrombin to generate a small amount of thrombin on the surface of TF-bearing cells. Any FXa that dissociates from the membrane surface is rapidly inactivated by either TFPI or AT–HSPG. Factor Xa, therefore, is effectively restricted to the surface of the TF-bearing cell on which it was generated. However, FIXa is not inhibited by TFPI, and much more slowly inhibited by AT than FXa. Consequently, trace amounts of generated FIXa can dissociate and move to the surface of nearby platelets or other cells.[22,45]

Since TF is always expressed in the perivascular space, any FVIIa that leaves the vasculature will bind to TF and potentially initiate coagulation. The gaps in the physiologic endothelial envelope under normal conditions are very small. Most of the upstream coagulation proteins are relatively small, whereas some of the downstream proteins are much larger. These downstream substrates, as well as platelets, are sequestered from the extravascular space. Coagulation progresses beyond initiation (and its generation of trace amounts of thrombin) only when the injury allows platelets and larger proteins to leave the vascular space and adhere to extravascular TF-bearing cells (Figure 87.7a).[22,45]

Amplification

The small amount of thrombin generated in the initiation phase is available to activate platelets that have leaked from the vasculature at the site of injury. Thrombin binding to platelet surface receptors causes extreme changes in the surface of the platelet, resulting in shape change, shuffling of membrane phospholipids to create a procoagulant membrane surface, and release of granule contents that provide additional "fuel for the fire." Platelet granules contain a large number of proteins and other substances which include raw materials for clotting reactions, agonists to induce further platelet activation, and calcium. Calcium may induce membrane externalization and clustering of PSer, and promotes binding of coagulation proteins to the activated membrane surface. In addition to activating platelets, thrombin generated in the initiation phase cleaves FXI to FXIa and activates FV to FVa on the platelet surface. Thrombin also cleaves VWF from FVIII and activates FVIII to FVIIIa (Figure 87.7b).[22,45]

Propagation

The release of platelet granule contents recruits additional platelets to the site of injury. The propagation phase occurs on the surface of these platelets. Expression of ligands on their surface results in cell–cell interactions that lead to platelet aggregation. Factor IXa generated by TF–FVIIa in the initiation phase can bind to FVIIIa (generated in the amplification phase) on the platelet surface. Additional FIXa is generated due to cleavage of FIX by FXIa (generated during amplification on the platelet surface). The intrinsic tenase complex (FIXa–FVIIIa) assembled on the activated platelet surface rapidly generates FXa. Since FXa formed on TF-bearing cells is rapidly inhibited in plasma, the majority of FXa in the propagation phase is generated directly on the platelet surface by the intrinsic tenase complex. The platelet-surface-generated FXa then rapidly binds to FVa (generated in the amplification phase), thus forming an active prothrombinase complex. The prothrombinase complex then rapidly and efficiently cleaves prothrombin resulting in a burst of thrombin. When enough thrombin is generated with enough speed to cleave fibrinogen, a clot forms (Figure 87.7c).[22,45]

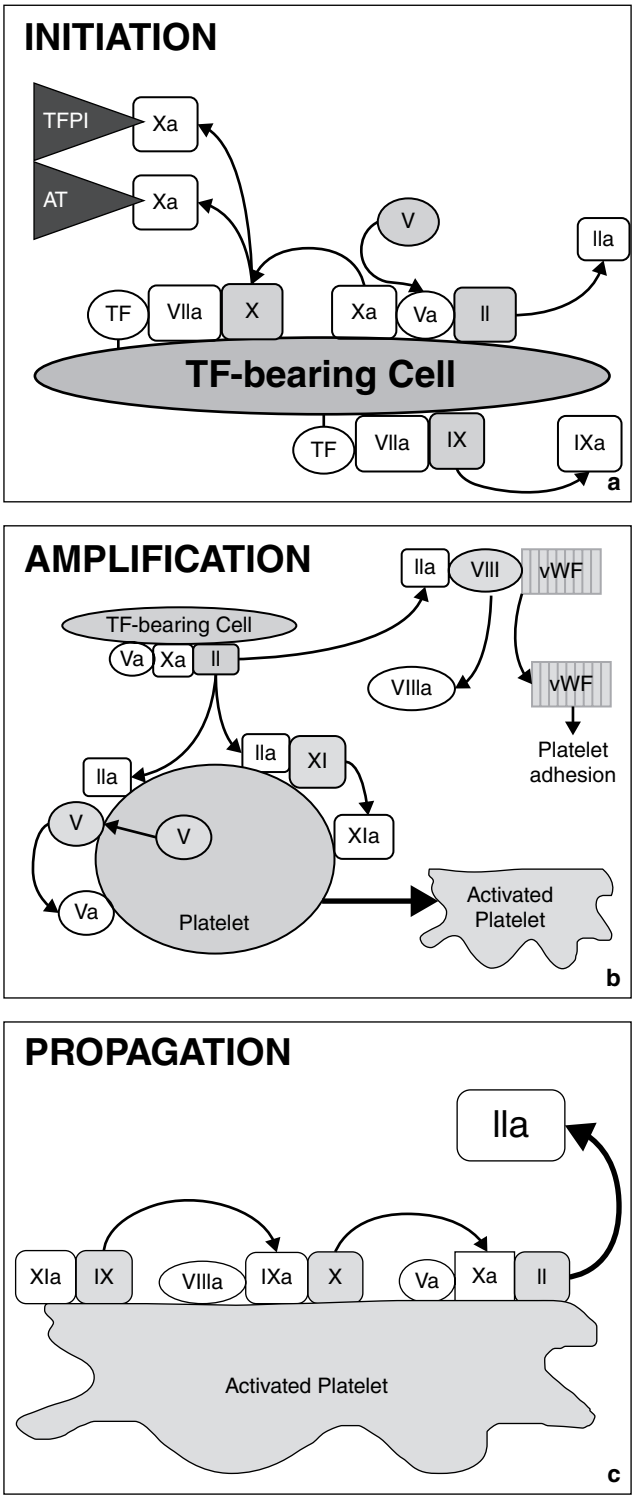

FIGURE 87.7 Cell-based model of fibrin formation. In this model, thrombin generation occurs in overlapping phases. (a) Initiation phase: This phase occurs on the TF-bearing cell and is initiated when injury exposes the TF-bearing cell to the flowing blood. It results in the generation of a small amount of FIXa and thrombin that diffuse away from the surface of the TF-bearing cell to the platelet; (b) Amplification phase: In the second phase, the small amount of thrombin generated on the TF-bearing cell activates platelets, releases VWF, and leads to generation of activated forms of FV, FVIII, and FXI; (c) Propagation phase: In the third phase, the various enzymes generated in earlier phases assemble on the procoagulant membrane surface of the activated platelet to form intrinsic tenase, resulting in FXa generation directly on the platelet surface. Prothrombinase complex forms and results in a burst of thrombin generation directly on the platelet. See Table 87.1 for abbreviations.

THROMBIN

Thrombin is generated from prothrombin by cleavage at two activation sites. Thrombin is the terminal coagulation protease responsible for fibrin formation. Thrombin generation, however, is not the end of coagulation. Many steps vital to normal hemostasis occur temporally *after* generation of a fibrin gel. Approximately 5% of the prothrombin that will be cleaved has been converted to thrombin at the time of fibrin gel formation, as detected in routine plasma-based clotting assays.[32]

Free thrombin has an extremely short plasma half-life of less than 15 seconds due to rapid inhibition by AT–HSPG.[11] Thrombin bound to the fibrin clot, however, is both enzymatically active and protected from inhibition. In addition to its function in cleavage of fibrinogen to fibrin, thrombin has many additional roles in coagulation and fibrinolysis, as well as functions in cell regulation (Figure 87.8).[32]

Feedback Regulation of Coagulation

Thrombin provides positive feedback to the process of coagulation by activating a number of upstream proteases and cofactors. These include FVII, FXI, FVIII, and FV. Thrombin bound to endothelial surface TM acts primarily to inhibit coagulation via activation of the PC anticoagulant pathways. Moreover, TM binding inhibits the interactions between thrombin and fibrinogen, limits thrombin activation of platelet PARs, and promotes activation of the fibrinolytic mediators, TAFI and scuPA. Through these feedback mechanisms, thrombin influences the quantity and speed of its own generation, and the amount of fibrin deposition and degradation.

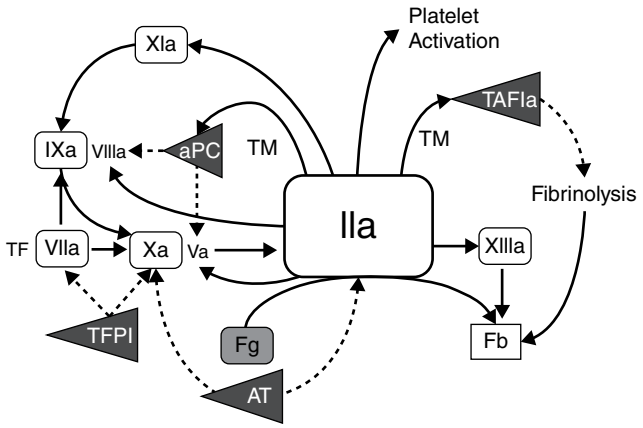

FIGURE 87.8 Central role of thrombin. Thrombin plays a central role in hemostasis, acting as both a procoagulant and an anticoagulant. Procoagulant thrombin is generated in small quantities during the initiation phase (which occurs on the TF-bearing cell), then in larger quantities on the platelet surface in the propagation phase. Thrombin is responsible for platelet activation, which provides the procoagulant surface needed for the burst of thrombin generation during propagation. Thrombin cleaves fibrinogen to fibrin, resulting in clot formation. Thrombin also impacts clot structure through activation of FXIII, which cross-links fibrin, and activation of the fibrinolysis inhibitor, TAFI. Thrombin becomes anticoagulant via thrombomodulin-mediated activation of the protein C system. See Table 87.1 for abbreviations. (**Source:** From Smith[50] © 2009 John Wiley & Sons)

Platelet Activation

Thrombin, along with many other serine proteases, can bind and cleave PARs. These cell-surface-associated G-coupled proteins are found on platelets, endothelial cells, smooth muscle cells, leukocytes, and other cell types. Cleavage by thrombin untethers a portion of the PAR molecule that self-inserts into the receptor, thereby initiating intracellular signaling. This PAR-mediated signaling is a major mechanism by which thrombin activates platelets (see Chapter 77). Thrombin also binds to the platelet GPIb/IX/V complex via a binding site in GPIbα, although how this binding mediates platelet activation is not clearly understood.[10]

Fibrin Formation

The primary function of thrombin is conversion of fibrinogen to fibrin. Thrombin cleaves two short peptides from the fibrinogen molecule, fibrinopeptide A (FpA) and fibrinopeptide B (FpB), thus exposing binding sites that interact with pre-existing sites on other fibrin molecules. The interaction between multiple fibrin molecules results in spontaneous polymerization into an insoluble fibrin gel.

Activation of Factor XIII

Factor XIII (FXIII) is a 320-kDa protein that consists of five chains arising from transcription of two different genes. Half of the circulating pool of functional FXIII is free in plasma, and the remainder is released from platelet α-granules. Factor XIII cleavage by thrombin releases an activation peptide, resulting in a 312-kDa active enzyme. Thrombin cleavage of free FXIII is slow; however, polymerized fibrin acts as a cofactor, markedly increasing the rate of FXIIIa generation. Consequently, FXIIIa is generated primarily after a critical weight of fibrin has polymerized.

Factor XIIIa is a transglutaminase whose primary function is cross-linkage of fibrillar fibrin. This activity is calcium-dependent, and critical for normal clot strength and stability. Factor XIIIa also cross-links fibronectin to fibrin and to collagen, which influences anchoring of the clot to the vessel wall. Additionally, FXIIIa has roles in cell adhesion, angiogenesis, and tissue repair.

FIBRINOGEN AND FIBRIN CLOT STRUCTURE

Fibrinogen is a soluble 340-kDa dimer consisting of three pairs of disulfide-bridge-linked polypeptides. It is the most abundant coagulation protein in plasma and is

abundant in platelet α-granules. In addition to the role of fibrinogen as a precursor to fibrin, fibrinogen mediates intracellular interactions between platelets in conjunction with thrombospondin (see Chapters 76 and 77).

Thrombin cleaves fibrinogen at two sites, releasing FpA and FpB. Upon FpA release, soluble fibrin monomer spontaneously assembles into an insoluble dimer. This polymerization occurs because removal of FpA exposes a binding site "A knob" that interacts with a complementary binding "hole" on separate fibrin molecules. Initial polymerization produces a dimer with a half-staggered structure. Dimers continue to associate to form longer, two-fibrin-wide strands, called protofibrils.[3,20] Subsequent removal of FpB allows for lateral aggregation of protofibrils of increasing width via the "B knob" interacting with its complementary binding site. Protofibrils are stabilized by the same A-a and B-b knob–hole interactions that allowed for initial dimer association. Protofibril growth continues, with branch points developing where multiple fibrin monomers interact laterally. The resulting fibrin polymer is a mesh-like network (Figure 87.9).[3,20]

Thrombin-mediated release of fibrinopeptides from fibrinogen is neither calcium-dependent nor membrane-dependent. However, fibrinogen contains several calcium-binding sites. Calcium influences fibrin assembly, enhancing the rate and extent of lateral protofibril association. Consequently, calcium influences the structure of the mature fibrin clot.[3,20] As the fibrin network forms, some thrombin is bound into the developing mesh via specific binding sites on the two molecules. Fibrin binding is important in activation of FXIII, and clot-bound thrombin also acts as a cofactor that accelerates fibrin assembly.[3,18,20]

FIBRINOLYSIS

Fibrin clot formation prevents hemorrhage, but the clot must be removed for later restoration of blood flow. Clot dissolution is referred to as fibrinolysis. The fibrinolytic system is normally quiescent due to the relative abundance of fibrinolysis inhibitors, and the requirement for fibrin as a cofactor for many of its processes. Although the primary function of fibrinolysis is removal of fibrin, many components of the system are involved in tissue-repair processes, such as cell adhesion, migration, and proliferation.

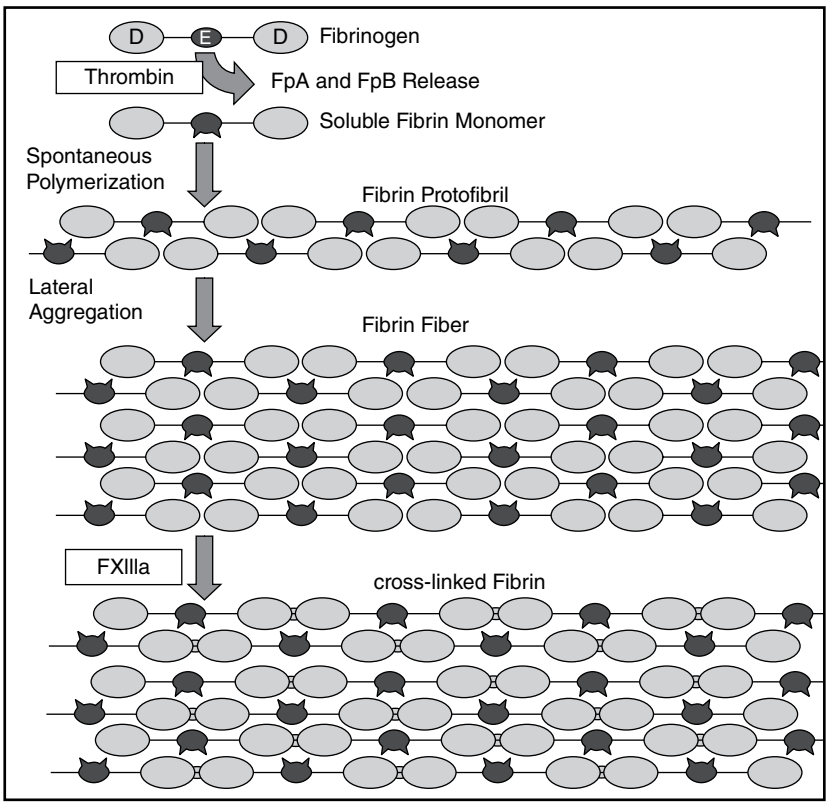

FIGURE 87.9 Fibrin formation. Fibrinogen consists of a central E domain connected by coiled chains to two lateral D domains. Thrombin cleaves fibrinogen to fibrin monomer by removing two short peptides from the E domain (fibrinopeptides A and B) exposing binding sites in the E domain. These exposed sites then interact with corresponding binding sites on the D domains of other fibrin molecules, resulting in spontaneous polymerization into a fibrin protofibril. Multiple protofibrils laterally polymerize, forming a fibrin fiber. FXIII is activated to FXIIIa by thrombin. FXIIIa creates cross-links between D domains of contiguous fibrin monomers. (**Sources:** Blomback and Bark[3]; Hantgan and Lord[20])

Plasminogen

Plasminogen (PLG) is a single-chain 92-kDa glycoprotein synthesized primarily in the liver. It circulates in plasma with a long half-life of approximately 2 days. Its complex structure consists of five kringle domains and a serine protease domain. Several of the kringle domains bind aminocarboxylic acids (such as α_2-aminocaproic acid and tranexamic acid) that are used as pharmacologic fibrinolysis inhibitors (see Chapter 94).

Plasminogen activators transform plasminogen to plasmin by cleavage at a single site, resulting in a two-chain molecule with an N-terminal glutamic acid residue (Glu-plasmin). In vitro, plasmin cleaves other plasmin molecules to remove part of the N-terminus, leaving an N-terminal lysine residue (Lys-plasmin). This additional cleavage probably does not occur in vivo due to rapid neutralization of free plasmin by inhibitors. The half-life of free plasmin is extremely short (0.1 seconds). Fibrin is a strong modulator of PLG activation. It enhances PLG activation due to binding and colocalization of PLG and its activators to the terminal lysine residues of fibrin monomers. Partially degraded fibrin exposes additional lysine sites, enhancing PLG activation through a positive feedback loop. Aminocarboxylic acids interfere with PLG binding to the lysine residues of fibrin. The fibrinolysis inhibitor, TAFI, acts by removing lysine residues, thereby limiting available PLG-binding sites.

The PLG molecule contains within its kringle domains the antiproliferative protein angiostatin. Tumor-mediated proteolysis or proteolysis by macrophages releases this fragment from plasmin. Angiostatin also inhibits endothelial cell and smooth muscle proliferation and migration, and induces apoptosis.[5]

Plasmin degrades polymerized fibrin to form heterogeneous fragments referred to collectively as FDPs. The D-dimer fragment is produced by degradation of the linked region between D domains of adjacent fibrin molecules. This linkage is created exclusively by FXIIIa; therefore, the presence of D-dimers indicates that polymerized fibrin was subject to cross-linking.

Plasminogen Activators

Mammals produce two physiologic PLG activators, tPA and uPA, named for the source from which they were originally isolated (tissue and urine). Some bacteria and vampire bats also produce unique plasminogen activators, distinct from tPA or uPA.[5]

Tissue-Type Plasminogen Activator

Tissue-type plasminogen activator is a 68-kDa serine protease glycoprotein produced and secreted by endothelial cells in response to a variety of triggers, including bradykinin, histamine, acetylcholine, α-adrenergic agents, and PAF. Very little tPA circulates in the bloodstream and most is bound to its major inhibitor, PAI-1. Free tPA and tPA–PAI-1 complexes are rapidly removed from circulation by binding to endothelial cell and hepatocyte receptors. The α_2-MG–LRP interaction is a major clearance mechanism.

Endothelial cells secrete tPA as a single-chain molecule (sctPA) that is a functional enzyme; however, its activity is weak in the absence of fibrin. Plasmin cleaves sctPA to form the two-chain mature enzyme form (tPA). Fibrin binds to either single-chain or two-chain tPA. The protease activity of fibrin–tPA is strong and highly specific for cleavage of PLG to form plasmin.[5]

Urokinase Plasminogen Activator

Urokinase plasminogen activator is a 54-kDa serine protease glycoprotein synthesized by fibroblast-like cells, epithelial cells, monocytes, and endothelial cells. It is secreted as a single-chain molecule (scuPA) with less than 1% protease activity of the two-chain mature enzyme, uPA. Plasmin, FXIIa, and kallikrein cleave scuPA to form uPA.[5] Monocytes express an important cellular receptor for scuPA (urokinase plasminogen activator receptor, uPAR). Colocalization of scuPA and uPAR on cell surfaces enhances PLG activation.

Unlike tPA, uPA can activate PLG in the absence of fibrin. It appears that tPA is the major PLG activator within the vasculature, whereas uPA is the major extravascular PLG activator. Consequently, uPA's primary roles include degradation of extracellular matrix in the processes of cell migration, and healing.[5]

Fibrinolysis Inhibitors

Plasminogen Activator Inhibitor-1

Plasminogen activator inhibitor-1, a 52-kDa serpin and acute phase reactant, is the major inhibitor of PLG activators. Elevated plasma levels of PAI-1 are strongly correlated with prothrombotic disease, while PAI-1 deficiencies are associated with bleeding and hyperfibrinolysis.[7] The primary source of plasma PAI-1 is unknown; however, many cell types, including megakaryocytes, endothelial cells, and hepatocytes, synthesize PAI-1. It is produced as an unstable, active form found primarily in blood and tissues, and a more stable latent form present in platelets. Most of the circulating PAI-1 is complexed with vitronectin, which stabilizes PAI-1's active conformation.[60]

The target enzymes of PAI-1 are sctPA, and the two-chain forms of tPA and uPA. When bound to a PLG activator, PAI-1 loses its affinity for vitronectin, but gains affinity for cell-surface LRP. This shift results in rapid clearance of PAI-1 by LRP-mediated internalization. Vitronectin-bound PAI-1 also inhibits thrombin, an activity enhanced by HSPG.[60] In addition to its protease inhibitory activities, PAI-1 mediates vitronectin's adhesive properties and its role in tissue remodeling.[5,60]

α_2-Antiplasmin

α_2-Antiplasmin is a single-chain, 70-kDa serpin that is the primary plasmin inhibitor. It is synthesized in the liver, circulating with a long half-life of approximately

3 days. It also binds to PLG, which interferes with PLG activation due to impaired PLG–fibrin interaction. Plasmin-bound fibrin is relatively resistant to α_2-AP inhibition. Factor XIIIa cross-links some forms of α_2-AP to fibrin, thereby making the fibrin more resistant to lysis.[5]

Thrombin-Activatable Fibrinolysis Inhibitor

Thrombin-activatable fibrinolysis inhibitor is a 60-kDa protein synthesized in the liver and released as a zymogen.[6] Thrombin and plasmin activate TAFI by cleavage at a single site; however, activation is extremely slow. Thrombomodulin-bound thrombin, however, increases the TAFI activation rate more than thousandfold. Activated TAFI inhibits fibrinolysis by removing the C-terminal lysines of polymerized fibrin. These residues are the primary binding site on fibrin for both PLG and its activators; therefore, modification of fibrin by TAFIa makes the fibrin clot resistant to fibrinolysis. Complement cascade proteins and adhesive proteins are secondary targets of TAFIa.

No TAFIa inhibitors have been identified, rather TAFIa appears to be regulated via spontaneous loss of activity. This inherent lability is temperature-dependent. At body temperature, TAFIa has a half-life of about 10 minutes.

Miscellaneous Inhibitors

The nonspecific protease inhibitor, α_2-MG, acts to inhibit plasmin (especially in the absence of free α_2-AP) and also binds to tPA and uPA. Protein C inhibitor and protease nexin-1 also inhibit tPA.

HEMOSTASIS AND INFLAMMATION

The inflammatory and hemostatic systems demonstrate apparent "cross-talk." This communication plays important roles in the healing processes necessary for tissue repair, and in the inflammatory and innate immune response to tissue injury and infection. Cross-talk may be responsible for inappropriate activation of hemostasis associated with systemic inflammation (see Chapter 91).

Effects of Hemostasis on Inflammation

Contact pathway activation produces two enzymes (kallikrein and FXIIa) that activate complement and induce neutrophil activation, and stimulate monocytes to downregulate Fc receptors and release inflammatory cytokines. Additionally, cleavage products of HK have effects on cellular adhesion, cellular proliferation, and apoptosis.[14,28,49]

The TF–FVIIa complex expressed on monocytes and endothelial cells activates cell surface PARs. This stimulation induces PAR-mediated signaling and increased expression of inflammatory cytokines (e.g., interleukin-1 and interleukin-6, tumor necrosis factor) and expression of chemotaxis proteins.[14,28,49]

Thrombin is chemotactic for macrophages and neutrophils, stimulates selectin expression that promotes neutrophil adhesion to endothelial cells, and activates endothelial cells to produce PAF, a potent neutrophil agonist. Thrombin activation of platelets releases CD40 ligand, which can induce TF formation and increase cytokine production. Thrombin also increases endothelial permeability.[14,28,49]

The inflammatory response is attenuated by APC's enzymatic action on PAR-1, which downregulates TF expression. Soluble EPCR, released by metalloproteinases from the endothelial cell surface, inhibits neutrophil adhesion. Downregulation of TM expression increases endothelial intracellular signaling pathways responsible for production of proinflammatory cytokines, and limits activation of TAFI, adversely affecting clearance of some complement proteins.[14,28,49]

Fibrin can directly stimulate production of proinflammatory cytokines by monocytes, and release of chemokines by endothelial cells and fibroblasts.[14,28,49]

Effects of Inflammation on Hemostasis

Inflammatory mediators, especially components of the complement system, induce transmembrane phospholipid movement, resulting in expression of a procoagulant surface. The acute phase response results in a shift in the balance of protein synthesis. Proteins whose synthesis increases include fibrinogen, PLG, tPA, uPA, C1-INH, C4BP, PS, vitronectin, PAI-1, and α_1-PI. Proteins whose synthesis is decreased include FXII, AT, and PC.[16,28]

Inflammatory cytokines downregulate the expression of EPCR and TM on the endothelial cell surface. This results in less activation of APC, and consequently less inactivation of FVa and FVIIIa. Proinflammatory cytokines also induce expression of TF by cell types that do not express this antigen under resting conditions. Proinflammatory cytokines also downregulate expression of HSPG on the endothelial cell surface, which decreases the anticoagulant activity of AT.[14] Neutrophil elastase cleaves a variety of coagulation and fibrinolysis proteins, including AT, PC, and TM.[28]

CONCLUSION

Our understanding of hemostatic pathways, and their regulation in health and disease, is continually evolving. The discovery of polyphosphate's in vivo activation of the contact pathway launched a new era of research into the differences between physiologic hemostasis and pathologic thrombosis. Studies demonstrating that lipopolysaccharide (LPS) induces TF expression on monocytes and endothelial cells, and their shed microvesicles, now confirm the role of the TF pathway as a trigger of both pathologic and physiologic hemostasis. Undoubtedly, these discoveries will lead to the further development of new models to help unravel the complexity of hemostasis.

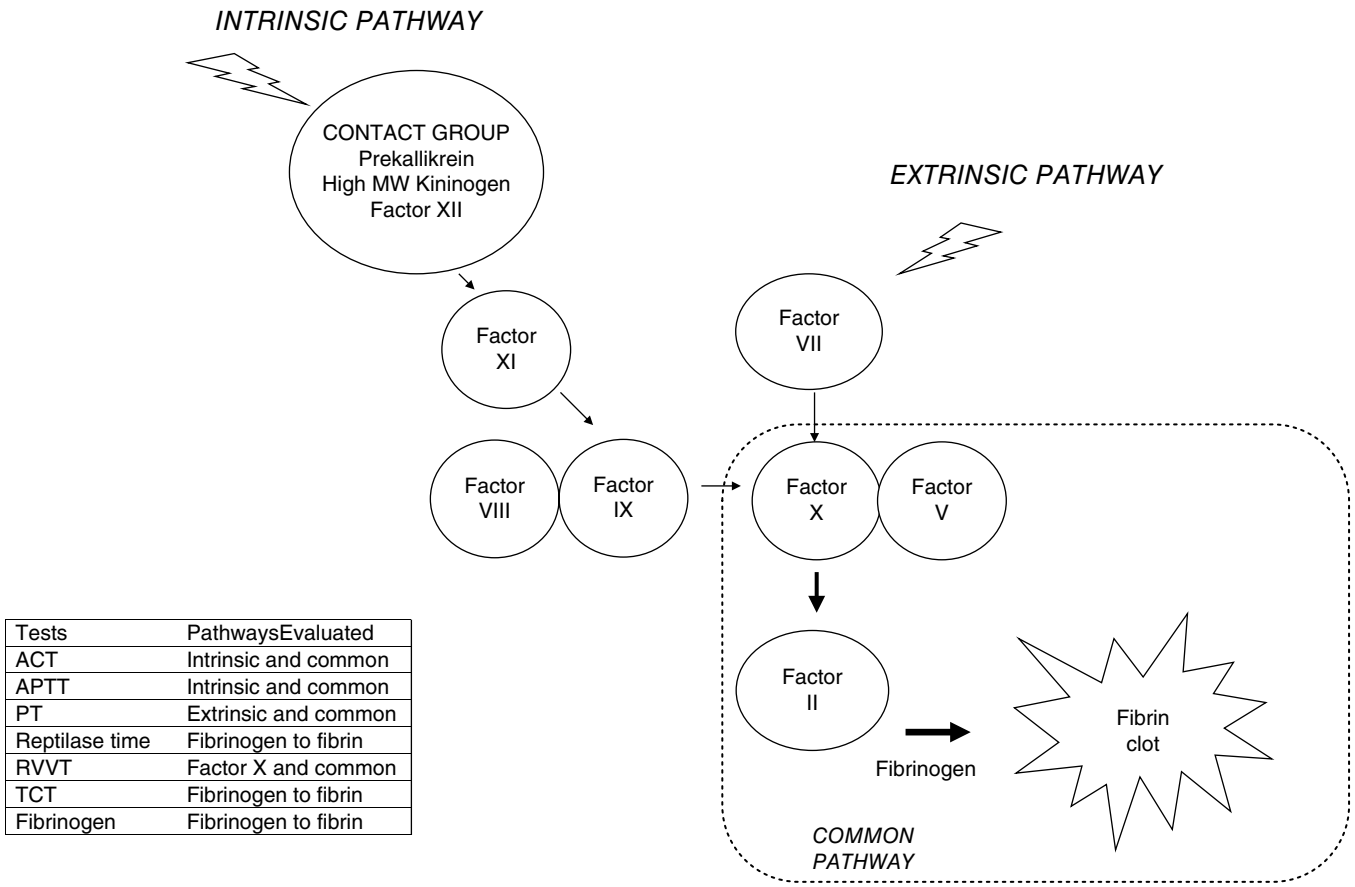
The coagulation cascade encompasses a series of rapid, cell-membrane-associated enzymatic reactions that culminate in a burst of thrombin. Thrombin then cleaves peptide fragments from plasma fibrinogen to form an insoluble, fibrin clot. Vascular patency is later restored, as the fibrinolytic pathway gradually degrades mature fibrin. While these processes are intricately related and tightly regulated in vivo, laboratory tests of coagulation and fibrinolysis typically follow a reductionist approach by evaluating single components in purified assay systems. New technologies facilitate more "global" assessments; however, traditional tests remain relevant for interpreting global assays and guiding patient management.

SAMPLE COLLECTION AND PROCESSING FOR COAGULATION TESTING

Careful blood sample collection and processing are critical for ensuring that assay results accurately reflect in vivo hemostatic function.[55,60] The key steps for sampling include atraumatic venipuncture and withdrawal of an exact volume of blood directly into tubes or syringes containing anticoagulant. With few exceptions, buffered citrate-based anticoagulants are utilized for coagulation and fibrinolysis tests. Blood is typically collected at a ratio of one part citrate (3.2% or 3.8% citrate) to nine parts blood. Marked deviations from this ratio will influence test results; excess anticoagulant can dilute factors and delay reaction rates, whereas inadequate anticoagulant risks factor activation, depletion, and clot formation. An adjusted citrate volume to accommodate high hematocrit (>55%) is recommended for some human tests: 0.00185 × (100-Hct) × volume of blood drawn = adjusted citrate volume.[61]

Citrate blood samples should be held at room temperature until centrifugation or use in whole blood assays.[1,55] Separation of plasma from whole blood should be performed as soon as possible after collection. A single centrifugation of 2500 g × 20 minutes to generate platelet-poor plasma is generally sufficient for routine coagulation testing. However, double centrifugation to reduce residual platelets and large microparticles in the supernatant plasma may be required for specialized hemostasis testing.[12,60,99] Most hemostatic proteins are stable and retain activity for prolonged (at least 1 year) storage at temperatures at or below −70 °C.[111] Storage at −20 °C is adequate for short-term (weeks) storage and factors from domestic species have been shown to retain activity under refrigeration for several days in transfusion units.[108,113]

CLOTTING TIME TESTS



Clotting time tests are functional bioassays that measure the time for clot formation in a reaction mixture containing the test sample and a "trigger" reagent. These reagents sequentially activate distinct series of coagulation factors, or pathways, of the coagulation cascade (Figure 88.1). The activated partial thromboplastin time (aPTT) and prothrombin time (PT) are often performed in tandem as a coagulation panel for initial screening to detect procoagulant factor deficiencies.[53] While traditionally performed on plasma samples in a testing laboratory, point-of-care instruments to measure aPTT and PT on canine or feline whole blood samples are now widely available for veterinary practice.[24,112] The kinetics of fibrin formation and the relative activities of coagulation factors and inhibitors vary among species.[36,48,77,90] Assay systems optimized for human coagulation testing may require modifications for animal testing, and different reagent and instrument combinations yield different results.[5,88] Species-specific methodologies, reference intervals, and same-species controls may be needed to appropriately interpret test results.

Assay Methodologies

The formation of an insoluble fibrin clot is the endpoint for all clotting time tests; however, coagulation instruments utilize a variety of endpoint detection methods.[3,21,58,75,92,102] The BBL Fibrometer, an early semi-automated coagulation instrument, detected clot formation in an electromechanical system based on change in conductivity due to fibrin strands connecting a stationary and fixed metal electrode. Several mechanical instruments employ magnetic sensors to monitor changes in movement of a steel ball, as viscosity increases due to fibrin formation. Photo-optical coagulometers detect changes in plasma optical density (OD), as fibrin polymerization increases light scatter. Nephelometry, a modification of photo-optical detection, measures increase in forward-angle and side-angle light scatter as fibrin forms. Photo-optical methods can be adapted to provide continuous readings and a dynamic clot "signature" or waveform analysis.[50,88] Mechanical endpoint coagulometers are not subject to interference from lipemia, bilirubinemia, or hemolysis and are generally able to use smaller sample volumes and detect weaker clot endpoints with shorter lag times than photo-optical methods.

Activated Partial Thromboplastin Time

The trigger reagent for the aPTT assay contains phospholipid and negatively charged particles.[53] Upon contact with these particles, factor XII undergoes a conformation change and autoactivation, and then participates in reciprocal activation of prekallikrein in an amplification loop referred to as the contact pathway (Figure 88.2). Coagulation complexes assemble during preincubation of the aPTT reaction mixture; the addition of calcium then drives activation of factor XI and the remaining intrinsic pathway factors (factors IX, VIII) and the common pathway factors [factors X, V, and thrombin (factor II)]. The aPTT is insensitive to factor VII deficiency, but is prolonged by deficiencies of any other factor (Figure 88.1). Similarly, the activated clotting time is a point-of-care whole blood assay triggered by contact pathway activation. The

Abbreviations: ACT, activated clotting time; aPTT, activated partial thromboplastin time; PT, prothrombin time; RT, reptilase time; RVVT, Russell's viper venom time; TCT, thrombin clotting time.

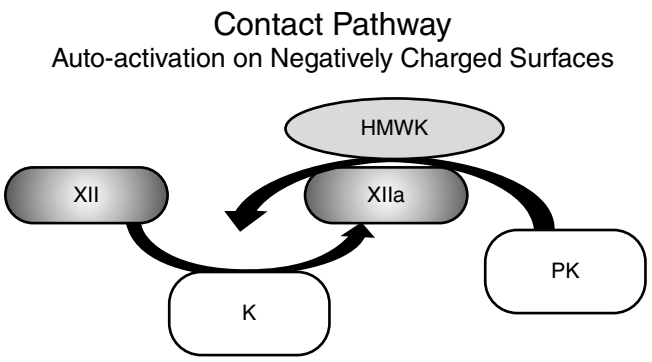

FIGURE 88.2 The contact pathway of coagulation. The contact pathway involves reciprocal activation of two proteases that assemble on negatively charged surfaces. A cofactor, high-molecular-weight kininogen (HMWK), participates in the process of transforming zymogen factor XII (XII) to its active form factor XIIa (XIIa) and prekallikrein (PK) to its active form kallikrein (K).

assay system lacks exogenous phospholipid, however, and is more susceptible to non-factor-specific influence of platelet count, hematocrit, and plasma protease activity.

Prothrombin Time

The PT trigger reagent contains tissue factor, phospholipids, and calcium and initiates coagulation through activation of factor VII.[53] The source of tissue factor and phospholipid composition vary among reagents, including traditional "thromboplastins" derived from brain extracts and recombinant, lipidated tissue factor reagents. The PT assay is sensitive to factor VII deficiency, and deficiencies of the common pathway factors (Figure 88.1). The international normalized ratio (INR) represents a data transformation of the PT result that accounts for differential reagent composition based on the manufacturers' supplied international sensitivity index (ISI).[53,55] The INR simplifies comparison of results among testing laboratories and is calculated using the formula: INR = [patient PT/mean normal PT]^{ISI}. In human medicine, the INR is often used to gauge the severity of coagulopathy and the anticoagulant intensity of coumadin therapy. Depending on disease indication, coumadin-target INR values typically range from 2 to 3, with values >4 indicating risk for excessive anticoagulation.[54,107]

Vitamin K deficiency results in a combined functional deficiency of factors II, VII, IX, and X (see Chapter 89).

The noncarboxylated (des-carboxyl) forms of these proteases accumulate in plasma and are collectively referred to as proteins induced by vitamin K absence or antagonism (PIVKA). A commercial bovine thromboplastin reagent (Thrombotest, Nyegaard & Co.) was developed as a sensitive clotting time test to monitor vitamin-K-deficiency states, and has been used for this purpose in veterinary clinical and toxicologic studies.[15,49] The assay, however, is nonspecific and is prolonged for patients deficient in any of the extrinsic or common pathway factors, regardless of vitamin K status. While Thrombotest is now used infrequently in human medicine, immunologic assays, specific for descarboxyprothrombin (PIVKA-II), are used as biomarkers of human hepatocellular carcinoma.[45]

Reptilase Time

The reptilase time is a functional test of fibrin formation based on the specific cleavage of fibrinopeptide A from fibrinogen.[64,75,102] The reptilase reagent is isolated from *Bothrops atrox* snake venom and contains no added calcium. The reptilase time is influenced by the concentration and conformation of fibrinogen (Figure 88.1), and is typically used to characterize hypofibrinogenemia/dysfibrinogenemia. Reptilase time is not affected by the presence of heparin or direct thrombin inhibitory drugs.

Russell's Viper Venom Time

Russell's viper venom (RVV) is a direct activator of factor X. Combined with phospholipid and calcium, RVV triggers coagulation through the common pathway (Figure 88.1). The RVV reagent demonstrates multispecies reactivity and is useful to detect vitamin-K-dependent coagulopathy in birds in the absence of an avian-source thromboplastin (see Chapter 95).[80] The dilute RVV time (dRVVT) is a modified assay using limiting dilution of venom and phospholipid to enhance assay sensitivity to the presence of inhibitors.[64,69]

Thrombin Time

The thrombin time, also referred to as thrombin clotting time (TCT), is triggered by the addition of a human or bovine thrombin reagent that directly cleaves fibrinopeptides A and B from fibrinogen (Figure 88.1). The TCT is a functional test of fibrinogen, sensitive to fibrinogen deficiency and dysfunction, fibrinogen inhibitors, and to the presence of heparin and direct thrombin inhibitory drugs.[54,75,102]

FIBRINOGEN AND PROCOAGULANT ASSAYS

Fibrinogen is a glycoprotein that circulates at high concentration in plasma, with values in most species ranging from 150 to 450 mg/dL (1.5–4.5 gm/L).[3,58] This high concentration allows detection of fibrinogen using physicochemical and viscoelastic methods, in addition to more sensitive immunologic and functional tests.[59,75,102] By contrast, coagulation factors are enzymes and coenzymes that circulate at much lower concentrations and are typically measured in functional assays with clotting time or colorimetric endpoints.[101,109] The use of same-species assay standards is ideal, and may be required to account for inherent species differences in hemostatic proteins, clotting times, and relative affinities of antibody reagents.[36,48,81,93]

Fibrinogen Assays

Heat precipitation assays provide semi-quantitative estimates of fibrinogen and are primarily used as screening tests to detect hyperfibrinogenemia.[59] The assays are typically performed on EDTA blood spun in microhematocrit tubes. Fibrinogen content represents the differential in plasma total protein by refractometry, measured before and after heat treatment.

Total clottable fibrinogen and gravimetric methods are performed by adding an excess of thrombin to plasma in a reaction lacking calcium but containing fibrinolysis inhibitors (clottable fibrinogen) or in the presence of calcium (gravimetric assay). In both methods, the insoluble clot is physically removed from the reaction mixture. In the clottable fibrinogen assay, the clot is then dissolved in urea for spectrophotometric determination of total protein. For the gravimetric method, the clot is dried and weighed. These assays are unsuitable for use as clinical diagnostic tests, but may be used to prepare fibrinogen standards or in research applications.[21,59]

Clauss fibrinogen assays are widely used in clinical diagnostic laboratories and are performed using commercial thrombin reagents and automated instruments for clot endpoint detection.[3,109] Assays are configured with dilute samples of test plasma and high-concentration thrombin. Clotting time is then converted to fibrinogen concentration by comparison with a calibration curve prepared from a fibrinogen reference standard. The choice of standard thus influences fibrinogen results. Clauss fibrinogen assays are sensitive to the presence of fibrin/fibrinogen degradation products (FDP) that impair fibrin polymerization; however, thrombin reagents often contain heparin inhibitors to allow measurement of fibrinogen in patients undergoing heparin therapy.

Prothrombin-derived fibrinogen (PT-Fg) assays are also based on clot endpoint detection and transformation of clotting time to fibrinogen concentration from a calibration standard.[3,75] These assays differ from Clauss fibrinogen by the use of a thromboplastin trigger reagent and results are more susceptible to variability based on reagent, instrument, and fibrinogen standard. Results of PT-fg and Clauss methods are generally correlated in healthy individuals; however, discrepant values may be found in samples with dysfibrinogenemia, high FDP, and marked hyperfibrinogenemia or hypofibrinogenemia.[59]

Turbidimetric fibrinogen assays monitor change in light scatter resulting from the transformation of soluble fibrinogen into a fibrin gel after the addition of a

thrombin reagent.[92] The assays are typically performed in research settings and can be configured with plasminogen activators to monitor clot formation and fibrinolysis.

Immunologic assays measure fibrinogen protein concentration regardless of its functional properties. Fibrinogen-reactive antibodies can be immobilized on microtiter plates in ELISA format or on microbeads in immunoturbidimetric assay platforms.[102] Fibrinogen is conserved among species, but reactivity of commercial fibrinogen assays must be confirmed for use in animal studies, and assay results will vary depending on calibration standard and antibody cross-reactivity to epitopes on FDP and fibrin.

Procoagulant Factor Assays

The specific procoagulant activities of individual coagulation factors and cofactors are commonly measured in modified aPTT and PT, referred to as "one-stage" assays.[64,99,114] The assays are configured with defined, single-factor-deficient plasmas combined with the test plasma in a series of assay mixtures. The time for clot formation in each reaction is inversely proportional to the deficient factor content of the test plasma. Results are transformed to percentage activity or units/mL based on comparison with clotting times of a plasma standard. Commercial suppliers of single-factor-deficient substrates are limited to human-origin factors (e.g., George King Bio-Medical, Precision Biologics) as are plasma standards containing defined factor activities. The factor activities for animal plasma obtained from these heterologous assay systems must be interpreted in the context of same-species controls. The use of same-species pooled plasma may also provide a more relevant assay standard.

Chromogenic substrate assays measure the specific amidolytic or cofactor activity of coagulation factors based on cleavage of factor-specific peptide substrates.[30,78,99] The test reagents contain purified recombinant or bovine factors and phospholipids, and the test sample provides the missing enzyme or coenzyme required to assemble an active factor complex. In these assays, the rate of color change resulting from substrate cleavage is directly proportional to factor activity in the test sample. Chromogenic assays avoid some of the species variability of clotting time tests; however, specific peptide substrates are not available for all factors, the assays are relatively expensive, and the use of same-species standards is often required to interpret test results.

Immunologic methods are typically reserved for specialized laboratories and research studies, due to the clinical relevance of measuring the functional activity of factors rather than their plasma concentration.[49,64,101] While antimurine factor antibodies and ELISA kits may be commercially available, confirmation of antibody reactivity and specificity for nontarget species are required due to the variability across species in factor sequence and post-translational processing.

Analyses of mass-spectrometry-based proteomics allow identification and quantification of any of the individual hemostatic proteins from any species without the need for species-reactive antibodies; however, these methods are currently limited to research applications.

Contact Pathway Factors

The contact pathway, consisting of serine protease factors (prekallikrein, factor XII) and a cofactor, high-molecular-weight kininogen, initiates coagulation in the aPTT assay system (Figure 88.2). This pathway, however, is not required for physiologic clot formation and the constituent factors are variably present in different classes and species of animals.[77] Non-mammalian vertebrates lack a well-developed contact pathway and cetaceans have no functional factor XII gene. For appropriate species, functional tests can be configured, as modified aPTT assays using human-deficient plasmas and a chromogenic substrate of prekallikrein is also commercially available (Diapharma).

Intrinsic Pathway Factors

Deficiencies of the intrinsic pathway factors (factors VIII, IX, XI) are associated with clinical bleeding diatheses, including the most common hereditary coagulopathies hemophilia A and B (see Chapter 90). Modified one-stage aPTTs are typically used for clinical diagnosis.[64,78,93,109] Chromogenic substrate assays to measure factor VIII coagulant activity are configured as two-stage tests. In the first stage, a reagent containing calcium, phospholipids, and purified factors IX and X is combined with test plasma, which supplies factor VIII. In the second stage, generated factor Xa is measured by cleavage of a factor Xa substrate.[30,99,114] Chromogenic factor VIII assays are often used to measure activity of purified and recombinant proteins, as they are more easily standardized across testing laboratories.[112,114] Molecular diagnostic tests for specific canine breed variants of hemophilia A and B are available (PennGen); however, molecular heterogeneity and frequent de novo mutations underlying these traits limit their utility (see Chapter 90).

Extrinsic and Common Pathway Factors

Deficiencies of thrombin and factors V, VII, and X are typically measured in modified one-stage PT assays, and chromogenic thrombin and factor X substrates are commercially available to configure two-stage assays.[30,109] A molecular diagnostic test to identify a common mutation associated with factor VII deficiency in beagles and several other breeds of dogs is offered through several commercial laboratories (see Chapter 90).

Factor XIII Assays

Factor XIII is a transglutaminase that, upon activation by thrombin, cross-links fibrin. Unlike deficiencies of serine protease factors and cofactors, factor XIII

deficiency does not cause prolongation of any clotting time test. Rather, functional tests are based on evaluation of fibrin clot stability or more specific measures of transglutaminase activity.[98] Screening tests to detect severe deficiency (<5% factor XIII activity) monitor solubility of a clot generated ex vivo from test plasma in concentrated urea or acetic acid solutions.[6,64] Non-cross-linked fibrin is unstable and rapidly dissolves. Quantitative functional assays are based on either detection of ammonia released during a transglutaminase reaction or the incorporation of a labeled amine group into a protein substrate. While generally applicable for animal plasmas, quantitative factor XIII assays are technically complex and not routinely available. As for other factors, immunologic methods require confirmation of antibody cross-reactivity with nonhuman species.

Thrombin Generation Assays

The fibrin endpoint of clotting time tests forms from the action of approximately 10 nM thrombin. This threshold value, however, represents only a small portion of the total thrombin enzymatic potential within a plasma sample. Thrombin generation assays (TGA) are kinetic assays that monitor the cumulative total thrombin formed over time based on the cleavage of a fluorogenic thrombin substrate.[50,99] The TGA reaction is triggered by a recombinant human tissue factor and phospholipid reagent and proceeds through assembly of the tenase and prothrombinase complexes to ultimately generate thrombin (see Chapter 87). The rate of increase and decrease in thrombin concentration over time is calculated from a thrombin calibrator and displayed as a thrombin generation curve or thrombogram (Figure 88.3). The area under the thrombogram profile is a summary of the overall capacity for thrombin production comprising net forces that promote and ultimately inhibit thrombin formation. The assay parameter endogenous thrombin potential (ETP) summarizes this net balance. Additional TGA numeric parameters include lag time, peak thrombin concentration, time to peak, and the total amount of thrombin generated (Figure 88.3). The TGA test principle is broadly applicable across species and two reagent/assay platforms are commercially available [Calibrated Automated Thrombin Generation Assay (CAT), Thrombinoscope; Technothrombin TGA, Technoclone]. Species variability in response to human-optimized trigger reagents and inherent species differences in the contact pathway influence thrombogram parameters such that assay adaptation and same-species controls are often needed to perform TGA in animal plasmas.[12,16,22,90] The use of defined sample collection procedures and centrifugation conditions are also important to standardize the influence of preanalytic processing on TGA parameters.[12,16,83]

ANTICOAGULANT ASSAYS

Deficiencies of physiologic coagulation inhibitors develop in a variety of prothrombotic disease conditions, due to decreased hepatic synthesis, excessive consumption, or renal or intestinal losses (see Chapter 91). By contrast, pathologic inhibitors and anticoagulant drug overdose induce hemorrhagic states. Assays that measure individual anticoagulant proteins and/or gauge anticoagulant intensity are useful to characterize and manage patients with either form of hemostatic imbalance.

Antithrombin

Antithrombin (AT) is a serine protease inhibitor (SERPIN) produced by the liver. It is a major plasma anticoagulant that localizes coagulation to membrane surfaces by inactivating circulating serine protease

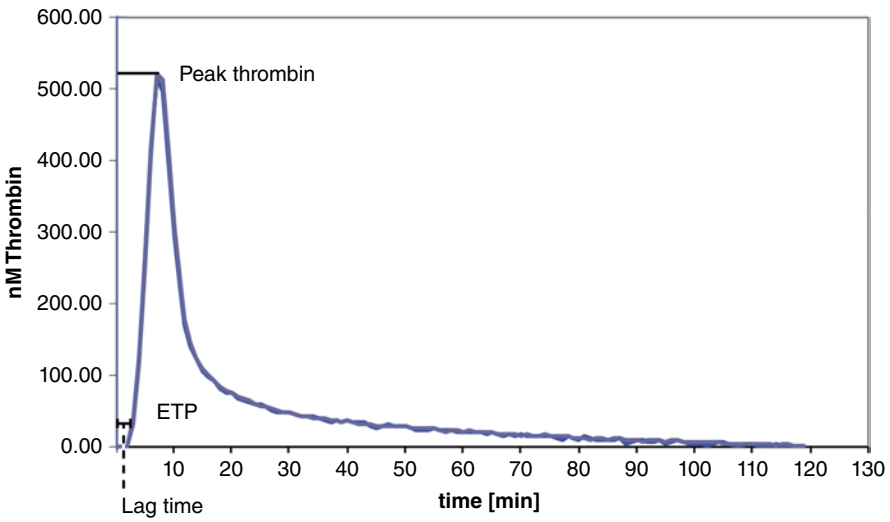

FIGURE 88.3 Thrombin generation curve (Thrombogram). The thrombogram displays the amount of thrombin formed (nM thrombin, Y axis) over a 2-hour reaction time (minutes, X axis). The "lag time" represents the delay for initial thrombin formation after initiation of the reaction, "peak thrombin" denotes maximal thrombin concentration, and "ETP" (endogenous thrombin potential) represents the summation of total thrombin as area under the curve.

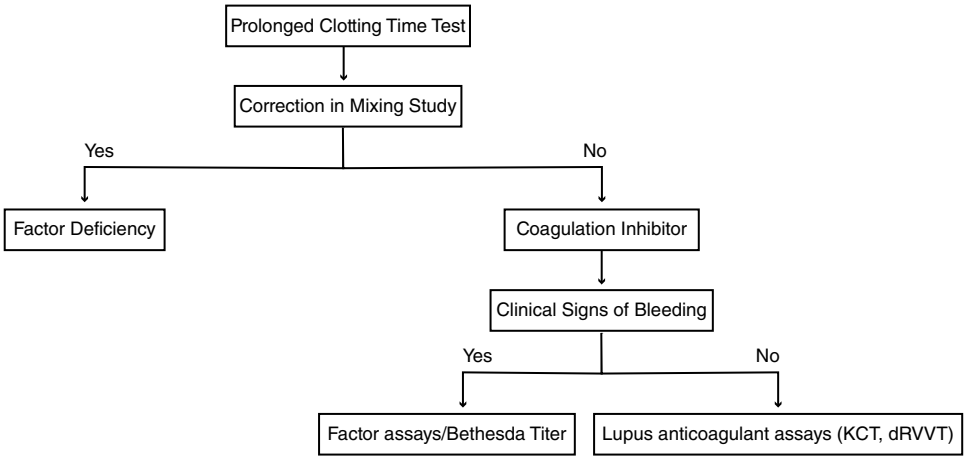

FIGURE 88.4 Diagnostic algorithm for identification of coagulation inhibitors. Abbreviations: KCT, kaolin clotting time; dRVVT, dilute Russell's viper venom time.

factors, particularly factor Xa and thrombin (see Chapter 87; Figure 88.4). The assay principle of functional AT assays is based on inhibition of a purified factor Xa or thrombin reagent. Chromogenic substrate assays are most common for clinical diagnosis and are performed by incubating the test plasma with a factor reagent containing heparin to enhance AT's interaction and inhibition of the target factor.[6,30,109] Absorbance change in the assay mixture is then monitored after addition of a peptide substrate. In these assays, AT activity is inversely related to color change in the assay mixture. Several commercially available chromogenic AT kits, configured as "anti-IIa" assays, have been used in animal studies.[5,39,113]

Thrombin–Antithrombin Complex

Upon binding with thrombin, AT forms a covalent thrombin–antithrombin (TAT) complex with a short plasma half-life of approximately 15 minutes. High circulating TAT complex concentration is an indicator of dysregulated and/or systemic thrombin generation, and often accompanies prothrombotic inflammatory states and disseminated intravascular coagulation (see Chapter 92). Plasma TAT concentration can be measured by sandwich ELISA, configured with an antithrombin capture antibody and anti-AT conjugated detector antibodies.[7] A commercially available TAT assay kit (Enzygnost TAT, Siemens) is configured with cross-reactive polyclonal antibodies and has been used for a variety of species in veterinary studies.[63,81,96]

Proteins C and S

Protein C is a vitamin-K-dependent, serine protease anticoagulant factor that circulates as a zymogen. in vivo. The activation of protein C to a functional protease, activated protein C (APC), occurs on cell membrane surfaces. Once formed, APC inactivates factor Va and factor VIIIa, and also exhibits endothelial cytoprotective effects through thrombin receptor signaling (see Chapter 87).

Functional assays for clinical diagnosis of protein C deficiency are commercially available with either clotting time or chromogenic endpoint.[46] Clot endpoint assays are typically configured as modified aPTT reaction mixtures containing the test plasma, a contact pathway activator, and a snake-venom-derived protein C activator. After recalcification, prolongation of clotting time compared to a calibrated standard indicates relatively high protein C concentration. Chromogenic assays are also configured with venom protein C activators, but contain a specific peptide substrate to directly measure the protease's amidolytic activity. Chromogenic protein C assays have been used in a variety of canine veterinary studies.[32,68,100] Protein C deficiency is a useful biomarker of liver function, with severe protein C deficiency a feature of portosystemic shunting and liver failure[100] (see Chapter 89).

Activated protein C resistance refers to a human prothrombotic condition resulting from ineffective APC-mediated inhibition of factor Va.[82] A point mutation in the gene encoding factor V (referred to as factor V Leiden) is worldwide in distribution and a common risk factor for thrombosis. Assays to detect APC resistance are typically configured as functional, clotting time tests with paired reactions measuring clotting times in the presence or absence of exogenous APC. A veterinary syndrome comparable to APC resistance has not yet been described.

Protein S is a vitamin-K-dependent serine protease that acts as a cofactor to enhance APC's inactivation of factors Va and VIIIa at membrane surfaces. Functional protein S assays are configured as modified aPTT or PT, containing the relevant coagulation triggers with either APC or protein C activators included in the reaction mixture.[62] Adaptation of a commercially available assay system (Diagnostica Stago) to measure protein S activity in dogs has been described; however, the assay's diagnostic utility is unknown.[5]

Pathologic Inhibitors: Factor Inhibitors and Lupus Anticoagulants

Pathologic coagulation inhibitors include antibodies targeting epitopes on individual coagulation factors, or on phospholipid-binding proteins (referred to lupus anticoagulants).[101,109] Antifactor antibodies either directly interfere with factor activity or enhance factor clearance, thereby causing severe factor deficiencies and clinical signs of bleeding.[56] Factor VIII is the most common targeted factor. Transfusion may trigger alloantibody formation; however, antifactor antibodies also develop as an autoimmune phenomenon (see Chapter 89).[33] Paradoxically, lupus anticoagulants are associated with hypercoagulability and signs of arterial or venous thrombosis, and pregnancy loss (see Chapters 89 and 91). Lupus anticoagulants represent a feature of the antiphospholipid syndrome, a primary autoimmune disorder that may also develop in patients with lupus erythematosus.[69]

Factor inhibitors and lupus anticoagulants are typically detected by prolongation of the aPTT screening test (Figure 88.4). A preliminary mixing study can be performed by incubating equal volumes of the test plasma with a pooled normal plasma and repeating the aPTT.[53,109] Persistent prolongation indicates the presence of a coagulation inhibitor, rather than uncomplicated factor deficiency. The specificity of antifactor antibodies is then further characterized by performing individual coagulant activity assays. By convention, the titer of factor inhibitory antibodies is defined in Bethesda units (BU).[103] Bethesda unit assays are clotting time tests configured with dilutions of patient plasma combined with equal volumes of pooled normal plasma for a 2-hour incubation at 37 °C. The coagulant activities of these mixtures, and an incubation mixture containing equal volumes of normal plasma with buffer, are then measured in one-stage assays. After calculation of residual activity of the sample dilutions versus the incubation mixture, values are data transformed to BU/mL. The antibody titer sufficient to inhibit 50% of the factor activity in normal plasma is defined as 1 BU/mL. While the original BU method has been refined, including a common "Nijmegen modification" to further standardize reaction mixture pH and protein content, the assay principle is unchanged and BU are still used to manage hemophilia A patients.[56]

Lupus anticoagulants are defined in clotting time tests configured with low concentration of phospholipid, such as the kaolin clotting time (KCT) or dilute RVVT[69,97] (Figure 88.4). The presence of antiphospholipid-binding antibodies in the test plasma impairs assembly of active coagulation complexes, thus delaying clot endpoint formation. Samples with prolonged KCT or dRVVT are then assayed in a 1:1 mixture with normal plasma to confirm that prolongation persists and was not due to factor deficiency. In human antiphospholipid syndrome, autoantibodies targeting cardiolipin or beta-2 glycoprotein often accompany lupus anticoagulant antibodies, and immunologic detection of these antibodies enhances diagnostic sensitivity and specificity. Lupus anticoagulant assays are readily adapted for animal plasmas, and adaptation of immunologic assays to detect anti-cardiolipin antibodies has also been described.[66,72] Prevalence of the antiphospholipid antibody syndrome appears low in the canine thrombotic syndromes studied to date.[66,86]

Anticoagulant Drugs: Unfractionated and Low-Molecular-Weight Heparins

The biologic activity of unfractionated heparin (UFH) is highly variable among patients, and high-dose UFH requires monitoring for individualized dose adjustments.[54] Traditionally, point-of-care activated clotting time (ACT) or aPTT were used to gauge UFH anticoagulant intensity with a target for prolongation of 1.5–2.5 times the control value. Refinements of this target include nomogram adjustments based on patient weight, pretreatment clotting times, and reagent sensitivity.[53]

Measurements of factor Xa inhibitory activity (anti-Xa) represent an alternate and more readily standardized method to monitor heparin therapy. These assays are also suitable to monitor newer low-molecular-weight heparins that do not prolong clotting times at therapeutic levels (see Chapter 94).[54] Chromogenic assays are widely used in human studies and are applicable for veterinary studies.[2,67] The assays are configured with a purified factor Xa reagent, and after incubation with test plasma, a peptide substrate of factor Xa is added to the reaction mixture. Heparin levels in the plasma are inversely related to color change. The assays are configured with calibrated standards containing defined concentration of either UFH or low-molecular-weight heparins.[11] Human anti-Xa therapeutic targets are approximately 0.3–0.70 U/mL for UFH, with a range of approximately 0.5–1.5 U/mL for low-molecular-weight heparin.[54,107] Clinical trials to define safe effective targets in veterinary studies are limited (see Chapter 94).

Anticoagulant Drugs: Vitamin K Antagonists and Direct Oral Acting Anticoagulant Drugs

Coumadin, a vitamin K antagonist, was the major oral anticoagulant drug used in human medicine for more than 50 years. Similar to monitoring UFH with the aPTT, the PT is used to ensure appropriate coumadin dosage and prevent major bleeding.[6,53] The INR is a data transformation of the PT based on thromboplastin composition and the testing laboratory's PT reference interval. Target INR values between 2 and 3 indicate appropriate anticoagulant intensity for many human thrombotic disorders.[54] The risk of hemorrhage and need for frequent monitoring and individualized dose adjustments have limited the use of coumadin in veterinary medicine (see Chapter 94).

Newer direct oral acting anticoagulants (DOACs) have begun to replace coumadin in human medicine. When used at therapeutic dosages in people, the DOACs do not reliably prolong routine clotting time tests.[26,27] Apixaban and rivaroxaban are DOACs that specifically inhibit factor Xa. Anti-Xa assays configured

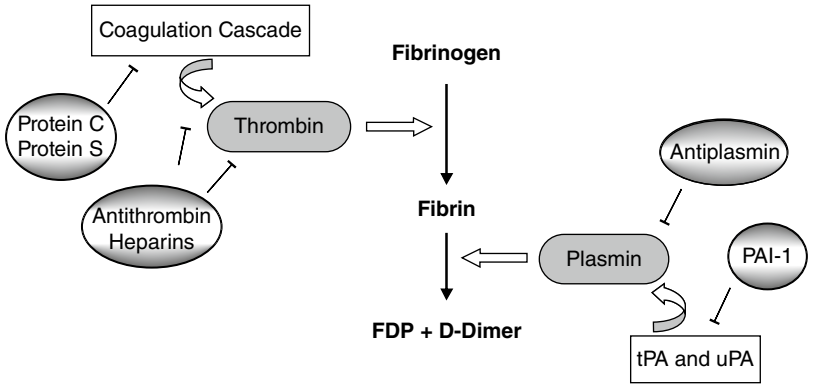

FIGURE 88.5 Regulation of fibrin formation and degradation. The coagulation cascade reactions generate thrombin, which acts on fibrinogen to form insoluble fibrin. Proteins C and S are major inhibitors of the procoagulant factors that generate thrombin. Antithrombin inhibits thrombin and the other procoagulant serine proteases. Endogenous heparins and heparin drug therapy greatly enhance antithrombin's inhibitory activity. Plasmin is the major protease that degrades fibrin. The zymogen plasminogen is activated by tissue plasminogen activator (t-PA) and urokinase (u-PA), whose actions are inhibited by plasminogen activator inhibitor-1 (PAI-1). Antiplasmin is the major circulating inhibitor of plasmin.

with apixaban or rivaroxaban standards can be used to monitor these drugs, and have shown excellent correlation with spectrophotometric assays in veterinary pharmacokinetic studies.[19,25,87]

FIBRINOLYTIC PATHWAY ASSAYS

Plasmin is the major protease responsible for fibrinolysis. Its zymogen, plasminogen, undergoes activation to plasmin primarily on the surface of fibrin fibrils through the action of tissue plasminogen activator (tPA) or urokinase (Figure 88.5). Clinical signs of bleeding develop in patients with dysregulated or "hyperfibrinolytic" syndromes, whereas delayed or impaired fibrinolysis is associated with signs of thrombosis.[17] Although the fibrinolytic pathway is less complex than the coagulation cascade, simple screening tests analogous to the aPTT and PT are lacking.[41,102] Quantitative measurements of circulating fibrin degradation products are the most widely used assays to evaluate fibrinolysis. Functional assays of specific pathway reactants and more global pathway assays are performed primarily in referral or research laboratories. Mass-spectrometry-based proteomics offers an alternate method for quantitation of fibrinolytic pathway proteins when cross-reactive antibodies are not available.

Plasminogen Assays

Functional, plasminogen activity assays have been adapted for veterinary clinical and research applications.[51,68] Commercially available kits are configured as chromogenic assays, including a peptide substrate of plasmin, and a plasminogen activator to transform plasminogen in the test sample to the active enzyme, plasmin. Human kits typically contain streptokinase as a plasminogen activator. A clinical study of fibrinolysis in dogs with babesiosis reported use of a chromogenic plasminogen assay configured with a streptokinase activator.[47] Streptokinase, however, has been reported to be an ineffective plasminogen activator for many species. An assay modification of plasma acidification, followed by neutralization and urokinase activation, has been described for measuring equine plasminogen,[106] and has been applied to other species, including dogs and rats.[13,52]

Plasminogen Activators: Tissue Plasminogen Activator and Urokinase

Two serine protease enzymes, tPA and urokinase, are the major plasminogen activators. Under physiologic conditions, these proteases act on the surface of fibrin formed within the vascular space (tPA) or extravascular tissues (urokinase). Free tPA and urokinase are rapidly cleared by complex formation with plasminogen activator inhibitor-1 (PAI-1). Assays to measure circulating levels of these activators are primarily performed in research settings. A functional assay has been described based on in vitro formation and lysis of fibrin with the time for lysis monitored by change in turbidity.[57] The assay is performed in microtiter plates by combining a mixture of fibrinogen, thrombin, and plasminogen and then adding test sample as the source of plasminogen activator. The lysis time of the test sample is then compared with a reaction configured with a streptokinase reagent representing a defined potency plasminogen activator. A canine-specific ELISA (MyBioSource) was used to measure urokinase concentration in a case series of dogs with cancer.[79] The reported mean concentration for healthy dogs (0.19 ng/mL) was not significantly different from that of the cancer patients.

Fibrinolysis Inhibitors

Antiplasmin

Antiplasmin (alpha-2-antiplasmin or serpin F2) is the major plasma inhibitor of free and fibrin-bound

plasmin. Antiplasmin is a SERPIN family protein that inactivates plasmin by forming plasmin–antiplasmin complexes.[20] Commercially available chromogenic assays of human antiplasmin activity have been used in clinical studies of fibrinolysis in horses, cats, and dogs.[18,52,68,105] The assays are configured with a human plasmin reagent that is first incubated with the test plasma, prior to addition of a plasmin substrate. Color change in the assay mixture is inversely related to plasma antiplasmin activity. Immunologic assays to measure human and murine antiplasmin concentration are available from several sources, as are human plasmin–antiplasmin complex kits. Use of these assays has not been described in companion animal studies.

Plasminogen Activator Inhibitor-1

The SERPIN family inhibitor PAI-1 (or serpin E1) is a major regulator of fibrinolysis. Circulating levels of PAI-1 are often increased in prothrombotic conditions including sepsis, obesity and metabolic syndrome, and neoplasia (see Chapter 91). It is synthesized primarily by endothelial cells and is also released from platelets and other cell types, including adipose tissue. A functional test of canine PAI-1 activity has been described based on its inhibitory action on an exogenous tPA reagent.[110] The assay is configured as a two-step chromogenic assay, wherein test plasma (containing PAI-1) is first reacted with a human recombinant tPA reagent to allow formation of the SERPIN/protease complex. In the second step, a recombinant human plasminogen reagent and a plasmin substrate are added to the reaction mixture. Free tPA generates plasmin, thus the rate and final absorbance change in the reaction are inversely related to PAI-1 content of the test plasma. Dogs with hyperlipidemia were found to have increased plasma PAI-1 activity compared with healthy dogs; however, PAI-1 activity was labile in plasma stored at 4 °C. Functional assays to detect rat or human PAI-1 are also commercially available (Molecular Innovations).[13] These assays are configured with microtiter plates coated with urokinase that will interact with PAI-1 in the test sample. The amount of bound PAI-1 is then detected immunologically with antibodies directed against human or rat PAI-1.

Thrombin-Activated Fibrinolysis Inhibitor

Thrombin-activated fibrinolysis inhibitor (TAFI) is a non-serpin, carboxypeptidase that acts at endothelial surfaces upon its activation by thrombomodulin-bound thrombin (see Chapter 87). Active TAFI cleaves plasminogen-binding residues from fibrin polymers, thus slowing fibrinolysis and facilitating clot stabilization. A commercially available, chromogenic assay has been used to measure TAFI activity in canine plasma.[43] The assay is configured with a thrombin–thrombomodulin reagent to activate TAFI in the test plasma, and a specific TAFI chromogenic substrate. Healthy dogs had TAFI activities ranging from approximately 32 to 71% of a human calibration standard, whereas the highest values (>200%) were found in dogs with neoplasia and thrombocytopenia.

Euglobulin Lysis Time

The euglobulin lysis time is a qualitative screening test of fibrinolysis that measures the time for in vitro dissolution of a fibrin clot.[41,91] The term "euglobulin fraction" refers to hemostatic proteins that precipitate from plasma under conditions of low pH and low temperature. This fraction contains procoagulant factors, fibrinogen, plasminogen, and plasminogen activators, but is largely depleted of fibrinolysis inhibitors, including antiplasmin, alpha-2-macroglobulin, TAFI, and PAI-1. The euglobulin lysis time test is performed by diluting the test plasma in a cold 1% acetic acid solution, followed by incubation at 4 °C, and cold centrifugation to precipitate the euglobulin fraction. After removal of the supernatant (containing inhibitors), the precipitate is resuspended in buffered saline and recalcified, with or without addition of thrombin, to initiate coagulation. The coagulation reaction is held at 37 °C and monitored over time for clot lysis. While originally performed in glass tubes with visual inspection, more recent modifications of the assay are performed in microtiter plates with spectrophotometric monitoring of OD to generate absorbance curves and numeric parameters of lysis time and lysis rate.[41] Human euglobulin fractions lyse over the course of hours, ranging from approximately 3–10 hours in one study of healthy adults. This broad range complicates interpretation of results to differentiate enhanced or impaired fibrinolysis from normal variation. In addition, plasma fibrinogen content influences clot stability, and lysis times have been shown to correlate with plasma fibrinogen levels.[57]

Turbidimetric Fibrinolysis Assays

Plasma-based assays, configured in microtiter plates containing exogenous coagulation and fibrinolysis activators, have been developed as global measures of hemostatic balance.[4] Adaptations of one of these assays, referred to as "overall hemostasis potential" (OHP), have been described for dogs and rats.[12,23,42] Initial fibrin formation and polymerization, followed by later fibrinolysis, is monitored as changes in turbidity of the reaction mixture, detected as absorbance change at 405 nM. Paired reactions, containing either a coagulation activator alone or coagulation activator with tPA, are each performed in replicates and the output absorbance change over the course of 1 hour is displayed as superimposed curves (Figure 88.6). Numeric parameters derived from these curves include: delay in time for first deflection from baseline, overall coagulation potential (area under the coagulation curve), maximal OD of the coagulation curve, and OHP (area under the lysis curve). First descriptions of the human OHP assay were

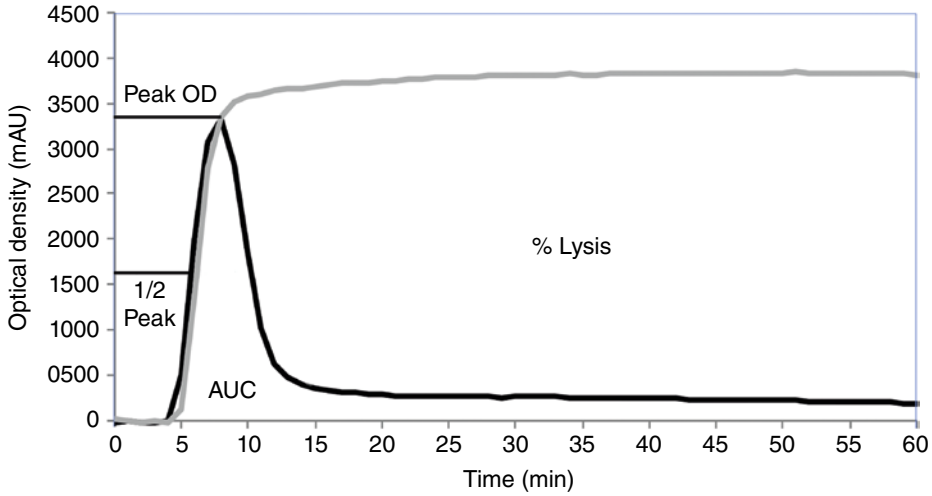

FIGURE 88.6 Microplate fibrinolysis assay tracings. Graphic overlays represent the change in absorbance (optical density, milli-absorbance units (mAU) on the Y axis versus reaction time (minutes) on the X axis. The dark line represents a lysis reaction containing a coagulation trigger reagent and tissue plasminogen activator, and the light gray line represents a reaction containing a coagulation trigger alone. The maximal and half-maximal changes in optical density are indicated by the parameters "peak OD" and "½ peak." The area under the lysis curve (AUC) and the difference in AUC between the two curves (% lysis) summarize overall hemostasis potential and coagulation potential, respectively.

configured with thrombin as coagulation activator, with subsequent modifications in thrombin dose, addition of platelet phospholipids, and tissue factor trigger reagents. Similarly, refinements in the composition and concentration of coagulation and fibrinolysis activators are described for the animal assays.

Viscoelastic Fibrinolysis Assay

Viscoelastic methods have also been developed to monitor clot formation, clot stabilization, and clot lysis. Thromboelastographic (TEG) assays, configured with coagulation activators and tPA, have been described to study drug effects in vitro and in pharmacodynamic studies in dogs and horses.[14,31,105] A plasma-based assay, referred to as clot life span analysis, has also been described for mechanistic studies of human thrombotic disorders.[73] The assay has been adapted for use in human studies of fibrinolysis inhibitors, in an equine pharmacodynamic study of a hemostatic herbal treatment, and in studies of snake venom and antidotes in dogs and several other species.[44,71] The clot life span analysis assay is performed in TEG reaction cups in reaction mixtures containing a coagulation activator (kaolin, celite, or tissue factor) with a tPA reagent. Coagulation is then initiated by the addition of calcium chloride. The TEG software generates standard numeric parameters including rate of coagulation, clot firmness, and lysis time, and displays a qualitative tracing. For clot life span analyses, additional TEG coagulation kinetic parameters related to elastic modulus (dyne/cm^2) and derived curves are included in the data compilation (Figure 88.7).

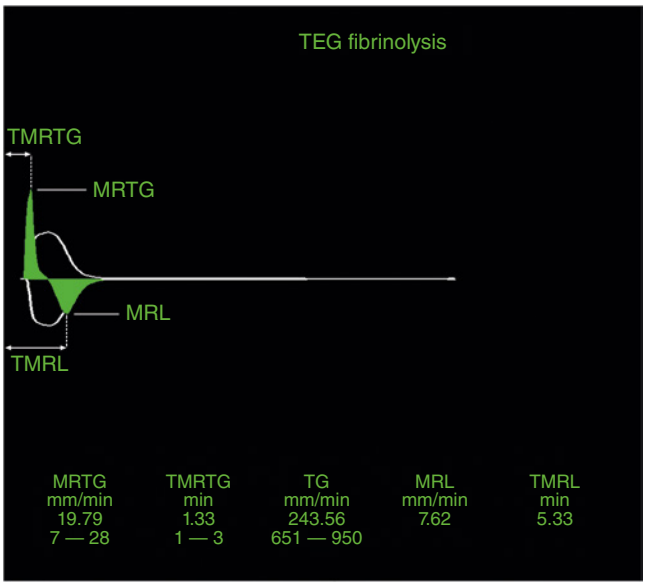

FIGURE 88.7 Clot life span model thromboelastographic variables. The data collected from cynomolgus monkey plasma treated with a coagulation activator [Innovin, Siemens (tissue factor reagent)] and fibrinolysis activator [Alteplase, Genentech (tissue plasminogen activator)] are displayed. The white tracing depicts rapid clot formation (symmetric upward and downward deflections from baseline) and complete lysis is represented by return to baseline. The green fill represents elastic modulus velocity variables of the same sample. MRTG = maximum rate of thrombus generation (dyne/cm^2); TMRTG = time to maximum rate of thrombus generation (minutes); TG = calculated thrombus generation (mm/minute); MRL = maximum rate of lysis (mm/minute); TMRL = time to maximal rate of lysis (minutes).

Fibrin/Fibrinogen Degradation Products and D-Dimer Concentration

The surface of fibrin thrombi is the major activation site of plasmin, resulting in plasmin cleavage of fibrin polymers and release of a series of degradation peptides, also referred to as fibrin split products.[41] Under pathologic conditions of hyperplasminemia, fibrinogen degradation and release of fibrinogen fragments may also occur. Fibrinogen and fibrin degradation products are collectively referred to as FDP. D-dimer fragments are the terminal products of plasmin's degradation of cross-linked fibrin and are generated only in the process of fibrinolysis. High concentrations of D-dimer, therefore, are markers of thrombin-mediated fibrin formation and secondary fibrinolysis (see Chapters 91 and 92).

A semi-quantitative latex slide agglutination test (Thrombo-Wellcotest, Thermo Fisher) has been widely used in clinical veterinary studies of disseminated intravascular coagulation (DIC).[95] The assay requires special collection tubes containing a coagulation activator and proteolysis inhibitor, and can be performed on blood or urine samples. The anti-FDP reagent is a polyclonal antibody raised against purified fibrinogen fragments D and E. More recently, commercially available semi-quantitative and quantitative D-dimer assays have been evaluated to aid in animal DIC diagnosis.[8,94] While D-dimer testing is included in diagnostic algorithms to exclude pulmonary thromboembolism or deep vein thrombosis in defined human patient populations,[6,109] cutoff values with similar diagnostic utility for animals are lacking (see Chapter 91).

WHOLE BLOOD ASSAYS

Cell-based models of hemostasis emphasize the importance of cell membrane surfaces in promoting and regulating coagulation (see Chapter 87). Assay techniques designed for whole blood samples attempt to capture the contribution of blood cells and hemostatic proteins for "global" assessment of overall hemostatic balance. Similar to other functional coagulation assays, preanalytic variables and reagent composition influence test results. Moreover, test interpretation often requires knowledge of platelet count, hematocrit, and plasma hemostatic protein content, particularly fibrinogen concentration.

Viscoelastic Assays

Thromboelastography (TEG®, Haemonetics), rotational thromboelastometry (ROTEM®, Instrumentation Laboratory), and microviscometry (Sonoclot, Sienco) are viscoelastic assays with associated software designed to measure and display the kinetics and tensile properties of clot formation in whole blood. These instruments monitor changes in clot strength and stability that occur beyond the time of initial fibrin formation. In addition to qualitative tracings, the instruments' software performs direct measurements and derived calculations that describe features of clot formation and subsequent clot lysis. The principles of operation and output parameters vary among these instruments[35] (Figures 88.8 and 88.9). These instruments are often placed in medical emergency room or operative or settings, and used to guide transfusion requirements for complex trauma patients and cardiovascular and transplant surgical procedures. The instruments require accurate pipetting skills and careful technique for operation. A handheld viscoelastic monitor (VCM™, Entegrion) designed for patient-side testing of non-anticoagulated blood has recently become available for human hemostasis monitoring, with a similar device (VCM Vet™) marketed for veterinary patients.

Thromboelastography has been the most widely used viscoelastic assay for clinical veterinary studies in the United States. A multi-institution veterinary panel [Partnership on Rotational ViscoElastic Standardization (PROVETS)] to standardize thromboelastography and thromboelastometry identified several sources of variation among testing centers, and confirmed the

(**Source:** Ganter and Hofer[35])

inherent biologic variability of viscoelastic testing.[37] The same group developed evidence-based guidelines for use of TEG® and ROTEM®. Consensus recommendations included practices to minimize preanalytic variation, development of instrument-specific assay configurations, and use of in-house reference intervals. The panel also identified areas of uncertainty for future research.[38]

Unlike traditional clotting time tests, viscoelastic monitors allow characterization of disease conditions of procoagulant excess (hypercoagulability) and defects of enhanced or delayed fibrinolysis. Thromboelastographic features of hypercoagulability have been described in dogs with immune-mediated hemolysis, protein-losing nephropathy, and neoplasia,[39,40,104] and in horses with acute gastrointestinal disease.[29] Conditions associated with hyperfibrinolysis include canine acute hemoabdomen,[32] hepatopathies,[34] and equine gastrointestinal diseases.[105] A modification of whole blood TEG® to include reactions containing tPA identified hyperfibrinolysis in dogs with acute hemoabdomen.[32] To date, clinical studies utilizing the handheld viscoelastic monitor have not yet been published.

The limitations common to all whole blood viscoelastic assays include the influence of hematocrit, platelet count, blood viscosity, and fibrinogen content on assay parameters such that interpretation of test results requires consideration of all of these parameters.[74] Low hematocrit and high fibrinogen are consistently associated with "hypercoagulable" TEG tracings; however, conditions within the in vitro reaction cup may not reflect in vivo hemostatic balance.[10,65] These features complicate the use of viscoelastic assays as clinical diagnostic tests. Nevertheless, viscoelastic assays have shown utility for serial patient monitoring, pharmacodynamic studies, and in mechanistic studies of hemostatic disorders.[35,38,50]

Microfluidic Flow Assays

In addition to fluid phase and cellular reactants, physiologic hemostasis is coordinated and regulated by blood flow properties. Microfluidic devices have been developed to study thrombus formation in whole blood under controlled conditions of shear stress.[9,84] This technology allows for low sample volume, and varying matrix compositions of the device walls to capture different aspects of platelet adhesion and activation, and fibrin polymerization in a cellular milieu under flow. Microfluidic chambers are also able to incorporate endothelial cell surfaces and model vascular stenosis. While primarily designed for research settings, commercialized devices have been developed for biomedical and clinical studies. The Total Thrombus-Formation Analysis System (T-TAS) is a novel whole blood microfluidic device that combines microscopic imagery and pressure sensors.[85] The instrument's output includes qualitative analyses of thrombus formation that generate time/pressure graphs and numeric parameters related to time for thrombus occlusion of the microcapillary chamber (Figure 88.10). The assay system is configured with disposable chips whose capillaries are coated with either collagen alone to assess platelet contribution, or with collagen and thromboplastin to assess coagulation. The shear rates are varied to mimic either arterial or venous flow conditions. Among human applications, the T-TAS device has been used in pharmacodynamic studies of antiplatelet and anticoagulant drugs, and monitoring recovery from cardiovascular procedures.[85] Preliminary studies indicate that the T-TAS system is capable of monitoring thrombus formation in canine samples, and demonstrates aberrant thrombus formation in dogs with hereditary bleeding disorders (Figure 88.11).

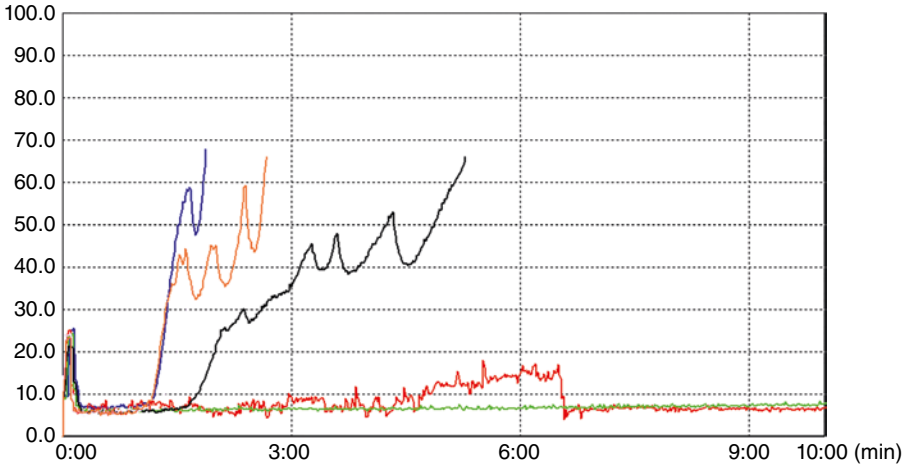

FIGURE 88.10 Total Thrombus-Formation Analysis System (T-TAS) pressure waveform output. Flow pressure waveform tracings demonstrating change in pressure [Y axis, kPa (kilopascal)] over time (X axis, minutes) of canine blood containing varying concentrations of von Willebrand factor. Note delay in occlusive thrombus formation or failure of thrombus formation depicted as slow pressure increment or lack of pressure increment. Blue line: Von Willebrand factor concentration = 100%. Orange line: Von Willebrand factor concentration = 40%. Black line: Von Willebrand factor concentration = 20%. Red line: Von Willebrand factor concentration = 0%.

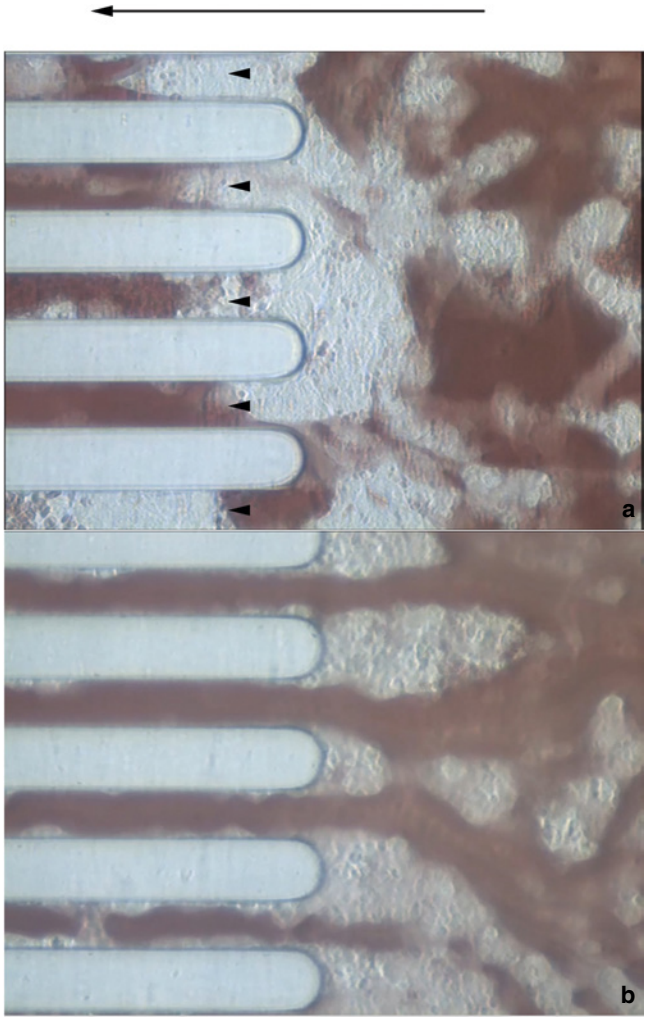

FIGURE 88.11 Total Thrombus-Formation Analysis System (T-TAS) microscopic imaging. Platelet thrombus formation in canine whole blood on collagen-coated microchip in the flow chamber. Arrow indicates direction of flow. Shear rate = 1500 s^{-1}. (a) Control dog, arrow heads indicate occluding thrombi; (b) Type 3 Von Willebrand disease; note the absence of occluding thrombi.

Continued technological advances in miniaturization, 3D fabrication, imaging, and data management will lead to the next generation of coagulation instruments.[70,84] These devices will help develop predictive models of physiologic and pathologic thrombus formation, and ultimately improve clinical diagnosis and treatment of hemostatic disorders.

  - Factor Inhibitory Antibodies
  - Antiphospholipid Syndrome Inhibitors
  - Anticoagulant Overdose

Acronyms and Abbreviations

ACOTS, acute coagulopathy of trauma and shock; APLA, antiphospholipid-protein antibody; APS, antiphospholipid syndrome; aPTT, activated partial thromboplastin time; AT, antithrombin; DIC, disseminated intravascular coagulation; DOAC, direct oral anticoagulant; FDP, fibrin degradation product; KH_2, vitamin K hydroquinone; KO, vitamin K epoxide; PIVKA, proteins induced by vitamin K absence/antagonism; PT, prothrombin time; TCT, thrombin clotting time; TEG, thromboelastography; t-PA, tissue plasminogen activator; UFH, unfractionated heparin.

Clinical signs of hemorrhage are usually the result of a breach in vascular integrity that overwhelms an individual's normal hemostatic response. For these cases, diagnosis and management are directed at defining the site and cause of blood vessel injury. A subset of patients, however, have abnormal bleeding due to impaired hemostasis. Thrombocytopenia (see Chapters 80 and 81) and acquired coagulopathies are the most common hemostatic defects encountered in clinical practice. An index of suspicion and consistent use of screening tests early in the diagnostic workup are key to recognition and effective management of acquired coagulopathies.

PATHOGENETIC CLASSIFICATION OF ACQUIRED COAGULOPATHIES

Acquired coagulopathies discussed in this chapter include disease processes that delay or prevent fibrin clot formation or increase the rate of fibrinolysis (Table 89.1).

Coagulation Factor Deficiencies

Coagulation factor activation generates a local burst of thrombin that transforms soluble plasma fibrinogen into an insoluble fibrin clot. Quantitative and/or functional

TABLE 89.1 Pathogenesis of acquired coagulopathies.

Mechanism	Disease syndromes	Associated factor defects
Synthetic failure	Liver disease: severe failure and markedly reduced functional hepatic mass	Most coagulation factors low but relative retention of factor VIII activity Hypofibrinogenemia and dysfibrinogenemia Antithrombin and protein C low
	Portosystemic shunting	Protein C low
Vitamin-K-dependent activation defect	Cholestasis, intestinal malabsorption, vitamin K antagonists, neonates	Factors II, VII, IX, and X low Protein C low
Excessive rate of consumption	Overt (hemorrhagic) disseminated intravascular coagulation, envenomation	Complex pattern of increased and decreased factor activities, hypofibrinogenemia Antithrombin low Hypofibrinogenemia, variable deficiency of other factors
Coagulation inhibitors	Alloimmune and autoimmune factor inhibitors Phospholipid-protein antibodies (associated with thrombosis) Anticoagulant overdose	Single-factor deficiency (factor VIII deficiency most common) Coagulation factor activities normal Heparins: Serine protease factors neutralized (especially factor X, factor II) DOACs: specific factor Xa or factor IIa inhibition
Hyperfibrinolysis	Disseminated intravascular coagulation, neoplasia, infectious agents, liver disease, prostate surgery, traumatic hemorrhage	Complex factor deficiencies High plasminogen activators Hypofibrinogenemia

deficiencies of coagulation factors influence the rate and amount of thrombin produced (see Chapter 87). The common acquired factor deficiencies, unlike hereditary coagulopathies, are characterized by combined deficiencies of multiple clotting factors.

Synthetic Failure

The liver is the sole or primary source of all the serine protease procoagulant and anticoagulant factors (i.e., factors II, VII, IX, X, XI, and XII, and proteins C and S) and other critical hemostatic proteins including factors V and XIII, antithrombin (AT), antiplasmin, and plasminogen. Liver disease is associated with complex abnormalities, with combined and variable deficiencies of procoagulant and anticoagulant proteins.[2,34] Liver failure, however, typically manifests as a hemorrhagic diathesis. A lack of hepatic synthetic capacity results in quantitative coagulation factor deficiencies, first detectable by decreased activities of factors with short plasma half-lives (e.g., factor VII, half-life of 6 hours). Plasma fibrinogen, as an acute phase reactant, is often normal or elevated in patients with inflammatory and cholestatic liver disease. Diseased hepatocytes, however, may produce a dysfunctional, "nonclottable" fibrinogen due to abnormal alpha chain conformation and high sialic acid content that impairs fibrin formation and polymerization. The development of hypofibrinogenemia in patients with liver disease is an indicator of severely compromised synthetic functional reserve, associated with poor prognosis.[2]

Activation Defects

Vitamin K is essential for the post-translational processing of the prothrombin group of coagulation factors (factors II, VII, IX, X) and the anticoagulants, proteins C and S. All of these factors require the addition of gamma-carboxyglutamic acid residues in order to interact with calcium, bind to membrane surfaces, and form active enzyme complexes (see Chapter 87). Vitamin K participates in the carboxylation reaction through oxidation of vitamin K hydroquinone (KH_2) to vitamin K epoxide (KO). The epoxide form of vitamin K is continually recycled to replenish KH_2 by the enzyme vitamin K epoxide reductase (Figure 89.1).

Coagulation factors synthesized in the absence of vitamin K circulate in plasma as inactive, descarboxy precursors referred to as proteins induced by vitamin K absence or antagonism (PIVKA). While PIVKA are sensitive indicators of vitamin K deficiency or antagonism, PIVKA assays are specialized tests thus limiting their clinical utility.[3,25] By contrast, the prothrombin time (PT) assay is widely available as a point-of-care or routine coagulation screening test that is commonly used to detect vitamin-K-dependent coagulopathies.

Factor Consumption and Dilutional Coagulopathies

Factor consumption can outpace hepatic synthesis in animals with severe systemic inflammation and other disease processes that trigger overt disseminated intravascular coagulation (DIC). The resultant coagulation factor depletion causes clinical signs of hemorrhage (see

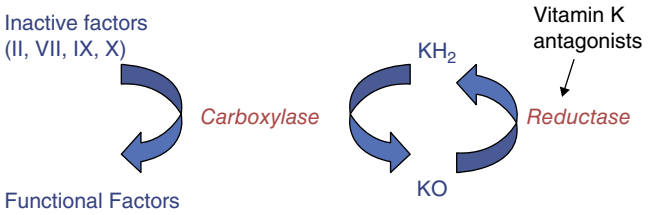

FIGURE 89.1 Vitamin K cycle. A vitamin-K-dependent carboxylase simultaneously converts vitamin K quinol (KH2) to vitamin K 2,3-epoxide (KO) as it transforms glutamate to functional gamma carboxyglutamate residues on factors II, VII, IX, and X. Vitamin K 2,3-epoxide is then reduced back to a quinol by vitamin K epoxide reductase. This enzyme is inhibited by coumarin-type anticoagulants.

Chapter 92). Systemic amyloidosis in people is associated with variable factor X deficiency, although the phenomenon has not been described in animals. Amyloid fibrils are believed to adsorb factor X and facilitate its rapid plasma clearance.[12] The bleeding tendency of amyloidosis is multifactorial; due to amyloid tissue infiltration and deposition in the microvasculature, and potentially exacerbated by severe factor X deficiency (e.g., values below 25%). Many snake venoms contain proteases that activate clotting factors and/or directly cleave fibrinogen, resulting in systemic factor depletion and defibrination in a consumptive process.[19]

Chronic hemorrhage does not result in factor deficiencies in animals with normal liver function; however, severe acute hemorrhage may be associated with a complex coagulopathy including factor depletion. Aggressive fluid resuscitation may also induce dilutional coagulopathy.[5,30] Factor dilution develops secondary to fluid shifts from the interstitial and intracellular space into the intravascular space. These shifts are triggered by reduced intravascular hydrostatic pressure and are compounded by administration of large volumes of intravenous fluids. Activation of coagulation secondary to trauma-induced tissue factor expression also contributes to factor consumption. Massive transfusion is defined as replacement of more than one blood volume within a 24-hour time interval or one-half of a blood volume within 6 hours.[15,30] Thrombocytopenia, acidosis, hypothermia, and hypocalcemia (due to citrate-based anticoagulants in blood products) further contribute to hemostatic compromise associated with aggressive transfusion of blood products.[15,30]

Coagulation Inhibitors

The classification of coagulation inhibitors includes antibodies (usually IgG) directed against specific coagulation factors.[28] The antibodies bind to and directly inhibit factor activity and/or speed the rate of factor clearance. Inhibitory alloantibodies develop in patients with hereditary factor deficiencies after transfusion exposure to the "foreign" factor antigen. Factor VIII inhibitory antibodies develop in approximately 20% of people with severe hemophilia A (factor VIII deficiency).[28,29] Alloimmunization and development of factor VIII and IX inhibitors has also been described in dogs with hemophilia A and B, respectively.[27] Autoantibodies directed against coagulation factors represent a loss of tolerance and can also develop in patients without hereditary factor defects, regardless of prior transfusion.[14] Factor VIII is the most commonly implicated factor and the resultant coagulopathy is referred to as "acquired hemophilia." The epitope specificities of factor VIII alloantibodies and autoantibodies generally overlap, with most binding to the protein's light chain C domain. Acquired factor V inhibitors have been recognized in people exposed perioperatively to topical bovine thrombin and fibrin glues.[18] These products contain trace amounts of bovine factor V, sufficient to induce cross-reactive antibody production, especially in multiply exposed patients.

The term "lupus anticoagulant" describes antibodies that prolong in vitro clotting times by blocking the interaction of coagulation factors with phospholipid reagents.[21] The immunogenic epitopes are actually phospholipid-binding proteins and a more accurate term for these inhibitors is antiphospholipid-protein antibodies (APLAs).[10] Paradoxically, people with APLA develop signs of thrombosis, rather than hemorrhage. Although their prothrombotic action is not fully defined, APLAs are believed to displace natural anticoagulants on cell surfaces and induce exposure of procoagulant phospholipids in the vascular space.

Pharmacologic anticoagulants include drugs that alter factor synthesis or directly inhibit factor activity, and heparin compounds that act indirectly to enhance antithrombin's ability to neutralize active factors. Traditionally, unfractionated heparin (UFH) was the sole anticoagulant used widely in clinical veterinary practice; however, dosage guidelines for low-molecular-weight heparins have recently been published for dogs and cats (see Chapter 94). While the antiplatelet drugs clopidogrel and aspirin are most often used for oral antithrombotic therapy, newer direct oral anticoagulants (DOACs) that interact directly with activated factor II and factor X are now under investigation (see Chapter 94). Finally, high plasma concentration of fibrin degradation products (FDPs) may act as coagulation inhibitors by interfering with normal fibrin polymerization.

Fibrinolysis Defects

Accelerated fibrinolysis causes hemorrhage by degrading fibrin clots before vascular repair is complete. Disease syndromes that enhance plasminogen activation, decrease plasminogen inhibitors, or combine these factors produce a hyperfibrinolytic state.[39] Hyperfibrinolysis, mediated by high tissue plasminogen activator (t-PA), develops in people infected with the agents causing Rocky Mountain spotted fever, African swine fever, and dengue fever, and secondary to extensive tissue trauma.[13] A syndrome of hyperfibrinolysis, referred to as acute coagulopathy of trauma and shock (ACOTS), has been described in people with severe traumatic hemorrhage and shock. In a large prospective trauma trial, early treatment with fibrinolytic inhibitors was found to significantly reduce the risk of

death due to bleeding.[4] In a potentially related syndrome, dogs with spontaneous hemoperitoneum experienced accelerated fibrinolysis that correlated with the severity of shock.[8] Hemostatic defects in dogs with hepatic disease vary, reflecting the complexity of their state of "rebalanced hemostasis." Studies using viscoelastic testing to investigate hemostatic alterations in dogs with hepatic disease have documented hyperfibrinolytic changes in up to 40% of affected dogs.[16] Certain neoplastic diseases are associated with hyperfibrinolysis due to specific elaboration of plasminogen activators by tumor cells (e.g., acute promyelocytic leukemia) or in the context of a DIC process (see Chapter 92). The prostate and uterus are rich in t-PA and urokinase plasminogen activators. Neoplasia and surgery involving these organs risk hemorrhagic complications due to local hyperfibrinolysis resulting in acute hemorrhage or delayed rebleeding.

CLINICAL EVALUATION

The initial evaluation of animals with signs of hemorrhage should aim to differentiate blood loss caused by vessel injury or vascular disease from a systemic failure of normal hemostasis (i.e., bleeding diathesis). The location and nature of hemorrhage and prior history of abnormal hemorrhage or underlying disease conditions provide clues to guide subsequent laboratory evaluation. Some animals with acquired coagulopathies do not manifest overt hemorrhage at initial presentation. Detection of factor deficiency in these cases requires an index of suspicion and consistent inclusion of coagulation screening tests early in the diagnostic workup.

History

A history of recurrent, episodic hemorrhage is suggestive of a hereditary hemostatic defect, rather than an acquired coagulopathy (see Chapters 83, 84, and 90). Hemostasis questionnaires have been developed for medical studies with the goal of simplifying history gathering and generating bleeding "scores" for standard comparison among trials.[31] A brief questionnaire with specific questions on hemostasis is also useful early in the clinical workup of animals suspected of having a bleeding disorder. Pertinent questions include: Has this animal ever had spontaneous bleeding from the nose, mouth, urinary tract, or noticeable bleeding when teething? Has this animal ever had a surgical procedure, dentistry, or traumatic injury, and were there any bleeding complications? Are you aware of any bleeding problems in relatives or in this breed? Is this animal receiving any medication or dietary supplements? Does this animal have any ongoing medical problems? Additional questions regarding housing conditions and potential access to drugs and toxins are useful; however, a negative exposure history does not preclude toxicity.

Physical Examination

The physical examination should define focal or multifocal sites of hemorrhage and detect evidence of gross and subtle hemorrhage. Funduscopic examination and careful inspection of mucous membranes and non-haired skin may reveal petechiae and ecchymoses, suggestive of platelet or von Willebrand factor defects or vasculopathies. Large vessel (arterial/venous) injury typically causes obvious blood loss from localized sites of vessel injury. Animals with severe coagulopathies may develop spontaneous hemorrhage into any body cavity or potential space, producing effusion, mass effect, or hematoma formation. Simultaneous hemorrhage from several sites, including prolonged hemorrhage from venipuncture or catheter sites, is evidence of severe coagulopathy. The possibility of an acquired coagulopathy should be included in the differential for any patient with unexplained hemorrhage, effusion or mass lesion, or disease conditions associated with factor deficiencies (see Table 89.1). Routine coagulation screening of these cases will minimize delays in instituting appropriate management.

Quick Assessment and Point-of-Care Tests

The initial assessment of any patient suspected of having a hemostatic defect should include platelet count or platelet estimate (see Chapter 78) and a point-of-care coagulation test. Point-of-care instruments are now available to perform clotting time tests in dogs and cats using whole blood samples. A clinical study of coagulopathies in dogs found similar diagnostic utility comparing results of laboratory and point-of-care coagulation panels.[35] These instruments have largely replaced the activated clotting time for rapid detection of moderate to severe factor deficiencies. Viscoelastic monitors provide a global assessment of hemostasis that incorporates the contribution of cellular elements and procoagulant and anticoagulant plasma proteins (see Chapter 88).[11] The thromboelastography (TEG) analyzer is the viscoelastic instrument used most widely to study coagulopathies in dogs.[27,37] This instrument provides a visual tracing and numeric parameters reflecting the rate and strength of fibrin formation. Clinically significant coagulopathies are expected to cause prolonged initiation times and diminished tracing amplitude. Evidence of hypocoagulability, in either simple or sophisticated point-of-care tests, may require follow-up with specific coagulation panel assays (and possibly more detailed factor and anticoagulant assays) for definitive diagnosis of acquired coagulopathies.[11]

Coagulation Panel

The screening tests to detect coagulopathies include activated partial thromboplastin time (aPTT), PT, thrombin clotting time (TCT), and fibrinogen concentration (see Chapter 88). The pattern of abnormalities in these screening tests reflects the deficient factor or factors (Figure 89.2).

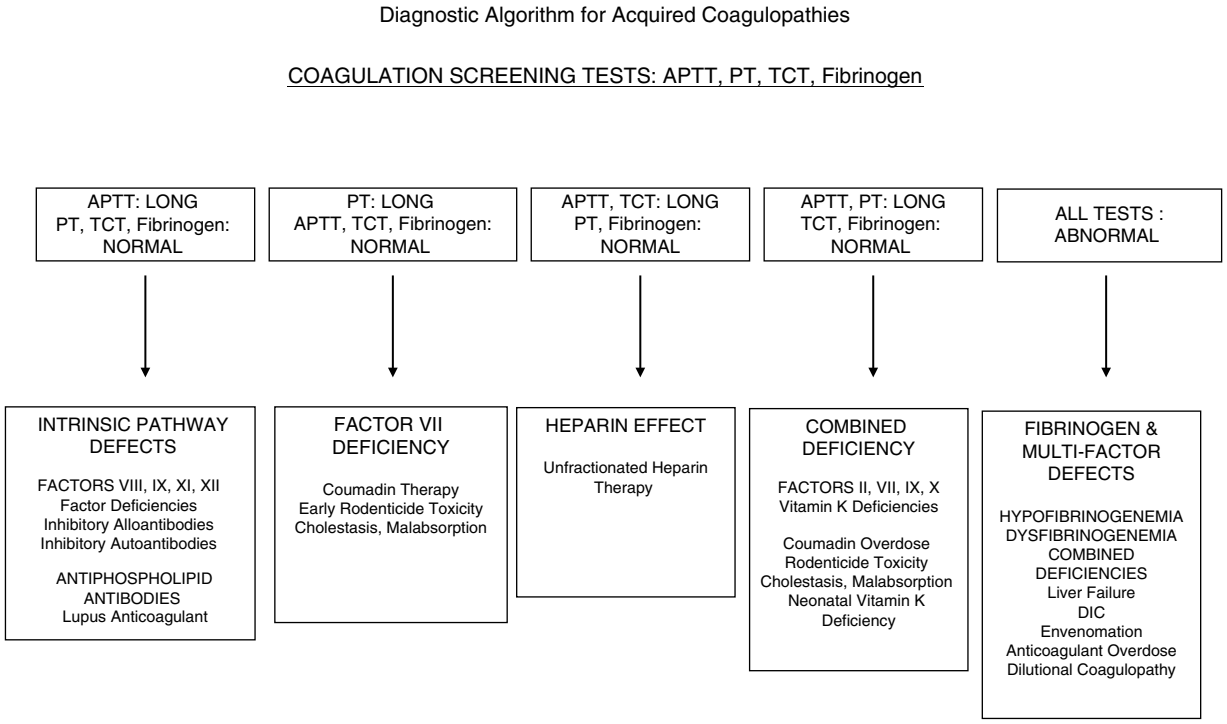

FIGURE 89.2 Coagulation screening test algorithm for acquired coagulopathies.

Coagulation panel results, combined with clinical presentation, are often sufficient for management of acquired coagulopathies. Complex cases may require specific analyses of individual coagulation factors, anticoagulant proteins, drugs, or measures of fibrinolysis to better define pathogenesis or facilitate case management. Collection of pretreatment samples of citrated plasma is critical for timely and accurate diagnosis of coagulopathies, and clinicians must bear in mind that the validity of all hemostasis testing depends on appropriate sampling techniques (see Chapter 88).

SPECIFIC DISORDERS

Liver Disease

Animals with hepatobiliary disease demonstrate variable signs of coagulopathy, ranging from spontaneous bleeding to subclinical prolongation of in vitro clotting times.[3,20,33,16] Liver disease causes major alterations in many hemostatic mechanisms, including platelet and endothelial cell reactivity, procoagulant and anticoagulant protein production and function, dysregulation of fibrinolysis, and complications arising from portal hypertension and splenomegaly. These changes often act as opposing procoagulant and anticoagulant forces, resulting in variable net bleeding risk (rebalanced hemostasis). Clinically severe hemorrhage is seen primarily in animals with fulminant or end-stage hepatic failure, or those with concomitant DIC. Other forms of liver disease may cause relatively milder bleeding tendencies, albeit sufficient to impair surgical hemostasis for animals undergoing biopsy or hepatobiliary surgery.

Marked prolongation of coagulation screening tests (aPTT, PT, TCT) and hypofibrinogenemia indicate high risk of spontaneous and postsurgical hemorrhage, and are overall poor prognostic signs. Mild prolongation or the absence of abnormal clotting times, however, does not rule out the risk of procedure-related bleeding. Newer hemostasis tests, such as endogenous thrombin potential and thromboelastography, are designed to assess net procoagulant and anticoagulant forces. Thromboelastography has demonstrated hyperfibrinolysis in dogs with both acute and chronic hepatic disease. In dogs with acute hepatic impairment, hyperfibrinolysis becomes more pronounced with disease severity.[16,9] The utility of these tests for predicting bleeding risk in patients with liver disease is under clinical investigation.[11] A preliminary study has shown that measurement of protein C activity may be useful as a biomarker of liver function and hepatoportal blood flow in dogs.[33] The finding of low protein C activity helps differentiate portosystemic vascular anomalies from microvascular dysplasia, and is a useful predictor of clinical outcome when combined with traditional biochemical assays.

Management strategies for coagulopathy of liver disease include prophylactic and "rescue" therapies. Prophylactic administration of vitamin K_1 is often included with specific and supportive medical therapy for liver disease. Preoperative vitamin K_1 administration is indicated for animals with cholestatic disorders and/or prolonged aPTT and PT (see Chapter 94). Current trends in human medicine favor

more restrictive use of prophylactic transfusion therapy.[2] Fresh frozen plasma is transfused to patients with liver failure and signs of hemorrhage to supply active procoagulant and anticoagulant factors (see Chapters 94 and 100). The need for preoperative transfusion is generally assessed on an individual patient basis in human and veterinary medicine. People undergoing liver transplantation invariably require transfusion and algorithms based on thromboelastographic parameters have been developed to guide the use of blood components in this patient population.[11]

Vitamin K Deficiency

Vitamin K deficiency is a common cause of coagulopathy, resulting from inadequate intestinal absorption or impaired intrahepatic recycling.[3,20,7,22] Biliary obstruction, intrahepatic cholestasis, chronic oral antibiotic administration, and infiltrative bowel disease may all reduce vitamin K absorption. Hemorrhagic disease of the newborn refers to vitamin K deficiency in infants within the first few days to weeks of life. Hemorrhage is attributed to inadequate placental transfer of vitamin K and inadequate hepatic recycling.[17] Coumadin (warfarin) and second-generation anticoagulant rodenticides (e.g., brodifacoum) act by irreversibly blocking the activity of epoxide reductase, the critical hepatic vitamin K recycling enzyme (see Figure 89.1). Severe coagulopathies due to anticoagulant rodenticide toxicity are commonly encountered in small animal practice, have been reported in equine practice, and are increasingly recognized in wild birds (see Chapter 95). Factor deficiency and resultant signs of a bleeding diathesis develop over a period of several days post ingestion of anticoagulant poisons as vitamin K stores become depleted. Signs of hemorrhage may be obvious as external blood loss, or may be nonspecific as pleural or abdominal effusion or mass lesions anywhere in the body due to hematoma formation. Treatment delays often lead to death from hemorrhagic shock, or respiratory or central nervous system compromise.

Prolongation of both the aPTT and PT screening tests, with normal TCT and fibrinogen, are the hallmarks of hemorrhage caused by severe vitamin K deficiency (Figure 89.2). Specific factor analyses reveal that deficiencies of factors II, VII, IX, and X cause this characteristic coagulation profile. Therapeutic dosages of the anticoagulant coumadin, while no longer recommended as a first-line anticoagulant, cause only mild deficiencies of the vitamin-K-dependent factors that should not cause prolongation of the aPTT. Coumadin monitoring to ensure adequate, but not excessive dosage, is based on PT analyses (see Chapter 94). In human medicine, the international normalization ratio (INR) is used to account for variability in PT reference ranges among testing laboratories. An INR target value between 2 and 3 indicates appropriate anticoagulant intensity for many human thrombotic disorders.

Management of vitamin K deficiency requires replacement therapy with vitamin K_1 (phytonadione), rather than vitamin K_3 (menadione). Vitamin K therapy is often given empirically pending results of pretreatment coagulation assays, because synthesis of sufficient active factors to correct the coagulopathy requires at least 12 hours from the start time of initiating vitamin K supplementation. Transfusion is also indicated for patients with severe signs at presentation (see Chapter 100).

Disseminated Intravascular Coagulation

Microvascular thrombosis is the characteristic feature of DIC; however, signs of a severe bleeding diathesis dominate some case presentations. Dogs with DIC secondary to neoplasia, sepsis, or heatstroke may develop consumptive coagulopathies, with coagulation factor and fibrinogen depletion, and concomitant increase in FDP and D-dimer (see Chapter 92). Hemorrhagic, overt DIC is often transfusion-resistant, requiring high-volume plasma replacement to sustain hemostasis (see Chapter 100).

Dilutional Coagulopathy and Traumatic Coagulopathy

The term dilutional coagulopathy describes a hemostatic defect that develops after high-volume fluid resuscitation. Acute traumatic coagulopathy secondary to shock and hypoperfusion occurs in up to one of four human trauma patients and is considered a negative prognostic indicator in people with severe trauma. Concomitant acidemia, hyperfibrinolysis, and hypothermia further exacerbate coagulopathy in these patients. Administration of high-volume fluid therapy exacerbates traumatic coagulopathy. The effect of crystalloids versus colloids in promoting a dilutional coagulopathy has been extensively studied, with colloids demonstrating a greater dilutional effect than crystalloids and a negative effect on clot stability.[24] Clinical studies in people also reveal that fibrinogen deficiency generally develops early in the course of hemodilution and signs of inadequate hemostasis manifest at fibrinogen concentration below 50–100 mg/dL (0.5–1.0 g/L).[30] A retrospective study of massive transfusion in dogs noted prolonged aPTT and PT in half the cases.[15] Correction of hemostatic abnormalities is associated with improved survival in people, and factor replacement in the form of fresh frozen plasma is typically administered after recognition of coagulopathy.[13]

Coagulation Inhibitors

Factor Inhibitory Antibodies

Pathologic antibodies that bind to and inhibit coagulation factor activity cause clinical signs of hemorrhage. Antibodies targeting factor VIII are a well-recognized complication of factor replacement therapy for people with hemophilia A, and factor IX inhibitory antibodies occasionally develop in hemophilia B patients. Patients with severe factor deficiency (i.e., ≤1% factor activity) are at highest risk for inhibitor development.[28] Case reports have described factor VIII or IX inhibitor formation in

dogs with hemophilia A or B, respectively.[26,1] Clinical signs of coagulopathy due to factor inhibitory antibodies also occur as an autoimmune phenomenon, with factor VIII the most commonly reported target antigen.[14] Underlying conditions associated with acquired factor VIII inhibitor development in people include systemic lupus erythematosus, rheumatoid arthritis, drug hypersensitivity, inflammatory bowel disease, malignancy, and the postpartum state. Although apparently rare in animals, an acquired coagulopathy due to factor VIII inhibitors has been described in a Thoroughbred mare.[38] Factor VIII inhibitors (alloantibodies and autoantibodies) often cause severe coagulopathies characterized by spontaneous hemorrhage refractory to standard replacement therapy.

Factor VIII or IX inhibitors are detected by specific prolongation of the aPTT that is not corrected by mixing patient plasma with normal plasma. The Bethesda unit (BU) assay is used to quantify the titer of inhibitory antibodies. Values below 5 BU/mL are considered low titers.[28,29] Active bleeding in patients with low BU titers often responds to transfusion of high-dose factor replacement therapy. Long-term management of high-titer factor inhibitors consists of specific therapy of underlying disorders (for autoantibody patients) and immune-modulating or immunosuppressive therapy.[29]

Antiphospholipid Syndrome Inhibitors

The antiphospholipid syndrome (APS) is recognized as a thrombotic risk factor in people. The syndrome typically develops in patients with autoimmune disorders and is characterized by the production of APLAs that prolong in vitro clotting time.[21] Long aPTT that fails to correct in a mixing study is compatible with the presence of APLA, and more specialized clotting time tests (e.g., dilute Russell's viper venom time) and quantitative immunoassays to detect antibodies directed against lipid-binding proteins are used as confirmatory assays.[10] Inhibitory antibodies were proposed as the cause of long clotting times in a case report of canine immune-mediated hemolytic anemia (IMHA) and thrombosis; however, the prevalence and clinical relevance of APLA and APS in animals are not well-defined.[32]

Anticoagulant Overdose

Thrombotic syndromes and indications for antithrombotic therapy are increasingly recognized in veterinary medicine (see Chapters 91 and 94). The growing use of anticoagulant therapy raises the possibility of iatrogenic coagulopathy due to drug overdose. Unfractionated heparin remains a widely used anticoagulant. The pharmacokinetic profile of UFH is complex due to its extensive protein and cell-binding and dose-dependent half-life (see Chapter 94).[6,23,36] Since hemorrhage is a major risk of high-dose UFH therapy, individual patient monitoring is required to prevent excessive anticoagulant effect. The aPTT is the most readily available coagulation screening test sensitive to therapeutic UFH levels. Adjustment of UFH dose to prolong aPTT to 1.5–2 times pretreatment values is the traditional method for guiding UFH therapy to prevent overdosage. Clinical signs of hemorrhage or marked prolongation of aPTT (i.e., >2.5 times baseline) are indications for discontinuing UFH therapy. Due to its short (2–3 hour) plasma half-life, hemorrhage is usually transient. People with major hemorrhage due to UFH overdosage are infused with protamine sulfate, a basic polypeptide that binds tightly to UFH and immediately neutralizes its anticoagulant activity.[36] Protamine administration causes systemic hypotension in dogs; therefore, transfusion therapy is used to control life-threatening hemorrhage caused by excessive UFH anticoagulant effect (see Chapter 100).

Newer anticoagulants do not consistently prolong clotting time tests at therapeutic levels. Laboratory assays that specifically detect anticoagulant inhibition of activated factor X (anti-Xa assays) are suitable, however, to monitor low-molecular-weight heparins, UFH, and the DOACs targeting factor Xa (e.g., rivaroxaban, apixaban). Dosing guidelines and appropriate anti-Xa target ranges for the various drugs are not yet established, but are undergoing investigation for a variety of thrombotic syndromes (see Chapter 94).

ACT, activated clotting time; aPTT, activated partial thromboplastin time; coagulation factors: FII, factor II; FVII, factor VII; FVIII, factor VIII; FIX, factor IX; FX, factor X; FXI, factor XI; FXII, factor XII; FXIII, factor XIII; DIC, disseminated intravascular coagulation; DSH, domestic shorthair; HMWK, high-molecular-weight kininogen; PIVKA, proteins induced by vitamin K absence/antagonism; OMIA, Online Mendelian Inheritance in Animals; OMIM, Online Mendelian Inheritance in Man; PK, prekallikrein; PT, prothrombin time; PTA, plasma thromboplastin antecedent; RVVT, Russell's viper venom time; SINE, short interspersed nuclear element; TCT, thrombin clotting time; VKOR, vitamin K epoxide reductase.

HEREDITARY COAGULATION FACTOR DEFICIENCIES

Hereditary coagulopathies arise from mutations within genes required for synthesis or processing of active coagulation factors. The bleeding tendency associated with each trait depends on the physiologic role of the deficient factors in fibrin clot formation and the degree of factor deficiency. Hemophilia A is the most common hereditary coagulopathy in human beings and animals, due in part to a high de novo mutation rate in the coagulation FVIII gene (*F8*).[2,13] New factor deficiencies, however, can arise within any breed population and breed frequencies of known defects may vary over time. The general breeding strategies to limit propagation of hereditary factor defects include exclusion of individuals expressing a bleeding tendency, avoidance of repeat matings that produce affected individuals, and familial screening (especially dams, sires, siblings) of affected patients to identify others with quantitative or functional factor deficiencies. In addition to the review of defects presented in this chapter (Table 90.1), public access databases, such as Online Mendelian Inheritance in Man and Online Mendelian Inheritance in Animals (OMIM, OMIA), provide information on hereditary factor deficiencies in animals. The PennGen website provides an online searchable database of veterinary genetic testing laboratories that offer diagnostic tests to identify hereditary defects, including bleeding disorders, in domestic dogs and cats.

X-LINKED FACTOR DEFICIENCIES: HEMOPHILIA A AND B

Hemophilia A (OMIM 306700) and hemophilia B (OMIM 306900) are distinct X-linked bleeding disorders caused by functional or quantitative deficiencies of FVIII and

TABLE 90.1 Hereditary factor deficiencies.

Factor deficiency	Coagulation screening test results		Species (breeds)
	Abnormal	Normal	
Fibrinogen	TCT,[a] fibrinogen,[a] all tests[b]	aPTT,[a] PT[a]	Dogs (Bichon Frise, Borzoi, Collie), cats (DSH), goat (Saanen), sheep (Leicester)
Factor II (prothrombin)	aPTT, PT	TCT, fibrinogen	Boxer
Factor VII (proconvertin)	PT	aPTT, TCT, fibrinogen	Dogs (Alaskan Klee Kai, Beagle, Deerhound, Malamute, Schnauzer), cats (DSH)
Factor VIII (hemophilia A)	aPTT	PT, TCT, fibrinogen	Dogs (any breed, mixed breeds, German Shepherd, Golden Retriever), cats (any breed, DSH), horse (any breed), sheep
Factor IX (hemophilia B)	aPTT	PT, TCT, fibrinogen	Dogs (any breed, mixed breeds), cats (any breed, DSH), horse
Factor X (Stuart–Prower factor)	aPTT, PT	TCT, fibrinogen	Dogs (Cocker Spaniel, Jack Russell Terrier), cats (DSH)
Factor XI (plasma thromboplastin antecedent (PTA) deficiency, hemophilia C)	aPTT	PT, TCT, fibrinogen	Dogs (English Springer Spaniel, Kerry Blue Terrier), cats (DSH, Maine coon)
Factor XII (Hageman factor)	aPTT	PT, TCT, fibrinogen	Dogs (Miniature Poodle, Shar Pei), Cats (DSH, DLH, Himalayan, Maine Coon, Siamese)
Contact pathway (prekallikrein) deficiency	aPTT	PT, TCT, fibrinogen	Dogs (German Shorthaired Pointer, Husky, others)
Combined vitamin-K-dependent factor deficiency (factors II, VII, IX, X)	aPTT, PT	TCT, fibrinogen	Dogs: Labrador Retriever Cats: Devon Rex

[a] Mild fibrinogen deficiency;
[b] Severe fibrinogen deficiency.
aPTT = activated partial thromboplastin time; PT = prothrombin time; TCT = thrombin clotting time.

FIX, respectively.[13] Although both genes (*F8* and *F9*) map to the long arm of the X chromosome, they are inherited independently. FIX (a serine protease enzyme) and FVIII (its coenzyme) play critical roles in the amplification phase of coagulation by participating in formation of the "tenase" enzyme complex (see Chapter 87).

Clinical Diagnosis of Hemophilia

Hemophilia A and B are diagnosed almost exclusively in males because of the sex-linked, recessive inheritance and expression pattern of these traits. Carrier (heterozygous) females are not at risk for abnormal bleeding due to the presence of one functional *F8* or *F9* allele. Signs of hemophilia include lameness due to hemarthrosis, intramuscular and subcutaneous hematoma formation, and prolonged hemorrhage from even minor wounds and from gingiva at tooth eruption sites (Figure 90.1). Severe hemophilia typically manifests within the first few months of life. Severely affected patients are at risk for spontaneous and fatal hemorrhage, whereas milder forms of hemophilia may become apparent only after surgery or trauma.

Hemophilia A is much more common than hemophilia B in all species, with an incidence of one to two cases per 10,000 male births (in human populations). Unlike many hereditary diseases in animals, hemophilia is not restricted to a single breed or inbred line. Cases of hemophilia A and B have been identified in mixed breed dogs and more than 50 different purebred lines.[2,3,5] Both traits have been reported in domestic and purebred cats[4,11,16] and horses,[6,27] and hemophilia A has been characterized in sheep.[1]

The laboratory diagnosis of hemophilia is based on results of coagulation assays. Both forms of hemophilia cause specific prolongation of intrinsic pathway screening tests (activated clotting time [ACT] and activated partial thromboplastin time [aPTT]), but do not affect tests of the extrinsic/common pathways or fibrinogen (see Table 90.1). Definitive diagnosis and

FIGURE 90.1 Clinical signs of hemophilia. Left: Intramuscular hematoma formation in the lateral thigh muscles of a German Shepherd with hemophilia B. Note distal limb swelling due to edema, venous obstruction, and extravasated blood. Right: Subcutaneous hematoma overlying the frontoparietal muscles of a mixed-breed puppy with hemophilia A.

differentiation of hemophilia A from hemophilia B requires specific measurements of FVIII and FIX coagulant activities (FVIII:C, FIX:C). Clinical severity generally relates to residual factor activity. In human medicine, severe hemophilia is characterized by FVIII:C or FIX:C < 2% of normal, whereas factor activities of 2–20% are associated with moderate to mild hemophilia. Factor assay values are derived from comparisons of patient plasma with the activity of plasma standards. Reaction kinetics of coagulation enzymes vary among species; therefore, animal factor activity assays are best performed using same-species plasma standards (see Chapter 88).

Treatment of Hemophilia

Transfusion is the primary means for controlling or preventing hemorrhage in animals affected with hemophilia A or B (see Chapter 94 and Section VIII). Fresh frozen plasma supplies both FVIII and FIX, whereas cryoprecipitate is a more specific product for replacement of FVIII, and cryosupernatant supplies FIX.[28] The transfusion interval for hemophiliacs varies depending on residual factor activity, and clinical features such as patient size, activity, the nature of hemostatic insult, and other factors influencing hemostasis. Maintenance of patients with severe hemophilia (<2% FVIII:C, FIX:C) can be difficult due to recurrent hemorrhage and short transfusion intervals. The most severely affected animals may be euthanized due to poor quality of life, or experience fatal bleeds before 1 year of age. Gene transfer therapy using adeno-associated viral vectors has been successful in correcting the bleeding tendency of dogs with hemophilia A and B, with sustained duration of factor expression in some cases for more than 1 year.[7,26] Inhibitory antibody formation and immune response directed against the viral vector were observed complications, and the cost and complexity of current gene transfer therapies limit its availability to research settings.

Genetics

New cases of hemophilia arise from frequent de novo mutations in *F8* and *F9*. Once present, these mutations are typically transmitted by asymptomatic carrier dams; however, males with mild forms of hemophilia may survive to adulthood and widely propagate the trait if they are bred (Figure 90.2). Males are accurately diagnosed as affected or clear of hemophilia based solely on FVIII and FIX assays. Obligate carrier females are then identified by pedigree review as the dams and daughters of the affected males. The status of suspect carrier females is difficult to classify with factor assays, however, because values overlap for carrier and clear females at the low end of the normal range. Pedigree review and preliminary molecular genetic analyses of hemophilia indicate that unique *F8* or *F9* mutations are likely causative for hemophilia in different breeds and families.[2,3,7,9,21,26] Distinct *F9* mutations have been identified in each unique breed variant of canine and feline hemophilia B. The discovery of hemophilia A causative mutations is more challenging because of *F8*'s large size and complex organization. Mutation detection through targeted gene sequencing, however, has been successful in identifying unique mutations in several breeds, including distinct point mutations in a Boxer, a German Shepherd, and a mixed-breed dog, and a complex inversion in a research colony derived from an Irish Setter.[7,9,21] Although direct mutation detection is the most accurate means of hemophilia carrier detection, this strategy requires knowledge of the causative mutation within each family. An alternate, indirect strategy applicable to

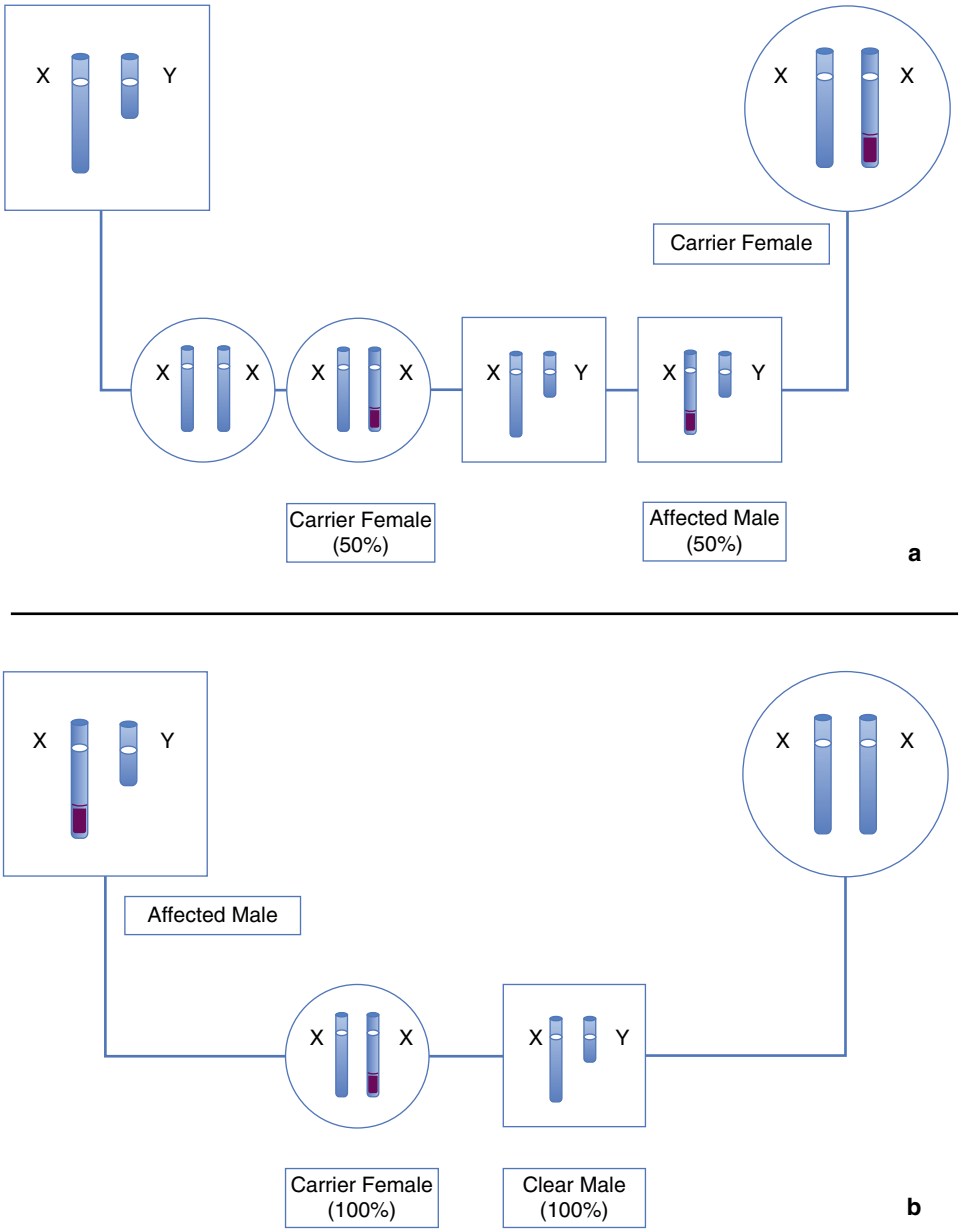

FIGURE 90.2 Inheritance of hemophilia A and B. (a) Propagation of hemophilia by a carrier female. If a carrier female is bred, on average one-half of her daughters and one-half of her sons will inherit her mutant gene (depicted as a purple bar on the X chromosome); (b) Propagation of hemophilia by an affected male. Males with mild forms of hemophilia may survive to reproduce. If bred, they transmit a mutation to all their daughters and none of their sons.

any family is based on utilizing DNA markers linked to *F8*. This strategy has proven feasible for hemophilia A carrier detection in sheep and dogs.[1,5]

AUTOSOMAL FACTOR DEFICIENCIES

All of the remaining factor deficiencies identified in animals (fibrinogen, FII, VII, X, XI, contact pathway, and combined factor defects) are less common than hemophilia, and are typically restricted to a few breeds or families (Table 90.1). These autosomal defects are typically recessive traits. In this form of inheritance, males and females express and transmit the traits with equal frequencies, affected individuals are homozygous for the disease-causing mutation, and heterozygous carriers do not express a bleeding tendency (Figure 90.3).

Fibrinogen Deficiency

Fibrinogen is the plasma precursor of fibrin and also supports intraplatelet bridging in the process of aggregation. Fibrinogen consists of three polypeptide chains (A-α, B-β, and γ), coded for by three closely linked genes. Mutations in any of these genes can impair fibrinogen function or secretion.

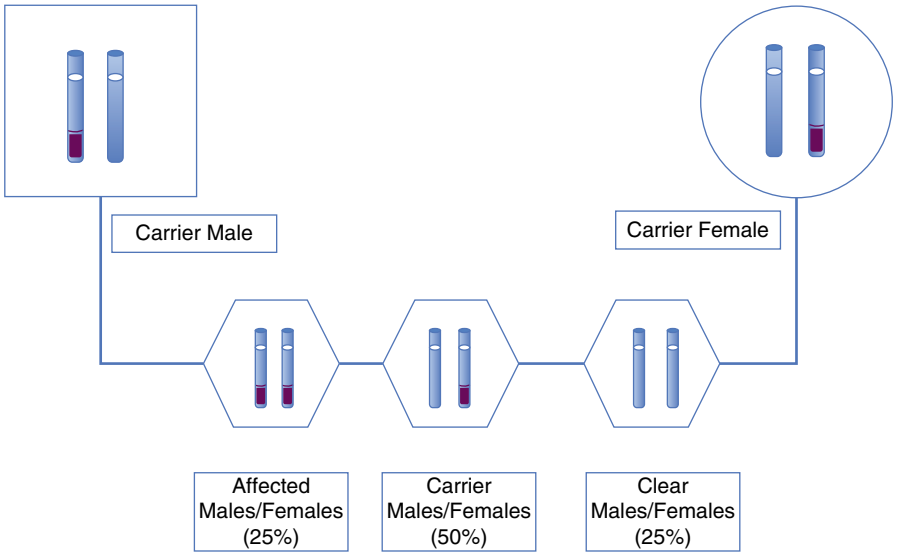

FIGURE 90.3 Inheritance of autosomal recessive factor deficiencies. Mutant genes (depicted as purple bars on an autosome) are transmitted from dam and sire to male and female offspring with equal frequencies. On average, one-quarter of the offspring will be homozygous (affected with the defect), one-half of the offspring will be asymptomatic heterozygous carriers, and one-quarter of offspring will inherit no mutant gene and therefore be clear of the trait.

Many distinct hereditary fibrinogen defects have been identified in people, broadly classified as quantitative deficiencies (i.e., afibrinogenemia and hypofibrinogenemia) and functional defects (dysfibrinogenemia and hypodysfibrinogenemia) (OMIM 202400). Afibrinogenemia is rare and causes a severe bleeding diathesis. Signs of dysfibrinogenemias are variable, ranging from severe hemorrhage to thrombosis. Hereditary fibrinogen defects have been identified in several breeds of dogs, and in cats, goats, and sheep (Table 90.1).[12,33] Reported manifestations include severe, spontaneous hemorrhage and hemarthrosis. Milder forms are characterized primarily by post-traumatic and postsurgical hemorrhage.

Fibrinogen deficiency affects formation of a fibrin clot endpoint in all clotting time tests (Table 90.1). The thrombin clotting time (TCT) is the most sensitive of these screening tests to detect mild fibrinogen deficiencies. A combination of functional (clottable) fibrinogen assays and quantitative methods, such as ELISA, is required for definitive diagnosis of hypofibrinogenemia/dysfibrinogenemia and afibrinogenemia (see Chapter 88).

Hereditary fibrinogen defects are much less common than acquired hypofibrinogemia, which often develops secondary to hepatic synthetic failure or consumption in a disseminated intravascular coagulation (DIC) process (see Chapters 89 and 92). Unlike acquired disorders, hereditary fibrinogen deficiencies are rarely associated with concomitant thrombocytopenia, or deficiencies of other coagulation factors. The absence of clinical and laboratory signs of hepatic failure or DIC further aids in differentiating hereditary from acquired fibrinogen defects.

Cryoprecipitate is the treatment of choice for fibrinogen defects, as it supplies high-concentration fibrinogen in low-volume transfusion. Fresh frozen plasma is an alternate component (see Chapter 100). Transfusion is indicated for patients with active hemorrhage, or for preoperative prophylaxis. The human dosage recommendation is transfusion to a target of 50–100 mg/dL fibrinogen.[28] Fibrinogen's half-life of 2–4 days is relatively long compared with most factors; thus, fewer transfusions at longer intervals are often sufficient to support hemostasis.

Fibrinogen defects in people are mutationally heterogeneous and display autosomal dominant and recessive inheritance patterns. Afibrinogenemia is usually a recessive trait caused by mutations in the fibrinogen A-α chain. Hypofibrinogenemias/dysfibrinogenemias have been described in patients with mutations in all three fibrinogen genes. With pending pedigree studies and molecular analyses, it is likely that animals will display the same variety of disease gene, mutation location, and mutation type found in human patients.

Prothrombin Deficiency

Hereditary FII (prothrombin) deficiency is uncommon, with fewer than 100 cases reported in human beings and isolated cases in a few breeds of dog (OMIM 176930).[12] Prothrombin is the zymogen of thrombin, the serine protease factor that transforms fibrinogen to fibrin. Thrombin also plays a central role in platelet activation, inflammation, and wound healing. Knockout mice lacking the prothrombin gene are nonviable and all naturally occurring human (and animal) cases have some residual thrombin activity.

Clinical signs of hemarthrosis and post-traumatic hemorrhage are generally seen in patients with residual thrombin activities below 10% of normal. Prothrombin deficiency causes prolongation of the aPTT and prothrombin time (PT) (and proteins induced by vitamin K

absence/antagonism [PIVKA]) screening tests, but does not affect the TCT or fibrinogen assay (Table 90.1). Differential diagnoses for this pattern of screening test abnormalities include deficiency of a single common pathway factor (i.e., FII, FV, FX) and combined deficiency of all vitamin-K-dependent factors (FII, FVII, FIX, FX). The finding of specific deficiency of FII coagulant activity (FII:C), with normal activity of the other factors, provides definitive diagnosis of prothrombin deficiency (see Chapter 88).

Fresh frozen plasma and plasma cryosupernatant supply FII. The half-life of FII is approximately 3 days, and transfusion to attain target FII:C of 20–40% is the recommended human guideline.[28]

The expression of FII deficiency in people is autosomal recessive; affected patients are homozygous with residual FII:C ranging from 2% to 20%. Heterozygotes have FII:C of approximately 50% and are clinically asymptomatic. Although new mutations could arise, FII deficiency is uncommon and rarely recognized in any breed at this time.

Factor VII Deficiency

Trace amounts of activated FVII (FVIIa) bind to membrane-bound tissue factor at sites of vascular injury. This FVIIa/tissue factor complex plays a central role in the initiation phase of coagulation. Hereditary FVII deficiency is often associated with a clinically mild or inapparent bleeding diathesis, suggesting that sufficient residual FVII remains for active complex assembly. The trait has been identified in people and several different breeds of dogs (OMIM 227500).[8,18]

Canine FVII deficiency is best characterized in Beagles.[8] Factor-VII-deficient Beagles rarely experience abnormal bleeding, even after surgery or trauma. By contrast, FVII deficiency in Malamutes is typically associated with more severe signs including hematoma formation, prolonged post-traumatic bleeding, and fatal hemorrhage.[2] Clinical severity may vary among individuals within a single breed. The index case of FVII deficiency in Alaskan Klee Kai experienced prolonged post-traumatic hemorrhage, whereas other related FVII-deficient dogs had undergone major surgery with no complications.[18]

Factor VII deficiency causes an isolated prolongation of the PT (and PIVKA) screening tests, with normal aPTT, TCT, and fibrinogen (Table 90.1). Hereditary FVII deficiency is differentiated from vitamin-K-dependent coagulopathies as a single factor, rather than a combined multifactor defect. In most canine and human kindreds, FVII-deficient patients have some residual FVII activity with FVII coagulant activity (FVII:C) generally ranging from 1% to 10% of normal. More detailed laboratory characterization of residual FVII includes measurement of FVII antigen and levels of circulating FVIIa (see Chapter 88).

Most FVII-deficient patients are transfusion-independent; however, those with severe forms can be transfused with fresh frozen plasma or cryosupernatant to supply FVII. Factor VII has a short plasma half-life of approximately 3–4 hours; therefore, transfusion intervals of 8–12 hours may be needed to sustain hemostasis after initial stabilization (see Chapter 100).

Factor VII deficiency is a recessive trait. A missense mutation in exon 5 of *F7* was first identified in FVII-deficient Beagles, and subsequently found to cause FVII deficiency in Alaskan Klee Kai and Deerhounds.[8,18] Heterozygous carriers of the mutation generally have FVII:C values intermediate between affected and clear dogs. Direct mutation detection is preferable for carrier detection because factor activities overlap between carrier and clear individuals. Mutations causative for FVII deficiency in other breeds or species have not yet been identified.

Factor X Deficiency

Factor X and its cofactor, FV, play a central role in generating thrombin. The factors assemble on cell membrane surfaces to form the prothrombinase complex, which rapidly converts prothrombin to the active enzyme, thrombin (see Chapter 87).

An absolute lack of FX is an apparently lethal trait; however, partial FX deficiency has been identified in human beings, dogs, and a domestic shorthair (DSH) cat (Table 90.1; OMIM 227600).[2,10,15] The defect is a relatively severe bleeding diathesis in these species, with signs of spontaneous epistaxis, hematoma formation, and severe hemorrhage post-trauma or surgery.

Factor X deficiency causes prolongation of the aPTT, PT, PIVKA, and Russell's viper venom time (RVVT) screening tests; however, TCT and fibrinogen are normal (see Chapter 88). Clotting time in the RVVT is initiated by direct activation of FX, independent of the intrinsic or extrinsic pathways. The differentials for this pattern of abnormalities include vitamin-K-dependent coagulopathy, and isolated deficiencies of FX, FV, or FII. Definitive diagnosis is based on the specific finding of low FX coagulant activity (FX:C). Acquired FX deficiency has been reported in people with systemic amyloidosis, attributed to adsorption of FX onto amyloid fibrils. This phenomenon has not been documented in animals.

Plasma products for replacement of Factor X include fresh frozen plasma and cryosupernatant (see Chapter 100). After initial control of active hemorrhage, subsequent transfusions can be given at relatively long (q12–24 hours) interval due to the long half-life of FX of 40 hours.

Missense and nonsense mutations are the most common mutation types causing human FX deficiency; however, specific FX mutations have not yet been discovered in animals. The trait demonstrates a recessive inheritance pattern in people and animals. Familial testing in dogs and cats revealed severe deficiency (FX:C < 10%) in clinically affected patients and moderate factor deficiencies (20–50% FX:C) in obligate carrier parents.

Factor XI Deficiency

Thrombin activates FXI to form FXIa in the early initiation phase of coagulation. This reaction takes place most efficiently on the surface of activated platelets,

where FXIa then generates FIXa and promotes assembly of the tenase coagulation complex (see Chapter 87).

Factor XI deficiency has been identified in people, dogs, cattle, and cats (Table 90.1; OMIM 264900).[12,20,23,31] The defect is clinically variable in all species, but typically causes a mild bleeding tendency. Spontaneous hemorrhage is rare and affected patients are often diagnosed because of prolonged hemorrhage or abnormal rebleeding after surgery or trauma. Clinical severity does not correlate as closely with residual factor activity as most other factor deficiencies; however, clinical expression of a bleeding tendency is more likely to occur in patients with FXI activities (FXI:C) below 30% of normal.

Factor XI deficiency causes specific prolongation of the aPTT, with normal PT, TCT, and fibrinogen (Table 90.1). Hemophilia A and B cause the same screening test abnormalities; however, specific coagulation factor analyses define isolated FXI deficiency (see Chapter 88).

Transfusion of fresh frozen plasma and cryosupernatant will supply FXI (see Chapter 100). Transfusion is usually required only for surgical or post-traumatic hemostasis. After an initial preoperative or loading transfusion, FXI half-life of approximately 50 hours allows repeat transfusions to be given at 12–24-hour intervals. Although their use has not been reported in animals, antifibrinolytic agents and topical fibrin sealants have been used successfully in human FXI-deficient patients (see Chapter 94).

An exonic short interspersed nuclear element (SINE) insertion has been identified in FXI-deficient Kerry Blue Terriers and insertions in exons 3 and 9 have been described in FXI-deficient Holstein and Japanese cattle, respectively.[23,30] Homozygous cattle have marked FXI deficiency (FXI:C < 5%), whereas affected Kerry Blue Terriers and DSH cats had relatively moderate reduction with FXI:C of approximately 2–15%.

Factor XII and Contact Factor Deficiencies

The contact group of coagulation factors includes FXII, prekallikrein (PK; Fletcher factor), and high-molecular-weight kininogen (HMWK). Contact factors interact in vitro to initiate coagulation on artificial surfaces through activation of FXI. However, these factors are not required for fibrin clot formation in vivo and deficiency of these factors does not cause a bleeding diathesis (see Chapter 87). The physiologic activities of the contact group factors are now believed to include regulation of blood pressure, cellular proliferation, angiogenesis, and inflammation. Early reports of FXII deficiency in people suggested an increased risk of systemic thrombosis; however, subsequent studies have not confirmed this phenomenon.

In addition to human beings, deficiencies of the contact pathway factors have been identified in dogs, cats, and horses (Table 86.1; OMIM 234000,229000, 228960).[4,12,14,19,24,32] Factor XII deficiency, in particular, is a common factor deficiency found in DSH and purebred cats.[4,24]

Contact pathway deficiencies are characterized by markedly prolonged aPTT (often >120 seconds), with normal PT, TCT, and fibrinogen. A prolonged aPTT that shortens by increasing activation time is a common characteristic of PK-deficient plasmas. Specific deficiencies of the contact group factors can be diagnosed based on functional assays of FXII, PK, and HMWK (see Chapter 88). Due to its high prevalence, FXII deficiency should be considered a likely cause of specific prolongation of aPTT in cats. Deficiency of FXII and other contact pathway factors causes persistent prolongation of aPTT, but is not an indication for transfusion.

FXII and contact factor deficiencies are recessive traits. Cats homozygous for FXII deficiency have residual FXII:C values of approximately 2–10%, whereas heterozygous carriers generally have moderate reduction in activity with residual FXII:C from 20% to 40%.[17] The high prevalence of FXII deficiency in cats has recently been attributed to the presence of two distinct mutations segregating in domestic and purebred cats.[24]

Combined Deficiencies of the Vitamin-K-Dependent Factors

Factors II, VII, IX, and X are serine protease enzymes that require post-translational γ-carboxylation in order to form active complexes with their coenzymes and substrates. Defects in the hepatic vitamin K reductase or carboxylase enzymes impair vitamin K recycling and cause coagulopathy due to a persistent vitamin K deficiency state.

Familial combined deficiency of FII, VII, IX, and X is a rare recessive trait in people and has been identified in Devon Rex cats, sheep, and in Labrador Retrievers (Table 90.1; OMIM 277450 and 607473).[17,25,29] Clinical signs range from moderate to severe coagulopathy, with reports of spontaneous hematoma formation, prolonged hemorrhage after surgery, and some fatal hemorrhage.

Combined deficiency of the vitamin-K-dependent factors causes prolongation of the aPTT and PT (and PIVKA) screening tests, but does not affect TCT and fibrinogen. Specific coagulation factor assays confirm deficiencies of FII, VII, IX, X, with normal activities of the non-vitamin-K-dependent factors. Since acquired vitamin K deficiency is common (see Chapter 89), initial diagnostic workup should rule out exposure to vitamin K antagonists, liver disease, or malabsorptive disorders. After exclusion of acquired disorders, specific analyses of hepatic microsomal vitamin K epoxide reductase (VKOR) and carboxylase enzyme activities further define the biochemical basis of a hereditary trait.

Patients with severe hemorrhage at presentation may require transfusion for rapid replacement of active factors (see Chapter 100). After an initial lag time of 1–2 days, case reports describe normalization of aPTT and PT and control of clinical signs of hemorrhage in response to oral vitamin K_1 at approximately 2.5 mg/kg per day. Long-term maintenance of hemostasis has been reported at reduced daily dosages (e.g., 1 mg/kg/day) given at 3-day intervals.

Familial studies to date in all species reveal a recessive inheritance and expression pattern; however,

causative mutations in disease genes have not yet been identified.

Uncharacterized Factor Deficiencies

Hereditary deficiencies of FV, FXIII, and antiplasmin have been reported as rare hemorrhagic defects in people, with an estimated case incidence of <1 per million (OMIM 612309; 134570; 262850). The traits are autosomal recessive and cause clinically severe bleeding diatheses. Factor V deficiency causes prolongation of the aPTT and PT screening tests; however, identification of FXIII and antiplasmin deficiencies requires specific functional analyses of the corresponding proteins. While not yet recognized in animals, these defects should be included in the differential for severe hereditary coagulopathy after ruling out more common disorders.

A syndrome of prolonged and potentially life-threatening hemorrhage within 1–4 days of surgery has been described in racing Greyhounds. Anecdotal reports describe similar signs in other Sighthound breeds. To date, coagulation assays and screening tests of primary hemostasis have not revealed the underlying cause. Prophylactic treatment with antifibrinolytic agents was shown to significantly decrease prevalence of postoperative bleeding in a randomized treatment trial of Greyhounds undergoing elective surgery, suggesting that more in-depth evaluation of fibrinolytic pathways is warranted.[22] The relationship between expression of a bleeding diathesis and the vasculitic syndrome also found in Greyhounds also remains unknown (see Chapter 93).

INTRODUCTION

Thrombosis is the partial or complete obstruction of a blood vessel by a thrombus, or blood clot. Thromboembolism (TE) refers collectively to obstruction due to local thrombus formation (primary thrombosis) or translocation from a distant site (embolism). Thromboembolism contributes to morbidity and mortality through blood flow obstruction, release of humoral factors from thrombi causing end-organ damage, and ultimately multiple organ dysfunction syndrome (MODS). Signs of TE range from clinically inapparent events to organ failure and death, depending on the site and extent of vascular occlusion, the degree of collateral circulation, and the compensatory reserves of affected organs. Early recognition maximizes therapeutic options, since interventions such as thrombolysis are time-sensitive. This chapter and the treatment guidelines in Chapter 94 include recommendations published under the auspices of the American College of Veterinary Emergency and Critical Care.[66]

PATHOPHYSIOLOGY

Models of cell-based hemostasis (see Chapter 87) describe a complex interplay among cellular and plasma factors that participate in physiologic and pathologic thrombus formation. Platelets, endothelium, and coagulation proteases combined with newly recognized elements, such as neutrophil extracellular trap (NET) formation[73] and hypofibrinolysis, all contribute to TE.[185]

The three risk factors of Virchow's triad: endothelial damage and dysfunction, blood flow abnormalities, and hypercoagulability still underpin our understanding of pathologic thrombosis and identify at-risk patients.[33] A single factor may predominate (Table 91.1); however, multiple abnormalities often act synergistically to imbalance hemostasis and favor thrombus formation.

TABLE 91.1 Virchow's triad categorization.

Criterion	Example diseases or disorders
Vascular injury	Trauma
	Catheterization
	Inflammation
	Neoplastic invasion
	Parasitic damage
	Plaque deposition, atherosclerosis, amyloidosis
Stasis or turbulent flow	Hypoperfusion, hypovolemia, cardiac insufficiency, distributive
	Blood vessel compression
	Immobility
	Hyperviscosity, dehydration, polycythemia, leukemia, hyperglobulinemia, hyperfibrinogenemia
	Decreased RBC deformability, spherocytosis
Hypercoagulability	Platelet hyperaggregability, increased activation, decreased negative modulation
	Excessive activation of coagulation
	Decreased natural anticoagulant activity, AT deficiency, protein C deficiency, TFPI deficiency
	Hypofibrinolysis, decreased plasminogen activators, increased plasminogen activator inhibitors

Endothelial Dysfunction

Endothelial damage and dysfunction may promote thrombosis or reflect the consequences of TE. Healthy endothelium supports blood flow through maintenance of an anticoagulant surface, including release of vasodilators and platelet inhibitors, and by enhancing fibrinolysis.[93] The anticoagulant actions of endothelial cells include cell membrane expression of endothelial protein C receptor (EPCR) and thrombomodulin (TM) that localize anticoagulant reactions, and release of tissue factor pathway inhibitor (TFPI), a potent plasma anticoagulant.[93] Endothelial cells secrete vasoactive mediators including endothelin-1 (ET-1), nitric oxide (NO), and prostacyclin (PGI_2).[218,135] Endothelial cells also express CD39, a nucleoside triphosphate diphosphohydrolase, that hydrolyzes the nucleosides ADP and ATP, thereby reducing local concentrations of platelet and endothelial cell activators.[98] The endothelium modulates fibrinolysis though release of tissue plasminogen activator (tPA) and its specific serpin family inhibitor, plasminogen activator inhibitor-1 (PAI-1).

The endothelial surface is lined by the glycocalyx, a carbohydrate-rich matrix of proteoglycans and glycoproteins that protects the cell surface, repels negatively charged blood cells, and generates a boundary layer through adsorption of plasma proteins and water. This endothelial surface layer (ESL) is the mechanical transducer of the physical shear stress induced by blood flow, and is the site of action of the anticoagulant proteins antithrombin (AT), TM, and proteins C and S.[47] Damage to the glycocalyx and disruption of the ESL contribute to the pathology of sepsis, trauma, ischemia-reperfusion injury, and diabetes mellitus, and the prothrombotic nature of these conditions.[137,161,180,26] In disease processes such as sepsis and severe pancreatitis, high concentrations of proinflammatory cytokines such as IL-1 and IL-6 lead to expression of tissue factor (TF) on the surfaces of activated monocytes and endothelial cells. This intravascular TF expression promotes thrombin generation.[27] In addition, reduced venous wall shear stress stimulates endothelial cell release of P-selectin and von Willebrand factor (VWF), further promoting thrombus formation.[219]

Abnormal Blood Flow

Blood flow abnormalities include stasis, turbulent flow created by cardiac valve degeneration, congenital cardiac anomalies, indwelling vascular devices, and the flow microenvironments downstream of venous valves.[19] Disease processes characterized by blood flow abnormalities include shock, cardiac disease, vascular anomalies, hyperviscosity, and cancer.

Reduced venous blood flow and stasis reduce wall shear stress. These conditions modulate endothelial cell phenotype through alterations in shear-stress-responsive transcription factors resulting in an imbalance of prothrombotic and antithrombotic protein expressions.[216] Recirculation zones in dilated cardiac chambers and downstream from venous valves are often characterized by low shear conditions and long blood-dwell times that increase the likelihood of interactions between procoagulant proteins and activated platelets.[197]

High shear stress associated with vascular stenoses also increases endothelial cell, platelet, and procoagulant protein interactions,[77] and induces flow-dependent platelet aggregation.[142] Shear-dependent expression of platelet P-selectin and formation of monocyte–platelet aggregates suggest that that these cells undergo activation when traversing stenotic regions.[220] Shear rate also affects fibrin monomer formation and polymerization by affecting the rates of delivery of procoagulant proteins and removal of coagulation end products.[139] High shear depletes local fibrin concentrations, thereby limiting thrombus growth, whereas low shear enables clot propagation. The structure of the fibrin meshwork affects clot stability and susceptibility to fibrinolysis.[205]

Endothelial cells are also subjected to blood pressure, the force per unit area acting perpendicular to the vessel wall. High pressure affects endothelial function through mechanical damage and increase in circulating microparticle (MP) levels and TF exposure.[158] This mechanism is believed to contribute to the thrombotic risk of systemic hypertension, particularly cerebrovascular accidents.[62]

Hypercoagulability

Hypercoagulability describes a state of altered hemostatic balance favoring thrombus formation that may result from increases in coagulation factor concentrations, inappropriate platelet activation, reductions in the availability of endogenous anticoagulants, or a lack of fibrinolysis (Table 91.1).[8] Heritable thrombophilias, thus far only described in people, represent a risk factor, but rarely are the sole cause of thrombosis.[36]

Excessive, unbalanced activation of coagulation often results from intravascular TF expression or massive exposure of extravascular TF to the vascular space. Heterogeneity across vascular beds in terms of endothelial cell prothrombotic and antithrombotic properties produces a variable tissue distribution of TE among patients, often related to their underlying disease.[168] Intravascular TF expression can be induced by lipopolysaccharide and inflammatory cytokines, particularly IL-1, IL-6, and tumor necrosis factor (TNF)-α.[117] This TF expression on monocytes, endothelial cells, and leukocyte and platelet-derived microparticles may initiate systemic thrombin generation. Some neoplastic cells express TF constitutively,[214] while others produce a protease, cancer procoagulant (CP), that directly activates factor X.[20]

Thrombosis may represent a protective response against pathogen invasion, a process termed immunothrombosis.[81] Dysregulated or excessive immunothrombosis, however, promotes TE in diseases characterized by intense inflammation such as severe trauma, sepsis, heat stroke, and hemolytic anemia. The innate immune system, including neutrophils, monocytes, and dendritic cells, can initiate and accelerate fibrin formation and activate platelets. The process of NETosis refers to neutrophils' release of chromatin and granule protein meshworks called "neutrophil extracellular traps."[155,13] Excessive NETosis appears detrimental to the host.[32] Histones within NETs may act as damage-associated molecular patterns that initiate apoptosis, cytotoxicity, and systemic inflammation via toll-like receptor signaling pathways.[24] Prothrombotic properties of NETs include contact pathway activation through intravascular expression of a polyanionic surface,[119] DNA–histone integration into fibrin clots, thus impairing clot dissolution,[24] and cell-free DNA competition with plasmin on fibrin, resulting in decreased clot lysis.[49] Cell-free DNA also accelerates the inactivation of tPA by PAI-1.[119]

Factors that promote platelet activation include stimulation by inflammatory cytokines and tumor cells, cytokine or cell-mediated release of platelet agonists, and hypoalbuminemia-mediated upregulation of thromboxane A_2 (TXA_2).[42,130] Agonist-triggered release of platelet polyphosphate directly activates factor V and may initiate contact-pathway-mediated thrombosis.[181,221] Finally, platelet inhibition is attenuated by endothelial damage, which decreases availability of prostacyclin, NO, and CD39.

Hypercoagulability may result from decreased synthesis, increased loss, or excess consumption of anticoagulant proteins. Increased glomerular permeability in protein-losing nephropathy (PLN) permits selective loss of low-molecular-weight plasma proteins including AT.[178] Pathologic AT consumption occurs in conditions of increased thrombin generation, such as disseminated intravascular coagulation (DIC) or massive TE. Drugs such as l-asparaginase may also lower plasma AT.[100] Acquired protein C deficiencies develop in association with sepsis, malignancy, hepatic or cardiac failure, pancreatitis, DIC, colic, laminitis, and postoperatively.[50,4,107,193] Low protein C activity in the context of portosystemic shunting in dogs is not associated with an increase in TE.[195] By contrast, recurrent TE developed in a foal with primary protein C deficiency.[46] Acquired TFPI deficiency has been related to hypercholesterolemia, and may represent a risk factor for TE[93]

Hypofibrinolysis, often mediated by upregulation of PAI-1, may result in relative hypercoagulability.[883] PAI-1 is an acute phase protein that complexed with subendothelial fibronectin has inhibitory action on activated protein C (APC) generation. High PAI-1 has been associated with increased TE risk in people with atherosclerosis, sepsis, diabetes mellitus, and post trauma and surgery.[83] Although fibrinolytic defects are relatively ill-defined in animals, hypoplasminogenemia has been reported in traumatized dogs and in horses with strangulating obstructions.[131,157] Increased PAI-1 has been described in hyperlipidemic dogs,[217] and increased α2-antiplasmin activities have been reported in septic foals.[4]

DISEASES ASSOCIATED WITH THROMBOSIS

While causal relationships are difficult to establish, numerous retrospective studies of veterinary patients with TE have identified comorbidities hypothesized to represent hypercoagulable states. Moreover, the high frequency of thrombotic complications in patients with specific disease processes supports disease-induced TE. The common diseases associated with thrombosis in dogs, cats, and horses are summarized in Tables 91.2, 91.3, and 91.4, respectively.

Immune-Mediated Hemolytic Anemia (IMHA)

Thromboembolism is a major cause of mortality in canine IMHA, with incidence at necropsy ranging from 30% to 80%.[17521] The pulmonary system is the most common, but not exclusive site of TE.[67,21] Although inflammatory mediators likely activate coagulation,[117] the pathogenesis of IMHA-associated TE is not completely understood. Potential prothrombotic mechanisms include increased TF expression,[154] platelet activation,[206] generation and release of procoagulant microparticles,[95] and the formation of NETs.[87,115] Common laboratory abnormalities in dogs with IMHA include hyperfibrinogenemia, high D-dimer, and low AT.[21] Multiple groups have documented hypercoagulability in whole blood thromboelastographic parameters in dogs with IMHA.[53,68,179] Two studies found that a lack of hypercoagulability (relative hypocoagulability) was a negative prognostic indicator.[68,179]

Protein-Losing Nephropathy and Enteropathy

An association between canine PLN and venous and/or arterial TE has been described in many studies, with incidence rates from 6% to 42%.[28,41,164,72] The pulmonary vasculature is most commonly affected,[2811289164] followed by aortic thromboembolism (ATE).[28,212,211] Urinary AT loss plays a major role in mediating the hypercoagulability of PLN, and markers of thrombin activation and platelet aggregation increase with even modest urinary protein loss.[72] Concomitant hyperfibrinogenemia, hypercholesterolemia, high FVIII, and increased PAI-1 are hypothesized to contribute to TE risk. Three prospective studies of dogs with PLN identified features of hypercoagulability based on thromboelastography (TEG) and AT.[41,116,209] Hypoalbuminemia (i.e., serum albumin concentration below 2 g/dL) is associated with enhanced canine platelet aggregability.[178,72]

Protein-losing enteropathy (PLE) is typically due to chronic intestinal inflammation, with malabsorption and protein loss into the gut lumen. Analogous to inflammatory glomerulonephritis and PLN,[116] intestinal inflammation with protein loss promotes a hypercoagulable state.[71] Clinically, PLE has been associated with portal vein[163] and pulmonary TE; however, splenic vein[85] and aortic thrombosis are also described.[84,25]

Pancreatitis

Canine studies of pancreatitis describe hypercoagulability[79,151], and overt TE involving the splenic vein[114,76,11476] portal vein,[163,210,109163210109] and aorta.[211,9921199] Pancreatitis is

also associated with venous TE in cats.[173,165] The high frequency of comorbidities, however, complicates risk attributable to pancreatitis alone.[114] Experimental studies in animals demonstrate platelet hyperaggregability, hyperfibrinogenemia, increased PAI-1 activity, and decreased tPA activity.[52] Pathogenic mechanisms of hypercoagulability include release of TF and inflammatory cytokines from damaged pancreatic tissue and inflammation-mediated hypofibrinolysis.[189,94,134] Pancreatitis also induces phospholipase A2, thereby increasing platelet-activating factor and cytokine production. High-plasma free fatty acids and hypoalbuminemia inhibit synthesis of PGI_2 and promote TXA_2 release, respectively, thus enhancing platelet reactivity. Septic peritonitis or acute pancreatitis may reduce hepatic, pulmonary, and splenic TM expression,[96] and reduce AT.[85]

Hypercortisolism

Hyperadrenocorticism (HAC) and corticosteroid therapy are considered risk factors for TE in dogs. Many retrospective case series have described thrombotic states or overt TE associated with glucocorticoid therapy in dogs.[150,112,89,163,114,211,76,150,163,210,114,108] Glucocorticoid therapy, typically associated with portal vein TE, occurs in dogs with cancer, immune-mediated disease, and pancreatitis. Various retrospective studies and case series suggest that canine HAC is associated with TE, but most lack a control group.[213,112,89,163,114,76,162,11181,94] Thus, the relative contribution of comorbidities remains ill-defined. Oral prednisone administration to healthy dogs has been reported to decrease AT, enhance platelet aggregation, and increase coagulation factors, fibrinogen, clot strength, and thrombin generation.[167,166,147,57] Proposed mechanisms for steroid-mediated hypercoagulability include hypercholesterolemia, hypofibrinolysis (due to increased PAI-1 and α2-antiplasmin), hyperfibrinogenemia, and procoagulant excess.[150] In contrast to dogs, glucocorticoid therapy is rarely associated with feline venous thrombosis or TE.[145,165,173]

Neoplasia

Neoplasia is a common underlying disease in retrospective studies of canine TE,[112,163,114,211,109] and TE is commonly documented in populations of dogs with cancer.[126,207] Multiple mechanisms promote TE, including release of procoagulant substances and inflammatory cytokines by malignant cells, and direct interaction among tumor cells, endothelial cells, platelets, and monocytes.[20,42] Human and animal tumor tissues demonstrate constitutive TF expression and release of CP. Acquired APC resistance and anticoagulant deficiencies are prothrombotic forces in some neoplastic disorders. Contributory factors include vascular invasion by tumor cells, immobility, venous catheterization, corticosteroid therapy, surgery, and chemotherapy.[42] Enhanced or impaired fibrinolysis may develop secondary to neoplasia, with resultant signs of hemorrhage or thrombosis. The balance between plasminogen activators and inhibitors may also play a role in tumor metastasis. Tumor cell production of TNF and IL-1β induces endothelial cell TF and PAI-1 expression, and downregulates TM expression. Tumor cells also release vascular endothelial growth factor, which induces macrophage expression of TF, increases microvascular permeability, and promotes tumor angiogenesis. Tumor cells, cell extracts, and membrane fragments promote platelet aggregation in vitro, and tumor cell injections cause in vivo platelet aggregation in experimental animals.[20,42] Viscoelastic testing demonstrates hypercoagulability in dogs with neoplasia.[2,102,202] The underlying mechanisms may include overexpression of circulating TF,[214] thrombocytosis,[202] platelet hyper-reactivity,[129] hyperfibrinogenemia,[202] and reduced AT[104] or endogenous fibrinolytic potential.[185]

Sepsis

Sepsis is a common trigger of microvascular thrombosis and DIC in animals, including overt venous and arterial TE.[150,157,112,173,163,211,76,109] The pathogenesis of sepsis-related TE is complex, mediated by inflammatory cytokines, hemostatic proteins, leukocytes, platelets, and endothelial cells and influenced by the underlying infection.[117,124] Features of hypercoagulability identified in dogs and people with sepsis include reduced protein C and AT,[104,106] hyperfibrinogenemia, increased thrombin-activatable fibrinolysis inhibitor,[88] TM downregulation,[96] and platelet hyper-reactivity.[118]

Cardiovascular Disease

Feline cardiac disease, in particular hypertrophic cardiomyopathy (HCM), is associated with left atrial thrombus formation and ATE.[182,169] The cumulative risks of ATE in cats with HCM at 1 year, 5 years, and 10 years were 3.5%, 9.5%, and 11.3%, compared to 0.0%, 0.4%, and 0.7% in healthy cats.[59] A positive association was found between renal infarction, HCM, and ATE.[80] Reported incidence rates of TE secondary to cardiomyopathy (CM) range from 12% to 50%.[182,169] In addition, feline cardiac disease accompanied by spontaneous echocontrast, left atrial (LA) dilation, reduced LA function, and low flow velocities may portend ATE and death.[182,174,153] However, feline cardiac disease does not appear to be a risk factor for venous TE. In addition to abnormal blood flow, cats with spontaneous echocontrast or atrial thrombi demonstrated laboratory criteria of hypercoagulability including high-plasma thrombin–antithrombin complexes (TAT) and D-dimers.[189] Endothelial disruption, platelet hyper-reactivity, and endothelial dysfunction secondary to metabolic imbalance may further promote TE.[182,127]

Plasma indices of hypercoagulability (i.e., hyperfibrinogenemia, high TAT, and low AT and APC) have been described in dogs with cardiac disease.[193] However, only a single study linked cardiac disease in dogs to overt TE,[108] a finding not confirmed by others.[212,213,76] By contrast, canine infective endocarditis and heartworm disease are frequently associated with TE.[112,89,190]

Although atherosclerosis is rare in animals, aortic and cerebrovascular TE have been reported in hypothyroid and diabetic dogs with atherosclerosis.[211,90,184] Mechanisms promoting TE include endothelial disruption by atherosclerotic plaques, hypercholesterolemia, and a prothrombotic lipoprotein profile.

Diabetes Mellitus

Thromboembolic disease is an uncommon complication of diabetes mellitus in dogs, and most cases have concomitant prothrombotic conditions.[211,162] Loss of insulin's modulating effects on platelet activation and decreased endothelial synthesis of PGI_2 and NO combine to potentiate platelet reactivity.[171] Hyperlipidemia can occur concurrently with diabetes mellitus, thus exacerbating TE risk.[184] In people, hyperglycemia correlates with increased plasma PAI-1, a relationship not identified in dogs.[217]

Hepatobiliary Disease

The hepatobiliary system plays crucial roles in normal hemostasis (see Chapters 87 and 89). The liver synthesizes almost all procoagulant and anticoagulant factors, and removes desialylated, aged platelets through the activity of the Ashwell–Morell receptor.[74] The biliary system is essential for vitamin K absorption required for effective carboxylation of factors II, VII, IX, and X. Liver dysfunction is associated with complex coagulopathies[60,159] and risk for TE.[146] Hemostatic balance in these patients is influenced by procoagulant deficiency, deficiencies of anticoagulant and profibrinolytic factors such as AT, proteins C and S, and plasminogen,[196] and variable increases in von Willebrand factor.[121] Canine hepatobiliary diseases have been associated with portal vein TE[163,210,165] and other sites.[210,211,76]

Endovascular Devices and Extracorporeal Circuits

Blood clot formation in the lumen of venous and arterial catheters is a daily occurrence in veterinary practice,[201] and often necessitates device removal. The thrombogenicity of different catheter materials varies.[31,30,6] The increased risk of thrombosis associated with long-term catheterization can be reduced by heparin or citrate instillation,[110,23] or managed by local tPA infusion.[111] Retrospective studies of thrombosis identify current or recent intravenous catheterization as a risk factor, among comorbidities.[150,112,89,145] TE solely due to endovascular devices such as catheters, vascular access ports, or cardiac pacing wires is rare.[299] Prosthetic cardiac valves (mechanical or biologic) are associated with a much greater likelihood of thrombosis and TE, necessitating long-term anticoagulation.[3,148]

Extracorporeal circuits used for cardiopulmonary bypass, intermittent hemodialysis, continuous renal replacement therapy, plasmapheresis/plasma exchange and extracorporeal CO_2 removal, or membrane oxygenation may predispose patients to TE. Exposure of blood to extracorporeal circuits initiates a well-recognized consumptive coagulopathy phenomenon,[7] but also carries the risk of clotting of the circuit and TE.[203]

Equine Thrombotic Disease

Vascular injury is a defined (or presumptive) cause of equine large- and small-vessel thrombosis (Table 91.4). Jugular vein catheter thrombosis and thrombophlebitis are relatively common in the horse, and reported risk factors include endotoxemia, hypoproteinemia, salmonellosis, and antidiarrheal and antiulcer therapy.[157] Parasitic endovascular migration and parasite-induced intestinal vasculopathy and TE cause acute and chronic colic, and signs of lameness in foals with aortic, iliac, and distal limb TE. Distal limb TE has also been reported secondary to sepsis and gastrointestinal inflammation.[143] Equine infectious agents cause small-vessel TE, including equine-viral-arteritis-induced panarteritis, and vasculitis due to disseminated aspergillosis (see Chapter 93). Severe gastrointestinal disease and resultant endotoxemia are often associated with renal microvascular TE. Microvascular thrombosis in the dermal lamina may play a role in the development of carbohydrate-induced laminitis. As in dogs and cats, pulmonary thromboembolism (PTE) is likely under-recognized in horses. In a small case series, endotoxemia-induced hypercoagulability was considered an underlying cause of equine PTE,[144] and reports describe toxin-induced hemolysis and pneumonia as primary disorders in horses with PTE.[14,122] Cardiac disease is an uncommon cause of TE in horses.

LABORATORY DIAGNOSIS OF THROMBOSIS

The complex pathogenesis of hypercoagulability and its associated disease states complicates TE diagnosis. Test strategies include assays measuring "global" or net hemostatic forces and scoring systems combining routine tests and clinical parameters (see Chapter 92). Establishing clinical utility of new and traditional diagnostic tests ultimately requires demonstrable improvement in patient outcomes, including minimizing hemorrhagic complications of antithrombotic therapy.

Coagulation Profile

The routine coagulogram (activated partial thromboplastin time [aPTT], prothrombin time [PT], and fibrinogen) screens for risk of hemorrhage due to coagulation factor deficiency (see Chapter 88). Although variable shortening or prolongation of aPTT and PT is often found in patients with TE, these changes are nonspecific and rarely aid in diagnosis or management.[183] Hyperfibrinogenemia, however, is an independent risk factor for TE in people,[199] and is a common finding in canine IMHA, feline CM, and sepsis.[4,157,175,189] The predictive value of fibrinogen determinations for animal TE has yet to be established.

Antithrombin

Antithrombin loss promotes hypercoagulability in conditions such as PLN and PLE.[85] While risk of TE has been attributed to AT values below 60%,[72] there is little empiric data in animals to define a threshold value.

D-Dimer

D-dimer is a distinct fibrin degradation product formed by plasmin's proteolysis of cross-linked fibrin (see Chapter 87). Latex-agglutination and immunoturbidimetric assays are the most common; however, human-specific antibodies in commercially available assays may demonstrate reduced reactivity with canine D-dimers.[133] Discordant results among assays were found in a canine DIC study.[188] Quantitative D-dimer assays are generally sensitive, but nonspecific and have proven diagnostic utility for ruling out PTE and predicting mortality in human thrombotic syndromes.[187,192] Comparable data are lacking for animals, with studies revealing low predictive value for canine PTE,[48] nonspecific increases in D-dimer in dogs with hemoabdomen,[141,56] and high D-dimer unrelated to overt TE in dogs with cancer.[2]

Thrombin–Antithrombin Complex

Free thrombin in plasma is neutralized by the formation of an irreversible 1:1 complex with AT. The plasma concentration of the TAT is an indirect measure of in vivo thrombin generation. High TAT is evidence of a hypercoagulable state and TAT has been used to characterize thrombotic syndromes in dogs, cats, and horses (see Chapter 92).

Thrombin Generation

Thrombin generation assays measure the in vitro capacity of plasma coagulant factors to generate thrombin over time. These assays use fluorogenic thrombin substrates to measure the kinetics of thrombin generation and provide numeric parameters and qualitative "thrombograms."[133] They are considered "global tests" that reflect the balance of coagulation activators and inhibitors. The calibrated automated thrombogram (CAT) refers to a thrombin generation assay platform and associated software that has recently been evaluated in healthy dogs,[177] and for heparin monitoring,[1] however, clinical utility for diagnosing TE has not been established.

Viscoelastic Testing

TEG (Figure 91.1), rotational thromboelastometry (ROTEM), and Sonoclot measure the viscoelastic properties of a nascent fibrin clot in whole blood.[70,92] These point-of-care tests generate qualitative tracings depicting clot formation and breakdown, and numeric values summarizing clot strength and stability. The assays are not interchangeable[128] and subject to activator-dependent variability.[37] Thromboelastography has been used in human patients to test for hypocoagulability and hypercoagulability, monitor anticoagulants, guide transfusion, and predict postoperative TE. Thromboelastographic features of hypercoagulability have been described in dogs with neoplasia, DIC, IMHA, parvoviral enteritis, PLN, PLE, renal failure, hyperadrenocorticism, and deracoxib therapy.[41,103,131,68,179,116]

The diagnostic utility of viscoelastic testing remains unproven and many dogs without TE have evidence of hypercoagulability.[67] Tests are influenced by hematocrit, fibrinogen, and platelet count.[125] Recent guidelines have been published to reduce the variability associated with viscoelastic testing and improve diagnostic utility.[55,37]

Examination of Platelets and Microparticles

Platelet assays include measurements of size, aggregability, and expression of activation markers; complex analyses are usually performed to diagnose bleeding disorders (see Chapter 79). While considered a gold standard measure of platelet function, aggregometry is not useful for clinical characterization of TE.

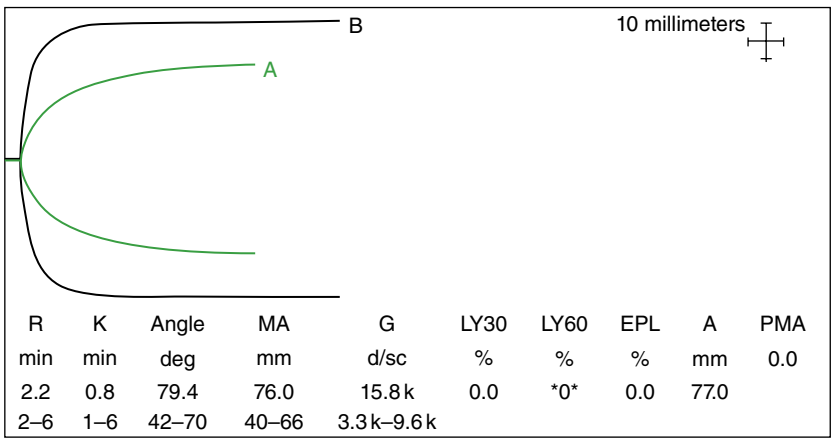

FIGURE 91.1 Tissue-factor activated TEG of a healthy dog and a dog with hyperadrenocorticism. (A) Healthy dog demonstrating normal TEG tracing. (B) Dog with hyperadrenocorticism demonstrating parameters of hypercoagulability: shortened clot formation time (K), increased angle (α), maximum amplitude (MA), and clot elasticity (G) values.

Automated Platelet-Sizing Parameters

Automated hematology analyzers measure several parameters of platelet function.[5,136] Mean platelet component concentration, a measure of refractive index, is linearly related to platelet density. Activated (i.e., degranulated) platelets have relatively low density compared to non-degranulated platelets. Mean platelet component distribution width measures the uniformity in activation status. Mean platelet component correlated with P-selectin expression in dogs with inflammatory disease;[136] however, additional studies are needed to clarify its diagnostic utility for TE.

Platelet Flow Cytometry

Flow cytometry is a method to evaluate platelet size, granularity, expression of activation markers, and presence of bound fibrinogen.[136,206] Exposure of P-selectin on the platelet outer membrane surface is an indicator of platelet degranulation and a common marker of platelet activation (Chapter 79). High platelet P-selectin expression has been demonstrated in clinical studies of dogs with inflammatory disease and IMHA.[136,206]

MPs are small (0.1–1 μm) membrane vesicles shed from apoptotic or activated cells, and cytometric assays to detect MP in a variety of species have been described.[35,186,101] Prothrombotic MPs bear externalized phosphatidylserine (PS) and express tissue factor.[15,149] Platelet-derived microparticles drove in vitro thrombin generation in a canine study.[78] In a clinical study of canine IMHA, some dogs had increased TF-bearing MP and PS activity, but MP numbers were no different between diseased and healthy dogs.[95] Similarly, cats with asymptomatic hypertrophic cardiomyopathy and healthy cats were found to have no difference in numbers of platelet-derived MPs.[101]

Assays to Quantify Neutrophil Extracellular Traps

Markers of NETosis include cell-free DNA, neutrophil-derived proteins, and protein–DNA complexes.[61,155] A recent study described detection of extracellular DNA in canine blood samples;[101] however, the diagnostic utility of NET assays requires further investigation.

CLINICAL DIAGNOSIS OF THROMBOSIS

The clinical signs of TE are highly variable, depending on anatomic site and inciting disease. Validated clinical scoring systems do not exist for animals, rather the diagnosis of TE is based on a characteristic clinical syndrome, such as feline ATE, or imaging that defines the presence of a thrombus.

Pulmonary Thromboembolism

Establishing a definitive diagnosis of PTE is challenging.[140] The most common signs include dyspnea, tachypnea, and depression, while coughing, hemoptysis, cyanosis, syncope, collapse, and sudden death are less frequent. Auscultation may reveal harsh lung sounds and crackles, or no abnormalities. Signs compatible with backward or forward heart failure may be present. Arterial blood gas abnormalities due to PTE may include hypoxemia, hypocapnia, and an increased A-a gradient.[89] While not a sensitive or specific test, relative hypoxemia represents the extent of thromboembolic occlusion and may predict poor response to oxygen therapy due to intrapulmonary shunting.[893438]

Imaging: Ultrasonography, Radiography, Echocardiography

Bedside ultrasound and echocardiography may reveal pulmonary parenchymal disease, denoted by the appearance of B-lines, comet-tail artifacts, and/or evidence of right heart dysfunction, dilation, or tricuspid regurgitation. Abnormalities are typically present in thoracic radiographs; however, their absence should not rule out a diagnosis of PTE.[89,145,58,39,40] Pulmonary infiltrates are focal or multifocal, with alveolar or alveolar–interstitial patterns.[58] Other abnormalities include uneven vessel diameter, pulmonary arterial enlargement, lobar vein or artery attenuation, pleural effusion, and right-sided cardiomegaly.[173,58,132] Hyperlucent pulmonary regions denoting zones of reduced blood flow distal to sites of vascular occlusion are pathognomonic for PTE, but rare.[58,208]

Echocardiographic abnormalities that have been identified in small animals with PTE include right atrial and ventricular enlargement, paradoxical septal motion, pulmonary hypertension, and thrombi in the heart or pulmonary artery (PA).[89,150,89,16,200] A recent prospective study of at-risk dogs revealed pulmonic and tricuspid regurgitation as the most common signs.[67]

Imaging: Computerized Tomographic Pulmonary Angiography

Rapid, multislice spiral computerized tomography pulmonary angiography (CTPA) is considered the definitive diagnostic test of PTE.[69] These studies combine rapid, spiral thoracic computerized tomography (CT) with bolus injection of contrast media to ensure peak enhancement of the pulmonary arteries.[75] The most advanced (256 slice) scanners are capable of scan rates up to 458 mm/s, which enables imaging within 1 second exposure times, thereby avoiding the problems of respiratory or cardiac motion and contrast drainage. Diagnostic criteria for PTE using CTPA are well-described.[215] A normal CTPA study essentially rules out PTE as the cause of the patient's respiratory distress, unless the index of suspicion is very high.[160] Multislice CTPA has been described in dogs using 16-slice[75] and 64-slice scanners,[43] including protocols to maximize PA contrast enhancement.[123] Multislice CT angiography has also been used to detect PTE in experimental dogs[191] and to identify a descending aortic thrombus secondary to spirocercosis in a parasitized dog.[97] A recent canine IMHA study confirmed the diagnostic utility of CTPA with a 16-slice scanner to identify PTE, using a sedation-only restraint protocol.[67]

Cardiac Biomarkers

In humans, echocardiographic RV dysfunction secondary to PTE is associated with elevated cardiac troponin (cTn) concentrations.[86] Peak cTnI levels develop at 8 hours post embolism in people and point-of-care tests are available to detect the protein.[54,17] In dogs with PTE secondary to dirofilariasis, cTnI values were significantly higher than controls,[22] and dogs with experimental PTE had increased cTnI levels proportional to the severity of occlusion.[198] While high cTn is not specific to PTE, it may assist in gauging PTE severity and risk of death.[91] Similar to cTNI, increases in N-terminal-pro-B-type natriuretic peptide (NT-proBNP) are related to severity of RV dysfunction,[152] and adverse outcome in people with PTE.[170] Although clinical studies are lacking, a recent canine experimental study indicated that NT-proBNP and atrial natriuretic peptide were significantly increased in dogs with severe pulmonary arterial hypertension secondary to PTE.[82]

Feline Aortic Thromboembolism

Feline aortic TE is a common, devastating condition with reported survival-to-discharge rates of approximately 30%.[182,113,169] The inciting cause is usually HCM. Non-HCM cases are attributed to other cardiac disease, or rarely neoplasia.[173,182] Up to 90% of afflicted cats have cardiomegaly, and heart failure, found in 50–70% of cases,[113] is a negative prognostic indicator.[182] Thrombi likely form in the left atrial appendage, atrium, or ventricle, with embolization to the aortic trifurcation ("saddle thrombus") causing hind limb blood flow obstruction. Less frequent sites of embolization include the renal, iliac, or brachial arteries. Acute obstruction of the left ventricle or proximal aorta may cause sudden death. The consequences of ATE include physical occlusion of the vessel and embolus-induced vasoconstriction that disrupts collateral flow.[172] Aortic occlusion increases left ventricular afterload, which may precipitate or exacerbate heart failure.

The diagnosis of ATE is usually based on characteristic history and clinical signs.[182] Thermal imaging will detect alterations in peripheral perfusion.[156] Blood samples from an affected limb have lower pH and glucose and higher lactate and CO_2 values than unaffected areas.[99] Serum biochemical profiles may reveal nonspecific abnormalities reflecting muscle ischemia and stress, and will identify hepatopathy, hyperkalemia, and uremia in patients with concurrent renal vascular TE. Many cats are dyspneic due to pulmonary edema or pleural effusion secondary to congestive heart failure, and may have a heart murmur or gallop rhythm and crackles on auscultation. Thoracic ultrasound typically reveals multiple B-lines,[120,204] and potentially pleural effusion. A brief focused echocardiography assessment to check the ratio of the LA to aorta (which should be <1.6) may identify cardiac disease. Caudal abdominal ultrasound, or less commonly angiography, can reveal the occlusion site. Measurement of cardiac troponin and NT-proBNP can also help assess cardiovascular function.[10]

Canine Aortic Thromboembolism

Canine ATE is less common than the feline syndrome, and most cases have chronic, insidious histories suggestive of in situ thrombus formation rather than embolization. Canine ATE has been reported in association with PLN, PLE, neoplasia, HAC, cardiac disease (infective endocarditis, heartworm, cardiomyopathy, valvular disorders), and localized vascular injury (e.g., *Spirocerca lupi*).[212,190,97] Clinical signs depend on the site, extent, and rapidity of occlusion, and collateral circulation. Prognosis generally depends on the underlying disease process.[97]

Biochemical profiles often reveal high creatine kinase and aspartate aminotransferase; however, biochemical abnormalities may assist in identifying a specific disease process. Glucose differentials >30 mg/dL between venous blood in the affected limbs and in central venous blood samples were highly sensitive and specific for ATE.[97] Definitive diagnosis of ATE is achieved via imaging.[109] Abdominal ultrasonography is usually informative, especially when combined with color flow Doppler assessment and additional techniques to assess blood flow include angiography, magnetic resonance imaging, and thermography.

Vena Cava Thrombosis

Cranial vena cava thrombosis is often accompanied by jugular vein thrombosis in patients with indwelling vascular devices such as central venous catheters or transvenous cardiac pacing leads.[29138] Most patients have a predisposing condition such as immune-mediated disease, sepsis, protein-losing disease, or cancer.[150] The most common clinical signs are edema of the head and neck, dyspnea, and pleural effusion. Jugular vein thrombi may be palpable, or ultrasonography with color flow Doppler may confirm the diagnosis. Thrombosis of the caudal vena cava is most commonly associated with pheochromocytoma and adrenocortical tumors.[12,65] These patients may present with signs of adrenal HAC, or develop ascites, abdominal pain, gastrointestinal signs, hypertension, and tachyarrhythmias due to pheochromocytoma. In patients with an adrenal mass, abdominal ultrasound is 80% sensitive and 90% specific for detection of caval thrombosis,[105] but differentiating tumor invasion from solitary blood clot is challenging, and CT angiography may help.

Portal Vein Thrombosis

Portal vein thrombosis is most common in older, large breed dogs and older domestic short-haired cats. The clinical signs resulting from portal vein thrombosis relate to speed of onset. Acute thrombosis is typically associated with signs of hypovolemic shock, vomiting, and abdominal pain, whereas ascites is suggestive of chronic thrombosis. Case reports of feline portal vein thrombosis identified liver disease as the primary disease process, with

three of six cases having congenital portosystemic shunts.[165] Most dogs with portal vein thrombosis have liver disease, with neoplasia, immune-mediated disease, and sepsis also described.[163,210] Portal vein thrombosis is typically diagnosed by abdominal ultrasound or CT angiography.

Splenic Vein Thrombosis

Splenic vein thrombosis is uncommon, but has been reported in dogs and cats with neoplasia, corticosteroid administration, pancreatitis, and immune-mediated disease.[114] Case reports typically describe splenic vein thrombosis as an incidental finding during abdominal ultrasound of older, large breed dogs. Infrequent clinical signs include splenomegaly, ascites, and abdominal pain. Concurrent portal vein thrombi may be present in approximately 20% cases. Isolated splenic vein thrombosis rarely requires treatment.

Mesenteric Vein Thrombosis

Mesenteric vein thrombosis is also uncommon. One case series described mesenteric vein thrombosis on postmortem exam of three dogs with concurrent portal vein thrombosis.[210] A second case report described a 4-year-old Cocker Spaniel with anorexia and vomiting and intestinal intussusception.[176] Techniques to identify mesenteric thrombosis include ultrasound, CT angiography, and direct visualization at surgery.

Cerebrovascular Accidents

Ischemic stroke is increasingly recognized with the advent of advanced diagnostic imaging in veterinary practice.[62,63,64] Thrombi are rarely identified in the cerebral vasculature and in most cases risk factors for human TE are absent.[62] Neurolocalization of signs reflect the area of vascular ischemia and infarction. The most commonly affected brain regions are the cerebellum and telencephalon.[64] Associated conditions include hypertension, HAC, diabetes mellitus, and cancer.

Coronary Thrombosis

Dogs are often used as models for evaluating luminal prosthetic stents and in preclinical studies of antithrombotic agents. However, spontaneous myocardial infarction appears to be extremely rare in dogs and cats, sometimes only identified post mortem.[45] Clinical signs are nonspecific and may be attributed to cardiac disease or underlying disease such as neoplasia, PLN, or IMHA. In one study, chronic cardiac disease was the most common associated disorder, with echocardiographic signs of systolic dysfunction and atrial fibrillation as the most common electrocardiograph (EKG) abnormality.[51] Coronary angiography by direct catheterization is feasible for definitive diagnosis in dogs, but CT angiography is more widely available.[44]
